1. On how many days in the last 3 months did you miss work or school because of your headaches? ..... ____ days
2. How many days in the last 3 months was your productivity at work or school reduced by half or more because of your headaches *(do not include days you counted in question 1 where you missed work or school)*? ..... ____ days
3. On how many days in the last 3 months did you **not** do household work because of your headaches? ..... ____ days
4. How many days in the last 3 months was your productivity in household work reduced by half or more because of your headaches *(do not include days you counted in question 3 where you did not do household work)*? ..... ____ days
5. On how many days in the last 3 months did you miss family, social, or leisure activities because of your headaches? ..... ____ days

A. On how many days in the last 3 months did you have a headache? *(If a headache lasted more than one day, count each day.)* ..... ____ days

B. On a scale of 0–10, on average how painful were these headaches? *(Where 0 = no pain at all, and 10 = pain as bad as it can be.)* ..... ____

*Migraine Disability Assessment Score
(Questions 1–5 are used to calculate the MIDAS score.)
Grade I—Minimal or Infrequent Disability: 0–5
Grade II—Mild or Infrequent Disability: 6–10
Grade III—Moderate Disability: 11–20
Grade IV—Severe Disability: > 20

TABLE 441-4 TREATMENT of Acute Migraine

DRUG	TRADE NAME	DOSAGE
Simple Analgesics		
Acetaminophen, aspirin, caffeine	Excedrin Migraine	Two tablets or caplets q6h (max 8 per day)
NSAIDs		
Naproxen	Aleve, Anaprox, generic	220–550 mg PO bid
Ibuprofen	Advil, Motrin, Nuprin, generic	400 mg PO q3–4h
Tolfenamic acid	Clotam Rapid	200 mg PO; may repeat ×1 after 1–2 h
Diclofenac K	Cambia	50 mg PO with water
5-HT$_{1B/1D}$ Receptor Agonists—Triptans		
Oral		
Ergotamine 1 mg, caffeine 100 mg	Cafergot	One or two tablets at onset, then one tablet q½h (max 6 per day, 10 per week)
Naratriptan	Amerge	2.5-mg tablet at onset
Rizatriptan	Maxalt	5–10-mg tablet at onset
	Maxalt-MLT	
Sumatriptan	Imitrex	50–100-mg tablet at onset
Frovatriptan	Frova	2.5-mg tablet at onset
Almotriptan	Axert	12.5-mg tablet at onset
Eletriptan	Relpax	40 or 80 mg at onset
Zolmitriptan	Zomig	2.5-mg tablet at onset
	Zomig Rapimelt	
Nasal		
Dihydroergotamine	Migranal Nasal Spray	Prior to nasal spray, the pump must be primed 4 times; 1 spray (0.5 mg) is administered, followed in 15 min by a second spray
	Trudhesa Nasal Spray	One spray into each nostril
Sumatriptan	Imitrex Nasal Spray	5–20 mg intranasal spray as 4 sprays of 5 mg or a single 20 mg spray
Zolmitriptan	Zomig	5 mg intranasal spray as one spray
Parenteral		
Dihydroergotamine	DHE-45	1 mg IV, IM, or SC at onset and q1h (max 3 mg/d, 6 mg per week)
Sumatriptan	Imitrex Injection	3, 4, or 6 mg SC at onset (may repeat once after 1 h for max of 2 doses in 24 h)
	Alsuma	
	Sumavel DosePro	
CGRP Receptor Antagonists—Gepants		
Oral		
Rimegepant	Nurtec	75 mg ODT PO
Ubrogepant	Ubrelvy	50 or 100 mg PO; a second dose may be taken 2 h after the first, if needed
Nasal		
Zavegepant	Zavzpret	10 mg intranasal, single spray to one nostril once in 24 h
5-HT$_{1F}$ Receptor Agonist—Ditans		
Oral		
Lasmiditan	Reyvow	50, 100, or 200 mg PO
Dopamine Receptor Antagonists		
Oral		
Metoclopramide	Reglan,[a] generic[a]	5–10 mg/d
Prochlorperazine	Compazine,[a] generic[a]	1–25 mg/d
Parenteral		
Chlorpromazine	Generic[a]	0.1 mg/kg IV at 2 mg/min; max 35 mg/d
Metoclopramide	Reglan,[a] generic	10 mg IV
Prochlorperazine	Compazine,[a] generic[a]	10 mg IV
Other		
Parenteral		
Opioids	Generic[a]	Multiple preparations and dosages; see Table 14-1
Other		
Neuromodulation		
Single-pulse transcranial magnetic stimulation (sTMS)	Savi Dual	Two pulses at onset followed by two further pulses
Noninvasive vagus nerve stimulation (nVNS)	gammaCore	Two doses each of 120 s
Remote electrical neuromodulation (REN)	Nerivio	30- to 45-min stimulation to the upper arm
Transcutaneous supraorbital nerve stimulation	Cefaly	60-min stimulation
External concurrent occipital and trigeminal neurostimulation (eCOT-NS)	Relivion	30- to 60-min stimulation

[a]Not all drugs are specifically indicated by the U.S. Food and Drug Administration for migraine. Local regulations and guidelines should be consulted.

Note: Antiemetics (e.g., domperidone 10 mg or ondansetron 4 or 8 mg) or prokinetics (e.g., metoclopramide 10 mg) are sometimes useful adjuncts.

Abbreviations: 5-HT, 5-hydroxytryptamine; NSAIDs, nonsteroidal anti-inflammatory drugs; ODT, orally disintegrating tablets.

TABLE 441-5 Clinical Stratification of Acute Specific Migraine Treatments

CLINICAL SITUATION	TREATMENT OPTIONS
Failed NSAIDs/ analgesics	**First tier**
	Sumatriptan 50 mg or 100 mg PO
	Almotriptan 12.5 mg PO
	Rizatriptan 10 mg PO
	Eletriptan 40 mg PO
	Zolmitriptan 2.5 mg PO
	Rimegepant 75 mg
	Ubrogepant 50 or 100 mg
	Lasmiditan 50, 100, or 200 mg
	Slower effect/better tolerability
	Naratriptan 2.5 mg PO
	Frovatriptan 2.5 mg PO
	Infrequent headache
	Ergotamine/caffeine 1–2/100 mg PO
	Dihydroergotamine nasal spray 2 mg
Early nausea or difficulties taking tablets	Zolmitriptan 5 mg nasal spray
	Sumatriptan 20 mg nasal spray
	Rizatriptan 10 mg MLT wafer
	Zavegepant 10 mg nasal spray
Headache recurrence	Ergotamine 2 mg (most effective PR/usually with caffeine)
	Naratriptan 2.5 mg PO
	Almotriptan 12.5 mg PO
	Eletriptan 40 mg
	Rimegepant 75 mg
	Ubrogepant 50 or 100 mg
Tolerating acute treatments poorly	Naratriptan 2.5 mg
	Almotriptan 12.5 mg
	Rimegepant 75 mg
	Ubrogepant 50, 100 mg
	Single-pulse transcranial magnetic stimulation
	Noninvasive vagus nerve stimulation
	Remote electrical neuromodulation
Early vomiting	Zolmitriptan 5 mg nasal spray
	Zavegepant 10 mg nasal spray
	Sumatriptan 25 mg PR
	Sumatriptan 6 mg SC
Menses-related headache	**Prevention**
	Ergotamine PO at night
	Estrogen patches
	Rimegepant 75 mg PO taken during the menses
	Treatment
	Triptans
	Dihydroergotamine nasal spray
Very rapidly developing symptoms	Zolmitriptan 5 mg nasal spray
	Zavegepant 10 mg nasal spray
	Sumatriptan 6 mg SC
	Dihydroergotamine 1 mg IM

Abbreviation: NSAIDs, nonsteroidal anti-inflammatory drugs.

comparable to a single dose of oral sumatriptan. Important side effects of NSAIDs include dyspepsia and gastrointestinal irritation.

5-$HT_{1B/1D}$ RECEPTOR AGONISTS—TRIPTANS AND ERGOTS

Oral Stimulation of 5-$HT_{1B/1D}$ receptors can stop an acute migraine attack. Ergotamine and dihydroergotamine are nonselective receptor agonists, whereas the triptans are selective 5-$HT_{1B/1D}$ receptor agonists. A variety of triptans—sumatriptan, almotriptan, eletriptan, frovatriptan, naratriptan, rizatriptan, and zolmitriptan—are available for the treatment of migraine.

Each drug in the triptan class has similar pharmacologic properties, varying slightly in terms of clinical efficacy. Rizatriptan and eletriptan are, on a population basis, the most efficacious of the triptans. Sumatriptan and zolmitriptan have similar rates of efficacy as well as time to onset, with an advantage of having multiple formulations, whereas almotriptan has a similar rate of efficacy to sumatriptan and is better tolerated, and frovatriptan and naratriptan are somewhat slower in onset and are also well tolerated. Clinical efficacy appears to be related more to the t_{max} (time to peak plasma level) than to the potency, half-life, or bioavailability. This observation is consistent with a large body of data indicating that faster-acting analgesics are more effective than slower-acting ones.

Unfortunately, monotherapy with a selective oral 5-$HT_{1B/1D}$ receptor agonist does not result in rapid, consistent, and complete relief of migraine in all patients. Triptans are generally not effective in migraine with aura unless given after the aura is completed and the headache initiated. Side effects are common, although often mild and transient. Moreover, 5-$HT_{1B/1D}$ receptor agonists are contraindicated in individuals with a history, symptoms, or signs of ischemic cardiac, cerebrovascular, or peripheral vascular syndromes. Recurrence of headache, within the usual time course of an attack, is another important limitation of triptan use and occurs at least occasionally in most patients. Evidence from randomized controlled trials shows that coadministration of a longer-acting NSAID, naproxen 500 mg, with sumatriptan will augment the initial effect of sumatriptan and, importantly, reduce rates of headache recurrence.

Ergotamine preparations offer a nonselective means of stimulating 5-HT_1 receptors. A nonnauseating dose of ergotamine should be sought because a dose that provokes nausea is too high and may intensify head pain. Oral (excluding sublingual) formulations of ergotamine also contain 100 mg caffeine (theoretically to enhance ergotamine absorption and possibly to add additional analgesic activity). The average oral ergotamine dose for a migraine attack is 2 mg. Because the clinical studies demonstrating the efficacy of ergotamine in migraine predated the clinical trial methodologies used with the triptans, it is difficult to assess the comparative efficacy of ergotamine versus the triptans. In general, with use of ergotamine there appears to be a much higher incidence of nausea than with triptans but less headache recurrence.

Nasal Nasal formulations of dihydroergotamine, zolmitriptan, or sumatriptan can be useful in patients requiring a nonoral route of administration. The nasal sprays result in substantial blood levels within 30–60 min. Although in theory nasal sprays might provide faster and more effective relief of a migraine attack than oral formulations, their reported pain relief rate is only ~50–60%. Studies with a new inhalational formulation of dihydroergotamine indicate that its absorption problems can be overcome to produce rapid onset of action with good tolerability.

Parenteral Administration of drugs by injection, such as dihydroergotamine and sumatriptan, is approved by the FDA for the rapid relief of a migraine attack. Peak plasma levels of dihydroergotamine are achieved 3 min after IV dosing, 30 min after intramuscular (IM) dosing, and 45 min after subcutaneous (SC) dosing. If an attack has not already peaked, SC or IM administration of 1 mg of dihydroergotamine is adequate for about 80–90% of patients. Sumatriptan, 3, 4, or 6 mg SC, depending on local availability, is effective in ~50–80% of patients and can now be administered by a needle-free device.

CALCITONIN GENE-RELATED PEPTIDE (CGRP) RECEPTOR ANTAGONISTS—GEPANTS

Gepants are small-molecule CGRP receptor antagonists that are effective in the acute treatment of migraine. Three are currently approved by the FDA: rimegepant, and ubrogepant are oral, and zavegepant is a nasal spray (Table 441-4). They are more likely to

render patients pain-free at 2 h and most bothersome symptom–free when compared with placebo in large phase 3 clinical trials. The most bothersome symptom is derived by asking patients to identify which symptom—of nausea, photophobia, or phonophobia—was most bothersome during the treated attack; success required that this symptom was eliminated at 2 h. Gepants are extremely well tolerated with only a small percentage of patients reporting troublesome side effects, such as mild nausea.

5-HT_{1F} RECEPTOR AGONISTS—DITANS

Lasmiditan, a highly selective, orally available, 5-HT_{1F} receptor agonist, has been approved by the FDA for the acute treatment of migraine based on large phase 3 studies where it was superior to placebo (Table 441-4). Ditans have no vascular effects because the 5-HT_{1F} receptor is located in the central and peripheral nervous system but not vasculature; the class thus unequivocally fills a gap in therapy for patients with cardiovascular and cerebrovascular disease. The major side effect is dizziness, occurring in ~15% of patients in clinical trials, and somnolence in 6%. Patients are advised not to drive for 8 h after treatment.

DOPAMINE RECEPTOR ANTAGONISTS

Oral Oral dopamine receptor antagonists can be considered as adjunctive therapy in migraine. Drug absorption is impaired during migraine because of reduced gastrointestinal motility. Delayed absorption occurs even in the absence of nausea and is related to the severity of the attack and not its duration. Therefore, when oral NSAIDs and/or triptan agents fail, the addition of a dopamine receptor antagonist, such as metoclopramide 10 mg, prochlorperazine 10 mg, or domperidone 10 mg (not available in the United States), should be considered to enhance gastric absorption. In addition, dopamine receptor antagonists decrease nausea/vomiting and restore normal gastric motility.

Parenteral Dopamine receptor antagonists (e.g., chlorpromazine, prochlorperazine, metoclopramide) by injection can also provide significant acute relief of migraine; they can be used in combination with parenteral 5-$HT_{1B/1D}$ receptor agonists. A common IV protocol used for the treatment of severe migraine is the administration over 2 min of a mixture of 5 mg of prochlorperazine and 0.5 mg of dihydroergotamine.

OTHER OPTIONS FOR ACUTE MIGRAINE

Oral For milder attacks of migraine, the combination of acetaminophen, aspirin, and caffeine is FDA approved (Table 441-4).

Parenteral Opioids are modestly effective in the acute treatment of migraine. For example, IV meperidine (50–100 mg) is given frequently in the emergency department (ED). This regimen "works" in the sense that the pain of migraine is eliminated. Importantly, it is clear from a randomized controlled trial that prochlorperazine is superior to hydromorphone in the ED setting. However, opioids are clearly suboptimal for patients with recurrent headache. Opioids do not treat the underlying headache mechanism; rather, they act to alter the pain sensation, and there is evidence their use may decrease the likelihood of a response to triptans in the future. Moreover, in patients taking oral opioids, such as oxycodone or hydrocodone, habituation or addiction can greatly confuse the treatment of migraine. Opioid craving and/or withdrawal can aggravate and accentuate migraine. Therefore, it is recommended that opioid use in migraine be limited to patients with severe, but infrequent, headaches that are unresponsive to other pharmacologic approaches or who have contraindications to other therapies.

Neuromodulation Single-pulse transcranial magnetic stimulation (sTMS) is FDA cleared for the acute treatment of migraine. Two pulses can be applied at the onset of an attack, and this can be repeated. The use of sTMS is safe where there is no cranial metal implant and offers an option to patients seeking nonpharmaceutical approaches to treatment. Similarly, a noninvasive vagus nerve stimulator (nVNS) is FDA cleared for the treatment of migraine attacks in adults. One to two 120-s doses may be applied for attack treatment. Remote electrical neuromodulation using a smartphone app that stimulates the upper arm for 30–45 min is also effective for treatment of acute migraine. Transcutaneous supraorbital nerve stimulation for 60 min and external concurrent occipital and trigeminal neurostimulation (eCOT-NS) for 30–60 min are both FDA cleared.

MEDICATION-OVERUSE HEADACHE

Acute attack medications, particularly opioid or barbiturate-containing compound analgesics, have a propensity to aggravate headache frequency and induce a state of refractory daily or near-daily headache called *medication-overuse headache*. This condition is likely not a separate headache entity but a reaction of the patient's underlying migraine biology to a particular medicine. Migraine patients who have two or more headache days a week should be cautioned about frequent analgesic use **(see "Chronic Daily Headache" in Chap. 17)**.

PREVENTIVE TREATMENTS FOR MIGRAINE

Patients with an increasing frequency of migraine attacks or with attacks that are either unresponsive or poorly responsive to abortive treatments are good candidates for preventive agents. In general, a preventive medication should be considered in patients with four or more migraine days a month. Significant side effects are associated with the use of many agents; furthermore, determination of dose can be difficult because the recommended doses have been derived for conditions other than migraine. The mechanism of action of older medicines is unclear; it seems likely that the brain sensitivity that underlies migraine is modified. Patients are usually started on a low dose of a chosen treatment; the dose is then gradually increased, up to a reasonable maximum, to achieve clinical benefit.

Treatments that have the capacity to stabilize migraine are listed in **Table 441-6**. Most treatments must be taken daily, and there is usually a lag of 2–12 weeks before an effect is seen. The drugs that have been approved by the FDA for the preventive treatment of migraine include propranolol, timolol, sodium valproate, topiramate, eptinezumab, erenumab, fremanezumab, galcanezumab, rimegepant, and atogepant. In addition, a number of other drugs appear to display preventive efficacy. This group includes amitriptyline, candesartan, nortriptyline, flunarizine, phenelzine, and cyproheptadine. Placebo-controlled trials of onabotulinum toxin type A in episodic migraine were negative, whereas, overall, placebo-controlled trials in chronic migraine were positive. The FDA has approved a range of neuromodulation approaches for the preventive treatment of migraine (Table 441-6). They offer a well-tolerated, effective option for patients. Phenelzine is a monoamine oxidase inhibitor (MAOI); therefore, tyramine-containing foods, decongestants, and meperidine are contraindicated, and it is reserved for only very recalcitrant cases. Methysergide is now of historical interest only because it is no longer manufactured. Melatonin has been reported to be useful, with controlled trial evidence, but is not approved for this indication in the United States.

The probability of success with any one of the antimigraine drugs is ~40–50%. Many patients are managed adequately with well-tolerated doses of candesartan, propranolol, amitriptyline, topiramate, or valproate. As data on fetal developmental issues have arisen, both topiramate and valproate are now considered less attractive for use in females during reproductive years. If these agents fail or produce unacceptable side effects, neuromodulation approaches can be used (Table 441-6). Once effective stabilization is achieved, the drug is continued for ~6–12 months and then slowly tapered, assuming the patient agrees, to assess the continued need. Many patients are able to discontinue medication and experience fewer and milder attacks for long periods. The advent of CGRP monoclonal antibodies and CGRP receptor antagonists has significantly changed the landscape of preventive treatment; with the combination of efficacy that is often within the first month and excellent tolerability, expectations of outcomes have changed.

TABLE 441-6 Preventive Treatments in Migraine[a]

DRUG	DOSE	SELECTED SIDE EFFECTS
Beta blocker		
Propranolol	40–120 mg bid	Reduced energy
Metoprolol	25–100 mg bid	Tiredness
		Postural symptoms
		Contraindicated in asthma
Antidepressants		
Amitriptyline	10–75 mg at night	Drowsiness
Dosulepin	25–75 mg at night	
Nortriptyline	25–75 mg at night	*Note:* Some patients may only need a total dose of 10 mg, although generally 1–1.5 mg/kg body weight is required.
Venlafaxine	75–150 mg/d	
Anticonvulsants		
Topiramate	25–200 mg/d	Paresthesias
		Cognitive symptoms
		Weight loss
		Glaucoma
		Caution with nephrolithiasis
Valproate	400–600 mg bid	Drowsiness
		Weight gain
		Tremor
		Hair loss
		Fetal abnormalities
		Hematologic or liver abnormalities
Serotonergic drugs	0.5–2 mg qd	Weight gain
Pizotifen[b]		
CGRP pathway blockers		
Eptinezumab	100 or 300 mg IV every 12 weeks	Nasopharyngitis
Erenumab	70 or 140 mg SC monthly	Nasopharyngitis, constipation
Fremanezumab	225 mg monthly or 675 mg q3 months, SC	Injection site reactions
Galcanezumab	240 mg loading then 120 mg monthly, SC	Nasopharyngitis
Rimegepant	75 mg every other day	Nausea abdominal pain/dyspepsia
Atogepant	10, 30, or 60 mg once daily	Constipation, nausea
Other classes		
Flunarizine[b]	5–15 mg qd	Drowsiness
		Weight gain
		Depression
		Parkinsonism
Candesartan	4–24 mg daily	Dizziness
Memantine	5–20 mg daily	Dizziness, tiredness
Melatonin	3–12 mg nightly	Drowsiness
Neuromodulation		Lightheadedness
Single-pulse transcranial magnetic stimulation (sTMS)	4–24 pulses per day	Tingling
Noninvasive vagus nerve stimulation (nVNS)	120-s treatments 2–3 times daily	Tinnitus
Remote electrical neuromodulation (REN)	45 min every other day	Site discomfort, irritation or pain
Transcutaneous supraorbital nerve stimulation	20 min daily	Muscle twitching
		Well-tolerated; some local sensory symptoms
		Local paresthesia
Chronic migraine		
Onabotulinum toxin type A	155 U	Loss of brow furrow
No convincing evidence from controlled trials		
Verapamil		
Controlled trials demonstrate *no effect*		
Nimodipine		
Clonidine		
Selective serotonin reuptake inhibitors: fluoxetine		

[a]Commonly used preventives are listed with typical doses and common side effects. Not all listed medicines are approved by the U.S. Food and Drug Administration; local regulations and guidelines should be consulted. [b]Not available in the United States.

TENSION-TYPE HEADACHE

Clinical Features The term *tension-type headache* is commonly used to describe a chronic head-pain syndrome characterized by bilateral tight, bandlike discomfort. The pain typically builds slowly, fluctuates in severity, and may persist more or less continuously for many days. The headache may be episodic or chronic (present >15 days per month).

A useful clinical approach is to diagnose TTH in patients whose headaches are completely without accompanying features such as nausea, vomiting, photophobia, phonophobia, osmophobia, throbbing, and aggravation with movement. Such an approach neatly separates migraine, which has one or more of these features and is the main differential diagnosis, from TTH. The International Headache Society's main definition of TTH allows an admixture of nausea, photophobia, or phonophobia in various combinations, although the appendix definition does not; this illustrates the difficulty in distinguishing these two clinical entities. In clinical practice, using the appendix definition to dichotomize patients on the basis of the presence of associated features (migraine) and the absence of associated features (TTH) is highly recommended. Indeed, patients whose headaches fit the TTH phenotype and who have migraine at other times, along with a family history of migraine, migrainous illnesses of childhood, or typical migraine triggers to their migraine attacks, may be biologically different from those who have TTH headache with none of the features. TTH may be infrequent (episodic) or occur on 15 days or more a month (chronic).

Pathophysiology The pathophysiology of TTH is incompletely understood. It seems likely that TTH is due to a primary disorder of central nervous system pain modulation alone, unlike migraine, which involves a more generalized disturbance of sensory modulation. Data suggest a genetic contribution to TTH, but this may not be a valid finding: given the current diagnostic criteria, the studies undoubtedly included many migraine patients. The name *tension-type headache* implies that pain is a product of *nervous tension*, but there is no clear evidence for tension as an etiology. Muscle contraction has been considered to be a feature that distinguishes TTH from migraine, but there appear to be no differences in contraction between the two headache types. In primary care, <10% of patients presenting with headache over 3 months or more without any neurologic symptoms or signs have tension-type headache; >90% have migraine.

TREATMENT

Tension-Type Headache

The pain of TTH can generally be managed with simple analgesics such as acetaminophen, aspirin, or NSAIDs. Behavioral approaches including relaxation can also be effective. Clinical studies have demonstrated that triptans in pure TTH are not helpful, although triptans are effective in apparent TTH when the patient also has migraine. For chronic TTH, amitriptyline is the only proven treatment (Table 441-6); other tricyclics, selective serotonin reuptake inhibitors, and the benzodiazepines have not been shown to be effective. There is no evidence for the efficacy of acupuncture. Placebo-controlled trials of onabotulinum toxin type A in chronic TTH were negative.

TRIGEMINAL AUTONOMIC CEPHALALGIAS, INCLUDING CLUSTER HEADACHE

The TACs describe a grouping of primary headache disorders including cluster headache, paroxysmal hemicrania (PH), SUNCT (*s*hort-lasting *u*nilateral *n*euralgiform headache attacks with *c*onjunctival injection and *t*earing)/SUNA (*s*hort-lasting *u*nilateral *n*euralgiform headache attacks with cranial *a*utonomic symptoms), and hemicrania continua (Table 441-1). TACs are characterized by relatively short-lasting attacks of head pain associated with lateralized cranial autonomic symptoms, such as lacrimation, conjunctival injection, aural fullness, or nasal congestion (Table 441-7). Pain is usually severe and may occur more than once a day. Because of the associated nasal congestion or rhinorrhea, patients are often misdiagnosed with "sinus headache" and treated with decongestants, which are ineffective.

TABLE 441-7 Clinical Features of the Trigeminal Autonomic Cephalalgias

	CLUSTER HEADACHE	PAROXYSMAL HEMICRANIA	SUNCT/SUNA
Gender	M > F	F = M	F ~ M
Pain			
Type	Stabbing, boring	Throbbing, boring, stabbing	Burning, stabbing, sharp
Severity	Excruciating	Excruciating	Severe to excruciating
Site	Orbit, temple	Orbit, temple	Periorbital
Attack frequency	1/alternate day–8/d	1–20/d (>5/d for more than half the time)	3–200/d
Duration of attack	15–180 min	2–30 min	5–240 s
Autonomic features	Yes	Yes	Yes (prominent conjunctival injection and lacrimation)[a]
Migrainous features[b]	Yes	Yes	Yes
Alcohol trigger	Yes	No	No
Cutaneous triggers	No	No	Yes
Indomethacin effect	—	Yes[c]	—
Abortive treatment	Sumatriptan injection or nasal spray Zolmitriptan nasal spray Oxygen nVNS[c]	No effective treatment	Lidocaine (IV)
Preventive treatment	Verapamil Galcanezumab Topiramate Melatonin Lithium	Indomethacin[d] nVNS	Lamotrigine Topiramate Gabapentin

[a]If conjunctival injection and tearing are not present, consider SUNA. [b]Nausea, photophobia, or phonophobia; photophobia and phonophobia are typically unilateral on the side of the pain. [c]Noninvasive vagus nerve stimulation is U.S. Food and Drug Administration approved in episodic cluster headache [d]Indicates complete response to indomethacin.

Abbreviations: nVNS, non-invasive vagus nerve stimulation; SUNA, *s*hort-lasting *u*nilateral *n*euralgiform headache attacks with cranial *a*utonomic features; SUNCT, *s*hort-lasting *u*nilateral *n*euralgiform headache attacks with *c*onjunctival injection and *t*earing.

TACs must be differentiated from short-lasting headaches that do not have prominent cranial autonomic syndromes, notably trigeminal neuralgia (TN), primary stabbing headache, and hypnic headache. The cycling pattern and length, frequency, and timing of attacks are useful in classifying patients. Patients with TACs should be considered, if clinically indicated, to undergo pituitary imaging and pituitary function tests because there is an excess of TAC presentations in clinical practice in patients with pituitary tumor–related headache, particularly prolactin and growth hormone secreting tumors.

Cluster Headache Cluster headache is a relatively rare form of primary headache, although nonetheless a common condition, with a population frequency of ~0.1%. The pain is deep, usually retroorbital, often excruciating in intensity, nonfluctuating, and explosive in quality. A core feature of cluster headache is periodicity. Usually one of the daily attacks of pain recurs at about the same hour each day for the duration of a cluster bout. The typical cluster headache patient has daily bouts of one to two attacks of relatively short-duration unilateral pain for 8–10 weeks a year; this is usually followed by a pain-free interval that averages a little less than 1 year. Cluster headache is characterized as chronic when there is <3 months of sustained remission without treatment. Patients are generally perfectly well between episodes. Onset of attacks is nocturnal in about 50% of patients, and men are affected three times more often than women. Patients with cluster headache tend to move about during attacks, pacing, rocking, or rubbing their head for relief; some may even become aggressive during attacks. This is in sharp contrast to patients with migraine, who prefer to remain motionless during attacks.

Cluster headache is associated with ipsilateral symptoms of cranial parasympathetic autonomic activation: conjunctival injection or lacrimation, aural fullness, rhinorrhea or nasal congestion, or cranial sympathetic dysfunction such as ptosis. The sympathetic deficit is peripheral and likely to be due to parasympathetic activation with injury to ascending sympathetic fibers surrounding a dilated carotid artery as it passes into the cranial cavity. When present, photophobia and phonophobia are more likely to be unilateral and on the same side of the pain, rather than bilateral, in contrast to migraine. This phenomenon of unilateral photophobia/phonophobia is characteristic of TACs. Cluster headache is likely to be a disorder involving central pacemaker neurons and neurons in the posterior hypothalamic region (Fig. 441-3).

TREATMENT

Cluster Headache

The most satisfactory treatment is the administration of drugs to prevent cluster attacks until the bout is over. However, treatment of acute attacks is required for all cluster headache patients at some time.

ACUTE ATTACK TREATMENT

Cluster headache attacks peak rapidly, and thus a treatment with rapid onset is required. Many patients with acute cluster headache respond very well to oxygen inhalation. This should be given as 100% oxygen at 10–12 L/min for 15–20 min. It appears that high flow and high oxygen content are important, thus ultra-high flow with a demand valve may be a better option for some patients. Sumatriptan 6 mg SC is rapid in onset and will usually shorten an attack to 10–15 min; where available, 3 or 4 mg SC can also be effective; there is no evidence of tachyphylaxis. Sumatriptan (20 mg) and zolmitriptan (5 mg) nasal sprays are both effective in acute cluster headache, offering a useful option for patients who may not wish to self-inject daily. nVNS is FDA cleared for the acute treatment of attacks in episodic cluster headache using three 2-min stimulation cycles applied consecutively at the onset of headache on the side of pain; this may be repeated after 9 min. Oral sumatriptan is not effective for prevention or for acute treatment of cluster headache.

PREVENTIVE TREATMENTS (**TABLE 441-8**)

The choice of a preventive treatment in cluster headache depends in part on the length of the bout. Patients with long bouts or those with chronic cluster headache require medicines that are safe when taken for long periods. For patients with relatively short bouts, limited courses of oral glucocorticoids can be very useful. A 10-day course of prednisone, beginning at 60 mg daily for 7 days and followed by a rapid taper, may interrupt the pain bout for many patients. Greater occipital nerve injection with lidocaine and corticosteroids has been shown to be effective in randomized controlled trials, with a benefit that lasts up to 6–8 weeks. The CGRP monoclonal antibody galcanezumab has been approved by the FDA for treatment of episodic cluster headache; it reduces attack frequency, is well tolerated, and is often an effective option.

Most experts favor verapamil as the first-line preventive treatment for patients with chronic cluster headache or with prolonged bouts. While verapamil compares favorably with lithium in practice, some patients require verapamil doses far in excess of those administered for cardiac disorders. The initial dose range is 40–80 mg twice daily; effective doses may be as high as 960 mg/d. Side effects such as constipation, leg swelling, or gingival hyperplasia can be problematic. Of paramount concern, however, is the cardiovascular safety of verapamil, particularly at high doses. Verapamil can cause heart block by slowing conduction in the atrioventricular node, a condition that can be monitored by following the PR interval on a standard electrocardiogram (ECG). Approximately 20% of patients treated with verapamil develop ECG abnormalities, which can be observed with doses as low as 240 mg/d; these abnormalities can worsen over time in patients on stable doses. A baseline ECG is recommended for all patients. The ECG is repeated 10 days after a dose change in patients whose dose is being increased above 240 mg daily. Dose increases are usually made in 80-mg increments. For patients on long-term verapamil, ECG monitoring every 6 months is advised.

TABLE 441-8 Preventive Management of Cluster Headache

SHORT-TERM PREVENTION	LONG-TERM PREVENTION
EPISODIC CLUSTER HEADACHE	EPISODIC CLUSTER HEADACHE AND PROLONGED CHRONIC CLUSTER HEADACHE
Prednisone 1 mg/kg up to 60 mg qd, tapering over 21 days Verapamil 160–960 mg/d Galcanezumab 300 mg SC Greater occipital nerve injection (local anesthetic and corticosteroids)	Verapamil 160–960 mg/d nVNS 6–24 stimulations/d Melatonin[a] 9–12 mg/d Topiramate[a] 100–400 mg/d Lithium 400–800 mg/d

Abbreviations: nVNS, noninvasive vagus nerve stimulation.

NEUROMODULATION THERAPY

When medical therapies fail in chronic cluster headache, neuromodulation strategies can be used. Sphenopalatine ganglion (SPG) stimulation with an implanted battery-free stimulator has been shown in randomized controlled trials to be effective in aborting attacks and reducing their frequency over time. nVNS compares favorably with standard-of-care in open-label experience. Similarly, occipital nerve stimulation has been used open label and appears to be beneficial. Deep-brain stimulation of the region of the posterior hypothalamic gray matter is successful in about 50% of patients treated, although its risk-versus-benefit ratio makes it inappropriate before all other less invasive options have been explored.

PAROXYSMAL HEMICRANIA

Paroxysmal hemicrania (PH) is characterized by frequent unilateral, severe, short-lasting episodes of headache. Like cluster headache, the pain tends to be retroorbital but may be experienced all over the head and is associated with cranial autonomic phenomena such as lacrimation and nasal congestion. Patients with remissions are said to have episodic PH, whereas those with the nonremitting form are said to have chronic PH. The essential features of PH are unilateral very severe

pain; short-lasting attacks (2–45 min); very frequent attacks (usually >5 a day); marked autonomic features ipsilateral to the pain; rapid course (<72 h); and excellent response to indomethacin. In contrast to cluster headache, which predominantly affects males, the male-to-female ratio in PH is close to 1:1.

Indomethacin (25–75 mg tid), which can completely suppress attacks of PH, is the treatment of choice. Although therapy may be complicated by indomethacin-induced gastrointestinal side effects, currently there are no consistently effective alternatives. Topiramate is helpful in some cases. nVNS can be very effective in PH. Melatonin may be indomethacin-sparing in some patients. Verapamil, an effective treatment for cluster headache, does not appear to be useful for PH. In occasional patients, PH can coexist with TN (PH-tic syndrome); similar to cluster-tic syndrome, each component may require separate treatment.

Secondary PH has been reported with lesions in the region of the sella turcica, including arteriovenous malformation, cavernous sinus meningioma, pituitary pathology, and epidermoid tumors. Secondary PH is more likely if the patient requires high doses (>200 mg/d) of indomethacin. In patients with apparent bilateral PH, raised cerebrospinal fluid (CSF) pressure should be suspected. It is important to note that indomethacin reduces CSF pressure. When a diagnosis of PH is considered, magnetic resonance imaging (MRI) is indicated to exclude a pituitary lesion.

SUNCT/SUNA

SUNCT is a rare primary headache syndrome characterized by severe, unilateral orbital or temporal pain that is stabbing or throbbing in quality. Diagnosis requires at least 20 attacks, lasting for 5–240 s; ipsilateral conjunctival injection and lacrimation should be present. In some patients, conjunctival injection or lacrimation is missing, and the diagnosis of SUNA can be made.

Diagnosis The pain of SUNCT/SUNA is unilateral and may be located anywhere in the head. Three basic patterns can be seen: single stabs, which are usually short-lived; groups of stabs; or a longer attack comprising many stabs between which the pain does not completely resolve, thus giving a "saw-tooth" phenomenon with attacks lasting many minutes. Each pattern may be seen in the context of an underlying continuous head pain. Characteristics that lead to a suspected diagnosis of SUNCT are the cutaneous (or other) triggers of attacks, a lack of refractory period to triggering between attacks, and the lack of a response to indomethacin. Apart from trigeminal sensory disturbance, the neurologic examination is normal in primary SUNCT/SUNA.

The diagnosis of SUNCT/SUNA is often confused with TN, particularly in first-division TN (Chap. 452). Minimal or no cranial autonomic symptoms and a clear refractory period to triggering indicate a diagnosis of TN.

Secondary (Symptomatic) SUNCT SUNCT can be seen with posterior fossa or pituitary lesions. All patients with SUNCT/SUNA should be evaluated with pituitary function tests and a brain MRI with pituitary views.

TREATMENT

SUNCT/SUNA

ABORTIVE THERAPY

Therapy of acute attacks is not a useful concept in SUNCT/SUNA because the attacks are of such short duration. However, IV lidocaine, which arrests the symptoms, can be used in hospitalized patients.

PREVENTIVE THERAPY

Long-term prevention to minimize disability and hospitalization is the goal of treatment. The most effective treatment for prevention is lamotrigine, 200–400 mg/d. Topiramate and gabapentin may also be effective. Carbamazepine, 400–500 mg/d, has been reported by patients to offer modest benefit.

Surgical approaches such as microvascular decompression or destructive trigeminal procedures are seldom useful and often produce long-term complications. Greater occipital nerve injection has produced limited benefit in some patients. nVNS may be useful. Occipital nerve stimulation is probably helpful in a subgroup of these patients. For intractable cases, short-term prevention with IV lidocaine can be effective.

HEMICRANIA CONTINUA

The essential features of hemicrania continua are moderate and continuous unilateral pain associated with fluctuations of severe pain; complete resolution of pain with indomethacin; and exacerbations that may be associated with cranial autonomic features, including conjunctival injection, lacrimation, and photophobia on the affected side. The age of onset ranges from 10 to 70 years; women are affected twice as often as men. The cause is unknown.

TREATMENT

Hemicrania Continua

Treatment consists of indomethacin; other NSAIDs appear to be of little or no benefit. The IM injection of 100 mg of indomethacin has been proposed as a diagnostic tool, and administration with a placebo injection in a blinded fashion can be very useful diagnostically. Alternatively, a trial of oral indomethacin, starting with 25 mg tid, then 50 mg tid, and then 75 mg tid, can be given. Up to 2 weeks at the maximal dose may be necessary to assess whether a dose has a useful effect. Topiramate can be helpful in some patients. nVNS can be very useful in these patients. Melatonin can be useful as an indomethacin-sparing agent. Occipital nerve stimulation probably has a role in patients with hemicrania continua who are unable to tolerate indomethacin.

OTHER PRIMARY HEADACHE DISORDERS

Primary Cough Headache Primary cough (Valsalva maneuver) headache is a generalized headache that begins suddenly, lasts for seconds or several minutes, sometimes up to a few hours, and is precipitated by coughing; it is preventable by avoiding coughing or other precipitating events, which can include sneezing, straining, laughing, or stooping. In all patients with this syndrome, serious etiologies must be excluded before a diagnosis of "benign" primary cough headache can be established. A Chiari malformation or any lesion causing obstruction of CSF pathways or displacing cerebral structures can be the cause of the head pain. Other conditions that can present with cough or exertional headache as the initial symptom include cerebral aneurysm, carotid stenosis, and vertebrobasilar disease. Benign cough headache can resemble benign exertional headache (below); patients with the former condition are typically older.

TREATMENT

Primary Cough Headache

Indomethacin 25–50 mg two to three times daily is the treatment of choice. Some patients with cough headache obtain complete cessation of their attacks with lumbar puncture; this is a simple option when compared to prolonged use of indomethacin, and it is effective in about one-third of patients. The mechanism of this response is unclear.

Primary Exercise Headache Primary exercise headache has features resembling both cough headache and migraine. It may be precipitated by any form of exercise; it often has the pulsatile quality of migraine. The pain lasts <48 h, is bilateral, and is often throbbing at onset; migrainous features may develop in patients susceptible to migraine. The duration tends to be shorter in adolescents than in older adults. Primary exercise headache can be prevented by avoiding excessive exertion, particularly in hot weather or at high altitude.

The mechanism of primary exercise headache is unclear. Acute venous distension likely explains one syndrome—the acute onset of headache with straining and breath holding, as in weightlifter's headache. Because exercise can trigger headache in a number of serious underlying conditions (Chap. 17), these must be considered in patients with exercise headache. Pain from angina may be referred to the head, probably by central connections of vagal afferents, and may present as exercise headache (cardiac cephalgia). The link to exercise is the main clinical clue that headache is of cardiac origin. Pheochromocytoma may occasionally cause exercise headache. Intracranial lesions and stenosis of the carotid arteries are other possible etiologies.

TREATMENT

Primary Exercise Headache

Exercise regimens should begin modestly and progress gradually to higher levels of intensity. Indomethacin at daily doses from 25–150 mg is generally effective in benign exertional headache. Indomethacin (50 mg), a gepant-rimegepant (75 mg orally) or ubrogepant (100 mg orally), ergotamine (1 mg orally), and dihydroergotamine (2 mg by nasal spray) are useful short-term preventive measures.

Primary Headache Associated with Sexual Activity Three types of sex headache are reported: a dull bilateral ache in the head and neck that intensifies as sexual excitement increases; a sudden, severe, explosive headache occurring at orgasm; and a postural headache developing after coitus. The latter arises from vigorous sexual activity and is a form of low CSF pressure headache and thus not a primary headache disorder (Chap. 17). Headaches developing at the time of orgasm are not always benign; 5–12% of cases of subarachnoid hemorrhage are precipitated by sexual intercourse. Sex headache is reported by men more often than women and may occur at any time during the years of sexual activity. It may appear on several occasions in succession and then not trouble the patient again, even without an obvious change in sexual activity. In patients who stop sexual activity when headache is first noticed, the pain may subside within a period of 5 min to 2 h. In about half of patients, sex headache will subside within 6 months. Most patients with sex headache do not have exercise or cough headache; this clinical paradox is generally a marker of primary sex headache. Migraine is probably more common in patients with sex headache.

TREATMENT

Primary Sex Headache

Benign sex headaches recur irregularly and infrequently. Management can often be limited to reassurance and advice about ceasing sexual activity if a mild, warning headache develops. Propranolol can be used to prevent headache that recurs regularly or frequently, but the dosage required varies from 40–200 mg/d. An alternative is the calcium channel–blocking agent diltiazem, 60 mg tid. Indomethacin (25–50 mg), a gepant-rimegepant (75 mg orally) or ubrogepant (100 mg orally), or frovatriptan (2.5 mg), taken 30–45 min prior to sexual activity can also be helpful.

Primary Thunderclap Headache Sudden onset of severe headache may occur in the absence of any known provocation. The differential diagnosis includes the sentinel bleed of an intracranial aneurysm, reversible cerebral vasoconstriction syndrome (RCVS), cervicocephalic arterial dissection, and cerebral venous thrombosis. Headaches of explosive onset may also be caused by the ingestion of sympathomimetic drugs or of tyramine-containing foods in a patient who is taking MAOIs, or they may be a symptom of pheochromocytoma. Whether thunderclap headache can be the presentation of an unruptured cerebral aneurysm is uncertain; some experts believe that RCVS is the cause of most or all cases of otherwise undiagnosed thunderclap headache. When neuroimaging studies and lumbar puncture exclude subarachnoid hemorrhage, patients with thunderclap headache usually do very well over the long term. In one study of patients whose computed tomography (CT) scans and CSF findings were negative, ~15% had recurrent episodes of thunderclap headache, and nearly half subsequently developed migraine or TTH.

The first presentation of any sudden-onset severe headache should be diligently investigated with neuroimaging (CT or, when possible, MRI with MR angiography) and CSF examination. In the presence of posterior leukoencephalopathy, the differential diagnosis includes cerebral angiitis, posterior reversible encephalopathy syndrome (PRES), drug toxicity (cyclosporine, intrathecal methotrexate/cytarabine, pseudoephedrine, or cocaine), posttransfusion effects, and postpartum angiopathy. Treatment with nimodipine may be helpful, although the vasoconstriction often resolves spontaneously.

Cold-Stimulus Headache This refers to head pain triggered by application or ingestion/inhalation of something cold. It is brought on quickly and typically resolves within 10–30 min of the stimulus being removed. It is best recognized as "brain-freeze" headache or ice-cream headache when due to ingestion. Although cold may be uncomfortable at some level for many people, it is the reliable, severe, and somewhat prolonged nature of these pains that set them apart. The transient receptor potential cation subfamily M member 8 (TRPM8) channel, a known cold-temperature sensor, may be a mediator of this syndrome. Naproxen 500 mg taken 30 min prior to exposure can be helpful for this problem.

External Pressure Headache External pressure from compression or traction on the head can produce a pain that may have some generalized component, although the pain is largely focused around the site of the pressure. It typically resolves within an hour of the stimulus being removed. Examples of stimuli include helmets, swimming goggles, or very long ponytails. Treatment is to recognize the problem and remove the stimulus.

Primary Stabbing Headache The essential features of primary stabbing headache are stabbing pain confined to the head or, rarely, the face, lasting from 1 to many seconds and occurring as a single stab or a series of stabs; absence of associated cranial autonomic features; absence of cutaneous triggering of attacks; and a pattern of recurrence at irregular intervals (hours to days). When present in adolescents, primary stabbing headache may be a presenting and very troublesome problem for the patient. The pains have been variously described as "ice-pick pains" or "jabs and jolts." They are more common in patients with other primary headaches, such as migraine, the TACs, and hemicrania continua. A key clinical feature is an irregular cadence compared to the regular cadence of the throbbing or pounding that characterizes migraine.

TREATMENT

Primary Stabbing Headache

The response of primary stabbing headache to indomethacin (25–50 mg two to three times daily) is usually excellent. As a general rule, the symptoms wax and wane, and after a period of control on indomethacin, it is appropriate to withdraw treatment and observe the outcome.

Nummular Headache Nummular headache is felt as a round or elliptical discomfort that is fixed in place, ranges in size from 1–6 cm, and may be continuous or intermittent. Uncommonly, it may be multifocal. It may be episodic but is more often continuous during exacerbations. Accompanying the pain there may be a local sensory disturbance, such as allodynia or hypesthesia. Local dermatologic or bony lesions need to be excluded by examination and investigation. This condition can be difficult to treat when present in isolation;

tricyclics, such as amitriptyline, or anticonvulsants, such as topiramate or valproate, are most often tried. This phenotype can be seen in combination with migraine and the TACs, in which cases treatment of the primary headache disorder is often effective for the nummular headache as well.

Hypnic Headache This headache syndrome typically begins a few hours after sleep onset. The headaches last from 15–30 min and are typically moderately severe and generalized, although they may be unilateral and can be throbbing. Patients may report falling back to sleep only to be awakened by a further attack a few hours later; up to three repetitions of this pattern occur through the night. Daytime naps can also precipitate head pain. Most patients are female, and the onset is usually after age 60 years. Headaches are typically bilateral but may be unilateral. Photophobia, phonophobia, and nausea are usually absent. The major secondary consideration in this headache type is poorly controlled hypertension; 24-h blood pressure monitoring is recommended to detect this treatable condition.

TREATMENT

Hypnic Headache

Patients with hypnic headache generally respond to a bedtime dose of lithium carbonate (200–600 mg). One to two cups of coffee, or caffeine 60 mg orally, at bedtime may be effective in approximately one-third of patients. Reports suggest that verapamil, 160 mg; flunarizine, 5 mg nightly; or indomethacin, 25–75 mg nightly, can be effective.

New Daily Persistent Headache Primary new daily persistent headache (NDPH) occurs in both men and women. It can be of the migrainous type, with features of migraine, or it can be featureless, appearing as new-onset TTH. Those with migrainous features are the most common form and include unilateral headache and throbbing pain; each feature is present in about one-third of patients. Nausea, photophobia, and/or phonophobia occur in about half of patients. Some patients have a previous history of migraine. NDPH may be more common in adolescents. Treatment of migrainous-type primary NDPH consists of using the preventive therapies effective in migraine (see above). Featureless NDPH is one of the primary headache disorders most refractory to treatment. Standard preventive therapies can be offered but are often ineffective. The secondary NDPHs are discussed elsewhere **(Chap. 17)**.

442 Alzheimer's Disease

Gil D. Rabinovici, Peter A. Ljubenkov, William W. Seeley, Bruce L. Miller

ALZHEIMER'S DISEASE

Approximately 55 million people across the world are living with dementia. Alzheimer's disease (AD) is the most common cause of dementia, contributing to an estimated 60–70% of all cases. Total U.S. health care costs related to dementia care are estimated at $360 billion in 2024, translating into an average of ~$25,000 per patient. Furthermore, the emotional toll for family members and caregivers is immeasurable. AD can manifest as early as the third decade of life, but it is the most common neuropathology contributing to dementia in the elderly. Patients most often present with an insidious loss of episodic memory followed by a slowly progressive dementia. In typical amnestic AD, brain atrophy begins in the medial temporal lobes before spreading to inferior temporal, lateral and medial parietal, and dorsolateral frontal cortices. Microscopically, there are widespread neuritic plaques containing amyloid beta (Aβ), neurofibrillary tangles (NFTs) composed of hyperphosphorylated tau filaments, and Aβ accumulation in blood vessel walls in cortex and leptomeninges (see "Pathology," below). The identification of causative mutations and susceptibility genes for AD has provided a foundation for rapid progress in understanding the biological basis of the disorder. The major genetic risk factor for AD is the ε4 allele of the apolipoprotein E (*ApoE*) gene. Carrying one ε4 allele increases the risk for AD by two- to threefold in women, whereas carrying two alleles increases the risk 10- to 15-fold in both sexes. Rapid progress in the development of imaging, cerebrospinal fluid (CSF), and plasma biomarkers of Aβ and phosphorylated tau has enabled detection of AD pathologic hallmarks in living people, opening the door to early detection and intervention with biologically specific therapies.

CLINICAL MANIFESTATIONS

The cognitive changes of AD tend to follow a characteristic pattern, beginning with memory impairment and progressing to deficits in executive, language, and visuospatial functions. Yet, ~20% of patients with AD present with nonmemory complaints such as word-finding, organizational, or navigational difficulty. In other patients, visual processing dysfunction (referred to as posterior cortical atrophy syndrome) or a progressive "logopenic" aphasia characterized by difficulties with naming and repetition is the primary manifestation of AD for years before progressing to involve memory and other cognitive domains. Still other patients may present with an asymmetric akinetic-rigid-dystonic ("corticobasal") syndrome or a dysexecutive/behavioral (i.e., "frontal" variant of AD). Depression, social withdrawal, and anxiety occur in early disease stages and may represent a prodrome before cognitive symptoms are apparent.

In early stages of typical amnestic AD, the memory loss may go unrecognized or be ascribed to benign forgetfulness of aging. The term *subjective cognitive decline* refers to self-perceived worsening in memory or other cognitive abilities that may not be noticeable to others or apparent on formal neuropsychological testing. Once the memory loss becomes noticeable to the patient and spouse and is confirmed on standardized memory tests, the term *mild cognitive impairment* (MCI) is often used. This construct provides useful prognostic information because ~50% of patients with MCI (roughly 12% per year) will progress to the dementia stage over 4 years. Increasingly, the MCI construct is being replaced by the notion of "early symptomatic AD" to signify that AD is considered the underlying disease (based on clinical or biomarker evidence) in a patient who remains functionally compensated. Even earlier in the course, "preclinical AD" refers to a person with biomarker evidence of amyloid pathology (with or without tau pathology) in the absence of symptoms. It is estimated that preclinical biomarker changes may precede clinical symptoms by 20 years or more, creating a window of opportunity for early-stage treatment and prevention

trials. Emerging evidence suggests that partial and sometimes generalized seizures herald AD and can occur even prior to dementia onset, especially in younger patients and those with autosomal dominant AD-causing mutations.

Eventually with AD, the cognitive problems begin to interfere with daily activities, such as keeping track of finances, following instructions on the job, driving, shopping, and housekeeping. Some patients are unaware of these difficulties (*anosognosia*), but most remain acutely attuned to their deficits in early disease stages. Changes in environment (travel, relocation, hospitalization) tend to destabilize the patient. Over time, patients become lost on walks or while driving. Social graces, routine behavior, and superficial conversation may be surprisingly intact, even into the later stages of the illness.

In the middle stages of AD, the patient is unable to work, is easily lost and confused, and requires daily supervision. Language becomes impaired—first naming, then comprehension, and finally fluency. Word-finding difficulties and circumlocution can be evident in the early stages, even when formal testing demonstrates intact naming and fluency. *Apraxia* emerges, manifesting as trouble performing learned sequential motor tasks such as using utensils or appliances. Visuospatial deficits begin to interfere with dressing, eating, or even walking, and patients fail to solve simple puzzles or copy geometric figures. Simple calculations and clock reading become difficult in parallel.

In the late stages, some persons remain ambulatory, wandering aimlessly. Loss of judgment and reasoning is inevitable. Delusions are prevalent and usually simple, with common themes of theft, infidelity, or misidentification. Disinhibition and uncharacteristic belligerence may occur and alternate with passivity and withdrawal. Sleep-wake patterns are disrupted, and nighttime wandering becomes disturbing to the household. Some patients develop a shuffling gait with generalized muscle rigidity associated with slowness and awkwardness of movement. Patients often look parkinsonian **(Chap. 446)** but rarely have a high-amplitude, low-frequency tremor at rest. There is a strong overlap between dementia with Lewy bodies (DLB) **(Chap. 445)** and AD, and some AD patients develop more classical parkinsonian features.

In the end stages, patients with AD become rigid, mute, incontinent, and bedridden, and need help with eating, dressing, and toileting. Hyperactive tendon reflexes and myoclonic jerks (sudden brief contractions of various muscles or the whole body) may occur spontaneously or in response to physical or auditory stimulation. Often death results from malnutrition, secondary infections, pulmonary emboli, heart disease, or, most commonly, aspiration. The typical duration of symptomatic AD is 8–10 years, but the course ranges from 1 to 25 years. For unknown reasons, some patients with AD show a steady decline in function while others have prolonged plateaus without major deterioration.

An increased risk for seizures is also increasingly recognized as a feature of AD; different seizure types (both generalized and focal onset) have been reported, and these occur more frequently as the disease progresses.

DIAGNOSIS

See also "Other Causes of Dementia," below, and the general discussion of dementia presented in Chap. 31. Early in the disease course, other etiologies of dementia should be excluded **(see Tables 31-1, 31-3, and 31-4)**. *Slowly progressive decline in memory and orientation, normal results on systemic laboratory tests, and a magnetic resonance imaging (MRI) or computed tomography (CT) scan showing only distributed or posteriorly predominant cortical and hippocampal atrophy (see below) are suggestive of AD.* A clinical diagnosis of AD reached after careful evaluation is confirmed at autopsy ~70–80% of the time, with misdiagnosed cases usually resulting from limbic-predominant age-related TDP-43 encephalopathy (LATE) with or without hippocampal sclerosis, primary age-related tauopathy (PART), Lewy body disease (LBD), vascular pathology, or frontotemporal lobar degeneration (FTLD; **Chap. 443**).

Simple clinical clues are useful in the differential diagnosis. Early prominent gait disturbance with only mild memory loss suggests vascular dementia or, rarely, normal pressure hydrocephalus (NPH), discussed later. Resting tremor with stooped posture, bradykinesia, and masked facies suggest PD **(Chap. 446)** or DLB **(Chap. 445)**. When dementia occurs after a well-established diagnosis of PD, PD dementia (PDD) is usually the correct diagnosis, but many patients with this diagnosis will show a mixture of AD and LBD at autopsy. The early appearance of parkinsonian features in association with fluctuating alertness, visual hallucinations, or delusional misidentification suggests DLB. Chronic alcoholism should prompt the search for vitamin deficiency. Loss of joint position and vibration sensibility accompanied by Babinski signs suggests vitamin B_{12} deficiency, especially in a patient with a history of autoimmune disease, small bowel resection or irradiation, or veganism **(Chap. 104)**. Early onset of a focal seizure suggests a metastatic or primary brain neoplasm **(Chap. 95)**. Previous or ongoing depression raises suspicion for depression-related cognitive impairment, although significant cognitive changes with depression is common and AD and DLB can feature a prodrome of depression or anxiety. A history of treatment for insomnia, anxiety, psychiatric disturbance, or epilepsy suggests chronic drug intoxication. Rapid progression over a few weeks or months associated with rigidity and myoclonus suggests Creutzfeldt-Jakob disease (CJD) **(Chap. 449)**. Prominent behavioral changes with intact navigation and focal anterior-predominant atrophy on brain imaging are typical of FTD. A positive family history of dementia suggests either one of the familial forms of AD or one of the other genetic disorders associated with dementia, such as FTD **(Chap. 443)**, Huntington's disease (HD) **(Chap. 447)**, prion disease **(Chap. 449)**, or rare hereditary ataxias **(Chap. 450)**.

Electroencephalogram (EEG) is usually normal or shows nonspecific slowing; prolonged EEG can be used to seek out intermittent nonconvulsive seizures.

Structural neuroimaging studies (CT and MRI) do not show a single specific pattern with AD and may be normal early in the disease. As AD progresses, more distributed but usually posterior-predominant cortical atrophy becomes apparent, along with atrophy of the medial temporal memory structures **(see Fig. 31-1)**. The main purpose of structural imaging is to exclude other disorders, such as primary and secondary neoplasms, vascular dementia, diffuse white matter disease, and normal-pressure hydrocephalus (NPH). Imaging also helps to distinguish AD from other degenerative disorders, such as frontotemporal dementia (FTD) **(Chap. 443)** or the prion disorder CJD **(Chap. 449)**, which feature imaging patterns that are different from AD. Functional imaging studies, such as fluorodeoxyglucose (FDG) positron emission tomography (PET), reveal hypometabolism in the posterior temporal-parietal cortex in AD **(see Fig. 31-1)**.

Amyloid PET imaging (e.g., with radiotracers [^{11}C]PIB, [^{18}F]florbetapir, [^{18}F]florbetaben, or [^{18}F]flutemetamol) confirms the presence of neuritic and diffuse Aβ plaques throughout the neocortex **(Fig. 442-1)**. [^{18}F]florbetapir, [^{18}F]florbetaben, and [^{18}F]flutemetamol are approved for clinical use in the United States and other countries. Although amyloid PET binding is detected in AD, ~25% of cognitively unimpaired older individuals also have positive scans, thought to represent preclinical disease and an increase in the risk of converting to clinical AD. Similarly, dementia due to a non-AD disorder can be the underlying etiology in a patient who tests positively on amyloid PET due to comorbid AD pathology. Amyloid PET ligands also bind to vascular Aβ deposits in cerebral amyloid angiopathy (CAA) **(Chap. 439)**. Therefore, clinical use of amyloid PET should be restricted to specific scenarios in which knowledge of amyloid status is expected to impact diagnosis and change management. For example, a negative amyloid PET scan in a patient with dementia makes an AD diagnosis unlikely. Conversely, a positive PET scan can be used to establish eligibility for novel amyloid-lowering therapies in a patient who meets the clinical criteria for treatment (see below).

Tau PET radiotracers (e.g., [^{18}F]flortaucipir, [^{18}F]MK-6240, [^{18}F]PI-2620) bind to the paired helical filaments that form neurofibrillary tangles and are primarily available in the research setting. [^{18}F]Flortaucipir is also approved for clinical use in the United States "to estimate the density and distribution of aggregated tau neurofibrillary tangles in adult patients with cognitive impairment who are being evaluated for AD." The pattern of binding is largely consistent with

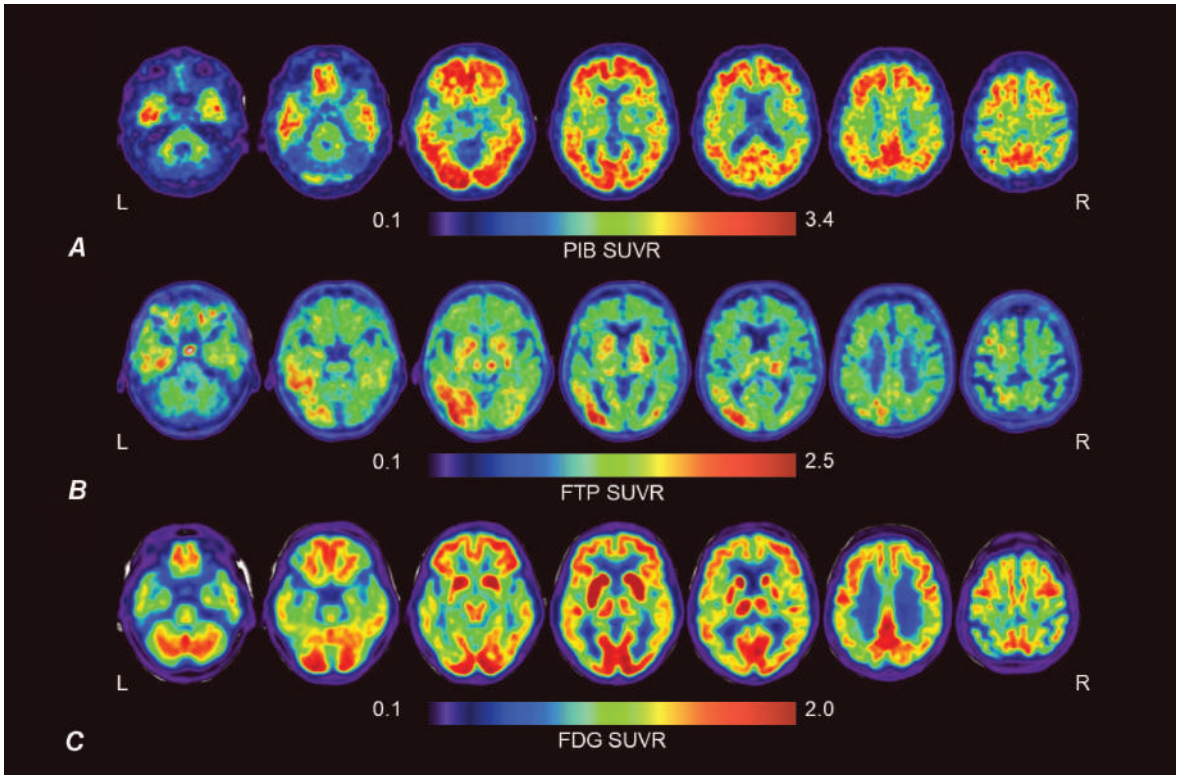

FIGURE 442-1 Molecular imaging of Alzheimer's disease pathophysiology in an 81-year-old with mild Alzheimer's disease. ***A.*** Aβ positron emission tomography (PET) with [^{11}C]PIB reveals extensive radiotracer retention in neocortex, consistent with the known distribution of amyloid plaques. ***B.*** Tau PET with [^{18}F]FTP shows asymmetric uptake predominantly in the left temporal cortex, consistent with intermediate-stage neurofibrillary tangles. Tracer uptake in midbrain and basal ganglia represents "off-target" (non-tau-related) tracer retention. ***C.*** Fluorodeoxyglucose (FDG)-PET reveals reduced tracer uptake in left greater than right temporal and parietal cortex, indicative of decreased synaptic activity. The pattern of hypometabolism corresponds more closely to the pattern of tau than amyloid deposition. ***A–C.*** Axial brain slices are shown in neurologic orientation. L, left; R, right; SUVR, standardized uptake value ratio, a quantitative measure of PET radiotracer retention.

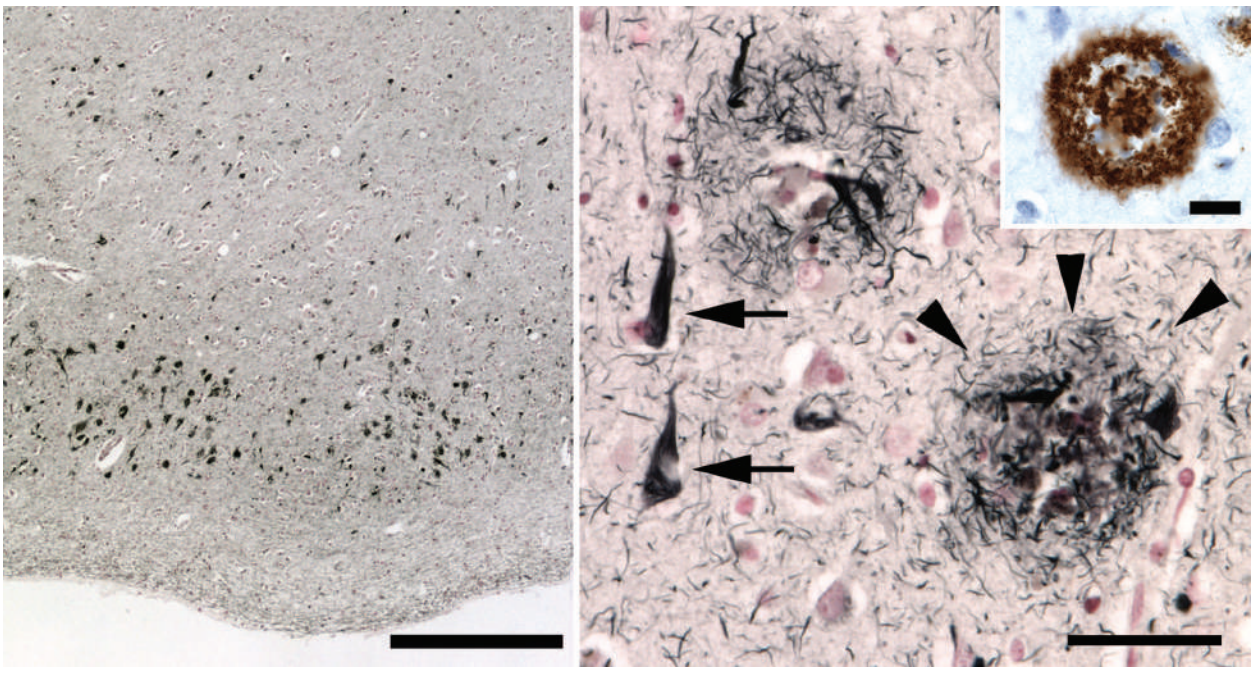
Braak neuropathologic staging of neurofibrillary tangles, with early retention in medial temporal regions, followed by spread into temporoparietal and cingulate cortices, dorsolateral prefrontal regions, and ultimately, primary sensory and motor areas. However, tau PET signal lags behind neuropathologic staging of tangles due to limited sensitivity, and completely negative tau PET does not rule out early neurofibrillary pathology (Braak stages I–III). Notably, tau PET radiotracers developed to detect AD-related tau aggregation have limited utility in detecting aggregated tau in non-AD tauopathies (e.g., progressive supranuclear palsy [PSP], cortical basal degeneration [CBD], chronic traumatic encephalopathy [CTE]).

Routine spinal fluid examination is generally normal, but CSF reductions in $A\beta_{42}$ levels and the $A\beta_{42}/A\beta_{40}$ ratio correlate with amyloid deposition, and increases in phosphorylated tau (at residue 181 or 217; p-Tau181 or p-Tau217) detect AD-related changes in tau phosphorylation and secretion. On the other hand, increases in total tau levels represent a nonspecific finding seen in AD but also in other causes of neurodegeneration. Several CSF AD biomarker assays are now approved for clinical use in the United States and other countries. Decreases in the $A\beta_{42}/A\beta_{40}$ ratio or increases in the p-Tau181/$A\beta_{42}$ ratio show higher agreement with amyloid PET results or AD neuropathology than any single CSF analyte. Increase in the microtubule-binding region (MTBR) of tau containing the residue 243 (MTBR-tau243) is an experimental biomarker (not yet available in clinical practice) that better correlates with neurofibrillary tangles and tau PET binding.

In recent years, there has been significant progress in the development of plasma measurements of Aβ and phosphorylated tau with ultra-sensitive immunoassays or mass spectrometry. These blood-based AD biomarkers are entering the clinical arena and will undoubtedly improve access, scalability, and cost-effectiveness of AD biomarker testing in diverse practice settings. Similar to CSF, decreases in the plasma $A\beta_{42}/A\beta_{40}$ ratio and increases in plasma p-Tau181, p-Tau217, or p-Tau231 show high concordance with positive amyloid PET scans and AD neuropathology at autopsy. In conjunction with a clinical evaluation, plasma assays may be sufficient to establish the diagnosis of AD for certain use cases, with the highest-performing assays showing comparable diagnostic performance to CSF biomarkers in detecting AD neuropathology. It is important to note that concentrations of Aβ and p-Tau in blood can be impacted by medical comorbidities (e.g., reduced creatinine clearance, elevated body mass index), which may lead to false-positive or false-negative results, particularly if values are near the test's threshold.

While positive AD imaging or fluid biomarkers are highly predictive of underlying AD neuropathology, the question of whether AD represents a primary or contributing cause to an individual patient's clinical presentation is not always straightforward. For example, in a patient who presents at a relatively young age with classical AD symptoms, compatible MRI changes, and positive CSF or amyloid PET, it is highly likely that AD neuropathology is the primary cause of cognitive decline. In an elderly patient with the same clinical profile, however, AD is still likely to be contributing to impairment, although a contribution of other non-AD co-pathologies is also likely. In the case of a patient who presents with classical FTD and positive AD biomarkers, FTLD pathology may be the primary cause of impairment, with the positive AD biomarkers indicating incidental preclinical AD. Conversely, a patient who presents with a clinical syndrome suggesting AD but with *negative* AD biomarkers is likely to have a non-AD neuropathology as the primary cause of impairment. In older patients, age-related conditions that selectively target the medial temporal lobes, such as LATE or PART, can mimic AD clinically, and these should be high on the list of diagnostic possibilities in biomarker-negative individuals presenting with a progressive amnestic dementia.

The proliferation of AD biomarkers has led to a movement to redefine AD on purely biological grounds, based solely on positivity of AD biomarkers and independent of the clinical syndrome. In the Revised Criteria for Diagnosis and Staging of AD proposed by the Alzheimer's Association, amyloid PET, CSF/plasma Aβ, and p-Tau measures are considered "core 1 biomarkers" that are necessary and sufficient for the diagnosis of AD, irrespective of clinical symptoms. Tau PET is designated a "core 2" biomarker to be used for biomarker-based disease



staging. Clinical staging is performed independent of biomarkers based on the level of functional impairment, spanning the range from asymptomatic "preclinical" AD to severe dementia.

EPIDEMIOLOGY

The most important risk factors for AD are increasing age and a positive family history. In the United States, ~10% of people over age 65 have AD, including 3% of people age 65–74, 17% of people age 75–84, and 32% of people age 85 and older. A positive family history of dementia suggests a genetic contribution to AD, which is usually attributable to the apolipoprotein E (ApoE) ε4 risk allele. Autosomal dominant inheritance occurs in only 1–2% of patients and is typically accompanied by a multigenerational history of early-onset dementia. Female sex is a risk factor independent of the greater longevity of females, and women who carry a single Apo ε4 allele are more susceptible than are male ε4 carriers. A history of mild-to-severe traumatic brain injury increases the risk for AD. AD is more common in groups with low educational attainment, but education influences test-taking ability, and it is clear that AD can affect persons of all intellectual levels. One study found that the capacity to express complex written language in early adulthood correlated with a decreased risk for AD. Similarly, illiteracy and low educational attainment are risk factors for dementia. Numerous environmental factors, including aluminum, mercury, and viruses, have been proposed as causes of AD, but rigorous studies have failed to demonstrate a significant role for any of these exposures. Similarly, several studies suggest that the use of nonsteroidal anti-inflammatory agents is associated with a decreased risk of AD, but this risk has not been confirmed in large prospective studies. Vascular disease, and stroke in particular, seems to lower the threshold for the clinical expression of AD. Also, in many patients with AD, amyloid angiopathy can lead to microhemorrhages, large lobar hemorrhages, ischemic infarctions most often in the subcortical white matter, or in rare cases an inflammatory leukoencephalopathy. Diabetes increases the risk of AD threefold. Elevated homocysteine and cholesterol levels; hypertension; obesity; hearing loss; tobacco use; diminished serum levels of folic acid; low dietary intake of fruits, vegetables, and red wine; sleep disorders; low levels of exercise; and air pollution exposure are all being explored as potential risk factors for dementia in general and AD in particular.

PATHOLOGY

At autopsy, the earliest and most severe degeneration is usually found in the medial temporal lobe (entorhinal/perirhinal cortex and hippocampus), inferolateral temporal cortex, and nucleus basalis of Meynert. The characteristic microscopic findings are neuritic plaques and NFTs **(Fig. 442-2)**. These lesions accumulate in small numbers during normal brain aging but dominate the picture in AD. The overall burden of AD neuropathologic changes can be graded based on the topography of Aβ plaques, the density of neuritic plaques, and the spatial extent of NFTs present. Increasing evidence suggests that soluble amyloid species called *oligomers* may cause cellular dysfunction and represent the early toxic molecule in AD. Eventually, further amyloid polymerization and fibril formation lead to neuritic plaques, which contain a central core of amyloid, proteoglycans, ApoE, α-antichymotrypsin, and other proteins. Aβ is a protein of 39–42 amino acids that is derived proteolytically from a larger transmembrane protein, *amyloid precursor protein* (APP), when APP is cleaved by β and γ secretases **(Fig. 442-3)**. The normal function of the Aβ peptides is uncertain. APP has neurotrophic and neuroprotective properties. The plaque core is surrounded by a halo, which contains dystrophic, tau-immunoreactive neurites and activated microglia. The accumulation of Aβ in cerebral arterioles is termed *amyloid angiopathy*. NFTs are composed of silver-staining neuronal cytoplasmic fibrils composed of abnormally phosphorylated tau protein; they appear as paired helical filaments by electron microscopy. Tau binds to and stabilizes microtubules, supporting axonal transport of organelles, glycoproteins, neurotransmitters, and other important cargoes throughout the neuron. Once hyperphosphorylated, tau can no longer bind properly to microtubules and redistributes from the axon to throughout the neuronal cytoplasm and distal dendrites, compromising function. Other theories emphasize that abnormal conformations of tau induce misfolding of native (unfolded) tau into pathologic conformations and that this prion-like templating process is responsible for tau spreading **(Chap. 435)**. Finally, patients with AD often show comorbid LBD, TDP-43, or vascular pathology. Most prevailing rodent models of AD involve expression of mutant transgenes that leads to $A\beta_{42}$ accumulation in the absence of tauopathy. Even in these models, diminishing neuronal tau ameliorates cognitive deficits and nonconvulsive seizures while $A\beta_{42}$ continues to accumulate,

A ***B***

FIGURE 442-2 Neuropathology of Alzheimer's disease. ***A.*** Early neurofibrillary degeneration, consisting of neurofibrillary tangles and neuropil threads, preferentially affects the medial temporal lobes, especially the stellate pyramidal neurons that compose the layer 2 islands of entorhinal cortex, as shown using Gallyas silver staining. ***B.*** Higher magnification view reveals the fibrillar nature of tangles (*arrows*) and the complex structure of neuritic plaques (*arrowheads*), whose major component is Aβ (*inset* shows immunohistochemistry for Aβ). Scale bars are 500 μM in ***A***, 50 μM in ***B***, and 20 μM in ***B*** inset.

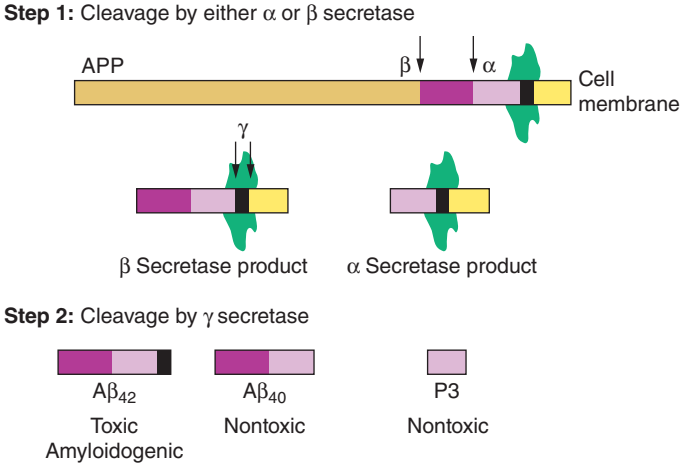


FIGURE 442-3 Amyloid precursor protein (APP) is catabolized by α, β, and γ secretases. A key initial step is the digestion by either β secretase (BASE) or α secretase (ADAM10 or ADAM17 [TACE]), producing smaller nontoxic products. Cleavage of the β secretase product by γ secretase (Step 2) results in either the toxic $A\beta_{42}$ or the nontoxic $A\beta_{40}$ peptide; cleavage of the α secretase product by γ secretase produces the nontoxic P3 peptide. Excess production of $A\beta_{42}$ is a key initiator of cellular damage in Alzheimer's disease (AD). Therapeutics for AD have focused on attempts to reduce accumulation of $A\beta_{42}$ by antagonizing β or γ secretases, promoting α secretase, or clearing $A\beta_{42}$ that has already formed by use of specific antibodies.

raising hope for tau-lowering therapies in humans. Biochemically, AD is associated with a decrease in the cortical levels of several proteins and neurotransmitters, especially acetylcholine, its synthetic enzyme choline acetyltransferase, and nicotinic cholinergic receptors. Reduction of acetylcholine reflects degeneration of cholinergic neurons in the nucleus basalis of Meynert, located just below the thalamus and adjacent to the third ventricle, that project throughout the cortex. There is also noradrenergic and serotonergic depletion due to degeneration of upper brainstem nuclei such as the locus coeruleus (norepinephrine) and dorsal raphe (serotonin), where tau-immunoreactive neuronal cytoplasmic inclusions can be identified in early adult life, even in individuals lacking entorhinal cortex NFTs.

GENETIC CONSIDERATIONS

Several genes play an important role in the pathogenesis of AD. One is the *APP* gene on chromosome 21. Adults with trisomy 21 (Down's syndrome) consistently develop the typical neuropathologic hallmarks of AD if they survive beyond age 40 years, and many develop a progressive dementia superimposed on their baseline deficits. The extra dose of the *APP* gene on chromosome 21 is the initiating cause of AD in adult Down's syndrome and results in excess cerebral amyloid production. Supporting this hypothesis, some families with early-age-of-onset familial AD (FAD) have point mutations in *APP*. Although very rare, these families were the first examples of single-gene autosomal dominant transmission of AD.

Investigation of large families with multigenerational FAD led to the discovery of two additional AD-causing genes, the *presenilins*. Presenilin-1 (*PSEN-1*) is on chromosome 14 and encodes presenilin-1 protein (also known as S182). Mutations in this gene cause an early-age-of-onset AD, with onset typically before age 60 and often before age 50, transmitted in an autosomal dominant, highly penetrant fashion. More than 100 different mutations have been found in the *PSEN-1* gene in families from a wide range of ethnic backgrounds. Presenilin-2 (*PSEN-2*) is on chromosome 1 and encodes the presenilin-2 protein (also known as STM2). A mutation in the *PSEN-2* gene was first found in a group of American families with Volga German ethnic background. Mutations in *PSEN-1* are much more common than those in *PSEN-2*. The presenilins are highly homologous and encode similar proteins that at first appeared to have seven transmembrane domains (hence the designation *STM*), but subsequent studies have suggested eight such domains, with a ninth submembrane region. Both presenilins are cytoplasmic neuronal proteins that are widely expressed throughout the nervous system. They are homologous to a cell-trafficking protein, sel 12, found in the nematode *Caenorhabditis elegans*. Prior to symptom onset, patients with mutations in the presenilin genes have elevated CSF levels of $A\beta_{42}$, and in cell culture, *PSEN-1* mutations produce increased $A\beta_{42}$. *PSEN-1* is involved in the cleavage of APP at the γ secretase site, and mutations in either gene (*PSEN-1* or *APP*) may disturb γ secretase cleavage. Mutations in *PSEN-1* are the most common cause of early-age-of-onset FAD, representing 40–70% of all cases. Mutations in *PSEN-1* tend to produce AD with an earlier age of onset (mean onset 45 years) and a shorter, more rapidly progressive course (mean duration 6–7 years) than mutations in *PSEN-2* (mean onset 53 years; duration 11 years). Although some carriers of *PSEN-2* mutations have had onset of dementia after the age of 70, mutations in the presenilins rarely lead to late-age-of-onset AD. Clinical genetic testing for these uncommon mutations is available but likely to be revealing only in early-age-of-onset FAD and should be performed in association with formal genetic counseling.

The *Apoε* gene on chromosome 19 is involved in the pathogenesis of AD. The protein product, ApoE, participates in cholesterol transport **(Chap. 419)**, and the gene has three alleles: ε2, ε3, and ε4. The Apo ε4 allele confers increased risk of AD in the general population, including sporadic and late-age-of-onset familial forms. Approximately 24–30% of the nondemented white population has at least one ε4 allele (12–15% allele frequency), and ~2% are ε4/ε4 homozygotes. Among patients with AD, 40–65% have at least one ε4 allele, a highly significant elevation compared with controls. The increased risk of AD associated with a single ε4 allele is approximately three times higher than in ε4 noncarriers (and higher in female than male heterozygotes), while the risk in ε4 homozygotes is 10–15 times higher than in ε4 noncarriers. The risk of AD in Apo ε4 carriers also varies by racial and ethnic background, with increased risk in East Asians and decreased risk in African Americans and Hispanics compared to whites. Additionally, many patients with AD have no ε4 allele, and ε4 carriers may never develop AD. Therefore, ε4 is neither necessary nor sufficient to cause AD. Nevertheless, the Apo ε4 allele represents the most important genetic risk factor for sporadic AD and acts as a dose-dependent disease modifier, with each Apo ε4 allele associated with an approximately 10-year earlier age of onset. The association between Apo ε4 and AD is strongest in patients between the ages of 60 and 85 and is weaker in younger patients and in the very old. The precise mechanisms through which Apo ε4 confers AD risk or hastens onset remain unclear, but ε4 leads to less efficient amyloid clearance and production of toxic fragments from cleavage of the molecule. Apo ε can be identified in neuritic plaques and may also be involved in neurofibrillary tangle formation, because it binds to tau protein. Interestingly, carriers of a point mutation in Apo ε3, termed the *Christchurch* mutation, may be protective against tau aggregation and dementia despite having amyloid plaques. Apo ε4 decreases neurite outgrowth in dorsal root ganglion neuronal cultures, perhaps indicating a deleterious role in the brain's response to injury. Increasing evidence suggests that the ε2 allele may reduce AD risk. The ε4 allele is also associated with increased risk for CAA, DLB, and vascular dementia, while its association with FTD is uncertain. Some evidence suggests that ε4 may worsen the expression of non-AD neurodegenerative disorders, as well as following head trauma and other brain injuries. Use of Apo ε4 testing in AD diagnosis remains controversial because its predictive value remains unclear and many individuals with the ε4 allele will never develop dementia. However, clinical Apo ε4 testing is recommended for patients who are being evaluated for treatment with anti-Aβ monoclonal antibodies in order to determine their risk of adverse effects (see below). ApoE genotyping is available in some straight-to-consumer genetic testing platforms.

Additional genes are also likely to be involved in AD, especially as minor risk alleles for sporadic forms of the disease. Genome-wide association studies have identified >40 additional common genetic variants that, individually, have small (i.e., odds ratios ~1.1–1.2 or 0.8–0.9) impact on the risk of AD. Implicated genes converge in biological pathways related to innate immunity, lipid metabolism, and synaptic function. Examples include the clusterin (*CLU*), phosphatidylinositol-binding clathrin assembly protein (*PICALM*), and complement component

(3b/4b) receptor 1 (*CR1*) genes, among others. *CLU* may play a role in synapse turnover, *PICALM* participates in clathrin-mediated endocytosis, and *CR1* may be involved in amyloid clearance or synapse loss through the complement pathway. *TREM2* is a gene involved with inflammation that increases the likelihood of dementia. Homozygous mutation carriers develop a frontal dementia with bone cysts (Nasu-Hakola disease), whereas heterozygotes are predisposed to the development of AD. *TREM2* risk alleles are rare but have strong effects, with odds ratios estimated at 3–4 for developing clinical AD. Polygenic hazard scores that integrate the presence of multiple risk and protective alleles may be useful in predicting an individual's lifetime risk of developing AD. The vast majority of AD genetic studies have focused on white populations of European descent, and much less is known about the genetics of AD in nonwhite populations.

TREATMENT

Alzheimer's Disease

The management of AD requires a multidomain approach that includes neurotransmitter-based therapies to manage symptoms, emerging molecular therapies that target AD pathophysiology with the goal of slowing disease progression and clinical decline, and ongoing patient and caregiver education.

NEUROTRANSMITTER-BASED THERAPIES

Donepezil (target dose, 10 mg daily), rivastigmine (target dose, 6 mg twice daily or 9.5-mg patch daily), galantamine (target dose, 24 mg daily, extended-release), and memantine (target dose, 10 mg twice daily) are approved by the U.S. Food and Drug Administration (FDA) for the treatment of AD. Dose escalations for each of these medications must be carried out over 4–6 weeks to minimize side effects. The pharmacologic action of donepezil, rivastigmine, and galantamine is inhibition of the cholinesterases, primarily acetylcholinesterase, with a resulting increase in cerebral acetylcholine levels. Memantine appears to act by blocking overexcited *N*-methyl-D-aspartate (NMDA) glutamate receptors. Double-blind, placebo-controlled, crossover studies with cholinesterase inhibitors (in mild-to-severe AD dementia) and memantine (in moderate-to-severe AD dementia) have shown them to be associated with modestly improved caregiver ratings of patients' functioning and with an apparent decreased rate of decline in cognitive test scores over periods of up to 3 years. The average patient on an anticholinesterase inhibitor maintains their mini-mental state examination (MMSE) score for close to a year, whereas a placebo-treated patient declines 2–3 points over the same time period. Memantine, used in conjunction with cholinesterase inhibitors or by itself, slows cognitive deterioration and decreases caregiver burden for patients with moderate to severe AD, but is not approved for mild AD. Neither cholinesterase inhibitors nor memantine have proven efficacious in patients with MCI, though the clinical trials lacked biomarkers at the time, and in retrospect likely included a mix of patients with AD and non-AD-related memory impairment. Cholinesterase inhibitors are easy to administer, and their major side effects are gastrointestinal symptoms (nausea, diarrhea, cramps), altered sleep with unpleasant or vivid dreams, bradycardia (usually benign), and muscle cramps. Potential side effects associated with memantine include constipation, dizziness, headache, and somnolence. A common approach to AD drug therapy is to initiate a cholinesterase inhibitor for a patient diagnosed with mild AD dementia and to add memantine when patients enter the moderate stage of disease. Cholinesterase inhibitors may also be effective in treating delusions and hallucinations, while memantine can reduce agitation.

THERAPIES TARGETING AMYLOID-β

A novel class of antiamyloid monoclonal antibodies has recently been approved for treatment of early clinical stages of AD. These drugs promote clearance of target Aβ epitopes, substantially lower amyloid plaque burden on amyloid PET, and comprise the first class of disease-modifying therapies to receive FDA approval for treatment of AD. Lecanemab (which targets Aβ protofibrils) and donanemab (which targets a pyroglutamate form of Aβ in plaques) are fully FDA approved for clinical use in early-stage AD based on evidence of clinical efficacy in phase 3, double-blinded, randomized, placebo-controlled clinical trials. Lecanemab is delivered as an intravenous infusion every 2 weeks, while donanemab is administered intravenously monthly. A third antibody, aducanumab, was the first to receive accelerated FDA approval based on reduction of amyloid PET signal, but evidence of clinical efficacy was ambiguous, and ultimately this drug has been removed from clinical use. All three of these antibodies lead to robust reductions in amyloid burden as measured by PET. Interestingly, drug trials of Aβ-targeting antibodies that showed less robust amyloid lowering on PET (e.g., solanezumab, crenezumab, gantenerumab) did not find a clinical benefit. Antiamyloid antibody therapy is currently restricted to patients with MCI or mild dementia and biomarker confirmation of Aβ pathology by PET or CSF. Clinical trials are underway for cognitively unimpaired individuals with biomarker evidence of Aβ pathology (i.e., preclinical AD). Patients with clinical features suggestive of non-AD causes of cognitive decline were excluded from the pivotal clinical trials and should not be treated, regardless of biomarker status.

In Clarity-AD, a phase 3, randomized, placebo-controlled trial of lecanemab in patients with early symptomatic AD, patients who received lecanemab for 18 months experienced an average 27% slowing in their rate of clinical decline compared to placebo, as measured by change in the Clinical Dementia Rating Scale sum of boxes score (CDR-SB), a clinical scale that measures cognition and function and was the study's primary outcome. Similar slowing of decline was reported on all secondary cognitive and functional outcomes. In TRAILBLAZER-ALZ2, a phase 3, randomized, placebo-controlled trial of donanemab in early symptomatic AD, patients on active treatment showed 22% slowing on the integrated Alzheimer Disease Rating Scale (iADRS; primary outcome) and 28% slowing on the CDR-SB (secondary outcome) over 76 weeks compared to placebo, with similar effects on all other secondary clinical endpoints. Patients in TRAILBLAZER-ALZ2 were stratified by tau PET at baseline, with patients with low-medium tau PET at trial entry showing the greatest clinical benefit (35% slowing on iADRS, 36% slowing on CDR-SB), suggesting that amyloid lowering may particularly benefit patients in earlier stages of tau spread. The duration of treatment was titrated based on amyloid PET response, with patients switched from donanemab to placebo when complete amyloid clearance was seen on PET. These findings suggest that limited-duration treatment until PET clearance may be sufficient to derive a robust clinical response. Given these results, future clinical practice may leverage baseline biomarkers of tau burden to identify patients more likely to benefit from antiamyloid therapy, whereas longitudinal biomarkers of Aβ burden may help to define the necessary duration of therapy.

Antiamyloid antibodies are associated with significant potential side effects, including infusion reactions and a form of secondary brain inflammation and hemorrhage, collectively referred to as amyloid-related imaging abnormalities (ARIA) **(Fig. 442-4)**. Rates of infusion reactions in the active treatment arms of the phase 3 trials were 26% for lecanemab and 9% for donanemab. ARIA-E manifests as focal areas of edema or sulcal effusions, detected by T2/fluid-attenuated inversion recovery (FLAIR) hyperintensities on MRI. ARIA-H typically manifests as microbleeds or superficial siderosis detected by gradient echo (GRE) or susceptibility-weighted imaging (SWI) MRI sequences, although lobar hemorrhages can rarely occur. Both ARIA-E and ARIA-H are thought to be related to CAA. Spontaneous ARIA-H occurs frequently in AD, but spontaneous ARIA-E (also known as inflammatory CAA) occurs very rarely in lieu of antiamyloid therapies. In the phase 3 trials, overall rates of ARIA-E were 13% for lecanemab and 24% for donanemab, whereas ARIA-H rates were 17% for lecanemab and 31% for donanemab. Approximately 75% of ARIA cases were asymptomatic and detected on safety MRI scans conducted throughout the study. When present,

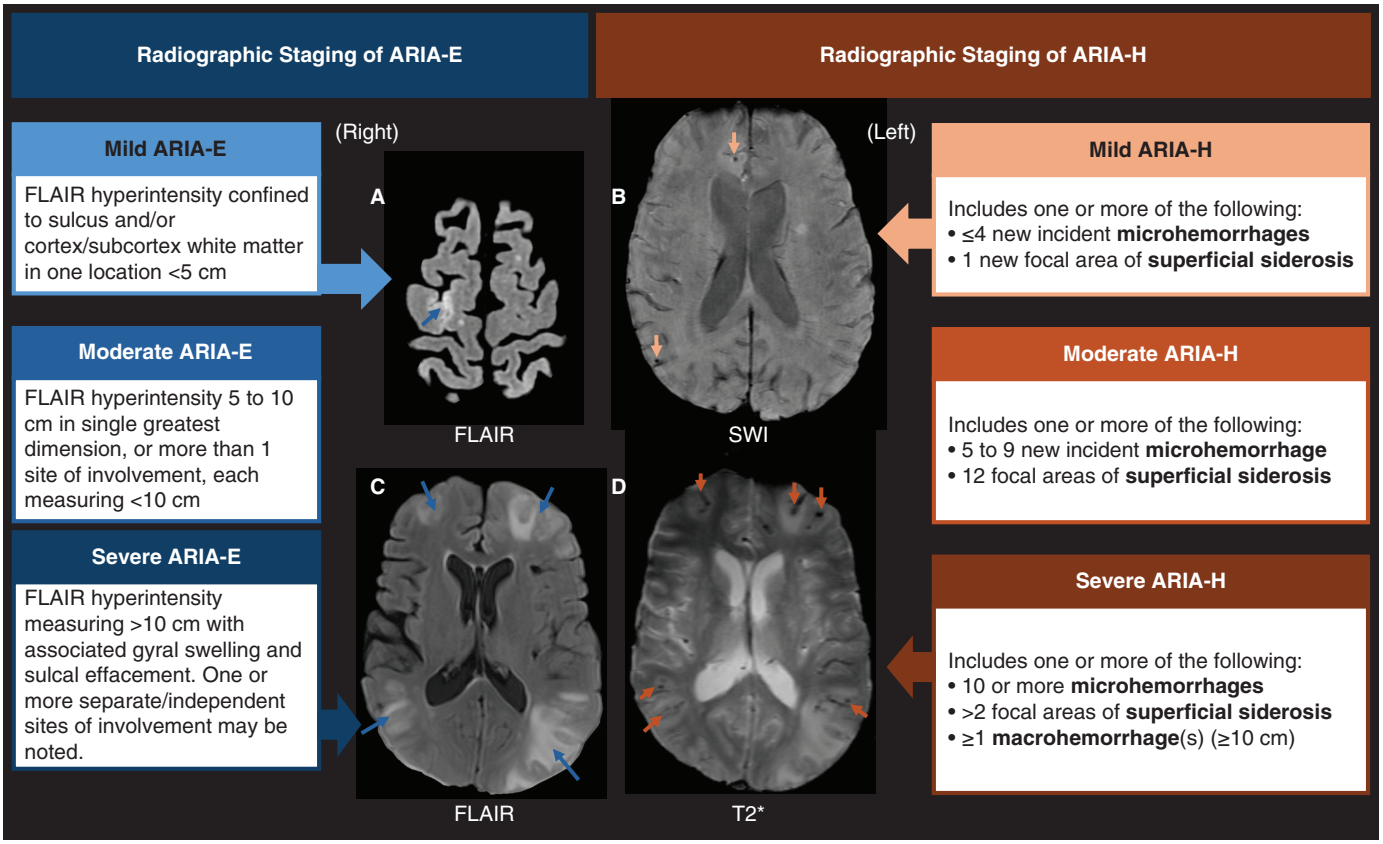

FIGURE 442-4 Radiographic staging of amyloid-related imaging abnormalities (ARIAs). ***A.*** Axial fluid-attenuated inversion recovery (FLAIR) image depicting radiographically mild ARIA-E in an asymptomatic patient receiving lecanemab treatment. Cortical edema and adjacent sulcal effacement are present in a right superior frontal region with <5 cm of involvement. ***B.*** Axial susceptibility-weighted imaging (SWI) depicting radiographically mild ARIA-H (including right anterior cingulate and right parietal lobar microhemorrhages) in an asymptomatic patient receiving lecanemab. ***C–D.*** Axial FLAIR and T2* sequence images depicting radiographically severe ARIA-E and radiographically severe ARIA-H, respectively, in a patient presenting with focal neurologic symptoms localized to the left occipital lobe during aducanumab treatment. FLAIR imaging reveals multiple regions of cortical edema, with adjacent subcortical edema and sulcal effacement. T2* reveals multiple regions of cortical siderosis, including in bilateral frontal and posterior regions of concomitant ARIA-E, as well as numerous lobar microhemorrhages.

ARIA symptoms are typically mild and nonspecific (e.g., headache, dizziness, greater confusion). However, severe symptoms, including seizures, stroke-like episodes, malignant hypertension, and (very rarely) death can occur. The risk of ARIA increases with each copy of the Apo ε4 allele and is highest in Apo ε4 homozygotes. Apo ε4 homozygotes are also at increased risk of symptomatic, severe, and recurrent ARIA, leading the FDA to issue a box warning for ε4 homozygotes in the prescribing information for both lecanemab and donanemab. Clinical Apo ε genotyping is recommended prior to initiating anti-Aβ antibody therapy to adequately inform shared decision-making about treatment risks and benefits.

In a clinical setting, uncontrolled hypertension, radiographic evidence of extensive CAA (>4 brain microhemorrhages or ≥1 region of cortical siderosis), and other factors that may increase ARIA risk are regarded as contraindications for antiamyloid antibodies. Limited data are available about the safety of anticoagulants in the context of anti-Aβ therapy, with the concern that anticoagulation may increase the risk of ARIA-H. Expert recommendations suggest excluding patients on anticoagulants from treatment until more safety data are available. Patients treated with a single antiplatelet agent do not appear to be at higher risk for ARIA.

Patients treated with lecanemab or donanemab should be monitored for ARIA with multiple surveillance MRIs during the first 6–12 months of treatment, following the schedule recommended by the FDA in the prescribing information. T2/FLAIR and GRE/SWI sequences should be performed, and patients should ideally be imaged longitudinally on the same MRI scanner and sequences to allow optimal comparisons between time points. An urgent MRI should be performed whenever ARIA is clinically suspected based on symptoms. The severity of ARIA is graded based on radiographic criteria, as well as the presence and severity of clinical symptoms. Patients can be treated safely through asymptomatic and radiographically mild ARIA, provided MRI scans are performed monthly to monitor evolution. Symptomatic or radiographically moderate to severe ARIA should lead to temporary suspension of treatment until ARIA-E resolves and ARIA-H stabilizes. Permanent cessation of treatment is recommended if symptoms are severe, ARIA has recurred more than twice, ARIA-H has led to macrohemorrhage or >10 additional microhemorrhages since treatment initiation, or more than one area of superficial siderosis has emerged.

Cases of catastrophic, multifocal brain hemorrhages due to severe ARIA-E and ARIA-H leading to death have been reported in patients receiving antiamyloid antibody therapy while being treated with thrombolytic medications (e.g., tissue plasminogen activator) for acute stroke. When presenting with stroke-like symptoms, patients receiving anti-Aβ monoclonal antibodies should receive an immediate MRI to differentiate acute stroke from ARIA. Until more data are available, treatment with lecanemab or donanemab should therefore be considered a contraindication to peripheral thrombolysis.

It is current practice at our institution to restrict use of antiamyloid monoclonal antibodies to patients with biomarker-confirmed Aβ pathology and early symptomatic disease, including MCI or mild AD dementia, who are not expected to require anticoagulant therapy. We corroborate interpretation of Aβ biomarkers and scrutinize baseline brain MRI for disqualifying lesions that may increase risk of ARIA and intracerebral hemorrhage, such as radiographic evidence of extensive CAA. All patients must know their ApoE allele status and understand their associated ARIA risk before starting treatment. Apo ε4 homozygous patients may elect to pursue therapy at our institution after careful consideration of their ARIA risk, although several institutions do prohibit or carefully restrict

use in Apo ε4 homozygous patients. Finally, and consistent with consensus clinical practice, all patients who receive therapy must undergo regular MRI safety screening to rule out ARIA.

PATIENT AND CAREGIVER EDUCATION

Building rapport with the patient, family members, and other caregivers is essential. In the early stages of AD, memory aids such as notebooks and posted daily reminders can be helpful. Family members should emphasize activities that are pleasant while curtailing those that increase stress on the patient. Kitchens, bathrooms, stairways, and bedrooms need to be made safe, and eventually, patients will need to stop driving. Patients can be encouraged to engage in lifestyle modifications that may be protective against aging and neurodegeneration, such as physical, cognitive, and social activity; vascular risk factor modification; healthy sleep habits; and dietary modifications (e.g., Mediterranean or Dietary Approaches to Stop Hypertension diets). Loss of independence and change of environment may worsen confusion, agitation, and anger. Communication and repeated calm reassurance are necessary. Caregiver "burnout" is common, often resulting in nursing home placement of the patient or new health problems for the caregiver. Respite breaks for the caregiver help to maintain a successful long-term therapeutic milieu. Use of adult day care centers can be helpful. Local and national support groups, such as the Alzheimer's Association and the Family Caregiver Alliance, are valuable resources. Internet access to these resources has become available to clinicians and families in recent years.

ADDITIONAL THERAPIES

Mild to moderate depression is common in the early stages of AD and may respond to antidepressants or cholinesterase inhibitors. Selective serotonin reuptake inhibitors (SSRIs) are commonly used due to their low anticholinergic side effects (e.g., escitalopram, target dose, 5–10 mg daily). Seizures can be treated with levetiracetam unless the patient had a different regimen that was effective prior to the onset of AD. Agitation, insomnia, hallucinations, and belligerence are especially troublesome characteristics of some AD patients, and these behaviors can lead to nursing home placement. The newer generation of atypical antipsychotics, such as risperidone, quetiapine, and olanzapine, are being used in low doses to treat these neuropsychiatric symptoms. Brexpiprazole, an atypical antipsychotic that acts on noradrenergic, serotonergic, and dopaminergic neurotransmitter systems, is the only drug to receive FDA approval for treatment of agitation in AD, based on a 12-week, double-blinded, randomized, placebo-controlled trial. The few controlled studies comparing drugs against behavioral intervention in the treatment of agitation suggest mild efficacy with significant side effects related to sleep, gait, and cardiovascular complications, including an increased risk of death. Antipsychotics carry a black box FDA warning for use in elderly patients with dementia and thus should be prescribed only with caution; however, careful, daily, nonpharmacologic behavior management is often not available, rendering medications necessary for some patients. Medications with strong anticholinergic effects should be vigilantly avoided, including prescription and over-the-counter sleep aids (e.g., diphenhydramine) or incontinence therapies (e.g., oxybutynin).

Several commonly used medications and supplements, including estrogen hormone replacement therapy, statins, vitamin E, and ginkgo biloba, appeared to be associated with a decreased risk of AD in epidemiologic or observational studies but did not show efficacy in prospective, randomized, double-blinded, placebo-controlled trials. Many vitamins and dietary supplements are marketed directly to consumers as "memory enhancing" or protective against AD without clinical evidence. Patients and families may come across anecdotal reports of "miraculous" responses to aggressive treatments such as anti-interferon intrathecal infusions, intravenous immunoglobulin, antibiotics (purportedly to treat Lyme disease or another questionable infection), metal chelation, and stem cell therapies, but there is no scientific evidence to support use of any of these approaches to treating AD and significant concern for harm.

EXPERIMENTAL THERAPIES

The design of AD clinical trials has been transformed by the availability of PET, CSF, and more recently blood-based biomarkers of Aβ and tau. Many trials now require biomarker evidence of AD for trial inclusion. Biomarkers help assess target engagement (e.g., changes in Aβ biomarkers in an antiamyloid trial) or modification of downstream disease pathophysiology (e.g., changes in tau biomarkers in an antiamyloid trial), with the pivotal trials leading to approval of lecanemab and donanemab being emblematic of this novel approach. Increasingly, many trials have shifted toward enrolling patients in the asymptomatic (preclinical) or very early symptomatic stages of AD, using positive biomarkers as the primary inclusion criterion. Primary (biomarker negative) and secondary (biomarker positive but no symptoms) prevention trials are underway in autosomal dominant mutation carriers, Apo ε4 homozygotes, and even in the normally aging population.

Active vaccination against Aβ is another approach that aims to promote immune-mediated clearance of amyloid pathology. The first $A\beta_{42}$ vaccine trial in humans was aborted after a minority of patients developed meningoencephalitis, but subsequent trials with less immunogenic formulations have shown more favorable safety profiles.

Oral drugs that inhibit β and γ secretase reduce the cleavage of APP to $A\beta_{42}$ and showed promise in ameliorating pathology and behavioral changes in AD transgenic mice. Unfortunately, placebo-controlled trials failed to show clinical efficacy, and trials of β secretase inhibitors, in particular, found significant *worsening* of cognition in treated patients versus placebo, although fortunately, this effect proved transient after discontinuing the drug. It is unclear whether toxicity of β and γ secretase inhibitors was directly related to changes in Aβ metabolism or to "off-target" drug effects.

Monoclonal antibodies directed against phosphorylated tau are in earlier stages of development. These antibodies aim to prevent the transsynaptic spread of tau and have proven effective in tau transgenic mice. Safety profiles in human studies have proven favorable thus far, but clinical results have been lacking. Lowering of tau expression via antisense oligonucleotides (ASOs) or small interfering RNA is a compelling therapeutic strategy that rescues most elements of the AD phenotype in AD transgenic mice. A recent phase 1 trial of the tau-targeting ASO $MAPT_{Rx}$, delivered intrathecally, showed the treatment to be well tolerated, with significant lowering of tau biomarkers in CSF and PET. A phase 2 clinical trial is currently underway. Additional therapeutic approaches targeting tau include active immunization; inhibition of tau phosphorylation, acetylation, and aggregation; and microtubule stabilization. Other druggable pathways represented in the AD drug development pipeline include those targeting neuroinflammation, metabolism/bioenergetics, synaptic plasticity, neuroprotection, and neurotransmitter-based cognitive enhancement or treatment of neuropsychiatric symptoms.

A general approach to the symptomatic management of dementia is presented in Chap. 31.

OTHER CAUSES OF DEMENTIA

FTD **(Chap. 443)**, vascular dementia **(Chap. 444)**, DLB **(Chap. 445)**, and prion diseases **(Chap. 449)** are covered in dedicated chapters.

Prion diseases such as CJD are rare neurodegenerative conditions (prevalence ~1 per million) that produce dementia. CJD is a rapidly progressive disorder associated with dementia, focal cortical signs, rigidity, and myoclonus, causing death <1 year after first symptoms appear. The rapidity of progression seen with CJD is uncommon in AD so that the distinction between the two disorders is usually straightforward, although AD can on occasion present as a rapidly progressive dementia. In general, CBD **(Chap. 443)** and DLB **(Chap. 445)**, more rapid degenerative dementias with prominent

movement abnormalities, are more likely to be mistaken for CJD. The differential diagnosis for CJD includes other rapidly progressive dementing conditions such as viral or bacterial encephalitides, Hashimoto's encephalopathy, central nervous system (CNS) vasculitis, lymphoma, or paraneoplastic/autoimmune syndromes **(Chap. 99)**. The markedly abnormal periodic complexes on EEG and cortical ribboning and basal ganglia hyperintensities on diffusion-weighted imaging or FLAIR MRI are diagnostic features of CJD, although rarely, prolonged focal or generalized seizures can produce a similar imaging appearance.

Huntington's disease (HD) **(Chap. 447)** is an autosomal dominant degenerative brain disorder. HD clinical hallmarks include chorea, behavioral disturbance, and executive impairment. Symptoms typically begin in the fourth or fifth decade, but there is a wide range, from childhood to >70 years. Memory is frequently not impaired until late in the disease, but attention, judgment, self-awareness, and executive functions are often deficient at an early stage. Depression, apathy, social withdrawal, irritability, and intermittent disinhibition are common. Delusions and obsessive-compulsive behavior may occur. Disease duration is variable but typically lasts ~15 years.

NPH is a relatively uncommon but treatable syndrome. The clinical, physiologic, and neuroimaging characteristics of NPH must be carefully distinguished from those of other dementias associated with gait impairment. Historically, many patients treated for NPH have suffered from other dementias, particularly AD, vascular dementia, DLB, and PSP **(Chap. 443)**. For NPH, the clinical triad includes an abnormal gait (ataxic or apractic), dementia (usually mild to moderate, with an emphasis on executive impairment), and urinary urgency or incontinence. Neuroimaging reveals enlarged lateral ventricles (hydrocephalus) with little or no cortical atrophy, although the sylvian fissures may appear propped open (so-called "boxcarring"), which can be mistaken for perisylvian atrophy. Crowding of dorsal frontal-parietal gyri helps distinguish NPH from other movement disorders, such as PSP and CBD, in which dorsal atrophy with sulcal widening is common. NPH is a communicating hydrocephalus with a patent aqueduct of Sylvius **(see Fig. 31-3)**, in contrast to aqueductal stenosis, in which the aqueduct is small. Lumbar puncture opening pressure falls in the high-normal range, and the CSF protein, glucose, and cell counts are normal. NPH may be caused by obstruction to normal CSF flow over the cerebral convexities and delayed resorption into the venous system. The indolent nature of the process results in enlarged lateral ventricles with relatively little increase in CSF pressure. Presumed edema, stretching, and distortion of subfrontal white matter tracts may lead to clinical symptoms, but the precise underlying pathophysiology remains unclear. Some patients provide a history of conditions that produce meningeal scarring (blocking CSF resorption) such as previous meningitis, subarachnoid hemorrhage, or head trauma. Others with longstanding but asymptomatic congenital hydrocephalus may have adult-onset deterioration in gait or memory that is confused with NPH. In contrast to AD, the patient with NPH complains of an early and prominent gait disturbance without cortical atrophy on CT or MRI.

Numerous attempts to improve NPH diagnosis with various special studies and predict the success of ventricular shunting have been undertaken. These tests include radionuclide cisternography (showing a delay in CSF absorption over the convexity) and various efforts to monitor and alter CSF flow dynamics, including a constant-pressure infusion test. None has proven to be specific or consistently useful. A transient improvement in gait or cognition may follow lumbar puncture (or serial punctures) with removal of 30–50 mL of CSF, but this finding has also not proved to be consistently predictive of postshunt improvement. Perhaps the most reliable strategy is a period of close inpatient evaluation before, during, and after lumbar CSF drainage. Occasionally, when a patient with AD presents with gait impairment (at times due to comorbid subfrontal vascular injury) and absent or only mild cortical atrophy on CT or MRI, distinguishing NPH from AD can be challenging. Hippocampal atrophy on MRI favors AD, whereas a characteristic "magnetic" gait with external hip rotation, low foot clearance, and short strides, along with prominent truncal sway or instability, favors NPH. The diagnosis of NPH should be avoided when hydrocephalus is not detected on imaging studies, even if the symptoms otherwise fit. Thirty to fifty percent of patients identified by careful diagnosis as having NPH will improve with ventricular shunting. Gait may improve more than cognition, but many reported failures to improve cognitively may have resulted from comorbid AD. Importantly, the presence of positive CSF AD biomarkers or amyloid PET is associated with lower likelihood of response to shunting. Short-lasting improvement is common. Patients should be carefully selected for shunting, because subdural hematoma, infection, and shunt failure are known complications and can be a cause for early nursing home placement in an elderly patient with previously mild dementia.

Intracranial hypotension, sometimes called sagging brain syndrome, is a disorder caused by low CSF pressure, leading to downward pressure on the subcortical structures and disruption of cerebral function. It presents in a variable manner with headache, often exacerbated by coughing or a Valsalva maneuver or by moving from lying to standing. Other common symptoms include dizziness, vomiting, disruption of sleep-wake cycles, and sometimes a progressive behavioral variant FTD-like syndrome **(Chap. 443)**. Although sometimes idiopathic, this syndrome can be caused by CSF leaks secondary to lumbar puncture, head trauma, or spinal cord arachnoid cysts. Treatment consists of finding and patching the CSF leak.

Dementia can accompany *chronic alcoholism* **(Chap. 464)** and may result from associated malnutrition, especially of B vitamins, particularly thiamine. Other poorly defined aspects of chronic alcoholism may, however, also produce cerebral damage. A rare idiopathic syndrome of dementia and seizures with degeneration of the corpus callosum has been reported primarily in male Italian red wine drinkers (Marchiafava-Bignami disease).

Thiamine (vitamin B_1) deficiency causes Wernicke's encephalopathy **(Chap. 318)**. The clinical presentation is usually a malnourished patient (frequently but not necessarily alcoholic) with confusion, ataxia, and diplopia resulting from inflammation and necrosis of periventricular midline structures, including dorsomedial thalamus, mammillary bodies, midline cerebellum, periaqueductal gray matter, and trochlear and abducens nuclei. Damage to the dorsomedial thalamus correlates most closely with the memory loss. Prompt administration of parenteral thiamine (100 mg intravenously for 3 days followed by daily oral dosage) may reverse the disease if given within the first days of symptom onset. Prolonged untreated thiamine deficiency can result in an irreversible and profound amnestic syndrome (Korsakoff's syndrome) or even death.

In *Korsakoff's syndrome*, the patient is unable to recall new information despite normal immediate memory, attention span, and level of consciousness. Memory for new events is seriously impaired, whereas knowledge acquired prior to the illness remains relatively intact. Patients are easily confused, disoriented, and cannot store information for more than a few minutes. Superficially, they may be conversant, engaging, and able to perform simple tasks and follow immediate commands. Confabulation is common, although not always present. There is no specific treatment because the previous thiamine deficiency has produced irreversible damage to the medial thalamic nuclei and mammillary bodies. Mammillary body atrophy may be visible on MRI in the chronic phase **(see Fig. 318-6)**.

Vitamin B_{12} deficiency, as can occur in pernicious anemia, causes a megaloblastic anemia and may also damage the nervous system **(Chaps. 104 and 453)**. Neurologically, it most commonly produces a spinal cord syndrome (myelopathy) affecting the posterior columns (loss of vibration and position sense) and corticospinal tracts (hyperactive tendon reflexes with Babinski signs); it also damages peripheral nerves (neuropathy), resulting in sensory loss with depressed tendon reflexes. Damage to myelinated axons may also cause dementia. The mechanism of neurologic damage is unclear but may be related to a deficiency of *S*-adenosyl methionine (required for methylation of myelin phospholipids) due to reduced methionine synthase activity or accumulation of methylmalonate, homocysteine, and propionate, providing abnormal substrates for fatty acid synthesis in myelin. Use of histamine blockers or metformin, vegan diets, autoimmunity against gastric parietal cells, and various causes of malabsorption are the typical causes for vitamin B_{12} deficiency. The neurologic sequelae of

vitamin B_{12} deficiency may occur in the absence of hematologic manifestations, making it critical to avoid using the complete blood count (CBC) and blood smear as a substitute for measuring B_{12} blood levels. Treatment with parenteral vitamin B_{12} (1000 μg intramuscularly daily for a week, weekly for a month, and monthly for life for pernicious anemia) stops progression of the disease if instituted promptly, but complete reversal of advanced nervous system damage will not occur.

Deficiency of nicotinic acid (*pellagra*) is associated with skin rash over sun-exposed areas, glossitis, and angular stomatitis **(Chap. 344)**. Severe dietary deficiency of nicotinic acid along with other B vitamins such as pyridoxine may result in spastic paraparesis, peripheral neuropathy, fatigue, irritability, and dementia. This syndrome has been seen in prisoners of war and in concentration camps but should be considered in any malnourished individual. Low serum folate levels appear to be a rough index of malnutrition, but isolated folate deficiency has not been proved as a specific cause of dementia.

CNS infections usually cause delirium and other acute neurologic syndromes. However, some chronic CNS infections, particularly those associated with chronic meningitis **(Chap. 144)**, may produce a dementing illness. The possibility of chronic infectious meningitis should be suspected in patients presenting with a dementia or behavioral syndrome, who also have headache, meningismus, cranial neuropathy, and/or radiculopathy. Between 20 and 30% of patients in the advanced stages of HIV infection become demented **(Chap. 208)**. Cardinal features include psychomotor retardation, apathy, and impaired memory. This syndrome may result from secondary opportunistic infections but can also be caused by direct infection of CNS neurons with HIV. Neurosyphilis **(Chap. 187)** was a common cause of dementia in the preantibiotic era; it is now uncommon but can still be encountered in patients with multiple sex partners, particularly among patients with HIV. Characteristic CSF changes consist of pleocytosis, increased protein, and a positive Venereal Disease Research Laboratory (VDRL) test. The recent SARS-CoV-2 pandemic was associated in some individuals with persistent postrecovery changes in memory, executive, and other cognitive functions; responsible mechanisms might include effects of inflammation, multiorgan system failure, or virus-associated vascular injury.

Primary and metastatic *neoplasms of the CNS* **(Chap. 95)** usually produce focal neurologic findings and seizures rather than dementia, but if tumor growth begins in the frontal or temporal lobes, the initial manifestations may be memory loss or behavioral changes. An autoimmune, sometimes paraneoplastic, syndrome of dementia associated with occult carcinoma (often small-cell lung cancer) is termed *limbic encephalitis*. In this syndrome, confusion, agitation, seizures, poor memory, emotional changes, and frank dementia may occur. Paraneoplastic *encephalitis associated with NMDA receptor antibodies* presents as a progressive psychiatric disorder with memory loss and seizures; affected patients are often young women with ovarian teratoma. Autoimmune etiologies also include antibodies targeting leucine-rich glioma-inactivated 1 (LGI1; faciobrachial dystonic seizures); contactin-associated protein-like 2 (Caspr2; insomnia, ataxia, myotonia); and α-amino-3-hydroxy-5-methylisoxazole-4-propionic acid (AMPA) receptor (limbic encephalitis with relapses), among others **(Chap. 99)**.

A *nonconvulsive seizure disorder* **(Chap. 436)** may underlie a syndrome of confusion, clouding of consciousness, and garbled speech. Often, psychiatric disease is suspected, but an EEG demonstrates the epileptic nature of the illness. If recurrent or persistent, the condition may be termed *complex partial status epilepticus*. The cognitive disturbance often responds to anticonvulsant therapy. The etiology may be previous small strokes or head trauma; some cases are idiopathic. Nonconvulsive temporal lobe seizures can also emerge early in the course of AD.

It is important to recognize *systemic diseases* that indirectly affect the brain and produce chronic confusion or dementia. Such conditions include hypothyroidism; vasculitis; and hepatic, renal, or pulmonary disease. Hepatic encephalopathy may begin with irritability and confusion and slowly progress to agitation, lethargy, and coma.

Isolated vasculitis of the CNS (CNS granulomatous angiitis) **(Chaps. 375 and 438)** occasionally causes a chronic encephalopathy associated with confusion, disorientation, and clouding of consciousness. Headache is common, and strokes and cranial neuropathies may occur. Brain imaging studies may be normal or nonspecifically abnormal. CSF analysis reveals a mild pleocytosis or protein elevation. Cerebral angiography can show multifocal stenoses involving medium-caliber vessels, but some patients have only small-vessel disease that is not revealed on angiography. The angiographic appearance is not specific and may be mimicked by atherosclerosis, infection, or other causes of vascular disease. Brain or meningeal biopsy demonstrates endothelial cell proliferation and mononuclear infiltrates within blood vessel walls. The prognosis is often poor, although the disorder may remit spontaneously. Some patients respond to glucocorticoids or chemotherapy.

Chronic metal exposure represents a rare cause of dementia. The key to diagnosis is to elicit a history of exposure at work or home. Chronic lead poisoning from inadequately fire-glazed pottery has been reported. Fatigue, depression, and confusion may be associated with episodic abdominal pain and peripheral neuropathy. Gray lead lines appear in the gums, usually accompanied by an anemia with basophilic stippling of red blood cells. The clinical presentation can resemble that of acute intermittent porphyria **(Chap. 428)**, including elevated levels of urine porphyrins as a result of the inhibition of δ-aminolevulinic acid dehydrase. The treatment is chelation therapy with agents such as ethylenediamine tetraacetic acid (EDTA). Chronic mercury poisoning produces dementia, peripheral neuropathy, ataxia, and tremulousness that may progress to a cerebellar intention tremor or choreoathetosis. The confusion and memory loss of chronic arsenic intoxication is also associated with nausea, weight loss, peripheral neuropathy, pigmentation and scaling of the skin, and transverse white lines of the fingernails (Mees' lines). Treatment is chelation therapy with dimercaprol (BAL). Aluminum poisoning is rare but was documented with the dialysis dementia syndrome, in which water used during renal dialysis was contaminated with excessive amounts of aluminum. This poisoning resulted in a progressive encephalopathy associated with confusion, nonfluent aphasia, memory loss, agitation, and, later, lethargy and stupor. Speech arrest and myoclonic jerks were common and associated with severe and generalized EEG changes. The condition has been eliminated by the use of deionized water for dialysis.

Recurrent head trauma in professional athletes may lead to a dementia previously referred to as "punch-drunk" syndrome or *dementia pugilistica* but now known as chronic traumatic encephalopathy (CTE) to signify its relevance to contact sport athletes other than boxers **(Chap. 454)**. The symptoms can be progressive, beginning late in an athlete's career or, more often, after retirement. Early in the course, a personality change occurs, associated with social instability, explosive rage, and sometimes paranoia and delusions. Later, memory loss progresses to full-blown dementia, often associated with parkinsonian signs and ataxia or intention tremor. At autopsy, the cerebral cortex shows tau-immunoreactive NFTs that are more prominent than amyloid plaques (which are usually diffuse or absent rather than neuritic). NFTs and tau-positive reactive astrocytes are often clustered in the depths of cortical sulci and in a perivascular distribution. TDP-43 inclusions have also been reported, highlighting the overlap with the FTD spectrum **(Chap. 443)**. Loss of neurons in the substantia nigra is a variable feature, and some with TDP-43 inclusions also develop motor neuron disease (MND) **(Chap. 448)**.

Chronic subdural hematoma **(Chap. 454)** is also occasionally associated with dementia, often in the context of underlying cortical atrophy from conditions such as AD or HD.

Transient global amnesia (TGA) is characterized by the sudden onset of a severe episodic memory deficit, usually occurring in persons aged >50 years. Often the amnesia occurs in the setting of an emotional stimulus or physical exertion. During the attack, the individual is alert and communicative, general cognition seems intact, and there are no other neurologic signs or symptoms. The patient may seem confused and repeatedly ask about their location in place and time. The ability to form new memories returns after a period of hours, and the individual returns to normal with no recall for the period of the attack. Frequently no cause is determined, but cerebrovascular disease, epilepsy (7% in

one study), migraine, or cardiac arrhythmias have all been implicated. Approximately one-quarter of patients experience recurrent attacks. Rare instances of permanent memory loss have been reported in patients with TGA-like spells, usually representing ischemic infarction of the hippocampus or dorsomedial thalamic nucleus bilaterally. Seizure activity due to AD should always be suspected in this syndrome.

The *ALS/parkinsonian/dementia complex of Guam* is a rare degenerative disease that has occurred in the Chamorro natives on the island of Guam. Individuals may have any combination of parkinsonian features, dementia, and MND. The most characteristic pathologic features are the presence of NFTs in degenerating neurons of the cortex and substantia nigra and loss of motor neurons in the spinal cord, although recent reanalysis has shown that some patients with this illness also show coexisting TDP-43 pathology. Epidemiologic evidence supports a possible environmental cause, such as exposure to a neurotoxin or an infectious agent with a long latency period. One interesting but unproven candidate neurotoxin is the seed of the false palm tree, which Guamanians traditionally used to make flour. The amyotrophic lateral sclerosis (ALS) syndrome is no longer present in Guam, but a dementing illness with rigidity continues to be seen.

Rarely, adult-onset leukodystrophies, lysosomal storage diseases, and other genetic disorders can present as a dementia in middle to late life. Metachromatic leukodystrophy (MLD) causes a progressive psychiatric or dementia syndrome associated with an extensive, confluent frontal white matter abnormality. MLD is diagnosed by measuring reduced arylsulfatase A enzyme activity in peripheral white blood cells. Adult-onset presentations of adrenoleukodystrophy have been reported in female carriers, and these patients often feature spinal cord and posterior white matter involvement. Adrenoleukodystrophy is diagnosed by demonstrating increased levels of plasma very-long-chain fatty acids. CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy) is another genetic syndrome associated with white matter disease, often frontally and temporally predominant. Diagnosis is made with skin biopsy, which shows osmophilic granules in arterioles, or increasingly through genetic testing for mutations in Notch 3. The neuronal ceroid lipofuscinoses are a genetically heterogeneous group of disorders associated with myoclonus, seizures, vision loss, and progressive dementia. Diagnosis is made by finding eosinophilic curvilinear inclusions within white blood cells or neuronal tissue.

Psychogenic amnesia for personally important memories can be seen. Whether this results from deliberate avoidance of unpleasant memories, outright malingering, or unconscious repression remains unknown and probably depends on the patient. Event-specific amnesia is more likely to occur after violent crimes such as homicide of a close relative or friend or sexual abuse. It may develop in association with severe drug or alcohol intoxication and sometimes with schizophrenia. More prolonged psychogenic amnesia occurs in fugue states that also commonly follow severe emotional stress. The patient with a fugue state suffers from a sudden loss of personal identity and may be found wandering far from home. *In contrast to neurologic amnesia, fugue states are associated with amnesia for personal identity and events closely associated with the personal past.* At the same time, memory for other recent events and the ability to learn and use new information are preserved. The episodes usually last hours or days and occasionally weeks or months while the patient takes on a new identity. On recovery, there is a residual amnesia gap for the period of the fugue. Very rarely does selective loss of autobiographic information reflect a focal injury to the brain areas involved with these functions.

Psychiatric diseases may mimic dementia. Severely depressed or anxious individuals may appear demented, a phenomenon sometimes called *pseudodementia*. Memory and language are usually intact when carefully tested, and a significant memory disturbance usually suggests an underlying dementia, even if the patient is depressed. Patients in this condition may feel confused and unable to accomplish routine tasks. Vegetative symptoms, such as insomnia, lack of energy, poor appetite, and concern with bowel function, are common. Onset is often more abrupt, and the psychosocial milieu may suggest prominent reasons for depression. Such patients respond to treatment of the underlying psychiatric illness. Schizophrenia is usually not difficult to distinguish from dementia, but occasionally the distinction can be problematic. Schizophrenia generally has a much earlier age of onset (second and third decades) than most dementing illnesses and is associated with intact memory. The delusions and hallucinations of schizophrenia are usually more complex, bizarre, and threatening than those of dementia. Some chronic schizophrenics develop an unexplained progressive dementia late in life that is not related to AD. Conversely, FTD, HD, vascular dementia, DLB, AD, or leukoencephalopathy can begin with schizophrenia-like features, leading to the misdiagnosis of a psychiatric condition. Later age of onset, significant deficits on cognitive testing, or the presence of abnormal neuroimaging suggest a degenerative condition. Memory loss may also be part of a *conversion disorder*. In this situation, patients commonly complain bitterly of memory loss, but careful cognitive testing either does not confirm the deficits or demonstrates inconsistent or unusual patterns of cognitive problems. The patient's behavior and "wrong" answers to questions often indicate that they understand the question and know the correct answer.

Clouding of cognition by *chronic drug or medication use*, often prescribed by physicians, is an important cause of dementia. Sedatives, tranquilizers, and analgesics used to treat insomnia, pain, anxiety, or agitation may cause confusion, memory loss, and lethargy, especially in the elderly. Discontinuation of the offending medication often improves mentation.

443 Frontotemporal Dementia

William W. Seeley, Bruce L. Miller

Frontotemporal dementia (FTD) refers to a group of clinical syndromes united by their links to underlying frontotemporal lobar degeneration (FTLD) pathology. FTD, like the other major neurodegenerative diseases, is considered a disease of abnormal protein aggregation, with either tau or transactive response DNA-binding protein of 43 kDa (TDP-43) implicated in most cases. FTD most often begins in the fifth to seventh decades of life and is nearly as prevalent as Alzheimer's disease (AD) in this age group. Early studies suggested that FTD may be more common in men than women; however, more recent reports

cast doubt on this finding. Although a family history of dementia is common, autosomal dominant inheritance is seen in only 10–20% of all FTD cases.

CLINICAL MANIFESTATIONS

Familial and sporadic forms of FTLD present with remarkable clinical heterogeneity. Three core clinical syndromes have been described **(Fig. 443-1)**. In the behavioral variant (bvFTD), the most common FTD syndrome, social and emotional dysfunction manifests as apathy, disinhibition, compulsivity, loss of empathy, and overeating, often but not always accompanied by deficits in executive control. Two forms of primary progressive aphasia (PPA), the semantic and nonfluent/agrammatic variants, are commonly due to FTLD and are included under the FTD umbrella. In the semantic variant, patients slowly lose the ability to decode word, object, person-specific, and emotion meaning, whereas patients with the nonfluent/agrammatic variant develop profound inability to produce words, often with prominent motor speech impairment. Any of these three clinical syndromes, but most often bvFTD, may be accompanied by motor neuron disease (MND) **(Chap. 448)**, in which case the term FTD-MND is applied. In addition, the corticobasal syndrome (CBS) and progressive supranuclear palsy–Richardson syndrome (PSP-RS) can be considered part of the FTD clinical spectrum. Furthermore, patients may evolve from any of the major syndromes described above to have prominent features of another syndrome.

Findings at the bedside are dictated by the anatomic localization of the disorder. Degeneration with atrophy occurs in the medial and orbital frontal cortex and anterior insula in bvFTD; the anterior temporal region in semantic variant PPA; and the opercular frontal and precentral gyrus of the dominant hemisphere in nonfluent/agrammatic PPA. Typically, parietal functions such as visuospatial processing and arithmetic calculations are unaffected even late in the FTD syndromes. Many patients with nonfluent aphasia or bvFTD later develop aspects of PSP-RS as disease spreads into subcortical or brainstem structures or CBS-like features appear as disease moves into perirolandic cortices.

GENETIC CONSIDERATIONS

Autosomal dominant forms of FTD can result from mutations in *C9orf72* (chromosome 9), *GRN* (chromosome 17), and *MAPT* (chromosome 17) genes. A hexanucleotide (GGGGCC) expansion in a noncoding exon of *C9ORF72* is the most common genetic cause of familial or sporadic FTD (usually presenting as bvFTD with or without MND) and amyotrophic lateral sclerosis (ALS). The expansion is associated with *C9orf72* haploinsufficiency, nuclear mRNA foci containing transcribed portions of the expansion and other mRNAs, neuronal cytoplasmic inclusions containing dipeptide repeat proteins translated from the repeat mRNA, and TDP-43 neuronal cytoplasmic and glial inclusions. The pathogenic significance of these various features is a topic of vigorous investigation. *MAPT* mutations lead to a change in the alternate splicing of tau or cause loss of function in the tau molecule, thereby altering microtubule binding. With *GRN*, mutations in the coding sequence of the gene encoding progranulin protein result in mRNA degradation due to nonsense-mediated decay, leading to a ~50% reduction in circulating progranulin protein levels. Intriguingly, homozygous *GRN* mutations cause neuronal ceroid lipofuscinosis, focusing investigators on the lysosome as a site of molecular dysfunction in *GRN*-related FTD. Progranulin is a growth factor that binds to tumor necrosis factor (TNF) and sortilin receptors and participates in tissue repair and tumor growth. How progranulin mutations lead to FTD remains unknown, but the most likely mechanisms include lysosomal dysfunction and neuroinflammation. Often, *MAPT* and *GRN* mutations are associated with parkinsonian features, whereas ALS is rare. Infrequently, mutations in the valosin-containing protein (*VCP*, chromosome 9), TANK binding kinase 1 (TBK-1), T cell–restricted intracellular antigen-1 (TIA1), and charged multivesicular body protein 2b (*CHMP2b,* chromosome 3) genes also lead to autosomal dominant familial FTD. Mutations in the *TARDBP* (encoding TDP-43) and *FUS* (encoding fused in sarcoma [FUS]) genes (see below) cause familial ALS, sometimes in association with an FTD syndrome, although a few patients presenting with FTD alone have been reported.

NEUROPATHOLOGY

The pathological hallmark of FTLD is a focal atrophy of frontal, insular, and/or temporal cortex, which can be visualized with neuroimaging studies (Fig. 443-1) and is often profound at autopsy. Neuroimaging studies suggest that atrophy often begins focally in one hemisphere before spreading to anatomically interconnected cortical and subcortical regions. Loss of cortical serotonergic innervation is seen in many patients. In contrast to AD, the cholinergic system is relatively spared in FTD, which accounts for the poor efficacy of acetylcholinesterase inhibitors in this group.

Although early studies suggested that 15–30% of patients with FTD showed underlying AD at autopsy, progressive refinement in clinical diagnosis has improved prediction accuracy, and most patients diagnosed with FTD at a dementia clinic will show underlying FTLD pathology. Microscopic findings seen across all patients with FTLD include gliosis, microvacuolation, and neuronal loss, but the disease is subtyped according to the protein composition of neuronal and glial inclusions, which contain either tau or TDP-43 in ~90% of patients, with the remaining ~10% showing inclusions containing the FET family of proteins (**F**US, **E**wing sarcoma protein, **T**AF-15) **(Fig. 443-2)**.

PATHOGENESIS

In FTLD-tau, the toxicity and spreading capacity of misfolded tau are critical for the pathogenesis of inherited and sporadic tauopathies, although loss of tau microtubule stabilizing function may also play a role. In recent years, the distinctive structures of the misfolded tau in each FTLD tauopathy have been resolved using cryo-electron microscopy, opening up new approaches to diagnosis and treatment. TDP-43 and FET family proteins in contrast, are RNA/DNA binding proteins whose roles in neuronal function are still being actively investigated. TDP-43 is a master regulator of gene expression, and loss of TDP-43 function results in mis-splicing events leading to mRNA degradation (via nonsense-mediated decay) or aberrant transcripts that give rise to stable but dysfunctional peptides. One key role of TDP-43 and FET family proteins may be the chaperoning of mRNAs to the distal neuron for activity-dependent translation within dendritic spines. Because these proteins also form intracellular aggregates and produce similar anatomic progression, protein toxicity and spreading may also factor heavily

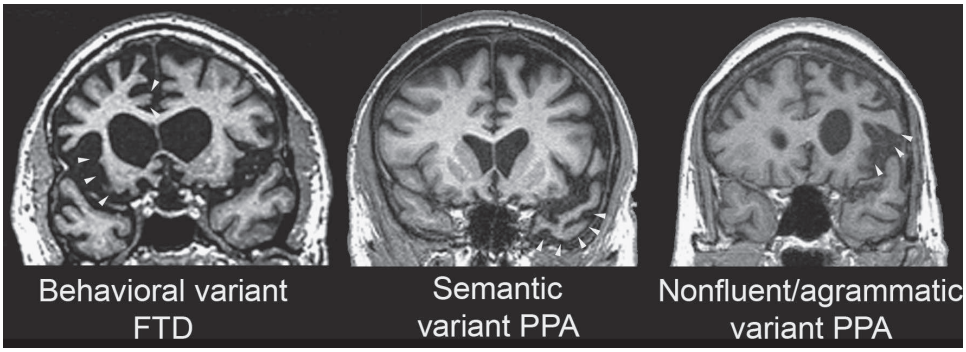

FIGURE 443-1 Three major frontotemporal dementia (FTD) clinical syndromes. Coronal magnetic resonance imaging sections from representative patients with behavioral variant FTD (*left*) and the semantic (*center*) and nonfluent/agrammatic (*right*) variants of primary progressive aphasia (PPA). Areas of early and severe atrophy in each syndrome are highlighted (*white arrowheads*). The behavioral variant features anterior cingulate and frontoinsular atrophy, spreading to orbital and dorsolateral prefrontal cortex. Semantic variant PPA shows prominent temporopolar atrophy, more often on the left. Nonfluent/agrammatic variant PPA is associated with dominant frontal opercular and dorsal insula degeneration.

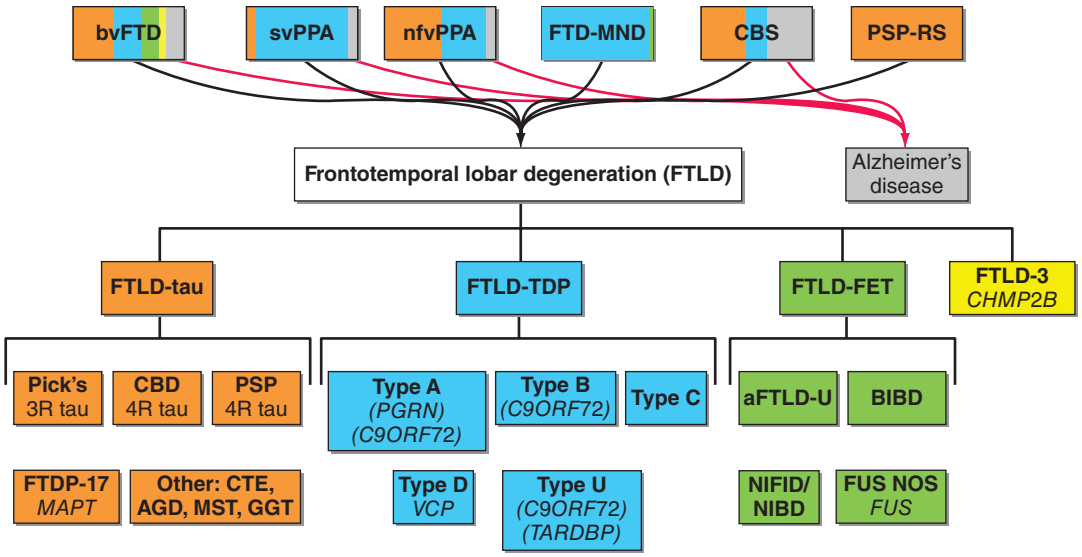

FIGURE 443-2 Frontotemporal dementia syndromes are united by underlying frontotemporal lobar degeneration pathology, which can be divided according to the presence of tau, TDP-43, or FUS-containing inclusions in neurons and glia. Correlations between clinical syndromes and major molecular classes are shown with colored shading. Despite improvements in clinical syndromic diagnosis, a small percentage of patients with some frontotemporal dementia syndromes will show Alzheimer's disease neuropathology at autopsy (*gray shading*). aFTLD-U, atypical frontotemporal lobar degeneration with ubiquitin-positive inclusions; AGD, argyrophilic grain disease; BIBD, basophilic inclusion body disease; bvFTD, behavioral variant frontotemporal dementia; CBD, corticobasal degeneration; CBS, corticobasal syndrome; CTE, chronic traumatic encephalopathy; FET, FUS, Ewing sarcoma protein, TAF-15 family of proteins; FTD-MND, frontotemporal dementia with motor neuron disease; FTDP-17, frontotemporal dementia with parkinsonism linked to chromosome 17; FUS, fused in sarcoma; GGT, globular glial tauopathy; MST, multisystem tauopathy; nfvPPA, nonfluent/agrammatic variant primary progressive aphasia; NIBD, neurofilament inclusion body disease; NIFID, neuronal intermediate filament inclusion disease; PSP, progressive supranuclear palsy; PSP-RS, progressive supranuclear palsy–Richardson syndrome; svPPA, semantic variant primary progressive aphasia; Type U, unclassifiable type.

in the pathogenesis of FTLD-TDP and FTLD-FET. As with tau, the ultrastructural characteristics of the TDP-43 and FET family protein misfolding events are now being actively characterized, with each pathologically recognized morphological subtype corresponding to a disease-specific fold.

Increasingly, misfolded proteins in neurodegenerative disease are recognized as having "prion-like" or "corruptive" properties in that they can template the misfolding of their natively folded (or unfolded) protein counterparts, a process that creates exponential amplification of protein misfolding within a cell and may promote transcellular and even transsynaptic protein propagation between cells. This hypothesis could provide a unifying explanation for the stereotypical and network-rooted patterns of disease spread observed in each syndrome **(Chap. 435)**.

Although the term *Pick's disease* was once used to describe a progressive degenerative disorder characterized by selective involvement of the anterior frontal and temporal neocortex and pathologically by intraneuronal cytoplasmic inclusions (*Pick bodies*), it is now used only in reference to a specific FTLD-tau histopathologic subtype. Classical Pick bodies are argyrophilic, staining positively with the Bielschowsky silver method (but not with the Gallyas method) and also with immunostaining for hyperphosphorylated tau. Recognition of the three FTLD major molecular classes has allowed delineation of distinct FTLD subtypes within each class. These subtypes, based on the morphology and distribution of the neuronal and glial inclusions **(Fig. 443-3)**, account for the vast majority of patients, and some subtypes show strong clinical or genetic associations (Fig. 443-2). Despite this progress, clinical features do not allow reliable prediction of the underlying FTLD subtype, or even the major molecular class, for all clinical syndromes. Molecular positron emission tomography (PET) imaging with ligands chosen to bind misfolded tau protein shows promise, but to date, these ligands only show robust and specific binding to AD-related misfolded tau. Because FTLD-tau and FTLD-TDP account for 90% of FTLD patients, the ability to detect pathologic tau (or TDP-43) protein deposition in vivo would greatly improve prediction accuracy, especially when amyloid PET imaging is negative.

TREATMENT

Caregivers for patients with FTD carry a heavy burden, especially when the illness disrupts core emotional and personality functions of the loved one. Treatment is symptomatic, and there are currently no therapies known to slow progression or improve symptoms. Many of the behaviors that may accompany FTD, such as depression, hyperorality, compulsions, and irritability, can be ameliorated with antidepressants, especially selective serotonin reuptake inhibitors (SSRIs). Because FTD is often accompanied by parkinsonism, antipsychotics, which can exacerbate this problem, must be used with caution. Experimental therapeutics, most targeting genetic forms of FTD, have just begun to enter clinical trials, but to date, no disease-modifying treatments have shown efficacy. **A general approach to the symptomatic management of dementia is presented in Chap. 31.**

PROGRESSIVE SUPRANUCLEAR PALSY SYNDROME

PSP-RS is a degenerative disorder that involves the brainstem, basal ganglia, diencephalon, and selected areas of cortex. Clinically, PSP-RS begins with falls and executive dysfunction or subtle personality changes (such as mental rigidity, impulsivity, or apathy). Shortly thereafter, a progressive oculomotor syndrome ensues that begins with square wave jerks, followed by slowed saccades (vertical worse than horizontal) before resulting in progressive supranuclear ophthalmoparesis. Dysarthria, dysphagia, and symmetric axial rigidity can be prominent features that emerge at any point in the illness. A stiff, unstable posture with hyperextension of the neck and a slow, jerky, toppling gait are characteristic. Frequent unexplained and sometimes spectacular falls are common secondary to a combination of axial rigidity, inability to look down, and impaired judgment. Even once patients have severely limited voluntary eye movements, they retain oculocephalic reflexes (demonstrated using a vertical doll's head maneuver); thus, the oculomotor disorder is supranuclear. The dementia overlaps with bvFTD, featuring apathy, frontal-executive dysfunction, poor judgment, slowed thought processes, impaired verbal fluency, and difficulty with sequential actions and shifting from one task to another. These features are common at presentation and often precede the motor syndrome. Some patients with a pathologic diagnosis of PSP begin with a nonfluent aphasia or motor speech disorder and progress to classical PSP-RS. Response to L-dopa is limited or absent; no other treatments exist. Death occurs within 5–10 years of onset. Like Pick's disease, increasingly the term *PSP* is used to refer to a specific histopathologic entity within the FTLD-tau class. In PSP, accumulation of hyperphosphorylated 4-repeat tau is seen within neurons and glia. Tau neuronal inclusions often appear tangle-like and may be large, spherical ("globose"), and coarse in subcortical and brainstem

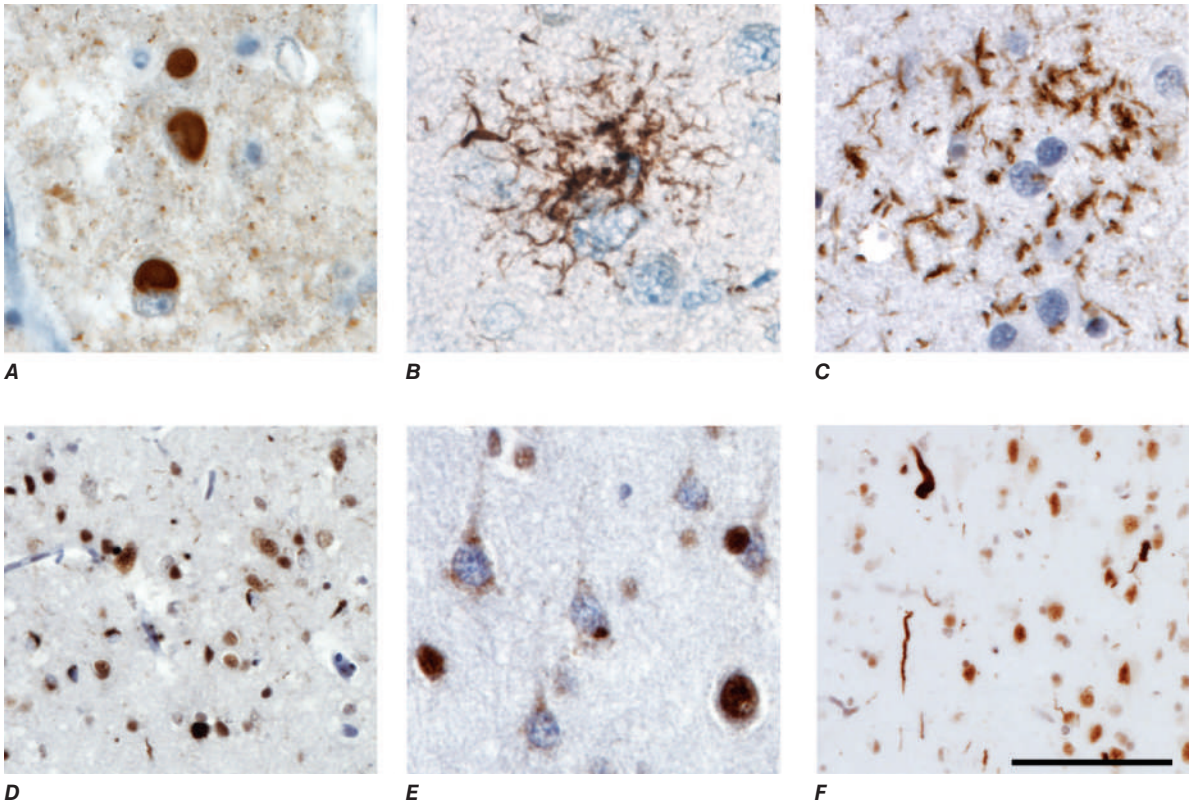

FIGURE 443-3 Neuropathology in frontotemporal lobar degeneration (FTLD). FTLD-tau (***A–C***) and FTLD-TDP (***D–F***) account for >90% of patients with FTLD, and immunohistochemistry reveals characteristic lesions in each of the major histopathologic subtypes within each class: ***A.*** Pick bodies in Pick's disease; ***B.*** a tufted astrocyte in progressive supranuclear palsy; ***C.*** an astrocytic plaque in corticobasal degeneration; ***D.*** small compact or crescentic neuronal cytoplasmic inclusions and short, thin neuropil threads in FTLD-TDP, type A; ***E.*** diffuse/granular neuronal cytoplasmic inclusions (with a relative paucity of neuropil threads) in FTLD-TDP, type B; and ***F.*** long, tortuous dystrophic neurites in FTLD-TDP, type C. TDP can be seen within the nucleus in neurons lacking inclusions but mislocalizes to the cytoplasm and forms inclusions in FTLD-TDP. Immunostains are 3-repeat tau (***A***), phospho-tau (***B*** and ***C***), and TDP-43 (***D–F***). Sections are counterstained with hematoxylin. Scale bar applies to all panels and represents 50 µm in ***A, B, C,*** and ***E*** and 100 µm in ***D*** and ***F.***

structures. The most prominent involvement is in the subthalamic nucleus, globus pallidus, substantia nigra, periaqueductal gray, tectum, oculomotor nuclei, pontine nuclei, and dentate nucleus of cerebellum. Neocortical tangle-like inclusions, like those in AD, often take on a more flame-shaped morphology, but the tau folds in AD and PSP are distinct. Prominent tau-positive glial inclusions are an essential feature of PSP. Tufted astrocytes in the neocortex or striatum are the signature lesion (Fig. 443-3). Coiled oligodendroglial inclusions ("coiled bodies") are common but nonspecific. Most patients with PSP-RS show PSP at autopsy, although small numbers will show another tauopathy (corticobasal degeneration [CBD] or globular glial tauopathy, or FTLD with a *MAPT* mutation; Fig. 443-2).

In addition to its overlap with FTD and CBS (see below), PSP is often confused with idiopathic *Parkinson's disease* (PD). Although elderly patients with PD may have restricted upgaze, they do not develop downgaze paresis or other abnormalities of voluntary eye movements typical of PSP. Dementia ultimately occurs in most patients with PD, often due to the emergence of a full-blown dementia with Lewy bodies (DLB)-like syndrome or comorbid AD-type dementia. Furthermore, the behavioral syndromes seen with DLB differ from PSP (see below). Dementia in PD becomes more likely with increasing age, increasing severity of extrapyramidal signs, long disease duration, and the presence of depression. Patients with PD who develop dementia also show cortical atrophy on brain imaging. Neuropathologically, there may be AD-related changes in the cortex or Lewy body disease (LBD)-related α-synuclein inclusions in both the limbic system and cerebral cortex. **DLB and PD are discussed in Chaps. 445 and 446, respectively.**

CORTICOBASAL SYNDROME

CBS is a slowly progressive dementia-movement disorder associated with severe degeneration in the perirolandic cortex and basal ganglia (substantia nigra and striatopallidum). Patients typically present with asymmetric rigidity, dystonia, myoclonus, and apraxia that render a progressively incapacitated limb, at times associated with *alien limb* phenomena in which the limb exhibits unintended motor actions such as grasping, groping, drifting, or undoing. Eventually CBS becomes bilateral and leads to dysarthria, slow gait, action tremor, and a frontal-predominant dementia. Whereas CBS refers to the clinical syndrome, CBD refers to a specific histopathologic FTLD-tau entity (Fig. 443-2). Although CBS was once thought to be pathognomonic for CBD, increasingly it has been recognized that CBS can be due to CBD, PSP, FTLD-TDP, and AD, with the latter accounting for up to 30% of CBS in some series. In CBD, the microscopic features include ballooned, achromatic, tau-positive neurons; astrocytic plaques (Fig. 443-3); and other dystrophic glial tau pathomorphologies that overlap with those seen in PSP. Most specifically, CBD features a severe tauopathy burden in the subcortical white matter, consisting of axonal threads and oligodendroglial coiled bodies. As shown in Fig. 443-2, patients with bvFTD, nonfluent/agrammatic PPA, and PSP-RS may also show CBD at autopsy, emphasizing the importance of distinguishing clinical and pathologic constructs and terminology. Treatment of CBS remains symptomatic; no disease-modifying therapies are available.

444 Vascular Dementia

Steven M. Greenberg, William W. Seeley

The term *vascular dementia* has traditionally been used to describe a subset of dementia cases due primarily to one or more symptomatic strokes. Considered as such, vascular dementia is usually ranked the second most frequent cause of dementia, exceeded only by Alzheimer's disease **(Chap. 442)**, and is especially common in populations with limited access to medical care, where vascular risk factors are undertreated. More recently, this relatively narrow definition of vascular dementia has been substantially broadened to encompass the full impact of cerebrovascular disease on age-related cognitive decline. The term *vascular contributions to cognitive impairment and dementia* (VCID) reflects the observation that pathologic changes involving the cerebral vasculature are highly prevalent in the elderly and contribute to cognitive impairment, whether occurring in isolation or—more commonly—in conjunction with other neurodegenerative processes. The concept of VCID is one facet of the contemporary understanding of age-related cognitive decline as due to cumulative effects of distinct and overlapping neuropathologic changes. Multifactorial or "mixed" dementias appear to be more prevalent than single-etiology dementias and thus represent the rule rather than the exception.

Symptomatic stroke and asymptomatic vascular lesions, most commonly detected with brain magnetic resonance imaging (MRI) scans, both contribute importantly to cognitive impairment. At least some cognitive impairment is present in approximately half of stroke survivors and progressively increases with longer periods of follow-up. Population-based studies also demonstrate substantially increased risk of cognitive impairment among individuals without symptomatic stroke but with MRI evidence of cerebrovascular disease. The high risk for subsequent cognitive impairment or dementia conferred by MRI markers of otherwise silent vascular brain injury highlights the cumulative impact of small distributed brain injuries—often associated with small-vessel brain disease—on compromising brain function. Further support for this framework comes from the correlation of cognitive performance during life with postmortem neuropathology. Analysis of large community-based samples demonstrates independent contributions to cognitive dysfunction and decline from both grossly visible infarcts and pathologic markers of overall cerebrovascular disease severity such as atherosclerosis, arteriolosclerosis, and cerebral amyloid angiopathy scores. The Religious Orders Study and Memory and Aging Project analysis of 1079 community-based participants, for example, found each of these cerebrovascular entities to be moderate to severe in >30% of postmortem brains and, when present, to each account for ~20% of an individual's premortem cognitive decline.

Recent epidemiologic evidence of a decline in age-adjusted dementia incidence hints at the potential public impact of improving vascular health. The population-based Framingham Study reported 5-year age- and sex-adjusted cumulative hazard rates for dementia of 3.6 per 100 persons during the late 1970s to early 1980s, 2.8 in the late 1980s to early 1990s, 2.2 in the late 1990s to early 2000s, and 2.0 in the late 2000s to early 2010s. These time intervals coincide with parallel trends in hypertension control and stroke prevention, though the associations do not prove causation. Evidence supporting a potential causative effect of blood pressure control came from the SPRINT-MIND trial targeting systolic blood pressure (SBP) of <120 mmHg versus 140 mmHg in hypertensive individuals aged ≥50 years. The study ended prematurely because of effective prevention of cardiovascular outcomes in the lower SBP target group but nonetheless demonstrated that SBP reduction reduced rates of mild cognitive impairment (hazard ratio [HR], 0.81; 95% confidence interval [CI], 0.69–0.95) and combined mild cognitive impairment or probable dementia (HR, 0.85; 95% CI, 0.74–0.97), although not dementia alone (HR, 0.83; 95% CI, 0.67–1.04). It is notable that both these studies measured all-cause cognitive impairment rather than just a vascular dementia subset, underlining the potential importance of VCID as a target for dementia prevention.

GLOBAL CONSIDERATIONS

A review of data from across the globe indicates good evidence for variability in vascular dementia. Intracranial atherosclerosis, for example, is higher in Asians, Hispanics, and American blacks than it is in European and American whites, while whites may have more extracranial disease. The causes of these disparities remain under investigation but likely include access to health care, lifestyle factors such as diet, and possible genetic influences.

SUBTYPES OF CEREBROVASCULAR DISEASE ASSOCIATED WITH VCID

Large Cerebral Strokes Symptomatic strokes, whether ischemic **(Chap. 438)** or hemorrhagic **(Chap. 439)**, reflect irreversible injury to discrete areas of cerebral cortex, subcortical white matter, or other subcortical and infratentorial structures and produce cognitive impairment as a function of their size and location. Rare individual infarcts in specific strategic locations such as thalamus, medial temporal cortex, anterior corpus callosum, or dominant-side angular gyrus can sufficiently impair episodic memory and functional skills to meet memory-based criteria for dementia. More commonly, strokes occur outside these strategic territories and affect various other aspects of cognition such as executive function, processing speed, and visuospatial performance that fall under the broader VCID concept. Multiple strokes and larger volumes of infarcted territory are associated with a higher likelihood of poststroke cognitive dysfunction.

Stroke patients who make good cognitive recovery nonetheless demonstrate accelerated poststroke cognitive decline. Community-based individuals in the longitudinal Reasons for Geographic and Racial Differences in Stroke study, for example, changed trajectory from an average prestroke cognitive gain of 0.021 points/year to poststroke cognitive loss of –0.035 points/year on the six-item screener global cognitive function scale. Mechanisms for poststroke cognitive decline likely include ongoing effects of the cerebrovascular disease that gave rise to the index stroke as well as loss of cognitive reserve that makes the brain less resilient to any additional age-related disorders.

Cerebral Small-Vessel Disease Diseases of the brain's small vessels **(Chap. 438)** can also cause symptomatic ischemic or hemorrhagic stroke but are more often clinically asymptomatic and recognized only during evaluation for cognitive decline or other symptoms. The two common age-related cerebral small-vessel pathologies are arteriolosclerosis and cerebral amyloid angiopathy. *Arteriolosclerosis* represents thickening of arterioles due to infiltration of plasma proteins into the vessel wall. The primary risk factors for this process are age, hypertension, and diabetes mellitus. Cerebrovascular arteriolosclerosis can present as a cause of ischemic or hemorrhagic symptomatic stroke, both most commonly centered in territories supplied by deep penetrating vessels such as thalamus, basal ganglia, or brainstem. *Cerebral amyloid angiopathy* is defined by deposition of the β-amyloid peptide in the walls of small cerebral arteries, arterioles, and capillaries, with consequent loss of normal wall structure. Its primary risk factor is advancing age. Cerebral amyloid angiopathy is most often recognized symptomatically as a cause of intracerebral hemorrhage **(Chap. 439)**, commonly located in cerebral cortex, subcortical white matter (collectively known as lobar hemorrhages), or the cerebral convexity subarachnoid space. This small-vessel pathology also appears to confer increased risk for the adverse amyloid-related imaging abnormalities (ARIA) associated with recently approved immunotherapies for Alzheimer's disease **(Chap. 442)**. The distinction between the deep penetrating territories most commonly affected by arteriolosclerosis and superficial lobar brain regions affected by cerebral amyloid angiopathy often allows the two small-vessel diseases to be radiographically distinguished.

Despite differences in their underlying pathogenic mechanisms, the two cerebral small-vessel diseases produce a similar range of ischemic and hemorrhagic brain lesions detectable by histopathology at autopsy or MRI scan during life **(Fig. 444-1)**. *Small (lacunar) infarcts* are a common feature of arteriolosclerosis and less commonly of cerebral amyloid angiopathy. Chronic lacunar infarcts can appear on MRI fluid-attenuated inversion recovery (FLAIR) sequences as a hyperintense rim surrounding a hypointense cavitated core with diameters typically

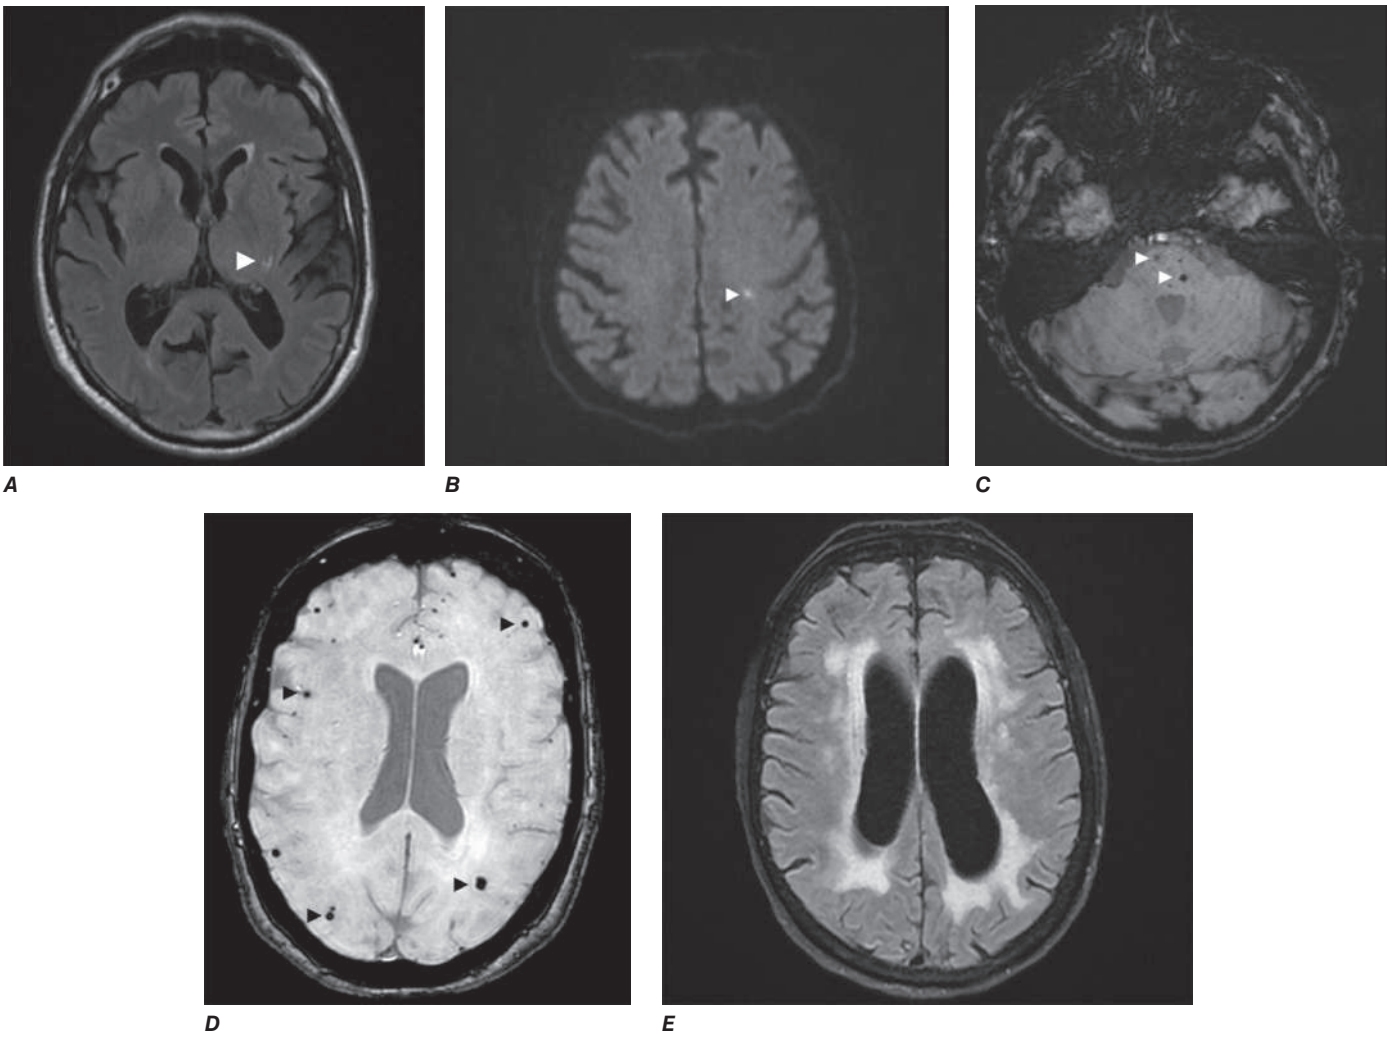

FIGURE 444-1 Magnetic resonance imaging (MRI) markers of cerebral small vessel disease. ***A.*** Lacunar infarct: fluid-attenuated inversion recovery (FLAIR) sequence showing hyperintense rim surrounding a hypointense cavitated core in the left thalamus (arrowhead). ***B.*** Acute microinfarct: diffusion-weighted sequence showing small hyperintense lesion in the left centrum semiovale (*arrowhead*). ***C.*** Cerebral microbleeds in deep penetrating brain region: T2*-weighted sequence showing multiple small hypointense lesions in the pons (*arrowheads*). ***D.*** Cerebral microbleeds in lobar brain regions: T2*-weighted sequence showing multiple small hypointense lesions lobar brain regions (*arrowheads*). ***E.*** White matter hyperintensities: FLAIR sequence showing confluent diffuse hyperintensities in white matter.

3–15 mm **(Fig. 444-1*A*)**, but this characteristic appearance evolves in only a subset of small infarctions, and many cannot be readily identified in the chronic stage. *Microinfarcts* <3 mm are characteristic of both small-vessel diseases. They are substantially more numerous than lacunar infarcts but less easily visualized. Acute microinfarcts may be visible as punctate hyperintensities on diffusion-weighted MRI images **(Fig. 433-1*B*)**, whereas a small subset of chronic microinfarcts is detectable on high-resolution T2-weighted MRI sequences as hyperintense lesions in the cerebral cortex. *Cerebral microbleeds* are less numerous than lacunes or microinfarcts but readily detected in their chronic stage because of the paramagnetic effects of iron products. These appear as round hypointense lesions on T2*-weighted MRI, primarily in deep penetrating brain regions if caused by arteriolosclerosis **(Fig. 444-1*C*)** or lobar regions if caused by cerebral amyloid angiopathy **(Fig. 444-1*D*)**.

Other MRI markers of small-vessel disease identify diffuse injury of the white matter. *White matter hyperintensities* on T2-weighted or FLAIR MRI sequences **(Fig. 444-1*E*)** are an almost ubiquitous feature of aging. Although these lesions are readily visible on clinical MRI, they represent a nonspecific marker of white matter gliosis, demyelination, or increased water content. Extremely severe diffuse white matter vascular injury is commonly referred to as *Binswanger's disease* or subcortical arteriosclerotic encephalopathy, recognized as a clinical syndrome with gradual cognitive deterioration and notable white matter changes of small-vessel ischemic disease. On neuroimaging, a progressive confluent subcortical and periventricular white matter disease is seen **(see Fig. 31-2)**, with hypoperfusion and hypometabolism. More subtle alterations in white matter structure can be sensitively and quantitatively detected by *diffusion tensor* MRI **(Chap. 434)** as increased water diffusivity or decreased diffusion directionality. Diffusion tensor measures of white matter structural integrity show a consistent association with cognitive performance and gait speed, reflecting the central role of disconnection of key brain networks in mediating the effects of cerebral small-vessel disease. These diffusion tensor–based methods often require complex processing and are typically used in research rather than clinical settings. A relatively simple diffusion tensor–based metric defined by the peak width of the skeletonized mean diffusivity (PSMD) histogram has emerged as a candidate method for quantifying white matter disconnection. Functional MRI measurement of cerebrovascular reactivity to physiologic stimuli is generally not performed in clinical practice, but it may become abnormal decades before appearance of structural brain injury and therefore represents a promising outcome marker for identifying disease-modifying interventions aimed to slow or prevent vascular brain injury.

Role of Accompanying Brain Pathologies The concept of VCID posits that large strokes and small-vessel disease often occur in combination with neurodegenerative brain diseases, most commonly Alzheimer's disease **(Chap. 442)**. Many clinicopathologic correlation studies have established that the co-occurrence of cerebrovascular and neurodegenerative lesions produces more cognitive and functional impairment than expected from the effects of each disease mechanism

considered independently. Interactions between cerebrovascular and neurodegenerative processes may also contribute to dementia. Such interactions might involve loss of blood-brain barrier integrity (possibly allowing brain penetration of neurotoxic or inflammatory agents) and impaired clearance of β-amyloid or other pathogenic molecules from the brain (postulated to occur along perivascular drainage pathways driven by physiologic vascular motion).

APPROACH TO THE PATIENT

Vascular Dementia

Identifying vascular contributors to a patient's cognitive impairment can clarify the etiologic diagnosis and point to specific interventions aimed at slowing progression. Clinical evaluation is focused on identifying vascular risk factors (hypertension, diabetes mellitus, dyslipidemia, tobacco use, atrial fibrillation, coronary artery disease, or peripheral vascular disease), history of prior symptoms of stroke or transient ischemic attack, and family history of early stroke or vascular disease. Although stepwise progression and certain cognitive deficits such as loss of executive function are particularly suggestive, most individuals with VCID follow the more typical pattern of gradual progression of impaired episodic memory.

The mainstay for detection and subtyping of cerebrovascular disease is brain MRI. The MRI should include FLAIR, diffusion-weighed, and T2*-weighted sequences to detect the range of lesions noted above: large and small chronic infarcts, acute microinfarcts, microbleeds, and white matter hyperintensities. Vessel imaging studies such as computed tomography or magnetic resonance angiography are not required for initial evaluation of cognitive impairment, though they may be useful for determining the cause of any macroscopic infarcts that are identified. Genetic testing for rare hereditary forms of VCID such as cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy (CADASIL) **(Chap. 438)** or hereditary cerebral amyloid angiopathy can be considered for cases in which there is a particularly young onset, positive family history, or suggestive neuroimaging, but is otherwise unnecessary.

TREATMENT

Vascular Dementia

Very few trials have addressed the optimal treatment for individuals with asymptomatic large- or small-vessel cerebrovascular disease, leaving uncertainty as to whether to follow primary or secondary stroke prevention guidelines. At a minimum, treatment should assiduously follow primary stroke prevention guidelines. The American Heart Association recommends the prudent approach for vascular health of managing blood pressure, controlling cholesterol, reducing blood sugar, maintaining an active lifestyle, adhering to a heart-healthy diet, losing weight, discontinuing tobacco, and getting healthy sleep (Life's Essential 8, *https://www.heart.org/en/healthy-living/healthy-lifestyle/lifes-essential-8*). Blood pressure targets are <140/90 mmHg for all individuals and <130/80 mmHg for those with estimated 10-year cardiovascular disease risk ≥10%, which likely applies to many individuals with imaging evidence of asymptomatic brain infarcts or advanced small-vessel disease. The usefulness of other treatments for secondary stroke prevention such as antiplatelet or statin therapy has not been established for asymptomatic infarcts. These agents are reasonable to consider, however, when the imaging appearance suggests embolic or large-vessel-related strokes. All individuals with asymptomatic infarcts should be screened for atrial fibrillation, and those with embolic-appearing infarcts can be considered for prolonged cardiac monitoring. Similarly, patients with infarcts in the territories of large arteries should be considered for vascular imaging.

The few trials of symptomatic medications for cognitive impairment due to vascular etiologies have suggested modest cognitive benefits comparable to those found in Alzheimer's disease patients. Therefore, it may be reasonable in VCID to consider agents such as the cholinesterase inhibitors donepezil, rivastigmine, or galantamine for mild to moderate cognitive impairment and high-dose donepezil or the *N*-methyl-D-aspartate receptor antagonist memantine for moderate to severe impairment **(Chap. 442)**. A shared decision-making approach in considering these medications is useful, given their relatively small impact on daily function.

445 Dementia with Lewy Bodies

Irene Litvan, William W. Seeley, Bruce L. Miller

Lewy body disease (LBD), manifesting as Parkinson's disease dementia (PDD) or dementia with Lewy bodies (DLB), is the second most common cause of neurodegenerative dementia, after Alzheimer's disease (AD) **(Chap. 442)**. Approximately 10% of patients with Parkinson's disease (PD) develop PDD per year, with the majority of PD patients developing PDD over time. The incidence of DLB is ~7 per 100,000 person-years. The prevalence of both PDD and DLB increases with aging, and both affect men more often than women. The development of increasingly useful biomarkers for PD and DLB is making possible new operational definitions, classifications, and staging for these disorders, and these are likely to continue to evolve over time.

CLINICAL MANIFESTATIONS

Most investigators conceptualize PDD and DLB as points on a spectrum of LBD pathology. Cognitively, PDD and DLB usually manifest with severe executive, attentional, and visuospatial deficits but preserved episodic memory. Cognitive decline in LBD affects performance of daily living activities beyond other PD symptoms. Early psychosis including well-formed visual hallucinations, fluctuating cognition, rapid eye movement sleep behavior disorder (RBD), and parkinsonism are the main diagnostic features in DLB. The sense of a presence behind the person may precede well-formed hallucinations. Delusions

are less frequent than hallucinations and are usually related to misidentification, infidelity, theft, or persecution. Fluctuating attention and concentration are other characteristic features. Minor day-to-day variation in cognitive functioning is common across dementias, but in DLB, these fluctuations can be marked, with short periods of confusion or severe lethargy that may rapidly resolve. Patients with PDD and DLB are highly sensitive to infectious or metabolic disturbances. The first manifestation of DLB in some patients is delirium, often precipitated by an infection, new medicine, or other systemic disturbance. Parkinsonism in DLB is usually associated with early postural instability and can present early or later in the course. RBD is a characteristic, often prodromal, feature. Normally, dreaming is accompanied by skeletal muscle paralysis, but patients with RBD enact dreams, often violently, leading to injuries to themselves or their bed partners. Both PDD and DLB may be accompanied or preceded by anosmia, constipation, RBD, depression, and anxiety.

The symptom profile in DLB and PDD can provide clues for the differential diagnosis at the clinic. Clinically, the time interval between parkinsonism and dementia differentiates PDD and DLB. PDD presents in patients with long-standing PD, who manifest dementia often with visual hallucinations, fluctuating attention or alertness, and RBD. On the other hand, when the dementia and the neuropsychiatric symptoms precede or co-emerge with the parkinsonism, the patient is diagnosed with DLB. Patients with DLB, more frequently than those with PDD, also have AD co-pathology, making the prediction of underlying pathology challenging for clinicians. Episodic memory disturbance points to the diagnosis of comorbid AD. Orthostatic hypotension that can lead to syncopal events, erectile dysfunction, and constipation can be present early in DLB, at times making it challenging to differentiate DLB from multiple system atrophy (MSA). In MSA, the autonomic disturbances occur early and are usually more severe than in DLB, and cognition is relatively preserved. Anosmia is also more characteristic of LBD than MSA. Skin biopsy and serum with biomarkers for α-synuclein oligomers, a major component of Lewy bodies, have shown potential for differentiating PD from MSA, and if validated for clinical use, this type of test may also differentiate DLB or PDD from MSA in the future.

PRODROMAL PHASE

Both DLB and PDD have a prodromal phase where patients have a mild cognitive impairment (MCI), with cognitive deficits that do not have a substantial impact on daily life. PD-MCI is characterized by deficits in executive, attention, and visuospatial disturbances, but can also present with an amnestic or multiple-domain MCI. Prodromal DLB is characterized by similar cognitive disturbances but is also associated with either hallucinations unrelated to medications, RBD, fluctuations in attention, or parkinsonism. It is at times challenging to differentiate prodromal MCI-DLB and PD-MCI when the major features are RBD and parkinsonism, for which the term *prodromal MCI–Lewy body* (MCI-LB) was recently proposed. RBD may precede the development of an LBD-related syndrome by many years, usually evolving into either PD or DLB. The clinical profile and several biomarkers can help differentiate MCI due to LBD versus AD pathology **(Table 445-1)**.

TABLE 445-1 Distinguishing MCI Due to Lewy Body Disease or Alzheimer's Disease

CLINICAL FEATURES	PRODROMAL MCI-LB PATHOLOGY	PRODROMAL MCI-AD PATHOLOGY
MCI	MCI usually affecting executive, attention, and/or visuospatial functions	MCI with impaired memory and semantic naming
Fluctuating cognition with variations in attention	Frequent and severe	Rare or not severe
Sleep	REM sleep behavior disorder	Insomnia, frequent awakenings
Recurrent visual hallucinations	Frequent	Rare
Biomarkers		
Polysomnogram	REM sleep behavior disorder without atonia	Normal
CSF	Decreased CSF α-synuclein by RT-QuIC	Decreased CSF β-amyloid and increased phospho-tau. This can now be performed in blood.
MRI	Atrophy of the amygdala	Atrophy of the parahippocampal/ hippocampal areas
^{18}F-deoxyglucose PET scan	Hypometabolism in occipital lobe and increased in posterior cingulate (cingulate island sign)	Hypometabolism in parietotemporal lobes
Amyloid PET scan	Normal, unless associated with AD	Abnormal parietotemporal areas
MIBG myocardial scintigraphy	Postganglionic sympathetic denervation	Normal
DAT scan or PET dopamine scan	Reduced dopamine transporter in the basal ganglia, particularly putamen	Normal

Abbreviations: AD, Alzheimer's disease; CSF, cerebrospinal fluid; DAT, dopamine transporter; LB, Lewy bodies; MCI, mild cognitive impairment; MIBG, meta-iodobenzylguanidine; MRI, magnetic resonance imaging; PET, positron emission tomography; REM, rapid eye movement; RT-QuIC, real-time quaking-induced conversion.

PATHOLOGY

The key neuropathologic feature in LBD is the presence of Lewy bodies and Lewy neurites throughout specific brainstem nuclei, substantia nigra, amygdala, cingulate gyrus, and, ultimately, the neocortex. Lewy bodies are intraneuronal cytoplasmic inclusions that stain with periodic acid–Schiff (PAS) and ubiquitin but are now identified with antibodies to the presynaptic protein α-synuclein. Lewy bodies are composed of straight neurofilaments 7–20 nm long with surrounding amorphous material and contain epitopes recognized by antibodies against phosphorylated and nonphosphorylated neurofilament proteins, ubiquitin, and α-synuclein. The presence of α-synuclein aggregates in neurons and glia in PDD and DLB molecularly classifies these diseases as synucleinopathies. In general, neuronal and synaptic loss, rather than Lewy pathology per se, best predicts the clinical deficits.

Formal criteria identify three stages of progression: (1) brainstem predominant; (2) transitional limbic; and (3) diffuse neocortical. Importantly, healthy older individuals may also show isolated scattered Lewy body pathology in the substantia nigra, amygdala, or olfactory bulb. Pathologic studies have shown that PD usually starts in the enteric nervous system and spreads through the vagus nerve to the heart, lower brainstem, substantia nigra, limbic system, and lastly the cerebral cortex. PD may also begin in the olfactory bulb and spread through olfactory system connections or start independently in enteric and olfactory bulb areas. Evidence from human anatomic pathology and animal models suggests that LBD may similarly propagate via a prion-like mechanism. Abnormally folded α-synuclein aggregates propagate transneuronally following connection pathways of the nervous system. This pathologic propagation from the periphery to the brain correlates with the evolution of clinical symptoms; PD usually manifests first with nonmotor features characterized by constipation and/or hyposmia, followed by anxiety, depression, RBD, parkinsonism, and lastly dementia. PDD is manifested clinically when limbic and cortical areas are involved.

A profound cholinergic deficit, owing to basal forebrain and pedunculopontine nucleus involvement, is present in most patients with DLB and may be associated with the characteristic fluctuations, inattention, and visual hallucinations. Adrenergic deficits from locus coeruleus involvement further undermine arousal and alerting.

PATHOGENESIS

Both genes and environmental factors are thought to contribute to the development of LBD. The presence of α-synuclein aggregates in Lewy bodies led to the discovery of α-synuclein duplications and

triplications that manifest clinically as PD or DLB. There are multiple genes associated with PD, but mutations of glucocerebrosidase (GBA) particularly lead to PDD or DLB presentations **(Chap. 446)**.

The origins of LBD in gastrointestinal and olfactory areas suggest that environmental toxins acting on a susceptible genetic background may contribute to LBD pathogenesis (a "double-hit" hypothesis). Several toxins have been associated with PD **(Chap. 446)**, but epidemiologic studies of risk factors in DLB remain inconclusive.

LABORATORY FEATURES

In patients presenting with cognitive disturbances, it is always necessary to rule out treatable causes of dementia such as drugs, infections, or metabolic disturbances **(Chap. 31)**. Magnetic resonance imaging (MRI) of the brain can be helpful to rule out vascular parkinsonism or subdural hematomas, or support the diagnosis of other disorders such as MSA (i.e., pontine "hot-cross buns" sign; see **Fig. 451-6**).

The biomarkers that can help diagnose LBD include the following: a polysomnogram showing RBD without atonia, seed amplification assays (SAAs) to detect αSyn in cerebrospinal fluid (CSF), demonstrating skin deposition of α-synuclein, iodine-123-meta-iodobenzylguanidine (MIBG) cardiac scintigraphy showing cardiac postganglionic sympathetic denervation, and dopamine transporter imaging using single-photon emission computed tomography (SPECT) or positron emission tomography (PET) or, if associated with AD, increased CSF or blood levels of phospho-tau217 or phospho-tau181 (Table 445-1).

TREATMENT

Dementia with Lewy Bodies

Although there are currently no disease-modifying agents to prevent, slow, or cure LBD-related dementias, several symptomatic treatments are available. By addressing the substantial cholinergic deficit in DLB, cholinesterase inhibitors such as rivastigmine (target dose 6 mg twice daily or 9.5 mg patch daily) or donepezil (target dose 10 mg daily) often improve cognition, reduce hallucinosis, and stabilize delusional symptoms. The atypical antipsychotic pimavanserin is frequently helpful to treat the psychosis and does not worsen parkinsonism; it is approved by the U.S. Food and Drug Administration (FDA) for patients with PDD and is often used off-label for DLB. Pimavanserin (34 mg daily) is a selective inverse agonist of the serotonin 5-HT_{2A} receptor that does not block dopamine receptors but carries an FDA warning regarding an increase in risk of death, especially in older patients. Low-dose clozapine (begin at 6.25 mg, increasing up to 25 mg, daily) is also effective for treating hallucinations and delusions, but requires frequent blood draws due to the risk of agranulocytosis. Patients with LBD are sensitive to dopaminergic medications, which must be carefully titrated; tolerability may be improved with concomitant use of a cholinesterase inhibitor. Patients with DLB should not be exposed to typical neuroleptics, which can lead to a neuroleptic malignant syndrome and death, or anticholinergics or dopamine agonists that can exacerbate their symptoms.

RBD usually responds to melatonin, requiring at times 20 mg/d. If melatonin is not effective, clonazepam, gabapentin, or codeine can be used with caution due to the possibility of worsening cognition or falls. Antidepressants, especially those with strong anxiolytic properties (escitalopram, paroxetine, duloxetine, or venlafaxine; see **Chap. 463**), are often necessary for mood and anxiety symptoms. Orthostatic hypotension may require treatment with nonpharmacologic measures (diet high in salt and liquids, a 30° elevation of the head of the bed) or pharmacologic therapies (i.e., fludrocortisone, midodrine, droxidopa). Physical therapy can maximize motor function and protect against fall-related injury. Home safety assessments and transfer instruction should also be provided. Education for patients and caregivers and social worker support are also important. Therefore, the care of patients with LBD requires a multidisciplinary approach.

An experimental treatment that aims to slow down the progression of the disease is neflamapimod, which targets the synapse and showed promising results in initial phase 2a studies, findings that await confirmation.

The majority of caregivers for individuals with DLB are women, often spouses, who frequently experience high levels of burden and depression. The severity of behavioral symptoms, sleep disturbances, and autonomic symptoms in the person with DLB is associated with higher caregiver burden, leading to a poorer quality of life for the caregiver. The most commonly reported caregiver concerns include the inability to plan for the future, prioritizing the needs of the person with DLB over their own, and worry about the person with DLB becoming too dependent on the caregiver, among others. Overall, caregivers expressed satisfaction with the support provided by the medical team, but they reported the lowest satisfaction with information about disease progression and the sharing of information among medical team members. Clinicians can address caregiver needs by providing support resources, educating caregivers about DLB, and developing management strategies for the range of troubling symptoms experienced by patients.

446 Parkinson's Disease

C. Warren Olanow*, Anthony H. V. Schapira, Christine Klein

PARKINSON'S DISEASE AND RELATED DISORDERS

Parkinson's disease (PD) is the second most common age-related neurodegenerative disease, exceeded only by Alzheimer's disease (AD). Its cardinal clinical features were first described by the English physician James Parkinson in 1817. James Parkinson was a general physician who captured the essence of this condition based on a visual inspection

*Deceased.

of a mere handful of patients, several of whom he only observed walking on the street and did not formally examine. It is estimated that the number of people with PD worldwide is ~10.8 million, and this number is expected to double within 20 years based on the aging of the population. The mean age of onset of PD is about 60 years, and the lifetime risk is ~3% for men and 2% for women. The frequency of PD increases with age, but cases can be seen in individuals in their twenties and even younger, particularly when associated with a pathogenic gene mutation.

Clinically, PD is characterized by bradykinesia (slowing), rest tremor, rigidity (stiffness), and gait dysfunction with postural instability. These are known as the classical or "cardinal" features of PD. Additional clinical features can include freezing of gait, speech difficulty, swallowing impairment, and a series of nonmotor features that include autonomic disturbances, sensory alterations, mood disorders, sleep disorders, and cognitive impairment/dementia (see **Table 446-1** and discussion below).

Pathologically, the hallmark features of PD are degeneration of dopaminergic neurons in the substantia nigra pars compacta (SNc), reduced striatal dopamine, and intraneuronal proteinaceous inclusions in cell bodies and axons that stain for α-synuclein (known as Lewy bodies and Lewy neurites; collectively as Lewy pathology) **(Fig. 446-1)**. While interest has focused on the dopamine system, neuronal degeneration with Lewy pathology can also affect cholinergic neurons of the nucleus basalis of Meynert (NBM), norepinephrine neurons of the locus coeruleus (LC), serotonin neurons in the raphe nuclei of the brainstem, and neurons of the olfactory system, cerebral hemispheres, spinal cord, and peripheral autonomic nervous system. This "nondopaminergic" pathology is likely responsible for the nonmotor clinical features listed above and in Table 446-1. It has been postulated that in some cases Lewy pathology can begin in the peripheral autonomic nervous system, gastrointestinal (GI) tract, olfactory system, or dorsal motor nucleus of the vagus nerve and then spread in a predictable and sequential manner to affect the SNc and cerebral hemispheres (Braak staging). These studies suggest that the classic degeneration of SNc dopamine neurons and the cardinal motor features of PD may develop at a mid-stage of the illness. Indeed, epidemiologic

TABLE 446-1 Clinical Features of Parkinson's Disease

CARDINAL MOTOR FEATURES	OTHER MOTOR FEATURES	NONMOTOR FEATURES
Bradykinesia	Micrographia	Anosmia
Rest tremor	Masked facies (hypomimia)	Sensory disturbances (e.g., pain, hyposmia)
Rigidity	Reduced eye blinking	Mood disorders (e.g., depression, anxiety, apathy)
Postural instability	Drooling	Sleep disturbances (e.g., fragmented sleep, RBD)
	Soft voice (hypophonia)	Autonomic disturbances
	Dysphagia	Orthostatic hypotension
	Freezing	Gastrointestinal disturbances
	Falling	Genitourinal disturbances
		Sexual dysfunction
		Cognitive impairment/dementia

Abbreviation: RBD, rapid eye movement sleep behavior disorder.

TABLE 446-2 Differential Diagnosis of Parkinsonism

Parkinson's disease	Atypical parkinsonism	Secondary parkinsonism	Other neurodegenerative disorders associated with parkinsonism
Sporadic	Multiple-system atrophy (MSA)	Drug-induced	Wilson's disease
Genetic	Cerebellar type (MSA-c)	Tumor	Huntington's disease
PD with dementia/dementia with Lewy bodies	Parkinson type (MSA-p)	Infection	Neurodegeneration with brain iron accumulation
	Progressive supranuclear palsy	Vascular	SCA 3 (spinocerebellar ataxia)
	Parkinsonian variant	Normal-pressure hydrocephalus	Fragile X–associated ataxia-tremor-parkinsonism
	Richardson variant	Trauma	Prion diseases
	Corticobasal syndrome	Liver failure	X-linked dystonia-parkinsonism
		Toxins (e.g., carbon monoxide, manganese, MPTP, cyanide, hexane, methanol, carbon disulfide)	Alzheimer's disease with parkinsonism
			Dopa-responsive dystonia

Abbreviation: MPTP, 1-methyl-4-phenyl-1,2,5,6-tetrahydropyridine.

studies suggest that clinical symptoms reflecting early involvement of nondopaminergic neurons such as constipation, anosmia, rapid eye movement (REM) behavior sleep disorder, and cardiac denervation can precede the onset of the classic motor features of PD by several years if not decades. Originally it was considered that these represent risk factors for developing PD, but based on pathological findings, it is now considered likely that they represent an early premotor form of the disease. These observations have led to the notion of "body-first" and "brain-first" forms of PD based on whether pathology initially develops in the brain or periphery. Efforts are underway to accurately define the premotor stage of PD with high sensitivity and specificity. This will be of particular importance when a neuroprotective therapy becomes available as it will be desirable to initiate a disease-modifying treatment at the earliest stage of the disease possible.

Recently, two new classifications have been developed aimed at defining the early stages of PD based on biological research criteria. The first stages PD based on neuronal α-synuclein accumulation. The second takes into account α-synuclein deposition, but also the distribution of neurodegeneration and pathogenic variants in known PD-causative genes.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Parkinsonism is a term that is used to define a syndrome manifest by bradykinesia with rigidity and/or tremor. The differential diagnosis includes PD, atypical parkinsonisms such as *multiple-system atrophy* (MSA) and *progressive supranuclear palsy* (PSP), secondary parkinsonism, and parkinsonism associated with other neurodegenerative conditions in which parkinsonian features are present (see **Table 446-2** and discussion below). These conditions affect the basal ganglia, a group of subcortical nuclei that include the striatum (putamen and caudate nucleus), subthalamic nucleus (STN), globus pallidus pars externa (GPe), globus pallidus pars interna (GPi), and the SNc **(Fig. 446-2)**. They differ, however, in the precise site of involvement within the basal ganglia, the specific pathologic characteristics, and the clinical picture. Among the different forms of parkinsonism, PD is the most common (~75% of cases). Historically, PD was diagnosed based on the presence of two of three parkinsonian features (tremor, rigidity, bradykinesia). However, postmortem studies found a 24% error rate when diagnosis was based solely on these criteria. Clinicopathologic correlation studies subsequently determined that parkinsonism (bradykinesia and rigidity) associated with rest tremor, asymmetry of motor impairment, and a good response to levodopa is much more likely to predict the correct pathologic diagnosis. With these revised criteria (known as the U.K. Brain Bank Criteria), a clinical diagnosis of PD could be confirmed pathologically in >90% of patients. Imaging of the dopamine system and new biomarkers (see below) further increase diagnostic accuracy. The International Parkinson's Disease and Movement Disorder Society (MDS) has proposed revised clinical criteria for PD (known as the MDS Clinical Diagnostic Criteria for Parkinson's disease), which are thought to increase diagnostic accuracy even further, particularly in early cases where levodopa has not yet been introduced. While motor parkinsonism has been retained as the core feature of the disease, in these criteria, the specific diagnosis of PD relies on three additional categories of diagnostic features: supportive criteria (features that increase confidence in the diagnosis of PD), absolute exclusion criteria, and red flags (which must be counterbalanced by supportive criteria to permit a diagnosis of PD). Utilizing these criteria, two levels of certainty have been delineated: clinically established PD and clinically probable PD (see Berg et al. in "Further Reading").

Imaging of the brain dopamine system can be helpful in diagnosing PD and is performed using positron emission tomography (PET) or single-photon emission computed tomography (SPECT). These studies typically show reduced and asymmetric uptake in the striatum, particularly in the posterior putamen with relative sparing of the caudate nucleus **(Fig. 446-3)**. These findings reflect the degeneration

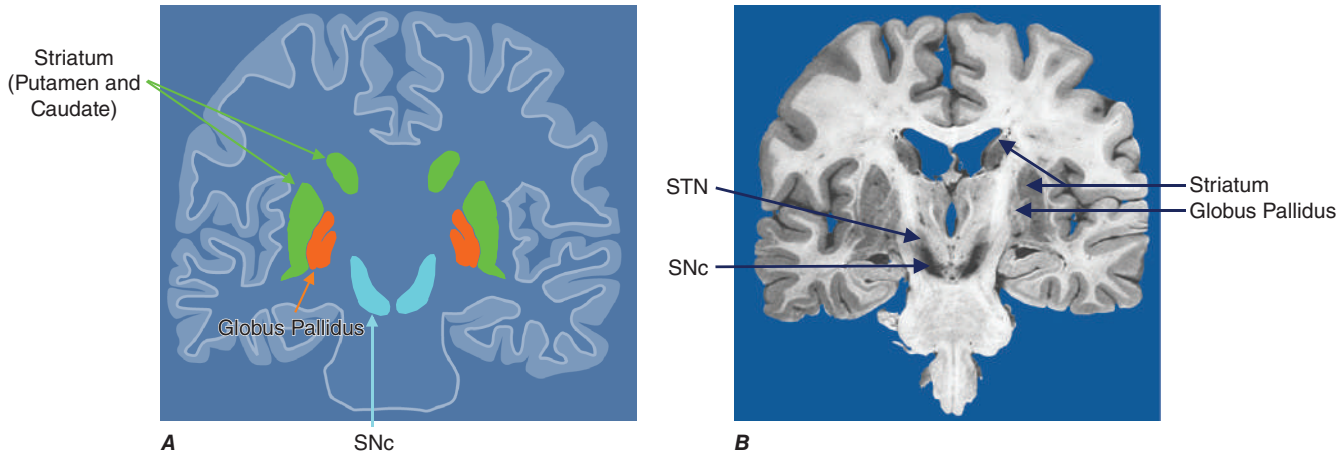

FIGURE 446-2 Basal ganglia nuclei. Schematic (***A***) and postmortem (***B***) coronal sections illustrating the various components of the basal ganglia. SNc, substantia nigra pars compacta; STN, subthalamic nucleus.

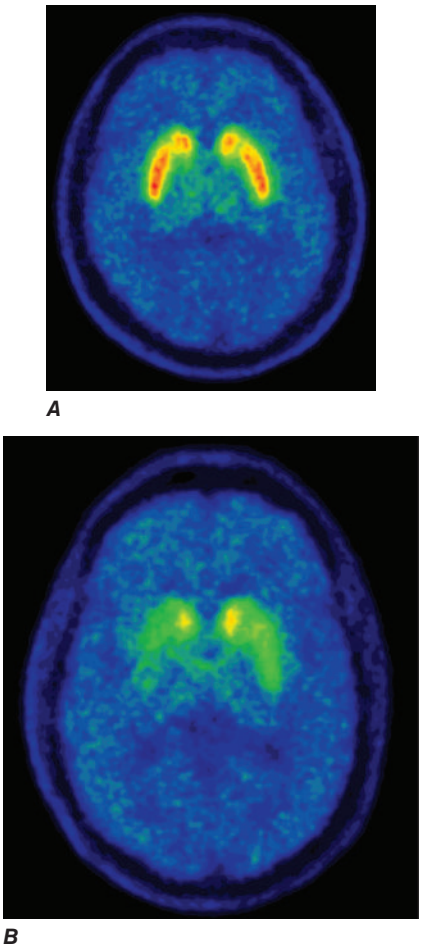

FIGURE 446-3 [^{11}C]Dihydrotetrabenazine positron emission tomography (a marker of VMAT2) in healthy control (*A*) and Parkinson's disease (*B*) patient. Note the reduced striatal uptake of tracer, which is most pronounced in the posterior putamen and tends to be asymmetric. *(Courtesy of Dr. Jon Stoessl.)*

of nigrostriatal dopaminergic neurons and the loss of their striatal terminals. Imaging is useful in patients where there is diagnostic uncertainty (e.g., early-stage disease, essential tremor, dystonic tremor, psychogenic tremor) or in research studies in order to ensure diagnostic accuracy, but it is not routinely required in clinical practice. This may change in the future when a disease-modifying therapy becomes available and it becomes critically important to make a correct diagnosis as early as possible. There is also some evidence suggesting that a diagnosis of PD, and even prodromal PD, may be made based on the presence of increased iron in the SNc using transcranial sonography or special magnetic resonance imaging (MRI) protocols. There have been intensive efforts to image α-synuclein in the brain but, in contrast to beta-amyloid or tau imaging in Alzheimer's disease, this has proven difficult as most of the abnormal α-synuclein protein is located within cells. This makes it difficult to develop a marker that binds to α-synuclein and that can be detected with imaging.

There has been a longstanding interest in developing a biomarker for PD that could aid in diagnosis, differentiate PD from other parkinsonian conditions, potentially assess the effects of a putative disease-modifying therapy, and be used as an endpoint in clinical trials. Considerable interest has focused on detecting abnormal α-synuclein deposits in cerebrospinal fluid (CSF), blood, muscle, and other tissues, but results to date have been inconsistent. The development of the α-synuclein seeding amplification assay (SAA) has provided a novel means to support a clinical diagnosis of PD. The SAA was developed for use on CSF and skin and provides a binary result indicating the presence or absence of endogenous α-synuclein sufficient to result in aggregation upon addition of α-synuclein "seeds." This assay has very high sensitivity and specificity and is able to distinguish PD from other parkinsonisms. At present, the test has been primarily applied in a research setting, but the development of a blood-based assay may extend its use into a clinical role. This assay also has the potential to permit diagnosis in early-stage and even prodromal PD.

Genetic testing can be helpful for establishing a diagnosis but is not routinely employed as monogenic forms of PD are relatively uncommon and account for only 5% of cases, although this increases to 15% when pathogenic variants in the strongest known risk gene, *glucocerebrosidase* (*GBA1*), are included (see discussion below), and this number may increase as more knowledge is acquired. A genetic form of PD should be considered in patients with a strong positive family history, early age of onset (<40 years), and a particular ethnic background (see below), and in research studies. Genetic variants of *GBA1* are the most common genetic association with PD. They are present in ~10% of PD patients and in 25% of Ashkenazi PD patients. However, only ~20–30% of people with *GBA1* variants will develop PD, and PD risk is correlated with the severity of the variant effect. Pathogenic variants in the *LRRK2* gene have also attracted particular interest as they are responsible for ~3% of typical sporadic cases of the disease. *LRRK2* mutations are a particularly common cause of PD (~25%) in Ashkenazi Jews and North African Berber Arabs; however, there is considerable variability in penetrance, and ~40–50% of carriers never develop clinical features of PD. Interestingly, some PD cases associated with *LRRK2* mutations and other genetic causes have been described without Lewy bodies. Genetic testing is of particular interest for identifying at-risk individuals in a research setting and for defining enriched populations for clinical trials of therapies directed at a pathogenic mutation or pathway.

Atypical, Secondary, and Other Forms of Parkinsonism

Atypical parkinsonism refers to a group of neurodegenerative conditions that are usually associated with more widespread pathology than found in PD (e.g., degeneration potentially involving the striatum, globus pallidus, cerebellum, and brainstem as well as the SNc). These conditions include MSA **(Chap. 451)**, PSP **(Chap. 443)**, and *corticobasal syndrome* (CBS) **(Chap. 443)**. As a group, they tend to present with parkinsonism (rigidity and bradykinesia) but manifest clinical differences from PD, reflecting their different pathologies. Clinical features that typically differ from classical PD include early involvement of speech and gait, absence of rest tremor, lack of motor asymmetry, poor or no response to levodopa, and a more aggressive clinical course. They can be difficult to distinguish from PD in the early stages where levodopa has not yet been tried and in some cases that show a modest benefit from levodopa, but the diagnosis usually becomes clear as the disease evolves over time.

Neuroimaging of the dopamine system is usually not helpful, as striatal dopamine depletion can be seen in both PD and atypical parkinsonism. By contrast, metabolic imaging of the basal ganglia/thalamus network (using 2-F-deoxyglucose) may be helpful, showing a pattern of decreased activity in the GPi with increased activity in the thalamus, the reverse of what is seen in PD.

MSA manifests as a combination of the atypical parkinsonian features described above, as well as varying degrees of cerebellar and autonomic features. Clinical syndromes can be divided into a predominantly parkinsonian (MSA-p), cerebellar (MSA-c), and more rarely, a primary autonomic form. Clinically, MSA is suspected when a patient has features of atypical parkinsonism in conjunction with cerebellar signs and/or prominent autonomic dysfunction, usually orthostatic hypotension and a poor or absent response to levodopa **(Chap. 451)**. The use of biomarkers (e.g., SAA) has increased the accuracy of diagnosis in the early stages of the disease, and the rate of progression is typically more aggressive than in classic PD. Pathologically, MSA is characterized by degeneration of the SNc, striatum, cerebellum, and inferior olivary nuclei coupled with characteristic glial cytoplasmic inclusions (GCIs) that stain positively for α-synuclein aggregates (Lewy bodies), which accumulate in oligodendrocytes rather than in SNc neurons as in PD. MRI can show pathologic iron accumulation in the striatum on T2-weighted scans, high signal change in the region of the external surface of the putamen (putaminal rim) in MSA-p, or cerebellar and brainstem atrophy (the pontine "hot cross bun" sign **[Fig. 451-6]**) in MSA-c. There is currently no established evidence

for any gene mutation or genetic risk factor for MSA, and no specific treatment exists.

PSP is characterized by the features noted above coupled with slow ocular saccades, eyelid apraxia, and restricted vertical eye movements with impairment of downward gaze. Patients frequently experience hyperextension of the neck with early gait disturbance and falls. In later stages, speech and swallowing difficulty and cognitive impairment may become evident. Two clinical forms of PSP have been identified: a "Parkinson" form that can closely resembles PD in the early stages and can include a positive response to levodopa, and the more classic "Richardson" form that is characterized by the features described above with little or no response to levodopa. MRI may reveal a characteristic atrophy of the midbrain with relative preservation of the pons on midsagittal images (the so-called "hummingbird sign"). Pathologically, PSP is characterized by degeneration of the SNc, striatum, STN, midline thalamic nuclei, and pallidum, coupled with neurofibrillary tangles and inclusions that stain for the tau protein. Mutations in the *MAPT* gene encoding the tau protein have been detected in some familial cases.

CBS is a relatively uncommon condition that usually presents with asymmetric dystonic contractions, and clumsiness of one hand coupled with cortical sensory disturbances manifest as apraxia, agnosia, focal limb myoclonus, or alien limb phenomenon (where the limb assumes a position in space without the patient being aware of its location or recognizing that the limb belongs to them). Dementia may occur at any stage of the disease. Both cortical and basal ganglia features are required to make this diagnosis. MRI frequently shows asymmetric cortical atrophy, but this must be carefully sought and may not be obvious on casual inspection. Pathologic findings include achromatic neuronal degeneration with tau deposits. Considerable overlap may occur both clinically and pathologically between CBS and PSP, and they may be difficult to distinguish without pathologic confirmation.

Secondary parkinsonisms occur as a consequence of other etiologic factors such as drugs, stroke, tumor, infection, or toxins (e.g., carbon monoxide, manganese) that cause basal ganglia dysfunction. Clinical features reflect the region of the basal ganglia that has been damaged. For example, strokes or tumors that affect the SNc may have a clinical picture that is very similar to PD, whereas toxins such as carbon monoxide or manganese that damage the globus pallidus more closely resemble atypical parkinsonism and have a poor response to levodopa. Dopamine-blocking agents such as neuroleptics are the most common cause of secondary parkinsonism. These drugs are most widely used in psychiatry, but physicians should be aware that drugs such as metoclopramide, which are primarily used to treat GI problems, are also neuroleptic *agents* and may induce secondary parkinsonism. These drugs can also cause acute and tardive dyskinesias **(see Chap. 447)**. Other drugs that can cause secondary parkinsonism include tetrabenazine, calcium channel blockers (flunarizine, cinnarizine), amiodarone, and lithium.

Parkinsonism can also be seen as a feature of *dopa-responsive dystonia* (DRD), a condition that typically results from pathogenic variants in the *GTP-cyclohydrolase 1* gene, which lead to a defect in a cofactor for tyrosine hydroxylase with impairment in the manufacture of dopa and dopamine. While it typically presents as dystonia **(Chap. 447)**, it can present as a biochemically based form of parkinsonism (due to reduced synthesis of dopamine) closely resembling PD. DRD patients respond to levodopa, but abnormalities on fluorodopa PET (FD-PET) are typically not seen, nor are drug-induced dyskinesias, reflecting a biochemical abnormality without degeneration of the underlying anatomic structures. DRD should be considered in individuals aged <20 years who present with parkinsonism, particularly if there are dystonic features.

Finally, parkinsonism can be seen as a feature of a variety of other neurodegenerative disorders such as Wilson's disease **(Chaps. 427 and 447)**, Huntington's disease (especially the juvenile form known as the Westphal variant) **(Chap. 447)**, certain spinocerebellar ataxias **(Chap. 450)**, and neurodegenerative disorders with brain iron accumulation such as pantothenate kinase (PANK)–associated neurodegeneration (formerly known as Hallervorden-Spatz disease). It is particularly important to rule out Wilson's disease, as progression can be prevented with the use of copper chelators.

TABLE 446-3 Features Suggesting an Atypical or Secondary Cause of Parkinsonism

SYMPTOMS/SIGNS	ALTERNATIVE DIAGNOSIS TO CONSIDER
History	
Early speech and gait impairment (lack of tremor, lack of motor asymmetry, early falls)	Atypical parkinsonism
Exposure to neuroleptics	Drug-induced parkinsonism
Onset prior to age 40 years	Genetic form of PD, Wilson's disease, DRD
Liver disease	Wilson's disease, non-Wilsonian hepatolenticular degeneration
Hallucinations and dementia which precede the development of PD features	Dementia with Lewy bodies
Diplopia, impaired vertical gaze	PSP
Poor or no response to an adequate trial of levodopa	Atypical or secondary parkinsonism
Physical Examination	
Dementia as first or early feature	Dementia with Lewy bodies
Prominent orthostatic hypotension	MSA
Prominent cerebellar signs	MSA-c
Slow saccades with impaired downgaze	PSP
High-frequency (6–10 Hz) symmetric postural tremor with a prominent kinetic component	Essential tremor

Abbreviations: DRD, dopa-responsive dystonia; MSA-c, multiple-system atrophy–cerebellar type; MSA-p, multiple-system atrophy–Parkinson's type; PD, Parkinson's disease; PSP, progressive supranuclear palsy.

Some features that suggest that parkinsonism might be due to a condition other than classic PD are shown in **Table 446-3**.

ETIOLOGY AND PATHOGENESIS

Most PD cases occur sporadically and are of unknown cause. Gene mutations (see below) are the only known causes of PD and may be found even in seemingly sporadic cases. Twin studies performed several decades ago suggested that environmental factors may play an important role in patients with an age of onset ≥50 years, with genetic factors being more important in younger-onset patients. However, the demonstration of genetic variants (e.g., *LRRK2* and *GBA1*) causing later onset PD shows that certain monogenic forms can manifest as late as in the eighth or ninth decade. With the advent of new sequencing technologies (long-read sequencing), numerous monogenic causes of late-onset neurodegenerative diseases have recently been identified, such as intronic repeat expansions in the *FGF14* gene causing late-onset ataxia **(Chap. 450)**, and it is conceivable that additional monogenic forms of PD will also be identified with this technology. In addition, it is likely that genetic factors could modify age at onset and severity of both genetic and nongenetic forms of PD.

The environmental hypothesis received some support in the 1980s with the demonstration that MPTP (1-methyl-4-phenyl-1,2,5,6-tetrahydropyridine), a by-product of the illicit manufacture of a heroin-like drug, caused a PD syndrome in addicts in northern California. MPTP is transported into the central nervous system, where it is oxidized to form MPP^+, a mitochondrial toxin that is selectively taken up by, and damages, dopamine neurons, but typically without the formation of Lewy bodies. Importantly, MPTP or MPTP-like compounds have not been linked to sporadic PD. Epidemiologic studies have reported an increased risk of developing PD in association with exposure to pesticides, solvents, rural living, farming, and drinking well water, but study results have been inconsistent. Additionally, dozens of other associations have also been reported in individual studies. To date, no environmental factor has yet been proven to be a cause of PD. Some possible protective factors have also been identified in epidemiologic studies, including caffeine, cigarette smoking, intake of nonsteroidal anti-inflammatory drugs, and calcium channel blockers.

The validity of these findings and the responsible mechanism remain to be established.

Large studies show that about 15% of PD cases are familial in origin, and mutations in several PD-linked genes have been identified (Table 446-4). While uncommon pathogenic variants in PD genes (i.e., mutations) have been shown to be causative of PD or to contribute to PD risk, a plethora of common genetic variants—alone or in combination as part of polygenic risk scores—are associated with an increased risk of developing PD. These include variants in the *SNCA, LRRK2, MAPT*, and *GBA1* genes and may be ethnicity-specific, such as a strong risk variant confined to the African or African-admixed population. It has been proposed that many cases of PD may be due to a "double hit" involving an interaction between (1) one or more genetic risk factors that induce susceptibility and (2) exposure to a toxic environmental factor that may induce epigenetic or somatic DNA alterations or has the potential to directly damage the dopaminergic system. In this scenario, two factors (or more) are required for PD to ensue, while the presence of either one alone is not sufficient to cause the disease. While the "double-hit" hypothesis is of interest, there is no direct evidence for its support at this time. Furthermore, even if a genetic or environmental risk factor doubles the risk of developing PD, this only results in a lifetime risk of 4–6% or lower, and thus cannot presently be used for individual patient counseling.

Thus, the bulk of accumulating evidence suggests that genetic factors play an important role in both familial and "sporadic" forms of PD, while the role of environmental factors remains unsettled. Although mutations in PD genes identified to date cause only a minority of cases of PD, they have been very helpful in pointing to specific targets, pathways, and molecular mechanisms that are likely to be central to the neurodegenerative process in the sporadic form of the disease. Detailed clinical and genetic features of monogenic PD are available in the MDSGene database (*www.mdsgene.org*).

The α-synuclein gene (*SNCA*) was the first to be linked to PD and is also the most intensely investigated with respect to causative mutations, risk variants, function, and role in the etiopathogenesis of PD. Shared clinical features of patients with *SNCA* mutations include earlier age of disease onset than in nongenetic PD, a faster progression of motor signs that are mostly levodopa-responsive, early occurrence of motor fluctuations, and presence of prominent nonmotor features, particularly cognitive impairment. Importantly, duplication or triplication of the wild-type *SNCA* gene also causes PD, with triplication carriers being more severely affected than carriers of duplications. These findings indicate that increased production of the normal protein alone can cause PD. Intriguingly, α-synuclein constitutes the major component of Lewy bodies, implicating the protein in sporadic forms of PD as well (Fig. 446-1). In a remarkable study, Lewy pathology was discovered to have developed in healthy embryonic dopamine neurons that had been implanted into the striatum of PD patients, suggesting that the abnormal protein had transferred from affected cells to healthy unaffected dopamine neurons. Based on these findings, it has been proposed that the α-synuclein protein may be a prion and PD a prion disorder (Chaps. 435 and 449). In this model, α-synuclein can misfold

TABLE 446-4 Confirmed Genetic Causes of Parkinson's Disease (PD) with a Clinical Presentation Similar to Idiopathic PD[a]

DESIGNATION[a] AND REFERENCE	GENEREVIEWS AND OMIM REFERENCE	CLINICAL CLUES[b]	COMMENTS
Dominantly Inherited PD			
PARK-*SNCA*	GeneReviews *http://www.ncbi.nlm.nih.gov/books/NBK1223/* OMIM 168601	Median AAO: 46 years (range 19–77 years); 25th/75th percentile: 36/54 years. Gene duplications cause classical PD. Most missense mutations and triplications cause early-onset, severe parkinsonism with prominent cognitive dysfunction	Very rare form of PD, α-synuclein protein main component of Lewy bodies, the pathological hallmark of PD
PARK-*LRRK2*	GeneReviews *http://www.ncbi.nlm.nih.gov/books/NBK1208/* OMIM 607060	Median AAO: 56 years (range 20–95 years); 25th/75th percentile: 47/64 years. Clinically typical PD with slightly slower progression	Most common known genetic form of PD
PARK-*VPS35*	GeneReviews *http://www.ncbi.nlm.nih.gov/books/NBK1223/* OMIM 616710	Median AAO: 52 years (range 26–75 years); 25th/75th percentile: 45/61 years. Clinically typical PD	Very rare form of PD
PARK-*CHCHD2*	GeneReviews N/A OMIM 614203	Likely clinically typical PD. Systematic MDSGene review not yet available	Very rare form of PD, predominantly found in Asia
PARK-*RAB32*	GeneReviews *N/A* OMIM 612906 (disease link not yet included)	Likely clinically typical PD, possibly more frequent dementia. Systematic MDSGene review not yet available	Most recently found form of PD. All currently identified patients and families carry the same founder pathogenic variant
PARK-*GBA1*	GeneReviews *http://www.ncbi.nlm.nih.gov/books/NBK1223/* OMIM 168600/606463	Clinically overall typical PD; however, faster progression and greater risk of cognitive impairment. Systematic MDSGene review not yet available	Strongest known genetic risk factor for PD; incomplete penetrance
Recessively Inherited PD			
PARK-*PRKN*	GeneReviews *http://www.ncbi.nlm.nih.gov/books/NBK1155/* OMIM 600116	Median AAO: 31 years (range 3–81 years); 25th/75th percentile: 23/38 years. Often presents with dystonia, typically in a leg	Most common early-onset form of genetic PD. Protein name: Parkin
PARK-*PINK1*	GeneReviews *http://www.ncbi.nlm.nih.gov/books/NBK1223/* OMIM 605909	Median AAO: 32 years (range 9–67 years); 25th/75th percentile: 24/40 years. Prominent psychiatric features have been described in several families	Clinically very similar to PARK-*PRKN* but much rarer
PARK-*PARK7*	GeneReviews *http://www.ncbi.nlm.nih.gov/books/NBK1223/* OMIM 606324	Median AAO: 27 years (range 15–40 years); 25th/75th percentile: 22/34	Clinically very similar to PARK-*PRKN* and PARK-*PINK1*, but rarest of all forms. Protein name: DJ-1

to form β-rich sheets, join to form toxic oligomers and aggregates, polymerize to form amyloid plaques (i.e., Lewy bodies), and cause neurodegeneration with spread to unaffected neurons. Indeed, injection of purified α-synuclein fibrils into the striatum of both transgenic and wild-type rodents produced Lewy pathology in host neurons, neurodegeneration, behavioral abnormalities, and spread of α-synuclein pathology to anatomically connected sites. Further support for this hypothesis comes from the demonstration that inoculation into the striatum of homogenates derived from human Lewy bodies induces dopamine cell degeneration and widespread Lewy pathology in mice and primates. Evidence also suggests that in some cases α-synuclein pathology might begin peripherally within the GI tract and spread by way of the vagus nerve to the lower brainstem (dorsal motor nucleus of the vagus) and ultimately to the SNc to cause the motor features of PD (the Braak hypothesis). There is also interest in the possibility that the gut microbiome in PD patients can cause inflammatory changes that promote α-synuclein misfolding with spread to the brain via the vagus nerve. The gut-brain axis might therefore offer a mechanism by which α-synuclein pathology could spread to the brain and cause PD. The prion hypothesis for PD represents an exciting, although still unproven, line of investigation.

Multiple lines of evidence support the concept that neuroprotective therapies for PD might be developed based on inhibiting the accumulation or accelerating the removal of toxic forms of α-synuclein, knocking down levels of host *SNCA* to prevent their misfolding, preventing the spread of misfolded *SNCA*, or blocking the templating phenomenon whereby misfolded α-synuclein promotes misfolding of the native protein in a prion-like chain reaction. Numerous studies testing different approaches to targeting α-synuclein are ongoing. Interestingly, postmortem studies in PD patients who had undergone a transplant procedure observed that inflammation with activated microglia at the transplant site preceded the development of α-synuclein aggregates by many years. This suggests the possibility that a chronic inflammatory milieu could promote misfolding of host α-synuclein, leading to neurodegeneration; to date, however, immune-based approaches to clearing α-synuclein have not been successful in PD.

Pathogenic variants of the *GBA1* gene represent the most important risk factor in terms of both the development of PD and its severity. GBA encodes the enzyme glucocerebrosidase (GCase), which promotes lysosomal function and enhances the clearance of misfolded α-synuclein. The identification of *GBA1* as a risk for PD resulted from the clinical observation that patients with Gaucher's disease (GD) and their relatives show features of parkinsonism more frequently than would be expected. This clinical observation led to the discovery that literally hundreds of variants in *GBA1* confer risk for the development of PD. Experimentally, it has been shown that reduced levels of GCase activity due to GBA variants impair lysosomal function, resulting in the accumulation of α-synuclein. Conversely, the accumulation of α-synuclein leads to inhibition of lysosomal function and a further reduction in levels of GCase by interfering with endoplasmic reticulum-to-Golgi trafficking. Thus, there is a vicious cycle in which decreased GCase activity leads to the accumulation of α-synuclein, and increased levels of α-synuclein lead to impairment in lysosomal function. In this regard, it is noteworthy that lysosomal function is impaired and levels of GCase are reduced in patients with sporadic PD, and not just in those with *GBA1* variants. These findings suggest that this molecular pathway may not only apply to patients with a *GBA1* variants but also to patients with sporadic PD or other synucleinopathies who have normal wild-type *GBA1* alleles. Some studies suggest that patients with certain GBA1 variants (e.g., L444P) have a faster rate of progression and an increased frequency of cognitive impairment. Drug and gene-based therapies that enhance GCase activity and promote lysosomal function are currently being tested in the clinic as putative neuroprotective therapies.

Multiple *LRRK2* pathogenic mutations have also been clearly linked to PD; p.G2019S is the most common, possibly due to a founder effect in the Ashkenazi Jewish and North African Arab populations. Pathogenic variants in *LRRK2* account for 2–41% of familial PD cases (depending on the specific population) and are also found in apparently sporadic cases, albeit at a lower rate. More than 200 variants have been reported. Recently developed functional assays testing activation of kinase activity as a gain-of-function effect help distinguish causative variants from those of uncertain significance. The phenotype of *LRRK2* p.G2019S mutations is largely indistinguishable from that of sporadic PD, although tremor appears to be more common and disease progression is slightly slower than in idiopathic PD. The penetrance of *LRRK2* pathogenic variants is incomplete (30–74% depending on the ethnic group), and patients tend to run a more benign course, with less cognitive impairment than seen in idiopathic PD. The mechanism responsible for cell death with this mutation is likely due to enhanced kinase activity with altered phosphorylation of target proteins (including autophosphorylation) with possible impairment of lysosomal function. In laboratory models, kinase inhibitors can block toxicity associated with *LRRK2* pathogenic variants. Accordingly, there has been interest in developing drugs directed at this target. However, nonselective kinase inhibitors are potentially toxic to the lungs and kidneys. Fortunately, LRRK2 inhibitors have now been developed that have good preclinical safety and are currently being tested in PD populations with and without pathogenic *LRRK2* variants. There has been particular interest in c-Abl inhibitors, which target the tyrosine residue on α-synuclein protein and potentially prevent conversion to a toxic species. A pathogenic variant in *RAB32* has been identified as a novel form of dominantly inherited PD with incomplete penetrance. Interestingly, *LRRK2* and *RAB32* interact directly, thus representing another potentially druggable target.

Pathogenic variants in *PRKN, PINK1,* and *PARK7* have also been identified as a cause of PD. *PRKN* mutations are the most common and the major cause of autosomal recessive early-onset PD, accounting for up to 77% of juvenile PD patients, with an age of onset <20 years, and for 10–20% of early-onset PD patients in general. The disease is slowly progressive, responds well to antiparkinsonian treatment, and is commonly complicated by dystonia, but rarely by dementia. Pathologically, neurodegeneration tends to be restricted to the SNc and LC in patients with *PRKN* mutations, and Lewy bodies are only present in ~20% of the brains. The reason for these differences from classic PD is not known but may be related to the fact that parkin is a ubiquitin ligase and ubiquitination of damaged proteins is required for their clearance and possibly for their incorporation into Lewy bodies. The clinical phenotypes linked to pathogenic variants in *PRKN, PINK1,* and *PRK7* are indistinguishable from one another. Parkin and PINK1 proteins are involved in cell protection mechanisms related to the turnover and clearance of damaged mitochondria (mitophagy). Indeed, mutations in *Parkin* and *PINK1* cause mitochondrial dysfunction in transgenic animals that can be corrected with overexpression of parkin. Improving mitochondrial function is another attractive therapeutic target as postmortem studies in PD patients show a defect in complex I of the respiratory chain in SNc neurons.

Several factors have been implicated in the pathogenesis of cell death in PD, including oxidative stress, inflammation, excitotoxicity, mitochondrial dysfunction, and lysosomal/proteasomal dysfunction. Inflammation and altered immunity have also been implicated as potentially key factors in the degenerative process. Genetic studies demonstrate an association of PD with the class II human leukocyte antigen (HLA) gene *DRB1* (variants of which are associated with either protection or risk for PD) and findings in monogenic forms of PD demonstrating a role of inflammation and the immune system. As noted above, this is supported by pathologic studies demonstrating that inflammation occurs years before the accumulation of α-synuclein aggregates in transplanted patients, suggesting that inflammation plays a triggering role. Altered immunity has also been suggested by studies showing that autoreactive T cells recognizing peptides derived from α-synuclein are present in PD patients. Further, drugs such as sargramostim that upregulate T-regulatory cells have shown positive results in studies in animal models, and early studies in PD patients are underway. Whatever the pathogenic mechanism, cell death appears to occur, at least in part, by way of a signal-mediated apoptotic or "suicidal" process. Each of these mechanisms offers a potential target for putative neuroprotective drugs; however, clinical

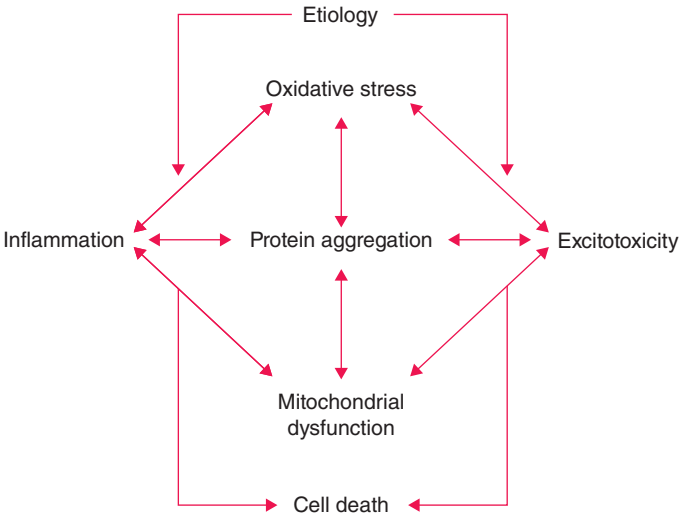

FIGURE 446-4 Schematic representation of how pathogenetic factors implicated in Parkinson's disease interact in a network manner, ultimately leading to cell death. This figure illustrates how interference with any one of these factors may not necessarily stop the cell death cascade. *(Reproduced with permission from CW Olanow: The pathogenesis of cell death in Parkinson's disease. Movement Disorders 22:S-335, 2007.)*

studies to date have not conclusively demonstrated a benefit using therapies directed against any of these targets. Moreover, it is not clear which of these factors is primary, if they are the same in all cases or specific to individual subgroups, if they act by way of a network such that multiple insults are required for neurodegeneration to ensue, or if the findings discovered to date merely represent epiphenomena unrelated to the true cause of cell death that still remains undiscovered (Fig. 446-4).

It is anticipated that a better understanding of the pathways involved in the etiology and pathogenesis of cell death in PD will permit the development of more relevant animal models and better-defined targets for the development of neuroprotective drugs.

PATHOPHYSIOLOGY OF PD

The classic model of the organization of the basal ganglia in the normal and PD states is provided in Fig. 446-5. With respect to motor function, a series of neuronal circuits with multiple feedback and feedforward loops link the basal ganglia nuclei with corresponding cortical and brainstem motor regions in a somatotopic manner. The striatum is the major input region of the basal ganglia, whereas the GPi and substantia nigra (SNr) are the major output regions. The input and output regions are connected via direct and indirect pathways that have reciprocal effects on basal ganglia activity and motor function. The output of the basal ganglia provides inhibitory (GABAergic) tone to modulate excitatory thalamic and brainstem neurons that, in turn, connect to motor systems in the cerebral cortex and spinal cord that control motor function. An increase in neuronal activity in the output regions of the basal ganglia (GPi/SNr) is associated with reduced thalamic activity and poverty of movement or parkinsonism, while decreased output results in movement facilitation. Dopaminergic projections from SNc neurons serve to modulate neuronal firing (in both directions) and thus to stabilize the basal ganglia network. Normal dopamine innervation thus serves to facilitate the selection of the desired movement and suppression or rejection of unwanted movements. Cortical loops integrating the cortex and the basal ganglia are thought to also play an important role in regulating other systems, such as behavioral, emotional, and cognitive functions.

In PD, dopamine denervation with loss of dopaminergic tone leads to increased firing of neurons in the STN and GPi, excessive inhibition of the thalamus, reduced activation of cortical motor systems, and the development of parkinsonian features (Fig. 446-5). The current role of surgery in the treatment of PD is based on this model, which predicted that lesions or high-frequency stimulation of the STN or GPi might reduce their inhibition of thalamocortical pathways and thus improve PD features. This model has not proven to be as valuable in understanding dyskinesia where benefits are also seen with lesions in these regions (see below) and where it is now thought that that dyskinesia arises from altered firing patterns and not just firing frequency.

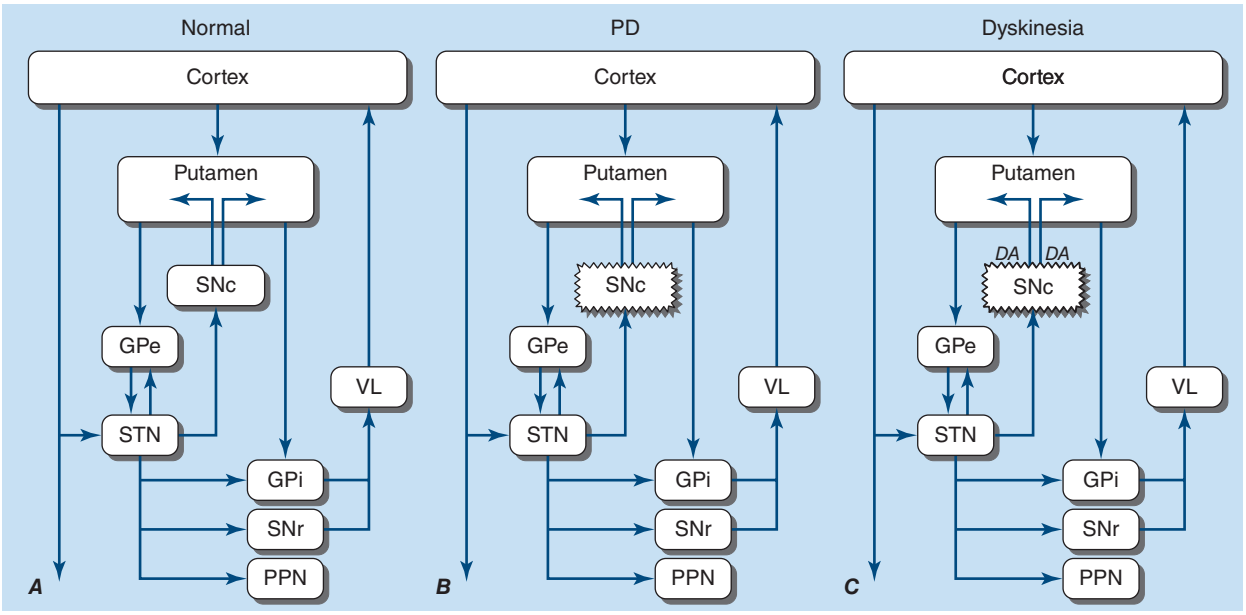

FIGURE 446-5 Basal ganglia organization. Classic model of the organization of the basal ganglia in the normal (***A***), Parkinson's disease (PD) (***B***), and levodopa-induced dyskinesia (***C***) state. Inhibitory connections are shown as *blue arrows* and excitatory connections as *red arrows*. The striatum is the major input region and receives its input from the motor regions of the cerebral cortex. The GPi and SNr are the major output regions, and they project to the thalamocortical and brainstem motor regions. The striatum and GPi/SNr are connected by direct and indirect striatal pathways whose neurons are D1- and D2-bearing, respectively. This model predicts that parkinsonism results from decreased dopamine inhibition of the indirect pathway, leading to increased neuronal firing in the STN and GPi with inhibition of thalamocortical firing. These observations suggested that lesions or DBS of these targets might provide antiparkinsonian benefit. The model also predicts that dyskinesia results from decreased firing of the output regions, resulting in excessive cortical activation by the thalamus. This component of the model is not completely correct because lesions of the GPi ameliorate rather than increase dyskinesia in PD, suggesting that firing frequency is just one of the components that lead to the development of dyskinesia and that other components of the neuronal firing pattern such as pauses and bursts are also important. DBS, deep brain stimulation; GPe, external segment of the globus pallidus; GPi, internal segment of the globus pallidus; PPN, pedunculopontine nucleus; SNc, substantia nigra, pars compacta; SNr, substantia nigra, pars reticulata; STN, subthalamic nucleus; VL, ventrolateral thalamus. *(Derived from JA Obeso et al: Trends Neurosci 23:S8, 2000.)*

COVID-19 AND PD

SARS-CoV-2 viral infection can worsen PD features and off time. In addition, having PD increases the risks of complications and death rate associated with having a SARS-CoV-2 infection. Interestingly, it has been shown that the SARS-CoV-2 virus can enter the brain and cause inflammation with microglial activation, and new-onset cases of PD have been reported following infection. In this regard, it raises similarities to PD cases associated with the influenza A epidemic in 1918. Home confinement due to the risks of acquiring SARS-CoV-2 infection has also altered conduct of clinical trials in PD patients and promoted "remote" clinical trials in which patients are evaluated online rather than in person. With validation of the reliability of this approach, it is likely that remote clinical trials will be increasingly employed in routine clinical trials of PD patients.

TREATMENT

Parkinson's Disease

LEVODOPA

Since its introduction in the late 1960s, levodopa has been the mainstay of therapy for PD. Experiments in the late 1950s by Carlsson and colleagues demonstrated that blocking dopamine uptake with reserpine caused rabbits to become parkinsonian; this could be reversed with the dopamine precursor levodopa. Subsequently, Hornykiewicz demonstrated a dopamine deficiency in the striatum of PD patients and suggested the potential benefit of dopamine replacement therapy. Dopamine does not cross the blood-brain barrier (BBB), so clinical trials were initiated with levodopa, the precursor of dopamine. Studies over the course of the next decade confirmed the value of levodopa and revolutionized the treatment of PD.

Levodopa is routinely administered in combination with a peripheral decarboxylase inhibitor to prevent its peripheral metabolism to dopamine and the development of nausea, vomiting, and orthostatic hypotension due to activation of dopamine receptors in the area postrema (the nausea and vomiting center) that are not protected by the BBB. In the United States, levodopa is combined with the decarboxylase inhibitor carbidopa (Sinemet), whereas in many other countries, it is combined with benserazide (Madopar). Levodopa plus a decarboxylase inhibitor is also available in a methylated formulation, a controlled-release formulation (Sinemet CR or Madopar HP), and in combination with a catechol-*O*-methyltransferase (COMT) inhibitor (Stalevo). A long-acting formulation of levodopa (Rytary), a levodopa-carbidopa intestinal gel administered continuously by intra-intestinal infusion, continuous subcutaneous infusions of a levodopa formulation, and an inhaled form of levodopa that is absorbed through the pulmonary alveoli are also now available (see below).

Levodopa remains the most effective symptomatic treatment for PD and the gold standard against which new therapies are compared. No current medical or surgical treatment provides antiparkinsonian benefits superior to what can be achieved with levodopa. Levodopa benefits the classic motor features of PD, prolongs independence and employability, improves quality of life, and increases life span. Indeed, levodopa also benefits some "nondopaminergic" features such as anxiety, depression, and sweating. Almost all PD patients experience improvement, and failure to respond to an adequate trial of levodopa should cause the diagnosis to be questioned.

There are important limitations of levodopa therapy. Acute dopaminergic side effects include nausea, vomiting, and orthostatic hypotension. These are usually transient and can generally be avoided by starting with low doses and gradual up-titration. If they persist, they can be treated with additional doses of a peripheral decarboxylase inhibitor (e.g., carbidopa) or administered with food or a peripheral dopamine-blocking agent such as domperidone (not available in the United States). As the disease continues to progress, features such as falling, freezing, autonomic dysfunction, sleep disorders, and dementia may emerge that are not adequately controlled by levodopa. Indeed, these nondopaminergic features (especially falls and dementia) are the primary source of disability and the main reason for hospitalization and nursing home placement for patients with advanced PD in the levodopa era.

The major concern with levodopa is that chronic treatment with ongoing disease progression is associated in most patients with the development of motor complications. Motor complications consist of fluctuations in motor response ("on" episodes when the drug is working and "off" episodes when Parkinsonian features return as the drug wears off) and involuntary movements known as dyskinesias, which typically complicate "on" periods **(Fig. 446-6)**. When patients initially take levodopa, benefits are long-lasting (many hours and to some degree even weeks—the "long-duration" response) even though the drug has a relatively short half-life (60–90 min). With continued treatment, however, the duration of benefit following an individual dose becomes progressively shorter until benefits approach the half-life of the drug. This loss of benefit is known as the *wearing-off effect*. Some patients may also experience a rapid and unpredictable switch from the on to the off state known as the *on-off phenomenon*. In advanced cases, because of variability in the bioavailability of standard oral levodopa, the response to an individual dose of levodopa may be variable and unpredictable with the patient experiencing a full-on response, a partial-on response, a delay in turning on (delayed-on), or no response at all (no-on). Peak-dose dyskinesias occur at the time of levodopa peak plasma concentration and maximal clinical benefit. They are usually choreiform but can manifest as dystonic movements, myoclonus, or other movement disorders. They are not troublesome when mild but can be disabling when severe and can limit the ability to use higher doses of levodopa to better control PD motor features. In more advanced states, patients may cycle between "on" periods complicated by disabling dyskinesias

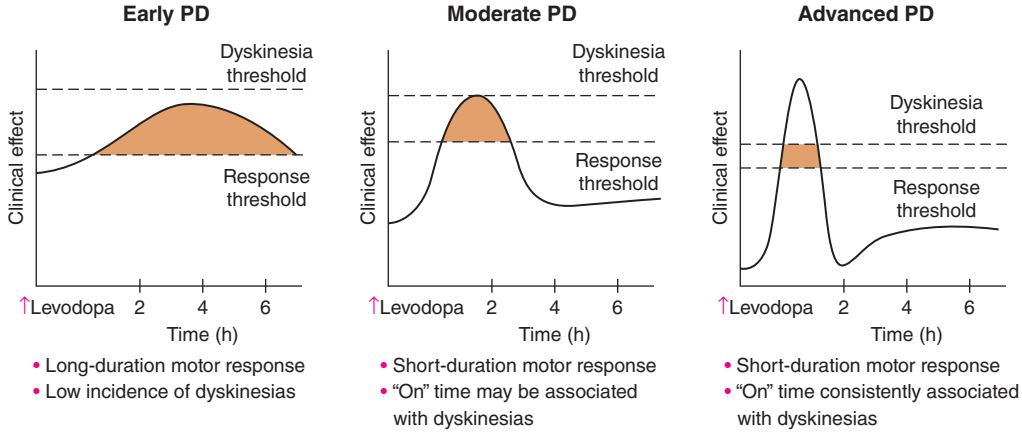

FIGURE 446-6 Changes in motor response associated with chronic levodopa treatment. Levodopa-induced motor complications. Schematic illustration of the gradual shortening of the duration of a beneficial motor response to levodopa (wearing off) and the appearance of dyskinesias complicating "on" time. PD, Parkinson's disease.

and "off" periods in which they suffer from severe parkinsonism and painful dystonic postures. Patients may also experience "diphasic dyskinesias," which occur with lower plasma levodopa levels and manifest as the levodopa dose begins to take effect and again as it wears off. These dyskinesias typically consist of transient, stereotypic, rhythmic movements that predominantly involve the lower extremities asymmetrically and are frequently associated with parkinsonism in other body regions. They can be relieved by increasing the dose of levodopa (although higher doses may induce peak-dose dyskinesia) and disappear as the concentration declines. Long-term double-blind studies show that the risk of developing motor complications can be minimized by using the lowest dose of levodopa that provides satisfactory benefit and through the use of polypharmacy to avoid the need for raising the dose of levodopa.

The precise cause of levodopa-induced motor complications is not known. They are more likely to occur in younger individuals, with the use of higher doses of levodopa, in females, and in those with more severe disease. The classic model of the basal ganglia has been useful for understanding the origin of motor features in PD, as noted above, but has proven less valuable for understanding levodopa-induced dyskinesias (Fig. 446-5). The model predicts that dopamine replacement might excessively inhibit the pallidal output system, thereby leading to increased thalamocortical activity, enhanced stimulation of cortical motor regions, and the development of dyskinesia. However, lesions of the pallidum that dramatically reduce its output are associated with amelioration rather than induction of dyskinesia as would be suggested by the classic model. It is now thought that dyskinesia results from alterations in the GPi/SNr neuronal firing pattern (pauses, bursts, synchrony, etc.) and not simply the firing frequency alone. This leads to the transmission of "misinformation" from pallidum to thalamus/cortex, which along with firing frequency contributes to the development of dyskinesia. Surgical or ultrasound lesions or high-frequency stimulation targeted at the GPi or STN presumably ameliorate dyskinesia by interfering with (blocking or masking) this abnormal neuronal activity and preventing the transfer of misinformation to motor systems.

A number of studies suggest that motor complications develop in response to nonphysiologic levodopa replacement. Striatal dopamine levels are normally maintained at a relatively constant level. In PD, where dopamine neurons and terminals have degenerated, striatal dopamine levels are dependent on the peripheral availability of levodopa. Intermittent oral doses of levodopa result in fluctuating plasma levels because of the short half-life of the drug and variability in the transit of the drug from the stomach to the jejunum where it is absorbed. These fluctuations are also reflected in the brain and result in striatal dopamine receptors being exposed to alternating pathologically high and low concentrations of dopamine. This in turn has been shown to induce molecular alterations in striatal neurons, neurophysiologic changes in pallidal output neurons, and ultimately the development of motor complications. It has been hypothesized that more continuous delivery of levodopa might be more physiologic and prevent the development or reduce the frequency of motor complications. Indeed, double-blind studies in PD patients have demonstrated that continuous intraintestinal infusion of levodopa/carbidopa and continuous subcutaneous infusion of apomorphine or levodopa are associated with significant improvement in "off" time and in "on" time without troublesome dyskinesia, compared with intermittent doses of standard oral levodopa. These benefits are superior to those observed in placebo-controlled studies with other dopaminergic agents. Intestinal infusion of levodopa is approved in the United States and Europe (Duodopa, Duopa). The treatment can, however, be complicated by potentially serious adverse events related to the surgical procedure, problems related to the tubing, and the inconvenience of having to wear an infusion system. Continuous subcutaneous delivery of levodopa or apomorphine avoids the need for a surgical procedure but is associated with a high frequency of cutaneous lesions and still requires wearing the inconvenient pump system. These are approved in Europe but not yet in the United States.

Behavioral complications can also be associated with levodopa treatment. A dopamine dysregulation syndrome has been described where patients have a craving for levodopa and take frequent and unnecessary doses of the drug in an addictive manner. (In this regard, it is noteworthy that cocaine binds to the dopamine uptake receptor.) PD patients taking high doses of levodopa can also develop purposeless, stereotyped behaviors such as the assembly and disassembly or collection and sorting of objects. This is known as punding, a term taken from the Swedish description of the meaningless behaviors seen in chronic amphetamine users. Hypersexuality and other impulse-control disorders are occasionally encountered with levodopa but are more commonly seen with dopamine agonists.

Finally, because levodopa undergoes oxidative metabolism and has the potential to generate toxic free radicals, there has been concern that independent of the drug's ability to provide symptomatic benefits, it might accelerate neuronal degeneration. Alternatively, as levodopa improves long-term outcomes in comparison to the pre-levodopa era, it has been suggested that by restoring striatal dopamine, levodopa has the potential to have a disease-modifying or neuroprotective effect. Neither of these hypotheses has been established. A recent delayed start study (explained below) showed neither beneficial nor deleterious effects of levodopa on the rate of clinical progression. Thus, it is generally recommended that levodopa be used solely based on its potential to provide symptomatic benefits balanced by the risk of inducing motor complications and other side effects.

DOPAMINE AGONISTS

Dopamine agonists are a diverse group of drugs that act directly on dopamine receptors. Unlike levodopa, they do not require metabolic conversion to an active product and do not undergo oxidative metabolism. Initial dopamine agonists were ergot derivatives (e.g., bromocriptine, pergolide) and were associated with potentially serious ergot-related side effects such as cardiac valvular damage and pulmonary fibrosis. They have largely been replaced by a second generation of non-ergot dopamine agonists (e.g., pramipexole, ropinirole, rotigotine). In general, dopamine agonists do not have comparable efficacy to levodopa. They were initially introduced as adjuncts to levodopa to enhance motor function and reduce "off" time in fluctuating patients. Subsequently, it was shown that dopamine agonists are less prone than levodopa to induce dyskinesia, possibly because they are relatively long acting in comparison to levodopa. For this reason, many physicians initiated therapy with a dopamine agonist, particularly in younger patients who are more prone to develop motor complications, although supplemental levodopa is eventually required in virtually all patients. This view has been tempered by the recognition that dopamine agonists are associated with potentially serious adverse effects such as unwanted sleep episodes and impulse control disorders (see below). Both ropinirole and pramipexole are available as orally administered immediate (three times a day) and extended-release (once a day) formulations. Rotigotine is administered as a once-daily transdermal patch and may be useful in managing surgical patients who are not able to be treated with an oral therapy. Apomorphine is the one dopamine agonist with efficacy thought to be comparable to levodopa, but it must be administered parenterally as it is rapidly and extensively metabolized if taken orally. It has a short half-life and duration of activity (45 min). It can be administered by subcutaneous injection as a rescue agent for the treatment of severe "off" episodes but can also be administered by continuous subcutaneous infusion where it has been shown to reduce both "off" time and dyskinesia in advanced patients. A sublingual bilayer formulation of apomorphine has been approved as a rapid and reliable therapy for individual "off" periods that avoids the need for a subcutaneous (SC) injection (see below).

Dopamine agonist use is associated with a variety of side effects. Acute side effects are primarily dopaminergic and include nausea, vomiting, and orthostatic hypotension. These can usually be

avoided or minimized by starting with low doses and slowly up-titrating over weeks. Side effects associated with chronic use include hallucinations, cognitive impairment, and leg edema. Sedation with sudden unintended episodes of falling asleep that can occur in dangerous situations, such as while driving a motor vehicle, have been reported. Patients should be informed about this potential problem and should not drive when tired. Dopamine agonists can also be associated with impulse-control disorders, including pathologic gambling, hypersexuality, and compulsive eating and shopping. Patients should be advised of these risks and specifically questioned for their occurrence at follow-up examinations. The precise cause of these problems, and why they appear to occur more frequently with dopamine agonists than levodopa, remains to be resolved, but differential effects on reward systems associated with dopamine and alterations in the ventral striatum and orbitofrontal regions have been implicated. In general, chronic side effects are dose-related and can be avoided or minimized with lower doses. Injections of apomorphine can be complicated by skin lesions at sites of administration, which can be minimized by proper cleaning and alternating the injection sites. The sublingual bilayer formulation of apomorphine can be associated with oropharyngeal side effects, but these are generally mild and resolve either spontaneously or with treatment withdrawal. A selective D1 agonist has been developed and shown to have mild antiparkinsonian effects but not greater than those seen with other available dopamine agonists.

MAO-B INHIBITORS

Inhibitors of monoamine oxidase type B (MAO-B) block central dopamine MAO-B-oxidative metabolism and thereby increase synaptic concentrations of the neurotransmitter. Selegiline and rasagiline are relatively selective suicide inhibitors of the MAO-B isoform of the enzyme. Clinically, these agents provide antiparkinsonian benefits when used as monotherapy in early disease stages and reduced "off" time when used as an adjunct to levodopa in patients with motor fluctuations. MAO-B inhibitors are generally safe and well tolerated. They may increase dyskinesia in levodopa-treated patients, but this can usually be controlled by down-titrating the dose of levodopa. Inhibition of the MAO-A isoform prevents metabolism of tyramine in the gut, leading to a potentially fatal hypertensive reaction known as a "cheese effect" because it can be precipitated by foods rich in tyramine such as some cheeses, aged meats, and red wine. Currently available MAO-B inhibitors are selective, do not functionally inhibit the MAO-A enzyme, and are not associated with a cheese effect with doses used in clinical practice. There are theoretical risks of a serotonin reaction in patients receiving concomitant selective serotonin reuptake inhibitor (SSRI) antidepressants, but these are rarely encountered. Safinamide is a reversible and selective MAO-B inhibitor that has been approved as an adjunct to levodopa for treating advanced PD patients with motor fluctuations. The drug also acts to block activated sodium channels and inhibit glutamate release and therefore has the potential to provide antidyskinetic as well as ant-parkinsonian effects.

Interest in MAO-B inhibitors has also focused on their potential to have disease-modifying effects (see below).

COMT INHIBITORS

When levodopa is administered with a decarboxylase inhibitor, it is primarily metabolized in the periphery by the COMT enzyme. Inhibitors of COMT block its peripheral metabolism, increase the elimination half-life of levodopa, and enhance its brain availability. Combining levodopa with a COMT inhibitor reduces "off" time and prolongs "on" time in fluctuating patients while enhancing motor scores. The COMT inhibitors tolcapone and entacapone have been available for more than a decade; tolcapone is administered three times daily, while entacapone is administered in combination with each dose of levodopa. Opicapone, a long-acting COMT inhibitor that only requires once-daily administration, has more recently been approved in both Europe and the United States. A combination tablet of levodopa, carbidopa, and entacapone (Stalevo) is also available.

Side effects of COMT inhibitors are primarily dopaminergic (nausea, vomiting, increased dyskinesia) and can usually be controlled by down-titrating the dose of levodopa by 20–30% if required. Severe diarrhea has been described with tolcapone, and to a lesser degree with entacapone, and necessitates stopping the medication in 5–10% of individuals. Rare cases of fatal hepatic toxicity have been reported with tolcapone. It is still used because it is the most effective of the COMT inhibitors, but periodic monitoring of liver function is required. Liver problems have not been encountered with entacapone or opicapone. Discoloration of urine can be seen with COMT inhibitors due to accumulation of a metabolite, but it is of no clinical concern.

It has been proposed that initiating levodopa in combination with a COMT inhibitor to enhance its elimination half-life could provide more continuous levodopa delivery and reduce the risk of motor complications (see below). While this result has been demonstrated in a preclinical MPTP model of PD, and continuous infusion reduces both "off" time and dyskinesia in advanced PD patients, no benefit of initiating levodopa with a COMT inhibitor compared to levodopa alone was detected in early PD patients in the STRIDE-PD study. This may have been because the combination was not administered at frequent enough intervals to provide continuous levodopa availability. For now, the main value of COMT inhibitors continues to be as an adjunct to levodopa.

OTHER MEDICAL THERAPIES

Adenosine $A2_A$ receptor antagonists are a class of drugs that inhibit $A2_A$ receptors that form heterodimers with D2 dopamine receptors on medium spiny striatal D2-bearing neurons of the indirect pathway. Blockade of $A2_A$ receptors decreases the excessive activation of the indirect pathway in PD and theoretically restores balance in the basal ganglia–thalamocortical circuit, providing a dopaminergic effect without the need to increase levodopa doses and activate D1-receptor-bearing neurons that comprise the direct pathway. Three $A2_A$ antagonists have been studied in PD, but development in two has been discontinued: preladenant because it failed in phase 3 studies and tozadenant because of agranulocytosis in a few patients. Istradefylline is the only agent that is currently approved for use. Clinical trials in advanced PD patients showed improvement in "off" time comparable to other available agents but not in dyskinesia. The drug is generally well tolerated, with adverse events similar to dopaminergic agents. Interestingly, caffeine is a potent $A2_A$ antagonist, and epidemiologic studies suggest that drinking coffee is associated with a reduced frequency of PD. This has raised the question as to whether this class of agent might be neuroprotective, but this has not been established in clinical trials.

Amantadine was originally introduced as an antiviral agent, but the drug was observed to also have antiparkinsonian effects, likely due to antagonism of the *N*-methyl-D-aspartate (NMDA) receptor. While some physicians use amantadine in patients with early disease for its mild symptomatic effects, it is most widely used as an antidyskinesia agent in patients with advanced PD. Indeed, it is the only oral agent demonstrated in controlled studies to reduce dyskinesia without worsening parkinsonian features (indeed, motor benefits have been reported to be improved). Cognitive impairment is a major concern, particularly with high doses. Other side effects include livedo reticularis and weight gain. Amantadine should always be discontinued gradually because patients can experience withdrawal-like symptoms. An extended-release formulation of amantadine has also been developed.

Central-acting anticholinergic drugs such as trihexyphenidyl and benztropine were used historically for the treatment of PD, but they lost favor with the introduction of levodopa. Their major clinical effect is on tremor, although it is not certain that this benefit is superior to what can be obtained with agents such as levodopa and dopamine agonists. Still, they can be helpful in individual patients with severe tremor. Their use is limited particularly in the elderly, due to their propensity to induce a variety of side effects, including urinary dysfunction, glaucoma, and particularly cognitive impairment.

TABLE 446-5 Drugs Commonly Used for Treatment of Parkinson's Disease[a]

AGENT	AVAILABLE DOSAGES	TYPICAL DOSING
Levodopa[a]		
Carbidopa/levodopa	10/100, 25/100, 25/250 mg	200–1000 mg levodopa/day
Benserazide/levodopa	25/100, 50/200 mg	
Carbidopa/levodopa CR	25/100, 50/200 mg	
Benserazide/levodopa MDS	25/200, 25/250 mg	
Parcopa	10/100, 25/100, 25/250 mg	
Rytary (carbidopa/levodopa)	23.75/95, 36.25/145, 48.75/195, 61.25/245	See conversion tables
Carbidopa/levodopa/entacapone	12.5/50/200, 18.75/75/200, 25/100/200, 31.25/125/200, 37.5/150/200, 50/200/200 mg	
Dopamine agonists		
Pramipexole	0.125, 0.25, 0.5, 1.0, 1.5 mg	0.25–1.0 mg tid
Pramipexole ER	0.375, 0.75, 1.5. 3.0, 4.5 mg	1–3 mg/d
Ropinirole	0.25, 0.5, 1.0, 3.0 mg	6–24 mg/d
Ropinirole XL	2, 4, 6, 8 mg	6–24 mg/d
Rotigotine patch	2-, 4-, 6-, 8-mg patches	4–24 mg/d
Apomorphine SC	2–8 mg	2–8 mg
COMT inhibitors		
Entacapone	200 mg	200 mg with each levodopa dose
Tolcapone	100, 200 mg	100–200 mg tid
Opicapone	50 mg	50 mg HS
MAO-B inhibitors		
Selegiline	5 mg	5 mg bid
Rasagiline	0.5, 1.0 mg	1 mg QAM
Safinamide	100 mg	100 mg QAM
On-demand therapy for off periods		
Inhaled levodopa	5–40 mg	Up to 5 doses per day
Apomorphine sublingual strip		Up to 5 doses per day
Others		
$A2_A$ antagonist—Istradefylline	20, 40 mg	20 or 40 mg/d
Amantadine—immediate, extended-release	100–400 mg	

[a]Treatment should be individualized. Generally, drugs should be started in low doses and titrated to optimal dose.

Note: Drugs should not be withdrawn abruptly but should be gradually lowered or removed as appropriate.

Abbreviations: COMT, catechol-*O*-methyltransferase; MAO-B, monoamine oxidase type B; QAM, every morning.

The anticonvulsant zonisamide has also been shown to have mild antiparkinsonian effects and is approved for use in Japan. Its mechanism of action is unknown. Several classes of drugs are currently being investigated in an attempt to enhance antiparkinsonian effects, reduce "off" time, and treat or prevent dyskinesia. These include a selective inhibitor of the GPR6 receptor, which is localized to D2-bearing striatal neurons, and a selective antagonist of the D3 receptor.

A list of the major drugs and available dosage strengths currently available to treat PD is provided in **Table 446-5**.

CONTINUOUS DOPAMINERGIC DELIVERY

As noted above, there is evidence suggesting that motor complications are related to nonphysiologic restoration of brain DA with intermittent oral doses of short-acting levodopa formulations. To overcome these problems, several approaches have been developed to deliver levodopa in a more continuous manner. These include continuous intraintestinal and continuous subcutaneous delivery. Each of these has been shown to provide more stable plasma levodopa levels than intermittent doses of standard levodopa and to be associated with reduced "off" time and increased "on" time without troublesome dyskinesia. Similar results have also been seen with continuous subcutaneous delivery of apomorphine, as well as continuous oral delivery using a small intraoral micropump attached to a retainer. Attempts continue to develop an oral formulation of levodopa that can provide relatively continuous plasma levodopa levels and avoid a surgical procedure with resulting risk for cutaneous nodules and abscesses and the need to wear an inconvenient and cumbersome infusion pump.

ON-DEMAND THERAPIES FOR OFF PERIODS

Despite all available therapies including continuous delivery, many patients still experience "off" periods. Off periods can be disabling for patients, placing them at risk for falling and choking. As noted above, taking an additional levodopa tablet does not reliably treat individual off episodes, and some patients may continue in the off state for hours despite a levodopa dose. This inability to reliably and rapidly treat off episodes causes many patients to become depressed, withdrawn, and unwilling to participate in social or business activities. Three therapies have now been approved as specific on-demand treatments for off periods: inhaled levodopa, subcutaneous injection of apomorphine, and sublingual apomorphine. Each of these is fast acting, avoids the variable bioavailability seen with standard oral levodopa, and provides a predictable return to the on state.

NEUROPROTECTION

Despite the many therapeutic agents available for the symptomatic treatment of PD, patients continue to progress and to develop intolerable disability. A neuroprotective or disease-modifying therapy that slows or stops disease progression remains the major unmet therapeutic need. Some trials have shown positive results (e.g., selegiline, rasagiline, pramipexole, ropinirole) consistent with a disease-modifying effect. However, it has not been possible to determine with certainty if the positive results were due to neuroprotection with slowing of disease progression or confounding symptomatic or pharmacologic effects that mask disease progression. Interest has focused on selegiline and rasagiline, as MPTP toxicity can be prevented experimentally by coadministration of an MAO-B inhibitor. These agents block the oxidative conversion of MPTP to the pyridinium ion MPP^+ that is taken up by and selectively damages dopamine neurons. MAO-B inhibitors also have the potential to block the oxidative metabolism of dopamine and prevent oxidative stress. In addition, both selegiline and rasagiline incorporate a propargyl ring within their molecular structure that provides antiapoptotic effects in laboratory models.

In the classic DATATOP study, selegiline delayed the time until the emergence of disability necessitating the introduction of levodopa in untreated PD patients. However, it could not be definitively determined whether this benefit was due to a neuroprotective effect that slowed disease progression or a symptomatic effect that merely masked ongoing neurodegeneration. The ADAGIO study tested the putative neuroprotective effects of rasagiline using a two-period delayed-start design. In the first period, patients are randomized to treatment with the active drug or placebo. In the second period, patients in both groups receive the active treatment. If early treatment provides an enduring benefit that cannot be achieved with delayed treatment, the result is consistent with a disease-modifying effect. In ADAGIO, early treatment with rasagiline 1 mg/d provided significant benefits that could not be achieved when treatment with the same drug was initiated at a later time point, consistent with a disease-modifying effect. However, this benefit was not seen with the 2-mg dose, and it did not receive regulatory approval for this indication. The reason the 2-mg dose failed remains uncertain, but many physicians use rasagiline in early-stage patients based on its potential to have neuroprotective effects.

Neuroprotective therapies that prevent the formation or accumulation of toxic α-synuclein species, inhibit LRRK2, or enhance GCase are currently being studied. GLP-1 agonists, developed for use in diabetes, have also shown some promise based on anti-inflammatory and pro-mitochondrial actions, but results in double-blind studies have been inconsistent.

SURGICAL TREATMENT

Surgical treatments for PD have been used for more than a century. Lesions were initially placed in the motor cortex and improved tremor but were associated with motor deficits, and this approach was abandoned. Subsequently, it was appreciated that lesions placed into the ventral intermediate (VIM) nucleus of the thalamus reduced contralateral tremor without inducing hemiparesis, but these lesions did not meaningfully help other more disabling features of PD. In the 1990s, it was shown that lesions placed in the posteroventral portion of the GPi (motor territory) improved rigidity and bradykinesia as well as tremor. Importantly, pallidotomy was also associated with marked improvement in contralateral dyskinesia. This procedure gained favor with greater understanding of the pathophysiology of PD (see above). However, this procedure is not optimal because PD affects both sides of the body and bilateral lesions are associated with side effects such as dysphagia, dysarthria, and impaired cognition. Lesions of the STN are also associated with antiparkinsonian benefit and reduced levodopa requirement, but there is a concern about the risk of hemiballismus, and this procedure is not commonly performed.

Most surgical procedures for PD performed today use deep brain stimulation (DBS). Here, an electrode is placed into the target area and connected to a stimulator inserted subcutaneously over the chest wall. DBS simulates the effects of a lesion without needing to make a brain lesion. The precise mechanism whereby DBS works is not fully understood but may act by disrupting the abnormal neurophysiological signals that are associated with PD and motor complications. The stimulation variables can be adjusted with respect to electrode configuration, voltage, frequency, and pulse duration in order to maximize benefit and minimize adverse side effects. The procedure does not require making a lesion in the brain and is thus suitable for performing bilateral procedures with relative safety. In cases where there are no benefits or with intolerable side effects, stimulation can be stopped and the system removed.

DBS for PD is primarily used to target the STN or the GPi. It provides antiparkinsonian benefits, particularly with respect to tremor, and reduces both "off" time and dyskinesias but does not provide antiparkinsonian benefits that are superior to levodopa. The procedure is thus primarily indicated for patients who suffer disability from severe tremor or from levodopa-induced motor complications that cannot be satisfactorily controlled with drug adjustments. Side effects can result from the surgical procedure (hemorrhage, infarction, infection), the DBS system (infection, lead break, lead displacement, skin ulceration), or the stimulation itself (ocular and speech abnormalities, muscle twitches, paresthesias, depression, and rarely suicide). Results of DBS of the STN and GPi are comparable, but GPi stimulation may be associated with a reduced frequency of depression. Although not all PD patients are candidates, the procedure can be profoundly beneficial for the appropriate patient. Long-term studies demonstrate continued benefits with respect to the dopaminergic features of PD, but DBS does not prevent the development of nondopaminergic features, which continue to evolve as the disease progresses and are a source of disability. Studies continue to evaluate the optimal way to use DBS (e.g., low- vs high-frequency stimulation, closed loop systems, adaptive approaches). Trials of DBS in early PD patients show benefits that may be superior to best medical therapy, but this must be weighed against the cost of the procedure and the risk of side effects in patients who might otherwise be well controlled with relatively safe medical therapies for many years especially if used correctly (see below). Additionally, the PD landscape is changing with the availability of on-demand therapies for treating off periods and the likelihood that future therapies may provide continuous levodopa availability with a reduced risk of motor complications. Controlled studies comparing DBS to other therapies aimed at improving motor function without causing dyskinesia, such as continuous intraintestinal or SC levodopa infusions, remain to be performed. The utility of DBS may also be reduced in the future if new medical therapies are developed that provide the benefits of levodopa without motor complications. New targets for DBS are also being actively explored directed at gait dysfunction, depression, and cognitive impairment, as well as "smart" closed-loop devices that sense the patient's need for stimulation **(Chap. 500)**.

MRI-guided ultrasound is also now being used to target critical regions such as the GPi or STN in PD patients with motor complications in a relatively noninvasive manner that avoids the needs for a surgical procedure. Preliminary results suggest good target localization and safety. Ultrasound has also been used to interrupt the BBB in a specific location, which might facilitate access to the brain for therapies that otherwise might not cross the BBB.

OTHER EXPERIMENTAL THERAPIES FOR PD

These include cell-based therapies (e.g., transplantation of dopamine neurons derived from stem cells), gene therapies, and trophic factors. Transplant strategies are based on the concept of implanting dopaminergic cells into the striatum to replace degenerating SNc dopamine neurons. Fetal nigral mesencephalic cells have been demonstrated to survive implantation, re-innervate the striatum in an organotypic manner, and restore motor function in PD models. However, two double-blind studies failed to show significant benefit of fetal nigral transplantation in comparison to a sham operation. Grafting of fetal nigral cells is associated with a previously unrecognized form of dyskinesia (graft-induced dyskinesia) that persists after lowering or even stopping levodopa. This has been postulated to be related to suboptimal release of dopamine from grafted cells, leading to a sustained form of diphasic dyskinesia. In addition, there is evidence that, after many years, transplanted healthy embryonic dopamine neurons from unrelated donors develop PD pathology and become dysfunctional, suggesting transfer of α-synuclein from affected to unaffected neurons in a prion-like manner (see discussion above). There are also concerns about immune reactions to the injection of foreign tissue. Stem cells, and specifically autologous induced pluripotent stem (IPS) cells derived from the recipient, may overcome problems related to immune reactions and physiologic integration, but many of the concerns listed above still apply. To date, stem cells have not yet been properly tested in double-blind studies and bear the additional theoretical concern of malignant transformation and other unanticipated side effects. Importantly, it is not clear how replacing dopamine cells alone will improve the nondopaminergic features of PD such as falling and dementia, which are the major sources of disability for patients with advanced disease. While there remains a need for scientifically based studies to evaluate the potential role of cell-based therapies in PD, there is no basis for treating PD patients with stem cells in nonresearch studies, as is being marketed in some countries.

Trophic factors are a series of proteins that enhance neuronal growth and potentially could restore function to damaged neurons. Based on laboratory studies, several different trophic factors appear to have beneficial effects on dopamine neurons, and glial-derived neurotrophic factor (GDNF) and neurturin have attracted particular attention as possible therapies for PD. However, double-blind trials of intraventricular and intraputaminal infusions of GDNF failed to benefit PD patients, possibly because of inadequate delivery of the trophic molecule to the target region. Gene therapy offers the potential of providing long-term expression of a therapeutic protein with a single procedure. Gene therapy involves placing the nucleic acid of a therapeutic protein into a viral vector that can then be taken up and incorporated into the genome of host cells and then synthesized and released on a continual basis. The AAV2 virus has been most often used as the vector because it does not promote an inflammatory response, is not incorporated into the host genome,

does not induce insertional mutagenesis, and is associated with long-lasting transgene expression. AAV2 delivery of the trophic factor neurturin (a member of the GDNF family) showed promising results in open-label trials but also failed in double-blind trials, even when injected into both the putamen and the SNc. Nonetheless, long-term postmortem studies have demonstrated transgene survival with biological effects as long as 10 years after treatment. However, the degree of putaminal coverage was very small, and it is likely that much higher gene doses will be required if this type of therapy is to provide clinically meaningful results.

Gene delivery is also being explored as a means of delivering aromatic amino acid decarboxylase with or without tyrosine hydroxylase into the striatum to facilitate the conversion of orally administered levodopa to dopamine. Animal studies suggest that this approach can provide antiparkinsonian benefits with reduced motor complications; clinical trials in PD patients are underway. Gene therapy is also being studied as a way to enhance *GBA1* and the gene product GCase in an attempt to promote lysosomal clearance of misfolded α-synuclein protein.

Importantly, no clinically significant adverse events have been encountered in gene therapy studies directed at the central nervous system to date, but there remains a risk of unanticipated side effects including mutagenesis. Further, it is not clear how current approaches directed at the dopamine system, even if successful, will address the nondopaminergic features of the illness.

MANAGEMENT OF NONMOTOR AND NONDOPAMINERGIC FEATURES OF PD

Although PD treatment has primarily focused on the dopaminergic features of the illness, management of the nondopaminergic features should not be ignored. Some nonmotor features benefit from dopaminergic drugs. For example, problems such as anxiety, panic attacks, depression, pain, sweating, sensory problems, freezing, and constipation all tend to be worse during "off" periods and have been reported to improve with better dopaminergic control. Recent studies with light therapy suggest that exposure to the specific light frequencies can restore a more normal circadian rhythm (which is altered in PD) and provide both motor and nonmotor benefits, particularly with respect to sleep and mood.

Approximately 50% of PD patients suffer depression during the course of the disease, and depression is frequently underdiagnosed and undertreated. Antidepressants should not be withheld, particularly for patients with major depression, although dopaminergic agents such as pramipexole may prove helpful for treating both depression and PD motor features. Anxiety is also a common problem, and if not adequately controlled with antiparkinsonian therapies, it can be treated with short-acting benzodiazepines.

Psychosis can be a problem for some PD patients and is often a harbinger of developing dementia. In contrast to AD, hallucinations in PD patients are typically visual, formed, and nonthreatening. Importantly, they can be associated with the use of dopaminergic drugs and may limit the use of these agents required for satisfactory motor control. Initial management is to withdraw agents that are less effective than levodopa, such as anticholinergics, amantadine, and dopamine agonists, followed by lowering the dose of levodopa if possible. Psychosis in PD often responds to low doses of atypical neuroleptics and may permit higher doses of levodopa to be tolerated. Clozapine is an effective drug, but it can be associated with agranulocytosis, and regular monitoring is required. Quetiapine avoids these problems, but it has not been established to be effective in placebo-controlled trials. Pimavanserin (Nuplazid) differs from other atypical neuroleptics in that it is an inverse agonist and antagonist of the serotonin 5-HT_{2A} receptor. It has been shown to be effective in short-term double-blind trials but has only mild efficacy (although it can be very effective in individual patients) and has been reported to be associated with QT prolongation and death in elderly patients.

Dementia in PD (PDD) is common, ultimately affecting as many as 80% of patients. Its frequency increases with aging and, in contrast to AD, primarily affects executive functions and attention, with relative sparing of language, memory, and calculation domains. When dementia precedes or develops within 1 year after onset of motor dysfunction, it is by convention referred to as dementia with Lewy bodies (DLB; **Chap. 445**). Interestingly, if dementia develops in a PD patient after 12 months, it is referred to as PD dementia, although it is not clear that these represent different disease entities. These patients are particularly prone to experience hallucinations and diurnal fluctuations. Pathologically, DLB is characterized by Lewy bodies distributed throughout the cerebral cortex (especially the hippocampus and amygdala) and is more likely to be associated with AD pathology. It is notable that variants of the *GBA1* gene are a significant risk factor for both PD and DLB. Mild cognitive impairment (MCI) frequently precedes the onset of dementia and is a more reliable index of impending dementia than in the general population as it occurs in the setting of a neurodegenerative disorder. Indeed, many PD patients demonstrate abnormalities in cognitive testing even at the earliest stages of the disease despite having no overt clinical dysfunction. Drugs used to treat PD can worsen cognitive function and should be stopped or reduced to try and provide a compromise between antiparkinsonian benefit and preserved cognitive function. Drugs are usually discontinued in the following sequence: anticholinergics, amantadine, dopamine agonists, COMT inhibitors, and MAO-B inhibitors. Eventually, patients with cognitive impairment should be managed with the lowest dose of standard levodopa that provides meaningful antiparkinsonian effects and does not worsen mental function. Anticholinesterase agents such as memantine and cholinesterase inhibitors such as rivastigmine improve measures of cognitive function and can improve attention in PD, but do not improve cognition or quality of life in any meaningful way. More effective therapies that treat or prevent dementia are a critical unmet need in the therapy of PD.

Autonomic disturbances are common and frequently require attention. Orthostatic hypotension can be problematic and contribute to falling. Initial treatment should include adding salt to the diet and elevating the head of the bed to prevent overnight sodium natriuresis. Low doses of fludrocortisone (Florinef) or midodrine provide control for most cases. The norepinephrine precursor 3-0-methylDOPS (Droxidopa) has been shown to provide mild but transient benefits for patients with orthostatic hypotension. Vasopressin and erythropoietin can be used in more severe or refractory cases. If orthostatic hypotension is prominent in early parkinsonian cases, a diagnosis of MSA should be considered **(Chap. 451)**. Sexual dysfunction may be helped with sildenafil or tadalafil. Urinary problems, especially in males, should be treated in consultation with a urologist to exclude prostate problems. Anticholinergic agents, such as oxybutynin (Ditropan), may be helpful. Constipation can be a very important problem for PD patients. Mild laxatives or enemas can be useful, but physicians should first ensure that patients are drinking adequate amounts of fluid and consuming a diet rich in bulk with green leafy vegetables and bran. Agents that promote GI motility can also be helpful. Several studies are evaluating the effect on constipation of agents that interfere with inflammation and α-synuclein misfolding in the GI tract.

Sleep disturbances are common in PD patients, with many experiencing fragmented sleep with excess daytime sleepiness. These can be severe and result in sudden-onset sleep episodes that may occur in dangerous situations such as while driving a car. These problems tend to be exaggerated by dopamine agonists, particularly in high doses. These problems may relate to alterations in circadian rhythm associated with degeneration in melanopsin-containing neurons in the retina and cells of the suprachiasmatic nucleus, which occur in PD patients. Recent studies suggest that both motor and nonmotor features may be improved with light therapy using specific wavelengths that restore circadian rhythm in PD patients.

Restless leg syndrome, sleep apnea, and other sleep disorders also occur with increased frequency in PD and should be treated as appropriate. REM behavior disorder (RBD) is a syndrome composed of violent movements and vocalizations during REM sleep, possibly representing acting out of dreams due to a failure of motor

inhibition that typically accompanies REM sleep **(Chap. 33)**. Many PD patients have a history of RBD preceding the onset of the classic motor features of PD by many years, and most cases of RBD eventually go on to develop an α-synucleinopathy (PD or MSA). Low doses of clonazepam (0.5–1 mg at bedtime) are usually effective in controlling this problem. Consultation with a sleep specialist and polysomnography may be necessary to identify and optimally treat sleep problems. Excess daytime sleepiness can be problematic for PD patients, and therapies such as sodium oxybate (Xyrem) that are effective in narcolepsy are currently being evaluated in PD

NONPHARMACOLOGIC THERAPY

Gait dysfunction with falling is an important cause of disability in PD. Dopaminergic therapies may be of help for patients whose gait is worse in "off" time, but there are currently no specific therapies for gait dysfunction. Canes and walkers may become necessary to increase stability and reduce the risk of falling. An effective therapy for gait impairment is an important unmet need in PD.

Freezing, where patients suddenly become stuck in place for seconds to minutes as if their feet were glued to the ground, is another important problem and a major cause of falling. Freezing may occur during "on" or "off" periods. Freezing during "off" periods may respond to dopaminergic therapies, but there are no specific treatments for "on" period freezing and the mechanism is not well understood. Some patients will respond to sensory cues such as marching in place, singing a song, or stepping over an imaginary line or obstacle.

Speech impairment is another source of disability for many advanced PD patients. Speech therapy programs may be helpful, but benefits are generally limited and transient.

Exercise has been shown to help maintain and even improve function for PD patients, and active and passive exercises with full range of motion reduce the risk of arthritis and frozen joints. Some laboratory studies suggest the possibility that exercise might also have neuroprotective effects, but this has not been confirmed in PD patients. Exercise is generally recommended for all PD patients. It is less clear that any specific type of physical therapy or exercise program, such as tai chi or dance, offers any specific advantage. It is important for patients to maintain social and intellectual activities to the extent possible. Education, assistance with financial planning, social services, and attention to home safety are important elements of the overall care plan. Information is available through numerous PD foundations and on the web but should be reviewed with physicians to ensure accuracy. The needs of the caregiver should not be neglected. Caring for a person with PD involves a substantial work effort, and there is an increased incidence of depression among caregivers. Support groups for patients and caregivers may be useful.

CURRENT MANAGEMENT OF PD

The management of PD should be tailored to the needs of the individual patient, and there is no single treatment approach that is universally accepted and applicable to all individuals. Clearly, if an agent could be demonstrated to have disease-modifying effects, it should be initiated at the time of diagnosis or even in the premotor stage once that can be diagnosed with confidence. Recent studies suggest that striatal dopamine terminal degeneration may be complete within 4 years of diagnosis and thus limit the potential benefit of a therapy started after that time, even if it has been shown to have protective effects. Epidemiologic and pathologic studies suggest that constipation, RBD, and anosmia may represent premotor features of PD and, along with imaging of the dopamine system and biomarkers (see above), could permit diagnosis and the initiation of a disease-modifying therapy prior to the onset of the classical motor features of the disease. However, no therapy has yet been conclusively proven to be a disease-modifying agent, although as noted above, rasagiline 1 mg/d met all three prespecified primary endpoints consistent with such a benefit. For now, physicians must use their judgment in deciding whether or not to introduce a drug such as rasagiline for its possible disease-modifying effects based on available preclinical and clinical information.

The next important issue to address is when to initiate symptomatic therapy and which agent to use. Several studies suggest that it may be best to start therapy at the time of diagnosis in order to preserve beneficial compensatory mechanisms and possibly provide functional benefits with improved quality of life even in the early stage of the disease. Levodopa remains the most effective symptomatic therapy for PD, and the American Academy of Neurology recommends starting it immediately using low doses (≤400 mg/d), as motor complications have now clearly been shown to be dose-related. Other experts, however, prefer to delay introduction of levodopa treatment, particularly in younger patients, in order to reduce the risk of inducing motor complications. An alternate approach is to begin with am MAO-B inhibitor and/or a dopamine agonist and reserve levodopa for later stages when these drugs no longer provide satisfactory control. In making this decision, the patient's age, degree of disability, and the side effect profile of the drug must all be considered. In patients with more severe disability, the elderly, and those with cognitive impairment, significant comorbidities, or uncertain diagnosis, most physicians would initiate therapy with levodopa. A new pill that combines very low doses of rasagiline and pramipexole in extended-release formulations has been developed that provides clinical benefits comparable to high-dose pramipexole in higher doses but without sleep-related and dopaminergic side effects. As such, it could represent an alternative to levodopa as initial therapy for PD.

Regardless of initial choice, most patients ultimately benefit from polypharmacy (a combination of levodopa, an MAO-B inhibitor, and a dopamine agonist) in order to minimize the total daily levodopa dose and reduce the risk of motor complications. While it is important to use low doses of each agent to reduce the risk of side effects, patients should not be denied levodopa when they cannot be adequately controlled with alternative medications. It is also important to discuss the risks and benefits of the different therapeutic options with patients so that they have informed opinions as to whether they wish to start therapy early and, if so, which drug to start.

If motor complications develop, patients can initially be treated by adjusting the frequency and dose of levodopa or by combining lower doses of levodopa with a dopamine agonist, a COMT inhibitor, or an MAO-B inhibitor. An $A2_A$ antagonist such as istradefylline is an additional therapy that can be used for treating off periods. Amantadine is the only drug that has been demonstrated to treat dyskinesia without worsening parkinsonism, but benefits may decline over time and there are important side effects related to cognitive function particularly with higher doses. On-demand therapies such as subcutaneous apomorphine, inhaled levodopa, and sublingual apomorphine can be used to treat individual off periods and can delay the need for surgery in some patients. In advanced cases where patients suffer motor complications that cannot be adequately controlled with medical therapies, it may be necessary to consider a surgical procedure such as DBS or a continuous dopaminergic therapy such as Duodopa or subcutaneous infusion of levodopa or apomorphine, but as described above, these procedures have their own set of complications. The use of DBS in early PD patients has been advocated by some, but there is considerable skepticism about this approach considering the costs and potential side effects, when inexpensive, well-tolerated, and effective medical alternatives are available. Continuous intraintestinal infusion of levodopa/carbidopa intestinal gel (Duodopa) offers similar benefits to DBS, but also requires a surgical intervention with potentially serious complications. Continuous subcutaneous infusion of levodopa or apomorphine does not require surgery but is associated with potentially troublesome skin nodules and abscesses and requires wearing an inconvenient infusion pump during the course of the day and potentially around the clock. Comparative studies of these approaches are awaited. There are ongoing efforts aimed at developing a long-acting formulation of levodopa that mirrors the pharmacokinetic properties of a levodopa infusion. Such a formulation might provide all of the benefits of levodopa without motor

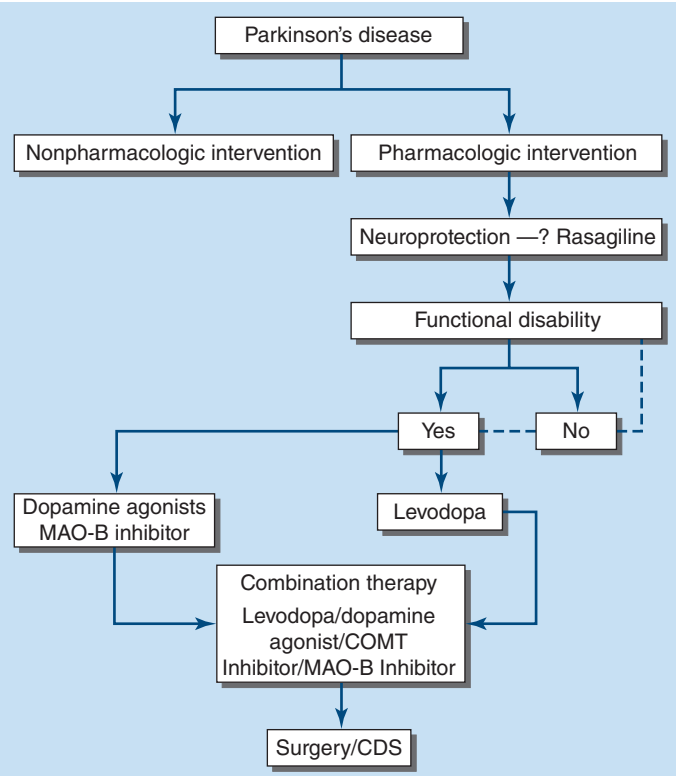

FIGURE 446-7 Treatment options for the management of Parkinson's disease (PD). Decision points include: (1) Introduction of a neuroprotective therapy: no drug has been established to have or is currently approved for neuroprotection or disease modification, but there are several agents that have this potential based on laboratory and preliminary clinical studies (e.g., rasagiline 1 mg/d). (2) When to initiate symptomatic therapy: There is a trend toward initiating therapy at the time of diagnosis or early in the course of the disease because patients may have some disability even at an early stage, and there is the possibility that early treatment may preserve beneficial compensatory mechanisms; however, some experts recommend waiting until there is functional disability before initiating therapy. (3) What therapy to initiate: many experts favor starting with low doses of levodopa particularly in the elderly and those with more advanced disease. A monoamine oxidase type B (MAO-B) inhibitor may be preferred in mildly affected patients because of their good safety profile and the potential for a disease-modifying effect. Some prefer dopamine agonists for younger patients with functionally significant disability as they have a reduced risk of inducing motor complications. All patients eventually require levodopa, but it is generally recommended to employ polypharmacy using low doses of multiple drugs to avoid side effects associated with high doses of any one agent and minimize the risks of levodopa-induced motor complications. (4) Management of motor complications: motor complications are typically approached with combination therapy to try and reduce dyskinesia and enhance the "on" time. When medical therapies cannot provide satisfactory control, surgical therapies such as deep brain stimulation (DBS) or continuous infusion of levodopa/carbidopa or apomorphine can be considered. (5) Nonpharmacologic approaches: interventions such as exercise, education, and support should be considered throughout the course of the disease. CDS, continuous dopaminergic stimulation; COMT, catechol-*O*-methyltransferase. *(Reproduced with permission CW Olanow et al: Neurology 72:S1, 2009.)*

complications and avoid the need for polypharmacy and surgical intervention. Treatment for the nonmotor features of PD should be instituted as deemed appropriate, and exercise therapy is recommended for all patients.

A decision tree that considers the various treatment options and decision points for the management of PD is provided in **Fig. 446-7**.

447 Tremor, Chorea, and Other Movement Disorders

C. Warren Olanow*, Christine Klein

HYPERKINETIC MOVEMENT DISORDERS

Hyperkinetic movement disorders are characterized by involuntary movements unaccompanied by weakness. The major clinical features are summarized in **Table 447-1**. The term is somewhat arbitrary and potentially misleading as hypokinetic disorders such as Parkinson's disease (PD) are often accompanied by tremor, while hyperkinetic disorders such as dystonia may be manifest as slow or restricted movement because of severe muscle contractions. Nonetheless, the terms continue to be used by convention. The major hyperkinetic movement disorders and the diseases with which they are associated are considered in this section.

TREMOR

CLINICAL FEATURES

Tremor is defined as an involuntary, rhythmic, oscillatory movement of a body part with alternating contraction of agonist and antagonist muscles. It can be most prominent at rest (rest tremor), on assuming a posture (postural tremor), on actively reaching for a target (kinetic or intention tremor), or on carrying out a movement (action tremor). Tremor may also be characterized based on its distribution, frequency, amplitude, and related neurologic dysfunction. Tremor is classified along two axes: Axis 1 covers the clinical characteristics and historical features (age at onset, family history, temporal evolution), tremor characteristics (body distribution, activation condition), associated signs (systemic, neurologic), and laboratory tests (electrophysiology, imaging). Axis 2 relates to the etiology of the tremor and distinguishes genetic, secondary, or idiopathic origins.

Essential tremor (ET) is characterized by a tremor that typically occurs while trying to sustain a posture and/or an action tremor that is noted when reaching toward a target. This contrasts with the resting tremor of PD **(Chap. 446)**, which is characterized by a predominant resting tremor and is less pronounced with action. Cerebellar dysfunction is characterized by a kinetic tremor (brought out by trying to touch an object) and is usually associated with hypotonia and past pointing. Healthy individuals can have a physiologic tremor that typically manifests as a mild, high-frequency (10–12 Hz), postural, or

*Deceased.

TABLE 447-1 Hyperkinetic Movement Disorders	
Tremor	Rhythmic oscillation of a body part due to intermittent muscle contractions
Dystonia	Involuntary, patterned, sustained, or repeated muscle contractions often associated with twisting movements and abnormal posture
Athetosis	Slow, distal, writhing, involuntary movements with a propensity to affect the arms and hands (this represents a form of dystonia with increased mobility)
Chorea	Rapid, semi-purposeful, graceful, dance-like nonpatterned involuntary movements involving distal or proximal muscle groups. When the movements are of large amplitude and predominant proximal distribution, the term *ballism* is used.
Myoclonus	Sudden, brief (<100 ms), jerk-like, arrhythmic muscle twitches
Tic	Brief, repeated, stereotyped muscle contractions that can often be suppressed for a short time. These can be simple and involve a single muscle group or complex and affect a range of motor activities.

action tremor typically affecting the upper extremities. This tremor is usually of no clinical consequence and often is only appreciated with an accelerometer or under stress. An enhanced physiologic tremor (EPT) can be seen in up to 10% of the population and tends to occur in association with lifting a weight, anxiety, fatigue, a metabolic disturbance (e.g., hyperthyroidism, electrolyte abnormalities), drugs (e.g., valproate, lithium), or toxins (e.g., caffeine, smoking, alcohol). Treatment is initially directed at control of any underlying disorder, and if necessary, it can often be improved with a beta blocker.

ESSENTIAL TREMOR

ET is the most common movement disorder, affecting ~1% of the population and 5% of those over 60 years (an estimated 5–10 million persons in the United States or Western Europe). It can present in childhood but dramatically increases in prevalence in those aged >70 years. ET is characterized by a high-frequency tremor (6–10 Hz) that predominantly affects the upper extremities. The tremor is most often manifest as a postural or action tremor and, in severe cases, can interfere with functions such as eating and drinking. It is typically bilateral and symmetric but may begin on one side and remain asymmetric. Patients with severe ET can have an intention tremor with overshoot and slowness of movement, along with mild ataxia, suggesting the possibility of a cerebellar origin. Tremor involves the head in ~30% of cases, voice in ~20%, tongue in ~20%, face/jaw in ~10%, and lower limbs in ~10%. Multiple body parts are involved in ~50% of cases. The tremor is characteristically improved by alcohol and worsened by stress. Usually, the neurologic examination is normal aside from tremor, but subtle impairment of coordination or tandem walking may be present, and disturbances of hearing, cognition, personality, mood, and olfaction have been described. The differential diagnosis includes dystonic tremor (see below) or PD. PD can usually be differentiated from ET because the former tends to be present primarily at rest and to be suppressed by a voluntary action. Further, PD is typically associated with bradykinesia with progressive slowing of sequential movements (sequence effect), rigidity, gait, postural instability, and other parkinsonian features. However, the examiner should be aware that PD patients may have a postural tremor and ET patients may develop a rest tremor, but these typically only begin after a latency of a few seconds (emergent tremor). In contrast to the micrographia of PD, ET patients have relatively large handwriting with evidence of tremor in writing samples. The examiner must be careful to identify tremor when assessing tone in order to distinguish the interruption of movement associated with tremor from the cogwheel rigidity found in PD.

ETIOLOGY AND PATHOPHYSIOLOGY

The etiology and pathophysiology of ET are not known. Approximately 50% of ET patients have a positive family history with an autosomal dominant pattern of inheritance. Linkage studies have detected possible loci in large ET families. Expansion of a GGC repeat in the human-specific *NOTCH2NLC* gene has been found to be associated with ET, but no independently confirmed causative gene has been identified to date. It is likely that there are several as yet undiscovered genes underlying ET that have thus far escaped detection because of the heterogeneity of the syndrome and the high frequency of ET in the population, likely resulting in a large number of phenocopies (i.e., family members with a similar clinical syndrome but not carrying the same causative mutation). The cerebellum and inferior olives have been implicated as possible sites of an altered "tremor pacemaker" based on the presence of cerebellar signs in ~10% of ET patients, as well as increased metabolic activity and blood flow in these regions in some patients. Some pathologic studies have described cerebellar pathology with a loss of Purkinje cells and axonal torpedoes, suggesting a neurodegenerative disease, but these findings remain controversial, and the precise pathologic correlate of ET remains to be defined. Interest has also focused on the possibility that ET is caused by degeneration of GABAergic cerebellar neurons with defects in neurotransmission. It is likely that multiple causes of ET will ultimately be identified.

TREATMENT

Many cases are mild, do not cause any functional impairment, and require no treatment other than reassurance. Occasionally, tremor can be severe and interfere with eating, writing, and activities of daily living. This is more likely to occur as the patient ages and is often associated with a reduction in tremor frequency. Beta blockers and primidone are the standard drug therapies for ET and are useful in ~50% of cases. Propranolol (20–120 mg daily, given in divided doses) is usually effective at relatively low doses, but higher doses may be needed in some patients. The drug is contraindicated in patients with bradycardia or asthma. Hand tremor tends to be most improved, while head tremor is often refractory. Primidone can be helpful but should be started at low doses (12.5 mg) and gradually increased as necessary (125–250 mg three times daily) to avoid sedation, nausea, and dizziness. Benefits have also been reported with gabapentin and topiramate, but these drugs have not been widely employed. Botulinum toxin injections may be helpful for limb or voice tremor, but treatment can be associated with muscle weakness. Surgical therapies targeting the ventro-intermediate (VIM) nucleus of the thalamus can be very effective for severe and drug-resistant cases. More recently, focal ultrasound (a procedure that does not require surgery) has also been shown to be an effective therapy against tremor in some cases of ET.

DYSTONIA

CLINICAL FEATURES

Dystonia is a movement disorder characterized by sustained or intermittent synchronous muscle contractions of agonist and antagonist muscles causing abnormal, often repetitive, painful movements and postures. Dystonic movements are typically patterned and twisting and may be associated with a "dystonic" tremor. This tremor can usually be distinguished from ET as the tremor is most pronounced when the body part is moved in the direction of the dystonia and relieved when the body part is moved in the direction opposite to the dystonia. Dystonia can range from minor contractions affecting only an individual muscle group (focal) to severe and disabling contractions with involvement of multiple muscle groups (i.e., multifocal, segmental, or generalized). Nonmotor features such as pain, depression, anxiety, and impaired sleep can be associated with, or even precede onset of, the dystonia. The frequency of dystonia is estimated to be about 30 per 100,000 but is likely to be higher because many cases are not recognized or correctly diagnosed. Dystonia is often brought out by voluntary movements (action dystonia) and can extend to involve other muscle groups and body regions not required for the intended action (overflow contractions). Dystonia can be aggravated by stress and fatigue and attenuated by relaxation and sensory tricks such as touching the affected body part (geste antagoniste).

Historically, dystonia has been described as primary or secondary. However, because of a confusing and not always congruent combination of phenotypic and etiologic features, the older terms are no longer

TABLE 447-2 Monogenic Forms of Isolated and Combined Dystonia

FORM OF DYSTONIA		GENE	DESIGNATION AND PHENOTYPIC SUBGROUP	ADDITIONAL DISTINGUISHING FEATURES	MODE OF INHERITANCE
Isolated[a]		*TOR1A*	DYT-TOR1A	Childhood or adolescent onset, generalized	AD
		KMT2B	DYT-KMT2B	Early onset, generalized, mild syndromic features	AD
		THAP1	DYT-THAP1	Adolescent onset, cranial or generalized	AD
		ANO3	DYT-ANO3	Adult onset, focal or segmental	AD
		GNAL	DYT-GNAL	Mostly adult onset, focal or segmental	AD
		VPS16	DYT-VPS16	Frequent cervical and laryngeal dystonia	AD or AR
		EIF2AK2	DYT-EIF2AK2	Childhood or adolescent onset, focal to generalized	AD or AR
		PRKRA	DYT-PRKRA	Generalized	AR
		HPCA	DYT-HPCA	Childhood onset	AR
		AOPEP	DYT-AOPEP	Frequent cervical and laryngeal dystonia	AR
Combined[b]	**Dystonia plus parkinsonism**	*GCH1*	DYT-GCH1	Dopa-responsive	AD
		TAF1	DYT-TAF1	Neurodegeneration	XL
		ATP1A3	DYT-ATP1A3	Rapid onset	AD
	Dystonia plus myoclonus	*SGCE*	DYT-SGCE	Alcohol responsive	AD
		KCTD17	DYT-KCTD17	Childhood onset	AD

[a] *KMT2B* pathogenic variants may present with mild syndromic features. [b] Selected examples.

Abbreviations: AD, autosomal dominant; AR, autosomal recessive; XL, X-linked.

recommended. A Movement Disorder Society Task Force recommended classifying dystonia along the same axes as ET: clinical and etiologic. On clinical grounds, dystonia can be categorized by age of onset (infancy, childhood, adolescence, early and late adulthood), body distribution (focal, segmental, multifocal, and generalized), temporal pattern (static or progressive, action-specific [diurnal and paroxysmal]), and association with additional features. Clinical description along these lines enables formulating specific dystonia syndromes (e.g., early-onset generalized isolated dystonia). From an etiologic point of view, dystonia primarily reflects genetic abnormalities, although occasionally it may be secondary to other causes, such as trauma and stroke. Genetic features used for classification include mode of inheritance or identification of a specific pathogenic gene variant. More than 200 genes have been linked to different types of dystonia, primarily childhood-onset and generalized forms. These include forms in which dystonia is the only disease manifestation with the exception of tremor ("isolated dystonia") and forms in which dystonia co-occurs with another movement disorder such as parkinsonism, myoclonus, or other neurologic and/or nonneurologic manifestations ("combined dystonia") and may not even be the dominant clinical feature. This group represents the most heterogeneous class in terms of clinical expression. A list of confirmed monogenic mutations associated with isolated or combined dystonias is provided in Table 447-2.

ISOLATED DYSTONIAS

Focal, Multifocal, and Segmental Dystonia Adult-onset, focal dystonia is by far the most frequent form of isolated dystonia. Women are affected about twice as often as men, with the exception of writer's cramp, which occurs more frequently in men than in women. Focal dystonia typically presents in the fourth to sixth decade. The major clinical phenotypes are: (1) *Cervical dystonia*—dystonic contractions of neck muscles causing the head to deviate to one side (*laterocollis*), twist (*torticollis*), move in a forward direction (*anterocollis*), or move in a backward direction (*retrocollis*). Muscle contractions can be painful and occasionally can be complicated by a secondary cervical radiculopathy and even myelopathy. (2) *Blepharospasm*—dystonic contraction of the eyelids resulting in increased blinking and eye closure that can interfere with reading, watching television, working on a computer, and driving. This can sometimes be so severe as to cause functional blindness. (3) *Oromandibular dystonia* (OMD)—contractions of muscles of the lower face, lips, tongue, and jaw (opening or closing). Meige's syndrome is a combination of OMD and blepharospasm that predominantly affects women aged >60 years. (4) *Spasmodic dysphonia*—dystonic contractions of the vocal cords during phonation, causing impaired speech. Most cases affect the adductor muscles and cause speech to have a choking or strained quality. Less commonly, the abductors are affected, leading to speech with a breathy or whispering quality. (5) *Limb dystonias*—these can be present in either arms or legs and are often brought out by task-specific activities such as handwriting (writer's cramp), playing a musical instrument (musician's cramp), or putting in golf (the yips). The vast majority of patients with focal dystonia have cervical dystonia (~40%) or blepharospasm (~15%). Focal hand or leg dystonia (~10%), musician's dystonia (~3%), spasmodic dysphonia (~2%), and OMD (~1%) are much less common. Focal dystonias can extend to involve other body regions (~30% of cases) and are frequently misdiagnosed as psychiatric or orthopedic in origin. Their cause is usually not known. They are rarely monogenic (~1%); autoimmunity and trauma have been suggested as other possible etiologies. Focal dystonias are often associated with a high-frequency tremor that can resemble ET. Dystonic tremor can usually be distinguished from ET because it tends to occur in the direction of the dystonic contraction and disappears when the dystonia is relieved (i.e., turning the head in the opposite direction of the dystonia).

Generalized Dystonia Generalized dystonia is often hereditary and, unlike focal dystonia, typically has an age of onset in childhood or adolescence. There are currently at least 10 well-established genes that, when mutated, can cause mostly isolated, segmental or generalized dystonia: *ANO3, AOPEP, EIF2AK2, GNAL, HPCA, KMT2B, PRKRA, THAP1, TOR1A,* and *VPS16*. The *AOPEP, HPCA*, and *PRKRA* pathogenic mutations are recessively inherited, while others (e.g., *EIF2AK2* and *VPS16*) can be either dominantly or recessively inherited. According to the recommendations of the International Parkinson's Disease and Movement Disorder Society, monogenic forms of dystonia are classified according to the absence or presence of accompanying additional clinical features and preceded by a "DYT" prefix, e.g., DYT-TOR1A.

Mutations in the *TOR1A* gene (torsin family 1 member A—formerly known as the *DYT1* gene) are the most common cause of early-onset generalized dystonia. The first, and currently the only, clearly established mutation is a 3-base pair deletion in the *TOR1A* gene. The mutation is frequently found among Ashkenazi Jewish patients due to a founder effect. Mutation carriers usually present with dystonia in an extremity in childhood that later progresses to affect other body parts, but the face and neck are typically spared. Rare carriers of two mutated alleles have been described and are characterized by a severe neurodevelopmental syndrome and arthrogryposis.

Missense mutations in *KMT2B* (*lysine methyltransferase 2B*) are another relatively frequent cause of early-onset generalized dystonia, which may be accompanied by other syndromic features, including intellectual disability, microcephaly, psychiatric features, dysmorphia, or skin lesions. The majority of the mutations occur de novo. *KMT2B* mutations may account for up to 10% of early-onset generalized dystonia, but further validation is warranted, and placement into the group of isolated versus complex dystonias is currently under debate.

Mutations in the *THAP1* gene (*THAP domain containing apoptosis-associated protein 1*) have been linked to adolescent-onset dystonia with mixed phenotype. About 100 different mutations have been reported in *THAP1*. Mutations typically manifest with dysphonia or writer's cramp beginning in late childhood or adolescence. Over the course of the disease, dystonia can spread to other body parts with prominent craniocervical involvement. While DYT-Tor1A and DYT-KMT2B typically respond well to deep brain stimulation (DBS) of the globus pallidus internus bilaterally, the DBS response is much more variable in carriers of pathogenic variants in the *THAP1* gene.

Mutations in the *ANO3* gene (*anoctamin 3*) were first reported in patients with predominantly craniocervical dystonia with a broad range of ages of onset. While a large number of missense variants can be found in healthy individuals, a pathogenic role of *ANO3* mutations has been confirmed by the description of additional families with dystonia and myoclonic jerks.

Mutations in the *GNAL* gene (*guanine nucleotide-binding protein subunit alpha L*) are a rare cause of cervical or cranial dystonia, with a few patients developing generalized dystonia. The mean age of onset is in the thirties.

Pathogenic variants in the *VPS16* gene can be inherited in a recessive or dominant fashion, with the latter mode of inheritance being more common. Currently, >30 carriers of ~20 different, often truncating, heterozygous pathogenic variants have been described. The median age of onset is 14 years. Dystonia tends to generalize and is typically isolated, although more complex phenotypes have also been described.

Pathogenic missense variants in *EIF2AK2*, coding for the eukaryotic translation initiation factor 2-alpha kinase 2, cause dystonia with a median age at onset of 6 years and onset often in the limbs followed by generalization. There is a recurrent missense variant (p.Gly130Arg) in most patients. The EIF2AK2 protein is one of the kinases responsible for eIF2a phosphorylation and is thus linked to the same pathway as PRKRA.

The vast majority of *PRKRA* mutation carriers develop a generalized dystonia, frequently with laryngeal involvement. Likewise, all patients described to carry *HPCA* mutations are characterized by generalized dystonia with childhood onset.

The median age at onset of carriers of recessively inherited, biallelic, and typically truncating pathogenic variants in the *AOPEP* gene is 20 years, with frequent onset in the hands. Most patients progress to isolated, generalized dystonia.

COMBINED DYSTONIAS

A number of other well-established genes have been described that are associated with combined forms of dystonia in which dystonia occurs in conjunction with a different movement disorder (e.g., parkinsonism or myoclonus) or with other neurologic and/or nonneurologic features.

Dopa-responsive dystonia (DRD; also known as Segawa syndrome) is caused by mutations in the *GCH1* gene (*GTP cyclohydrolase-1*) that encodes for the rate-limiting enzyme in the biosynthesis of dopamine via the biopterin pathway. It manifests as a childhood-onset form of dystonia with diurnal fluctuations, and it is important to recognize as the condition dramatically responds to low doses of levodopa. Parkinsonism can be a major or even the only finding, and there may be a presynaptic dopaminergic deficit as evidenced by single-photon emission computed tomography. Younger patients are frequently misdiagnosed as having cerebral palsy, mistaking dystonia for spasticity, and it is important that young-onset forms of dystonia should be tested with levodopa to exclude the possibility of DRD. To date, >100 different mutations have been reported with a penetrance of ~50% and incidence considerably higher in women compared to men. Recessively inherited (biallelic) mutations in *GCH1* result in a much more severe clinical phenotype with developmental delay and infantile onset. Due to the enzymatic defect in the levodopa biosynthesis, there is a lifelong and dramatic response to levodopa therapy. Importantly, since dopamine terminals do not degenerate and the dopamine neuronal network is anatomically preserved, fluctuations in dopamine levels can be avoided, and accordingly, these patients do not develop dyskinesia with chronic levodopa treatment.

X-linked dystonia-parkinsonism (Lubag) presents with a combined form of dystonia and parkinsonism that is found exclusively in patients of Filipino origin due to a founder effect that seems to be fully penetrant. The typical presentation is a focal (cranial) dystonia that rapidly generalizes and, after 5–10 years, is gradually replaced by a form of L-dopa-unresponsive parkinsonism. A retrotransposon insertion in the *TAF1* (*TATA-box binding protein associated factor 1*) gene is the cause of the disease. Sixty-five percent of the age-at-onset variability is explained by the variable length of a hexameric repeat expansion within the retrotransposon and genotypes at three single-nucleotide polymorphisms in the *MSH3* and *PMS1* genes acting as age-at-onset modifiers.

Mutations in the *ATP1A3* (*ATPase Na^+/K^+ transporting subunit alpha 3*) gene present with a characteristic, sudden-onset dystonia, usually in adolescence or young adulthood, often triggered by high fever, physical exertion, or emotional stress. Dystonic symptoms frequently show a rostrocaudal gradient with a strong involvement of the bulbar region, often accompanied by parkinsonian features such as bradykinesia. In addition, mutations in *ATP1A3* have been linked to a variety of clinical syndromes (pleiotropy), including epileptic or hemiplegic attacks, ataxia, cognitive decline, and other neurologic disorders, often with a more severe course and an earlier age at onset.

Myoclonic-dystonia is characterized by action-induced, alcohol-responsive myoclonic jerks predominantly involving the upper body half. Onset is usually in childhood or adolescence. Many individuals also develop psychiatric features such as depression, anxiety-related disorders, and alcohol dependence. The disorder is primarily related to mutations in the *SGCE* gene (*sarcoglycan epsilon*), which codes for the ε member of the sarcoglycan family. About 80 different mutations have been reported in *SGCE,* including deletions of the entire gene. The latter type of mutation often also involves loss of adjacent genes, leading to additional clinical features such as joint problems. *SGCE* mutations are incompletely penetrant and only manifest when inherited from the father due to the epigenetic effect of maternal imprinting of *SGCE*. *KCTD17* mutations are another recently identified cause of myoclonus-dystonia.

A number of additional monogenic causes have been suggested for isolated and combined forms of dystonia but still await independent confirmation. Table 447-2 provides a list of the confirmed monogenic forms of isolated and combined dystonias.

Diagnostic Considerations In the largest group of combined dystonias, dystonia is a part of a more complex syndrome that is characterized by multiple different clinical manifestations of the disease. Most frequently, they are hereditary, such as Wilson's disease (WD), Lesch-Nyhan syndrome, corticobasal ganglionic disorders, and a variety of other neurologic, neurometabolic, neurodevelopmental, and mitochondrial disorders. Dystonia may also develop as a consequence of drugs or toxins. Drug-induced dystonia may be acute or chronic and is most commonly seen with neuroleptic drugs or after chronic levodopa treatment in PD patients. Dystonia can also be observed following discrete lesions in the striatum (e.g., caudate/putamen) and occasionally in the globus pallidus, thalamus, cortex, or brainstem due to infarction, hemorrhage anoxia, trauma, tumor, infection, or toxins such as manganese or carbon monoxide. In these cases, dystonia often assumes a segmental distribution but may be generalized when lesions are bilateral or widespread. More rarely, dystonia can develop following peripheral nerve injury and be associated with features of complex regional pain syndrome **(Chap. 19)**. A psychogenic origin is responsible for some cases of dystonia; these typically present with fixed, immobile dystonic postures (see below).

PATHOPHYSIOLOGY OF DYSTONIA

Even in cases with a known dystonia gene mutation, the pathophysiologic basis of dystonia is not completely known. Physiologically, dystonia is characterized by co-contracting synchronous bursts of agonist and antagonist muscle groups with recruitment of muscle groups that are not required for a given movement (overflow). Dystonia is characterized by derangement of the basic physiologic principle of action selection, leading to abnormal recruitment of inappropriate muscles for a given action with inadequate inhibition of this undesired motor activity. Loss of surround inhibition is observed at multiple levels of the motor system (e.g., cortex, brainstem, spinal cord), accompanied by increased cortical excitability and reorganization. Attention has focused on the basal ganglia as the site of origin of most types of dystonia, as there are alterations in blood flow and metabolism in these structures. Further, lesions of the basal ganglia (particularly the putamen) can induce dystonia, and surgical ablation or DBS of specific regions of the globus pallidus may ameliorate dystonia. The dopamine system has been specifically implicated because dopaminergic therapies can both induce and treat some forms of dystonia in different circumstances. However, no specific pathology has been consistently identified that underlies dystonia.

TREATMENT

Dystonia

Treatment of acute dystonia should include the immediate withdrawal of any precipitating agent. A variety of drug therapies may be beneficial including diphenhydramine, benztropine, benzodiazepines, or dopamine agonists.

Treatment of chronic dystonia is for the most part symptomatic except in rare cases where correction of a primary underlying condition is possible. WD should be ruled out, particularly in young patients with dystonia. Levodopa should be tried in all cases of childhood-onset dystonia to test for DRD. High-dose anticholinergics (e.g., trihexyphenidyl 20–120 mg/d) may be beneficial in children, but adults can rarely tolerate high doses because of side effects related to cognitive impairment and hallucinations. Oral baclofen (20–120 mg) may also be helpful, but benefits, if present at all, are usually modest, and side effects of sedation, weakness, and memory loss can be problematic. Intrathecal infusion of baclofen is more likely to be useful, particularly for leg and trunk dystonia, but benefits are frequently not sustained, and complications can be serious and include infection, seizures, and coma. Tetrabenazine is another consideration; the usual starting dose is 12.5 mg/d and the average treating dose is 25–75 mg/d, but its use may be limited by sedation and the development of parkinsonism. Parkinsonian side effects can be minimized with deuterated tetrabenazine (discussed below). Neuroleptics can both improve and induce dystonia, but they are typically not recommended because of their potential to induce parkinsonism and other movement disorders, including tardive dystonia. Clonazepam and diazepam are sometimes effective.

Botulinum toxin is the preferred treatment for patients with focal and segmental dystonia, particularly where involvement is limited to small muscle groups such as in blepharospasm, torticollis, and spasmodic dysphonia. Botulinum toxin acts by blocking the release of acetylcholine at the neuromuscular junction, leading to reduced dystonic muscle contractions. However, treatment with botulinum toxin can be complicated by excessive weakness that can be troublesome, particularly if injections involve the neck and swallowing muscles. No systemic side effects are encountered with the doses typically used, but benefits are transient, and repeat injections are typically required at 2- to 4-month intervals. Some patients fail to respond after having experienced an initial benefit. This has been attributed to the development of neutralizing antibodies, but improper muscle selection, injection technique, and inadequate dose should be excluded. A new long-acting formulation of botulinum toxin (daxibotulinumtoxinA-l) that provides benefits for up to 6 months has recently been approved in the United States for the treatment of cervical dystonia.

Surgical therapy is a consideration for patients with severe generalized dystonia who are not responsive to other treatments. Peripheral procedures such as rhizotomy and myotomy were used in the past to treat cervical dystonia but are now rarely employed. DBS of the pallidum can provide dramatic benefits for some patients with various forms of hereditary and nonhereditary generalized dystonia. This represents a major therapeutic advance because previously there was no consistently effective therapy, especially for patients with generalized dystonia and severe disability. Benefits tend to be obtained with a lower frequency of stimulation than used in PD or ET and often occur only after a relatively long latency (weeks to months). Better results are typically obtained in younger patients with shorter disease duration and in those with certain monogenic forms, such as DYT-Tor1A. DBS may also be valuable for patients with focal and secondary dystonias, although results are less consistent. Neurophysiologic studies suggest that DBS acts by suppressing theta oscillations in the basal ganglia network that correlate with the dystonia. Adverse effects of DBS in dystonia patients include paresthesia, dysarthria, gait disturbance, and mood change. Dyskinesia can occur with stimulation of the subthalamic nucleus (STN), while bradykinesia and impaired coordination have been reported with stimulation of the globus pallidus pars interna (GPi). Focal ultrasound is being assessed as a possible alternative to surgical therapy. Supportive treatments such as physical therapy and education should be a part of the treatment regimen for all types of dystonia.

Physicians should be aware of dystonic storm, a rare but potentially fatal condition that can occur in response to a stress situation such as a surgical procedure or a systemic infection in patients with preexisting dystonia. It consists of the acute onset of generalized and persistent dystonic contractions that can involve the vocal cords or laryngeal muscles leading to airway obstruction. Patients may experience rhabdomyolysis with renal failure and should be managed in an intensive care unit with airway protection if required. Treatment can be instituted with one or a combination of anticholinergics, diphenhydramine, baclofen, benzodiazepines, and dopaminergic agents. In severe cases, anesthesia with muscle paralysis may be required.

CHOREAS

HUNTINGTON'S DISEASE

Huntington's disease (HD) is a progressive, fatal, highly penetrant autosomal dominant disorder characterized by motor, behavioral, oculomotor, and cognitive dysfunction. The disease is named for George Huntington, a family physician who described cases on Long Island, New York, in the nineteenth century. Onset is typically between the ages of 25 and 45 years (range, 3–70 years) with a prevalence of 2–8 cases per 100,000 and an average age at death of 60 years. It is prevalent in Europe, North America, South America, and Australia but is rare in African blacks and Asians. HD is characterized by rapid, nonpatterned, semi-purposeful, involuntary choreiform movements, and for this reason was formerly referred to as Huntington's chorea. However, dysarthria, gait disturbance, parkinsonism, oculomotor abnormalities, behavioral disturbance, and cognitive impairment with dementia are also common clinical features. Thus, the condition is currently referred to as Huntington's disease. In the early stages, chorea tends to be focal or segmental but progresses over time to involve multiple body regions. With advancing disease, there tends to be a reduction in chorea and the emergence of dystonia, rigidity, bradykinesia, and myoclonus. Functional decline is often predicted by progressive weight loss despite adequate calorie intake. In younger patients (~10% of cases), HD can present as an akinetic-rigid parkinsonian syndrome known as the Westphal variant. Eye movement abnormalities may be an early manifestation of HD. These include slowed and reduced amplitude saccades with intrusions in smooth pursuit movements and impaired convergence. HD patients eventually develop behavioral and cognitive disturbances, and the majority progress to dementia. Depression with suicidal tendencies, aggressive behavior, and psychosis can be prominent features. HD patients may also develop non-insulin-dependent diabetes mellitus

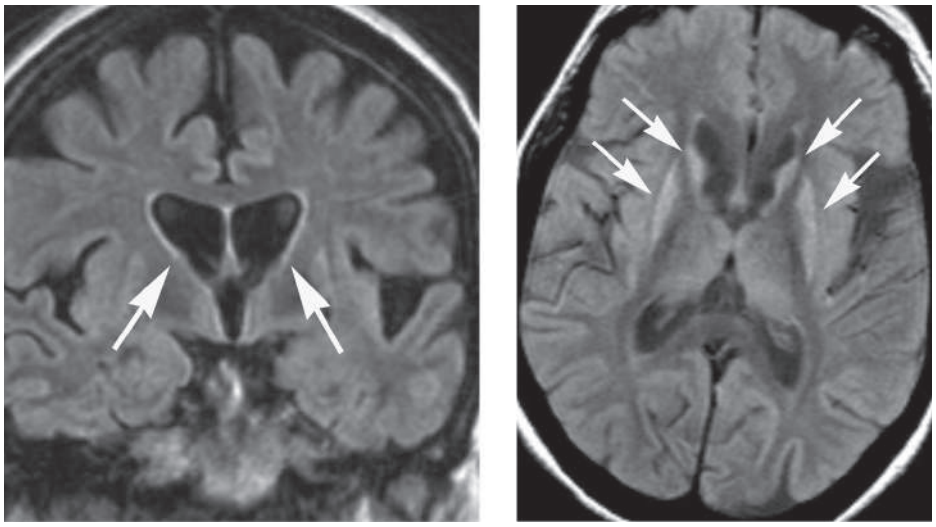

FIGURE 447-1 Huntington's disease. ***A.*** Coronal fluid-attenuated inversion recovery (FLAIR) magnetic resonance imaging shows enlargement of the lateral ventricles reflecting typical atrophy (*arrows*). ***B.*** Axial FLAIR image demonstrates abnormal high signal in the caudate and putamen (*arrows*).

and neuroendocrine abnormalities (e.g., hypothalamic dysfunction). A clinical diagnosis of HD can be strongly suspected in cases of chorea with a positive family history, but genetic testing provides the ultimate confirmation of the diagnosis.

The disease predominantly affects the striatum but progresses to involve the cerebral cortex and other brain regions. Progressive atrophy of the head of the caudate nucleus, which forms the lateral margin of the lateral ventricles, can be readily visualized on magnetic resonance imaging (MRI) **(Fig. 447-1)**, but the putamen can be equally or even more severely affected. More diffuse cortical atrophy can be seen in the middle and late stages of the disease. Supportive studies include reduced metabolic activity in the caudate nucleus and putamen and reduced brain metabolites on magnetic resonance spectroscopy. Genetic testing can be used to confirm the diagnosis and to detect at-risk individuals in the family, but it must be performed in conjunction with trained counselors because advising patients of positive results can worsen depression and even generate suicidal reactions. Indeed, genetic counseling is a requirement in some regions. The neuropathology of HD consists of prominent neuronal loss and gliosis in the caudate nucleus and putamen; similar changes can also be widespread in the cerebral cortex. Intraneuronal inclusions containing aggregates of ubiquitin and the mutant protein huntingtin are found in the nuclei of some affected neurons.

In anticipation of developing neuroprotective therapies, an intensive effort has been made to define the earliest stage of HD. Subtle motor impairment, cognitive alterations, and imaging changes can be detected in at-risk individuals who later develop the manifest form of the disease. Defining the rate of progression of these features is paramount for future studies of putative disease-modifying therapies designed to slow the rate of disease progression and the development of cumulative disability.

ETIOLOGY

HD is caused by a mutation in which there is an increase in the number of polyglutamine (CAG) repeats (>40) in the coding sequence of the *Huntingtin* gene located on the short arm of chromosome 4. The larger the number of repeats, the earlier the disease is manifest. Intermediate forms of the disease with 36–39 repeats are described in some patients, typically with less severe clinical involvement and reduced penetrance (i.e., not every mutation carrier develops the disease). These clinic-genetic observations have recently been incorporated into a new research classification of HD. Carriers of a fully penetrant (>40 repeats) allele are defined as having stage 0 HD, irrespective of their affected status. These developments are meant to facilitate the inclusion of at-risk individuals or those in the earliest disease stages into clinical trials.

Expansion of repeat length tends to occur, particularly in males, with subsequent generations having larger numbers of repeats and earlier age of disease onset, a phenomenon referred to as anticipation. There is also evidence of postnatal somatic gene expansion that occurs over time as well as genetic modifiers of disease progression, for example, in the *FAN1* and *MSH3* genes, the latter overlapping with X-linked dystonia-parkinsonism. New-onset gene expansion in patients with no family history is rare.

The *Huntingtin* gene encodes the highly conserved cytoplasmic protein huntingtin (HTT), which is widely distributed in neurons throughout the central nervous system (CNS). Mutated HTT RNA is toxic and disrupts transcription, impairs immune and mitochondrial function, and is aberrantly modified posttranslationally. Genome-wide association studies have nominated DNA repair pathways as modifiers of somatic instability and disease course in HD. Fragments of the mutant HTT can also be toxic, possibly by translocating into the nucleus and interfering with transcriptional regulation of proteins. Neuronal inclusions found in affected regions in HD may represent a protective mechanism aimed at segregating and facilitating the clearance of these toxic proteins. There is also interest in the possibility that the accumulation and aggregation of toxic proteins in HD, like Alzheimer's disease **(Chap. 442)** and PD **(Chap. 446)**, may be critical to the disease process and reflect a prion-like disorder **(Chap. 449; see also Chap. 435)**. Models of HD with striatal pathology can be induced in multiple transgenic animals that express the mutant gene and by excitotoxic agents such as kainic acid and 3-nitropropionic acid, which promote calcium entry into the cell and cytotoxicity. These relevant animal models can be helpful in assessing potential therapeutic agents. Interestingly, when correcting the neurotransmitter deficit present in HD mice in the very first week of life, disease development can be prevented.

TREATMENT

Huntington's Disease

Although the gene for HD was identified >30 years ago, there is still no disease-modifying therapy for this disorder, and clinically meaningful symptomatic treatment is limited. Current treatment involves a multidisciplinary approach, with medical, neuropsychiatric, and social approaches, as well as genetic counseling for patients and their families. Dopamine-blocking agents such as tetrabenazine and valbenazine have been approved to treat the choreiform movements but can be associated with secondary parkinsonism as an adverse event. Deuterated tetrabenazine (Austedo) and a long-acting version of deuterated tetrabenazine have also been approved as treatments for chorea in HD. Deuteration interferes with the metabolism of

tetrabenazine and avoids the high maximum concentration (C_{max}), which is thought to contribute to adverse effects. In clinical trials, deuterated tetrabenazine has been shown to have fewer dose-related side effects and less parkinsonism than tetrabenazine and, therefore, can be administered in higher doses with potentially superior clinical benefits. Neuroleptics are generally not recommended because of their potential to induce other troubling movement disorders and because HD chorea tends to be self-limited and is usually not disabling. These drugs may be used, however, in patients with severe and disabling chorea. There are currently no therapies approved for treating the more disabling motor features of HD, but large-scale platform studies are ongoing, which are assessing a variety of different therapeutic approaches using a common placebo group. Depression and anxiety can be major problems, and patients should be treated with appropriate antidepressant and antianxiety drugs and monitored for mania and suicidal ideations. Psychosis can be treated with atypical antipsychotics such as clozapine (50–600 mg/d), quetiapine (50–600 mg/d), and risperidone (2–8 mg/d).

A neuroprotective therapy that slows or stops disease progression is the major unmet medical need. Some strategies are designed to reduce the formation or accumulation of mutant HTT. These largely focus on inhibiting mRNA synthesis either by blocking transcription (zinc finger motif protein), preventing posttranscriptional processes, promoting early mRNA degradation (antisense oligonucleotides [ASO]), or inhibiting translation with short interfering RNA. The most advanced of these experimental therapeutic approaches investigated intrathecal administration of an ASO in patients with early HD in a randomized, placebo-controlled, double-blind clinical trial. While a dose-dependent reduction in concentrations of mutant HTT was observed and there were no side effects, the study was terminated early because no clinical benefit was detected. Drugs that enhance mitochondrial function and increase the clearance of defective mitochondria are also being tested as possible disease-modifying therapies. Other investigative approaches include immunotherapy, dietary supplements (resveratrol), lipid-lowering medication (fenofibrate), anaplerotic therapy (triheptanoin), and DBS of the GPi. A promising therapy is the sigma 1 receptor agonist pridopidine. Various clinical trials have suggested that the drug may provide benefit with respect to total motor function and total functional capacity, particularly in patients with relatively mild disease. Double-blind studies are currently underway. Preliminary clinical trials testing cell-based therapies (stem cells and fetal striatal cells) have been initiated, aimed at replacing damaged striatal neurons, but efficacy and safety of these procedures have not yet been determined. Experimentally, there is great interest in the potential of using CRISPR (gene editing) techniques to target and destroy or prevent the formation of mutant *Huntingtin* RNA and to reduce accumulation of the abnormal protein. Numerous other molecular and gene-based approaches are being evaluated to interfere with the formation and promote the clearance of the toxic protein, and many clinical studies are anticipated to begin within the next few years.

HUNTINGTON'S DISEASE–LIKE DISORDERS

A group of rare inherited conditions that can mimic HD, designated HD-like (HDL) disorders, have also been identified. HDL-1, -2, and -4 are autosomal dominant conditions that typically present in adulthood. HDL-3 is recessively inherited, presents in early childhood, and differs markedly from HD and the other HDLs. HDL-1 is due to expansion of an octapeptide repeat in *PRNP*, the gene encoding the prion protein **(Chap. 449)**. Thus, HDL-1 is properly considered a prion disease. Patients exhibit onset of personality change in the third or fourth decade, followed by chorea, rigidity, myoclonus, ataxia, and epilepsy. HDL-2 manifests in the third or fourth decade with a variety of movement disorders, including chorea, dystonia, or parkinsonism, and dementia. Most patients are of African descent. Acanthocytosis can sometimes be seen in these patients, and this condition must be distinguished from neuroacanthocytosis (below). HDL-2 is caused by an abnormally expanded CTG/CAG trinucleotide repeat expansion in the *junctophilin-3* (*JPH3*) gene. The pathology of HDL-2 consists of intranuclear inclusions immunoreactive for ubiquitin and expanded polyglutamine repeats. HDL-4, the most common condition in this group, is caused by expansion of trinucleotide repeats in *TBP*, the gene that encodes the TATA box-binding protein involved in regulating transcription; this condition is identical to spinocerebellar ataxia (SCA) 17 **(Chap. 450)**, and most patients present with ataxia rather than chorea. Like in HD, a certain range of repeat expansions in the *TBP* gene is associated with reduced penetrance, whereby penetrance was recently identified to be full when a variant in the *Stub1* gene is present in conjunction with the repeat expansion. Mutations of the *C9Orf72* gene associated with frontotemporal dementia and amyotrophic lateral sclerosis **(Chaps. 443 and 448)** have also been reported in some individuals with an HDL phenotype.

OTHER CHOREAS

Chorea can be seen in a number of other disorders related to genetic mutations or other disease states.

Among the hereditary forms of childhood-onset chorea, mutations in the *NKX2-1* gene cause a benign hereditary chorea. Mutations in the *ADCY5* (adenylate cyclase 5) gene are an increasingly recognized and relatively common cause of childhood-onset chorea, often in combination with dystonia and developmental delay. Characteristic perioral movements are a hallmark of the disorder. Notably, patients respond well to caffeine.

Chorea-acanthocytosis (neuroacanthocytosis) is a progressive and typically fatal autosomal recessive disorder that is characterized by chorea coupled with red cell abnormalities on peripheral blood smear (acanthocytes). The chorea can be severe and associated with self-mutilating behavior, dystonia, tics, seizures, and a polyneuropathy. Mutations in the *VPS13A* gene encoding chorein have been described. A phenotypically similar X-linked form of the disorder has been described in older individuals who have reactivity with Kell blood group antigens (McLeod syndrome). A benign hereditary chorea of childhood (BHC1) due to mutations in the gene for thyroid transcription factor 1 and a late-onset benign senile chorea (BHC2) have also been reported. It is important to do genetic testing in these patients to ensure that they do not have HD.

Chorea may also occur in association with a variety of infections and degenerative disorders as well as vascular diseases and hypo- and hyperglycemia. *Sydenham's chorea* (originally called St. Vitus's dance) is more common in females and is typically seen in childhood (5–15 years). It often develops in association with prior exposure to group A streptococcal infection **(Chap. 153)** and is thought to be autoimmune in nature. It is characterized by the acute onset of choreiform movements and behavioral disturbances. With the reduction in the incidence of rheumatic fever, the incidence of Sydenham's chorea has fallen, but it can still be seen in developing countries. The chorea generally responds to dopamine-blocking agents, valproic acid, and carbamazepine, and is usually self-limited. Treatment is generally restricted to those with severe chorea. Chorea may recur in later life, particularly in association with pregnancy (chorea gravidarum) or treatment with sex hormones. Several reports have documented cases of chorea associated with *N*-methyl-D-aspartate (NMDA) receptor antibody–positive encephalitis, following herpes simplex virus encephalitis, and in paraneoplastic syndromes associated with anti-CRMP-5 or anti-Hu antibodies **(Chap. 99)**. *Systemic lupus erythematosus* **(Chap. 368)** is the most common systemic disorder that is associated with chorea. The chorea may last for only a few days but can be long-lasting and persist for years. Chorea can also be seen with hyperthyroidism, autoimmune disorders including Sjögren's syndrome, infectious disorders including HIV, metabolic alterations, and polycythemia rubra vera. Chorea has been described following open-heart surgery in the pediatric population. It may also occur in association with many medications (especially anticonvulsants, cocaine, CNS stimulants, estrogens, and lithium). In particular, chorea is commonly seen as a side effect of chronic levodopa treatment in patients with PD **(Chap. 446)**.

BALLISM/HEMIBALLISMUS

Ballism is a violent form of choreiform movement composed of wild, flinging, large-amplitude movements most frequently affecting proximal limb muscles on one side of the body (hemiballism). The movements may only affect one limb (monoballism) or, more exceptionally, both upper or lower limbs (paraballism). The movements may be so severe as to cause exhaustion, dehydration, local injury, and, in extreme cases, death. Fortunately, dopamine-blocking drugs can be very helpful, and importantly, hemiballismus is usually self-limiting and tends to resolve spontaneously after weeks or months. The most common cause is a partial lesion (infarct or hemorrhage) in the STN, but in 30–40% of cases, the lesion is found in the putamen, thalamus, or parietal cortex. In extreme cases, pallidotomy or DBS of the GPi can be effective and abolish the involuntary movements. Interestingly, surgically induced lesions and DBS of the STN in PD patients are usually not associated with hemiballismus.

TICS

A *tic* is a brief, rapid, recurrent, stereotyped and seemingly purposeless motor contraction. Motor tics can be simple, with movement only affecting an individual muscle group (e.g., blinking, twitching of the nose, jerking of the neck), or complex, with coordinated involvement of multiple muscle groups (e.g., jumping, sniffing, head banging, and echopraxia [mimicking movements]). Phonic (or vocal) tics can also be simple (e.g., grunting) or complex (e.g., echolalia [repeating other people's words], palilalia [repeating one's own words], and coprolalia [expression of obscene words]). Patients may also experience sensory tics, composed of unpleasant focal sensations in the face, head, or neck. These can be mild and of little clinical consequence or severe and disabling. Tics may present in adulthood and can be seen in association with a variety of disorders, including PD, HD, trauma, dystonia, drugs (e.g., levodopa, neuroleptics), and toxins.

TOURETTE'S SYNDROME

Tourette's syndrome (TS) is a neurobehavioral disorder named after the French neurologist Georges Gilles de la Tourette. It predominantly affects males, and the prevalence is estimated to be 0.03–1.6%, but it is likely that many mild cases do not come to medical attention. TS is characterized by multiple motor tics, often accompanied by vocalizations (phonic tics). Patients characteristically can voluntarily suppress tics for short periods of time but then experience an irresistible urge to express them. Tics vary in intensity and may be absent for days or weeks only to recur, occasionally in a different pattern. Tics tend to present between ages 2 and 15 years (mean 7 years) and often lessen or even disappear in adulthood, particularly in males. Associated behavioral disturbances include anxiety, depression, attention-deficit hyperactivity disorder (ADHD), and obsessive-compulsive disorder. Patients may experience personality disorders, self-destructive behaviors, difficulties in school, and impaired interpersonal relationships.

Etiology and Pathophysiology TS has a high heritability and is thus thought to be a genetic disorder, but no specific monogenic cause has yet been identified. Current evidence supports a complex inheritance pattern with an important contribution of de novo, likely gene-disrupting variants. Genome-wide linkage studies have suggested *Slit*, *Trk-like 1,* and *histidine decarboxylase* (*HDC*) genes as conferring genetic risk for TS. The risk of a family with one affected child having a second one with TS is ~25%. The pathophysiology of TS is not known, but alterations in dopamine neurotransmission, opioids, and second-messenger systems have been proposed.

TREATMENT

Tics and Tourette's Syndrome

There is no cure for tics or TS. Patients with mild disease often only require education and counseling (for themselves and family members). In a high proportion of patients, the severity of tics wanes in adult life, becoming less of a medical problem, thus arguing for conservative management if possible during the first decades of life.

Drug treatment to help control tics is indicated when the tics are disabling and interfere with quality of life and social interactions. Therapy is individualized, and few treatment regimens have been properly evaluated in double-blind trials. Some physicians use the α-agonist clonidine, starting at low doses and gradually increasing the dose and frequency until satisfactory control is achieved. Guanfacine (0.5–2 mg/d) is an α-agonist that is preferred by some because it only requires once-daily dosing. Other physicians prefer to use neuroleptics, but treatment can be complicated by tardive dyskinesia and weight gain. Atypical neuroleptics are usually used initially (risperidone, olanzapine, ziprasidone) because they are thought to be associated with a reduced risk of tardive dyskinesia. If they are not effective, low doses of classical neuroleptics such as haloperidol, fluphenazine, pimozide, or tiapride can be tried because the risk of tardive dyskinesia in young people is relatively low. Tetrabenazine and deuterated tetrabenazine may be recommended but are associated with depression. The dopamine D1 antagonist ecopipam was reported to provide benefits without serious side effects in a controlled trial of short duration in TS. Antiepileptic drugs such as topiramate may provide benefit for some patients. Botulinum toxin injections can be effective in controlling focal tics that involve small muscle groups. There is also interest in the potential value of a wrist device that delivers electrical pulses and has been reported to reduce the frequency and severity of tics in an open-label study. The potential value of closed-loop DBS targeting the anterior portion of the internal capsule, the GPi, or the thalamus is currently being explored for severely affected patients. A large-scale public database and registry for DBS in TS has been established. Behavioral features, and particularly anxiety and compulsions, can be a disabling feature of TS and should be treated as appropriate. Behavioral and speech therapies are also occasionally employed but have not been formally tested. ADHD medications such as methylphenidate are sometimes used to increase attention and concentration but may also exacerbate tics.

MYOCLONUS

Myoclonus is a brief, rapid (<100 ms), shock-like, jerky movement consisting of single or repetitive muscle discharges that can occur with or without a pattern and with a variable frequency. Myoclonic jerks can be focal, multifocal, segmental, or generalized and can occur spontaneously, in association with voluntary movement (action myoclonus), or in response to an external stimulus (reflex myoclonus). Myoclonic jerks can be severe and interfere with normal movement or benign and of no clinical consequence, as is commonly observed in normal people who can experience myoclonic jerks when waking up or falling asleep (hypnagogic jerks). Negative myoclonus consists of a brief loss of muscle activity (e.g., asterixis in hepatic failure). Palatal myoclonus (or palatal tremor) involves contractions of the soft palate and may be associated with an audible click that can be disturbing to the patient and family members. This is usually idiopathic and benign but can be related to a lesion in the cerebellum or brainstem. Myoclonus may also occur consequent to injury to a peripheral or cranial nerve (e.g., hemifacial spasm).

Myoclonic jerks differ from tics in that they are typically not repetitive, are not suppressible, and can severely interfere with normal voluntary movement. They can be associated with abnormal neuronal discharges in cortical, subcortical, brainstem, or spinal cord regions, particularly in cases related to hypoxemia (especially following cardiac arrest), encephalopathy, and neurodegeneration. Reversible myoclonus can be seen with metabolic disturbances (renal failure, electrolyte imbalance, hypocalcemia), toxins, and many medications. Hereditary myoclonus syndromes can be grouped into three classes based on clinical features: prominent myoclonus, prominent myoclonus combined with another prominent movement disorder, and disorders that usually present with other phenotypes but can also manifest as a prominent myoclonus syndrome. An additional movement disorder is seen in nearly all myoclonus syndromes, most commonly ataxia or dystonia. Furthermore, cognitive decline and epilepsy are present in the majority

of patients. The frequent association with epilepsy suggests that a brief epileptic-like discharge could underlie myoclonus in some situations.

Myoclonic epilepsy is a disorder comprised of myoclonus and epilepsy. It can be associated with other focal neurologic deficits, has a variable but progressive course, and may ultimately be fatal. The most common form of action myoclonus of cortical origin with generalized epilepsy is myoclonic epilepsy or Unverricht-Lundborg disease (EPM-1). Ataxia may also be a feature. This is an autosomal recessive disease caused by pathogenic variants in the *CSBT* gene. Other causes are Lafora body epilepsy or progressive myoclonic epilepsy (PME-2) caused by mutations in the *EPM2A* or *NHLRC1* genes. Neuronal ceroid lipofuscinosis (Batten's disease) is another consideration. In patients with less severe or absent epilepsy, mitochondrial disorders and neurodegenerative disorders affecting the cerebellum (i.e., SCAs) should be considered. Essential myoclonus is a relatively benign familial condition characterized by multifocal, very brief, lightning-like movements that are frequently alcohol sensitive. Mutations in the *epsilon-sarcoglycan* gene have been associated with myoclonus seen in association with dystonia (myoclonus-dystonia).

The precise cause of myoclonus is not known but, in some cases, is thought to be due to overexcitability or impaired inhibition of cortical or peripheral nerve stimuli related to a particular movement. Imaging studies are seeking to define the altered connectivity in neuronal circuits that underlies myoclonus.

TREATMENT

Myoclonus

Treatment primarily consists of managing the underlying condition or removing an offending agent. Pharmacologic therapy involves one or a combination of GABAergic agents such as valproic acid (800–3000 mg/d), piracetam (8–20 g/d), clonazepam (2–15 mg/d), levetiracetam (1000–3000 mg/d), or primidone (500–1000 mg/d). Treatment may be associated with striking clinical improvement in chronic cases in which a cortical origin for the myoclonic discharges has been identified (e.g., postanoxic myoclonus, progressive myoclonic epilepsy). In some cases, combinations of drugs may prove helpful. The serotonin precursor 5-hydroxytryptophan (plus carbidopa) may be useful in cases of postanoxic myoclonus. DBS can be highly effective in myoclonus-dystonia. Botulinum toxin has been used successfully in some patients with focal myoclonus, palatal myoclonus, and hemifacial spasm. Some patients with hemifacial spasm have also been reported to benefit from neurosurgical decompression of the involved facial nerve.

DRUG-INDUCED MOVEMENT DISORDERS

This important group of movement disorders is primarily associated with drugs that block dopamine receptors (neuroleptics) or central dopaminergic transmission. These drugs are widely used in psychiatry, but it is important to appreciate that drugs used in the treatment of nausea or vomiting (e.g., prochlorperazine [Compazine]) or gastroesophageal disorders (e.g., metoclopramide [Reglan]) are neuroleptic agents and can cause these disorders. Hyperkinetic movement disorders secondary to neuroleptic drugs can be divided into those that present acutely, subacutely, or after prolonged exposure (tardive syndromes). Dopamine-blocking drugs can also be associated with a reversible parkinsonian syndrome for which anticholinergics are often concomitantly prescribed, but these drugs are not effective antiparkinsonian agents and are associated with cognitive side effects, and there is concern that such treatment might actually increase the risk of developing a tardive syndrome.

ACUTE

Dystonia is the most common acute hyperkinetic drug reaction (see above). It is typically generalized in children and focal in adults (e.g., blepharospasm, torticollis, or OMD). The reaction can develop within minutes of exposure and can be successfully treated in most cases with parenteral administration of anticholinergics (benztropine), diphenhydramine, benzodiazepines (lorazepam, clonazepam, or diazepam), or dopamine agonists. The abrupt onset of severe spasms may occasionally be confused with a seizure; however, there is no loss of consciousness, and no automatisms, electroencephalogram abnormalities, or postictal features typical of epilepsy. The acute onset of chorea, stereotypic behavior, and tics may also be seen, particularly following exposure to CNS stimulants such as methylphenidate, cocaine, or amphetamines. In rare cases, the airway may be affected and must be protected.

SUBACUTE

Akathisia is the most common reaction in this category. Akathisia consists of motor restlessness with a need to move that is alleviated by movement. It is most frequently associated with use of neuroleptic drugs and generally starts within 2 weeks of initiating therapy. It can also be seen with calcium channel blockers, antiemetics, cocaine, and sedatives. The cause is not known but is thought to relate to blocking the dopaminergic system. Therapy consists of lowering the dose or removing the offending agent. When this is not possible, symptoms may be ameliorated with benzodiazepines, anticholinergics, beta blockers, or dopamine agonists. Treatment is generally effective, but in chronic cases, it may become associated with anxiety, depression, and even suicide.

TARDIVE SYNDROMES

These disorders develop months to years after initiation of a neuroleptic agent. Tardive dyskinesias (TD) are most common and typically present with choreiform movements involving the mouth, lips, and tongue. In severe cases, the trunk, limbs, and respiratory muscles may also be affected. In approximately one-third of patients, TDs remit within 3 months of stopping the drug, and most patients gradually improve over the course of several years. However, abnormal movements may also develop, persist, or worsen after stopping the offending agent. The movements are often mild and more upsetting to the family than to the patient, but in some cases, they can be severe and disabling, particularly in the context of an underlying psychiatric disorder. Second-generation or atypical antipsychotics (e.g., clozapine, risperidone, olanzapine, quetiapine, ziprasidone, and aripiprazole) are thought to be associated with a lower risk of causing TD in comparison to traditional antipsychotics, although they do not eliminate this risk. Younger patients have a lower risk of developing neuroleptic-induced TD, whereas the elderly, females, and those with underlying organic cerebral dysfunction are at greater risk. Chronic neuroleptic use is associated with increased risk of TD, and the U.S. Food and Drug Administration has specifically warned that use of metoclopramide for >12 weeks increases the risk of TD. Because TD can be permanent and resistant to treatment, antipsychotics should be used judiciously and atypical neuroleptics should be the preferred agent whenever possible, although there are now questions as to the risk of TD with atypical neuroleptics as well. In all patients on these agents, the need for continued use should be regularly evaluated. The cause of TD is not known with certainty, but it is thought to be related to hypersensitivity of dopamine receptors following the use of dopamine D2–blocking agents. This concept is based on observations that acute discontinuation can lead to accentuation of TD, while higher doses of these agents or the introduction of more potent neuroleptics can alleviate symptoms (at least transiently). Another hypothesis is that structural changes at the receptor level due to toxic effects of the neuroleptic may be causative. It has also been suggested that there may be a genetic predisposition in individuals who develop TD.

Treatment primarily consists of tapering and withdrawal of the offending agent. If the patient is receiving a traditional antipsychotic, and withdrawal is not possible, replacement with an atypical antipsychotic (e.g., clozapine) should be tried. Abrupt cessation of a neuroleptic should be avoided because acute withdrawal can induce worsening. TD can persist after withdrawal of antipsychotics and can be difficult to treat. Tetrabenazine, a vesicular monoamine transporter type 2 (VMAT-2) inhibitor that blocks storage of dopamine, has been used to treat TD but is short-acting and is associated with a dose-related

new onset or worsening of parkinsonian features. Valbenazine, an ester of tetrabenazine, has been approved for the treatment of tardive dyskinesia in a dose of 80 mg/d based on efficacy in double-blind trials, but it is associated with sleepiness and QT prolongation. Deuterated tetrabenazine has also been approved for this indication. Deuteration provides a longer half-life with lower C_{max}, reducing risk of parkinsonian side effects. It can be individually titrated and permits the use of higher doses with lower risk of side effects. In open-label studies, benefits have also been reported with valproic acid (750–3000 mg/d), anticholinergics, and botulinum toxin injections. Other approaches include baclofen (40–80 mg/d) and clonazepam (1–8 mg/d). In some refractory cases, pallidal DBS may be an option.

Chronic neuroleptic exposure can also be associated with a tardive dystonia, with preferential involvement of axial muscles and characteristic rocking movements of the trunk and pelvis. Gray coloration of skin can be a clue that the patient is receiving a neuroleptic in patients for whom the cause of the dystonia is not obvious. Tardive dystonia can be more troublesome than tardive dyskinesia and frequently persists despite stopping medication. Valproic acid, anticholinergics, and botulinum toxin may occasionally be beneficial, but patients are frequently refractory to medical therapy. Tardive akathisia, tardive TS, and tardive tremor syndromes are rare but may also occur after chronic neuroleptic exposure.

Neuroleptic medications can also be associated with a neuroleptic malignant syndrome (NMS). NMS is characterized by the acute or subacute onset of muscle rigidity, elevated temperature, altered mental status, hyperthermia, tachycardia, labile blood pressure, and renal failure with markedly elevated creatine kinase levels. Symptoms typically evolve within days or weeks after initiating the drug. NMS can also be precipitated by the abrupt withdrawal of dopaminergic medications in PD patients. Treatment involves immediate cessation of the offending antipsychotic drug and the introduction of a dopaminergic agent (e.g., a dopamine agonist or levodopa), dantrolene, or a benzodiazepine. In very severe cases, when oral intake is not possible, a patch (delivering rotigotine subcutaneously) or an infusion pump (delivering apomorphine or levodopa subcutaneously) may be required. Treatment may need to be undertaken in an intensive care setting and include supportive measures such as control of body temperature (antipyretics and cooling blankets), hydration, electrolyte replacement, and control of renal function and blood pressure.

Drugs that have serotonin-like activity (tryptophan, MDMA or "ecstasy," meperidine) or that block serotonin reuptake can induce a rare, but potentially fatal, serotonin syndrome that is characterized by confusion, hyperthermia, tachycardia, and coma, as well as rigidity, ataxia, and tremor. Myoclonus is often a prominent feature, in contrast to NMS, which it resembles in other respects. Patients can be managed with propranolol, diazepam, diphenhydramine, chlorpromazine, or cyproheptadine, as well as supportive measures.

A variety of other drugs can be associated with hyperkinetic movement disorders. Some examples include phenytoin (chorea, dystonia, tremor, myoclonus), carbamazepine (tics and dystonia), tricyclic antidepressants (dyskinesias, tremor, myoclonus), fluoxetine (myoclonus, chorea, dystonia), oral contraceptives (dyskinesia), β-adrenergics (tremor), buspirone (akathisia, dyskinesias, myoclonus), digoxin, cimetidine, diazoxide, lithium, methadone, and fentanyl (dyskinesias). And as described in an earlier chapter **(Chap. 446)**, treatment of PD with levodopa can be associated with dyskinetic movements; these are typically choreiform, but dystonia and myoclonus may also occur.

PAROXYSMAL DYSKINESIAS

Paroxysmal dyskinesias are a group of rare disorders characterized by episodic, brief involuntary movements that can manifest as various types of hyperkinetic movements, including chorea, dystonia, tremor, myoclonus, and ballism. There are three main types: (1) *paroxysmal kinesigenic dyskinesia (PKD)*, where the involuntary movements are triggered by sudden movement; (2) *paroxysmal nonkinesigenic dyskinesias (PNKD)*, where the attacks are not induced by movement; and (3) rare cases of *paroxysmal exertion-induced dyskinesia (PED)*, where attacks are induced by prolonged exercise.

PKDs are characterized by brief, self-limited attacks induced by the onset of movement such as running but also occasionally by unexpected sound or photic stimulation. Attacks may affect one side of the body, last seconds to minutes at a time, and recur several times a day. They usually manifest as a mixed hyperkinetic movement disorder with dystonic posturing of a limb, ballismus, and chorea, which may also become generalized. PKD is most commonly familial with an autosomal dominant pattern of inheritance and mutations in the *proline-rich transmembrane protein 2* (*PRRT2*) gene but may also occur secondary to various brain disorders such as multiple sclerosis or hyperglycemia. PKD is more frequent in males (4:1), and the onset is typically in the first or second decade of life. About 70% report sensory symptoms such as tingling or numbness of the affected limb preceding the attack by a few milliseconds. The evolution is relatively benign, and there is a trend toward resolution of the attacks over time. Treatment with low-dose anticonvulsant therapy such as carbamazepine or phenytoin is advised when the attacks are frequent and interfere with daily life activities and is effective in ~80% of patients. Some clinical features of PKD (abrupt and short-lasting attacks preceded by an "aura"), the association with true seizure episodes, and its favorable response to anticonvulsant drugs have led to speculation that it is epileptic in origin, but this has not been established.

PNKD involves attacks of generalized dyskinesias precipitated by alcohol, caffeine, stress, or fatigue. In comparison to PKD, the episodes have a relatively longer duration (minutes to hours) and are less frequent (one to three per day). PNKD is inherited as an autosomal dominant condition with high (~80%) but incomplete penetrance. A missense mutation in the *myofibrillogenesis regulator* (*PNKD*) gene has been identified in several families. Recognition of the condition and elimination of the underlying precipitating factors, where possible, are the first priorities. Tetrabenazine, neuroleptics, dopamine-blocking agents, propranolol, clonazepam, and baclofen may be helpful. Treatment may not be required if the condition is mild and self-limited. Most patients with PNKD do not benefit from anticonvulsant drugs, but these should be tried, and some may respond to clonazepam or other benzodiazepines.

PED is characterized by a combination of chorea, athetosis, and dystonia in excessively exercised body regions, with the legs being most frequently affected. They are frequently familial. A single attack lasts from a few minutes to an hour and occurs after prolonged physical exercise. In addition to the movement disorder, several patients have other disease manifestations between episodes such as epilepsy, hemolytic anemia, and migraine. The *SLC2A1* (solute carrier family 2 member 1) gene, previously linked to GLUT1 (glucose transporter of the blood-brain barrier) deficiency syndrome, can also cause paroxysmal PED. Treatment includes avoiding prolonged physical exercise. Whereas anticonvulsants and most medications are typically not effective, a ketogenic diet may be an effective therapeutic option.

Other (rare) forms of paroxysmal dyskinesia are caused by pathogenic variants in the *ECHS1*, *GLDC*, *KCNMA1, SCN8A*, and *TMEM151A* genes.

RESTLESS LEGS SYNDROME

Restless legs syndrome (RLS) is a neurologic disorder that affects ~10% of the adult population (it is rare in Asians). It was first described in the seventeenth century by the English physician Thomas Willis but has only recently been appreciated to be a bona fide movement disorder. The four core symptoms required for diagnosis are an urge to move the legs usually caused or accompanied by an unpleasant sensation in the legs; symptoms that begin or worsen with rest; partial or complete relief by movement; and worsening during the evening or night. Symptoms are often mild but can cause significant morbidity in some individuals.

Symptoms most commonly begin in the legs but can spread to, or even begin in, the upper limbs. The unpleasant sensation is often described as a creepy-crawly feeling, paresthesia, or burning. In ~80% of patients, RLS is associated with periodic leg movements (PLMs) during sleep and occasionally while awake. These involuntary movements are usually brief, lasting no more than a few seconds, and recur every 5–90 s. The restlessness and PLMs are a major cause of

sleep disturbance, leading to poor-quality sleep and daytime sleepiness. RLS is also commonly associated with depression, anxiety, and hypertension.

The mean age of onset in familial forms is in the third decade, although pediatric cases are recognized. The severity of symptoms is variable. Secondary RLS may be associated with pregnancy or a range of underlying disorders, including anemia, ferritin deficiency, renal failure, and peripheral neuropathy. There is an association with abnormalities of iron metabolism, possibly because low iron can result in reduced dopamine levels. Diagnosis is made on clinical grounds but can be supported by polysomnography and the demonstration of PLMs. Recent studies suggest that age, sex, and genetic markers can be used to accurately predict who is likely to develop RLS in 90% of cases. The neurologic examination is normal. Secondary causes of RLS should be excluded, and ferritin levels, glucose, and renal function should be measured. The pathogenesis is thought to be associated with an alteration in dopamine function, which may be peripheral or central, but this has not been specifically defined. Primary RLS is often familial and has a strong genetic component; however, no causative gene has yet been identified. Genome association studies have identified >150 variants associated with RLS risk, with the strongest candidates in the *PTPRD*, *BTBD9*, and *MEIS1* genes. Interestingly no genetic linkage to iron has been identified.

Most RLS sufferers have mild symptoms that do not require specific treatment. General measures to improve sleep hygiene and quality should be attempted first. If symptoms remain intrusive, low doses of dopamine agonists, e.g., pramipexole (0.25–0.5 mg), ropinirole (1–2 mg), or patch rotigotine (2–3 mg), taken 1–2 h before bedtime are generally effective. Levodopa may also be effective but is more likely to be associated with augmentation (spread and worsening of symptoms and emergence during the day) or rebound (reappearance sometimes with worsening of symptoms at a time related to the drug's short half-life). Augmentation can also be seen with chronic use of drugs such as dopamine agonists, particularly if higher doses are employed. Other drugs that have been reported to be effective in individual cases include anticonvulsants, analgesics, and opiates, but these are not commonly employed. Tonic motor activation (TOMAC) is a nonpharmacologic approach to RLS that has not responded to drug therapy and has recently been approved in the United States. The treatment involves electrical stimulation of the peroneal nerves during the night and is reported to be effective and to improve sleep quality. Management of secondary RLS should be directed to correcting the underlying disorder (e.g., iron replacement for anemia).

OTHER DISORDERS THAT MAY PRESENT WITH A COMBINATION OF PARKINSONISM AND HYPERKINETIC MOVEMENTS

WILSON'S DISEASE (SEE ALSO CHAP. 427)

Wilson's disease (WD) is an inherited autosomal recessive disorder of copper metabolism that produces neurologic, psychiatric, and liver manifestations, alone or in combination. It is caused by mutations in the *ATP7B* gene encoding a P-type ATPase. The disease was first described by the English neurologist Kinnier Wilson at the beginning of the twentieth century, although at around the same time, the German physicians Kayser and Fleischer separately noted the characteristic association of corneal pigmentation (Kayser-Fleischer rings) along with hepatic and neurologic features. WD has a worldwide prevalence of ~1 in 30,000, with a mutation carrier frequency of 1 in 90. About half of WD patients (especially younger patients) present with liver abnormalities. The remainder present with neurologic disease (with or without underlying liver abnormalities), and a small proportion have hematologic or psychiatric problems at disease onset.

Neurologic onset usually manifests in the second decade with tremor, rigidity, and dystonia. The tremor is usually in the upper limbs, bilateral, and asymmetric. Tremor can be on intention or occasionally at rest, and in advanced disease can take on a wing-beating characteristic (a flapping movement when the arms are held outstretched with the fingers opposed). Other features can include parkinsonism with bradykinesia, dystonia (particularly facial grimacing), dysarthria, and dysphagia. More than half of those with neurologic features have a history of psychiatric disturbances, including depression, mood swings, and overt psychosis. Kayser-Fleischer (KF) rings are seen in virtually all patients with neurologic features and 80% of those with hepatic presentations. KF rings represent the deposition of copper in Descemet's membrane around the cornea. They consist of a characteristic grayish rim or circle at the limbus of the cornea and are best detected by slit-lamp examination. Neuropathologic examination is characterized by neurodegeneration and astrogliosis in the basal ganglia, particularly in the striatum.

WD should always be considered in the differential diagnosis of a movement disorder, particularly when arising in the first decades of life. Low levels of blood copper and ceruloplasmin and high levels of urinary copper may be present, but normal levels do not exclude the diagnosis. Brain imaging usually reveals generalized brain atrophy in established cases, and ~50% have signal hypointensity in the caudate head, putamen, globus pallidus, substantia nigra, and red nucleus on T2-weighted MRI scans. However, the correlation of imaging changes with clinical features is not good. Liver biopsy with demonstration of high copper levels and genetic testing remain the gold standard for diagnosis.

In the absence of treatment, the course is progressive and leads to severe neurologic dysfunction and early death in most patients, although a small proportion experience a relatively benign course. Treatment is directed at reducing tissue copper levels and maintenance therapy to prevent reaccumulation. There is no clear consensus on optimal treatment, and patients should be managed in a unit with expertise in treating this disease. Penicillamine is frequently used to increase copper excretion but may lead to a worsening of symptoms in the initial stages of therapy. Side effects are common and can to some degree be attenuated by co-administration of pyridoxine. Tetrathiomolybdate blocks the absorption of copper and can be used instead of penicillamine. Trientine tetrahydrochloride and zinc are useful drugs for maintenance therapy. Effective treatment can reverse the neurologic features in most patients, particularly when started early. However, some patients may still progress, especially those with hepatocerebral disease. KF rings tend to decrease after 3–6 months and disappear by 2 years. Adherence to maintenance therapy is a major challenge in long-term care. Patients with advanced hepatic disease may require a liver transplant, and the potential role of organ-specific chelation therapy is under investigation. Gene therapy studies that involve an infusion of a working copy of the *ATP7B* gene into the liver are being investigated clinically, while preclinical studies are testing the novel chelator methanobactin.

NEURODEGENERATION WITH BRAIN IRON ACCUMULATION

Neurodegeneration with brain iron accumulation (NBIA) represents a group of inherited disorders characterized by iron accumulation in the basal ganglia. Clinically, they can manifest as a progressive neurologic disorder with a variety of clinical features including parkinsonism, dystonia, neuropsychiatric abnormalities, and retinal degeneration. Cognitive disorders and cerebellar dysfunction may also be seen. Presentation is usually in childhood, but adult cases have been described. Multiple genes have been identified. Pantothenate kinase-associated neurodegeneration (PKAN), formerly known as Hallervordan-Spatz disease, is caused by a mutation in the *PANK2* gene and is the most common form of NBIA, accounting for ~50% of cases. Onset is usually in early childhood and is manifest as a combination of dystonia, parkinsonism, and spasticity. MRI shows a characteristic low signal abnormality in the center of the globus pallidus on T2-weighted scans caused by iron accumulation and known as the "eye of the tiger" sign. Numerous other gene mutations have been described associated with iron accumulation, including *PLA2G6, C19orf12, FA2H, ATP13A2, WDR45, FTL, CP*, *COASY*, and *DCAF17*. One must be cautious, however, not to assume that all cases with iron accumulation in the basal ganglia represent an NBIA because iron accumulation in some basal ganglia regions is normal, and excess iron accumulation may occur in the basal ganglia as a nonspecific secondary consequence of

neurodegeneration unrelated to a defect in iron metabolism. There are no specific treatments; iron binding may help slow progression, but this has not been established.

FUNCTIONAL (PSYCHOGENIC) DISORDERS

Virtually all movement disorders including tremor, tics, dystonia, myoclonus, chorea, ballism, and parkinsonism can be psychogenic in origin. The term *functional neurologic symptom disorder (FND)/conversion disorder* has been suggested to replace the term *psychogenic disorder* in order to remove the criterion of psychological stress as a prerequisite for diagnosis; however, the terminology remains controversial and both terms are used. A diagnosis can be made by identifying neurologic signs that are specific to FNDs without reliance on psychological stressors or suggestive historical clues. Tremor affecting the upper limbs is the most common psychogenic movement disorder. Psychogenic movements can result from a somatoform or conversion disorder, malingering (e.g., seeking financial gain), or a factitious disorder (e.g., seeking psychological gain) **(Chap. 463)**. Functional movement disorders are relatively common (estimated at 2–3% of patients seen in a movement disorder clinic), more frequent in women, disabling for the patient and family, and expensive for society. Clinical features suggesting a functional or psychogenic movement disorder include an acute onset with a pattern of abnormal movement that is inconsistent with the phenotype of a known movement disorder. Diagnosis is based on the nonorganic quality of the movement, the absence of findings of an organic disease process, and positive features that specifically point to a functional illness such as variability and distractibility. For example, in a functional tremor disorder, the magnitude of the tremor is increased with attention and diminishes or even disappears when the patient is distracted by being asked to perform a different task or is unaware that he or she is being observed. This is the opposite of what is seen with an organic tremor where the magnitude of tremor is increased with distraction and tends to be reduced when observed. Other positive features suggesting a psychogenic problem include variable tremor frequency, entrainment of the tremor frequency with the frequency of a designated movement in the contralateral limb such as tapping, and a response to placebo interventions. Associated features can include nonanatomic sensory findings, give-way weakness, astasia-abasia (an odd, gyrating gait or posture) **(Chap. 28)**, and multiple somatic complaints with no underlying pathology (somatoform disorder). Comorbid psychiatric problems such as anxiety, depression, and emotional trauma may be present but are not necessary for the diagnosis, which is why some prefer to call the movement disorder functional rather than psychogenic. Functional movement disorders typically occur as an isolated entity but may be seen in association with an underlying organic problem. The diagnosis can usually be made based on history and clinical features alone, and unnecessary tests or medications can be avoided. If there are underlying psychiatric problems, they should be identified and treated, but as noted, many patients with functional movement disorders have no obvious psychiatric pathology. Treatment of FND starts with explaining the diagnosis to the patient in a nonthreatening manner, but many are resistant to accepting this diagnosis. Psychological therapies (especially cognitive-behavioral) are the method of choice. An increasing role of physiotherapy has also recently been recognized, and a recent trial of physiotherapy and cognitive-behavioral therapy in combination was found to effectively improve symptoms in nearly half of patients. Comorbid depression, anxiety, and pain may be treated pharmacologically. Patients with hypochondriasis, factitious disorders, and malingering have a poor prognosis.

448 Amyotrophic Lateral Sclerosis and Other Motor Neuron Diseases

Robert H. Brown, Jr.

AMYOTROPHIC LATERAL SCLEROSIS

Amyotrophic later sclerosis (ALS) is the most common progressive motor neuron disease. It is a prime example of a neurodegenerative disease and is arguably the most devastating of the neurodegenerative disorders.

PATHOLOGY

The pathologic hallmark of motor neuron degenerative disorders is death of lower motor neurons (consisting of anterior horn cells in the spinal cord and their brainstem homologues innervating bulbar muscles) and upper, or corticospinal, motor neurons (originating in layer five of the motor cortex and descending via the pyramidal tract to synapse with lower motor neurons, either directly or indirectly via interneurons) **(Chap. 26)**. Although at its onset ALS may involve selective loss of function of only upper or lower motor neurons, it ultimately causes progressive loss of both categories of motor neurons. Indeed, in the absence of clear involvement of both motor neuron types, the diagnosis of ALS is questionable. In a subset of cases, ALS arises concurrently with frontotemporal dementia **(Chap. 443)**; in these instances, there is degeneration of frontotemporal cortical neurons and corresponding cortical atrophy.

Other motor neuron diseases involve only particular subsets of motor neurons **(Tables 448-1 and 448-2)**. Thus, in bulbar palsy and spinal muscular atrophy (SMA, predominantly in children) and progressive muscular atrophy (PMA, in adults), the lower motor neurons of brainstem and spinal cord, respectively, are most severely involved. By contrast, pseudobulbar palsy, primary lateral sclerosis (PLS), and hereditary spastic paraplegia (HSP) affect only upper motor neurons innervating the brainstem and spinal cord.

In each of these diseases, the affected motor neurons undergo shrinkage, often with accumulation of the pigmented lipid (lipofuscin) that normally develops in these cells with advancing age. In ALS, the motor neuron cytoskeleton is typically affected early in the illness. Focal enlargements are frequent in proximal motor axons; ultrastructurally, these "spheroids" are composed of accumulations of neurofilaments and other proteins. Commonly in both sporadic and familial ALS, the affected neurons demonstrate ubiquitin-positive aggregates, often associated with the protein TDP43 (see below). Also seen is

TABLE 448-1 Etiology of Motor Neuron Disorders

DIAGNOSTIC CATEGORY	INVESTIGATION
Structural lesions	MRI scan of head (including foramen magnum and cervical spine)
Parasagittal or foramen magnum tumors	
Cervical spondylosis	
Chiari malformation of syrinx	
Spinal cord arteriovenous malformation	
Infections	CSF exam, culture
Bacterial—tetanus, Lyme	Lyme titer
Viral—poliomyelitis, herpes zoster	Antiviral antibody
Retroviral—myelopathy	HTLV-1 titers
Intoxications, physical agents	24-h urine for heavy metals
Toxins—lead, aluminum, others	Serum lead level
Drugs—strychnine, phenytoin	
Electric short, x-irradiation	
Immunologic mechanisms	Complete blood count[a]
Plasma cell dyscrasias	Sedimentation rate[a]
Autoimmune polyradiculopathy	Total protein[a]
Motor neuropathy with conduction block	Anti-GM1 antibodies[a]
	Anti-Hu antibody
Paraneoplastic	MRI scan, bone marrow biopsy
Paracarcinomatous	
Metabolic	Fasting blood sugar[a]
Hypoglycemia	Routine chemistries including calcium[a]
Hyperparathyroidism	PTH
Hyperthyroidism	Thyroid function[a]
Deficiency of folate, vitamin B_{12}, vitamin E	Vitamin B_{12}, vitamin E, folate[a]
	Serum zinc, copper[a]
Malabsorption	24-h stool fat, carotene, prothrombin time
Deficiency of copper, zinc	Fasting lactate, pyruvate, ammonia
Mitochondrial dysfunction	Consider mtDNA
Hyperlipidemia	Lipid electrophoresis
Hyperglycinuria	Urine and serum amino acids
	CSF amino acids
Hereditary disorders	WBC DNA for mutational analysis
C9orf72	
Superoxide dismutase	
TDP43	
FUS/TLS	
Androgen receptor defect (Kennedy's disease)	

[a]Should be obtained in all cases.

Abbreviations: CSF, cerebrospinal fluid; FUS/TLS, fused in sarcoma/translocated in liposarcoma; HTLV-1, human T-cell lymphotropic virus; MRI, magnetic resonance imaging; PTH, parathyroid; WBC, white blood cell.

TABLE 448-2 Sporadic Motor Neuron Diseases

CHRONIC	ENTITY
Upper and lower motor neuron	Amyotrophic lateral sclerosis
Predominantly upper motor neuron	Primary lateral sclerosis
Predominantly lower motor neuron	Multifocal motor neuropathy with conduction block
	Motor neuropathy with paraproteinemia or cancer
	Motor predominant peripheral neuropathies
Other	
Associated with other neurodegenerative disorders	
Secondary motor neuron disorders (see Table 448-1)

Poliomyelitis	
Herpes zoster	
Coxsackie virus	
West Nile virus	

proliferation of astroglia and microglia, the inevitable accompaniment of all degenerative processes in the central nervous system (CNS).

The death of the peripheral motor neurons in the brainstem and spinal cord leads to denervation and atrophy of the corresponding muscle fibers. Histochemical and electrophysiologic evidence indicates that in the early phases of the illness denervated muscle can be reinnervated by sprouting of nearby distal motor nerve terminals, although reinnervation in this disease is considerably less extensive than in most other disorders affecting motor neurons (e.g., poliomyelitis, peripheral neuropathy). As denervation progresses, muscle atrophy is readily recognized in muscle biopsies and on clinical examination. This is the basis for the term *amyotrophy*. The loss of cortical motor neurons results in thinning of the corticospinal tracts that travel via the internal capsule (Fig. 448-1) and pyramidal tracts in the brainstem to the lateral and anterior white matter columns of the spinal cord. The loss of fibers in the lateral columns and resulting fibrillary gliosis impart a particular firmness (*lateral sclerosis*). A remarkable feature of the disease is the selectivity of neuronal cell death. By light microscopy, the entire sensory apparatus and cerebellar structures that control the coordination of movement remain intact. Except in cases of frontotemporal dementia, the components of the brain required for cognitive processing are also preserved. However, immunostaining indicates that neurons bearing ubiquitin, a marker for degeneration, are also detected in nonmotor systems. Moreover, studies of glucose metabolism in the illness also indicate that there is neuronal dysfunction outside of the motor system. Pathologic studies reveal proliferation of microglial cells and astrocytes in affected regions; in some cases, this phenomenon, designated neuroinflammation, can be visualized using positron emission tomography (PET) scanning for ligands that are recognized by activated microglia. Within the motor system, there is some selectivity

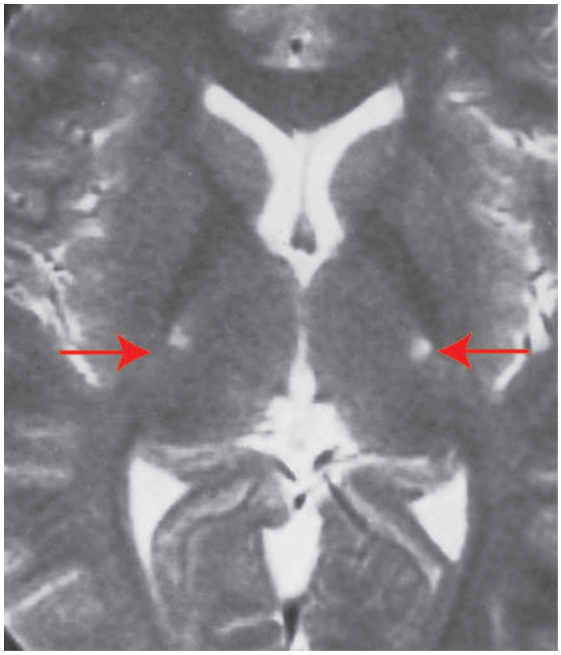

FIGURE 448-1 Amyotrophic lateral sclerosis. Axial T2-weighted magnetic resonance imaging (MRI) scan through the lateral ventricles of the brain reveals abnormal high signal intensity within the corticospinal tracts (*arrows*). This MRI feature represents an increase in water content in myelin tracts undergoing Wallerian degeneration secondary to cortical motor neuronal loss. This finding is commonly present in ALS but can also be seen in AIDS-related encephalopathy, infarction, or other disease processes that produce corticospinal neuronal loss in a symmetric fashion.

of involvement. Thus, motor neurons required for ocular motility remain unaffected, as do the parasympathetic neurons in the sacral spinal cord (the nucleus of Onufrowicz, or Onuf) that innervate the sphincters of the bowel and bladder.

CLINICAL MANIFESTATIONS

The manifestations of ALS are somewhat variable depending on whether corticospinal neurons or lower motor neurons in the brainstem and spinal cord are more prominently involved. With lower motor neuron dysfunction and early denervation, typically the first evidence of the disease is insidiously developing asymmetric weakness, usually first evident distally in one of the limbs. A detailed history often discloses recent development of cramping with volitional movements, typically in the early hours of the morning (e.g., while stretching in bed). Weakness caused by denervation is associated with progressive wasting and atrophy of muscles and, particularly early in the illness, spontaneous twitching of motor units, or fasciculations. In the hands, a preponderance of extensor over flexor weakness is common. When the initial denervation involves bulbar rather than limb muscles, the problem at onset is difficulty with chewing, swallowing, and movements of the face and tongue. Rarely, early involvement of the muscles of respiration may lead to death before the disease is far advanced elsewhere. With prominent corticospinal involvement, there is hyperactivity of the muscle-stretch reflexes (tendon jerks) and, often, spastic resistance to passive movements of the affected limbs. Patients with significant reflex hyperactivity complain of muscle stiffness often out of proportion to weakness. Degeneration of the corticobulbar projections innervating the brainstem results in dysarthria and exaggeration of the motor expressions of emotion. The latter leads to involuntary excess in weeping or laughing (pseudobulbar affect).

Virtually any muscle group may be the first to show signs of disease, but, as time passes, more and more muscles become involved until ultimately the disorder takes on a symmetric distribution in all regions. It is characteristic of ALS that, regardless of whether the initial disease involves upper or lower motor neurons, both will eventually be implicated. Even in the late stages of the illness, sensory, bowel and bladder, and cognitive functions are preserved. Even when there is severe brainstem disease, ocular motility is spared until the very late stages of the illness. As noted, in some cases (particularly those that are familial), ALS develops concurrently with frontotemporal dementia, characterized by early behavioral abnormalities with prominent behavioral features indicative of frontal lobe dysfunction.

A committee of the World Federation of Neurology has established diagnostic guidelines for ALS. Essential for the diagnosis is simultaneous upper and lower motor neuron involvement with progressive weakness and the exclusion of all alternative diagnoses. The disorder is ranked as "definite" ALS when three or four of the following are involved: bulbar, cervical, thoracic, and lumbosacral motor neurons. When two sites are involved, the diagnosis is "probable," and when only one site is implicated, the diagnosis is "possible." An exception is made for those who have progressive upper and lower motor neuron signs at only one site and a mutation in the gene encoding superoxide dismutase (SOD1; see below).

It is now recognized that another clinical manifestation in most cases of ALS is the presence in cerebrospinal fluid (CSF) and serum of markers of neurodegeneration, such as elevated levels of neurofilament light chains (Nfl) or phosphorylated neurofilament heavy chains; some markers of inflammation (e.g., monocyte chemoattractant protein 1) are also elevated. Higher levels of serum or CSF Nfl are correlated with more aggressive disease and more rapid disease progression. Accordingly, these CSF biomarkers are increasingly used as endpoints in clinical trials.

EPIDEMIOLOGY

The illness is relentlessly progressive, leading to death from respiratory paralysis; the median survival is from 3 to 5 years. There are very rare reports of stabilization or even regression of ALS. In most societies, there is an incidence of 1–3 per 100,000 and a prevalence of 3–5 per 100,000. It is striking that about 1 in 500 deaths in North America and Western Europe (and probably elsewhere) are due to ALS; this finding predicts that >500,000 individuals now alive in the United States will die of ALS. Several endemic foci of higher prevalence exist in the western Pacific (e.g., in specific regions of Guam or Papua New Guinea). In the United States and Europe, men are somewhat more frequently affected than women. Epidemiologic studies have incriminated risk factors for this disease including exposure to pesticides and insecticides, silica, smoking, and possibly service in the military. Although ALS is overwhelmingly a sporadic disorder, some 10% of cases are inherited as an autosomal dominant trait.

FAMILIAL ALS

Several forms of selective motor neuron disease are inheritable **(Table 448-3)**. Familial ALS (FALS) involves both corticospinal and lower motor neurons. Apart from its inheritance as an autosomal dominant trait, it is clinically indistinguishable from sporadic ALS. Genetic studies have identified mutations in multiple genes, including those encoding the protein C9orf72 (open reading frame 72 on chromosome 9), cytosolic enzyme SOD1 (superoxide dismutase), the RNA binding proteins TDP43 (encoded by the TAR DNA binding protein gene), and fused in sarcoma/translocated in liposarcoma (FUS/TLS), as the most common causes of FALS. Mutations in *C9orf72* account for ~45–50% of FALS and perhaps 5–10% of sporadic ALS cases. Mutations in SOD1 explain another 20% of cases of FALS, whereas TDP43 and FUS/TLS each represent about 5% of familial cases. Mutations in several other genes (e.g., *NEK1*, *optineurin*, *TBK1*, *KIF5A*, *TUBA4*, and *PFN11*) each cause ~1% of cases.

Rare mutations in other genes are also clearly implicated in ALS-like diseases. Thus, a familial, dominantly inherited motor disorder that in some individuals closely mimics the ALS phenotype arises from mutations in a gene that encodes a vesicle-binding protein. Mutations in *senataxin*, a helicase, cause an early-adult-onset, slowly evolving ALS variant. Kennedy's syndrome is an X-linked, adult-onset disorder that may mimic ALS, as described below. *Tau* gene mutations usually underlie frontotemporal dementia but in some instances may be associated with prominent motor neuron findings.

Genetic analyses are also beginning to illuminate the pathogenesis of some childhood-onset motor neuron diseases. For example, a slowly disabling degenerative, predominantly upper motor neuron disease that starts in the first decade is caused by mutations in a gene that expresses a novel signaling molecule with properties of a guanine-exchange factor, termed *alsin*.

DIFFERENTIAL DIAGNOSIS

Because ALS is currently untreatable, it is imperative that potentially remediable causes of motor neuron dysfunction be excluded (Table 448-1). This is particularly true in cases that are atypical by virtue of (1) restriction to either upper or lower motor neurons, (2) involvement of neurons other than motor neurons, and (3) evidence of motor neuronal conduction block on electrophysiologic testing. Compression of the cervical spinal cord or cervicomedullary junction from tumors in the cervical regions or at the foramen magnum or from cervical spondylosis with osteophytes projecting into the vertebral canal can produce weakness, wasting, and fasciculations in the upper limbs and spasticity in the legs, closely resembling ALS. The absence of cranial nerve involvement may be helpful in differentiation, although some foramen magnum lesions may compress the twelfth cranial (hypoglossal) nerve, with resulting paralysis of the tongue. Absence of pain or of sensory changes, normal bowel and bladder function, normal radiologic studies of the spine, and normal CSF all favor ALS. Where doubt exists, magnetic resonance imaging (MRI) scans and possibly contrast myelography should be performed to visualize the cervical spinal cord.

Another important entity in the differential diagnosis of ALS is *multifocal motor neuropathy with conduction block* (MMCB), discussed below. A diffuse, lower motor axonal neuropathy mimicking ALS sometimes evolves in association with hematopoietic disorders such as lymphoma or multiple myeloma. In this clinical setting, the presence of an M-component in serum should prompt consideration of a bone

TABLE 448-3 Genetic Motor Neuron Diseases

DISEASE	GENE SYMBOL	GENE NAME	INHERITANCE	U.S. FREQUENCY % FALS	USUAL ONSET	PROTEIN FUNCTION	UNUSUAL FEATURES
I. Selected Upper and Lower Motor Neurons (Familial ALS) + Frontotemporal Dementia (FTD)							
ALS/ALS-FTD	*C9ORF72*	Chromosome 9 open reading frame 72	AD	45% (6–10% SALS)	Adult	Regulates vesicle trafficking	May also be associated with parkinsonism, PLS
ALS	*SOD1*	Cu/Zn superoxide dismutase 1	AD	20% (2% SALS)	Adult	Protein antioxidant	
ALS/ALS-FTD	*TARDBP*	TAR DNA binding protein	AD	5%	Adult	DNA, RNA binding	
ALS/ALS-FTD	*FUS/TLS*	Fused in sarcoma/ translocated in liposarcoma	AD	5%	Adult	DNA, RNA binding	
ALS/ALS-FTD	*CCNF*	E3 ubiquitin ligase cyclin F	AD	2%	Adult	Mediates ubiquitination	
ALS	*NEK1*	NMA-related kinase	AR	2%	Adult	Microtubules, nuclear transport	
ALS/ALS-FTD	*TBK1*	Tank binding kinase 1	AD	2%	Adult	Regulates autophagy, inflammation	
ALS	*KIF5A*	Kinesin family member 5A	AD	1–2%	Early adult	Microtubule motor	CMT
ALS	*PFN1*	Profilin 1	AD	~1%	Adult	Involved in actin polymerization	
ALS/ALS-FTD	*OPTN*	Optineurin	AD/AR	~1%	Adult	Attenuates NF-κB	
ALS	*SPG11*	Spastic paraplegia 11	AR	~1%	Adult	Vesicle trafficking	Spastic paraplegia
ALS	*SETX*	Senataxin	AD	~1%	Late juvenile	DNA helicase	Late childhood onset
ALS/ALS-FTD	*VCP*	Valosin-containing protein	AD	~ 1%	Adult	ATPase	Paget's, myopathy
ALS-FTD	*UBQLN2*	Ubiquilin 2	XR	<1%	Adult or juvenile	Protein degradation	
ALS-FTD	*CHMP2B*	Chromatin modifying protein 2B	AD	<1%	Adult	Chromatin binding protein	
ALS-FTD	*MAPT*	Microtubule Associated Protein Tau	AD	<1%	Adult	Cytoskeletal protein	Usually causes only FTD
ALS2	*ALS2*	Alsin	AR	<1%	Juvenile	GEF signaling	Corticobulbar/ corticospinal may mimic PLS
ALS-FTD	*CHMP2B*	Chromatin modifying protein 2B	AD	<1%	Adult	Chromatin binding protein	
II. Lower Motor Neurons							
Spinal muscular atrophies	*SMN*	Survival motor neuron	AR	1/10,000 live births	Infancy	RNA metabolism	
GM2-gangliosidosis							
1. Sandhoff's disease	*HEXB*	Hexosaminidase B	AR		Childhood	Ganglioside recycling	
2. AB variant	*GM2A*	GM2-activator protein	AR		Childhood	Ganglioside recycling	
3. Adult Tay-Sachs disease	*HEXA*	Hexosaminidase A	AR		Childhood	Ganglioside recycling	
X-linked spinobulbar muscular atrophy	*AR*	Androgen receptor	XR		Adult	Nuclear signaling	
III. Upper Motor Neuron (Selected HSPs)							
SPG3A	*ATL1*	Atlastin	AD	10% AD FSP	Childhood	GTPase—vesicle recycling	
SPG4	*SPAST*	Spastin	AD	50–60% AD FSP	Early adulthood	ATPase family—microtubule associate	Some sensory loss
SPG10	*KIF5A*	Kinesin heavy chain isoform 5A	AD	10% AD FSP	Second–third decade	Motor-associated protein	± Peripheral neuropathy, retardation
SPG31	*REEP1*	Receptor Expression Enhancing Protein 1	AD	10% AD FSP	Early	Mitochondrial protein	Rarely, amyotrophy
SPG5	*CYP7B1*	Cytochrome P450	AR	5–10% AR FSP	Variable	Degrades endogenous substances	Sensory loss
SPG7	*SPG7*	Paraplegin	AR	5–10% AR FSP	Variable	Mitochondrial protein	Rarely, optic atrophy, ataxia, rarely PLS

TABLE 448-3 Genetic Motor Neuron Diseases (Continued)

DISEASE	GENE SYMBOL	GENE NAME	INHERITANCE	U.S. FREQUENCY % FALS	USUAL ONSET	PROTEIN FUNCTION	UNUSUAL FEATURES
SPG11	*SPG11*	Spatacsin	AR	20–70% AR FSP depends on ethnicity	Predominantly childhood	Cytosolic,? membrane-associated	Some sensory loss, thin corpus callosum; may mimic ALS (ALS5)
SPG2	*PLP*	Proteolipid protein	XR	<1%	Early childhood	Myelin protein	Sometimes multiple CNS features
Adrenoleukodystrophy	*ALDP*	Adrenoleukodystrophy protein	XR	<1%	Early adulthood	ATP binding transporter protein	Possible adrenal insufficiency, CNS inflammation

Abbreviations: AD, autosomal dominant; ALS, amyotrophic lateral sclerosis; AR, autosomal recessive; CNS, central nervous system; CMT, Charcot-Marie-Tooth; BSCL2, Bernadelli-Seip congenital lipodystrophy 2B; FALS, familial amyotrophic lateral sclerosis; FSP, familial spastic paraplegia; FUS/TLS, fused in sarcoma/translocated in liposarcoma; GEF, guanidine nucleotide exchange factor; HSP, hereditary spastic paraplegia; NF-κB, nuclear factor-κB; PLS, primary lateral sclerosis; SALS, sporadic amyotrophic lateral sclerosis; TDP43, Tar DNA binding protein 43 kd; XR, X-linked recessive.

marrow biopsy. Lyme disease **(Chap. 191)** may also cause an axonal, lower motor neuropathy, although typically with intense proximal limb pain and a CSF pleocytosis.

Other treatable disorders that occasionally mimic ALS are chronic lead poisoning and thyrotoxicosis. These disorders may be suggested by the patient's social or occupational history or by unusual clinical features. When the family history is positive, disorders involving the genes encoding C9orf72, cytosolic SOD1, TDP43, FUS/TLS, and adult hexosaminidase A or α-glucosidase deficiency **(Chap. 429)** must be excluded. These are readily identified by appropriate laboratory tests; importantly, panels for simultaneous analysis of multiple ALS and frontotemporal dementia (FTD) genes are now commercially available. Benign fasciculations are occasionally a source of concern because on inspection they resemble the fascicular twitchings that accompany motor neuron degeneration. The absence of weakness, atrophy, or denervation phenomena on electrophysiologic examination usually excludes ALS or other serious neurologic disease. Patients who have recovered from poliomyelitis may experience a delayed deterioration of motor neurons that presents clinically with progressive weakness, atrophy, and fasciculations. Its cause is unknown, but it is thought to reflect sublethal prior injury to motor neurons by poliovirus **(Chap. 210)**.

Rarely, ALS develops concurrently with features indicative of more widespread neurodegeneration. Neuropsychological testing may detect subtle cognitive impairment in ~15% of cases that clinically are purely ALS; these cognitive deficits worsen with disease progression. Importantly, one often encounters the combination of ALS and FTD in individuals who harbor *C9orf72* mutations. The simultaneous occurrence of these disorders reflects shared embryologic origins and transcription factor expression in corticospinal motor neurons and neurons implicated in FTD (von Economo neurons). Overall, up to 40% of FTD cases harbor mutations in the *C9orf72* gene. Beyond *C9orf72*, several other ALS genes can trigger both ALS and FTD (see Table 448-3). As another example of an atypical phenotype, prominent amyotrophy has been described as a dominantly inherited disorder in individuals with bizarre behavior and a movement disorder suggestive of parkinsonism; many such cases have now been ascribed to mutations that alter the expression of tau protein in the brain **(Chap. 443)**. An ALS-like disorder has also been described in some individuals with chronic traumatic encephalopathy **(Chap. 454)**, associated with deposition of TDP43 and neurofibrillary tangles in motor neurons.

PATHOGENESIS

The cause of sporadic ALS is not well defined, in part because there is no animal model for this form of ALS. Strikingly, motor neurons derived from stem cells of individuals with sporadic ALS can display diminished viability, suggesting that heritable factors play a role. Several mechanisms that impair motor neuron viability have been elucidated in rodents that harbor transgenes with mutant *SOD1, profilin-1*, or *C9orf72*. One may loosely group the genetic causes of ALS into three categories. In one group, the primary problem is inherent instability of the mutant proteins, with subsequent perturbations in protein degradation (SOD1, ubiquilin-1 and 2, p62). In the second category, the causative mutant genes perturb RNA processing, transport, and metabolism (C9orf73, TDP43, FUS). In the case of C9orf72, the molecular pathology is an expansion of an intronic hexanucleotide repeat (-GGGGCC-) beyond an upper normal of 30 repeats to hundreds or even thousands of repeats. As observed in other intronic repeat disorders such as myotonic dystrophy **(Chap. 460)** and spinocerebellar atrophy type 8 **(Chap. 450)**, the expanded intronic repeats generate expanded RNA repeats that form intranuclear foci and may confer toxicity by sequestering transcription factors or by undergoing noncanonical protein translation across all possible reading frames of the expanded RNA tracts. Importantly, the latter process generates lengthy dipeptides that are detected in the spinal fluid and are a unique biomarker for C9orf72 ALS. TDP43 and FUS are multifunctional proteins that bind RNA and DNA and shuttle between the nucleus and the cytoplasm, playing multiple roles in the control of cell proliferation, DNA repair and transcription, and gene translation, both in the cytoplasm and locally in dendritic spines in response to electrical activity. How mutations in *FUS/TLS* provoke motor neuron cell death is not clear, although this may represent loss of function of FUS/TLS in the nucleus or an acquired, toxic function of the mutant proteins in the cytosol. In the third group of ALS genes, the primary problem is defective axonal cytoskeleton and transport (dynactin, profilin-1). It is striking that variants in other genes influence survival in ALS but not ALS susceptibility. Intermediate-length polyglutamine-coding expansions (-CAG-) in the gene *ataxin-2* confer increased ALS susceptibility; suppression of ataxin-2 expression extends survival in transgenic ALS mice. Beyond the upstream, primary defects, it is also evident that the ultimate neuronal cell death process is complex, involving multiple cellular processes acting in diverse components of the motor neuron (dendrites, cell body, axons, neuromuscular junction) to accelerate cell death. These include but are not limited to excitotoxicity, defective autophagy, impairment of axonal transport, oxidative stress, activation of endoplasmic reticulum stress and the unfolded protein response, and mitochondrial dysfunction. In addition, the hexanucleotide expansions that cause C9orf72 ALS disrupt nucleocytoplasmic transport; the importance of this observation is underscored by the finding that mutations in the gene encoding GLE1, a protein that mediates mRNA export, cause an aggressive, infantile motor neuron disease.

Multiple studies have convincingly demonstrated that proliferating, activated nonneuronal cells such as microglia and astrocytes importantly influence the disease course, at least in ALS-transgenic mice. A striking additional finding in ALS and most neurodegenerative disorders is that miscreant proteins arising from gene defects in familial forms of these diseases are often implicated in sporadic forms of the same disorder. For example, some reports propose that nonheritable, posttranslational modifications in SOD1 are pathogenic in sporadic ALS; indeed, SOD1 aggregates are sometimes observed in spinal cord in sporadic ALS without SOD1 mutations.

TREATMENT

Amyotrophic Lateral Sclerosis

No treatment arrests the underlying pathologic process in ALS. The drug riluzole (100 mg/d) was approved for ALS because it produces a modest lengthening of survival. In one trial, the survival rate at 18 months with riluzole was similar to placebo at 15 months. The mechanism of this effect is not known with certainty; riluzole may reduce excitotoxicity by diminishing glutamate release. Riluzole is generally well tolerated; nausea, dizziness, weight loss, and elevated liver enzymes occur occasionally. A second drug, edaravone, has also been approved by the U.S. Food and Drug Administration (FDA) based on a single 6-month study in a highly selected ALS population that demonstrated a modest reduction in the trajectory of worsening on an ALS disability scale; survival was not included as an endpoint. This drug, which is believed to act as an antioxidant, was initially administered via recurring monthly 10-day series of daily intravenous infusions. A formulation for oral use is now available.

Interventions such as antisense oligonucleotides (ASO) and microRNAs that diminish expression of mutant SOD1 protein prolong survival in transgenic-ALS rodent models and are also now under investigation in SOD1-mediated ALS. Tofersen, an ASO that suppresses SOD1 expression following intrathecal delivery, is now FDA approved for SOD1-mediated ALS. Pilot studies of an ASO targeting FUS/TLS have also been promising. Pathophysiologic studies of cell lines and animal models incorporating mutant SOD1, C9orf72, and other ALS genes have disclosed diverse targets for therapy; consequently, multiple therapies are presently in clinical trials for ALS including experimental trials of small molecules, mesenchymal stem cells, and immunosuppression.

In the absence of a primary therapy for ALS, a variety of rehabilitative aids may substantially assist ALS patients. Foot-drop splints facilitate ambulation by obviating the need for excessive hip flexion and by preventing tripping on a floppy foot. Finger-extension splints can potentiate grip. Respiratory support may be life-sustaining. For patients electing against long-term ventilation by tracheostomy, positive-pressure ventilation by mouth or nose provides transient (weeks to months) relief from hypercarbia and hypoxia. Also extremely beneficial for some patients is a respiratory device (cough assist machine) that produces an artificial cough. This is highly effective in clearing airways and preventing aspiration pneumonia. When bulbar disease prevents normal chewing and swallowing, gastrostomy is uniformly helpful, restoring normal nutrition and hydration. Fortunately, an increasing variety of speech synthesizers are now available to augment speech when there is advanced bulbar palsy. These facilitate oral communication and may be effective for telephone use.

In contrast to ALS, several of the disorders (Tables 448-1 and 448-3) that bear some clinical resemblance to ALS are treatable. For this reason, a careful search for causes of secondary motor neuron disease is warranted.

OTHER MOTOR NEURON DISEASES

SELECTED LOWER MOTOR NEURON DISORDERS

In these motor neuron diseases, the peripheral motor neurons are affected without evidence of involvement of the corticospinal motor system (Tables 448-1, 448-2, and 448-3).

X-Linked Spinobulbar Muscular Atrophy (Kennedy's Disease) This is an X-linked lower motor neuron disorder in which progressive weakness and wasting of limb and bulbar muscles begins in males in mid-adult life and is conjoined with androgen insensitivity manifested by gynecomastia and reduced fertility (Chap. 403). In addition to gynecomastia, which may be subtle, two findings distinguishing this disorder from ALS are the absence of signs of pyramidal tract disease (spasticity) and the presence of a subtle sensory neuropathy in some patients. The underlying molecular defect is an expanded trinucleotide repeat (CAG) in the first exon of the androgen receptor gene on the X chromosome. An inverse correlation appears to exist between the number of CAG repeats and the age of onset of the disease.

Adult Tay-Sachs Disease Several reports have described adult-onset, predominantly lower motor neuropathies arising from deficiency of the enzyme β-hexosaminidase (hex A). These tend to be distinguishable from ALS because they are very slowly progressive and in some cases may have been symptomatic for years; dysarthria and radiographically evident cerebellar atrophy may be prominent. In rare cases, spasticity may also be present, although it is generally absent (Chap. 429).

Spinal Muscular Atrophy The SMAs are a family of selective lower motor neuron diseases of early onset. Despite some phenotypic variability (largely in age of onset), the defect in the majority of families with SMA is loss of a protein (SMN, for survival motor neuron) that is important in the formation and trafficking of RNA complexes across the nuclear membrane. Neuropathologically, these disorders are characterized by extensive loss of large motor neurons; muscle biopsy reveals evidence of denervation atrophy. Several clinical forms exist.

Infantile SMA (SMA I, Werdnig-Hoffmann disease) has the earliest onset and most rapidly fatal course. In some instances, it is apparent even before birth, as indicated by decreased fetal movements late in the third trimester. Though alert, afflicted infants are weak and floppy (hypotonic) and lack muscle-stretch reflexes. Death generally ensues within the first year of life. *Chronic childhood SMA* (SMA II) begins later in childhood and evolves with a more slowly progressive course. *Juvenile SMA* (SMA III, Kugelberg-Welander disease) manifests during late childhood and runs a slow, indolent course. Unlike most denervating diseases, in this chronic disorder, weakness is greatest in the proximal muscles; indeed, the pattern of clinical weakness can suggest a primary myopathy such as limb-girdle dystrophy. Electrophysiologic and muscle biopsy evidence of denervation distinguish SMA III from the myopathic syndromes. Remarkably, two treatments have shown dramatic benefit in infantile SMA. One, nusinersen, now an approved therapy, entails administering small oligonucleotides that alter mRNA splicing of one of the SMN genes, generating sufficient normal SMN protein to provide clinical benefit (including prolonged survival). The other treatment uses systemically administered adeno-associated virus (AAV) to deliver the missing SMN gene to motor neurons and other cells.

Multifocal Motor Neuropathy with Conduction Block In this disorder, lower motor neuron function is regionally and chronically disrupted by focal blocks in conduction. Many cases have elevated serum titers of mono- and polyclonal antibodies to ganglioside GM1; it is hypothesized that the antibodies produce selective, focal, paranodal demyelination of motor neurons. MMCB is not typically associated with corticospinal signs. In contrast with ALS, MMCB may respond dramatically to therapy such as IV immunoglobulin or chemotherapy; thus, it is imperative that MMCB be excluded when considering a diagnosis of ALS.

Other Forms of Lower Motor Neuron Disease In individual families, other syndromes characterized by selective lower motor neuron dysfunction in an SMA-like pattern have been described. There are rare X-linked and autosomal dominant forms of apparent SMA. There is an ALS variant of juvenile onset, the Fazio-Londe syndrome, that involves mainly the musculature innervated by the brainstem. A component of lower motor neuron dysfunction is also found in degenerative disorders such as Machado-Joseph disease and the related olivopontocerebellar degenerations (Chap. 450). Finally, a group of lower motor neuron disorders, sometimes mimicking Charcot-Marie-Tooth disease, and sometimes spinal muscular atrophy, are caused by mutations in the enzymes (tRNA synthetases) that charge tRNA with specific amino acids, an early step in protein synthesis.

SELECTED DISORDERS OF THE UPPER MOTOR NEURON

Primary Lateral Sclerosis This rare disorder arises sporadically in adults in mid-to-late life. Clinically, PLS is characterized by progressive spastic weakness of the limbs, preceded or followed by spastic dysarthria and dysphagia, indicating combined involvement of the corticospinal and corticobulbar tracts. Fasciculations, amyotrophy, and sensory changes are absent; neither electromyography nor muscle biopsy shows denervation. On neuropathologic examination, there is selective loss of the large pyramidal cells in the precentral gyrus and degeneration of the corticospinal and corticobulbar projections. The peripheral motor neurons and other neuronal systems are spared. The course of PLS is usually indolent; infrequently, there is conversion to a more aggressive course with lower motor neuron degeneration as in ALS. Early in its course, PLS raises the question of multiple sclerosis, other demyelinating diseases, or adult-onset spastic paraplegia as diagnostic considerations **(Chap. 455)**. A myelopathy suggestive of PLS is infrequently seen with infection with the retrovirus human T-cell lymphotropic virus 1 (HTLV-1) **(Chap. 453)**. The clinical course and laboratory testing will distinguish these possibilities.

Hereditary Spastic Paraplegia In its pure form, HSP is usually transmitted as an autosomal trait; most adult-onset cases are dominantly inherited. There are >80 genetic types of HSP for which causative mutations in >60 genes have been identified. Table 448-3 lists more commonly identified genetic types of HSP. Symptoms usually begin in the third or fourth decade of life, presenting as progressive spastic weakness beginning in the lower extremities; however, there are variants with onset so early that the differential diagnosis includes cerebral palsy. HSP typically has a long survival, presumably because respiratory function is spared. Late in the illness, there may be urinary urgency and incontinence and sometimes fecal incontinence; sexual function tends to be preserved.

In pure forms of HSP, the spastic leg weakness is often accompanied by posterior column (vibration and position) abnormalities and disturbance of bowel and bladder function. Some family members may have spasticity without clinical symptoms.

By contrast, particularly when recessively inherited, HSP may have complex or complicated forms in which altered corticospinal and dorsal column function is accompanied by significant involvement of other regions of the nervous system, including amyotrophy, intellectual disability, optic atrophy, and sensory neuropathy.

Neuropathologically, in HSP, there is degeneration of the corticospinal tracts, which appear nearly normal in the brainstem but show increasing atrophy at more caudal levels in the spinal cord; in effect, this pathologic picture is of a dying-back or distal axonopathy of long neuronal fibers within the CNS.

Defects at numerous loci underlie both dominantly and recessively inherited forms of HSP (Table 448-3). The gene most commonly implicated in dominantly inherited HSP is *spastin*, which encodes a microtubule interacting protein. The most common childhood-onset dominant form arises from mutations in the *atlastin* gene.

An infantile-onset form of X-linked, recessive HSP arises from mutations in the gene for myelin proteolipid protein. This is an example of rather striking allelic variation, as most other mutations in the same gene cause not HSP but Pelizaeus-Merzbacher disease, a widespread disorder of CNS myelin. Another recessive variant is caused by defects in the *paraplegin* gene. Paraplegin has homology to metalloproteases that are important in mitochondrial function in yeast. A slowly progressive, adult-onset X-linked progressive spastic paralysis designated adrenomyeloneuropathy is caused by mutations in the *ABCD1* gene; these cases are associated with elevated serum levels of very-long-chain fatty acids **(Chap. 453)**.

449 Prion Diseases

Stanley B. Prusiner, Michael D. Geschwind

Prions are proteins that adopt alternative conformations, which become self-propagating. Some prions cause degeneration of the central nervous system (CNS). Once relegated to causing a group of rare CNS disorders, such as Creutzfeldt-Jakob disease (CJD), increasing evidence argues that prions also cause more common neurodegenerative diseases (NDs) including Alzheimer's disease (AD) and Parkinson's disease (PD). While CJD is caused by the accumulation of PrP^{Sc} prions **(Table 449-1)**, α-synuclein prions cause multiple system atrophy (MSA) **(Chap. 451)**. Infectious MSA prions have been recovered from human brain samples stored in formalin for up to 20 years. Similar resistance to formalin was demonstrated for brain samples from sheep with scrapie. Increasing data suggest that Aβ and tau prions together may cause AD, α-synuclein prions PD in addition to MSA, and tau prions frontotemporal lobar degeneration (FTLD). CJD typically presents as a rapidly progressive dementia accompanied by other motor abnormalities and behavioral changes. The illness is relentlessly progressive and generally causes death within ~7 months from onset. Most patients with sporadic CJD (sCJD) are between 50 and 75 years of age, although patients as young as 12 and as old as 96 have been described.

TABLE 449-1 Glossary of PrP Prion Terminology

Prion	*Pro*teinaceous *in*fectious particle that lacks nucleic acid. Prions are composed entirely of alternatively folded proteins that undergo self-propagation. Distinct strains of prions exhibit different biologic properties, which are epigenetically heritable. PrP prions cause scrapie in sheep and goats, mad cow disease, and related neurodegenerative diseases of humans such as Creutzfeldt-Jakob disease (CJD).
PrP^{Sc}	Disease-causing *Sc*rapie isoform of the prion protein. This protein is the only identifiable macromolecule in purified preparations of scrapie prions.
PrP^{C}	*C*ellular isoform of the prion protein. PrP^{C} is the precursor of PrP^{Sc}.
PrP 27-30	A fragment of PrP^{Sc}, generated by truncation of the NH_2-terminus by limited digestion with proteinase K. PrP 27-30 retains prion infectivity and polymerizes into amyloid.
PRNP	PrP gene located on human chromosome 20.
Prion rod	An aggregate of prions composed largely of PrP 27-30 molecules. Created by detergent extraction and limited proteolysis of PrP^{Sc}. Morphologically and histochemically indistinguishable from many amyloids.
PrP amyloid	Amyloid containing PrP in the brains of animals or humans with prion disease; often accumulates as plaques.

TABLE 449-2 The PrP Prion Diseases

DISEASE	HOST	MECHANISM OF PATHOGENESIS
Human		
Kuru	Fore people	Infection through ritualistic cannibalism
iCJD	Humans	Infection from prion-contaminated hGH, dura mater grafts, etc.
vCJD	Humans	Infection from bovine prions
fCJD	Humans	Germline mutations in *PRNP*
GSS	Humans	Germline mutations in *PRNP*
FFI	Humans	Germline mutation in *PRNP* (D178N, M129)
sCJD	Humans	Somatic mutation or spontaneous conversion of PrP^{C} into PrP^{Sc}?
sFI	Humans	Somatic mutation or spontaneous conversion of PrP^{C} into PrP^{Sc}?
Animal		
Scrapie	Sheep, goats	Infection in genetically susceptible sheep and goats
BSE	Cattle	Infection with prion-contaminated MBM
TME	Mink	Infection with prions from sheep or cattle
CWD	Mule deer, elk, or moose	Unknown
FSE	Cats	Infection with prion-contaminated beef
Exotic ungulate encephalopathy	Greater kudu, nyala, or oryx	Infection with prion-contaminated MBM

Abbreviations: BSE, bovine spongiform encephalopathy; CJD, Creutzfeldt-Jakob disease; CWD, chronic wasting disease; fCJD, familial Creutzfeldt-Jakob disease; FFI, fatal familial insomnia; FSE, feline spongiform encephalopathy; GSS, Gerstmann-Sträussler-Scheinker disease; hGH, human growth hormone; iCJD, iatrogenic Creutzfeldt-Jakob disease; MBM, meat and bone meal; sCJD, sporadic Creutzfeldt-Jakob disease; sFI, sporadic fatal insomnia; TME, transmissible mink encephalopathy; vCJD, variant Creutzfeldt-Jakob disease.

The potential role of prions in the pathogenesis of NDs is reviewed in **Chap. 435**.

CJD is one malady in a group of disorders caused by prions composed of the human prion protein (PrP). PrP prions reproduce by binding to the normal, *c*ellular isoform of the *p*rion *p*rotein (PrP^{C}) and stimulating conversion of PrP^{C} into the disease-causing isoform PrP^{Sc}. PrP^{C} is rich in α-helix and has little β-structure, whereas PrP^{Sc} has less α-helix and a high amount of β-structure. The α-to-β structural transition in PrP is the fundamental event underlying this group of prion diseases.

Four new concepts have emerged from studies of PrP prions: (1) Prions are the only known transmissible pathogens that are devoid of nucleic acid; all other infectious agents possess genomes composed of either RNA or DNA that direct the synthesis of their progeny. (2) Prion diseases may manifest as infectious, genetic, or sporadic disorders; no other group of illnesses with a single etiology presents with such a wide spectrum of clinical manifestations. (3) Prion diseases result from the accumulation of PrP^{Sc}, the conformation of which differs substantially from that of its precursor, PrP^{C}. (4) Distinct strains of prions exhibit different biologic properties, which are epigenetically inherited. In other words, PrP^{Sc} can exist in a variety of different conformations, many of which seem to specify disease phenotypes.

How a specific conformation of a PrP^{Sc} molecule is imparted to PrP^{C} during prion replication to produce nascent PrP^{Sc} with the same conformation is not well understood. Additionally, it is unclear what factors determine where in the CNS a particular PrP^{Sc} molecule will be created.

SPECTRUM OF PRP PRION DISEASES

The sporadic form of CJD is the most common PrP prion disorder in humans. sCJD accounts for ~85% of all cases of human PrP prion disease, and genetic prion diseases account for 10–15% of all cases **(Table 449-2)**. Genetic prion diseases were historically divided into three forms: familial CJD (fCJD), Gerstmann-Sträussler-Scheinker (GSS) disease, and fatal familial insomnia (FFI). All dominantly inherited PrP prion diseases are caused by mutations in the PrP gene.

Although infectious PrP prion diseases account for <1% of all cases and infection does not seem to play an important role in the natural history of these illnesses, the transmissibility of PrP prions is an important biologic feature. Kuru of the Fore people of Papua New Guinea resulted from the consumption of brains from dead relatives during ritualistic cannibalism. After the cessation of this practice in the late 1950s, kuru nearly disappeared, with the exception of a few recent patients exhibiting incubation periods of >50 years. Iatrogenic CJD (iCJD) results from the accidental inoculation of patients with prions through medical procedures such as cadaver-derived dura mater grafts and human pituitary hormones. Variant CJD (vCJD) that mostly occurs in teenagers and young adults in Europe, predominantly the United Kingdom and France, is the result of exposure to tainted beef from cattle with bovine spongiform encephalopathy (BSE). Although occasional cases of iCJD still occur, this form of CJD is currently on the decline due to public health measures aimed at preventing the spread of PrP prions.

More than seven diseases of animals are caused by prions (Table 449-2). Scrapie of sheep and goats is the prototypic PrP prion disease. Mink encephalopathy, BSE, feline spongiform encephalopathy, exotic ungulate encephalopathy, and nonhuman primate prion disease are all thought to occur after the consumption of prion-infected foodstuffs. The BSE epidemic emerged in Britain in the late 1980s and was shown to be due to industrial cannibalism. Whether BSE began as a sporadic case of BSE in a cow or started with scrapie in sheep is unknown. The origin of chronic wasting disease (CWD), a prion disease endemic in deer and elk in regions of North America, and more recently identified in isolated populations in Scandinavia and Korea, is uncertain. In contrast to other prion diseases, CWD is highly transmissible among cervids. Bodily excretions, such as feces, urine, and saliva, from asymptomatic, infected cervids contain prions that are likely to be responsible for the spread of CWD. Notably, mink are carnivores and mink encephalopathy is spread from one animal to another.

EPIDEMIOLOGY

CJD is found throughout the world. The incidence of sCJD is ~1–2 cases per million population, although a person's lifetime risk of dying from CJD is ~1 in 5000 to 6000 deaths. Because sCJD is an age-dependent ND, its incidence is expected to increase steadily as older segments of populations in developed and developing countries continue to expand. Although many geographic clusters of CJD have been reported, each has been shown to segregate with a PrP gene mutation and/or included misdiagnoses. Attempts to identify common exposure to some etiologic agent have been unsuccessful for both the sporadic

and familial cases. Ingestion of scrapie-infected sheep or goats as a cause of CJD in humans has not been demonstrated, and epidemiologic studies do not support this, although speculation about this potential route of infection continues. Whether PrP prion disease in deer, elk, or moose has passed to cows, sheep, or directly to humans remains unknown. Studies with mice modified to carry the human *PRNP* gene demonstrate that oral infection with CWD prions can occur, but the process is inefficient compared to intracerebral inoculation. The U.S. Centers for Disease Control and Prevention (CDC) conducts surveillance of CJD in the United States to ascertain the number and type of cases annually. Because up to 90% of culled deer in some game herds have been shown to harbor CWD prions, the CDC also has a study following deer hunters to determine if they have an increased rate of prion disease and whether it is a novel prion disorder.

PATHOGENESIS

The human PrP prion diseases were initially classified as NDs of unknown etiology. Even though the familial nature of GSS and a subset of CJD cases was well described, the significance of this observation became more obscure with the transmission of GSS and CJD to animals since genetic NDs were not considered transmissible. With the transmission of kuru and CJD to nonhuman primates, investigators began to view these diseases as infectious CNS illnesses caused by slow viruses. Eventually, the true cause of GSS and a minority of CJD cases became clear with the discovery in 1989 of mutations in the *PRNP* gene of these familial patients. The prion concept explains how a single disease can manifest as sporadic, heritable (i.e., genetic), and infectious. Moreover, the hallmark of all PrP prion diseases, whether sporadic, dominantly inherited, or acquired by infection, is that they involve the aberrant folding of the PrP protein.

A major feature that distinguishes PrP prions from viruses is the finding that both the normal and disease-causing PrP isoforms are encoded by a chromosomal gene. In humans, the PrP gene is designated *PRNP* and is located on the short arm of chromosome 20. Limited proteolysis of PrP^{Sc} produces a smaller, protease-resistant molecule of ~142 amino acids designated PrP 27-30, whereas PrP^{C} is completely hydrolyzed under the same conditions **(Fig. 449-1)**. PrP 27-30 polymerizes into prion rods that are morphologically indistinguishable from the filaments that aggregate to form PrP amyloid plaques in the CNS. This discovery raised the possibility that many other NDs might be caused by different proteins, all of which can fold into prions.

Prion Strains Distinct strains of PrP prions exhibit different biologic properties, which are epigenetically heritable. The existence of prion strains raised the question of how heritable biologic information can be enciphered in a molecule other than nucleic acid. Various strains of PrP prions have been defined by incubation times, distribution of neuronal vacuolation (i.e., spongiform change) on neuropathology, and stabilities of PrP^{Sc} to denaturation. Subsequently, the patterns of PrP^{Sc} deposition were found to correlate with the neuroanatomic location and pattern of vacuolation, and these patterns were also used to characterize prion strains.

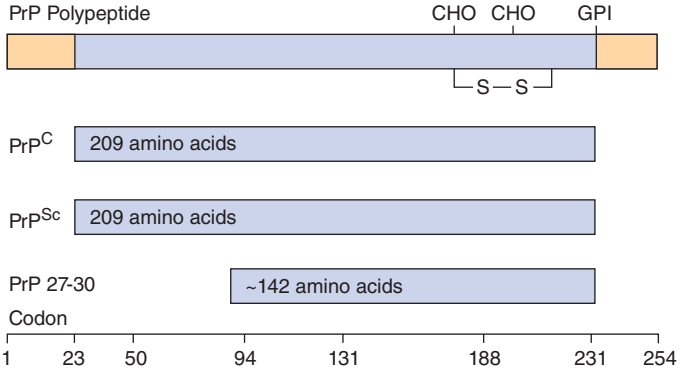

FIGURE 449-1 PrP prion protein isoforms. Bar diagram of Syrian hamster PrP, which consists of 254 amino acids. After processing of the NH_2 and COOH termini, both PrP^{C} and PrP^{Sc} consist of 209 residues. After limited proteolysis, the NH_2 terminus of PrP^{Sc} is truncated to form PrP 27-30 composed of ~142 amino acids. CHO, N-linked sugars; GPI, glycosylphosphatidylinositol anchor attachment site; S–S, disulfide bond.

Persuasive evidence that strain-specific information is enciphered in the tertiary structure of PrP^{Sc} comes from transmission of two different inherited human prion diseases to mice expressing a chimeric human–mouse PrP transgene. In most forms of fCJD and the majority of sCJD cases, the protease-resistant fragment of PrP^{Sc} after deglycosylation has a molecular mass of 21 kDa (i.e., type 1 prions), whereas in FFI, and a minority of sCJD cases, it is 19 kDa (type 2 prions) **(Table 449-3)**. This difference in molecular mass was shown to be due to different sites of proteolytic cleavage at the NH_2 termini of the two human PrP^{Sc} molecules, reflecting different tertiary structures. These distinct conformations were not unexpected because the amino acid sequences of the PrP fragments differ. Extracts from the brains of patients with FFI transmitted disease to the mice expressing the chimeric human–mouse PrP transgene and resulted in the formation of 19-kDa PrP^{Sc}, whereas brain extracts from patients with fCJD and sCJD harboring 21-kDa PrP^{Sc} resulted in 21-kDa PrP^{Sc} in mice expressing the same transgene. On second passage, these differences were maintained, demonstrating that chimeric PrP^{Sc} can exist in two different conformations as demonstrated by the sizes of the protease-resistant fragments, even though the amino acid sequence of PrP^{Sc} is invariant.

This analysis was extended when patients with sporadic fatal insomnia (sFI) were identified. Although they did not carry a *PRNP* mutation, the patients demonstrated a clinical and pathologic phenotype that was indistinguishable from that of patients with FFI. Furthermore, 19-kDa PrP^{Sc} was found in their brains, and on passage of sFI prion disease to mice expressing the chimeric human–mouse PrP transgene, 19-kDa PrP^{Sc} was also found. These findings indicate that the disease phenotype is dictated by the conformation of PrP^{Sc} and not the amino acid sequence. PrP^{Sc} acts as a template for the conversion of PrP^{C} into nascent PrP^{Sc}. On the passage of prions into mice expressing a chimeric hamster–mouse PrP transgene, a change in the conformation of PrP^{Sc} was accompanied by the emergence of a new strain of prions.

Many new strains of prions were generated using recombinant PrP (recPrP) produced in bacteria; recPrP was polymerized into amyloid fibrils to make "synthetic prions," which were inoculated into transgenic mice overexpressing high levels of wild-type mouse PrP^{C}. Approximately 500 days later, the mice died of prion disease. The incubation times (i.e., time to clinical disease onset) of the "synthetic prions" in mice were dependent on the conditions used for polymerization of the amyloid fibrils, which affected the stability of those amyloid fibrils. Highly stable amyloids gave rise to stable prions with long incubation times; low-stability amyloids led to prions with short incubation times. Amyloids of intermediate stability gave rise to prions with intermediate stabilities and intermediate incubation times. Such findings are consistent with earlier studies showing that the incubation times of synthetic and naturally occurring prions are directly proportional to the stability of the prion.

Species Barrier Studies on the role of the primary and tertiary structures of PrP in the transmission of prion disease have provided new insights into the pathogenesis of these maladies. The amino acid sequence of PrP encodes the species of the prion, and the prion derives its PrP^{Sc} sequence from the last mammal in which it was passaged. While the primary structure (i.e., amino acid sequence) of PrP is likely to be the most important or even the sole determinant of the tertiary structure of PrP^{C}, PrP^{Sc} seems to function as a template in determining the tertiary structure of nascent PrP^{Sc} molecules as they are formed from PrP^{C}. In turn, prion diversity appears to be enciphered in the conformation of PrP^{Sc}, and thus prion strains seem to represent different conformers of PrP^{Sc}.

In general, transmission of PrP prion disease from one species to another is inefficient, in that not all intracerebrally inoculated animals develop disease, and those that fall ill do so only after long incubation times that can approach the natural life span of the animal. This "species barrier" to transmission is correlated with the degree of similarity between the amino acid sequences of PrP^{C} in the inoculated host and of PrP^{Sc} in the inoculum. The importance of sequence similarity between

TABLE 449-3 Distinct Prion Strains Generated in Humans with Inherited Prion Diseases and Transmitted to Transgenic Mice[a]

INOCULUM	HOST SPECIES	HOST PrP GENOTYPE	INCUBATION TIME [DAYS ± SEM] (n/n_0)	PrP^{Sc} (kDa)
None	Human	FFI(D178N, M129)		19
FFI	Mouse	Tg(MHu2M)	206 ± 7 (7/7)	19
FFI → Tg(MHu2M)	Mouse	Tg(MHu2M)	136 ± 1 (6/6)	19
None	Human	fCJD(E200K)		21
fCJD	Mouse	Tg(MHu2M)	170 ± 2 (10/10)	21
fCJD → Tg(MHu2M)	Mouse	Tg(MHu2M)	167 ± 3 (15/15)	21

[a]Tg(MHu2M) mice express a chimeric mouse–human PrP gene.

Notes: Clinicopathologic phenotype is determined by the conformation of PrP^{Sc} in accord with the results of the transmission of human prions from patients with FFI to transgenic mice.

Abbreviations: fCJD, familial Creutzfeldt-Jakob disease; FFI, fatal familial insomnia; SEM, standard error of the mean.

the host and donor PrP argues that PrP^{C} directly interacts with PrP^{Sc} in the prion conversion process.

SPORADIC AND INHERITED PrP PRION DISEASES

Several different scenarios might explain the initiation of sporadic prion disease: (1) A somatic mutation in a single cell may be the cause and thus follow a path similar to that for germline mutations in inherited disease. In this situation, the primary structure of PrP^{C} made from the mutated gene would be more susceptible to misfolding into PrP^{Sc}. This mutant PrP^{Sc} then must be capable of targeting wild-type PrP^{C}, a process known to be possible for some mutations (i.e., high penetrance) but less likely for others (low penetrance). (2) The activation energy barrier separating wild-type PrP^{C} from PrP^{Sc}, preventing conversion to PrP^{Sc}, could be crossed on rare occasions in the context of a population. Most individuals would be spared, but presentations in older persons who have had more time for this conversion to occur would be seen. (3) PrP^{Sc} may be present at low levels in some normal cells, where it performs an important, but yet unknown, function. The level of PrP^{Sc} in such cells is hypothesized to be sufficiently low as not to be detected by routine bioassay. In some altered metabolic states, the cellular mechanisms for clearing PrP^{Sc} might become compromised, and the rate of PrP^{Sc} formation would then begin to exceed the capacity of the cell to clear it. The third possible mechanism is attractive because it suggests that PrP^{Sc} is not simply a misfolded protein, as proposed for the first and second mechanisms, but that it is an alternatively folded molecule with a function. Moreover, the multitude of conformational states that PrP^{Sc} can adopt, as described above, raises the possibility that PrP^{Sc} or another protein might function in a process such as short-term memory where information storage is thought to occur in the absence of new protein synthesis.

More than 40 different mutations resulting in nonconservative substitutions in the human *PRNP* gene have been found to segregate with inherited human prion diseases. Missense mutations, a deletion, expansions in the octapeptide repeat region of the gene, called octapeptide repeat insertions (OPRIs), and stop codon mutations are responsible for genetic forms of prion disease.

Although phenotypes may vary dramatically, even within families, specific phenotypes observed with certain mutations appear to cause fCJD. More than 20 missense variants—including substitutions at codons 102, 105, 117, 198, and 217, and mid to longer OPRIs—cause the GSS form of PrP prion disease, with prominent parkinsonism and/or cerebellar features and typically onset of dementia later in the course. Regarding OPRI mutations, the normal human PrP sequence contains an unstable section in the N-terminal region comprised of five repeats—a nine-amino-acid sequence or nonapeptide (R1) followed by four octapeptide repeats (R2, R2, R3, R4), which includes two tandem R2 domains. Insertions from 2 to 12 extra octapeptide repeats cause variable phenotypes including conditions indistinguishable from sCJD, GSS-like presentations, and even a slowly progressive dementing illness of many years' duration to an early-age-of-onset disorder that is similar to AD. A mutation at codon 178 that results in substitution of asparagine for aspartic acid generally causes FFI if methionine is encoded at codon 129 on the same allele. In contrast, a typical CJD phenotype generally occurs when there is a valine at codon 129 of the same allele. Stop codon (nonsense) mutations are rare and cause a range of phenotypes, including some with a prolonged course of years to decades, GSS- or AD-like presentations, autonomic and sensory peripheral nervous system involvement, chronic gastrointestinal upset, and extensive PrP^{Sc} amyloid deposits.

HUMAN *PRNP* GENE POLYMORPHISMS

Polymorphisms influence the susceptibility to sporadic, genetic, and acquired forms of PrP prion disease. The methionine [M] or valine [V] polymorphism at codon 129 of human *PRNP* not only modulates the age of onset of some genetic prion diseases but also can affect the clinical phenotype. Sporadic CJD can be divided into six different molecular subtypes, based on the combination of codon 129 polymorphism (MM, MV, or VV) and the prion type (1 or 2), with each subtype having a particular clinical and pathological presentation. MM1/MV1 subtypes are the most common (~40–70% of cases) and usually have the most prototypic form of sCJD with rapidly progressive dementia, ataxia, and myoclonus and a mean survival of ~4–7 months. The VV2 subtype represents ~15% of sCJD cases, usually starts with ataxia, and has a similar survival as MM1/MV1. The MV2 subtype represents ~10% of cases and has a longer mean survival of ~17 months. The vast majority of MV2 cases are a form with kuru plaques in the cerebellum, called MV2K, which are clinically similar to VV2 (i.e., early ataxia) but have a slower progression and longer survival. A minority of MV2 cases are of a cortical subtype called MV2-cortical (MV2C) with significant vacuolation (spongiform change) surrounded by perivacuolar PrP^{Sc} staining in all cortical layers and are usually without kuru plaques or cerebellar involvement. The MV2C cases present as a slowly progressive cognitive/dementia syndrome with motor symptoms occurring late in the disease course. The MM2 subtype represents ~4% of sCJD cases, has a mean survival of ~15.5 months, and is divided about equally into two subtypes: MM2-thalamic (MM2T, also called sFI) and MM2-cortical (MM2C). MM2T is clinicopathologically nearly identical to FFI (see below), whereas MM2C presents similarly to MV2C with a relatively slow progressive dementia and has a mean age of onset in the 50s, about a decade younger than most sCJD. VV1 is the least common subtype, representing ~1% of cases, presenting as a progressive dementia with a mean age of onset in the mid to late 40s, about two decades earlier than most other sCJD subtypes.

Substitution of the basic residue lysine for glutamine at position 218 in mouse PrP produced dominant-negative inhibition of prion replication in transgenic mice. This same lysine substituted for glutamine at position 219 in human PrP has been found in 12% of the Japanese population, a group that appears to be resistant to prion disease. Dominant-negative inhibition of prion replication was also found with substitution of the basic residue arginine at position 171; sheep with arginine were resistant to scrapie prions but were susceptible to BSE prions that were inoculated intracerebrally. A very interesting polymorphism at codon 127 in *PRNP* was identified among longtime survivors of the kuru epidemic in the Fore people of Papua New Guinea, which when expressed in transgenic mice with humanized *PRNP* prevented the animals from acquiring prion disease.

ACQUIRED (TRANSMITTED) PrP PRION DISEASES

IATROGENIC CJD

Accidental transmission of CJD to humans through medical procedures (i.e., iatrogenic) appears to have occurred with cadaver-derived human pituitary hormones, dura mater grafts, and corneal transplants, as well as through contaminated electroencephalogram (EEG) electrode implantation and possibly through other neurosurgical procedures. Corneas from donors with unsuspected CJD have been transplanted to apparently healthy recipients who developed CJD after variable incubation periods. Two other cases arose due to contamination during epilepsy surgery from depth EEG electrodes previously used in a patient who unknowingly had CJD; these electrodes were subsequently implanted in a chimpanzee, causing CJD 18 months later.

Surgical procedures may have resulted in other accidental inoculations of patients with prions, presumably because some instrument or apparatus in the operating theater became contaminated when a CJD patient underwent surgery. Although the epidemiology of these studies is highly suggestive, no proof for such episodes exists.

Dura Mater Grafts More than 200 cases of CJD after implantation of dura mater grafts (dCJD) have been recorded. Dura mater is normally collected from cadavers, mass sterilized in a heated vat, freeze-dried, and prepared for use in a variety of surgical procedures. Unfortunately, some of the donor cadavers unknowingly had prion disease. All but possibly two of the grafts appear to have been acquired from a single manufacturer. More than two-thirds of the cases occurred in Japan. Patients with dCJD usually present with cerebellar ataxia, visual symptoms, and dementia and have a mean incubation period of 12 years (range 1.3–30 years). Two subtypes of dCJD have been identified in Japan, a type with PrP^{Sc} plaques and a type without plaques (synaptic PrP^{Sc}).

Human Growth Hormone and Pituitary Gonadotropin Therapy The transmission of CJD prions from contaminated human growth hormone (hGH) preparations derived from human pituitaries has been responsible for fatal cerebellar disorders with dementia in >200 patients ranging in age from 5 to 42 years, most occurring in France, the United Kingdom, and the United States. These patients received injections of hGH every 2–4 days for ~2–12 years. If it is thought that these patients developed CJD from injections of prion-contaminated hGH preparations, the possible incubation periods range from 4 to 30 years. Recombinant hGH is now exclusively used therapeutically so that possible contamination with prions is no longer an issue. Four cases of CJD also occurred in women in Australia receiving human pituitary gonadotropin, with incubation periods of 12–16 years.

Notably, there is some evidence that deceased patients who received hGH early in life may have inadvertently received Aβ prions also, which can lead to amyloid and even tau pathology. Whether iatrogenic propagation of Aβ or tau prions in the human CNS led to an ND, such as AD or cerebral amyloid angiopathy (CAA), in these patients is still controversial.

VARIANT CJD

The restricted geographic occurrence and chronology of vCJD raised the possibility that BSE prions had been transmitted to humans through the consumption of tainted beef. More than 200 cases of vCJD have occurred, with >90% of these in Britain. Variant CJD has also been reported in people either living in or originating from France, Ireland, Italy, the Netherlands, Portugal, Spain, Saudi Arabia, the United States, Canada, and Japan. For some of these patients, such as those from North America, evidence suggests they acquired the disease while living or traveling outside their home country.

The steady decline in the number of vCJD cases over the past decade argues that there will not be a prion disease epidemic in Europe, similar to those seen for BSE and kuru. What is certain is that PrP-prion-tainted meat should be prevented from entering the human food supply.

The most compelling evidence that vCJD is caused by BSE prions was obtained from experiments in mice expressing the bovine PrP transgene. Both BSE and vCJD prions were efficiently transmitted to these transgenic mice and with similar incubation periods. In contrast to sCJD prions, vCJD prions did not transmit disease efficiently to mice expressing a chimeric human–mouse PrP transgene. Earlier studies with nontransgenic mice suggested that vCJD and BSE might be derived from the same source because both inocula transmitted disease with similar but very long incubation periods.

Attempts to determine the origin of BSE and vCJD prions have relied on passaging studies in mice, some of which are described above, as well as studies of the conformation and glycosylation of PrP^{Sc}. One scenario suggests that a particular conformation of bovine PrP^{Sc} was selected for heat resistance during the rendering process and was then reselected multiple times as cattle infected by ingesting prion-contaminated meat and bone meal (MBM) were slaughtered and their offal rendered into more MBM. Variant CJD cases have virtually disappeared with protection of the beef supply in Europe. Interestingly, almost all of the ~238 cases of vCJD reported as of 2024 have been homozygous for methionine (MM) at codon 129 in *PRNP*. However, two cases (one probable and one definite) were codon 129 MV, which is the most common codon 129 polymorphism in most of the world. This finding raises the concern that persons with this polymorphism might have a longer incubation period and that another rise in cases might still occur. Of particular concern is that four known (and a fifth possible) secondary cases of vCJD infection occurred from blood product transfusions. These persons received blood components (non-leukodepleted red blood cells [RBCs] in the four known cases and factor X in the fifth case) from asymptomatic donors who later developed vCJD infection. The second of four RBC recipients did not die from vCJD but was found to have vCJD prions in the lymphoreticular system. The RBC donors did not develop vCJD infection until ~1.5–3.3 years after donation, and the incubation period for recipients of RBCs ranged from 5 to 8.5 years. Thus, vCJD is the only form of human prion disease proven to be transmissible by blood. Further evidence of the transmissibility of vCJD is that among the two most recent cases of vCJD identified, one in France and one in Italy, both had laboratory exposure to BSE-infected brain tissue. The French patient accidentally stabbed herself with forceps being used on frozen brain sections from a transgenic mouse overexpressing human PrP and inoculated with BSE. She developed symptoms 7.5 years later at age 31 and died from definite vCJD after 19 months in 2019. The last reported case of vCJD worldwide was in France in 2021, and the prior two cases occurred in the United Kingdom in 2013 and 2016.

NEUROPATHOLOGY

Frequently, the brains of patients with CJD have no recognizable abnormalities on gross examination. Patients who survive for several years have variable degrees of cerebral atrophy.

On light microscopy, the pathologic hallmarks of CJD are spongiform degeneration (vacuolation), neuronal loss, and astrocytic gliosis. The lack of an inflammatory response in CJD and other prion diseases is an important pathologic feature of these degenerative disorders. Spongiform degeneration is characterized by many 1- to 5-μm vacuoles in the neuropil between nerve cell bodies. Generally, the vacuolation occurs in the cerebral cortex, putamen, caudate nucleus, thalamus, and molecular layer of the cerebellum. Astrocytic gliosis is a constant but nonspecific feature of PrP prion diseases. Widespread proliferation of fibrous astrocytes is found throughout the gray matter of brains infected with CJD prions. Astrocytic processes filled with glial filaments form extensive networks. The degree and location of these pathologic hallmarks vary depending on the type of human prion disease, including between sCJD subtypes described above.

Amyloid plaques have been found in ~10% of CJD cases. Purified CJD prions from humans and animals exhibit the ultrastructural and histochemical characteristics of amyloid when treated with detergents during limited proteolysis. On first passage of samples from some human Japanese CJD cases into mice, amyloid plaques were found. These plaques stain with antibodies raised against PrP, demonstrating that the amyloid is composed of PrP.

The amyloid plaques of GSS disease are morphologically distinct from those seen in kuru or scrapie. GSS plaques consist of a central dense core of amyloid surrounded by smaller globules of amyloid. Ultrastructurally, they consist of a radiating fibrillar network of amyloid fibrils, with scant or no neuritic degeneration. The plaques can be distributed throughout the brain but are most frequently found in the cerebellum. They are often located adjacent to blood vessels. Congophilic angiopathy has been noted in some cases of GSS disease.

In vCJD, a characteristic feature is the presence of "florid plaques." These are composed of a central core of PrP amyloid, surrounded by vacuoles in a pattern suggesting petals on a flower.

CLINICAL FEATURES

Nonspecific prodromal symptoms occur in approximately a third of patients with CJD and may include fatigue, sleep disturbance, weight loss, headache, anxiety, vertigo, malaise, and ill-defined pain. Most patients with CJD present with cognitive and/or motor deficits. Behavioral and psychiatric symptoms, such as depression, anxiety, irritability, apathy, insomnia, appetite changes, psychosis, and visual hallucinations, are very common and often early features. These deficits usually progress over weeks or months to a state of profound dementia characterized by memory loss, impaired judgment, and a decline in virtually all aspects of intellectual function. A minority of patients present early with either isolated visual impairment or cerebellar gait and coordination deficits, referred to as the Heidenhain and Brownell-Oppenheim variants, respectively. Frequently, the cerebellar deficits are rapidly followed by progressive dementia. Visual problems often begin with blurred vision and diminished acuity, rapidly followed by dementia. Patients with early visual deficits often have a faster decline overall.

Motor symptoms and signs other than cerebellar ataxia include extrapyramidal dysfunction manifested as rigidity, masklike facies, dystonia, myoclonus, or less commonly choreoathetoid movements and pyramidal signs (usually mild and not actual weakness). Some uncommon features include seizures (usually major motor), hypoesthesia, supranuclear gaze palsy, motor neuron disease, or dysautonomic signs such as changes in body temperature and sweating.

Most patients with the most common subtype of CJD will eventually develop myoclonus. Unlike other involuntary movements, myoclonus usually persists during sleep. Startle myoclonus elicited by loud sounds, bright lights, or a person or object suddenly appearing in a patient's visual field is frequent. It is important to stress that myoclonus is neither specific nor confined to CJD and tends to occur later in the course of CJD. Dementia with myoclonus can also be due to AD **(Chap. 442)**, dementia with Lewy bodies **(Chap. 445)**, corticobasal degeneration **(Chap. 443)**, cryptococcal encephalitis **(Chap. 221)**, or the myoclonic epilepsy disorder Unverricht-Lundborg disease **(Chap. 436)**.

Clinical Course Most patients with sCJD and most types of fCJD live ~6–12 months after the onset of clinical signs and symptoms. Life expectancies can be longer, up to a few years, for less common sCJD subtypes, and some mutations causing genetic prion disease can have durations of a decade or longer.

DIAGNOSIS

The constellation of a rapid onset of cognitive impairment over weeks to months, with myoclonus and other motor symptoms, and typical magnetic resonance imaging (MRI) findings (see below) in an afebrile 60- to 70-year-old patient generally indicates CJD—most commonly sCJD.

Variations in the typical course appear in genetic and transmitted (i.e., acquired) forms of the disease. As noted above, most mutations causing fCJD have a slightly earlier mean age of onset, although usually an otherwise similar clinical and radiologic presentation as sCJD. In GSS, cerebellar ataxia is usually a prominent and presenting feature, with dementia occurring late in the disease course. GSS also presents earlier than sCJD (mean age ~43 years) and usually progresses more slowly, leading to death ~5 years after symptom onset. FFI is typically characterized by insomnia and dysautonomia; dementia occurs only in the terminal phase of the illness; survival is typically <2 years and sometimes just a few months.

Variant CJD has a different clinical course from most other prion diseases, with an early psychiatric prodrome (most commonly depression, anxiety, apathy, withdrawal, and/or delusions) that persists for several months prior to the appearance of other neurologic symptoms including cerebellar ataxia, painful sensory symptoms, a movement disorder (often myoclonus, dystonia, and/or chorea), and cognitive impairment progressing to dementia. The mean age of onset for vCJD is 28 years (median 26, range 12–74), with the majority of patients being <55 years old.

LABORATORY TESTS

The only highly specific diagnostic tests for CJD and other human PrP prion diseases measure PrP^{Sc}. The most widely used method involves limited proteolysis that generates PrP 27-30, which is detected by immunoassay after denaturation. In humans, the diagnosis of CJD can be established by brain biopsy if PrP^{Sc} is detected, although with current ancillary testing available, biopsy is rarely indicated. Because PrP^{Sc} is not uniformly distributed throughout the CNS, the absence of PrP^{Sc} in a limited sample such as a biopsy does not rule out prion disease. The use of reverse templated quake-induced conversion assay (RT-QuIC; see below), a method for amplifying prions into amyloid fibrils and detecting them with thioflavin fluorescence, has greatly increased the sensitivity of brain biopsy. If no attempt is made to measure or detect PrP^{Sc} but pathologic changes typical of CJD are seen in a brain biopsy, then the diagnosis is reasonably secure.

Brain MRI has become an important diagnostic tool for prion diseases, especially CJD, and can help distinguish CJD from most other conditions. The first reported MRI findings were on T2-weighted MRI and were hyperintensities in the striatum (caudate and putamen) and less commonly in the thalamus (depending on the type of prion disease). Subsequently, with fluid-attenuated inversion recovery (FLAIR) sequences, hyperintensity of the cortex (cortical ribboning) could also be seen. Diffusion MRI, with a combination of diffusion-weighted imaging (DWI) and attenuation deficient coefficient (ADC) sequences, greatly improved sensitivity and specificity (to mid to high 90th percentile) of MRI for prion disease, showing hyperintensity (i.e., brightness or high signal) on DWI with corresponding hypointensity (i.e., darkness or low signal) on ADC in the cortex (cortical ribboning) and striatum and less commonly in the thalamus and/or cerebellum **(Fig. 449-2)**. This abnormal signal on DWI and ADC is due to reduced or restricted diffusion of water molecules in these brain regions secondary to vacuolation. DWI and FLAIR MRI, however, often show areas of artifactual hyperintensity, particularly in regions where there is air adjacent to brain tissue, such as near sinuses. The true abnormal signal of reduced or restricted diffusion can be distinguished from artifact by (1) acquiring the diffusion MRI in multiple planes (e.g., axial and coronal), (2) looking for corresponding hypointensity in the cortex or deep nuclei on ADC, and/or increasing the degree of diffusion weighting. T2, FLAIR, and diffusion MRI are often normal, however, particularly in GSS, FFI, sFI, and in some rare genetic prion diseases such as those due to stop-codon mutations. Any prion disease with a long duration (e.g., >1–2 years) often will show nonspecific atrophy on brain MRI or head computed tomography (CT). To a limited extent, the pattern of these MRI abnormalities can also help determine the subtype of sCJD present. For example, MRI findings in the MM1/MV1 subtype are typically located in the cortex (i.e., cortical ribboning) and deep nuclei (striatum +/– thalamus), MV2K and VV2 involve deep nuclei, and MM2/MV2C are predominantly cortical. These abnormalities may be unilateral or bilateral; when they are bilateral, they may be symmetric or asymmetric. The pattern and type of MRI abnormalities in CJD are not seen with other NDs but can overlap with viral encephalitis, paraneoplastic/autoimmune encephalopathy syndromes, metabolic disorders, or seizures.

To establish the diagnosis of either sCJD or familial prion disease, sequencing the *PRNP* gene must be performed. Finding the wild-type *PRNP* gene sequence permits the diagnosis of sCJD if there is no history to suggest infection from an exogenous source of prions. The identification of a mutation in the *PRNP* gene sequence that encodes a nonconservative amino acid substitution argues for familial prion disease.

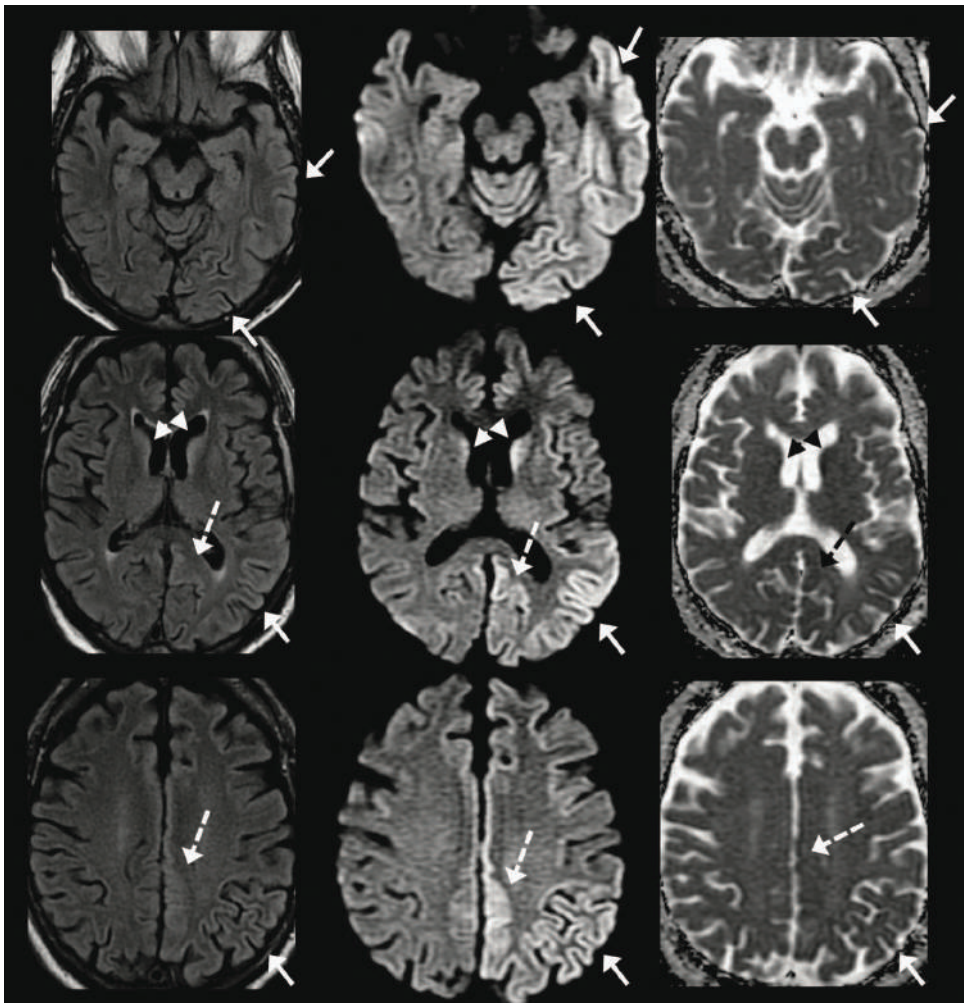

FIGURE 449-2 Brain magnetic resonance imaging (MRI) in a 72-year-old patient with sporadic Creutzfeldt-Jakob disease, MM1 subtype (classic subtype), showing axial (***A***) fluid-attenuated inversion recovery (FLAIR), (***B***) diffusion-weighted imaging (DWI), and (***C***) attenuation deficient coefficient (ADC) sequences at three different levels. There is cortical ribboning indicating restricted diffusion in the left much greater than right temporal (*solid white arrow*), occipital (*solid white arrow*), parietal (*solid white arrow*), insular (*no arrow*), and posterior cingulate cortices (*dashed arrows*). There is also restricted diffusion in the left greater than the right caudate head (*arrowheads*). The corresponding hypointensity (very dark) areas on the ADC sequence confirm that the hyperintensity (bright) areas on DWI and FLAIR are regions of reduced diffusion, not artifacts. Note that the abnormalities are best seen on DWI sequences. Images are radiologic orientation (right side of image is left side of brain).

General cerebrospinal fluid (CSF) laboratory testing (i.e., cell count, protein, glucose) is nearly always normal, except that mild and nonspecific protein elevation and, rarely, mild pleocytosis can be seen in a minority of cases. The first CSF surrogate biomarker used in clinical practice and still incorporated in several diagnostic criteria for sCJD is the 14-3-3 protein, which is elevated in many forms of brain cell injury. Although newer enzyme-linked immunosorbent assays (ELISAs) quantitatively measuring the 14-3-3γ isoform have improved sensitivity and specificity, this test is still less accurate diagnostically than some other biomarkers. The sensitivity of 14-3-3 ELISAs in sCJD ranges from ~60% to almost 90% depending on the sCJD subtype (highest in MM1/MV1), whereas the range of specificity has been reported to be as low as 40% to as high as 96% depending on the controls used, making its utility questionable. The level of total tau protein (t-tau), a microtubule-associated protein expressed in neurons and glia, is elevated in the CSF in many conditions associated with brain cell injury. ELISAs measuring t-tau appear to have a sensitivity and a specificity in the low to mid 90%, which is clinically superior to 14-3-3; however, there is no consensus at this time regarding the best t-tau ELISA or cutoff that should be used to support a diagnosis of sCJD.

Assays that amplify PrP^{Sc} into amyloid PrP^{Sc} fibrils and detect the fibrils by adding thioflavin, which binds amyloid and fluoresces, have greatly enhanced premortem diagnosis of human prion diseases. The first such assay developed was the protein misfolding cyclic amplification (PMCA), which was modified into the more user-friendly RT-QuIC assay that is now widely used in clinical practice but still primarily performed at national prion surveillance centers. The sensitivity and specificity of the current CSF RT-QuIC assay (i.e., second generation) for sCJD are about 90–95% and 98–99%, respectively. The advantage of PMCA and RT-QuIC is that they detect prions; however, false positives for RT-QuIC do occur, and as noted by the sensitivity, upward of 10% of sCJD cases are negative for RT-QuIC. As with other surrogate biomarkers, RT-QuIC is less sensitive for some uncommon sCJD subtypes, for several genetic prion diseases (i.e., GSS and other slower progressing forms), and particularly for vCJD. In contrast, PMCA seems to be more sensitive when applied to CSF and possibly blood and urine from patients with vCJD, but this test is not available for clinical practice in most countries. Improved methods to detect prions in blood, urine, skin, and even tears will be welcomed.

EEG can be useful in the diagnosis of CJD, particularly when other ancillary tests are unrevealing, although only ~60% of patients (mostly with the MM1/MV1 subtype of sCJD) show the typical pattern of periodic sharp wave complexes (PSWCs). PSWCs are usually repetitive, high-voltage, bi- or triphasic sharp discharges that normally appear quite late in the clinical course. Even when PSWCs are seen, they may be transient and might require serial EEGs to detect. During the early phase of CJD, the EEG is usually normal or shows only scattered theta and even delta slow wave activity. The presence of these stereotyped periodic bursts of PSWCs, <200 ms in duration and occurring every

1–2 s, makes the diagnosis of CJD very likely. These discharges are frequently but not always symmetric; there may be a one-sided predominance in amplitude. As CJD progresses, normal background rhythms become fragmentary and slower.

DIFFERENTIAL DIAGNOSIS

Many conditions mimic CJD, including various NDs, autoimmune/paraneoplastic encephalopathies or ataxias, infections, and even psychiatric conditions. Dementia with Lewy bodies (DLB) **(Chap. 445)** is one of the most common disorders to be mistaken for CJD, particularly when there is a phase of the illness with a fast decline. It can present rarely in a subacute fashion with delirium, myoclonus, and extrapyramidal features. Other NDs to consider include AD, frontotemporal dementia, corticobasal degeneration, progressive supranuclear palsy, ceroid lipofuscinosis, and myoclonic epilepsy with Lafora bodies. Usually when these diseases are mistaken for CJD, they have a more slowly progressive and perhaps subtle onset over a few years and then a sudden decline, which makes clinicians consider CJD. A thorough history of the earliest features of the illness—obtained through speaking with friends, family members, or coworkers—often reveals a slower onset over a few years with a more recent rapid decline, suggesting a non-CJD etiology. There have been, however, rapidly progressive cases of AD with a course of <3 years from first symptom onset, often with ataxia, myoclonus, and other symptoms similar to those seen in CJD. Many of these cases have elevated CSF biomarkers such as 14-3-3. The absence of abnormalities on diffusion MRI (i.e., DWI and ADC) will almost always distinguish these conditions from CJD. CSF RT-QuIC, if positive, can also be helpful.

Several autoantibody-mediated autoimmune encephalopathies (AEs) **(Chap. 99)**, such as anti-LGI1 (leucine-rich glioma inactivated 1), anti-Crmp5 (collapsin response-mediator protein-5 or anti-CV2), and anti-AMPAR (α-amino-3-hydroxy-5-methyl-4-isoxazolepropionic acid receptor) antibody-mediated AEs, can have significant clinical overlap with CJD. Detection of autoantibodies in the serum and/or CSF, depending on the specific antibody-mediated syndrome, and the absence of brain MRI and CSF prion-specific biomarkers can help distinguish these cases from CJD. In AE with seizures, however, brain MRI may show diffusion MRI abnormalities similar to those in CJD, though this is rare, and these abnormalities disappear soon after seizures are treated. In contrast, these MRI abnormalities generally persist in CJD, except in very long-lived cases.

Intracranial vasculitides **(Chap. 375)** may produce nearly all the symptoms and signs associated with CJD, sometimes without systemic abnormalities. Myoclonus is uncommon with cerebral vasculitis, but focal seizures may confuse the diagnosis. Prominent headache, absence of myoclonus, stepwise change in deficits, abnormal CSF, and focal white matter change on MRI or angiographic abnormalities all favor vasculitis.

Other diseases that can simulate CJD include neurosyphilis **(Chap. 187)**, AIDS dementia complex **(Chap. 208)**, progressive multifocal leukoencephalopathy **(Chap. 142)**, subacute sclerosing panencephalitis, progressive rubella panencephalitis, herpes simplex encephalitis **(Chap. 142)**, diffuse intracranial tumor (gliomatosis cerebri; **Chap. 95**), anoxic encephalopathy, dialysis dementia, uremia, hepatic encephalopathy, and lithium or bismuth intoxication.

Fever, elevated sedimentation rate, leukocytosis in blood, or a pleocytosis in CSF should alert the physician to another etiology that explains the patient's CNS dysfunction, although there are rare cases of CJD in which mild CSF pleocytosis or mild elevation in IgG index or oligoclonal bands are observed.

CARE OF CJD PATIENTS

There are no disease-modifying treatments for prion diseases, and treatment is symptomatic.

Although CJD is communicable, the likelihood of transmission from one patient to another is remote. The risk of accidental inoculation by aerosols is minuscule; nonetheless, procedures producing aerosols should be performed in certified biosafety cabinets. Biosafety level 2 practices, containment equipment, and facilities are recommended by the CDC and the National Institutes of Health. The primary concern in caring for patients with CJD is the inadvertent infection of healthcare workers by needle and stab wounds, although with the possible exception of vCJD (as noted above) in which blood transfusions appear to carry some minimal risk for transmission. When caring for patients with prion disease, standard universal precautions used in the clinical setting (e.g., gloves, gowns, and/or eye protection) are recommended when handling bodily fluids (e.g., blood, urine, and feces). Electroencephalographic and electromyographic needles should not be reused after studies on patients with CJD have been performed.

Autopsies on patients whose clinical diagnosis is CJD can be performed with minimal risk to pathologists or other morgue employees if proper prion-specific precautions are followed. Standard microbiologic practices outlined here, along with specific recommendations for decontamination, are generally adequate precautions for the care of patients with CJD and the handling of infected specimens.

DECONTAMINATION OF CJD PRIONS

Prions are generally resistant to commonly used inactivation procedures, and there is some disagreement about the optimal conditions for sterilization. Some investigators recommend treating CJD-contaminated materials once with 1 *N* NaOH at room temperature, but we believe this procedure may be inadequate for sterilization. Autoclaving at 134°C for 5 h or treatment with 2 *N* NaOH for several hours is recommended for sterilization of prions. The term *sterilization* implies complete destruction of prions; any residual infectivity can be hazardous. Transgenic mouse studies show that sCJD prions bound to stainless-steel surfaces are resistant to inactivation by autoclaving at 134°C for 2 h; exposure of bound prions to an acidic detergent solution prior to autoclaving rendered prions susceptible to inactivation. Recent studies show that α-synuclein prions in brain homogenates prepared from MSA patients bind to stainless-steel wires and that the bound prions can be transmitted to transgenic mice expressing mutant human α-synuclein.

Prion precaution protocols should be used for any patient with known or suspected CJD who is undergoing a surgical procedure that has a high risk of exposure to prions (e.g., neurosurgery). In such protocols, procedures should be implemented to reduce exposure of operating room staff and to isolate surgical equipment until the diagnosis has been definitively determined. If the patient is known to have prion disease, the equipment should be destroyed if possible or, if not possible, then thoroughly cleansed to eliminate risk of prion exposure. Importantly, as human prions appear to be more resistant than many animal prions to denaturation, particularly when bound to metal, prion removal methods used in the clinical setting should be based on data from studies using human prions.

PREVENTION AND THERAPEUTICS

There is no known effective therapy for preventing or treating CJD. The finding that phenothiazines and acridines inhibit PrP^{Sc} formation in cultured cells led to clinical studies of quinacrine in CJD patients. Unfortunately, quinacrine failed to slow the rate of cognitive decline in CJD, possibly because therapeutic concentrations of quinacrine were not achieved in the brain. Although inhibition of the P-glycoprotein (Pgp) transport system resulted in substantially increased quinacrine levels in the brains of mice, the prion incubation times were not extended by treatment with the drug. Whether such an approach can be used to treat CJD remains to be established.

Like the acridines, anti-PrP antibodies have been shown to eliminate PrP^{Sc} from cultured cells. Additionally, such antibodies in mice, either administered by injection or produced from a transgene, have been shown to prevent prion disease when prions are introduced by a peripheral route, such as intraperitoneal inoculation. Unfortunately, the antibodies were ineffective in mice inoculated intracerebrally with prions. Several drugs, including pentosan polysulfate as well as porphyrin and phenylhydrazine derivatives, delay the onset of disease in animals inoculated intracerebrally with prions if the drugs are given intracerebrally beginning soon after inoculation.

New treatment trials are underway and, based on animal models, hold promise even when treatment is begun close to symptom onset.

The best method to treat human prion diseases may be by reducing PrP, the substrate for PrP^{Sc}, rather than trying to directly reduce or eliminate PrP^{Sc}. The lifespan of mice is normal when PrP^{C} is reduced or even eliminated; when *PRNP* is knocked out, mice live a normal span of time with minimal deficits detected, aside from a mild neuropathy. Identification of adults hemizygous for *PRNP* suggests that humans can also live with reduced levels of PrP^{C}. Currently, antisense oligonucleotides (ASOs) against PrP^{C} are being tested in symptomatic prion disease. One advantage of treatment methods reducing PrP^{C} is that if they are effective, they should work for all strains and types of human prion disease, as the method is independent of the form of PrP^{Sc} that is pathogenic in a given individual.

450 Ataxic Disorders

Roger N. Rosenberg, Vikram G. Shakkottai

APPROACH TO THE PATIENT

Ataxic Disorders

Symptoms and signs of ataxia consist of gait impairment, unclear ("scanning") speech, visual blurring due to nystagmus, hand incoordination, and tremor with movement. These result from the involvement of the cerebellum and its afferent and efferent pathways, including the spinocerebellar pathways, and the frontopontocerebellar pathway originating in the rostral frontal lobe. True cerebellar ataxia must be distinguished from ataxia associated with vestibular nerve or labyrinthine disease, as the latter results in a disorder of gait associated with a significant degree of dizziness, light-headedness, or the perception of movement **(Chap. 24)**. True cerebellar ataxia is devoid of these vertiginous complaints and is clearly an unsteady gait due to imbalance. Sensory disturbances can also on occasion simulate the imbalance of cerebellar disease; with sensory ataxia, imbalance dramatically worsens when visual input is removed (Romberg sign). Rarely, weakness of proximal leg muscles mimics cerebellar disease. In the patient who presents with ataxia, the rate and pattern of the development of cerebellar symptoms help to narrow the diagnostic possibilities **(Table 450-1)**. A gradual and progressive increase in symptoms with bilateral and symmetric involvement suggests a genetic, metabolic, immune, or toxic etiology. Conversely, focal, unilateral symptoms with headache and impaired level of consciousness accompanied by ipsilateral cranial nerve palsies and contralateral weakness imply a space-occupying cerebellar lesion.

SYMMETRIC ATAXIA

Progressive and symmetric ataxia can be classified with respect to onset as acute (over hours or days), subacute (weeks or months), or chronic (months to years). Acute and reversible ataxias include those caused by intoxication with alcohol, phenytoin, lithium, barbiturates, and other drugs. Intoxication caused by toluene exposure, gasoline sniffing, glue sniffing, spray painting, or exposure to methyl mercury or bismuth are additional causes of acute or subacute ataxia, as is treatment with cytotoxic chemotherapeutic drugs such as fluorouracil and paclitaxel. Patients with a postinfectious syndrome (especially after varicella) may develop gait ataxia and mild dysarthria, both of which are reversible **(Chap. 456)**. Rare infectious causes of acquired ataxia include poliovirus, coxsackievirus, echovirus, Epstein-Barr virus, toxoplasmosis, *Legionella*, and Lyme disease.

The subacute development of ataxia of gait over weeks to months (degeneration of the cerebellar vermis) may be due to the combined effects of alcoholism and malnutrition, particularly with deficiencies of vitamins B_1 and B_{12}. Hyponatremia has also been associated with ataxia. Paraneoplastic cerebellar ataxia is associated with a number of different tumors (and autoantibodies) such as breast and ovarian cancers (anti-Yo), small-cell lung cancer (anti-PQ-type voltage-gated calcium channel), and Hodgkin's disease (anti-Tr) **(Chap. 99)**. Another paraneoplastic syndrome associated with myoclonus and opsoclonus occurs with breast (anti-Ri) and lung cancers and neuroblastoma. For all of these paraneoplastic ataxias, the neurologic syndrome may be the presenting symptom of the cancer. Autoantibody-associated cerebellar syndromes also occur without a cancer association. The most common is a progressive ataxic syndrome affecting speech and gait associated with serum anti-glutamic acid decarboxylase (GAD65) antibodies **(Chap. 99)**. Another immune-mediated progressive ataxia is associated with antigliadin (and antiendomysium) antibodies and the human leukocyte antigen (HLA) DQB1*0201 haplotype; in some affected patients, biopsy of the small intestine reveals villus atrophy consistent with gluten-sensitive enteropathy **(Chap. 336)**. Finally, subacute progressive ataxia may be caused by a prion disorder, especially when an infectious etiology, such as transmission from contaminated human growth hormone, is responsible **(Chap. 449)**.

Chronic symmetric gait ataxia suggests an inherited ataxia (discussed below), a metabolic disorder, or a chronic infection. Hypothyroidism must always be considered as a readily treatable and reversible form of gait ataxia. Infectious diseases that can present with ataxia are meningovascular syphilis and tabes dorsalis due to degeneration of the posterior columns and spinocerebellar pathways in the spinal cord.

FOCAL ATAXIA

Acute focal ataxia commonly results from cerebrovascular disease, usually ischemic infarction or cerebellar hemorrhage. These lesions typically produce cerebellar symptoms ipsilateral to the injured cerebellum and may be associated with an impaired level of consciousness due to brainstem compression and increased intracranial pressure; ipsilateral pontine signs, including sixth and seventh nerve palsies, may be present. Focal and worsening signs of acute ataxia should also prompt consideration of a posterior fossa subdural hematoma, bacterial abscess, or primary or metastatic cerebellar

TABLE 450-1 Etiology of Cerebellar Ataxia

SYMMETRIC AND PROGRESSIVE SIGNS			FOCAL AND IPSILATERAL CEREBELLAR SIGNS		
ACUTE (HOURS TO DAYS)	SUBACUTE (DAYS TO WEEKS)	CHRONIC (MONTHS TO YEARS)	ACUTE (HOURS TO DAYS)	SUBACUTE (DAYS TO WEEKS)	CHRONIC (MONTHS TO YEARS)
Intoxication: alcohol, lithium, phenytoin, barbiturates (positive history and toxicology screen) Acute viral cerebellitis (CSF supportive of acute viral infection) Postinfection syndrome	Intoxication: mercury, solvents, gasoline, glue Cytotoxic chemotherapeutic drugs Alcoholic-nutritional (vitamin B_1 and B_{12} deficiency) Lyme disease	Paraneoplastic syndrome Antigliadin antibody syndrome Hypothyroidism Inherited diseases Tabes dorsalis (tertiary syphilis) Phenytoin toxicity Amiodarone	Vascular: cerebellar infarction, hemorrhage, or subdural hematoma Infectious: cerebellar abscess (mass lesion on MRI/CT, history in support of lesion)	Neoplastic: cerebellar glioma or metastatic tumor (positive for neoplasm on MRI/CT) Demyelinating: multiple sclerosis (history, CSF, and MRI are consistent) AIDS-related multifocal leukoencephalopathy (positive HIV test and CD4+ cell count for AIDS)	Stable gliosis secondary to vascular lesion or demyelinating plaque (stable lesion on MRI/CT older than several months) Congenital lesion: Chiari or Dandy-Walker malformations (malformation noted on MRI/CT)

Abbreviations: CSF, cerebrospinal fluid; CT, computed tomography; MRI, magnetic resonance imaging.

tumor. Computed tomography (CT) or magnetic resonance imaging (MRI) studies will reveal clinically significant processes of this type. Many of these lesions represent true neurologic emergencies, as sudden herniation, either rostrally through the tentorium or caudal herniation of cerebellar tonsils through the foramen magnum, can occur and is usually devastating. Acute surgical decompression may be required **(Chap. 318)**. Lymphoma or progressive multifocal leukoencephalopathy (PML) in a patient with AIDS may present with an acute or subacute focal cerebellar syndrome. Chronic etiologies of progressive ataxia include multiple sclerosis **(Chap. 455)** and congenital lesions such as a Chiari malformation **(Chap. 453)** or a congenital cyst of the posterior fossa (Dandy-Walker syndrome).

THE INHERITED ATAXIAS

Inherited ataxias may show autosomal dominant, autosomal recessive, or maternal (mitochondrial) modes of inheritance. A genomic classification **(Table 450-2)**[1] has now largely superseded previous ones based on clinical expression alone.

Although the clinical manifestations and neuropathologic findings of cerebellar disease dominate the clinical picture, there may also be characteristic changes in the basal ganglia, brainstem, spinal cord, optic nerves, retina, and peripheral nerves. In large families with dominantly inherited ataxias, many gradations are observed from purely cerebellar manifestations to mixed cerebellar and brainstem disorders, cerebellar and basal ganglia syndromes, and spinal cord or peripheral nerve disease. Rarely, dementia is present as well. The clinical picture may be homogeneous within a family with dominantly inherited ataxia, but sometimes most affected family members show one characteristic syndrome, while one or several members have an entirely different phenotype.

AUTOSOMAL DOMINANT ATAXIAS

The autosomal spinocerebellar ataxias (SCAs) include SCA types 1 through 50, dentatorubropallidoluysian atrophy (DRPLA), and episodic ataxia (EA) types 1 to 7 (Table 450-2). SCA1, SCA2, SCA3 (Machado-Joseph disease [MJD]), SCA6, SCA7, and SCA17 are caused by CAG triplet repeat expansions in different genes. SCA8 is due to an untranslated CTG repeat expansion, SCA12 is linked to an untranslated CAG repeat, and SCA10 is caused by an untranslated pentanucleotide repeat. The clinical phenotypes of these SCAs overlap. The genotype has become the gold standard for diagnosis and classification. CAG encodes glutamine, and these expanded CAG triplet repeat expansions result in expanded polyglutamine proteins, termed *ataxins*, that produce a toxic gain of function with autosomal dominant inheritance. Although the phenotype is variable for any given disease gene, a pattern of neuronal loss with gliosis is produced that is relatively unique for each ataxia. Immunohistochemical and biochemical studies have shown cytoplasmic (SCA2), neuronal (SCA1, MJD, SCA7), and nucleolar (SCA7) accumulation of the specific mutant polyglutamine-containing ataxin proteins. Expanded polyglutamine ataxins with more than ~40 glutamines are potentially toxic to neurons for a variety of reasons including the following: high levels of gene expression for the mutant polyglutamine ataxin in affected neurons; conformational change of the aggregated protein to a β-pleated structure; abnormal transport of the ataxin into the nucleus (SCA1, MJD, SCA7); binding to other polyglutamine proteins, including the TATA-binding transcription protein and the CREB-binding protein, impairing their functions; altering the efficiency of the ubiquitin-proteasome system of protein turnover; and inducing neuronal apoptosis. An earlier age of onset (anticipation) and more aggressive disease in subsequent generations are due to further expansion of the CAG triplet repeat and increased polyglutamine number in the mutant ataxin. The most common disorders are discussed below.

SCA1

SCA1 was previously referred to as *olivopontocerebellar atrophy*, but genomic data have shown that that entity represents several different genotypes with overlapping clinical features.

Symptoms and Signs SCA1 is characterized by the development in early- or middle-adult life of progressive cerebellar ataxia of the trunk and limbs, impairment of equilibrium and gait, slowness of voluntary movements, scanning speech, nystagmoid eye movements, and oscillatory tremor of the head and trunk. Dysarthria, dysphagia, and oculomotor and facial palsies may also occur. Extrapyramidal symptoms include rigidity, an immobile face, and parkinsonian tremor. The reflexes are usually normal, but knee and ankle jerks may be lost, and extensor plantar responses may occur. Dementia may be noted but is usually mild. Impairment of sphincter function is common, with urinary and sometimes fecal incontinence. Cerebellar and brainstem atrophy are evident on MRI **(Fig. 450-1)**.

Marked shrinkage of the ventral half of the pons, disappearance of the olivary eminence on the ventral surface of the medulla, and atrophy of the cerebellum are evident on gross postmortem inspection of the brain. Variable loss of Purkinje cells, reduced numbers of cells in the molecular and granular layer, demyelination of the middle cerebellar peduncle and the cerebellar hemispheres, and severe loss of cells in the pontine nuclei and olives are found on histologic examination. Degenerative changes in the striatum, especially the putamen, and loss of the pigmented cells of the substantia nigra may be found in cases with extrapyramidal features. More widespread degeneration in the central nervous system (CNS), including involvement of the posterior columns and the spinocerebellar fibers, is often present.

GENETIC CONSIDERATIONS

SCA1 encodes a gene product, called *ataxin-1*, that regulates transcriptional repression with various nuclear factors. As a protein that can bind RNA, ataxin-1 may also regulate gene transcription posttranslationally. The mutant allele has 40 CAG repeats located

[1]Table 450-2 can be found online at *accessmedicine.com*.

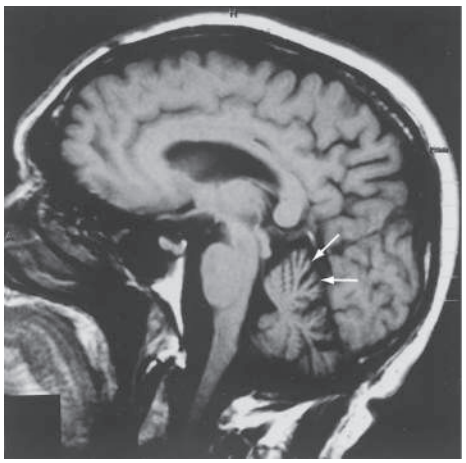

FIGURE 450-1 Sagittal magnetic resonance imaging (MRI) of the brain of a 60-year-old man with gait ataxia and dysarthria due to spinocerebellar ataxia type 1 (SCA1), illustrating cerebellar atrophy (*arrows*). *(Reproduced with permission from RN Rosenberg, P Khemani, in RN Rosenberg, JM Pascual [eds]: Rosenberg's Molecular and Genetic Basis of Neurological and Psychiatric Disease, 5th ed. London, Elsevier, 2015.)*

within the coding region, whereas alleles from unaffected individuals have ≤36 repeats. A few patients with 38–40 CAG repeats have been described. There is a direct correlation between a larger number of repeats and a younger age of onset for SCA1. Juvenile patients have higher numbers of repeats, and anticipation is present in subsequent generations. Transgenic mice carrying SCA1 developed ataxia and Purkinje cell pathology. Leucine-rich acidic nuclear protein localization, but not aggregation, of ataxin-1 appears to be required for cell death initiated by the mutant protein.

SCA2

Symptoms and Signs Another clinical phenotype, SCA2, has been described in patients from Cuba and India. Cuban patients probably are descendants of a common ancestor, and the population may be the largest homogeneous group of patients with ataxia described. The age of onset ranges from 2 to 65 years, and there is considerable clinical variability within families. Although neuropathologic and clinical findings are compatible with a diagnosis of SCA1, including slow saccadic eye movements, ataxia, dysarthria, parkinsonian rigidity, optic disc pallor, mild spasticity, and retinal degeneration, SCA2 is a unique form of cerebellar degenerative disease.

GENETIC CONSIDERATIONS

The gene in SCA2 families also contains CAG repeat expansions coding for a polyglutamine-containing protein, ataxin-2. Normal alleles contain 15–32 repeats; mutant alleles have 35–77 repeats. Ataxin-2 has recently been shown to assemble with polyribosomes. Ataxin-2 is also an important risk factor for sporadic amyotrophic lateral sclerosis (ALS).

MACHADO-JOSEPH DISEASE/SCA3

MJD was first described among the Portuguese and their descendants in New England and California. Subsequently, MJD has been found in families from Portugal, Australia, Brazil, Canada, China, England, France, India, Israel, Italy, Japan, Spain, Taiwan, and the United States. In most populations, it is the most common autosomal dominant ataxia.

Symptoms and Signs MJD has been classified into three clinical types. In type I MJD (ALS-parkinsonism-dystonia type), neurologic deficits appear in the first two decades and involve weakness and spasticity of extremities, especially the legs, often with dystonia of the face, neck, trunk, and extremities. Patellar and ankle clonus are common, as are extensor plantar responses. The gait is slow and stiff, with a slightly broadened base and lurching from side to side; this gait results from spasticity, not true ataxia. There is no truncal titubation. Pharyngeal weakness and spasticity cause difficulty with speech and swallowing. Of note is the prominence of horizontal and vertical nystagmus, loss of fast saccadic eye movements, hypermetric and hypometric saccades, and impairment of upward vertical gaze. Facial fasciculations, facial myokymia, lingual fasciculations without atrophy, ophthalmoparesis, and ocular prominence are common early manifestations.

In type II MJD (ataxic type), true cerebellar deficits of dysarthria and gait and extremity ataxia begin in the second to fourth decades along with corticospinal and extrapyramidal deficits of spasticity, rigidity, and dystonia. Type II is the most common form of MJD. Ophthalmoparesis, upward vertical gaze deficits, and facial and lingual fasciculations are also present. Type II MJD can be distinguished from the clinically similar disorders SCA1 and SCA2.

Type III MJD (ataxic-amyotrophic type) presents in the fifth to seventh decades with a pancerebellar disorder that includes dysarthria and gait and extremity ataxia. Distal sensory loss involving pain, touch, vibration, and position senses and distal atrophy are prominent, indicating the presence of peripheral neuropathy. The deep tendon reflexes are depressed to absent, and there are no corticospinal or extrapyramidal findings.

The mean age of onset of symptoms in MJD is 25 years. Neurologic deficits invariably progress and lead to death from debilitation within 15 years of onset, especially in patients with types I and II disease. Usually, patients retain full intellectual function.

The major pathologic findings are variable loss of neurons and glial replacement in the corpus striatum and severe loss of neurons in the pars compacta of the substantia nigra. A moderate loss of neurons occurs in the dentate nucleus of the cerebellum and in the red nucleus. Purkinje cell loss and granule cell loss occur in the cerebellar cortex. Cell loss also occurs in the dentate nucleus and in the cranial nerve motor nuclei. Sparing of the inferior olives distinguishes MJD from other dominantly inherited ataxias.

GENETIC CONSIDERATIONS

The gene for MJD maps to 14q24.3-q32. Unstable CAG repeat expansions are present in the MJD gene coding for a polyglutamine-containing protein named ataxin-3, or MJD-ataxin. An earlier age of onset is associated with longer repeats. Alleles from normal individuals have between 12 and 37 CAG repeats, whereas MJD alleles have 60–84 CAG repeats. Polyglutamine-containing aggregates of ataxin-3 (MJD-ataxin) have been described in neuronal nuclei undergoing degeneration. MJD-ataxin codes for a ubiquitin protease, which is inactive due to expanded polyglutamines. Proteosome function is impaired, resulting in altered clearance of proteins and cerebellar neuronal loss.

SCA6

Genomic screening for CAG repeats in other families with autosomal dominant ataxia and vibratory and proprioceptive sensory loss have yielded another locus. Of interest is that different mutations in the same gene for the α_{1A} voltage-dependent calcium channel subunit (CACNLIA4; also referred to as the *CACNA1A* gene) at 19p13 result in different clinical disorders. CAG repeat expansions (21–27 in patients; 4–16 triplets in normal individuals) result in late-onset progressive ataxia with cerebellar degeneration. Missense mutations in this gene result in familial hemiplegic migraine. Nonsense mutations resulting in termination of protein synthesis of the gene product yield hereditary paroxysmal cerebellar ataxia or EA. Some patients with familial hemiplegic migraine develop progressive ataxia and also have cerebellar atrophy.

SCA7

This disorder is distinguished from all other SCAs by the presence of retinal pigmentary degeneration. The visual abnormalities first appear as blue-yellow color blindness and proceed to frank visual loss with macular degeneration. In almost all other respects, SCA7 resembles several other SCAs in which ataxia is accompanied by various noncerebellar findings, including ophthalmoparesis and extensor plantar responses. The genetic defect is an expanded CAG repeat in the SCA7

gene at 3p14-p21.1. The expanded repeat size in SCA7 is highly variable. Consistent with this, the severity of clinical findings varies from essentially asymptomatic to mild late-onset symptoms to severe, aggressive disease in childhood with rapid progression. Marked anticipation has been recorded, especially with paternal transmission. The disease protein, ataxin-7, forms aggregates in nuclei of affected neurons, as has also been described for SCA1 and SCA3/MJD. Ataxin-7 is a subunit of GCN5, a histone acetyltransferase-containing complex.

SCA8

This form of ataxia is caused by a CTG repeat expansion in an untranslated region of a gene on chromosome 13q21. There is marked maternal bias in transmission, perhaps reflecting contractions of the repeat during spermatogenesis. The mutation is not fully penetrant. Symptoms include slowly progressive dysarthria and gait ataxia beginning at ~40 years of age with a range between 20 and 65 years. Other features include nystagmus, leg spasticity, and reduced vibratory sensation. Severely affected individuals are nonambulatory by the fourth to sixth decades. MRI shows cerebellar atrophy. The mechanism of disease may involve a dominant "toxic" effect occurring at the RNA level, as occurs in myotonic dystrophy.

SCA27B

SCA27B is a recently discovered entity, resulting from an intronic GAA repeat expansion in the *FGF14* gene, and is one of the most common late-onset inherited ataxias. SCA27B occurs with a median age of onset of 60 years and presents as a relatively pure cerebellar ataxia with episodic symptoms at the disease onset. Other clinical features include afferent sensory deficits and dysautonomia. Cognitive impairment is infrequent. Both the episodic symptoms and symptom severity of ataxia appear to improve with 4-aminopyridine, although randomized clinical trials have not yet been performed in this population.

DENTATORUBROPALLIDOLUYSIAN ATROPHY

DRPLA has a variable presentation that may include progressive ataxia, choreoathetosis, dystonia, seizures, myoclonus, and dementia. DRPLA is due to unstable CAG triplet repeats in the open reading frame of a gene named *atrophin* located on chromosome 12p12-ter. Larger expansions are found in patients with earlier onset. The number of repeats is 49 in patients with DRPLA and ≤26 in normal individuals. Anticipation occurs in successive generations, with earlier onset of disease in association with an increasing CAG repeat number in children who inherit the disease from their father. One well-characterized family in North Carolina has a phenotypic variant known as the *Haw River syndrome*, now recognized to be due to the DRPLA mutation.

EPISODIC ATAXIA

EA types 1 and 2 are two rare dominantly inherited disorders that have been mapped to chromosomes 12p (a potassium channel gene, *KCNA1*, Phe249Leu mutation) for type 1 and 19p for type 2. Patients with EA-1 have brief episodes of ataxia with myokymia and nystagmus that last only minutes. Startle, sudden change in posture, and exercise can induce episodes. Acetazolamide or anticonvulsants may be therapeutic. Patients with EA-2 have episodes of ataxia with nystagmus that can last for hours or days. Stress, exercise, or excessive fatigue may be precipitants. Acetazolamide may be therapeutic and can reverse the relative intracellular alkalosis detected by magnetic resonance spectroscopy. Stop codon, nonsense mutations causing EA-2 have been found in the *CACNA1A* gene, encoding the α_{1A} voltage-dependent calcium channel subunit (see "SCA6," above).

AUTOSOMAL RECESSIVE ATAXIAS

Friedreich's Ataxia This is the most common form of inherited ataxia, composing one-half of all hereditary ataxias. It can occur in a classic form or in association with a genetically determined vitamin E deficiency syndrome; the two forms are clinically indistinguishable.

SYMPTOMS AND SIGNS Friedreich's ataxia presents before 25 years of age with progressive staggering gait, frequent falling, and titubation. The lower extremities are more severely involved than the upper ones. Dysarthria occasionally is the presenting symptom; rarely, progressive scoliosis, foot deformity, nystagmus, or cardiopathy is the initial sign.

The neurologic examination reveals nystagmus, loss of fast saccadic eye movements, truncal titubation, dysarthria, dysmetria, and ataxia of trunk and limb movements. Extensor plantar responses (with normal tone in trunk and extremities), absence of deep tendon reflexes, and weakness (greater distally than proximally) are usually found. Loss of vibratory and proprioceptive sensation occurs. The median age of death is 35 years. Women have a significantly better prognosis than men.

Cardiac involvement occurs in 90% of patients. Cardiomegaly, symmetric hypertrophy, murmurs, and conduction defects are reported. Moderate intellectual disability or psychiatric syndromes are present in a small percentage of patients. A high incidence (20%) of diabetes mellitus is found and is associated with insulin resistance and pancreatic β-cell dysfunction. Musculoskeletal deformities are common and include pes cavus, pes equinovarus, and scoliosis. MRI of the spinal cord shows atrophy **(Fig. 450-2)**.

The primary sites of pathology are the spinal cord, dorsal root ganglion cells, and the peripheral nerves. Slight atrophy of the cerebellum and cerebral gyri may occur. Sclerosis and degeneration occur predominantly in the spinocerebellar tracts, lateral corticospinal tracts, and posterior columns. Degeneration of the glossopharyngeal, vagus, hypoglossal, and deep cerebellar nuclei is described. The cerebral cortex is histologically normal except for loss of Betz cells in the precentral gyri. The peripheral nerves are extensively involved, with a loss of large myelinated fibers. Cardiac pathology consists of myocytic hypertrophy and fibrosis, focal vascular fibromuscular dysplasia with subintimal or medial deposition of periodic acid-Schiff (PAS)-positive material, myocytopathy with unusual pleomorphic nuclei, and focal degeneration of nerves and cardiac ganglia.

GENETIC CONSIDERATIONS

The classic form of Friedreich's ataxia has been mapped to 9q13-q21.1, and the mutant gene, *frataxin*, contains expanded GAA triplet repeats in the first intron. There is homozygosity for expanded GAA repeats in >95% of patients. Normal persons have 7–22 GAA repeats, and patients have 200–900 GAA repeats. A more varied clinical syndrome has been described in compound heterozygotes who have one copy of the GAA expansion and the other copy a point mutation in the *frataxin* gene. When the point mutation is located in the region of the gene that encodes the amino-terminal half of frataxin, the phenotype is milder, often consisting of a spastic gait, retained or exaggerated reflexes, no dysarthria, and mild or absent ataxia.

Patients with Friedreich's ataxia have undetectable or extremely low levels of *frataxin* mRNA, as compared with carriers and unrelated

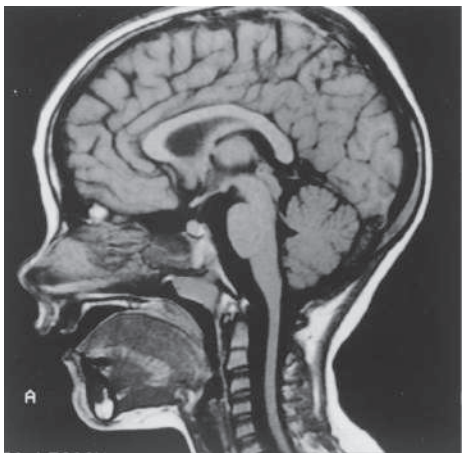

FIGURE 450-2 Sagittal magnetic resonance imaging (MRI) of the brain and spinal cord of a patient with Friedreich's ataxia, demonstrating spinal cord atrophy. *(Reproduced with permission from RN Rosenberg, P Khemani, in RN Rosenberg, JM Pascual [eds]: Rosenberg's Molecular and Genetic Basis of Neurological and Psychiatric Disease, 5th ed. London, Elsevier, 2015.)*

individuals; thus, disease appears to be caused by a loss of expression of the frataxin protein. Frataxin is a mitochondrial protein involved in iron homeostasis. Mitochondrial iron accumulation due to loss of the iron transporter coded by the mutant *frataxin* gene results in a deficiency in iron/sulfur clusters containing mitochondrial enzymes, decreased ATP production, and accumulation of iron in the heart. Excess oxidized iron results in turn in the oxidation of cellular components and irreversible cell injury.

Two forms of hereditary ataxia associated with abnormalities in the interactions of vitamin E (α-tocopherol) with very-low-density lipoprotein (VLDL) have been delineated. These are abetalipoproteinemia (Bassen-Kornzweig syndrome) and ataxia with vitamin E deficiency (AVED). Abetalipoproteinemia is caused by mutations in the gene coding for the larger subunit of the microsomal triglyceride transfer protein (MTP). Defects in MTP result in impairment of formation and secretion of VLDL in liver. This defect results in a deficiency of delivery of vitamin E to tissues, including the central and peripheral nervous system, as VLDL is the transport molecule for vitamin E and other fat-soluble substitutes. AVED is due to mutations in the gene for α-tocopherol transfer protein (α-TTP). These patients have an impaired ability to bind vitamin E into the VLDL produced and secreted by the liver, resulting in a deficiency of vitamin E in peripheral tissues. Hence, either absence of VLDL (abetalipoproteinemia) or impaired binding of vitamin E to VLDL (AVED) causes an ataxic syndrome. Once again, a genotype classification has proved to be essential in sorting out the various forms of the Friedreich's disease syndrome, which may be clinically indistinguishable.

RFC1-Related CANVAS Syndrome Biallelic intronic AAGGG repeat expansions in the replication factor C subunit 1 (*RFC1*) gene are the cause of late-onset ataxia, particularly if associated with sensory neuronopathy and bilateral vestibular areflexia (CANVAS syndrome). A chronic unexplained cough is often associated with and may precede the onset of neurologic symptoms.

Ataxia Telangiectasia • **SYMPTOMS AND SIGNS** Patients with ataxia telangiectasia (AT) present in the first decade of life with progressive telangiectatic lesions associated with deficits in cerebellar function and nystagmus. The neurologic manifestations correspond to those in Friedreich's disease, which should be included in the differential diagnosis. Truncal and limb ataxia, dysarthria, extensor plantar responses, myoclonic jerks, areflexia, and distal sensory deficits may develop. There is a high incidence of recurrent pulmonary infections and neoplasms of the lymphatic and reticuloendothelial system in patients with AT. Thymic hypoplasia with cellular and humoral (IgA and IgG2) immunodeficiencies, premature aging, and endocrine disorders such as type 1 diabetes mellitus are described. There is an increased incidence of lymphomas, Hodgkin's disease, acute T-cell leukemias, and breast cancer.

The most striking neuropathologic changes include loss of Purkinje, granule, and basket cells in the cerebellar cortex as well as of neurons in the deep cerebellar nuclei. The inferior olives of the medulla may also have neuronal loss. There is a loss of anterior horn neurons in the spinal cord and of dorsal root ganglion cells associated with posterior column spinal cord demyelination. A poorly developed or absent thymus gland is the most consistent defect of the lymphoid system.

GENETIC CONSIDERATIONS

The gene for AT (the *ATM* gene) at 11q22-23 encodes a protein that is similar to several yeast and mammalian phosphatidylinositol-3′ kinases involved in mitogenic signal transduction, meiotic recombination, and cell cycle control. Defective DNA repair in AT fibroblasts exposed to ultraviolet light has been demonstrated. The discovery of *ATM* permits early diagnosis and identification of heterozygotes who are at risk for cancer (e.g., breast cancer). Elevated serum alpha-fetoprotein and immunoglobulin deficiency are noted.

MITOCHONDRIAL ATAXIAS

Spinocerebellar syndromes have been identified with mutations in mitochondrial DNA (mtDNA). Thirty pathogenic mtDNA point mutations and 60 different types of mtDNA deletions are known, several of which cause or are associated with ataxia **(Chap. 460)**.

TREATMENT

Ataxic Disorders

The most important goal in management of patients with ataxia is to identify treatable disease entities. Mass lesions must be recognized promptly and treated appropriately. Autoimmune paraneoplastic disorders can often be identified by the clinical patterns of disease that they produce, measurement of specific autoantibodies, and uncovering the primary cancer; these disorders are often refractory to therapy, but some patients improve following removal of the tumor or immunotherapy **(Chap. 99)**. Ataxia with antigliadin antibodies and gluten-sensitive enteropathy may improve with a gluten-free diet. Malabsorption syndromes leading to vitamin E deficiency may lead to ataxia. The vitamin E deficiency form of Friedreich's ataxia must be considered, and serum vitamin E levels measured. Vitamin E therapy is indicated for these rare patients. Vitamin B_1 and B_{12} levels in serum should be measured, and the vitamins administered to patients having deficient levels. Hypothyroidism is easily treated. The cerebrospinal fluid should be tested for a syphilitic infection in patients with progressive ataxia and other features of tabes dorsalis. Similarly, antibody titers for Lyme disease and *Legionella* should be measured and appropriate antibiotic therapy should be instituted in antibody-positive patients. Aminoacidopathies, leukodystrophies, urea-cycle abnormalities, and mitochondrial encephalomyopathies may produce ataxia, and some dietary or metabolic therapies are available for these disorders. The deleterious effects of phenytoin and alcohol on the cerebellum are well known, and these exposures should be avoided in patients with ataxia of any cause.

There is no proven therapy for any of the autosomal dominant ataxias (SCA1 to SCA43). Omaveloxolone, a NRF2 agonist, is the only U.S. Food and Drug Administration–approved agent for Friedreich's ataxia. NRF2 is a transcription factor that regulates gene transcripts involved in mitochondrial energy production and addresses the root cause of mitochondrial dysfunction in Friedreich's ataxia. Iron chelators and antioxidant drugs are potentially harmful in Friedreich's patients because they may increase heart muscle injury. Acetazolamide can reduce the duration of symptoms of EA. At present, identification of an at-risk person's genotype, together with appropriate family and genetic counseling, can reduce the incidence of these cerebellar syndromes in future generations **(Chap. 480)**.

GLOBAL FEATURES

Ataxias with autosomal dominant, autosomal recessive, X-linked, or mitochondrial forms of inheritance are present on a worldwide basis. MJD (SCA3) (autosomal dominant) and Friedreich's ataxia (autosomal recessive) are the most common types in most populations. Genetic markers are now commercially available to precisely identify the genetic mutation for correct diagnosis and also for family planning. Early detection of asymptomatic preclinical disease can reduce or eliminate the inherited form of ataxia in some families on a global, worldwide basis.

451 Disorders of the Autonomic Nervous System

Safwan S. Jaradeh

The autonomic nervous system (ANS) has a large central nervous system (CNS) organization and an extensive peripheral nervous system (PNS) network that innervates and influences all organ systems. As such, it is important in securing normal homeostasis. The ANS has three major components: parasympathetic, sympathetic, and enteric. The parasympathetic component has mainly a craniosacral localization (brainstem and sacral cord), while the sympathetic component has mainly a thoracolumbar localization (first thoracic to second lumbar segments). ANS neurons of these components project thinly myelinated fibers to autonomic ganglia, where they synapse with postganglionic, mainly unmyelinated fibers that innervate the respective target organs. The enteric nervous system (ENS) has its own set of autonomic neurons and neurotransmitters but is heavily regulated by the central and peripheral autonomic nervous systems. The ANS also sensitizes endocrine organs to the effect of hormones, influencing how hormonal balances may affect neurologic diseases.

The classification of autonomic dysfunction (or dysautonomia) can be based on the impaired component (sympathetic, parasympathetic, or enteric), but a more practical clinical approach is based on organ specificity: heart, blood vessels, sweat glands, pupils, gastrointestinal, and genitourinary, either in isolation or in any potential combination. The time course of the development of dysautonomia (acute, subacute, or chronic; progressive or static) is especially useful in the differential etiologic diagnosis.

The ANS functions as a reflex circuit, using the sensory and sensorial feedback from the organs to modulate the ANS output and maintain homeostasis. This requires exquisite integration of the central ANS, peripheral ANS, and target organs. In the CNS, autonomic circuits operate at several levels: cerebral supratentorial, cerebral infratentorial, and spinal. Supratentorial areas include the insular cortex, prefrontal cortex, limbic lobe located on the medial surface of the cerebral hemispheres, hypothalamus, and hypothalamic-pituitary axis. Infratentorial areas are mainly the nucleus tractus solitaries (NTS), dorsal motor nucleus of the vagus (DMV) and nucleus ambiguous (NA). Spinal areas are in the intermediate lateral horns (IML) of the spinal cord gray matter between the first thoracic segment and the fourth sacral segment. Descending CNS information to the brainstem and IML allows the CNS to modulate autonomic activity. Peripheral, visceral, spinal, and brainstem afferent information conveyed to the CNS is also important in influencing autonomic function in health and disease. ANS dysfunction may explain many symptoms related to the aging process and various degenerative neurologic disorders, such as Parkinson's disease, multiple system atrophy, Lewy body disease, and pure autonomic failure. It features prominently in various autoimmune disorders, particularly autoimmune autonomic ganglionopathy and certain paraneoplastic disorders. ANS dysfunction in a more restricted form is present in various cyclical disorders such as migraine, cyclic vomiting, and other circadian rhythm disorders. It plays an important role in the genesis of various conditions of orthostatic intolerance (OI) including orthostatic hypotension (OH), postural orthostatic tachycardia syndrome (POTS), and syncope. **A detailed discussion of syncope can be found in Chap. 23.**

ANATOMIC, BIOCHEMICAL, AND PHARMACOLOGIC ORGANIZATION

Connections between ANS centers in the cerebral cortex and brainstem coordinate autonomic outflow and their integration with emotional and higher mental functions.

The preganglionic parasympathetic neurons leave the CNS in the third, seventh, ninth, and tenth cranial nerves as well as the second to fourth sacral nerves. The preganglionic sympathetic neurons exit the spinal cord between the first thoracic and the second lumbar segments **(Fig. 451-1)**. The autonomic ganglia reside outside the CNS. The sympathetic ganglia are located in paravertebral and prevertebral ganglia, while the parasympathetic ganglia are located near, or sometimes within, the target organs. Responses to sympathetic and parasympathetic stimulation are frequently antagonistic **(Table 451-1)**, allowing fine-tuning of autonomic responses. In general, increased sympathetic activity leads to the "fight or flight" response, while parasympathetic activity leads to the "rest and digest" response.

Biochemically, acetylcholine (ACh) is the preganglionic neurotransmitter for both sympathetic and parasympathetic divisions of the ANS as well as the postganglionic neurotransmitter of the parasympathetic neurons; all preganglionic receptors are nicotinic, while postganglionic receptors are muscarinic in type. Norepinephrine (NE) is the neurotransmitter of postganglionic sympathetic neurons, except for sympathetic cholinergic neurons innervating the eccrine sweat glands where the neurotransmitter is also ACh.

As stated above, the ENS has a large number of neurons organized in plexuses. Meissner's (submucosal) plexus, Auerbach's (myenteric) and interstitial cells of Cajal (circular muscular) compose the majority of the ENS; they contain numerous neurotransmitters. Parasympathetic control of the gastrointestinal system is mediated through the craniospinal nerves (vagus and S2–S4 nerves), while sympathetic control is mediated through the thoracolumbar (T1–L2) nerves.

CLINICAL EVALUATION

Disorders of the ANS are rather common and can occur with either CNS or PNS pathology that disrupts the afferent limb, CNS processing center, efferent limb, or any combination of these. It is also important to recognize that clinical manifestations can result from decreased function, overactivity, or dysregulation of autonomic circuits.

The evaluation begins by taking an accurate and complete autonomic medical history. The chief complaint and history of present illness should be sought from the patient, assisted by family members or significant others when necessary. Records from previous hospitalizations and test results are useful but cannot substitute for direct history taking. It is important to obtain the sequence of symptoms as accurately as possible. Antecedent events such as a viral illness or surgical procedure followed by subacute OI suggests an autoimmune cause, while a history of frequent fainting since childhood or adolescence favors a congenital or genetic condition. Therefore, a detailed family history is often essential, particularly in younger patients. In a patient with POTS, which occurs mainly in young women, it is important to ask privately about emotional or physical abuse in childhood. Physical deconditioning often exacerbates chronic OI and POTS. A prior history of irradiation to the neck in a patient with labile blood pressure and OI suggests arterial baroreflex failure due to injury to the carotid sinus baroreceptors.

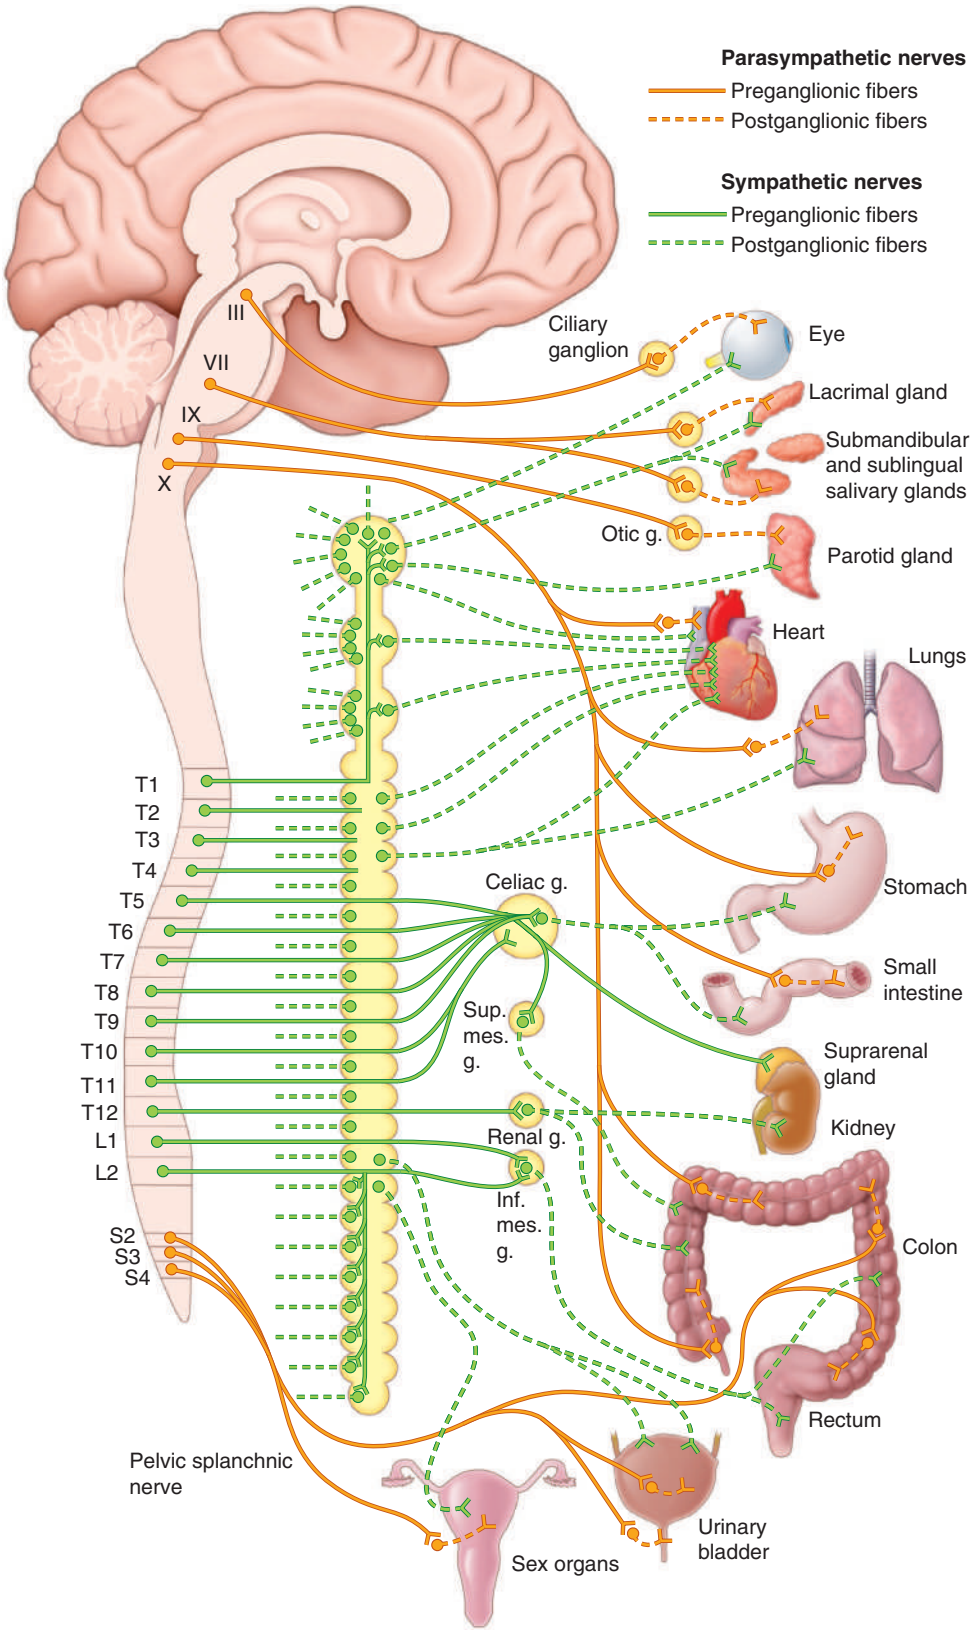

FIGURE 451-1 Schematic representation of the autonomic nervous system. *(Reproduced with permission from R Snell: Clinical Neuroanatomy, 7th ed. Philadelphia: Wolters Kluwer Health/Lippincott Williams & Wilkins, 2009.)*

Like other medical histories, it is important to determine exacerbating and alleviating factors. In patients with OI, the positional nature of symptoms (standing vs supine or sitting) can be a key clue to diagnosis. Patients with neurogenic OH are often more symptomatic in the morning, after exercise particularly in the heat, or after eating a large meal, especially with alcohol. Patients with POTS may feel worse when standing in a warm shower and notice reddish or purplish feet in that situation. However, given the widespread autonomic network underlying many dysautonomic states, these conditions are often multisystemic, and specific symptoms can vary from day to day.

A review of autonomic symptoms begins with questions about OI (lightheadedness, dizziness, orthostatic weakness or dyspnea, orthostatic neck and shoulder discomfort, orthostatic headache), a history of supine hypertension, unpredictable blood pressure swings,

TABLE 451-1 Effects of Sympathetic and Parasympathetic Systems on Various Effector Organs

	SYMPATHETIC	PARASYMPATHETIC
Pupil	Pupillodilation (alpha)	Pupilloconstriction
Accommodation	Decreased	Increased
Heart	Positive chronotropic effect (beta) Positive inotropic effect (beta)	Negative chronotropic effect Negative inotropic effect
Arteries	Vasoconstriction (alpha) Vasodilation (beta)	Vasodilation
Veins	Vasoconstriction (alpha) Vasoconstriction (beta)	
Tracheobronchial tree	Bronchodilation (beta)	Bronchoconstriction Increased bronchial gland secretions
Gastrointestinal tract	Decreased motility (beta) Contraction of sphincters (alpha)	Increased motility Relaxation of sphincter
Bladder	Detrusor relaxation (beta) Contraction of sphincter (alpha)	Detrusor contraction Relaxation of sphincter
Salivary glands	Scant, thick, viscid saliva (alpha)	Copious, thin, watery saliva
Skin	Piloerection (cutis anserina)	No piloerection
Sweat glands	Increased secretion (cholinergic)	Decreased secretion
Genitalia	Ejaculation	Ejaculation/Erection
Adrenal medulla	Catecholamine release	
Glycogen	Glycogenolysis (alpha and beta) Lipolysis (alpha and beta)	Glycogen synthesis

or syncopal episodes. Gastrointestinal symptoms may resemble those of irritable bowel syndrome (constipation, diarrhea, or both), but also constant nausea and bloating, unexplained vomiting, or dumping syndrome may be present, both in diabetics and in others. Genitourinary symptoms include dysuria, incontinence, urgency, and male erectile dysfunction. Sweating abnormalities (dry skin, excessive sweating) and body temperature changes reflect disordered thermoregulation and heat dissipation. Sicca syndrome may resemble that of Sjögren syndrome. Blurred vision from dark to light suggests slow, tonic pupillary dilation.

Pertinent nonautonomic symptoms such as acroparesthesias or burning feet (and hands) suggest an autonomic small-fiber neuropathy. Impaired olfaction, impaired balance, abnormal movements, and abnormal sleep behavior (apnea, stridor, or excessive moving and talking during sleep known as dream enactment behavior) are red flags for a degenerative neurologic extrapyramidal disorder.

A complete listing of all prescribed drugs, over-the-counter medications, herbal remedies, and dietary supplements is important because they can affect autonomic function and may produce unexpected adverse events. For instance, certain diet supplements have sympathomimetic activity and cause unexpected hypertension, tachycardia, or both.

Physical examination begins by obtaining full vital signs, including supine blood pressure and heart rate, followed by orthostatic blood pressure values at 1 and 3 min after rising from a seated position. An abnormal body temperature, either hyperthermia or hypothermia, may be a clue to a systemic or endocrine illness. Next comes the inspection of the limbs, looking for changes in the feet (pes cavus or planus), vasomotor color changes in the distal limbs, neuropathic foot or toe ulcers, scoliosis, chest deformity (pectus excavatum or carinii), hypermobility, skin elasticity, arachnodactyly, an abnormal pattern of sweating or hair distribution, or angiokeratoma (Fabry's disease). Head and neck evaluation begins with a careful pupillary examination in a dark room, looking for asymmetry, miosis, mydriasis, reaction to light and accommodation, and rate and symmetry of redilation. A high-arched palate is present in some patients with OI and Ehlers-Danlos syndrome **(Chap. 425)**. The tongue's appearance (smooth vs normal) and size (macroglossia suggests amyloidosis) should be noted.

For patients in whom a neurologic cause is likely, a complete evaluation of the cranial nerves, strength and muscle tone, reflexes, sensory function including small-fiber modalities (pinprick, temperature), cerebellar function, and gait is important **(Chap. 433)**. This may require a neurologic referral if the primary care physician is uncomfortable with the assessment.

LOCALIZATION

Once the history and examination are complete, an initial localization is usually possible, based on a working knowledge of the anatomy and pharmacology of ANS components. For example, parasympathetic dysfunction is mainly cholinergic. Patients will report dry mouth and constipation, urinary retention, and erectile failure in men. On the other hand, sympathetic dysfunction is mainly adrenergic (norepinephrine, epinephrine, dopamine) and symptoms and signs of OI predominate, given the prominent effect of these neurotransmitters on cardiac function and vasomotor tone. These patients will report lightheadedness, dizziness, faintness, visual changes, and a need to sit down.

Muscarinic dysfunction leads to reduced sweating, hyperthermia, reduced salivation and lacrimation (sicca syndrome), mydriasis with blurred vision, slow gastrointestinal motility, and urinary retention. Tachycardia and arrhythmias are less common. Some CNS symptoms such as delirium and hallucinations may occur.

Adrenergic dysfunction presents with excessive sweating, vasomotor changes, irritable bowel syndrome, dysuria and stress incontinence. Tachycardia and arrhythmias are common. Miosis or mydriasis may occur, usually without blurred vision. Some CNS symptoms are panic, anxiety, and mood disorders.

Certain features favor preganglionic versus postganglionic localization. Preganglionic disorders are more likely to cause body temperature dysregulation, syncope and POTS, sleep disturbances, and autonomic storms. Postganglionic disorders are more likely in the presence of acral pain, acral anhidrosis, severe OH, and severe gastrointestinal or urinary dysmotility. However, overlap may occur as some pathologic conditions involve both preganglionic and postganglionic systems; examples include autoimmune, paraneoplastic, and neurodegenerative disorders.

LABORATORY EVALUATION

Testing begins by obtaining basic blood tests (complete blood count with differential, comprehensive metabolic panel, erythrocyte sedimentation rate). It is important to check iron, ferritin, vitamin B_{12}, and vitamin D levels as well as folic acid. In patients with gastrointestinal distress, particularly with significant weight loss, measurement of various nutritional factors and vitamins is important, including less common ones such as thiamine, vitamin B_6, niacin, riboflavin, vitamin C, vitamin E, serum copper, coenzyme Q10, and carnitine levels. A search for endocrine disorders such as diabetes, thyroid disease, or disorders of adrenal cortical (cortisol) and medullary (catecholamine) function may be necessary, as well as 5-hydroxyindoleacetic acid (5-HIAA) to look for carcinoid tumors. In patients with small-fiber neuropathy and normal hemoglobin A_{1c}, a 2-h glucose tolerance test is necessary, as glucose intolerance is a rather frequent cause of isolated small-fiber neuropathy in the absence of overt diabetes. In patients with OI, supine and upright catecholamine levels can provide useful information. In patients with central or preganglionic adrenergic dysautonomia, supine catecholamine levels tend to be normal but fail to rise significantly in the upright position; the normal healthy response is a doubling or greater. In patients with peripheral or postganglionic adrenergic dysautonomia, supine catecholamine levels tend to be low and also fail to rise significantly in the upright position.

In some acquired autonomic disorders, rheumatologic test screening, particularly for Sjögren's syndrome **(Chap. 373)**, scleroderma **(Chap. 372)**, and mixed connective tissue disease **(Chap. 372)**, is useful. If the bedside examination or autonomic testing shows evidence

for a peripheral autonomic neuropathy, serum free light chains and protein electrophoresis to look for paraproteinemia is important, as it may be the sign of early primary amyloidosis (Chap. 117). In probable acquired autonomic disorders, serologic tests to check for autoimmune markers are indicated, including antibodies to the ganglionic ACh nicotinic receptor (see "Autoimmune Autonomic Ganglionopathy," below), voltage-gated potassium and calcium P/Q channel, plexin, and glutamic acid decarboxylase (GAD). If a paraneoplastic etiology is suspected, testing for anti-Hu, anti-CRMP5, anti-amphiphysin, or other autoantibodies may also be indicated (Chap. 99). If there is a history of infection, appropriate serologic tests can be requested (e.g., HIV, Epstein-Barr virus, herpes simplex virus, varicella-zoster virus, cytomegalovirus). In young patients or those with a positive family history, testing for porphyria (Chap. 428) and Fabry's disease (Chap. 429) is important, as these conditions are now treatable (Table 451-2).

AUTONOMIC EVALUATION TESTS

The most commonly employed autonomic tests evaluate cardiovascular function.

HEART RATE VARIATION TO DEEP BREATHING

This tests the parasympathetic cardiovascular reflexes mediated via the vagus nerve. The patient is instructed to breathe deeply at a rate of 6 breaths/min, and the acceleration and deceleration of the heart rate accompanying the inspiratory/expiratory cycle is calculated and averaged. The score is the average of the heart rate variability, or the expiratory to inspiratory ratio (Fig. 451-2). The ratio decreases gradually with age and is therefore age-corrected.

VALSALVA MANEUVER

This test is performed in the supine position. The patient blows into a closed mouthpiece to increase the intrathoracic pressure by

TABLE 451-2 Classification of Clinical Autonomic Disorders

I. Autonomic Disorders with Brain Involvement

A. Associated with multisystem degeneration
1. Multisystem degeneration: autonomic failure clinically prominent
   a. Multiple-system atrophy (MSA)
   b. Parkinson's disease with autonomic failure
   c. Diffuse Lewy body disease with autonomic failure
2. Multisystem degeneration: autonomic failure clinically not usually prominent
   a. Parkinson's disease without autonomic failure
   b. Other extrapyramidal disorders (inherited spinocerebellar atrophies, progressive supranuclear palsy, corticobasal degeneration, Machado-Joseph disease, fragile X syndrome [FXTAS])

B. Unassociated with multisystem degeneration (focal CNS disorders)
1. Disorders mainly due to cerebral cortex involvement
   a. Frontal cortex lesions causing urinary/bowel incontinence
   b. Focal seizures (temporal lobe or anterior cingulate)
   c. Cerebral infarction of the insula
2. Disorders of the limbic and paralimbic circuits
   a. Limbic encephalitis
   b. Autonomic seizures
   c. Shapiro's syndrome (agenesis of corpus callosum, hyperhidrosis, hypothermia)
3. Disorders of the hypothalamus
   a. Thiamine deficiency (Wernicke-Korsakoff syndrome)
   b. Diencephalic syndrome
   c. Neuroleptic malignant syndrome
   d. Serotonin syndrome
   e. Fatal familial insomnia
   f. Antidiuretic hormone (ADH) syndromes (diabetes insipidus, inappropriate ADH secretion)
   g. Disturbances of temperature regulation (hyperthermia, hypothermia)
   h. Disturbances of sexual function
   i. Disturbances of appetite
   j. Disturbances of BP/HR and gastric function
   k. Horner's syndrome
4. Disorders of the brainstem and cerebellum
   a. Posterior fossa tumors
   b. Syringobulbia and Arnold-Chiari malformation
   c. Disorders of BP control (hypertension, hypotension)
   d. Cardiac arrhythmias
   e. Central sleep apnea
   f. Baroreflex failure
   g. Horner's syndrome
   h. Vertebrobasilar and lateral medullary (Wallenberg's) syndromes
   i. Brainstem encephalitis

II. Autonomic Disorders with Spinal Cord Involvement

A. Traumatic quadriplegia
B. Syringomyelia
C. Subacute combined degeneration
D. Multiple sclerosis and neuromyelitis optica
E. Amyotrophic lateral sclerosis (mild, late)
F. Tetanus
G. Stiff-person syndrome
H. Spinal cord tumors

III. Autonomic Neuropathies

A. Acute/subacute autonomic neuropathies
   a. Subacute autoimmune autonomic ganglionopathy (AAG)
   b. Subacute paraneoplastic autonomic neuropathy
   c. Guillain-Barré syndrome
   d. Botulism
   e. Porphyria
   f. Drug-induced autonomic neuropathies—stimulants, drug withdrawal, vasoconstrictor, vasodilators, beta-receptor antagonists, beta-agonists
   g. Toxin-induced autonomic neuropathies
   h. Subacute cholinergic neuropathy

B. Chronic peripheral autonomic neuropathies
1. Small fiber neuropathy, including cryptogenic sensory polyneuropathy (CSPN)
2. Combined sympathetic and parasympathetic failure
   a. Amyloid
   b. Diabetic autonomic neuropathy
   c. AAG (paraneoplastic and idiopathic)
   d. Sensory neuronopathy with autonomic failure
   e. Fabry's disease
   f. Diabetic, uremic, or nutritional deficiency
   g. Familial dysautonomia (Riley-Day syndrome)
   h. Hereditary sensory and autonomic neuropathy
   i. HIV-related autonomic neuropathy
   j. Geriatric dysautonomia (age >80 years)
3. Disorders of orthostatic intolerance: OH; POTS; reflex syncope; prolonged bed rest; space flight; chronic fatigue

Abbreviations: BP, blood pressure; CNS, central nervous system; HR, heart rate; OH, orthostatic hypotension; POTS, postural orthostatic tachycardia syndrome.

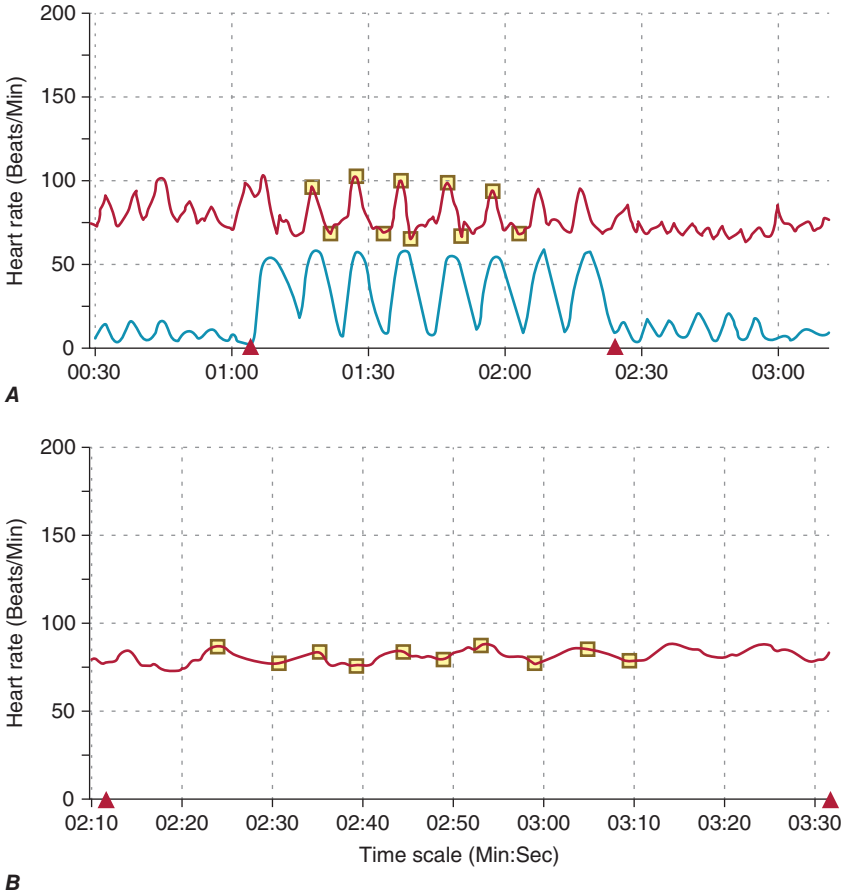

FIGURE 451-2 Examples of normal (*A*) and reduced (*B*) heart rate variability to deep breathing.

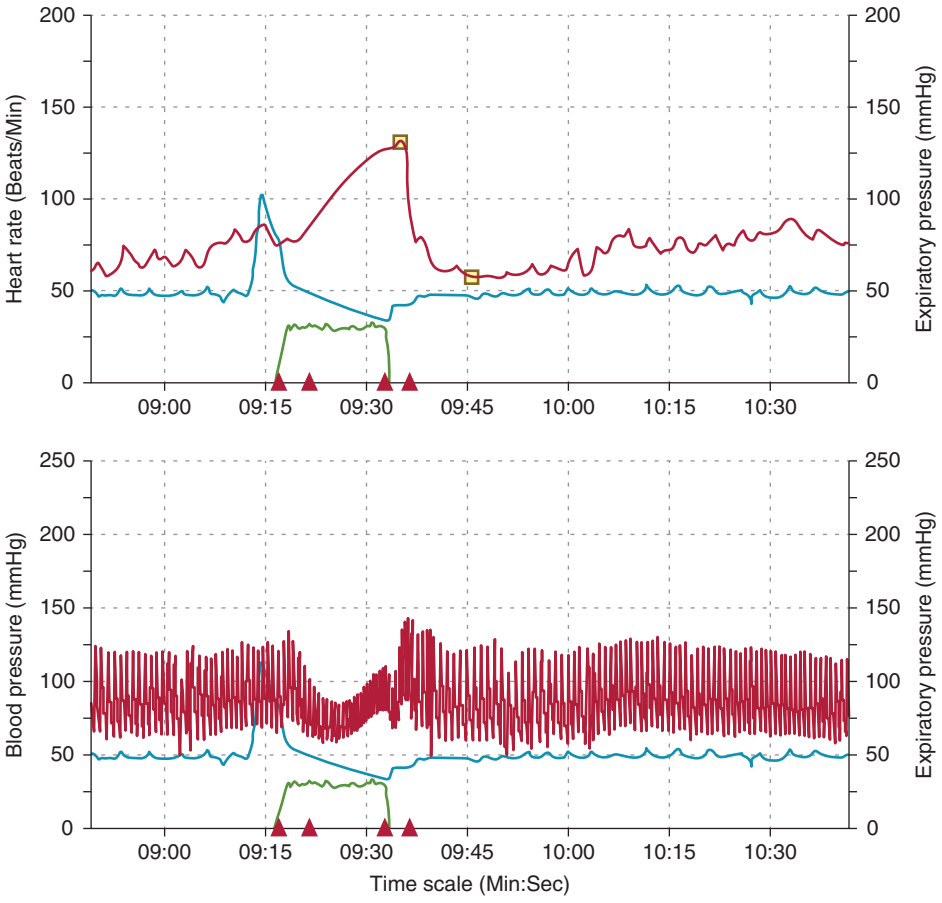
>40 mmHg for 15 s. During blowing, there is a decrease in venous return to the heart, leading to a fall in blood pressure and an associated compensatory tachycardia. Reduced blood pressure induces a compensatory peripheral sympathetic vasoconstriction in the lower extremities, which stops the blood pressure fall and reverses it close to baseline. Following release of the effort, blood pressure rises due to increased cardiac filling from the venous return, along with persistent sympathetic vasoconstriction. This leads to transient hypertension (an overshoot response) that stimulates the aortic and carotid baroreceptors leading to reflex bradycardia. The Valsalva ratio is the ratio of the higher to the lower heart rate and is a measure of the parasympathetic arm of the baroreflex. The magnitude of the drop in blood pressure, and of recovery in the overshoot phase, produces an adrenergic index score that, along with the blood pressure recovery time, is a marker of the sympathetic arm of the baroreflex **(Fig. 451-3)**.

The heart rate variation to deep breathing and the Valsalva ratio are diminished in most patients with autonomic failure, including diabetes and α-synuclein disorders and also in patients who take anticholinergic medications.

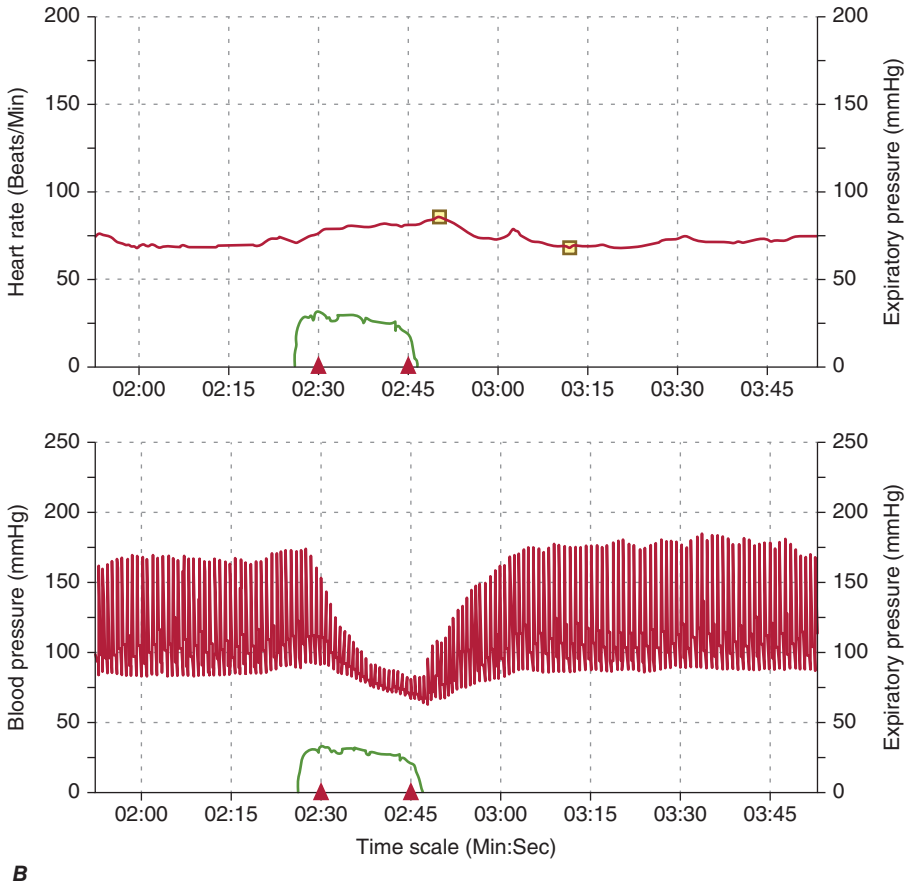
TILT TABLE TESTING

This test of great value for patients with all syndromes of OI, with or without syncope. Many autonomic laboratories are equipped with special devices and a finger cuff that enables the accurate reproduction of beat-to-beat arterial waveforms. The tilt test is an excellent test of sympathetic vasomotor and cardiovascular innervation, as it detects OH in all its forms, as well as excessive orthostatic tachycardia **(Fig. 451-4)**. When syncope occurs, testing allows differentiation between the various types (i.e., vasovagal, vasodepressor, and cardiodepressor syncope).



Tilt Table Testing for Recurrent Syncope When an initial phase of tilt at an angle of 60–70° for 30–40 min is negative, pharmacologic provocation of syncope (with intravenous, sublingual, or spray nitroglycerin, or intravenous isoproterenol) can be used. This increases the sensitivity of testing, at the expense of specificity (i.e., some patients with normal sympathetic function may also faint after administration of these drugs).

SUDOMOTOR FUNCTION TESTING



Sweating is secondary to the release of ACh from sympathetic postganglionic fibers. The quantitative sudomotor axon reflex test (QSART) measures regional ACh-induced sweating. The test is usually performed at four different sites (forearm, proximal leg, distal leg, and foot) to provide information on both the extent and distribution of postganglionic sudomotor impairment **(Fig. 451-5)**. A low or absent response indicates a lesion of the postganglionic sudomotor axon. If the equipment necessary to perform the test is not available, sympathetic skin responses recorded from the foot and the hand using standard nerve conduction equipment can be used, although results obtained in this manner may be less sensitive and specific. As a general rule, autonomic or small-fiber neuropathies often lead to reduced sweating in the feet. The thermoregulatory sweat test (TST) is a qualitative measure of global sweat production in response to an elevation of body temperature under controlled conditions. An indicator powder dusted on the anterior surface of the forehead and body changes color with sweat production in a hot and humid chamber. The pattern of color change measures the integrity of both preganglionic and postganglionic sudomotor functions. A postganglionic lesion is present if both QSART and TST show absent sweating. In a preganglionic lesion, the QSART is preserved but TST shows anhidrosis.

SKIN BIOPSY

Skin biopsies are commonly performed to diagnose small-fiber neuropathies. These consist of small punch biopsy specimens, often 2–4 mm in diameter, stained for special axonal markers. This allows the identification of epidermal nerve fiber density as well as sudomotor innervation density. Patients often undergo biopsies from two to four sites, usually from the distal and proximal lower extremity as well

FIGURE 451-5 (*Continued*)

as the forearm. The reduction in the number of nerve fibers and the pattern of reduction assist in establishing the diagnosis but also provide a clue to the underlying etiology, particularly when the fiber loss is not length-dependent. Skin biopsies are also useful in diagnosing autonomic dysfunction secondary to synucleinopathies, as at least one specimen may demonstrate phosphorylated α-synuclein inclusions in postganglionic sympathetic adrenergic and cholinergic nerve fibers. In these cases, a more proximal biopsy obtained near the cervical paraspinal region can be a helpful diagnostic tool if it shows accumulation of α-synuclein (see specific disorders below).

If all testing remains unrevealing, it is reasonable to consider a fat aspirate biopsy to check for amyloidosis.

SPECIFIC CONDITIONS OF ANS DYSFUNCTION

■ ORTHOSTATIC HYPOTENSION

OH is a common disorder with many underlying conditions. It can be debilitating, leading to fatigue, falls, syncope, cognitive impairment, and end-organ damage. OH increases with advancing age and is commonly associated with a variety of general medical, neurologic, and primary autonomic disorders including diabetes, heart failure, kidney failure, and neurodegenerative and autoimmune diseases.

Upon standing or with tilt testing, ~500–700 mL of blood shifts to peripheral venous vessels in the lower limbs and splanchnic bed, reducing venous return. In a healthy person, there is slight increase in heart rate and peripheral venoconstriction and arteriolar constriction that maintains systolic blood pressure (SBP) and increases slightly diastolic blood pressure (DBP). This normal response depends on interactions between multiple homeostatic systems, including baroreceptors, autonomic afferents, central processing centers, autonomic efferents, and peripheral vascular sympathetic receptors.

Classical OH is defined as a sustained reduction of SBP ≥20 mmHg or DBP ≥10 mmHg within 3 min of active standing or on a head-up tilt (HUT) test ≥60°. Variants of OH include smaller but symptomatic reductions in SBP when the supine SBP is low (90–100 mmHg) but drops well below this level with standing or tilt. In patients with hypertension, OH is defined as an orthostatic drop of SBP/DBP ≥30/15 mmHg.

The prevalence of OH in the general population ranges from <5% below age 50 up to 20% above age 70. The diagnosis can be overlooked, as most patients are asymptomatic or have only minor symptoms. OH is associated with increased risk of falls, coronary heart disease, heart failure, stroke, and death.

When the orthostatic compensatory heart rate (HR) increase exceeds 15 beats/min, OH is nonneurogenic. On the contrary, neurogenic OH

is associated with a blunted compensatory HR increase of <15 beats/min, provided there are no other possible explanations, such as cardioactive medications or intrinsic cardiac rhythm disturbances preventing an orthostatic HR increase. A more accurate way to diagnose neurogenic OH (NOH) is by dividing the HR increase by the fall in SBP (ΔHR/ΔSBP), as this metric provides a marker of cardiac baroreflex gain. A ratio <0.5 beats/min/mmHg after 3 min of standing (or tilt) more accurately indicates NOH. NOH is characterized by inadequate release of peripheral norepinephrine leading to impaired systemic vascular tone. The distinction is important because patients with NOH have a greater risk of mortality, approaching 44% over 30 months of follow-up, and exceeding 60% over 10 years. Furthermore, NOH can be associated with supine hypertension in patients with baroreflex impairment or autonomic failure, particularly in neurodegenerative conditions.

Clinical Presentation OH symptoms result from decreased blood flow to the brain. The most common symptom is lightheadedness on standing. Patients may report other orthostatic symptoms, such as palpitations, flushing, or pallor. More severe OH may lead to fainting or near-fainting. Triggers include bed rest (explaining the common occurrence upon waking up in the morning), food ingestion (particularly a large meal with alcohol), fever, heat, exercise, hyperventilation, medications, sepsis, or surgery. Aging, long periods of exercise, and intensification of antihypertensive treatment sometimes trigger the symptoms. Patients with underlying cardiac conditions (heart failure, chronotropic insufficiency) often have an added cardiogenic component to their OH. However, in the absence of triggers, many patients with mild OH remain asymptomatic, as cerebral autoregulation can compensate for mild swings in blood pressure and blood flow. Remarkably, in cases of chronic OH, particularly NOH, symptoms may remain quite mild in the face of significant blood pressure decrements.

Many patients with chronic OH have indirect symptoms. Instead of lightheadedness and near fainting, they may report dizziness (usually feeling wobbly, falling, or rarely vertigo), wooziness, or orthostatic imbalance. They may report fatigue and tiredness. Some may complain of generalized weakness after prolonged standing or walking. Some report neck and shoulder discomfort (coat hanger syndrome) secondary to hypoperfusion of the cervical paraspinal and trapezius muscles. In others, orthostatic dyspnea, known as platypnea, develops secondary to hypoperfusion of the lung apex. Myocardial hypoperfusion may cause orthostatic angina. A few patients also report orthostatic headache that may be mistaken as low-pressure cerebrospinal fluid headache.

OH can be classified into four functional classes. In functional class I, patients are asymptomatic but may show symptoms of OH including syncope and falls. In functional class II, symptoms occur weekly or monthly, with mild to moderate limitation of daily living. In functional class III, symptoms are more severe and frequent and markedly limit daily activities. In functional class IV, severe symptoms are daily, leading to significant disability.

Other OH variants include initial, delayed, and postprandial OH. Initial OH is an exaggerated, abrupt decrease in blood pressure (>40 mmHg SBP and >20 mmHg DBP) within 15–30 s upon standing due to transient mismatch between cardiac output and systemic vascular resistance. This condition occurs almost exclusively in young subjects (adolescents and young adults) but may also occur in older patients treated with antihypertensive drugs. The magnitude of the initial OH is often less with tilt than it is with active standing.

In delayed OH, SBP often remains steady for the first 3–5 min and then begins to decrease. In some cases, delayed OH does not appear until after 10 min of tilt. While the primary etiology in such cases may be secondary to medications, it often denotes some type of autonomic dysfunction, such as autonomic neuropathy.

Postprandial OH is a blood pressure drop after eating. OH often appears within 2 h of a larger meal, particularly if there is a high-carbohydrate load or alcohol ingestion. In these conditions, the meal produces gastric and esophageal distension and an increase in the splanchnic blood volume. It is more frequent in elderly patients with underlying neurologic conditions, particularly autonomic disorders. These patients sometimes faint after getting up from the dining table.

When OH is accompanied by baroreflex impairment, as seen with autonomic neuropathies or degenerative autonomic disorders, it can be associated with supine hypertension. In these patients, supine SBP during sleep may be higher than when they wake up in the morning, a pattern known as reverse dipping. Supine hypertension is a particular risk factor for end-organ damage (kidney, cardiac, or cerebrovascular). Over time, affected individuals develop alterations in the renin-angiotensin-aldosterone axis, leading to worse daytime OH by inducing pressure diuresis and volume loss during sleep.

Management Management of OH includes nonpharmacologic and pharmacologic measures. Nonpharmacologic measures are essential and may be sufficient in earlier stage I OH. However, the physician needs to ascertain whether the patient is actually asymptomatic and safe. This begins by addressing possible identifiable confounders, such as medications interfering with cardiovascular reflexes (e.g., diuretics, antihypertensives, tricyclic antidepressants, antipsychotics, dopamine agonists). Comorbidities can include iron deficiency, vitamin B_{12} and D deficiencies, and frailty. Increasing fluid intake up to 3 L/d and salt intake to 2 g up to 3 times a day can expand plasma and blood volume and often improve orthostatic tolerance. It is important to monitor the patient's weight and blood pressure on this regimen. In some patients, it would be reasonable to check the 24-h urine sodium before and after initiation of the fluid and salt load. Other simple remedies include lower limb stockings applied before getting out of bed. An abdominal binder is also quite effective in reducing the amount of splanchnic blood pooling. Physical countermaneuvers, such as crossing the legs while standing, are also helpful. It is also prudent to recommend elevating the head of bed by up to 30° to prevent the recurrence of supine hypertension and decrease nocturia.

Pharmacologic agents are quite effective. Fludrocortisone is a mineralocorticoid that expands the plasma volume, in addition to having a mild α-agonist effect. The dose is 0.1–0.2 mg/d (sometimes up to 0.4 mg/d) taken usually once in the morning. Because of its long duration of effect, it is important to monitor for supine hypertension. By increasing fluid retention, it can predispose to pedal edema, a low potassium level, headaches, and occasional mood changes. For older patients who require treatment for several years or longer, it is also prudent to check their bone density intermittently.

Midodrine is a direct agonist of α_1-adrenoceptors. It is prudent to start at a dose of 2.5 mg 3 times daily and increase gradually up to 15 mg 3 times daily. Most patients respond to 7.5–10 mg TID. The drug's onset of action is between 30 and 60 min, and its effect lasts up to 4 h. A usual schedule is to take it before getting out of bed, before lunch, and in mid-to-late afternoon, with the last dose usually before 6:00 P.M. to avoid nocturia and supine hypertension. Side effects include scalp tingling and goosebumps because of its stimulatory effect on pilomotor nerve fibers and urinary urgency because of its stimulatory effect at the bladder neck.

Pyridostigmine, a drug commonly used in myasthenia gravis, acts as a cholinesterase inhibitor and increases ganglionic transmission. Patients may be sensitive to the drug, so it is practical to start with 30 mg TID and increase gradually to 60 mg TID. It potentiates the effect of midodrine. It may cause abdominal cramps and diarrhea in susceptible patients. It is particularly beneficial for autonomic patients with OH and slow gastrointestinal motility. It does not promote supine hypertension, an advantage for this drug.

Atomoxetine is a norepinephrine reuptake inhibitor that is useful as an adjuvant therapy. Most patients benefit from 18 mg in the morning. While some patients may need it midday to early afternoon, it is important to monitor for symptoms and signs of CNS stimulation such as anxiety and tremor.

Droxidopa is the newest agent approved for treatment of NOH. It is a norepinephrine precursor. Treatment should start with 100 mg TID and be gradually increased to 400–600 mg TID. The medication improved orthostatic symptoms and decreased falls in PD patients. Supine hypertension remains an issue in most patients.

Desmopressin increases water reabsorption and reduces urination. Low-dose oral administration or nasal spray can be useful in reducing the frequency of nocturia that often interrupts sleep. Patients should be monitored for hyponatremia.

When patients with OH or NOH develop supine hypertension, it is important to revise their medications, monitor end-organ function, ensure elevation of the head of bed during sleep (30–45°), and use short-acting blood pressure–lowering drugs at bedtime.

POSTURAL ORTHOSTATIC TACHYCARDIA SYNDROME

POTS is a common syndrome of chronic (>3 months) OI without sustained OH, accompanied by an increase in HR of ≥30 beats/min in adults (≥40 beats/min if under the age of 19 years) or an orthostatic HR >120 beats/min within 10 min of standing that subsides on sitting or lying down. The symptoms reflect a combination of cerebral hypoperfusion (lightheadedness, blurred vision, cognitive decline, and brain fog) and sympathetic activation (palpitations, chest pain, and tremulousness). Near-syncope is common, but complete syncope is less frequent. The condition is four to five times more common in women, and most develop the syndrome between the ages of 15 and 45 years. Symptoms may flare up around menstrual cycles.

POTS is often multifactorial, as the pathophysiology is heterogeneous: distal sympathetic denervation in the feet and legs with preserved cardiovascular sympathetic function (so-called neuropathic POTS), venous pooling, reduced cardiac function due to deconditioning, hypovolemia, altered baroreceptor regulation, increased sympathetic activity, and rarely reduced parasympathetic activity may play a role. About half the cases follow a viral illness. Most prominent among these are Epstein-Barr virus, coronavirus, and enteroviral illnesses. The condition has increased since the COVID-19 pandemic; it is the leading manifestation of long COVID. Other POTS triggers include surgery, the postpartum period, puberty, pregnancy, concussion, and chronic emotional distress. Ehlers-Danlos syndrome is a significant predisposing condition, present in up to 25% of patients. When symptoms of POTS are prominent, patients become sedentary, exacerbating their deconditioning and leading to a vicious cycle with prolongation of the syndrome. In the chronic state, cardiovascular deconditioning becomes the common pathway.

POTS comorbidities include migraine and various headache disorders, symptoms of gastrointestinal dysmotility, chronic fatigue, fibromyalgia, gastrointestinal and bladder visceral pain, and sleep disturbances. Some patients report temperature intolerance, more to heat than cold, with impaired sweating (either increased or decreased). Patients often appear anxious in the clinic and have a tendency to be hypervigilant with respect to somatic symptoms, but the incidence of significant psychiatric disorders does not differ from that in the general population. Some patients report a new onset of various allergic symptoms (flushing, hives, and environmental and food allergies) suggestive of some type of mast cell activation syndrome.

While there is no standardized approach to the diagnosis, it is important to rule out primary cardiac causes, including arrhythmias (POTS is a sinus rhythm disorder), as well as endocrine conditions that lead to sympathetic activation, such as pheochromocytoma and hyperthyroidism. In addition to routine complete blood count and electrolyte panel, it is important also to measure ferritin and vitamin D levels and correct these if low, as this helps the condition respond better to other treatments.

Management has some similarities to the management of OH. Typically, it encourages the expansion of fluid volume with water (8–10 cups daily) and salt (6–8 g/d). Elastic stockings, waist high with 20–30 mmHg counterpressure, reduce venous pooling and improve venous return. Pharmacotherapy with low-dose fludrocortisone can be helpful. When symptoms of sympathetic overactivity are prominent, low doses of a beta blocker, increased gradually, can be helpful. These patients can be sensitive to beta blockers, so it is important to measure their blood pressure while on treatment; if it decreases, they would need a higher dose of fludrocortisone or the addition of a vasoactive drug such as midodrine. The latter is particularly useful in patients with neuropathic POTS, as it counteracts the significant peripheral vasodilation that is present. In patients with gastrointestinal hypomotility, low-dose pyridostigmine can be helpful and may improve the patient's fatigue as well. When tachycardia proves refractory to the above measures, low-dose ivabradine can also be tried. A graduated program of exercise to improve cardiac deconditioning is essential and often needs at least 6 months before significant benefit is obtained. Because of the orthostatic nature of the condition, exercise is better tolerated in the supine or sitting position (recumbent bike, rowing, swimming) and should involve a combination of aerobic cardiovascular training and resistance training primarily to the leg muscles. If the patient's symptoms and tolerance improve after 3 months, exercise in the upright position (treadmill, elliptical) can be gradually advanced.

SYNUCLEINOPATHIES

This group of disorders is secondary to the accumulation of phosphorylated α-synuclein in various parts of the ANS. They include multiple system atrophy (MSA), Parkinson's disease (PD; **Chap. 446**) with autonomic failure, Dementia with Lewy bodies (DLB; **Chap. 445**), and primary autonomic failure (PAF). Pathologically, there are aggregates of misfolded α-synuclein in the CNS and PNS. Cardiovascular autonomic denervation is more common in PD and PAF, whereas it tends to occur later in MSA and DLB.

PAF is a sporadic peripheral autonomic degenerative disease that has clinical manifestations similar to those in other autonomic neuropathies, such as diabetic autonomic neuropathy, and the autoimmune autonomic neuropathies. NOH is the prominent clinical feature and frequently associated with supine hypertension. After 5–10 years, a significant number of PAF patients develop a CNS synucleinopathy, particularly PD or DLB but also MSA. In addition to the presence of autonomic dysfunction, skin punch biopsy with immunohistochemistry staining can demonstrate small nerve fibers and intraneural α-synuclein deposition.

MSA, or *Shy-Drager syndrome*, is a disorder that combines autonomic failure *and* either parkinsonism (MSA-P) or a cerebellar syndrome (MSA-C). MSA is uncommon, with a prevalence estimated at 2–5 per 100,000 individuals. Onset is typically in the mid-fifties, men are slightly more affected than women, and most cases are sporadic. MSA generally progresses relentlessly to death 7–10 years after onset, but some patients may survive beyond 10 years. MSA-C is more common in Asian population, particularly in Japan, while MSA-P is the more common form in the rest of the world, including Western countries. A characteristic of the extrapyramidal parkinsonian phenotype is the relatively poor response to levodopa; when a response occurs, it tends to be transient. Rigidity dominates, while rest tremor is not prominent. Other distinguishing features that favor MSA-P over idiopathic PD is the early impairment of urinary control in both genders, early erectile dysfunction in men, symptomatic OH within 2 years of onset, preserved olfaction, and a lower frequency of gastrointestinal symptomatology, especially colonic hypomotility and constipation. Early autonomic dysfunction, early bladder dysfunction, female gender, and rapid progression of disability imply a worse prognosis.

Brain magnetic resonance imaging (MRI) can show iron deposition in the striatum in MSA-P, and cerebellar atrophy with a characteristic T2 hyperintense signal ("hot cross bun" sign) in the pons in MSA-C **(Fig. 451-6)**. However, the typical MRI findings may be present only with advanced disease. Cardiac postganglionic adrenergic innervation, measured by the uptake of meta-iodobenzylguanidine (MIBG) on a radionuclear scan or fluorodopamine on positron emission tomography, is usually intact in MSA, whereas it is low in the dysautonomias of PD, LBD, and PAF. The neuropathology of MSA shows neuronal loss and gliosis in many CNS regions, including the brainstem, cerebellum, striatum, and intermediolateral cell column of the thoracolumbar spinal cord. The characteristic pathologic feature is the presence of glial cytoplasmic inclusions that stain positively for α-synuclein (early Lewy bodies) primarily in oligodendrocytes, in contrast to their neuronal localization in PD or LBD. Research has shown some transfer of these cytoplasmic inclusions from cell to cell, akin to that of a prion **(Chap. 449)**.

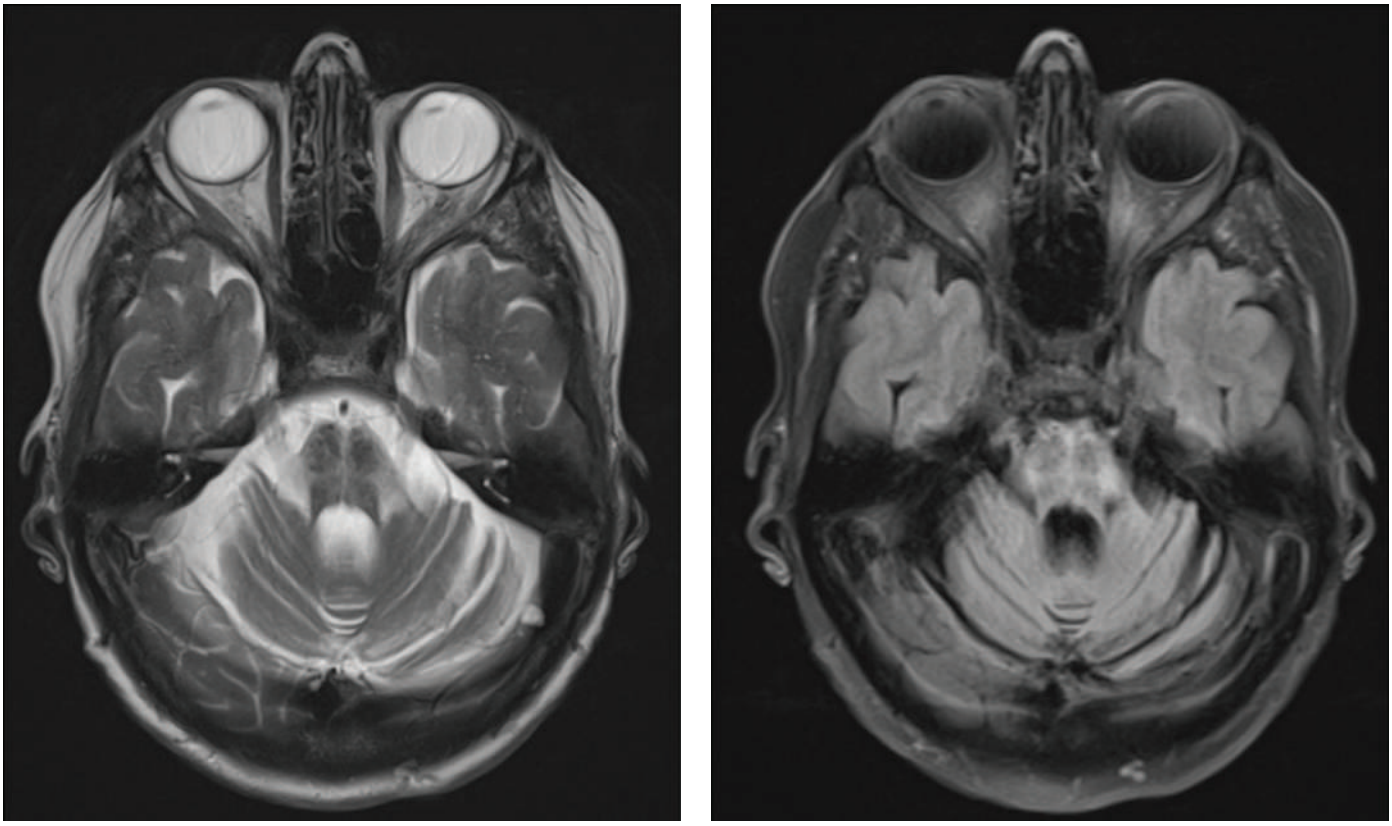

FIGURE 451-6 Multiple system atrophy, cerebellar type (MSA-C). Axial T2-weighted and FLAIR (fluid-attenuated inversion recovery) magnetic resonance images at the level of the pons demonstrate a characteristic cruciform hyperintense signal in the pons, the "hot cross bun" sign. This appearance is characteristic but not pathognomonic of MSA-C, as it can also be seen in some spinocerebellar atrophies and other neurodegenerative conditions affecting the brainstem. The images additionally demonstrate atrophy of the pons, bilateral middle cerebellar peduncles, and cerebellum. *(Courtesy of Dr. Nancy Fischbein, Stanford University School of Medicine.)*

Management is symptomatic for NOH (see earlier section on OH), sleep disorders including laryngeal stridor, and gastrointestinal and urinary dysfunction. Gastrointestinal symptoms can be managed with frequent small meals, a soft diet, stool softeners, and bulk agents. Persistent significant gastric and colonic hypomotility requires the administration of the newer motility stimulation drugs, such as prucalopride, linaclotide, plecanatide, or lubiprostone. Metoclopramide stimulates gastric emptying but should be used only as a short-term measure, if at all, because it worsens parkinsonism by blocking central dopamine receptors. Domperidone, a peripheral dopamine (D_2 and D_3) receptor antagonist, is also effective but is not U.S. Food and Drug Administration approved for use in the United States because of its potential arrhythmogenic risk. Pharmacologic management of neurogenic bladder relies usually on muscarinic blockers to reduce bladder urgency. Oxybutynin is often a first-line agent, but increasing the dose may cause other antimuscarinic side effect such as dry mouth, dry eyes, and anhidrosis. More selective blockers (tolterodine, darifenacin, or solifenacin) produced fewer systemic side effects. Mirabegron and vibegron are selective β_3-adrenergic agonists that reduces detrusor overactivity and are quite effective. A potential beneficial side effect is their gentle hypertensive effect that may help with OH management but may also require adjusting doses of other OH medications to avoid significant supine hypertension.

Autonomic dysfunction also occurs in DLB **(Chap. 445)** with the severity usually intermediate between that of MSA and PD. In multiple sclerosis (MS; **Chap. 455**), autonomic complications reflect the CNS location of MS lesions (more common with brainstem and spinal cord demyelination) and generally worsen with disease duration and disability but are generally less severe than with synucleinopathies.

SPINAL CORD DISORDERS

Spinal cord lesions may cause focal autonomic deficits dominated by OH, bowel dysfunction, and genitourinary dysfunction, as well as temperature dysregulation secondary to anhidrosis below the level of the lesion. Quadriparesis predisposes to supine hypertension and OH after upward tilting. *Autonomic dysreflexia* is a dramatic blood pressure increase that occurs in response to irritation of the bladder, skin, or muscles. It usually follows traumatic spinal cord lesions above the T6 level, as lesions below T6 allow for compensatory splanchnic vasodilation and a lesser likelihood of autonomic dysreflexia. The condition sometimes interferes with patient care, particularly when patients require urinary catheterization for distended bladder or rectal management for constipation and fecal impaction. In addition to blood pressure surges that may induce intracranial vasospasm or hemorrhage, other symptoms include facial flushing, headache, hypertension, piloerection, and even cardiac arrhythmia. Sitting the patient up reduces excessive supine hypertension. Prophylactic clonidine can reduce the hypertension resulting from bladder or rectal stimulation. **Disorders of the spinal cord are discussed in Chap. 453.**

PERIPHERAL NERVE AND NEUROMUSCULAR TRANSMISSION DISORDERS

Peripheral autonomic neuropathies are the most common cause of autonomic insufficiency. These complex disorders can impact cardiovascular, gastrointestinal, urogenital, and sudomotor systems. They affect small myelinated and unmyelinated fibers of the sympathetic and parasympathetic nerves and commonly occur in diabetes mellitus, amyloidosis, chronic alcoholism, porphyria, idiopathic small-fiber polyneuropathy, and Guillain-Barré syndrome. Neuromuscular junction disorders with autonomic involvement include botulism and Lambert-Eaton myasthenic syndrome **(Chaps. 457–459)**.

Diabetes Mellitus Diabetes mellitus remains one of the leading causes of peripheral autonomic neuropathy. The presence of autonomic neuropathy increases the mortality rate of diabetes up to threefold, even after adjusting for other cardiovascular risk factors. The neuropathy risk correlates with the product of the patient's hemoglobin A_{1c} values and the duration of the diabetes. Early autonomic impairment is most often

manifest as cardiovascular parasympathetic hypofunction. As diabetes progresses, sympathetic hypofunction follows, dominated by OH. The autonomic involvement also predicts other complications including coronary artery disease, renal disease, stroke, and sleep apnea. It also plays a significant role in the gastrointestinal dysmotility, which may further complicate glycemic control. Improved glycemic control significantly reduces the long-term risk of autonomic cardiovascular neuropathy. **Diabetes mellitus is discussed in Chaps. 415–417.**

Amyloidosis Amyloidosis, both acquired primary (AL) and hereditary transthyretin (hATTR) types, leads to autonomic neuropathy. Patients usually present with a distal sensorimotor polyneuropathy accompanied by autonomic insufficiency, but an autonomic neuropathy in isolation may also occur. A history of carpal tunnel syndrome is common. Postmortem studies reveal amyloid deposition in many organs, including two sites that contribute to autonomic failure: intraneural blood vessels and autonomic ganglia. For AL amyloidosis, the diagnosis is made by blood tests showing monoclonal gammopathy and elevated free light chains (with lambda more often than kappa being the culprit). For hATTR, If genetic testing for *TTR* mutations is negative, confirmation usually requires histologic diagnosis (abdominal fat pad, rectal mucosa, nerve/muscle biopsy, or myocardial biopsy in cases with cardiomyopathy) to search for amyloid deposits. Gene-based treatments (either RNA silencing or antisense oligonucleotides) are effective for hATTR amyloidosis. Treatment for AL amyloidosis usually relies on chemotherapeutic drugs. Death is usually due to cardiac or renal involvement. **Amyloidosis is discussed in Chap. 117.**

Alcoholic Neuropathy Abnormalities in parasympathetic vagal and efferent sympathetic function are usually mild in alcoholic polyneuropathy. OH is usually due to brainstem involvement, rather than injury to the PNS. Impotence is a common symptom, but concurrent gonadal hormone abnormalities may play a role in this symptom. Clinical symptoms of autonomic failure generally appear only when the stocking-glove polyneuropathy is severe, and there may be coexisting ataxia or Wernicke's encephalopathy **(Chap. 318)**. Autonomic involvement may contribute to the high mortality rates associated with alcoholism. **Alcohol use disorders are discussed in Chap. 464.**

Porphyria Autonomic dysfunction occurs only in the hepatic porphyrias. It is documented in acute intermittent porphyria, but may also occur with variegate porphyria and hereditary coproporphyria. Sympathetic overactivity dominates the clinical presentation. Autonomic symptoms include tachycardia, sweating, urinary retention, abdominal pain, nausea and vomiting, insomnia, hypertension, and (less commonly) hypotension. Often, patients have psychiatric symptoms dominated by anxiety, but depression and bipolar-like presentations may occur. Abnormal autonomic function can occur both during acute attacks and during remissions. Elevated catecholamine levels during acute attacks correlate with the degree of tachycardia and hypertension that is present. **Porphyria is discussed in Chap. 428.**

Guillain-Barré Syndrome (GBS) GBS often causes autonomic instability, more often but not exclusively in more severe cases. Cardiovascular dysautonomia can be life-threatening, and gastrointestinal autonomic involvement, abnormal sweating, and pupillary dysfunction may also occur. The dysautonomia is secondary to the demyelination of the vagus and glossopharyngeal nerves and the preganglionic sympathetic white rami communicantes. In some cases, autonomic involvement outweighs other manifestations of the motor or sensory neuropathy. *Acute autonomic and sensory neuropathy* is a variant that spares the motor system and presents with NOH and varying degrees of sensory loss. The treatment is similar to that for GBS (IV immunoglobulin or plasma exchange), but the prognosis is less favorable, with persistent sensory deficits and variable degrees of OH present in many patients. **GBS is discussed in Chap. 458.**

Autoimmune Autonomic Ganglionopathy (AAG) AAG is a rare form of dysautonomia. Approximately 100 Americans are diagnosed each year. It affects people of both sexes and all ages, although it is more common in women and in adults. Other names for this condition are acute pandysautonomia, idiopathic subacute autonomic neuropathy, and autoimmune autonomic neuropathy. It is typically associated with high titers of autoantibodies against the α3 subunit of the ganglionic acetylcholine nicotinic receptor (g-AChR α3). AAG often follows a triggering event: infection, surgery, autoimmunity, or malignancy in most patients. This condition is important to recognize because it is a treatable disorder. Symptoms mimic those caused by ganglion-blocking drugs *without* neuromuscular block, depending upon on which ANS division predominates. Ocular involvement leads to mydriasis and cycloplegia with blurred vision. Bronchial involvement leads to bronchodilation. Gastrointestinal involvement leads to reduced motility and secretion. Genitourinary involvement leads to urinary retention and impaired erection and ejaculation. Cardiac involvement leads to mild tachycardia. Vascular involvement reduces sympathetic tone and produces postural hypotension. Involvement of salivary and sweat glands leads to dry mouth and impaired sweating. Symptoms of autonomic failure occur in various combinations: syncope and OH; labile blood pressure; gastrointestinal hypomotility; bladder hypomotility; pupillary dysfunction with Adie's tonic pupil (slow reaction to light, bitter reaction to accommodation, slow relaxation afterward); dry mouth and eyes; and anhidrosis. Optic neuritis has also been reported in smokers with positive g-AChR α3 antibodies.

Some patients with higher titers of AAG have a paraneoplastic form of the disease associated with small cell lung carcinoma, thymoma, or lymphoma **(Chap. 99)**. Therefore, it is prudent to search for malignancy in the initial workup of AAG. Although no large studies have evaluated the efficacy of various treatments in AAG, IV immunoglobulin or plasmapheresis is generally used as first-line therapy, with glucocorticoids, rituximab, or mycophenolate mofetil, alone or in combination, used for nonresponders. Symptomatic treatment is of utmost importance, with attention to OI, gastrointestinal dysmotility, and genitourinary disturbances. Nonpharmacologic treatments such as exercise, increasing salt and fluid intake, compression stockings, and good sleep habits can also help.

Seronegative Autoimmune Autonomic Neuropathy (SAAN) SAAN is likely a seronegative variant of AAG, as this condition presents with subacute autonomic disturbances similar to AAG. Pathology shows preferential involvement of small unmyelinated nerve fibers, with sparing of larger myelinated ones. The neuropathy follows a viral infection in about half of cases. Several cases have been associated with use of checkpoint inhibitors. About one-third of untreated patients improve over time. Management is similar to that for AAG, although some patients may respond better to glucocorticoids as first-line therapy.

Botulism Botulinum toxin binds presynaptically to cholinergic nerve terminals and blocks ACh release. This condition presents with motor paralysis and signs of cholinergic failure that include blurred vision, sluggishly reactive pupils, dry mouth, dry skin, reduced gastric and colonic motility, and urinary retention **(Chap. 138)**.

Chronic Idiopathic Anhidrosis Chronic idiopathic anhidrosis is a rare condition in which patients present with heat intolerance but preserved vasomotor function. There is no associated somatic neuropathy. Some patients may have Adie's tonic pupils as well (Ross syndrome).

452 Trigeminal Neuralgia, Bell's Palsy, and Other Cranial Nerve Disorders

Vanja C. Douglas, Stephen L. Hauser

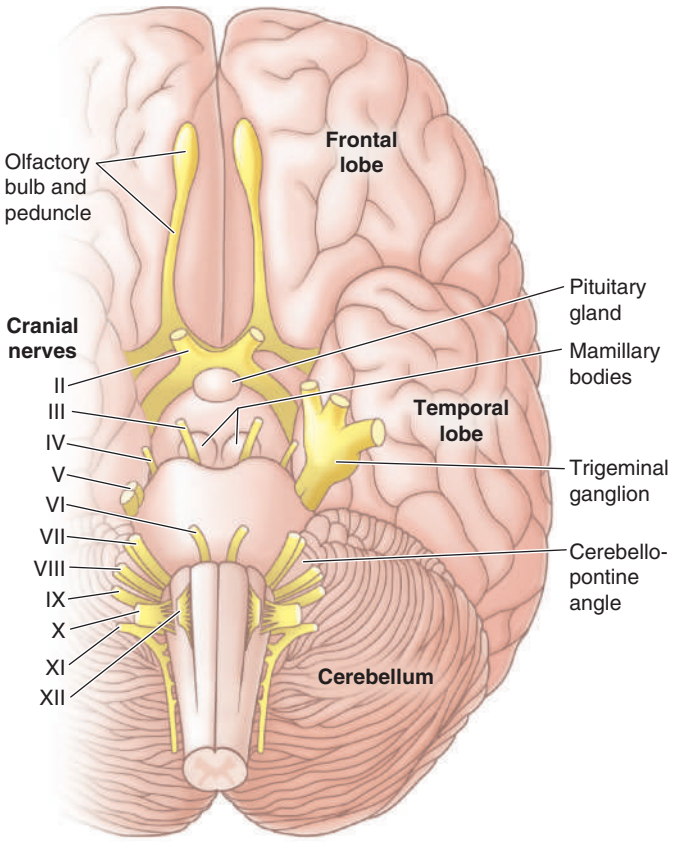

FIGURE 452-1 Ventral view of the brain, illustrating relationships between the 12 pairs of cranial nerves and the brainstem. *(Adapted from SG Waxman: Clinical Neuroanatomy, 29th ed. http://www.accessmedicine.com.)*

The cranial nerves consist of 12 paired nerves that mediate variable combinations of motor, sensory, and autonomic functions. They are considered as a group because of their close anatomic relationship to the brainstem **(Fig. 452-1)** and to one another, and tendency to be involved together in a variety of disease states. Nine cranial nerves connect directly with brainstem nuclei; the exceptions are cranial nerves 1 (olfactory) and 2 (optic) that are more accurately considered fiber tracts of the brain, and cranial nerve 11 (spinal accessory) whose motor neurons reside largely in the upper cervical cord. Analogous to spinal nerves **(Chap. 453)**, motor fibers of the cranial nerves have their origin in the brainstem or upper cervical cord, while sensory nerves are pseudounipolar, with ganglia outside the central nervous system and a synapse with second-order fibers in the brainstem.

Symptoms and signs of cranial nerve pathology are common in internal medicine. They may develop in the context of a widespread neurologic disturbance, and in such situations, cranial nerve involvement may represent the initial manifestation of the illness. In other disorders, involvement is largely restricted to one or several cranial nerves; these distinctive disorders are reviewed in this chapter. **Disorders of olfaction are discussed in Chap. 35, vision and ocular movement in Chap. 34, hearing in Chap. 36, and vestibular function in Chap. 24.**

FACIAL PAIN OR NUMBNESS

ANATOMIC CONSIDERATIONS

The trigeminal (fifth cranial) nerve supplies sensation to the skin of the face, anterior half of the head, and the nasal and oral mucosa **(Fig. 452-2)**. The motor part innervates the muscles involved in chewing (including masseter, temporalis, and pterygoids) as well as the anterior belly of the digastric, mylohyoid, tensor veli palatini, and the tensor tympani (hearing especially for high-pitched tones). It is the largest of the cranial nerves. It exits in the lateral midpons and traverses the middle cranial fossa to the semilunar (gasserian, trigeminal) ganglion in Meckel's cave, where the nerve splits into three divisions (ophthalmic [V1], maxillary [V2], and mandibular [V3]). V1 and V2 traverse the cavernous sinus to exit in the superior orbital fissure and foramen rotundum; V3 exits through the foramen ovale. The trigeminal nerve is predominantly sensory, and motor innervation is exclusively carried in V3. The cornea is primarily innervated by V1, although an inferior crescent may be V2. Upon entering the pons, pain and temperature fibers descend ipsilaterally as far as the upper cervical spinal cord as the spinal tract of V, before synapsing with the spinal nucleus of V; this accounts for the facial numbness that can occur with spinal cord lesions above C2. In the brainstem, the spinal tract of V is also located adjacent to crossed ascending fibers of the spinothalamic tract, producing a "crossed" sensory loss for pain and temperature (ipsilateral face, contralateral arm/trunk/leg) with lesions of the lateral lower brainstem. CN V is also ensheathed by oligodendrocyte-derived, rather than Schwann cell–derived, myelin for up to 7 mm after it leaves the brainstem, unlike just a few millimeters for other cranial and spinal nerves; this may explain some instances of trigeminal neuralgia in multiple sclerosis (MS) **(Chap. 455)**, a disorder of oligodendrocyte myelin.

TRIGEMINAL NEURALGIA (TIC DOULOUREUX)

Clinical Manifestations Trigeminal neuralgia is characterized by excruciating paroxysms of pain in the lips, gums, cheek, or chin and, very rarely, in the distribution of the ophthalmic division of the fifth nerve. The pain seldom lasts more than a few seconds or a minute or two but may be so intense that the patient winces, hence the term tic. The paroxysms, experienced as single jabs or clusters, tend to recur frequently, both day and night, for several weeks at a time. They may occur spontaneously or be brought on with movements of affected areas by speaking, chewing, or smiling. Another characteristic feature is the presence of trigger zones, typically on the face, lips, or tongue, that provoke attacks; patients may report that tactile stimuli—e.g., washing the face, brushing the teeth, or exposure to a draft of air—generate excruciating pain. An essential feature of trigeminal neuralgia is that objective signs of sensory loss cannot be demonstrated on examination.

Trigeminal neuralgia is relatively common, with an estimated annual incidence of 4–8 per 100,000 individuals. Middle-aged and

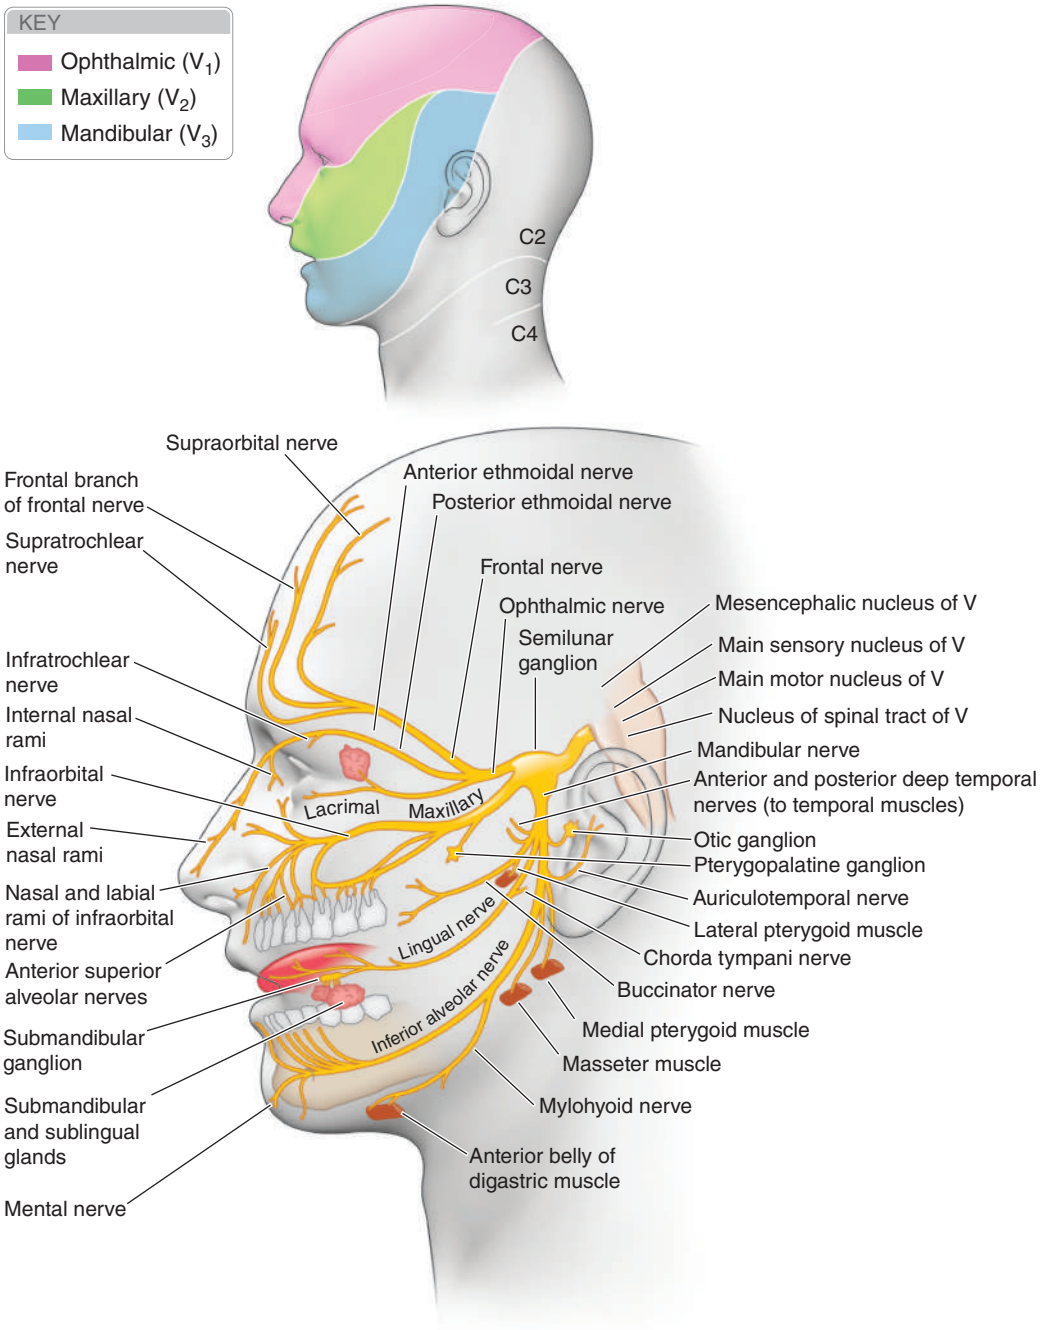

FIGURE 452-2 The trigeminal nerve and its branches and sensory distribution on the face. The three major sensory divisions of the trigeminal nerve consist of the ophthalmic, maxillary, and mandibular nerves. *(Reproduced with permission from Waxman SG: Clinical Neuroanatomy, 26th ed. New York, McGraw-Hill, 2009.)*

elderly persons are affected primarily, and ~60% of cases occur in women. Onset is typically sudden, and bouts tend to persist for weeks or months before remitting spontaneously. Remissions may be long-lasting, but in most patients, the disorder ultimately recurs.

Pathophysiology Symptoms result from ectopic generation of action potentials in pain-sensitive afferent fibers of the fifth cranial nerve root just before it enters the lateral surface of the pons. Compression or other pathology in the nerve leads to demyelination of large myelinated fibers that do not themselves carry pain sensation but become hyperexcitable and electrically coupled with smaller unmyelinated or poorly myelinated pain fibers in close proximity; this may explain why tactile stimuli, conveyed via the large myelinated fibers, can stimulate paroxysms of pain. Compression of the trigeminal nerve root by a blood vessel, most often the superior cerebellar artery or on occasion a tortuous vein, is believed to be the source of trigeminal neuralgia in most patients. In cases of vascular compression, age-related brain sagging and increased vascular thickness and tortuosity may explain the prevalence of trigeminal neuralgia in later life.

Differential Diagnosis Trigeminal neuralgia must be distinguished from other causes of face and head pain (Chap. 17) and from pain arising from diseases of the jaw, teeth, or sinuses. Pain from migraine or cluster headache tends to be deep-seated and steady, unlike the superficial stabbing quality of trigeminal neuralgia; rarely, cluster headache is associated with trigeminal neuralgia, a syndrome known as *cluster-tic*. Other rare, paroxysmal headache disorders such as short-lasting unilateral headache attacks with conjunctival injection and tearing, short-lasting unilateral headache attacks with cranial autonomic symptoms, and paroxysmal hemicrania (Chap. 441) are distinguished by the frequency and duration of attacks and associated autonomic symptoms. In temporal arteritis, superficial facial pain is present but is not typically shocklike, the patient frequently complains of myalgias and other systemic symptoms, and an elevated erythrocyte

sedimentation rate (ESR) or C-reactive protein (CRP) is usually present (Chap. 375). When trigeminal neuralgia develops in a young adult or is bilateral, MS is a key consideration, and in such cases, the cause is often a demyelinating plaque near the root entry zone of the fifth nerve in the pons, especially when there is evidence of superimposed facial sensory loss, which can be subtle. Cases that are secondary to mass lesions—such as aneurysms, neurofibromas, acoustic schwannomas, or meningiomas—usually produce objective signs of sensory loss in the trigeminal nerve distribution (trigeminal neuropathy, see below).

Laboratory Evaluation An ESR or CRP is indicated if temporal arteritis is suspected. Neuroimaging studies are often necessary to exclude secondary causes and help assess overlying vascular lesions in order to plan for decompression surgery.

TREATMENT

Trigeminal Neuralgia

Drug therapy with carbamazepine is effective in ~50–75% of patients. Carbamazepine should be started as a single daily dose of 100 mg taken with food and increased gradually (by 100 mg daily in divided doses every 1–2 days) until substantial (>50%) pain relief is achieved. Most patients require a maintenance dose of 200 mg four times daily. Doses >1200 mg daily provide no additional benefit. Dizziness, imbalance, sedation, and rare cases of agranulocytosis are the most important side effects of carbamazepine. If treatment is effective, it is usually continued for 1 month and then tapered as tolerated. Oxcarbazepine (300–1200 mg bid) is an alternative to carbamazepine that has less bone marrow toxicity and probably is equally efficacious. If these agents are not well tolerated or are ineffective, phenytoin (300–400 mg daily) is another option. Lamotrigine (400 mg daily), baclofen (10–20 mg tid), or topiramate (50 mg bid) may also be tried. Gabapentin, up to 3600 mg daily in divided doses, may occasionally provide relief.

If drug treatment fails, surgical therapy should be offered. The most widely used method is currently microvascular decompression to relieve pressure on the trigeminal nerve as it exits the pons. This procedure requires a suboccipital craniotomy. This procedure appears to have a >70% efficacy rate and a low rate of pain recurrence in responders; the response is better for classic ticlike symptoms than for nonlancinating facial pains. High-resolution magnetic resonance angiography is useful preoperatively to visualize the relationships between the fifth cranial nerve root and nearby blood vessels.

Gamma knife radiosurgery of the trigeminal nerve root is also used for treatment and results in complete pain relief, sometimes delayed in onset, in approximately one-half of patients and a low risk of persistent facial numbness; the response is sometimes long-lasting, but recurrent pain develops over 2–3 years in one-third of patients. Compared with surgical decompression, gamma knife surgery appears to be somewhat less effective but has few serious complications.

Another procedure, radiofrequency thermal rhizotomy, creates a heat lesion of the trigeminal ganglion or nerve. Short-term relief is experienced by >95% of patients; long-term studies indicate that pain recurs in up to one-third of treated patients. Postoperatively, partial numbness of the face is common, masseter (jaw) weakness may occur especially following bilateral procedures, and corneal denervation with secondary keratitis can follow rhizotomy for first-division trigeminal neuralgia. Percutaneous balloon compression of the trigeminal ganglion is an alternative approach performed under general anesthesia that results in similar rates of short- and long-term pain relief and is also commonly complicated by ipsilateral facial numbness.

TRIGEMINAL NEUROPATHY

A variety of diseases can affect the trigeminal nerve (Table 452-1). Most present with sensory loss on the face or with weakness of the jaw muscles. Deviation of the jaw on opening indicates weakness of the pterygoids on the side to which the jaw deviates. Some cases are due to Sjögren's syndrome or a collagen-vascular disease such as systemic lupus erythematosus, scleroderma, or mixed connective tissue disease. Among infectious causes, herpes zoster (acute or postherpetic) and leprosy should be considered. Tumors of the middle cranial fossa (meningiomas), of the trigeminal nerve (schwannomas), or of the base of the skull (metastatic tumors) may cause a combination of motor and sensory signs. Lesions in the cavernous sinus can affect the first and second divisions of the trigeminal nerve, and lesions of the superior orbital fissure can affect the first (ophthalmic) division; the accompanying corneal anesthesia increases the risk of ulceration (neurokeratitis).

Isolated sensory loss over the chin (mental neuropathy) can be the only manifestation of systemic malignancy. Rarely, an idiopathic form of trigeminal neuropathy is observed. It is characterized by numbness and paresthesias, sometimes bilaterally, with loss of sensation in the territory of the trigeminal nerve but without weakness of the jaw. Gradual recovery is the rule. Tonic spasm of the masticatory muscles, known as trismus, is symptomatic of tetanus (Chap. 157) or may occur in patients treated with phenothiazines.

TABLE 452-1 Trigeminal Nerve Disorders

Nuclear (Brainstem) Lesions
Multiple sclerosis
Stroke
Syringobulbia
Glioma
Lymphoma
Preganglionic Lesions
Acoustic neuroma

Cavernous Sinus Lesions (see Table 452-2)
Peripheral Nerve Lesions
Tumor (e.g., nasopharyngeal carcinoma, squamous cell carcinoma, lymphoma)
Trauma
Guillain-Barré syndrome
Sjögren's syndrome
Collagen-vascular diseases
Sarcoidosis
Leprosy
Drugs (stilbamidine, trichloroethylene)
Idiopathic trigeminal neuropathy

FACIAL WEAKNESS

ANATOMIC CONSIDERATIONS

(Fig. 452-3) The seventh cranial nerve supplies all the muscles concerned with facial expression, as well as the stapedius, stylohyoid, and posterior belly of the digastric. The sensory and parasympathetic components (the nervus intermedius) convey taste sensation from the anterior two-thirds of the tongue, cutaneous impulses from the anterior wall of the external auditory canal, and preganglionic parasympathetic signals to the pterygopalatine and submandibular ganglia, stimulating lacrimation, rhinorrhea, and salivation. The cell bodies of pseudounipolar sensory neurons lie in the geniculate ganglion. The motor nucleus of the seventh nerve lies anterior and lateral to the abducens nucleus. After leaving the pons, the seventh nerve enters the internal auditory meatus with the acoustic nerve. The nerve continues its course

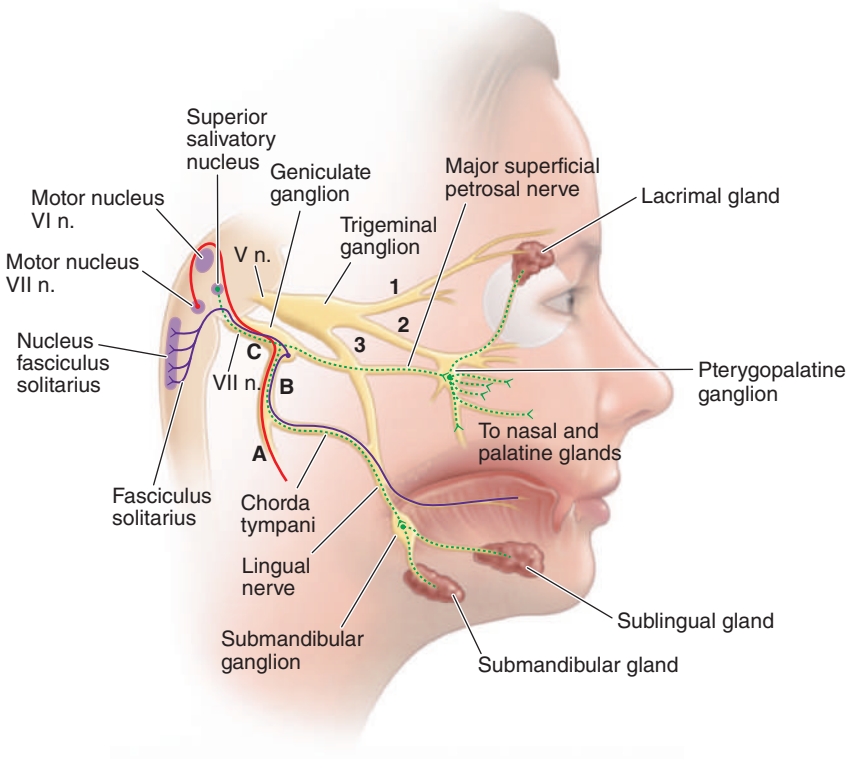

FIGURE 452-3 The facial nerve. A, B, and C denote lesions of the facial nerve at the stylomastoid foramen, distal and proximal to the geniculate ganglion, respectively. *Green lines* indicate the parasympathetic fibers, *red line* indicates motor fibers, and *purple lines* indicate visceral afferent fibers (taste). *(Reproduced with permission from MB Carpenter: Core Text of Neuroanatomy, 2nd ed. Williams & Wilkins, 1978.)*

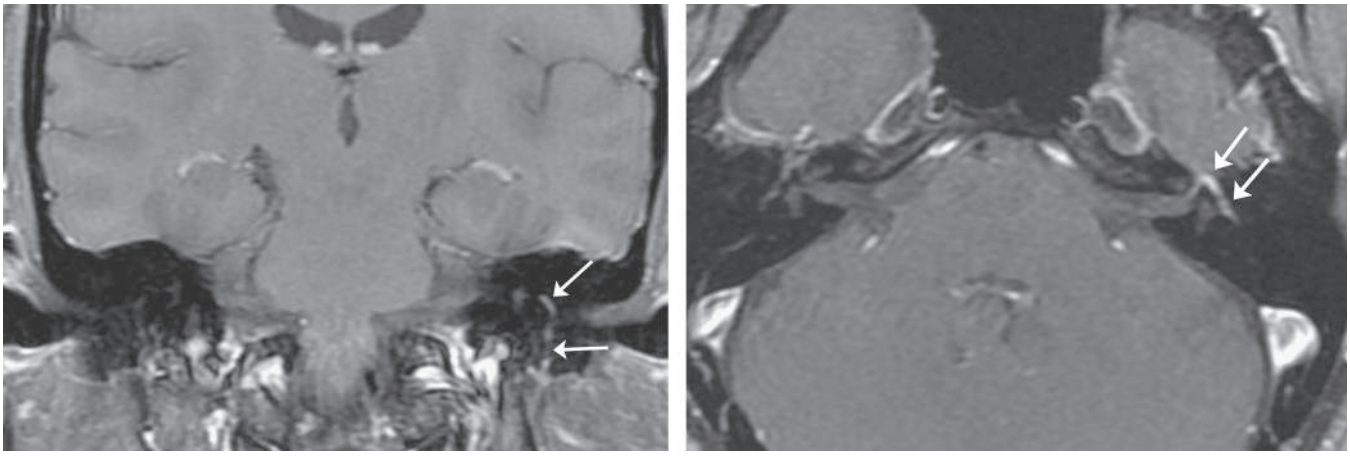
in its own bony channel, the facial canal, and exits from the skull via the stylomastoid foramen. It then passes through the parotid gland and subdivides to supply the facial muscles.

A complete interruption of the facial nerve at the stylomastoid foramen paralyzes all muscles of facial expression. The corner of the mouth droops, the creases and skinfolds are effaced, the forehead is unfurrowed, and the eyelids will not close. Upon attempted closure of the lids, the eye on the paralyzed side rolls upward (Bell's phenomenon). The lower lid sags and falls away from the conjunctiva, permitting tears to spill over the cheek. Food collects between the teeth and lips, and saliva may dribble from the corner of the mouth. The patient complains of a heaviness or numbness in the face, but sensory loss is rarely demonstrable and taste is intact.

If the lesion is in the middle-ear portion, taste is lost over the anterior two-thirds of the tongue on the same side. If the nerve to the stapedius is interrupted, there is hyperacusis (sensitivity to loud sounds). Lesions in the internal auditory meatus may affect the adjacent auditory and vestibular nerves, causing deafness, tinnitus, or dizziness. Intrapontine lesions that paralyze the face usually affect the abducens nucleus as well, and often the corticospinal and sensory tracts.

If the peripheral facial paralysis has existed for some time and recovery of motor function is incomplete, a continuous diffuse contraction of facial muscles may appear. The palpebral fissure becomes narrowed, and the nasolabial fold deepens. Facial spasms, initiated by movements of the face, may develop (hemifacial spasm). Anomalous regeneration of seventh nerve fibers may result in other troublesome phenomena. If fibers originally connected with the orbicularis oculi come to innervate the orbicularis oris, closure of the lids may cause a retraction of the mouth (synkinesis), or if parasympathetic fibers originally connected with salivary glands later innervate the lacrimal gland, anomalous tearing ("crocodile tears") may occur with eating. Another facial synkinesia is triggered by jaw opening, causing closure of the eyelids on the side of the facial palsy (jaw-winking).



BELL'S PALSY

The most common form of facial paralysis is Bell's palsy. The annual incidence of this idiopathic disorder is ~25 per 100,000 annually, or about 1 in 60 persons in a lifetime. Risk factors include pregnancy and diabetes mellitus.

Clinical Manifestations The onset of Bell's palsy is fairly abrupt, with maximal weakness being attained by 48 h as a general rule. Pain behind the ear may precede the paralysis for a day or two. Taste sensation may be lost unilaterally, and hyperacusis may be present. In some cases, there is mild cerebrospinal fluid lymphocytosis. MRI may reveal swelling and uniform enhancement of the geniculate ganglion and facial nerve and, in some cases, entrapment of the swollen nerve in the temporal bone. Approximately 80% of patients recover within a few weeks or months. Electromyography may be of some prognostic value; evidence of denervation after 10 days indicates there has been axonal degeneration, that there will be a long delay (3 months as a rule) before regeneration occurs, and that it may be incomplete. The presence of incomplete paralysis in the first week is the most favorable prognostic sign. Recurrences are reported in ~7% of cases.

Pathophysiology In acute Bell's palsy, there is inflammation of the facial nerve with mononuclear cells, consistent with an infectious or immune cause. Herpes simplex virus (HSV) type 1 DNA was frequently detected in endoneurial fluid and posterior auricular muscle, suggesting that a reactivation of this virus in the geniculate ganglion may be responsible for most cases. Reactivation of varicella-zoster virus is associated with Bell's palsy in up to one-third of cases and may represent the second most frequent cause. A variety of other viruses including SARS-CoV-2 have also been implicated less commonly, and Bell's palsy can be observed in the setting of human immunodeficiency virus (HIV) seroconversion.

Differential Diagnosis There are many other causes of acute facial palsy that must be considered in the differential diagnosis of Bell's palsy. Lyme disease can cause unilateral or bilateral facial palsies; in endemic areas, ≥10% of cases of facial palsy are likely due to infection with *Borrelia burgdorferi* (Chap. 191). Ramsay Hunt syndrome, caused by reactivation of herpes zoster in the geniculate ganglion, consists of a severe facial palsy associated with a vesicular eruption in the external auditory canal and sometimes in the pharynx and other parts of the

A B

FIGURE 452-4 Axial and coronal T1-weighted images after gadolinium with fat suppression demonstrate diffuse smooth linear enhancement of the left facial nerve, involving the genu, tympanic, and mastoid segments within the temporal bone (*arrows*), without evidence of mass lesion. Although highly suggestive of Bell's palsy, similar findings may be seen with other etiologies such as Lyme disease, sarcoidosis, and perineural malignant spread.

cranial integument; often the eighth cranial nerve is affected as well. Facial palsy that is often bilateral occurs in sarcoidosis **(Chap. 379)** and in Guillain-Barré syndrome **(Chap. 458)**. Leprosy frequently involves the facial nerve, and facial neuropathy may also occur in diabetes mellitus, connective tissue diseases including Sjögren's syndrome, and amyloidosis. The rare Melkersson-Rosenthal syndrome consists of recurrent facial paralysis; recurrent—and eventually permanent—facial (particularly labial) edema; and, less constantly, plication of the tongue. Its cause is unknown. Acoustic neuromas frequently involve the facial nerve by local compression. Infarcts, demyelinating lesions of MS, and tumors are common pontine lesions that interrupt the facial nerve fibers; other signs of brainstem involvement are usually present. Tumors that invade the temporal bone (carotid body, cholesteatoma, dermoid) may produce a facial palsy, but the onset is insidious and the course progressive. Facial palsy after temporal bone fracture can present acutely or after a delay of several days; blunt head injury without temporal bone fracture may also trigger facial palsy.

All these forms of nuclear or peripheral facial palsy must be distinguished from the supranuclear type. In the latter, the frontalis and orbicularis oculi muscles of the forehead are involved less than those of the lower part of the face, since the upper facial muscles are innervated by corticobulbar pathways from both motor cortices, whereas the lower facial muscles are innervated only by the opposite hemisphere. In supranuclear lesions, there may be a dissociation of emotional and voluntary facial movements, and often some degree of paralysis of the arm and leg or an aphasia (in dominant-hemisphere lesions) is present.

Laboratory Evaluation The diagnosis of Bell's palsy can usually be made clinically in patients with (1) a typical presentation, (2) no risk factors or preexisting symptoms for other causes of facial paralysis, (3) absence of cutaneous lesions of herpes zoster in the external ear canal, and (4) a normal neurologic examination apart from the facial nerve. Particular attention to the eighth cranial nerve, which courses near to the facial nerve in the pontomedullary junction and in the temporal bone, and to other cranial nerves is essential. In atypical or uncertain cases, an ESR or CRP, testing for diabetes mellitus, a Lyme titer, HIV serologies, angiotensin-converting enzyme and chest imaging studies for possible sarcoidosis, a lumbar puncture for possible Guillain-Barré syndrome, or MRI scanning may be indicated. MRI often shows swelling and enhancement of the facial nerve in idiopathic Bell's palsy **(Fig. 452-4)**.

TREATMENT

Bell's Palsy

Symptomatic measures include (1) the use of paper tape to depress the upper eyelid during sleep and prevent corneal drying, (2) artificial tears, and (3) massage of the weakened muscles. A course of glucocorticoids, given as prednisone 60–80 mg daily during the first 5 days and then tapered over the next 5 days, modestly shortens recovery and improves the functional outcome. Although large and well-controlled randomized trials found no added benefit of the antiviral agents valacyclovir (1000 mg daily for 5–7 days) or acyclovir (400 mg five times daily for 10 days) compared to glucocorticoids alone, either of these agents should be used if vesicular lesions are observed in the palate or external auditor canal. For patients with permanent paralysis from Bell's palsy, a number of cosmetic surgical procedures have been used to restore a relatively symmetric appearance to the face.

OTHER MOTOR DISORDERS OF THE FACE

Hemifacial spasm consists of painless irregular involuntary contractions on one side of the face. Most cases appear related to vascular compression of the exiting facial nerve in the pons. Other cases develop as a sequela to Bell's palsy or are secondary to compression and/or demyelination of the nerve by tumor, infection, or MS. Local injections of botulinum toxin into affected muscles can relieve spasms for 3–4 months, and the injections can be repeated. Refractory cases due to vascular compression usually respond to surgical decompression of the facial nerve. Anecdotal reports describe success using carbamazepine, gabapentin, or baclofen. Blepharospasm is an involuntary recurrent spasm of both eyelids that usually occurs in elderly persons as an isolated phenomenon or with varying degrees of spasm of other facial muscles. Severe, persistent cases of blepharospasm can be treated by local injection of botulinum toxin into the orbicularis oculi. Clonazepam, baclofen, and trihexyphenidyl have also been used to treat this disorder. Facial myokymia refers to a fine rippling activity of the facial muscles; it may be caused by MS or follow Guillain-Barré syndrome **(Chap. 458)**.

OTHER CRANIAL NERVE DISORDERS

GLOSSOPHARYNGEAL NEURALGIA

The ninth cranial (glossopharyngeal) nerve **(Fig. 452-5)** conveys somatic sensation from the pharynx, middle ear, tympanic membrane, eustachian tube, and posterior third of the tongue to the spinal trigeminal nucleus. It also relays taste from the posterior third of the tongue and information about blood pressure from baroreceptors in the carotid sinus to the nucleus solitarius, which also serves as the sensory nucleus for the vagus nerve. Motor function originates in the nucleus ambiguus and is limited to the stylopharyngeus muscle. Parasympathetic fibers from the medullary inferior salivatory nucleus synapse in the otic ganglion with postganglionic fibers that innervate the parotid gland. Glossopharyngeal neuralgia resembles trigeminal neuralgia in many respects but is much less common. Sometimes it involves portions of the tenth (vagus) nerve. The pain is intense and paroxysmal; it originates on one side of the throat, approximately in the tonsillar fossa.

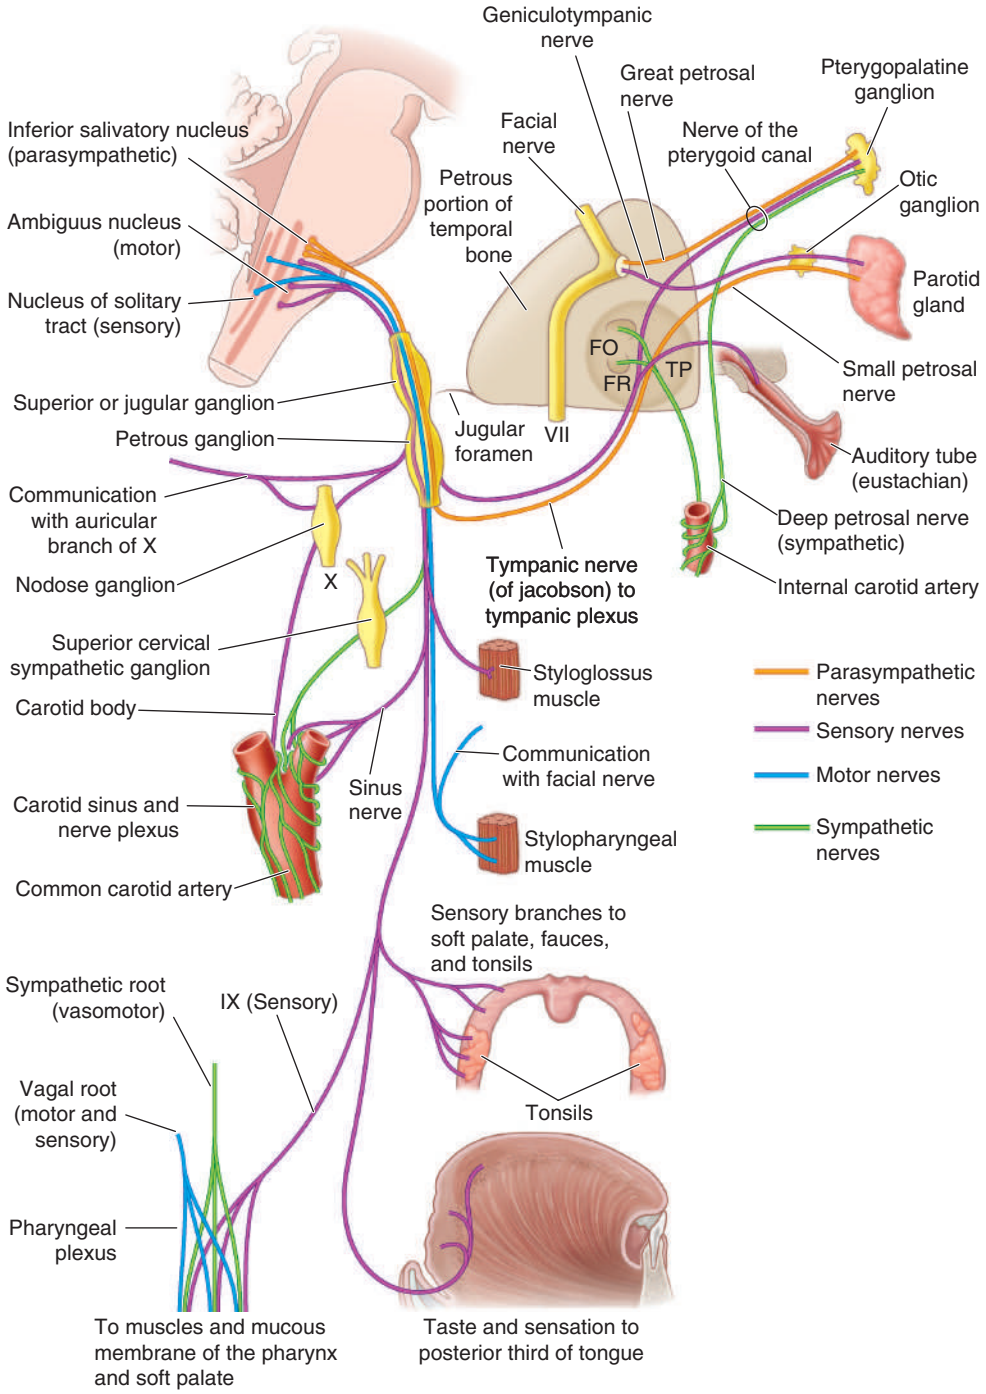


FIGURE 452-5 The ninth cranial (glossopharyngeal) nerve. FO, foramen ovale; FR, foramen rotundum; TP, tympanum plexus. *(Reproduced with permission from SG Waxman: Clinical Neuroanatomy, 29th ed. New York, McGraw Hill, 2020.)*

In some cases, the pain is localized in the ear or may radiate from the throat to the ear because of involvement of the tympanic branch of the glossopharyngeal nerve. Spasms of pain may be initiated by swallowing or coughing. There is no demonstrable motor or sensory deficit. Cardiac symptoms—bradycardia or asystole, hypotension, and fainting—have been reported. Glossopharyngeal neuralgia can result from vascular compression, MS, or tumors, but many cases are idiopathic. Medical therapy is similar to that for trigeminal neuralgia, and carbamazepine is generally the first choice. If drug therapy is unsuccessful, surgical procedures—including microvascular decompression if vascular compression is evident—or rhizotomy of glossopharyngeal and vagal fibers in the jugular bulb is frequently successful.

DYSPHAGIA AND DYSPHONIA

The tenth cranial (vagus) nerve **(Fig. 452-6)** carries somatic sensation from the posterior aspect of the external auditory canal, laryngopharynx, superior larynx, and meninges of the posterior fossa to the spinal trigeminal nucleus, as well as taste from the epiglottis and pharynx and visceral sensation from chemoreceptors and baroreceptors in the aortic arch, heart, and gastrointestinal tract to the splenic flexure to the nucleus solitarius. The motor part originates in the nucleus ambiguous and innervates most muscles of the oropharynx and soft palate as well as all laryngeal muscles. Parasympathetic fibers originate in the dorsal motor nucleus of the vagus nerve and decrease the heart rate through action at the sinoatrial and atrioventricular nodes; others promote peristalsis and secretion of the alimentary tract from the esophagus to the splenic flexure. When the intracranial portion of one vagus (tenth cranial) nerve is interrupted, the soft palate droops ipsilaterally and does not rise in phonation. There is loss of the gag reflex on the affected side, as well as of the "curtain movement" of the lateral wall of the pharynx, whereby the faucial pillars move medially as the palate rises in saying "ah." The voice is hoarse and slightly

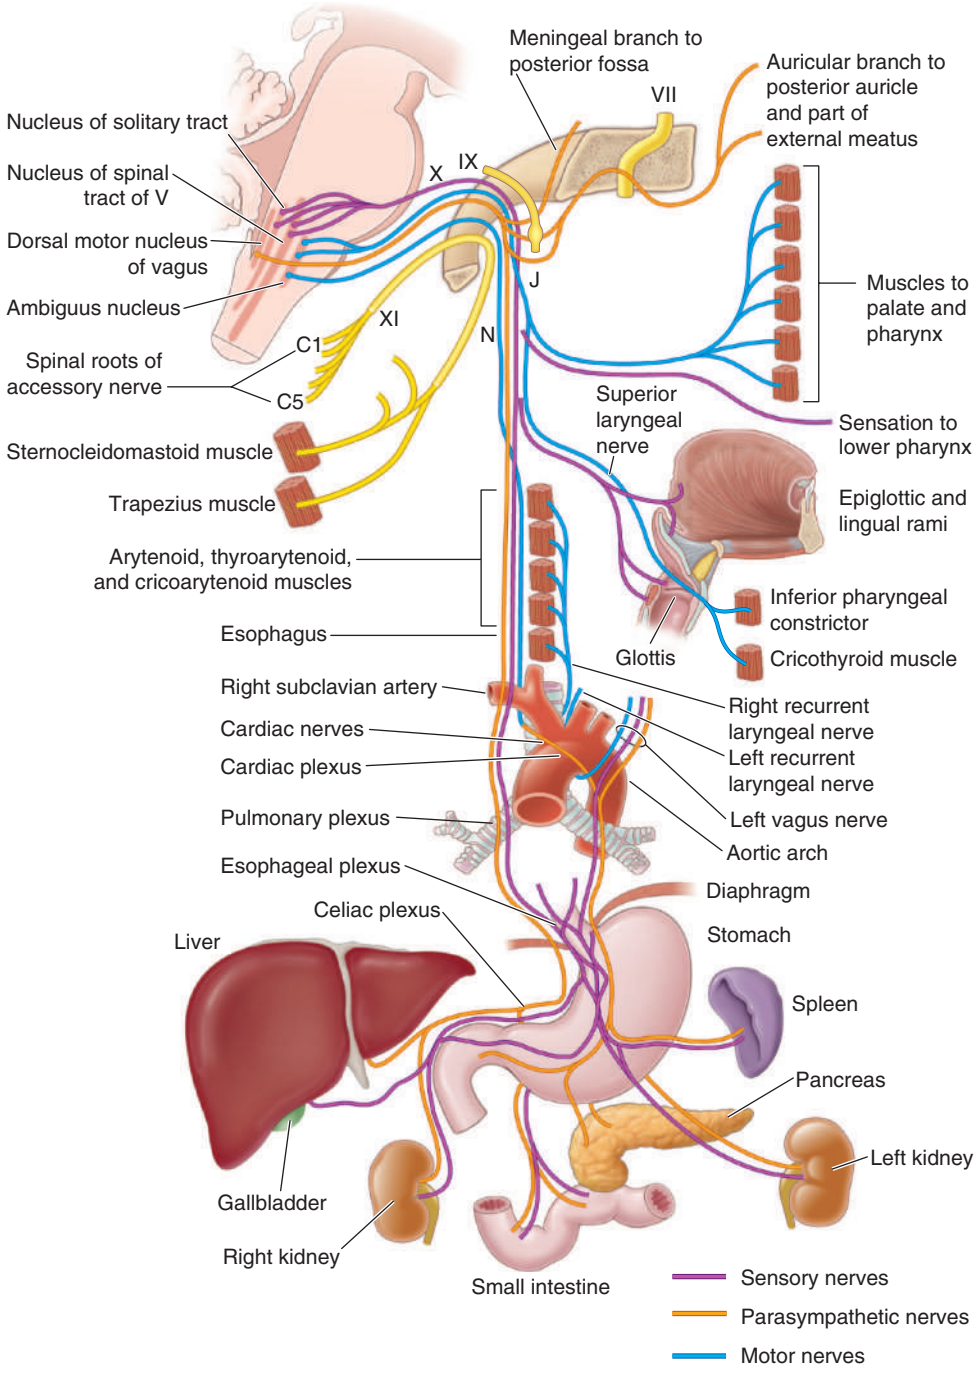

FIGURE 452-6 The vagus nerve. J, jugular (superior) ganglion; N, nodose (inferior) ganglion. *(Reproduced with permission from SG Waxman: Clinical Neuroanatomy, 29th ed. New York, McGraw Hill, 2020.)*

nasal, and the vocal cord lies immobile midway between abduction and adduction. Loss of sensation at the external auditory meatus and the posterior pinna may also be present.

The vagus nerve may be involved at the meningeal level by neoplastic and infectious processes and within the medulla by tumors, vascular lesions (e.g., the lateral medullary syndrome), and motor neuron disease. The nerve may be involved by infection with varicella-zoster virus. Injury to the vagus nerve in the carotid sheath can occur with carotid dissection or following endarterectomy. The pharyngeal branches of both vagal nerves may be affected in diphtheria; the voice has a nasal quality, and regurgitation of liquids through the nose occurs during swallowing. Polymyositis and dermatomyositis, which cause hoarseness and dysphagia by direct involvement of laryngeal and pharyngeal muscles, may be confused with diseases of the vagus nerves. Dysphagia is also a symptom in some patients with myotonic dystrophy. **Nonneurologic causes of dysphagia are discussed in Chap. 47.**

The recurrent laryngeal nerves, especially the left, are most often damaged as a result of intrathoracic disease. Aneurysm of the aortic arch, an enlarged left atrium, and tumors of the mediastinum and bronchi are much more frequent causes of an isolated vocal cord palsy than are intracranial disorders. However, a substantial number of cases of recurrent laryngeal palsy remain idiopathic.

When confronted with a case of laryngeal palsy, the physician must attempt to determine the site of the lesion. If it is intramedullary, there are usually other signs, such as ipsilateral cerebellar dysfunction, loss of pain and temperature sensation over the ipsilateral face and contralateral arm and leg, and an ipsilateral Horner's syndrome. If the lesion is extramedullary, the glossopharyngeal and spinal accessory nerves are frequently involved (jugular foramen syndrome). If it is extracranial in the posterior laterocondylar or retroparotid space, there may be a combination of ninth, tenth, eleventh, and twelfth cranial nerve palsies and Horner's syndrome **(Table 452-2)**. If there is no sensory loss over

TABLE 452-2 Cranial Nerve Syndromes

SITE	CRANIAL NERVES	USUAL CAUSE
Orbital apex	II, III, IV, first division V, VI	Invasive fungal infections, amyloidosis, granulomatous disease
Sphenoid fissure (superior orbital)	III, IV, first division V, VI	Invasive tumors of sphenoid bone; aneurysms
Lateral wall of cavernous sinus	III, IV, first division V, VI, often with proptosis	Infection, thrombosis, aneurysm or fistula of cavernous sinus; invasive tumors from sinuses and sella turcica; benign granuloma responsive to glucocorticoids
Retrosphenoid space	II, III, IV, V, VI	Large tumors of middle cranial fossa
Apex of petrous bone	V, VI	Petrositis; tumors of petrous bone
Internal auditory meatus	VII, VIII	Tumors of petrous bone (dermoids, etc.); infectious processes; acoustic neuroma
Pontocerebellar angle	V, VI, VII, VIII, and sometimes IX	Acoustic neuroma; meningioma
Jugular foramen	IX, X, XI	Tumors and aneurysms
Posterior laterocondylar space	IX, X, XI, XII	Tumors of parotid gland and carotid body and metastatic tumors
Posterior retroparotid space	IX, X, XI, XII, and Horner's syndrome	Tumors of parotid gland, carotid body, lymph nodes; metastatic tumor; tuberculous adenitis

the palate and pharynx and no palatal weakness or dysphagia, the lesion is below the origin of the pharyngeal branches, which leave the vagus nerve high in the cervical region; the usual site of disease is then the mediastinum.

NECK WEAKNESS

The eleventh cranial nerve (spinal accessory) is a pure motor nerve arising from the nucleus ambiguus and the ventral horn of the spinal cord from C1–C6. The nerve travels superiorly through the foramen magnum and exits through the jugular foramen to innervate the ipsilateral sternocleidomastoid and trapezius muscles. Isolated involvement of the accessory (eleventh cranial) nerve can occur anywhere along its route, resulting in partial or complete paralysis of the sternocleidomastoid and trapezius muscles. Spinal accessory nerve palsy does not result in significant neck weakness because several other muscles also turn the head and flex the neck; therefore, detection of accessory nerve injury relies on palpating the absence of sternocleidomastoid contraction during head turning. Similarly, shoulder shrug is only slightly impacted by trapezius weakness, although the affected shoulder is lower at rest, scapular winging occurs, and the arm cannot abduct beyond 90°. Isolated spinal accessory nerve palsy is often iatrogenic due to neck surgery or jugular vein cannulation, or traumatic. An idiopathic form of accessory neuropathy, akin to Bell's palsy, has been described, and it may be recurrent in some cases. Most but not all patients recover.

TONGUE PARALYSIS

The twelfth cranial nerve (hypoglossal) supplies the ipsilateral muscles of the tongue. Nerve lesions cause the tongue to deviate toward the ipsilateral side during protrusion due to ipsilateral genioglossus weakness, in addition to weakness of tongue movements toward the affected side to weakness of ipsilateral intrinsic tongue musculature. Atrophy and fasciculations of the tongue develop weeks to months after interruption of the nerve. The nucleus of the nerve or its fibers of exit may be involved by intramedullary lesions such as tumor, poliomyelitis, or most often motor neuron disease. Lesions of the basal meninges and the occipital bones (platybasia, invagination of occipital condyles, Paget's disease) may compress the nerve in its extramedullary course or as it exits the skull in the hypoglossal canal. Isolated lesions of unknown cause can occur.

MULTIPLE CRANIAL NERVE PALSIES

When multiple cranial nerves are affected by a disease process, the clinical approach begins by determining whether the pathology lies within or outside of the brainstem. Lesions that lie on the surface of the brainstem are characterized by involvement of adjacent cranial nerves (often occurring in succession) and late and rather slight involvement of the long sensory and motor pathways and segmental structures lying within the brainstem. The opposite is true of primary lesions within the brainstem. Extramedullary lesions are more likely to cause bone erosion or enlargement of the foramens of exit of cranial nerves. By contrast, intramedullary lesions involving cranial nerves often produce a crossed sensory or motor paralysis (cranial nerve signs on one side of the body and tract signs on the opposite side).

Involvement of multiple cranial nerves outside the brainstem is frequently the result of trauma, localized infections including varicella-zoster virus, infectious and noninfectious (especially carcinomatous) causes of meningitis **(Chaps. 143 and 144)**, granulomatous diseases such as granulomatosis with polyangiitis **(Chap. 375)**, Behçet's disease **(Chap. 376)**, vascular disorders including those associated with diabetes, enlarging aneurysms, or locally infiltrating tumors. Among the tumors, nasopharyngeal cancers, lymphomas, neurofibromas, meningiomas, chordomas, cholesteatomas, carcinomas, and sarcomas have all been observed to involve a succession of lower cranial nerves. Owing to their anatomic relationships, the multiple cranial nerve palsies form a number of distinctive syndromes, listed in Table 452-2. Sarcoidosis **(Chap. 379)** is the cause of some cases of multiple cranial neuropathy; tuberculosis, the Chiari malformation, platybasia, and basilar invagination of the skull are additional causes.

Cavernous sinus syndrome **(Fig. 452-7)** is a distinctive and frequently life-threatening disorder. It often presents as orbital or facial pain; orbital swelling, chemosis due to occlusion of the ophthalmic veins; fever; oculomotor neuropathy affecting the third, fourth, and sixth cranial nerves; and trigeminal neuropathy affecting the ophthalmic (V1) and occasionally the maxillary (V2) divisions of the trigeminal nerve. Cavernous sinus thrombosis, often secondary to infection from orbital cellulitis (frequently *Staphylococcus aureus*), a cutaneous source on the face, or sinusitis (especially with mucormycosis in diabetic patients), is the most frequent cause; other etiologies include aneurysm of the carotid artery, a carotid-cavernous fistula (orbital bruit may be present), meningioma, nasopharyngeal carcinoma, other tumors, or an idiopathic granulomatous disorder (Tolosa-Hunt syndrome, discussed below). The two cavernous sinuses directly communicate via intercavernous channels; thus, involvement on one side may extend to become bilateral. Early diagnosis is essential, especially when due to infection, and treatment depends on the underlying etiology.

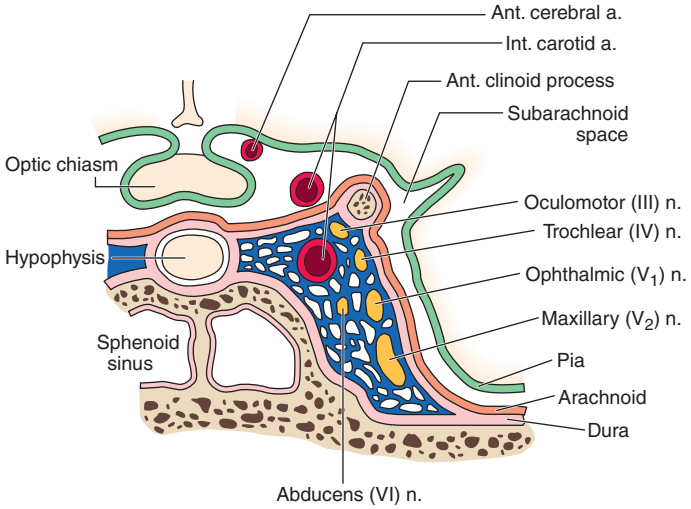

FIGURE 452-7 Anatomy of the cavernous sinus in coronal section, illustrating the location of the cranial nerves in relation to the vascular sinus, internal carotid artery (which loops anteriorly to the section), and surrounding structures.

In infectious cases, prompt administration of broad-spectrum antibiotics, drainage of any abscess cavities, and identification of the offending organism are essential. Anticoagulant therapy may benefit cases of primary thrombosis. Repair or occlusion of the carotid artery may be required for treatment of fistulas or aneurysms.

Tolosa-Hunt syndrome is characterized by onset, over days or a few weeks, of severe orbital pain with variable ophthalmoparesis and numbness of the upper face (V1 and V2 divisions of the trigeminal nerve) and by a dramatic clinical response to glucocorticoids. Although distinctive, the presentation can be mimicked by numerous other conditions that involve the cavernous sinus and orbit, including sarcoid **(Chap. 379)**, vasculitis **(Chap. 375)**, IgG4-related disease **(Chap. 380)**, lymphoma, and fungal infections. MRI can suggest the presence of granulomatous inflammation, but biopsy is sometimes required for diagnosis. A dramatic improvement in pain is usually evident within a few days; oral prednisone (60 mg daily) is usually continued for 2 weeks and then gradually tapered over a month, or longer if pain recurs. Occasionally an immunosuppressive medication, such as azathioprine or methotrexate, needs to be added to maintain an initial response to glucocorticoids.

Lesions in the superior orbital fissure and orbital apex cause more prominent vision loss than those in the cavernous sinus due to compression of the optic nerve; the second branch of the trigeminal nerve is usually spared. The cause is often an invasive fungal infection, frequently due to osseous erosion through the wall of the maxillary, sphenoid, or ethmoid sinuses. Infiltrative processes such as amyloidosis, granulomatosis with polyarteritis, an idiopathic granulomatous inflammation similar to Tolosa-Hunt, and IgG4-related disease are additional causes. Biopsy is often necessary for diagnosis.

As noted above, Guillain-Barré syndrome commonly affects the facial nerves bilaterally. In the Fisher variant of Guillain-Barré syndrome, oculomotor paresis occurs with ataxia and areflexia in the limbs **(Chap. 458)**. Wernicke's encephalopathy can cause a severe ophthalmoplegia combined with other brainstem signs **(Chap. 318)**.

Progressive bulbar palsy is a slowly progressive purely motor disorder affecting multiple cranial nerve nuclei. Weakness of the face, jaw, pharynx, neck, and tongue is usually present accompanied by atrophy and fasciculations. It is a form of motor neuron disease **(Chap. 448)**. Pure motor syndromes without atrophy raise the question of myasthenia gravis **(Chap. 459)**, and when rapidly evolving, Guillain-Barré syndrome, diphtheria, and poliomyelitis are additional considerations.

Glossopharyngeal neuropathy in conjunction with vagus and accessory nerve palsies may occur with herpes zoster infection or with a tumor or aneurysm in the posterior fossa or in the jugular foramen, through which all three nerves exit the skull. Hoarseness due to vocal cord paralysis, some difficulty in swallowing, deviation of the soft palate to the intact side, anesthesia of the posterior wall of the pharynx, and weakness of the upper part of the trapezius and sternocleidomastoid muscles make up jugular foramen syndrome.

Paralysis of the vagus and hypoglossal nerves (Tapia syndrome) can rarely follow endotracheal intubation and has been reported during the COVID-19 pandemic; symptoms consist of dysphonia and tongue deviation and usually resolve within a few months.

An idiopathic form of multiple cranial nerve involvement on one or both sides of the face is occasionally seen. The syndrome consists of a subacute onset of boring facial pain, followed by paralysis of motor cranial nerves. The clinical features overlap those of Tolosa-Hunt syndrome and appear to be due to idiopathic inflammation of the dura mater, which may be visualized by MRI. The syndrome is usually responsive to glucocorticoids.

453 Diseases of the Spinal Cord

Stephen L. Hauser

Diseases of the spinal cord are frequently devastating. They produce quadriplegia, paraplegia, and sensory deficits far beyond the damage they would inflict elsewhere in the nervous system because the spinal cord contains, in a small cross-sectional area, almost the entire motor output and sensory input of the trunk and limbs. Many spinal cord diseases are reversible if recognized and treated at an early stage **(Table 453-1)**; thus, they are among the most critical of neurologic emergencies. Proper management requires the efficient use of diagnostic procedures, guided by knowledge of the anatomy and clinical features of spinal cord diseases.

APPROACH TO THE PATIENT

Spinal Cord Disease

SPINAL CORD ANATOMY RELEVANT TO CLINICAL SIGNS

The spinal cord is a thin, tubular extension of the central nervous system contained within the bony spinal canal. It originates at the medulla and continues caudally to the conus medullaris at the lumbar level; its fibrous extension, the filum terminale, terminates at the coccyx. The adult spinal cord is ~46 cm (18 in.) long, oval in shape, and enlarged in the cervical and lumbar regions, where neurons that innervate the upper and lower extremities, respectively, are located. The white matter tracts containing ascending sensory and descending motor pathways are located peripherally, whereas nerve cell bodies are clustered in an inner region of gray matter shaped like a four-leaf clover that surrounds the central canal (anatomically an extension of the fourth ventricle). The membranes that cover the spinal cord—the pia, arachnoid, and dura—are continuous with those of the brain, and the cerebrospinal fluid is contained within the subarachnoid space between the pia and arachnoid.

The spinal cord has 31 segments, each defined by an exiting ventral motor root and entering dorsal sensory root. During embryologic development, growth of the cord lags behind that of the vertebral column, and the mature spinal cord ends at approximately the first lumbar vertebral body. The lower spinal nerves take an increasingly downward course to exit via intervertebral foramina. The first seven pairs of cervical spinal nerves exit above the same-numbered vertebral bodies, whereas all the subsequent nerves exit below the same-numbered vertebral bodies; this is because there are eight cervical spinal cord segments but only seven cervical vertebrae. The relationship between spinal cord segments and the corresponding vertebral bodies is shown in **Table 453-2**. These relationships assume particular importance for localization of lesions that cause spinal cord compression. Sensory loss below

TABLE 453-1 Treatable Spinal Cord Disorders

Compressive
Epidural, intradural, or intramedullary neoplasm
Epidural abscess
Epidural hemorrhage
Cervical spondylosis
Herniated disk
Posttraumatic compression by fractured or displaced vertebra or hemorrhage
Vascular
Arteriovenous malformation and dural fistula
Antiphospholipid syndrome and other hypercoagulable states
Inflammatory
Multiple sclerosis
Neuromyelitis optica
Sarcoidosis
Systemic immune-mediated disorders: SLE, Sjögren's, Behcet's disease, APL antibody syndrome, others vasculitis
Other CNS disorders: anti-MOG, anti-GFAP, paraneoplastic,[a] CLIPPERS, Erdheim-Chester
Infectious
Viral: VZV, HSV-1 and -2, CMV, HIV, HTLV-1, others
Bacterial and mycobacterial: *Borrelia*, *Listeria*, syphilis, others
Mycoplasma pneumoniae
Parasitic: schistosomiasis, toxoplasmosis, cysticercosis
Developmental
Syringomyelia
Meningomyelocele
Tethered cord syndrome
Metabolic
Vitamin B_{12} deficiency (subacute combined degeneration)
Folate deficiency
Copper deficiency

[a]Including anti-amphiphysin, CRMP-5, Hu.

the level of the umbilicus, for example, corresponds to pathology at the T10 cord segment, which is located adjacent to the seventh or eighth thoracic vertebral body (see Figs. 27-2 and 27-3). In addition, at every level, the main ascending and descending tracts are somatotopically organized with a laminated distribution that reflects the origin or destination of nerve fibers.

Determining the Level of the Lesion The presence of a horizontally defined level below which sensory, motor, and autonomic function is impaired is the hallmark of a spinal cord lesion. This *sensory level* is sought by asking the patient to identify a pinprick or cold stimulus applied to the proximal legs and lower trunk and successively moved up toward the neck on each side. Sensory loss below this level is the result of damage to the spinothalamic tract on the opposite side, one to two segments higher in the case of a unilateral spinal cord lesion, and at the level of a bilateral lesion. The discrepancy in the level of a unilateral lesion is the result of the course of the second-order sensory fibers, which originate in the dorsal horn and ascend for one or two levels as they cross anterior to the central canal to join the opposite spinothalamic tract. Lesions that transect the descending corticospinal and other motor tracts cause paraplegia or quadriplegia with heightened deep tendon reflexes, Babinski signs, and eventual spasticity (upper motor neuron syndrome). Transverse damage to the cord also produces autonomic disturbances consisting of absent sweating below the implicated cord level and bladder, bowel, and sexual dysfunction.

The uppermost level of a spinal cord lesion can also be localized by attention to the *segmental signs* corresponding to disturbed motor or sensory innervation by an individual cord segment. A band of altered sensation (hyperalgesia or hyperpathia) at the upper end of the sensory disturbance, fasciculations or atrophy in muscles innervated by one or several segments, or a muted or absent deep tendon reflex may be noted at this level. These signs also can occur with focal root or peripheral nerve disorders; thus, they are most useful when they occur together with signs of long-tract damage. With severe and acute transverse lesions, the limbs initially may be flaccid rather than spastic. This state of "spinal shock" lasts for several days, rarely for weeks, and may be mistaken for extensive damage to the anterior horn cells over many segments of the cord or for an acute polyneuropathy.

The main features of transverse damage at each level of the spinal cord are summarized below.

Cervical Cord Upper cervical cord lesions produce quadriplegia and weakness of the diaphragm. The uppermost level of weakness and reflex loss with lesions at C5–C6 is in the biceps; at C7, in finger and wrist extensors and triceps; and at C8, finger and wrist flexion. Horner's syndrome (miosis, ptosis, and facial hypohidrosis) may accompany a cervical cord lesion at any level.

Thoracic Cord Lesions here are localized by the sensory level on the trunk and, if present, by the site of midline back pain. Useful markers of the sensory level on the trunk are the nipples (T4) and umbilicus (T10). Leg weakness and disturbances of bladder and bowel function accompany the paralysis. Lesions at T9–T10 paralyze the lower—but not the upper—abdominal muscles, resulting in upward movement of the umbilicus when the abdominal wall contracts (*Beevor's sign*).

Lumbar Cord Lesions at the L2–L4 spinal cord levels paralyze flexion and adduction of the thigh, weaken leg extension at the knee, and abolish the patellar reflex. Lesions at L5–S1 paralyze only movements of the foot and ankle, flexion at the knee, and extension of the thigh, and abolish the ankle jerks (S1).

Sacral Cord/Conus Medullaris The conus medullaris is the tapered caudal termination of the spinal cord, comprising the sacral and single coccygeal segments. The distinctive conus syndrome consists of bilateral saddle anesthesia (S3–S5), prominent bladder and bowel dysfunction (urinary retention and incontinence with lax anal tone), and impotence. The bulbocavernosus (S2–S4) and anal (S4–S5) reflexes are absent (Chap. 433). Muscle strength is largely preserved. By contrast, lesions of the cauda equina, the nerve roots derived from the lower cord, are characterized by low back and radicular pain, asymmetric leg weakness and sensory loss, variable areflexia in the lower extremities, and relative sparing of bowel and bladder function. Mass lesions in the lower spinal canal often produce a mixed clinical picture with elements of both cauda equina and conus medullaris syndromes.

Special Patterns of Spinal Cord Disease The location of the major ascending and descending pathways of the spinal cord are shown in Fig. 453-1. Most fiber tracts—including the posterior columns and the spinocerebellar and pyramidal tracts—are situated on the side of the body they innervate. However, afferent fibers mediating pain and temperature sensation ascend in the spinothalamic

TABLE 453-2 Spinal Cord Levels Relative to the Vertebral Bodies

SPINAL CORD LEVEL	CORRESPONDING VERTEBRAL BODY
Upper cervical	Same as cord level
Lower cervical	1 level higher
Upper thoracic	2 levels higher
Lower thoracic	2–3 levels higher
Lumbar	T10–T12
Sacral	T12–L1

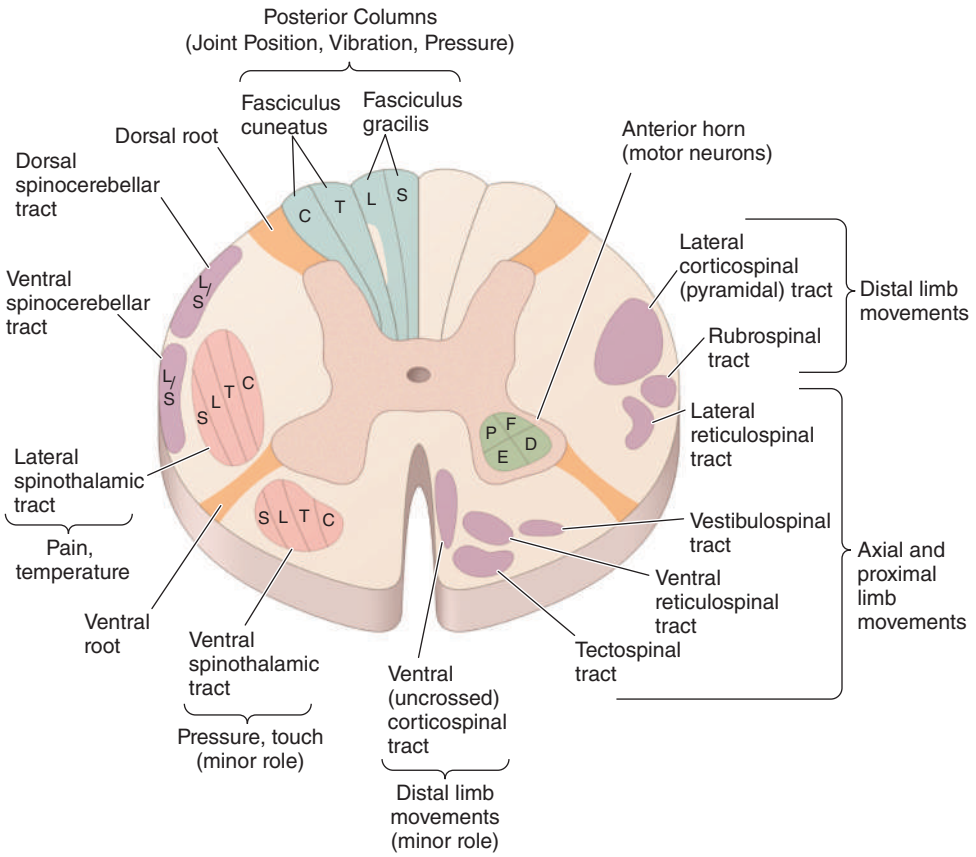

FIGURE 453-1 Transverse section through the spinal cord, composite representation, illustrating the principal ascending (*left*) and descending (*right*) pathways. The lateral and ventral spinothalamic tracts ascend contralateral to the side of the body that is innervated. In humans, the lateral corticospinal (pyramidal) tract is thought to lack strict somatotopic organization in the spinal cord. C, cervical; D, distal; E, extensors; F, flexors; L, lumbar; P, proximal; S, sacral; T, thoracic.

tract contralateral to the side they supply. The anatomic configurations of these tracts produce characteristic syndromes that provide clues to the underlying disease process.

Brown-Sequard Hemicord Syndrome This consists of ipsilateral weakness (corticospinal tract) and loss of joint position and vibratory sense (posterior column), with contralateral loss of pain and temperature sense (spinothalamic tract) one or two levels below the lesion. Segmental signs, such as radicular pain, muscle atrophy, or loss of a deep tendon reflex, are unilateral. Partial forms are more common than the fully developed syndrome.

Central Cord Syndrome This syndrome results from selective damage to the gray matter nerve cells and crossing spinothalamic tracts surrounding the central canal. In the cervical cord, the central cord syndrome produces arm weakness out of proportion to leg weakness and a "dissociated" sensory loss, meaning loss of pain and temperature sensations over the shoulders, lower neck, and upper trunk (cape distribution), in contrast to preservation of light touch, joint position, and vibration sense in these regions. Spinal trauma, syringomyelia, and intrinsic cord tumors are the main causes.

Anterior Cord Syndrome Infarction of the cord is generally the result of occlusion or diminished flow in the anterior spinal artery. The result is bilateral tissue destruction at several contiguous levels that spares the posterior columns. All spinal cord functions—motor, sensory, and autonomic—are lost below the level of the lesion, with the striking exception of retained vibration and position sensation.

Foramen Magnum Syndrome Lesions in this area interrupt decussating pyramidal tract fibers destined for the legs, which cross caudal to those of the arms, resulting in weakness of the legs (*crural paresis*). Compressive lesions near the foramen magnum may produce weakness of the ipsilateral shoulder and arm followed by weakness of the ipsilateral leg, then the contralateral leg, and finally the contralateral arm, an "around-the-clock" pattern that may begin in any of the four limbs. There is typically suboccipital pain spreading to the neck and shoulders.

Intramedullary and Extramedullary Syndromes It is useful to differentiate *intramedullary* processes, arising within the substance of the cord, from *extramedullary* ones that lie outside the cord and compress the spinal cord or its vascular supply. The differentiating features are only relative and serve as clinical guides. With extramedullary lesions, radicular pain is often prominent, and there is early sacral sensory loss and spastic weakness in the legs with incontinence due to injury to the corresponding sensory and motor fibers in the spinothalamic and corticospinal tracts (Fig. 453-1). Intramedullary lesions tend to produce poorly localized burning pain rather than radicular pain and to spare sensation in the perineal and sacral areas ("sacral sparing"), reflecting the laminated configuration of the spinothalamic tract with sacral fibers outermost; corticospinal tract signs appear later. Regarding extramedullary lesions, a further distinction is made between extradural and intradural masses, as the former are generally malignant and the latter benign (neurofibroma being a common cause). Consequently, a long duration of symptoms favors an intradural origin.

ACUTE AND SUBACUTE SPINAL CORD DISEASES

Symptoms of the cord diseases that evolve over days or weeks typically present as focal neck or back pain, followed by various combinations of paresthesias, sensory loss, motor weakness, and sphincter disturbance. There may be mild sensory symptoms only or a devastating functional transection of the cord. When paresthesias begin in the feet and then ascend, a polyneuropathy is often considered, and in such cases, the presence of bladder disturbances and a sharply demarcated spinal cord level provide important clues to the spinal cord origin of the disease.

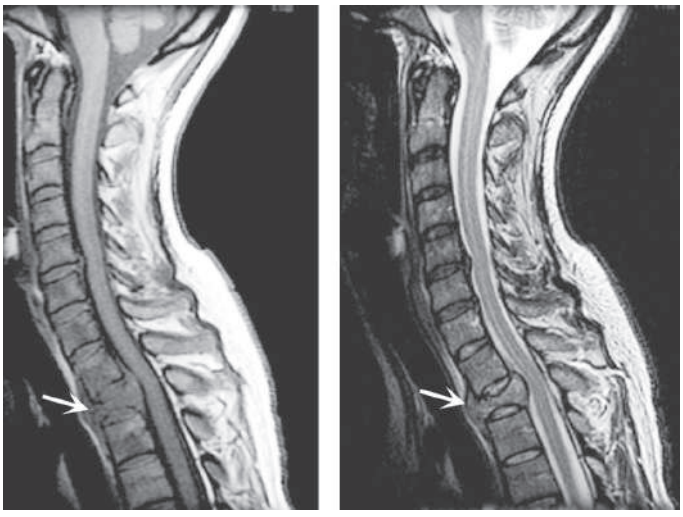
In severe and abrupt cases, areflexia reflecting spinal shock may be present, but hyperreflexia supervenes over days or weeks; persistent

areflexic paralysis with a sensory level usually indicates necrosis over multiple segments of the spinal cord.

APPROACH TO THE PATIENT

Compressive and Noncompressive Myelopathy

DISTINGUISHING COMPRESSIVE FROM NONCOMPRESSIVE MYELOPATHY



The first priority is to exclude treatable compression of the cord by a mass lesion. The common causes are tumor, epidural abscess or hematoma, herniated disk, and spondylitic vertebral pathology. Epidural compression due to malignancy or abscess often causes warning signs of neck or back pain, bladder disturbances, and sensory symptoms that precede the development of paralysis. Spinal subluxation, hemorrhage, and noncompressive etiologies such as infarction are more likely to produce myelopathy without antecedent symptoms. Magnetic resonance imaging (MRI) with gadolinium, centered on the clinically suspected level, is the initial diagnostic procedure if it is available; it is often appropriate to image the entire spine (cervical through sacral regions) to search for additional clinically silent lesions. Once compressive lesions have been excluded, noncompressive causes of acute myelopathy that are intrinsic to the cord are considered, primarily vascular, inflammatory, and infectious etiologies.

COMPRESSIVE MYELOPATHIES

Neoplastic Spinal Cord Compression In adults, most neoplasms are epidural in origin, resulting from metastases to the adjacent vertebral column. The propensity of solid tumors to metastasize to the vertebral column probably reflects the high proportion of bone marrow located in the axial skeleton. Almost any malignant tumor can metastasize to the spinal column, with breast, lung, prostate, kidney, lymphoma, and myeloma being particularly frequent. The thoracic spinal column is most commonly involved; exceptions are metastases from prostate and ovarian cancer, which occur disproportionately in the sacral and lumbar vertebrae, probably from spread through Batson's plexus, a network of veins along the anterior epidural space. Retroperitoneal neoplasms (especially lymphomas or sarcomas) enter the spinal canal laterally through the intervertebral foramina and produce radicular pain with signs of weakness that corresponds to the level of involved nerve roots.

Pain is usually the initial symptom of spinal metastasis; it may be aching and localized or sharp and radiating in quality and typically worsens with movement, coughing, or sneezing and characteristically awakens patients at night. A recent onset of persistent back pain, particularly if in the thoracic spine (which is uncommonly involved by spondylosis), should prompt consideration of vertebral metastasis. Rarely, pain is mild or absent. Plain radiographs of the spine and radionuclide bone scans have a limited role in diagnosis because they do not identify 15–20% of metastatic vertebral lesions and fail to detect paravertebral masses that reach the epidural space through the intervertebral foramina. MRI provides excellent anatomic resolution of the extent of spinal tumors (Fig. 453-2) and is able to distinguish between malignant lesions and other masses—epidural abscess, tuberculoma, lipoma, or epidural hemorrhage, among others—that present in a similar fashion. Vertebral metastases are usually hypointense relative to a normal bone marrow signal on T1-weighted MRI; after the administration of gadolinium, contrast enhancement may deceptively "normalize" the appearance of the tumor by increasing its intensity to that of normal bone marrow. Infections of the spinal column (osteomyelitis and related disorders) are distinctive in that, unlike tumor, they often cross the disk space to involve the adjacent vertebral body.

If spinal cord compression is suspected, imaging should be obtained promptly. If there are radicular symptoms but no evidence of myelopathy, it may be safe to defer imaging for 24–48 h. Up to 40% of patients who present with cord compression at one level are found to have asymptomatic epidural metastases elsewhere; thus, imaging of the entire length of the spine is important to define the extent of disease.

A ***B***

FIGURE 453-2 Epidural spinal cord compression due to breast carcinoma. Sagittal T1-weighted (***A***) and T2-weighted (***B***) magnetic resonance imaging scans through the cervicothoracic junction reveal an infiltrated and collapsed second thoracic vertebral body with posterior displacement and compression of the upper thoracic spinal cord. The low-intensity bone marrow signal in ***A*** signifies replacement by tumor.

TREATMENT

Neoplastic Spinal Cord Compression

Proper management is based on multiple considerations, including radiosensitivity of the primary tumor, extent of compression, prior therapy to the site, and stability of the spine. Treatment includes glucocorticoids to reduce cord edema, surgery and/or local radiotherapy (initiated as early as possible) to the symptomatic lesion, and specific therapy for the underlying tumor type. Glucocorticoids (typically dexamethasone, 10 mg intravenously) can be administered before an imaging study if there is clinical suspicion of cord compression and continued at a lower dose (4 mg every 6 h orally) until definitive treatment with radiotherapy and/or surgical decompression is completed. In one trial, initial management with surgery followed by radiotherapy was more effective than radiotherapy alone for patients with a single area of spinal cord compression by extradural tumor; however, patients with recurrent cord compression, brain metastases, radiosensitive tumors, or severe motor symptoms of >48 h in duration were excluded from this study. Stereotactic body radiotherapy, which delivers high doses of focused radiation, is preferred for radioresistant tumor types and for patients requiring re-irradiation.

Biopsy of the epidural mass is unnecessary in patients with known primary cancer, but it is indicated if a history of underlying cancer is lacking. Surgical treatment, either decompression by laminectomy or a spinal fixation procedure, is also indicated when signs of cord compression worsen despite radiotherapy; the maximum-tolerated dose of radiotherapy has been delivered previously to the site; a vertebral compression fracture or spinal instability contributes to cord compression; or in cases of high-grade spinal cord compression from a radioresistant tumor.

A good response to therapy can be expected in individuals who are ambulatory at presentation. Treatment usually prevents new weakness, and some recovery of motor function occurs in up to one-third of patients. Motor deficits (paraplegia or quadriplegia), once established for >12 h, do not usually improve, and beyond 48 h, the prognosis for substantial motor recovery is poor. Although most patients do not experience recurrences in the months following radiotherapy, with survival beyond 2 years, recurrence becomes increasingly likely and can be managed with additional radiotherapy.

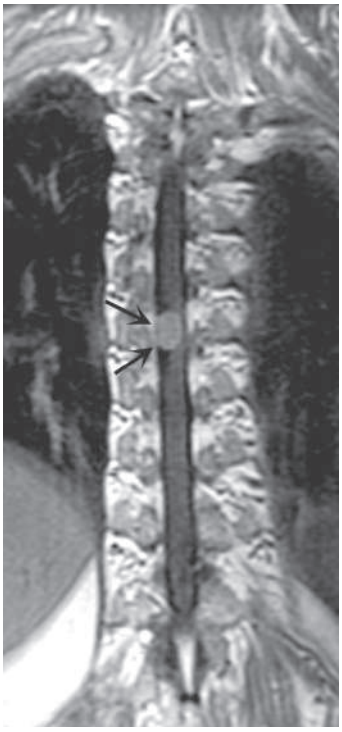


FIGURE 453-3 Magnetic resonance imaging of a thoracic meningioma. Coronal T1-weighted postcontrast image through the thoracic spinal cord demonstrates intense and uniform enhancement of a well-circumscribed extramedullary mass (*arrows*) that displaces the spinal cord to the left.

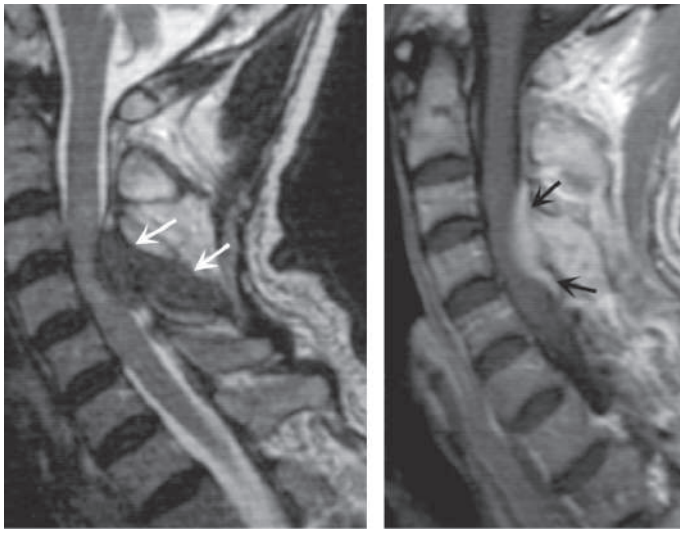
FIGURE 453-4 Magnetic resonance imaging of an intramedullary astrocytoma. Sagittal T1-weighted postcontrast image through the cervical spine demonstrates expansion of the upper cervical spine by a mass lesion emanating from within the spinal cord at the cervicomedullary junction. Irregular peripheral enhancement occurs within the mass (*arrows*).



In contrast to tumors of the epidural space, most intradural mass lesions are slow-growing and benign. Meningiomas and neurofibromas account for most of these, with occasional cases caused by chordoma, lipoma, dermoid, or sarcoma. Meningiomas **(Fig. 453-3)** are often located posterior to the thoracic cord or near the foramen magnum, although they can arise from the meninges anywhere along the spinal canal. Neurofibromas are benign tumors of the nerve sheath that typically arise from the posterior root; when multiple, neurofibromatosis is the likely etiology. Symptoms usually begin with radicular sensory symptoms followed by an asymmetric, progressive spinal cord syndrome. Therapy is surgical resection.

Primary intramedullary tumors of the spinal cord are uncommon. They present as central cord or hemicord syndromes, often in the cervical region. There may be poorly localized burning pain in the extremities and sparing of sacral sensation. In adults, these lesions are ependymomas, hemangioblastomas, or low-grade astrocytomas **(Fig. 453-4)**. Complete resection of an intramedullary ependymoma is often possible with microsurgical techniques. Debulking of an intramedullary astrocytoma can also be helpful, as these are often slowly growing lesions; the value of adjunctive radiotherapy and chemotherapy is uncertain. Secondary (metastatic) intramedullary tumors also occur, especially in patients with advanced metastatic disease **(Chap. 95)**, although these are not nearly as frequent as brain metastases.

Spinal Epidural Abscess Spinal epidural abscess presents with midline back or neck pain, fever, and progressive limb weakness. Prompt recognition of this distinctive process may prevent permanent sequelae. Aching pain is almost always present, either over the spine or in a radicular pattern. The duration of pain prior to presentation is generally ≤2 weeks but may on occasion be several months or longer. Fever is typically but not invariably present, accompanied by elevated white blood cell count, sedimentation rate, and C-reactive protein. As the abscess expands, further spinal cord damage results from venous congestion and thrombosis. Once weakness and other signs of myelopathy appear, progression may be rapid and irreversible. A more chronic sterile granulomatous form of abscess is also known, usually after treatment of an acute epidural infection.

Risk factors include an impaired immune status (HIV, diabetes mellitus, renal failure, alcoholism, malignancy), intravenous drug abuse, and infections of the skin or other tissues. Two-thirds of epidural infections result from hematogenous spread of bacteria from the skin (furunculosis), soft tissue (pharyngeal or dental abscesses; sinusitis), or deep viscera (bacterial endocarditis). The remainder arises from direct extension of a local infection to the subdural space; examples of local predisposing conditions are vertebral osteomyelitis, decubitus ulcers, lumbar puncture, epidural anesthesia, or spinal surgery. Most cases are due to *Staphylococcus aureus*; gram-negative bacilli, *Streptococcus*, anaerobes, and fungi can also cause epidural abscesses. Methicillin-resistant *Staphylococcus aureus* (MRSA) is an important consideration, and therapy should be tailored to this possibility. Tuberculosis from an adjacent vertebral source (Pott's disease) remains an important cause in the developing world.

MRI **(Fig. 453-5)** localizes the abscess and excludes other causes of myelopathy. Blood cultures are positive in more than half of cases, but direct aspiration of the abscess at surgery is often required for a

A ***B***

FIGURE 453-5 Magnetic resonance (MR) imaging of a spinal epidural abscess due to tuberculosis. ***A.*** Sagittal T2-weighted free spin-echo MR sequence. A hypointense mass replaces the posterior elements of C3 and extends epidurally to compress the spinal cord (*arrows*). ***B.*** Sagittal T1-weighted image after contrast administration reveals a diffuse enhancement of the epidural process (*arrows*) with extension into the epidural space.

microbiologic diagnosis. Lumbar puncture is only required if encephalopathy or other clinical signs raise the question of associated meningitis, a feature that is found in <25% of cases. The level of the puncture should be planned to minimize the risk of meningitis due to passage of the needle through infected tissue. A high cervical tap is sometimes the safest approach. Cerebrospinal fluid (CSF) abnormalities in epidural and subdural abscesses consist of pleocytosis with a preponderance of polymorphonuclear cells, an elevated protein level, and a reduced glucose level, but the responsible organism is not cultured unless there is associated meningitis.

TREATMENT

Spinal Epidural Abscess

Treatment is by decompressive laminectomy with debridement combined with long-term antibiotic treatment. Surgical evacuation prevents development of paralysis and may improve or reverse paralysis in evolution, but it is unlikely to improve fixed deficits more than several days in duration. Broad-spectrum antibiotics, typically vancomycin 15–20 mg/kg q12h (*Staphylococcus* including MRSA, *Streptococcus*), ceftriaxone 2 g q12h (gram-negative bacilli), and when indicated, metronidazole 30 mg/kg per day divided into q6h intervals (anaerobes), should be started empirically before surgery and then modified on the basis of culture results; medication is generally continued for 6–8 weeks. If surgery is contraindicated or if there is a fixed paraplegia or quadriplegia that is unlikely to improve following surgery, long-term administration of systemic and oral antibiotics can be used; in such cases, the choice of antibiotics may be guided by results of blood cultures. Surgical management remains the treatment of choice unless the abscess is limited in size and causes few or no neurologic signs.

With prompt diagnosis and treatment, up to two-thirds of patients experience significant recovery.

Spinal Epidural Hematoma Hemorrhage into the epidural (or subdural) space causes acute focal or radicular pain followed by variable signs of a spinal cord or conus medullaris disorder. Therapeutic anticoagulation, trauma, tumor, or blood dyscrasias are predisposing conditions. Rare cases complicate lumbar puncture or epidural anesthesia. MRI and computed tomography (CT) confirm the clinical suspicion and can delineate the extent of the bleeding. Treatment consists of prompt reversal of any underlying clotting disorder and surgical decompression. Surgery may be followed by substantial recovery, especially in patients with some preservation of motor function preoperatively. Because of the risk of hemorrhage, lumbar puncture should be avoided whenever possible in patients with severe thrombocytopenia or other coagulopathies.

Hematomyelia Hemorrhage into the substance of the spinal cord is a rare result of trauma, intraparenchymal vascular malformation (see below), vasculitis due to polyarteritis nodosa or systemic lupus erythematosus (SLE), bleeding disorders, or a spinal cord neoplasm. Hematomyelia presents as an acute painful transverse myelopathy. With large lesions, extension into the subarachnoid space results in subarachnoid hemorrhage **(Chap. 440)**. Diagnosis is by MRI or CT. Therapy is supportive, and surgical intervention is generally not useful. An exception is hematomyelia due to an underlying vascular malformation, for which spinal angiography and endovascular occlusion may be indicated, or surgery to evacuate the clot and remove the underlying vascular lesion.

Acute Spondylytic Myelopathy Of particular concern are hyperextension injuries in patients with underlying degenerative cervical spine disease **(Chap. 19)**. The provoking stimulus may be obvious, such as a forward fall, or occur after seemingly innocuous low-impact movements of the neck. A preexisting stenotic spinal canal is often present, and "buckling" of the posterior ligamentum flavum (less commonly acute disk herniation or subluxation) is believed to produce the cord compression, sometimes with a central cord syndrome (see above) and involvement of the upper, more than lower, limbs. Deficits can be transient, resulting in a "concussion" of the spinal cord, or permanent. *The more common syndrome of chronic spondylitic myelopathy is discussed below.*

NONCOMPRESSIVE MYELOPATHIES

Once a compressive etiology has been excluded as the cause of an acute myelopathy, the principal challenge is to distinguish vascular/ischemic from inflammatory/infectious causes. This is often not straightforward because clinical presentations can overlap. Moreover, findings that usually point to an inflammatory etiology—such as focal gadolinium enhancement on MRI scans or pleocytosis in the CSF—can also occur with spinal cord ischemia. Ischemia is likely in hyperacute presentations with back or neck pain and when an anterior pattern of spinal cord injury is identified on clinical examination or by MRI. By contrast, inflammation is more likely in cases that develop subacutely or when systemic symptoms, CSF oligoclonal bands, or multiple discrete spinal cord MRI lesions are present. The most frequent inflammatory causes of acute myelopathy are multiple sclerosis (MS); neuromyelitis optica (NMO); sarcoidosis; systemic inflammatory diseases such as SLE and Behcet's disease; postinfectious or idiopathic transverse myelitis, which is presumed to be an immune condition related to acute disseminated encephalomyelitis **(Chap. 456)**; and infectious (primarily viral) causes.

The evaluation generally requires a lumbar puncture and a search for underlying systemic disease **(Table 453-3)**.

Spinal Cord Infarction The cord is supplied by three arteries that course vertically over its surface: a single anterior spinal artery and paired posterior spinal arteries. The anterior spinal artery originates in paired branches of the vertebral arteries at the craniocervical junction and is fed by additional radicular vessels that arise at C6, at an upper thoracic level, and, most consistently, at T11–L2 (artery of Adamkiewicz). At each spinal cord segment, paired penetrating vessels branch from the anterior spinal artery to supply the anterior two-thirds of the

TABLE 453-3 Considerations in the Evaluation of Myelopathy

1. MRI of spinal cord with and without contrast (exclude compressive causes).
2. CSF studies: Cell count, protein, glucose, IgG index/synthesis rate, oligoclonal bands, VDRL; Gram's stain, acid-fast bacilli, and India ink stains; PCR for VZV, HSV-2, HSV-1, EBV, CMV, HHV-6, enteroviruses, HIV; antibody for HTLV-1, *Borrelia burgdorferi*, *Mycoplasma pneumoniae*, and *Chlamydia pneumoniae*; viral, bacterial, mycobacterial, and fungal cultures.
3. Blood studies for infection: HIV; RPR; IgG and IgM enterovirus antibody; IgM WNV, group B arbovirus, mumps, measles, rubella, *Brucella melitensis*, *Chlamydia psittaci*, *Bartonella henselae*, schistosomal antibody; PCR and antigen tests for SARS-CoV-2; cultures for *B. melitensis*. Also consider nasal/pharyngeal/anal cultures for enteroviruses; stool O&P for *Schistosoma* ova.
4. Vascular causes: MRI, CT myelogram; spinal angiogram.
5. Multiple sclerosis: Brain MRI scan; evoked potentials.
6. Neuromyelitis optica and related disorders: Serum anti-aquaporin-4 antibody, anti-MOG antibody, anti-GFAP antibody.
7. Sarcoidosis: Serum angiotensin-converting enzyme; serum Ca; 24-h urine Ca; chest x-ray; chest CT; slit-lamp eye examination; total-body gallium scan; lymph node biopsy.
8. Systemic immune-mediated disorders: ESR; ANA; ENA; dsDNA; rheumatoid factor; anti-SSA; anti-SSB, complement levels; antiphospholipid and anticardiolipin antibodies; pANCA; antimicrosomal and antithyroglobulin antibodies; if Sjögren's syndrome suspected, Schirmer test, salivary gland scintigraphy, and salivary/lacrimal gland biopsy.
9. Paraneoplastic disorders: Antibody for amphiphysin, CRMP5, Hu, others.
10. Other: vitamin B_{12}, copper, zinc.

Abbreviations: ANA, antinuclear antibodies; Ca, calcium; CMV, cytomegalovirus; CRMP5, collapsin response mediator 5-IgG; CSF, cerebrospinal fluid; CT, computed tomography; EBV, Epstein-Barr virus; ENA, epithelial neutrophil-activating peptide; ESR, erythrocyte sedimentation rate; GFAP, glial fibrillary acidic protein; HHV, human herpes virus; HSV, herpes simplex virus; HTLV, human T-cell leukemia/lymphoma virus; MOG, myelin oligodendrocyte glycoprotein; MRI, magnetic resonance imaging; O&P, ova and parasites; pANCA, perinuclear antineutrophilic cytoplasmic antibodies; PCR, polymerase chain reaction; RPR, rapid plasma reagin (test); VDRL, Venereal Disease Research Laboratory; VZV, varicella-zoster virus; WNV West Nile virus.

cord; the posterior spinal arteries, which often become less distinct below the midthoracic level, supply the posterior columns.

Spinal cord ischemia can occur at any level; however, the presence of the artery of Adamkiewicz below, and the anterior spinal artery circulation above, creates a region of marginal blood flow in the upper thoracic segments. With hypotension or cross-clamping of the aorta, cord infarction typically occurs at the level of T3–T4 and also at boundary zones between the anterior and posterior spinal artery territories. The latter may result in a rapidly progressive syndrome over hours of weakness and spasticity with little sensory change.

Acute infarction in the territory of the *anterior spinal artery* produces paraplegia or quadriplegia, dissociated sensory loss affecting pain and temperature sense but sparing vibration and position sense, and loss of sphincter control (anterior cord syndrome). Onset may be sudden but more typically is progressive over minutes or a few hours, unlike stroke in the cerebral hemispheres. Sharp midline or radiating back pain localized to the area of ischemia is frequent. Areflexia due to spinal shock is often present initially; with time, hyperreflexia and spasticity appear. Less common is infarction in the territory of the *posterior spinal arteries*, resulting in loss of posterior column function either on one side or bilaterally.

Causes of spinal cord infarction include aortic atherosclerosis, dissecting aortic aneurysm, vertebral artery occlusion or dissection in the neck, aortic surgery, or profound hypotension from any cause. Cardiogenic emboli, vasculitis **(Chap. 375)**, and collagen vascular disease (particularly SLE **[Chap. 368]**, Sjögren's syndrome **[Chap. 373]**, and the antiphospholipid antibody syndrome **[Chap. 369]**) are other etiologies. Occasional cases develop from *embolism of nucleus pulposus* material into spinal vessels, usually from local spine trauma. A *surfer's myelopathy,* usually in the thoracic region, has been associated with prolonged back extension due to lifting the upper body off the board while waiting for waves; it typically manifests as back pain followed by an anterior cord syndrome with progressive paralysis and loss of sphincter control and is likely vascular in origin. A few reports have also been associated with cocaine use, as well as with heroin. In a substantial number of cases, no cause can be found, and thromboembolism in arterial feeders is suspected.

MRI may fail to demonstrate infarctions of the cord, especially in the first day, but often the imaging becomes abnormal at the affected level. MRI features suggestive of cord infarction include diffusion-weighted restriction; longitudinally extensive anterior T2 signal brightness on sagittal images ("pencil-like sign"); focal enhancement in the anterior horns; and paired areas of focal T2 hyperintensity in the anterior medial cord on axial images ("owl's eyes"). When present, infarction of a vertebral body adjacent to the area of cord involvement is diagnostically helpful.

With cord infarction due to presumed thromboembolism, acute anticoagulation is not indicated, with the possible exception of the unusual transient ischemic attack or incomplete infarction with a stuttering or progressive course. The antiphospholipid antibody syndrome is treated with anticoagulation **(Chap. 369)**. Increasing systemic blood pressure to a mean arterial pressure of >90 mmHg, or lumbar drainage of spinal fluid, was reportedly helpful in a few published cases of cord infarction, but neither of these approaches has been studied systematically. Prognosis following spinal cord infarction is influenced by the severity of the deficits at presentation; patients with severe motor weakness and those with persistent areflexia usually do poorly, but in one large series, some improvement over time occurred in many patients, with more than half ultimately regaining some ambulation.

Inflammatory and Immune Myelopathies (Myelitis) This broad category includes MS, NMO, and postinfectious myelitis, as well as sarcoidosis, systemic autoimmune disease, and infections. In approximately one-quarter of cases of myelitis, no underlying cause can be identified. Some will later manifest additional symptoms of an immune-mediated disease. *Transverse myelitis* refers to a pattern of extensive spinal cord injury due to inflammation, clinically manifest as bilateral sensory symptoms, unilateral or bilateral weakness, and bladder and/or bowel disturbance. In most of the developed world, MS is the most common inflammatory cause of an acute myelitis, but involvement is usually partial and not transverse. *Recurrent episodes of myelitis* are usually due to one of the immune-mediated diseases or to infection with herpes simplex virus (HSV) type 2 (below).

MULTIPLE SCLEROSIS MS may present with acute myelitis, particularly in individuals of Asian or African ancestry. In whites, MS attacks rarely cause a transverse myelopathy (i.e., attacks of bilateral sensory disturbances, unilateral or bilateral weakness, and bladder or bowel symptoms), but MS is among the most common causes of a partial cord syndrome. MRI findings in MS-associated myelitis typically consist of mild swelling of the cord and diffuse or multifocal "shoddy" areas of abnormal signal on T2-weighted sequences. Contrast enhancement, indicating disruption in the blood-brain barrier associated with inflammation, is present in many acute cases. In one study 68% of patients presenting with partial myelitis developed MS after a mean follow-up of 4 years; risk factors for conversion to MS included age <40 years, inflammatory CSF, and more than three periventricular lesions on brain MRI.

Treatment of acute episodes of MS-associated myelitis consists of intravenous methylprednisolone (500 mg qd for 3 days) followed by oral prednisone (1 mg/kg per day for several weeks, then a gradual taper). A course of plasma exchange may be indicated for severe cases if glucocorticoids are ineffective. **MS is discussed in Chap. 455.**

NEUROMYELITIS OPTICA NMO is an immune-mediated disorder consisting of a severe myelopathy that is typically longitudinally extensive, meaning that the lesion typically spans three or more vertebral segments. NMO is associated with optic neuritis that is often bilateral and may precede or follow myelitis by weeks or months and also by brainstem and, in some cases, hypothalamic or focal cerebral white matter involvement. Recurrent myelitis without optic nerve or other involvement can also occur in NMO. CSF studies reveal a variable mononuclear pleocytosis of up to several hundred cells per microliter (higher than in typical MS) with occasional cases showing polymorphonuclear predominant pattern; oligoclonal bands are present in <20% of NMO cases. Diagnostic serum autoantibodies against the water channel protein aquaporin-4 (AQP-4) are present in 90% of patients with NMO; in some AQP-4-negative cases, autoantibodies against the central nervous system (CNS) myelin protein myelin oligodendrocyte glycoprotein (MOG) are found. NMO is also associated with SLE (see below) as well as with other systemic autoimmune diseases; rare cases are paraneoplastic. Acute relapses of NMO are treated with glucocorticoids and, for severe or refractory cases, plasma exchange. Three monoclonal antibodies are now available for prophylactic treatment: eculizumab, a terminal complement inhibitor; inebilizumab, a B-cell depleter; and satralizumab, an interleukin (IL) 6 receptor blocker. Other options include off-label use of azathioprine, mycophenolate, or rituximab. Treatment for 5 years or longer is generally recommended. **NMO is discussed in Chap. 456.**

SARCOIDOSIS Sarcoid myelopathy may present as a slowly progressive or relapsing disorder. Clinically, sensory involvement often predominates. MRI may show edematous swelling of the spinal cord mimicking tumor and in some cases longitudinally extensive involvement resembling NMO. Subpial gadolinium enhancement of active lesions, which may appear nodular, are typically located along the dorsal surface of the cord; on axial images, these dorsal lesions combined with enhancement of the central canal can produce a characteristic "trident sign." The typical CSF profile consists of a mild lymphocyte-predominant pleocytosis and elevated protein level; in a minority of cases, reduced glucose and oligoclonal bands are found. When present, the hypoglycorrhachia can be helpful in distinguishing neurosarcoid from other noninfectious causes of myelitis. The diagnosis is particularly difficult when systemic manifestations of sarcoid are minor or absent (nearly 50% of cases) or when other typical neurologic manifestations of the disease, such as cranial neuropathy, hypothalamic involvement, or meningeal enhancement visualized by MRI, are lacking. A slit-lamp examination of the eye to search for uveitis, chest x-ray and CT to assess pulmonary involvement and mediastinal lymphadenopathy, serum or CSF angiotensin-converting enzyme (ACE; lacks specificity

and values are elevated in only a minority of cases), serum calcium, and a gallium scan may assist in the diagnosis. Initial treatment is with high doses of glucocorticoids, which need to be administered long term and tapered slowly while monitoring resolution of clinical and MRI signs of active disease; relapses are managed with high-dose glucocorticoids plus a steroid-sparing immunosuppressant drug (typically mycophenolate mofetil, azathioprine, or methotrexate) or with the tumor necrosis factor α-inhibitor infliximab. **Sarcoidosis is discussed in Chap. 379.**

SYSTEMIC IMMUNE-MEDIATED DISORDERS Myelitis occurs in a small number of patients with SLE, many cases of which are associated with antibodies to AQP-4 and satisfy diagnostic criteria for NMO (discussed above). These patients are at high risk of developing future episodes of myelitis and/or optic neuritis. In others, the etiology of SLE-associated myelitis is uncertain. Antiphospholipid antibodies have been suggested to play a role; however, the frequency of these antibodies is similar in SLE patients with and without myelitis. NMO-associated myelitis typically produces severe clinical disease, CSF pleocytosis with polymorphonuclear leukocytes, and an MRI pattern of central gray matter spinal cord involvement; in cases not due to NMO, less severe and more subacutely evolving clinical findings are often present, with milder CSF lymphocytic pleocytosis and MRI changes consistent with white matter involvement of the cord. In both forms, CSF oligoclonal bands are variable findings. There are no systematic trials of therapy for SLE myelitis, but based on limited data, patients with AQP-4 antibodies should be treated as for NMO (above), and in others, high-dose glucocorticoids followed by cyclophosphamide have been recommended. Severe episodes that do not initially respond to glucocorticoids are often treated with a course of plasma exchange. Sjögren's syndrome **(Chap. 373)** can also be associated with NMO and also with cases of chronic progressive myelopathy. Other immune-mediated myelitides include Behçet's disease **(Chap. 376)**, antiphospholipid antibody syndrome **(Chap. 369)**, mixed connective tissue disease **(Chap. 372)**, and vasculitis related to polyarteritis nodosa, perinuclear antineutrophilic cytoplasmic (pANCA) antibodies, or primary CNS vasculitis **(Chap. 375)**. Occasional cases of myelitis, often accompanied by other manifestations that can include encephalitis or optic neuritis, have been associated with autoantibodies against glial fibrillary acidic protein (GFAP) **(Chap. 456)**. Other rare etiologies are chronic lymphocytic inflammation with pontine perivascular enhancement responsive to steroids (CLIPPERS) and Erdheim-Chester disease producing inflammatory mass-like lesions that can be intramedullary or extra-axial and compressive.

POSTINFECTIOUS MYELITIS Many cases of myelitis, termed *postinfectious* or *postvaccinal*, follow an infection or vaccination. Numerous organisms have been implicated, including Epstein-Barr virus (EBV), cytomegalovirus (CMV), and mycoplasma most frequently, with many others including influenza, measles, varicella, mumps, and yellow fever also described. Recently, vaccination (or active infection) with SARS-CoV-2 virus has been associated with a small number of cases of myelitis and NMO. As in the related disorder acute disseminated encephalomyelitis **(Chap. 456)**, postinfectious myelitis often begins as the patient appears to be recovering from an acute febrile infection or in the subsequent days or weeks, but an infectious agent cannot be isolated from the nervous system or CSF. Serum anti-MOG antibodies are present acutely in some cases, especially in children. The presumption is that the myelitis represents an autoimmune disorder triggered by infection and is not due to direct infection of the spinal cord. No randomized controlled trials of therapy exist; treatment is usually with glucocorticoids or, in fulminant cases, plasma exchange.

ACUTE INFECTIOUS MYELITIS Many viruses have been associated with an acute myelitis that is infectious in nature rather than postinfectious. Nonetheless, the two processes are often difficult to distinguish. Herpes zoster is a well characterized agent of viral myelitis, with direct spread to the spinal cord from dorsal root ganglia, and HSV types 1 and 2, EBV, CMV, and rabies virus are other well-described causes. Zika virus has also been recognized as a cause of infectious myelitis, as has a rare association with monkeypox. HSV-2 (and less commonly HSV-1) produces a distinctive syndrome of recurrent sacral and cauda equina neuritis in association with outbreaks of genital herpes (Elsberg's syndrome). Poliomyelitis is a prototypic viral myelitis that is more or less restricted to the anterior gray matter of the cord containing the spinal motoneurons. A polio-like syndrome can also be caused by a large number of enteroviruses (including enterovirus A-71 and coxsackie) and, importantly, by West Nile virus and other flaviviruses such as Japanese encephalitis. Beginning in 2012, cases of acute flaccid paralysis in children and adolescents have appeared associated with enterovirus A-71 and D-68 infection. Chronic viral myelitic infections, such as those due to HIV or human T-cell lymphotropic virus type 1 (HTLV-1), are discussed below.

Bacterial and mycobacterial myelitis (most are essentially abscesses) are less common than viral causes and much less frequent than cerebral bacterial abscess. Almost any pathogenic species may be responsible, including *Borrelia burgdorferi* (Lyme disease), *Listeria monocytogenes, Mycobacterium tuberculosis,* and *Treponema pallidum* (syphilis). *Mycoplasma pneumoniae* may be a cause of myelitis, but its status is uncertain because many cases are more properly classified as postinfectious.

Schistosomiasis **(Chap. 241)** is an important cause of parasitic myelitis in endemic areas. The process is intensely inflammatory and granulomatous, caused by a local response to tissue-digesting enzymes from the ova of the parasite, typically *Schistosoma haematobium* or *Schistosoma mansoni*. Toxoplasmosis **(Chap. 235)** can occasionally cause a focal myelopathy, and this diagnosis should especially be considered in patients with AIDS **(Chap. 208)**. *Cysticercosis* **(Chap. 242)** is another consideration, although myelitis from this helminth is far less common than parenchymal brain or meningeal involvement.

In cases of suspected viral myelitis, it may be appropriate to begin specific therapy pending laboratory confirmation. Herpes zoster, HSV, and EBV myelitis are treated with intravenous acyclovir (10 mg/kg q8h) or oral valacyclovir (2 g tid) for 10–14 days; CMV is treated with ganciclovir (5 mg/kg IV bid) plus foscarnet (60 mg/kg IV tid) or cidofovir (5 mg/kg per week for 2 weeks, then biweekly for two additional doses).

High-Voltage Electrical Injury Spinal cord injuries are prominent following electrocution from lightning strikes or other accidental electrical exposures. The syndrome consists of transient weakness acutely (often with an altered sensorium and focal cerebral disturbances), sometimes followed several days or even weeks later by a myelopathy that can be severe and permanent. This is a rare injury type, and limited data incriminate a vascular pathology involving the anterior spinal artery and its branches in some cases. Therapy is supportive.

CHRONIC MYELOPATHIES

SPONDYLOTIC MYELOPATHY

Spondylotic myelopathy is the most common cause of myelopathy and of gait difficulty in the elderly, accounting for more than half of nontraumatic spinal cord injuries in some series. Neck and shoulder pain with stiffness are early symptoms; impingement of bone and soft tissue overgrowth on nerve roots results in radicular arm pain, most often in a C5 or C6 distribution. Compression of the cervical cord, which occurs in fewer than one-third of cases, produces a slowly progressive spastic paraparesis, at times asymmetric and often accompanied by paresthesias in the feet and hands. Vibratory sense is diminished in the legs, there is a Romberg sign, and occasionally there is a sensory level for vibration or pinprick on the upper thorax. In some cases, coughing or straining produces leg weakness or radiating arm or shoulder pain. Dermatomal sensory loss in the arms, atrophy of intrinsic hand muscles, increased deep-tendon reflexes in the legs, and extensor plantar responses are common. Urinary urgency or incontinence occurs in advanced cases, but there are many alternative causes of these problems in older individuals. A tendon reflex in the arms is often diminished at some level, most often at the biceps (C5–C6). In individual cases, radicular, myelopathic, or combined signs may predominate. The diagnosis should always be considered in cases of progressive cervical myelopathy, paresthesias of the feet and hands, or wasting of the hands.

Diagnosis is usually made by MRI and may be suspected from CT images; plain x-rays are less helpful. Extrinsic cord compression and deformation are appreciated on axial MRI views, and T2-weighted sequences may reveal areas of high signal intensity within the cord adjacent to the site of compression. A cervical collar may be helpful in milder cases, but the likelihood of progression of medically treated myelopathy is high, estimated at 8% over 1 year. Definitive therapy consists of surgical decompression, either posterior laminectomy or an anterior approach with resection of the protruded disk and bony material. **Cervical spondylosis and related degenerative diseases of the upper spine are discussed in Chap. 19.**

VASCULAR MALFORMATIONS OF THE CORD AND DURA

Vascular malformations, comprising ~4% of all mass lesions of the cord and overlying dura, are treatable causes of progressive myelopathy. Most common are fistulas located within the dura or posteriorly along the surface of the cord. Most dural arteriovenous (AV) fistulas are located at or below the midthoracic level, usually consisting of a direct connection between a radicular feeding artery in the nerve root sleeve with dural veins. The typical presentation is a middle-aged man with a progressive myelopathy that worsens slowly or intermittently and may have periods of remission, sometimes mimicking MS. Acute deterioration due to hemorrhage into the spinal cord (hematomyelia) or subarachnoid space may also occur but is rare. In many cases, progression results from local ischemia and edema due to venous congestion. Most patients have incomplete sensory, motor, and bladder disturbances. The motor disorder may predominate and produce a mixture of upper and restricted lower motor neuron signs, simulating amyotrophic lateral sclerosis (ALS). Pain over the dorsal spine, dysesthesias, or radicular pain may be present. Other symptoms suggestive of AV malformation (AVM) or dural fistula include intermittent claudication; symptoms that change with posture, exertion, Valsalva maneuver, or menses; and fever.

Less commonly, AVM disorders are intramedullary rather than dural. One unusual disorder is a progressive thoracic myelopathy with paraparesis developing over weeks or months, characterized pathologically by abnormally thick, hyalinized vessels within the cord (subacute necrotic myelopathy or Foix-Alajouanine syndrome).

Spinal bruits are infrequent but may be sought at rest and after exercise in suspected cases. A vascular nevus on the overlying skin may indicate an underlying vascular malformation as occurs with Klippel-Trenaunay-Weber syndrome. MR angiography and CT angiography can detect the draining vessels of many AVMs **(Fig. 453-6)**. Definitive diagnosis requires selective spinal angiography, which defines the feeding vessels and the extent of the malformation. Treatment is tailored to the anatomy and location of the lesion and generally consists of microsurgical resection, endovascular embolization of the major feeding vessels, or a combination of the two approaches.

RETROVIRUS-ASSOCIATED MYELOPATHIES

The myelopathy associated with HTLV-1, formerly called tropical spastic paraparesis, is a slowly progressive spastic syndrome with variable sensory and bladder disturbance. Approximately half of patients have mild back or leg pain. The neurologic signs may be asymmetric, often lacking a well-defined sensory level; the only sign in the arms may be hyperreflexia after several years of illness. The onset is usually insidious, and the tempo of clinical progression occurs at a variable rate; in one study, median time for progression to cane-, walker-, or wheelchair-dependent state was 6, 13, and 21 years, respectively. Progression appears to be more rapid in older patients and those with higher viral loads. Diagnosis is made by demonstration of HTLV-1-specific antibody in serum by enzyme-linked immunosorbent assay (ELISA), confirmed by radioimmunoprecipitation or Western blot analysis. Especially in endemic areas, a finding of HTLV-1 seropositivity in a patient with myelopathy does not necessarily prove that HTLV-1 is causative. The CSF/serum antibody index may provide support by establishing intrathecal synthesis of antibodies, including oligoclonal antibodies, favoring HTVL-1 myelopathy over asymptomatic carriage.

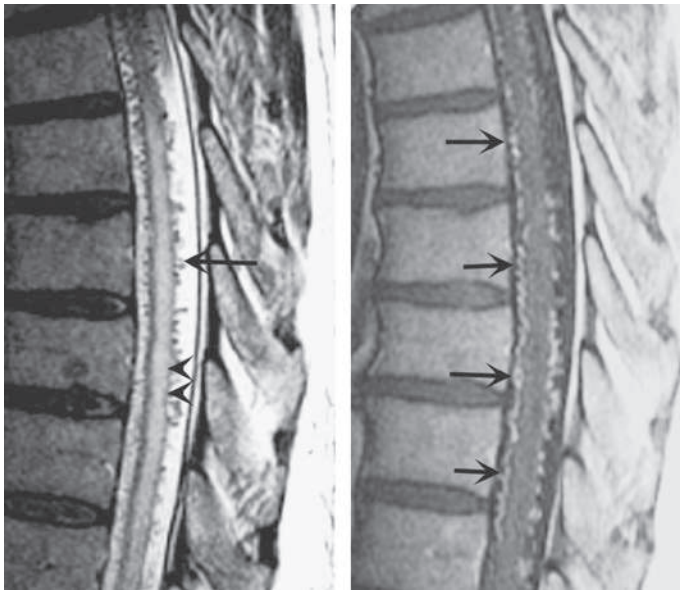


FIGURE 453-6 Arteriovenous malformation. Sagittal magnetic resonance scans of the thoracic spinal cord: T2 fast spin-echo technique (*left*) and T1 postcontrast image (*right*). On the T2-weighted image (*left*), abnormally high signal intensity is noted in the central aspect of the spinal cord (*arrowheads*). Numerous punctate flow voids indent the dorsal and ventral spinal cord (*arrow*). These represent the abnormally dilated venous plexus supplied by a dural arteriovenous fistula. After contrast administration (*right*), multiple, serpentine, enhancing veins (*arrows*) on the ventral and dorsal aspect of the thoracic spinal cord are visualized, diagnostic of arteriovenous malformation. This patient was a 54-year-old man with a 4-year history of progressive paraparesis.

Measuring proviral DNA by polymerase chain reaction (PCR) in peripheral blood and CSF cells can be useful as an ancillary part of diagnosis. The pathogenesis of the myelopathy is uncertain. It could result from an immune response directed against HTLV-1 antigens in the nervous system or, alternatively, to secondary autoimmunity triggered by the viral infection. There is no proven effective treatment. Based on limited evidence, systemic glucocorticoids, pulsed high-dose induction followed by low-dose chronic maintenance, can be tried, and mogamulizumab, a monoclonal antibody directed against CCR4, has been reported in one preliminary trial to slow progression and reduce neurologic disability in some recipients.

A progressive myelopathy can also result from HIV infection **(Chap. 208)**. It is characterized by vacuolar degeneration of the posterior and lateral tracts, resembling subacute combined degeneration (see below).

SYRINGOMYELIA

Syringomyelia is a developmental cavity in the cervical cord that may enlarge and produce progressive myelopathy or may remain asymptomatic. Symptoms begin insidiously in adolescence or early adulthood, progress irregularly, and may undergo spontaneous arrest for several years. Many young patients acquire a cervical-thoracic scoliosis. More than half of all cases are associated with Chiari type 1 malformations in which the cerebellar tonsils protrude through the foramen magnum and into the cervical spinal canal. The pathophysiology of syrinx expansion is controversial, but some interference with the normal flow of CSF seems likely, perhaps by the Chiari malformation. Acquired cavitations of the cord in areas of necrosis are also termed *syrinx cavities*; these follow trauma, myelitis, necrotic spinal cord tumors, and chronic arachnoiditis due to tuberculosis and other etiologies.

The presentation is a central cord syndrome consisting of a regional dissociated sensory loss (loss of pain and temperature sensation with sparing of touch and vibration) and areflexic weakness in the upper limbs. The sensory deficit has a distribution that is "suspended" over the nape of the neck, shoulders, and upper arms (cape distribution) or in the hands. Most cases begin asymmetrically with unilateral sensory loss in the hands that leads to injuries and burns that are not

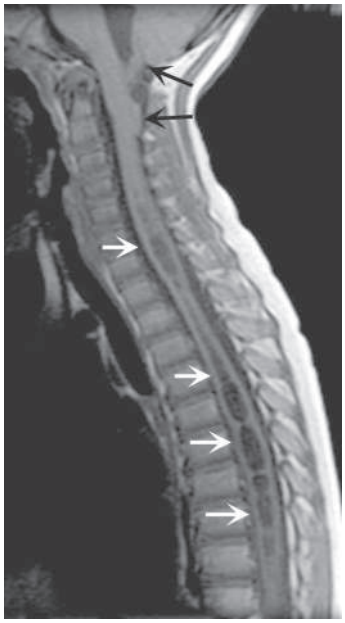

FIGURE 453-7 Magnetic resonance imaging of syringomyelia associated with a Chiari malformation. Sagittal T1-weighted image through the cervical and upper thoracic spine demonstrates descent of the cerebellar tonsils below the level of the foramen magnum (*black arrows*). Within the substance of the cervical and thoracic spinal cord, a cerebrospinal fluid collection dilates the central canal (*white arrows*).

appreciated by the patient. Muscle wasting in the lower neck, shoulders, arms, and hands with asymmetric or absent reflexes in the arms reflects expansion of the cavity in the gray matter of the cord. As the cavity enlarges and compresses the long tracts, spasticity and weakness of the legs, bladder and bowel dysfunction, and Horner's syndrome appear. Some patients develop facial numbness and sensory loss from damage to the descending tract of the trigeminal nerve (C2 level or above). In cases with Chiari malformations, cough-induced headache and neck, arm, or facial pain may be reported. Extension of the syrinx into the medulla, syringobulbia, causes palatal or vocal cord paralysis, dysarthria, horizontal or vertical nystagmus, episodic dizziness or vertigo, and tongue weakness with atrophy.

MRI accurately identifies developmental and acquired syrinx cavities and their associated spinal cord enlargement **(Fig. 453-7)**. Images of the brain and the entire spinal cord should be obtained to delineate the full longitudinal extent of the syrinx, assess posterior fossa structures for the Chiari malformation, and determine whether hydrocephalus is present.

TREATMENT

Syringomyelia

Surgical decompression is the treatment of choice, with mixed results reported in most series. The Chiari tonsillar herniation may be decompressed, generally by suboccipital craniectomy, upper cervical laminectomy, and placement of a dural graft. Fourth ventricular outflow is reestablished by this procedure. If the syrinx cavity is large, some surgeons recommend direct decompression or drainage, but an added benefit of this procedure has not been demonstrated, and complications are common. Shunting of hydrocephalus, when present, generally precedes any attempt to correct the syrinx. Surgery may stabilize the neurologic deficit, and some patients improve. Patients with few symptoms and signs from the syrinx do not require surgery and are followed by serial clinical and imaging examinations.

Syrinx cavities secondary to trauma or infection, if symptomatic, can be treated with a decompression and drainage procedure in which a small shunt is inserted between the cavity and subarachnoid space; alternatively, the cavity can be fenestrated. Cases due to intramedullary spinal cord tumor are generally managed by resection of the tumor.

CHRONIC MYELOPATHY OF MULTIPLE SCLEROSIS

A chronic progressive myelopathy is the most frequent cause of disability in both primary progressive and secondary progressive forms of MS. Involvement is typically bilateral but asymmetric and produces motor, sensory, and bladder/bowel disturbances. Fixed motor disability appears to result from extensive loss of axons in the corticospinal tracts. Diagnosis is facilitated by identification of earlier attacks such as optic neuritis. MRI, CSF, and evoked-response testing are confirmatory. Treatment with ocrelizumab, an anti-CD20 B-cell monoclonal antibody, is effective in patients with primary progressive MS, and disease-modifying therapy is also indicated in patients with secondary progressive MS who have clinical or MRI evidence of active disease. **MS is discussed in Chap. 455.**

SUBACUTE COMBINED DEGENERATION (VITAMIN B_{12} DEFICIENCY)

This treatable myelopathy presents with subacute paresthesias in the hands and feet, loss of vibration and position sensation, and a progressive spastic and ataxic weakness. Loss of reflexes due to an associated peripheral neuropathy in a patient who also has Babinski signs is a helpful diagnostic clue. Optic atrophy and irritability or other cognitive changes may be prominent in advanced cases and are occasionally the presenting symptoms. The myelopathy of subacute combined degeneration tends to be diffuse rather than focal; signs are generally symmetric and reflect predominant involvement of the posterior and lateral tracts, including Romberg sign. Causes include dietary deficiency, especially in vegans, and gastric malabsorption syndromes including pernicious anemia **(Chap. 104)**. The diagnosis is confirmed by the finding of macrocytic red blood cells, a low serum B_{12} concentration, and elevated serum levels of homocysteine and methylmalonic acid. Treatment is by replacement therapy, beginning with 1000 μg of intramuscular vitamin B_{12} daily for 5–7 days and then continued as a once-weekly dose for 4–8 weeks and then as a monthly maintenance dose; oral maintenance with high doses of cyanocobalamin (1–2 mg daily) can also be used for maintenance, as small amounts of vitamin B_{12} are absorbed passively by the gut even in pernicious anemia.

Two closely related conditions deserve mention here. The first is folate deficiency–associated myelopathy, now only rarely seen since widespread programs of dietary fortification with folate have been implemented. A second is due to inhalation with nitrous oxide (laughing gas), an irreversible inhibitor of vitamin B_{12}, which also produces a myelopathy identical to subacute combined degeneration. Exposure to nitrous oxide may occur during dental or surgical procedures or from recreational inhalation ("doing whippets").

HYPOCUPRIC MYELOPATHY

This myelopathy is similar to subacute combined degeneration, except serum levels of B_{12} are normal. Low levels of serum copper are found, and often there is also a low level of serum ceruloplasmin. Some cases follow gastrointestinal procedures, particularly bariatric surgery, that result in impaired copper absorption; others have been associated with excess zinc from health food supplements or, in the past, zinc-containing denture creams, all of which impair copper absorption via induction of metallothionein, a copper-binding protein. Many cases are idiopathic. There is often a coexisting anemia. Improvement or at least stabilization may be expected with reconstitution of copper stores by oral supplementation (2 mg/d).

TABES DORSALIS

The classic syphilitic syndromes of tabes dorsalis and meningovascular inflammation of the spinal cord are now less frequent than in the past but must be considered in the differential diagnosis of spinal cord disorders. The characteristic symptoms of tabes are fleeting and repetitive lancinating pains, primarily in the legs or less often in the back, thorax, abdomen, arms, and face. Ataxia of the legs and gait due to loss of position sense occurs in half of patients. Paresthesias, bladder disturbances, and acute abdominal pain with vomiting (visceral crisis) occur in 15–30% of patients. The cardinal signs of tabes are loss of reflexes in the legs; impaired position and vibratory sense; Romberg sign; and,

in almost all cases, bilateral Argyll Robertson pupils, which fail to constrict to light but accommodate. Diabetic polyradiculopathy may simulate this condition. Treatment of tabes dorsalis and other forms of neurosyphilis consists of penicillin G administered intravenously, or intramuscularly in combination with oral probenecid **(Chap. 187)**.

HEREDITARY SPASTIC PARAPLEGIA

Many cases of slowly progressive myelopathy are genetic in origin **(Chap. 448)**. More than 90 different causative loci have been identified, including autosomal dominant, autosomal recessive, and X-linked forms. Especially for the recessive and X-linked forms, a family history of myelopathy may be lacking. Most patients present with almost imperceptibly progressive spasticity and weakness in the legs, usually but not always symmetrical. Sensory symptoms and signs are absent or mild, but sphincter disturbances may be present. In some families, additional neurologic signs are prominent, including nystagmus, ataxia, or optic atrophy. The onset may be as early as the first year of life or as late as middle adulthood. Only symptomatic therapies are available.

PRIMARY LATERAL SCLEROSIS

This is a mid- to late-life-onset degenerative disorder characterized by progressive spasticity with weakness, eventually accompanied by dysarthria and dysphonia; bladder symptoms occur in approximately half of patients. Sensory function is spared. The disorder resembles ALS and is considered a variant of the motor neuron degenerations, but without the characteristic lower motor neuron disturbance and with typically a slower progression. Some cases may represent late-onset cases of hereditary spastic paraplegia, particularly autosomal recessive or X-linked varieties in which a family history may be absent. **(See also Chap. 448.)**

ADRENOMYELONEUROPATHY

This X-linked peroxisomal disorder is a variant of adrenoleukodystrophy (ALD). Most affected males have a history of adrenal insufficiency and then develop a progressive spastic (or ataxic) paraparesis beginning in early or sometimes middle adulthood; some patients also have cerebral involvement and/or a mild peripheral neuropathy. Female heterozygotes may develop a slower, insidiously progressive spastic myelopathy beginning later in adulthood and without adrenal insufficiency. Diagnosis is usually made by demonstration of elevated levels of very-long-chain fatty acids in plasma and in cultured fibroblasts. The responsible gene encodes the adrenoleukodystrophy protein (ALDP), a peroxisomal membrane transporter involved in carrying long-chain fatty acids to peroxisomes for degradation. Corticosteroid replacement is indicated if hypoadrenalism is present. Allogeneic bone marrow transplantation has been successful in slowing progression of cognitive decline in some patients with ALD treated early in their disease but appears to be ineffective for the myelopathy. A preliminary study of leriglitazone, a peroxisome proliferator-activated receptor gamma (PPARγ) agonist, reported suggestive slowing of myelopathic signs in some patients, but the primary endpoint was not met. Nutritional supplements (Lorenzo's oil) have also been attempted for this condition without evidence of efficacy.

CANCER-RELATED SYNDROMES

Cancer-related causes of chronic myelopathy, besides the common neoplastic compressive myelopathy discussed earlier, include radiation injury **(Chap. 95)** and a myelopathy resembling subacute combined degeneration that can follow intrathecal administration of methotrexate (a folate antagonist). Rare paraneoplastic myelopathies are most often associated with lung cancer and anti-amphiphysin (also breast), anti-collapsin response mediator 5 (CRMP5) (also lymphoma), or anti-Hu antibodies **(Chap. 99)**. Another uncommon lymphoma-associated paraneoplastic syndrome is a progressive flaccid paresis with destruction of anterior horn cells. NMO with AQP-4 antibodies **(Chap. 456)** can also rarely be paraneoplastic in origin. Several series have reported cases of myelopathy associated with use of checkpoint inhibitors in cancer treatment; some are associated with development of paraneoplastic or NMO antibodies. Metastases to the cord are probably more common than any of these disorders in patients with cancer.

OTHER CHRONIC MYELOPATHIES

Tethered cord syndrome is a developmental disorder of the lower spinal cord and nerve roots that rarely presents in adulthood as low back pain accompanied by a progressive lower spinal cord and/or nerve root syndrome. Some patients have a leg or foot deformity indicating a long-standing process, and in others, a dimple, patch of hair, or sinus tract on the skin overlying the lower back is the clue to a congenital lesion. Diagnosis is made by MRI, which demonstrates a low-lying conus medullaris and thickened filum terminale. The MRI may also reveal diastematomyelia (division of the lower spinal cord into two halves), lipomas, cysts, or other congenital abnormalities of the lower spine coexisting with the tethered cord. Treatment is with surgical release.

There are a number of rare toxic causes of spastic myelopathy, including lathyrism due to ingestion of chickpeas containing the excitotoxin β-*N*-oxalylamino-L-alanine (BOAA), seen primarily in the developing world or during famines, and Konzo due to ingestion of the cyanogen-containing casava plant found in sub-Saharan Africa.

Often, a cause of intrinsic myelopathy can be identified only through periodic reassessment.

REHABILITATION OF SPINAL CORD DISORDERS

The prospects for recovery from an acute destructive spinal cord lesion fade after ~6 months. There are currently no effective means to promote repair of injured spinal cord tissue; promising but entirely experimental approaches include the use of factors that influence reinnervation by axons of the corticospinal tract, nerve and neural sheath graft bridges, forms of electrical stimulation at the site of injury, and the local introduction of stem cells. The disability associated with irreversible spinal cord damage is determined primarily by the level of the lesion and by whether the disturbance in function is complete or incomplete **(Table 453-4)**. Even a complete high cervical cord lesion may be compatible with a productive life. The primary goals are development of a rehabilitation plan framed by realistic expectations and attention to the neurologic, medical, and psychological complications that commonly arise.

Many of the usual symptoms associated with medical illnesses, especially somatic and visceral pain, may be lacking because of the destruction of afferent pain pathways. Unexplained fever, worsening of spasticity, or deterioration in neurologic function should prompt a search for infection, thrombophlebitis, or an intraabdominal pathology. The loss of normal thermoregulation and inability to maintain normal body temperature can produce recurrent fever (*quadriplegic fever*), although most episodes of fever are due to infection of the urinary tract, lung, skin, or bone.

Bladder dysfunction generally results from loss of supraspinal innervation of the detrusor muscle of the bladder wall and the

TABLE 453-4 Expected Neurologic Function Following Complete Cord Lesions

LEVEL	SELF-CARE	TRANSFERS	MAXIMUM MOBILITY
High quadriplegia (C1–C4)	Dependent on others; requires respiratory support	Dependent on others	Motorized wheelchair
Low quadriplegia (C5–C8)	Partially independent with adaptive equipment	May be dependent or independent	May use manual wheelchair, drive an automobile with adaptive equipment
Paraplegia (below T1)	Independent	Independent	Ambulates short distances with aids

sphincter musculature. Detrusor spasticity is treated with anticholinergic drugs (oxybutynin, 2.5–5 mg qid) or tricyclic antidepressants with anticholinergic properties (imipramine, 25–200 mg/d). Failure of the sphincter muscle to relax during bladder emptying (urinary dyssynergia) may be managed with the α-adrenergic blocking agent terazosin hydrochloride (1–2 mg tid or qid), with intermittent catheterization, or, if that is not feasible, by use of a condom catheter in men or a permanent indwelling catheter. Surgical options include the creation of an artificial bladder by isolating a segment of intestine that can be catheterized intermittently (enterocystoplasty) or can drain continuously to an external appliance (urinary conduit). Bladder areflexia due to acute spinal shock or conus lesions is best treated by catheterization. Bowel regimens and disimpaction are necessary in many patients to ensure at least biweekly evacuation and avoid colonic distention or obstruction.

Patients with acute cord injury are at risk for venous thrombosis and pulmonary embolism. Use of calf-compression devices and anticoagulation with low-molecular-weight heparin are recommended. In cases of persistent paralysis, anticoagulation should probably be continued for 3 months.

Prophylaxis against decubitus ulcers should involve frequent changes in position in a chair or bed, the use of special mattresses, and cushioning of areas where pressure sores often develop, such as the sacral prominence and heels. Early treatment of ulcers with careful cleansing, surgical or enzyme debridement of necrotic tissue, and appropriate dressing and drainage may prevent infection of adjacent soft tissue or bone.

Spasticity is aided by stretching exercises to maintain mobility of joints. Drug treatment is effective but may result in reduced function, as some patients depend on spasticity as an aid to stand, transfer, or walk. Baclofen (up to 240 mg/d in divided doses) is effective; it acts by facilitating γ-aminobutyric acid–mediated inhibition of motor reflex arcs. Diazepam acts by a similar mechanism and is useful for leg spasms that interrupt sleep (2–4 mg at bedtime). Tizanidine (2–8 mg tid), an α_2 adrenergic agonist that increases presynaptic inhibition of motor neurons, is another option. For nonambulatory patients, the direct muscle inhibitor dantrolene (25–100 mg qid) may be used, but it is potentially hepatotoxic. In refractory cases, intrathecal baclofen administered via an implanted pump, botulinum toxin injections, or dorsal rhizotomy may be required to control spasticity.

Despite the loss of sensory function, many patients with spinal cord injury experience chronic pain sufficient to diminish their quality of life. Randomized controlled studies indicate that gabapentin or pregabalin is useful in this setting. Epidural electrical stimulation and intrathecal infusion of pain medications have been tried with some success. **Management of chronic pain is discussed in Chap. 14.**

A paroxysmal autonomic hyperreflexia may occur following lesions above the major splanchnic sympathetic outflow at T6. Headache, flushing, and diaphoresis above the level of the lesion, as well as hypertension with bradycardia or tachycardia, are the major symptoms. The trigger is typically a noxious stimulus—for example, bladder or bowel distention, a urinary tract infection, or a decubitus ulcer—below the level of the cord lesion. Treatment consists of removal of offending stimuli; ganglionic blocking agents (mecamylamine, 2.5–5 mg) or other short-acting antihypertensive drugs are useful in some patients.

Emerging neuro-therapeutic technologies, including rehabilitation robotics and brain-machine interfaces, offer real hope to advance prospects for full and productive lives in patients with disabling myelopathies **(Chap. 500)**.

454 Concussion and Other Traumatic Brain Injuries

Geoffrey T. Manley, Benjamin L. Brett, Michael McCrea

Traumatic brain injury (TBI) represents a significant global public health problem. In the United States, estimates of the frequency of TBI range between 2.5 and 4.8 million cases per year, depending on the study and methods used to define and include cases. Age-specific rates show a bimodal distribution, with highest risk in younger individuals and older adults. The most common mechanism of injury in the young is motor vehicle accidents and is more common in men, whereas in older adults, falls are the major cause of injury and are more likely to occur in women. Nonfatal TBI-related hospitalization rates are comparable across non-Hispanic white, non-Hispanic black, and Hispanic persons with age adjustment.

TBI imposes substantial demands on health care systems. Worldwide, at least 10 million TBIs are serious enough to result in death or hospitalization, producing a global economic burden of $400 billion annually. In the United States, the estimated annual cost is >$76 billion. Due to advances in medical care and other factors, more people are surviving TBI than ever before. Brain injury accounts for more lost productivity at work among Americans than any other form of injury. An estimated 5.3 million Americans are living with significant disabilities resulting from TBI that complicate their return to a full and productive life. Increased media attention to military and sports-related TBI has highlighted the growing concern that injuries that were previously dismissed can have lifelong consequences for some individuals.

Head injuries are so common that almost all physicians will be called upon to provide some aspect of immediate care or to see patients who are suffering from various sequelae. Patients and their families initially need education regarding the natural history of TBI along with treatment of acute symptoms such as headache. Continued follow-up is important to ensure that the sequelae experienced by some patients—such as the persistent postconcussion symptoms (PPCS) of headache, disturbances in balance, depression, and sleep disorder—are identified and treated appropriately. Effective management of TBI and its consequences often requires a coordinated multidisciplinary care team.

DEFINITION AND CLASSIFICATION

TBI is commonly defined as an alteration in brain function, or other evidence of brain pathology, caused by an external force, and characterized by the following: (1) any period of loss or decreased level of consciousness (LOC), (2) any loss of memory for events immediately before (retrograde) or after (posttraumatic) the injury, (3) any neurologic deficits, and/or (4) any alteration in mental state at the time of injury.

Evidence of TBI can include visual, neuroradiologic, or laboratory confirmation of damage to the brain, but TBI is more often diagnosed on the basis of acute clinical criteria. In addition to standard computed tomography (CT) imaging and conventional clinical magnetic resonance imaging (MRI), advanced MRI imaging (functional MRI, cerebral blood flow, diffusion MRI) techniques show increasing sensitivity, and it is likely that sensitive blood-based biomarkers will play an increasingly important role in the diagnosis and treatment of these patients (described below).

Mechanisms of TBI Common mechanisms of TBI include the head being struck by an object, the head striking an object, the brain undergoing an acceleration/deceleration movement, a foreign body penetrating the brain, or forces generated from events such as a blast or explosion. Unintentional falls and motor vehicle crashes have historically been cited as the most common cause of TBI. All forms of transportation, however, are common causes of TBI, including motorcycle crashes, bicycle accidents, skateboarding, and pedestrian injuries. The other leading causes of TBI are falls, assaults, and sports, with varied frequency across the lifespan. Certainly, there has been an increased focus on the high frequency of mild TBI (mTBI), often referred to as concussion, encountered by athletes participating in contact and collision sports at all competitive levels, as well as the potential short-term effects and long-term risks associated with sport-related concussion.

Classification of TBI Severity Numerous systems have been developed over the years to define and classify TBI severity along a continuum from mild to moderate to severe. These systems are usually most applicable to closed head injuries. In nearly all classification systems, TBI severity is graded based on acute injury characteristics rather than post-acute injury status, as other factors can intervene to influence functional outcome. This can be problematic, as some patients with severe TBI will have a full recovery and some with mild TBI will be left with lifetime disability. Historically, the presence and duration of unconsciousness and amnesia have been the main points of distinction along the gradient of TBI severity. Efforts to develop more advanced classification systems that incorporate patho-anatomical features reflecting biological response to injury, such as blood-based biomarkers, as well as socioenvironmental factors that may influence ultimate prognosis are currently underway. A recent working group convened by the National Institutes of Health has proposed a new framework for TBI characterization that includes clinical features, blood-based biomarkers, and imaging features, along with modifiers. As this more precise nomenclature is validated, it is anticipated that it will replace the current approach of characterizing patients based solely on their clinical exam and symptoms.

The Glasgow Coma Scale (GCS) is the most recognized and widely used method for grading TBI severity. The GCS provides a practical indicator of gross neurologic status by assessing motor function, verbal responses, and the patient's ability to open his or her eyes voluntarily or in response to external commands and stimuli. The grading is applied to the best response that can be elicited from the patient at the time of assessment, preferably before any paralyzing or sedating medication is administered or the patient is intubated, as these interventions confound interpretation of the score. The GCS assessment produces scores ranging from 3 to 15 **(Table 454-1)**.

Upon the 40th anniversary of the GCS in 2014, the wording for responses was revised, and recommendations were made to improve its utility. Importantly, individual patients are best described by the three components of the coma scale (eye, verbal, motor, e.g., E3V4M6); the derived total coma score (e.g., 13) is less informative and should only be used to characterize groups of patients.

Several injury-classification systems have been developed to go beyond GCS score or acute injury characteristics and incorporate chief signs and symptoms in defining mTBI. The use of multiple severity indicators is intended to improve sensitivity in the detection of mTBI (GCS 13–15), while also taking into consideration traditional acute injury characteristics that have been presumed to predict outcome following mild and moderate brain injury. LOC and posttraumatic amnesia (PTA) remain the most common injury characteristics referenced in these classification systems. In the case of moderate (GCS 9–12) and severe (GCS 3–8) TBI, GCS score and the duration of LOC and PTA can be robust predictors of long-term outcome and morbidity. In cases of mTBI, however, while PTA and LOC are important indicators of acute injury, they are less predictive of eventual recovery time and outcome, particularly within sport-related concussion.

TBI TYPES AND PATHOLOGIES

Mild TBI (Concussion) It is estimated that 70–90% of all treated TBIs are mild in severity based on traditional case definitions and acute injury characteristics, with most reported estimates in the order of 85%. The published figures likely underrepresent the true incidence of mTBI because of variable case definitions and heterogeneous methods. Moreover, because a subgroup of individuals with milder brain injuries does not seek medical attention, epidemiologic studies that depend on hospital-based data also underestimate the true incidence. In fact, it has been estimated that current data collection sources and methods may only capture one of every nine mTBI/concussions in the United States.

The term *concussion*, while popular, is vague and is not based on widely accepted objective criteria, resulting in multiple definitions from various groups. There has been debate as to whether concussion is part of the TBI spectrum or a separate entity. The Concussion in Sports Group has concluded that "concussion is a traumatic brain injury" as part of the consensus statement definition of the injury. By firmly placing concussion in the spectrum of TBI, the underlying pathophysiologic processes common to all TBI presentations can now be considered together.

CT imaging is often normal in this population. However, emerging evidence indicates that 3-tesla (3T) MRI scans with greater image resolution can identify pathology consistent with acute brain injury such as contusion and microhemorrhage. When patients with mTBI have CT and/or MRI abnormalities, they are often referred to as having complicated mTBI and are more likely to have an unfavorable outcome.

SKULL FRACTURE, EXTRA-AXIAL HEMATOMA, CONTUSION, AND AXONAL INJURY

SKULL FRACTURE

A blow to the skull that exceeds the elastic tolerance of the bone causes a fracture. Intracranial lesions accompany roughly two-thirds of skull fractures, and the presence of a fracture increases many-fold

the chances of an underlying subdural or epidural hematoma. Consequently, fractures are primarily markers of the site and severity of injury. If the underlying arachnoid membrane has been torn, fractures also provide potential pathways for entry of bacteria to the cerebrospinal fluid (CSF) with a risk of meningitis and for leakage of CSF outward through the dura. If there is leakage of CSF, severe orthostatic headache results from lowered pressure in the spinal fluid compartment.

Most fractures are linear and extend from the point of impact toward the base of the skull. Basilar skull fractures are often extensions of adjacent linear fractures over the convexity of the skull but may occur independently owing to stresses on the floor of the middle cranial fossa or occiput. Basilar fractures are usually parallel to the petrous bone or along the sphenoid bone and directed toward the sella turcica and ethmoidal groove. Although most basilar fractures are uncomplicated, they can cause CSF leakage, pneumocephalus, and delayed cavernous-carotid fistulas. Hemotympanum (blood behind the tympanic membrane), ecchymosis over the mastoid process (Battle sign), and periorbital ecchymosis ("raccoon sign") are clinical signs associated with basilar fractures.

EPIDURAL AND SUBDURAL HEMATOMAS

Hemorrhages between the dura and skull (epidural) or beneath the dura (subdural) have characteristic clinical and imaging features. They are sometimes associated with underlying brain contusions and other injuries, often making it difficult to determine the relative contribution of each component to the clinical state. The mass effect of raised intracranial pressure (ICP) caused by these hematomas can be life threatening, making it imperative to identify them rapidly by CT or MRI scan and to surgically remove them when appropriate.

Epidural Hematoma (Fig. 454-1) These highly dangerous lesions usually arise from an injury to a meningeal arterial vessel and evolve rapidly. They are often accompanied by a "lucid interval" of several minutes to hours prior to neurologic deterioration. They occur in up to 10% of cases of severe head injury but are less often associated with underlying cortical damage compared to subdural hematomas. Rapid surgical evacuation and ligation or cautery of the damaged vessel, usually the middle meningeal artery that has been lacerated by an overlying skull fracture, is indicated. If recognized and treated rapidly, patients often have a favorable outcome.

Acute Subdural Hematoma (Fig. 454-2) Direct cranial trauma may be minor and is not always required for acute subdural hemorrhage to occur, especially in the elderly and those taking anticoagulant medications. Acceleration forces alone, as from whiplash, are sometimes sufficient to produce subdural hematoma. Up to one-third of patients have a lucid interval lasting minutes to hours before coma supervenes, but most are drowsy or comatose from the moment of injury. A unilateral headache and slightly enlarged pupil on the side of the hematoma are frequently, but not invariably, present. Small subdural hematomas may be asymptomatic and usually do not require surgical evacuation if they do not enlarge. Stupor or coma, hemiparesis, and unilateral pupillary enlargement are signs of larger hematomas. The bleeding that causes larger subdural hematomas is primarily venous in origin, although arterial bleeding sites are sometimes found at operation, and a few large hematomas have a purely arterial origin. In an acutely deteriorating patient, an emergency craniotomy is required. In contrast to epidural hematomas, there is significant morbidity and mortality associated with acute subdural hematomas that require surgery.

FIGURE 454-2 Acute subdural hematoma. Noncontrast computed tomography scan reveals a hyperdense clot that has an irregular border with the brain and causes more horizontal displacement (mass effect) than might be expected from its thickness. The disproportionate mass effect is the result of the large rostral-caudal extent of these hematomas. Compare to Fig. 454-1.

Chronic Subdural Hematoma A subacutely evolving syndrome due to subdural hematoma occurs days or weeks after injury with drowsiness, headache, confusion, or mild hemiparesis, usually in the elderly with age-related atrophy and often after only minor or unnoticed trauma. On imaging studies, chronic subdural hematomas appear as crescentic clots over the convexity of one or both hemispheres, most commonly in the frontotemporal region (Fig. 454-3). A history of trauma may or may not be elicited in relation to chronic subdural hematoma; the injury may have been trivial and forgotten, particularly in the elderly and those with clotting disorders. Headache is common

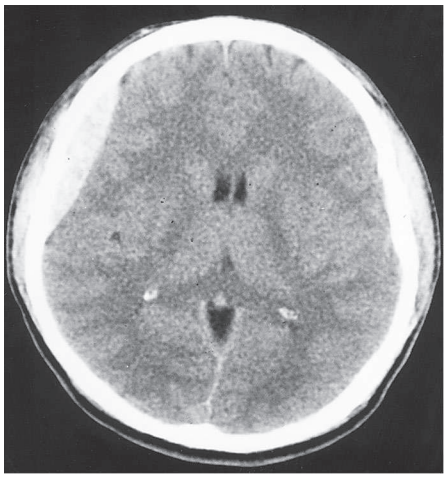

FIGURE 454-1 Acute epidural hematoma. The tightly attached dura is stripped from the inner table of the skull, producing a characteristic lenticular-shaped hemorrhage on noncontrast computed tomography scan. Epidural hematomas are usually caused by tearing of the middle meningeal artery following fracture of the temporal bone.

FIGURE 454-3 Computed tomography scan of chronic bilateral subdural hematomas of different ages. The collections began as acute hematomas and have become hypodense in comparison to the adjacent brain after a period during which they were isodense and difficult to appreciate. Some areas of resolving blood are contained on the more recently formed collection on the left (*arrows*).

but not invariable. Additional features that may appear weeks later include slowed thinking, vague change in personality, seizure, or a mild hemiparesis. The headache typically fluctuates in severity, sometimes with changes in head position. Drowsiness, inattentiveness, and incoherence of thought are generally more prominent than focal signs such as hemiparesis. Rarely, chronic hematomas cause brief episodes of hemiparesis or aphasia that are indistinguishable from transient ischemic attacks.

CT without contrast initially shows a low-density mass over the convexity of the hemisphere. Between 2 and 6 weeks after the initial bleeding, the clot becomes isodense compared to adjacent brain and may be inapparent. Many subdural hematomas that are several weeks in age contain areas of blood and intermixed serous fluid. Infusion of contrast material demonstrates enhancement of the vascular fibrous capsule surrounding the collection. MRI reliably identifies both subacute and chronic hematomas.

Clinical observation coupled with serial imaging is a reasonable approach to patients with few symptoms and small chronic subdural collections that do not cause mass effect. Treatment with surgical evacuation through burr holes is usually successful, if a cranial drain is used postoperatively. The fibrous membranes that grow from the dura and encapsulate the collection may require removal with a craniotomy to prevent recurrent fluid accumulation.

TRAUMATIC SUBARACHNOID HEMORRHAGE

Subarachnoid hemorrhage (SAH) is common in TBI. Rupture of small cortical arteries or veins can cause bleeding into the subarachnoid space. Traumatic SAH is often seen in the sulci and is frequently the only radiographic finding on CT following mild TBI. SAH occurs diffusely after severe TBI and confers an increase in mortality. In mild TBI, SAH provides an objective imaging biomarker for TBI and, in some patients, is associated with unfavorable outcomes.

CONTUSION (FIG. 454-4)

A surface bruise of the brain, or contusion, consists of varying degrees of petechial hemorrhage, edema, and tissue destruction. Contusions and deeper hemorrhages result from mechanical forces that displace and compress the hemispheres forcefully and by deceleration of the brain against the inner skull, either under a point of impact (coup lesion) or, as the brain swings back, in the antipolar area (contrecoup lesion). Trauma sufficient to cause prolonged unconsciousness usually produces some degree of contusion. Blunt deceleration impact, as occurs against an automobile dashboard or from falling forward onto a hard surface, causes contusions on the orbital surfaces of the frontal lobes and the anterior and basal portions of the temporal lobes. With lateral forces, as from impact on an automobile door frame, contusions are situated on the lateral convexity of the hemisphere. The clinical signs of contusion are determined by the location and size of the lesion; often, there are no focal abnormalities with a routine neurologic exam, but these injured regions are later the sites of gliotic scars that may produce seizures. A hemiparesis or gaze preference is fairly typical of moderately sized contusions. Large bilateral contusions produce stupor with extensor posturing, while those limited to the frontal lobes cause a taciturn state. Contusions in the temporal lobe may cause delirium or an aggressive, combative syndrome. Torsional or shearing forces within the brain can cause hemorrhages of the basal ganglia and other deep regions. Large contusions and hemorrhages after minor trauma should raise concerns for coagulopathy due to an underlying disease or more commonly anticoagulant therapy.

Acute contusions are easily visible on CT and MRI scans, appearing as inhomogeneous hyperdensities on CT and as hyperintensities on T2 and fluid-attenuated inversion recovery (FLAIR) MRI sequences; there is usually surrounding localized brain edema and some subarachnoid bleeding. Blood in the CSF due to trauma may provoke a mild inflammatory reaction. Over a few days, contusions acquire a surrounding contrast enhancement and edema that may be mistaken for tumor or abscess.

AXONAL INJURY (FIG. 454-5)

Traumatic axonal injury (TAI) is one of the most common injuries after TBI. There is disruption, or shearing, of axons at the time of impact, and this is associated with microhemorrhages. It occurs following high-speed deceleration injuries, such as motor vehicle collisions (see Johnson et al, 2013, in Further Readings). The presence of four or more areas of TAI is called diffuse axonal injury (DAI) and, when widespread, has been proposed to explain persistent coma and the vegetative state after TBI (Chap. 30). Only severe TAI lesions that contain substantial blood are visualized by CT, usually in the corpus callosum and centrum semiovale. More commonly, the CT will be negative for TAI, but subsequent MRI, particularly gradient-echo or susceptibility-weighted imaging, will show hemosiderin deposits reflective of microhemorrhages in addition to the axonal damage on diffusion sequences. Traditionally, TAI and DAI have been considered as sequelae much more likely to result from moderate and severe injuries. Accumulating evidence has demonstrated that diffuse white matter abnormalities purportedly reflective of axonal injury, such as changes in microstructure and neurite density, are quite common in mild TBI as well. The degree of these changes correlates with metrics of injury severity (e.g., symptom burden) and recovery duration.

CRANIAL NERVE INJURIES

The cranial nerves most often injured with TBI are the olfactory, optic, oculomotor, and trochlear nerves; the first and second branches of the trigeminal nerve; and the facial and auditory nerves. Anosmia and an apparent loss of taste (actually a loss of perception of aromatic flavors,

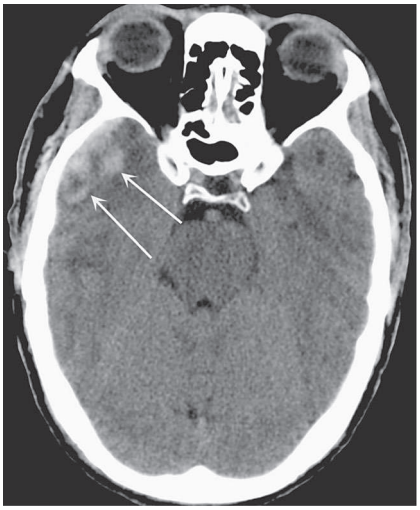

FIGURE 454-4 Traumatic cerebral contusion. Noncontrast computed tomography scan demonstrating a hyperdense hemorrhagic region in the anterior temporal lobe.

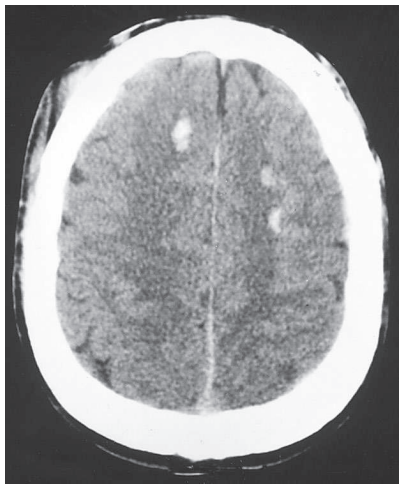

FIGURE 454-5 Multiple small areas of hemorrhage and tissue disruption in the white matter of the frontal lobes on noncontrast computed tomography scan. These appear to reflect an extreme type of the diffuse axonal shearing lesions that occur with closed head injury.

with retained elementary taste perception) occur in ~10% of persons with serious head injuries, particularly from falls on the back of the head. This is the result of displacement of the brain and shearing of the fine olfactory nerve filaments that course through the cribriform bone. At least partial recovery of olfactory and gustatory function is expected, but if bilateral anosmia persists for several months, the prognosis is poor. Partial optic nerve injuries from closed trauma result in blurring of vision, central or paracentral scotomas, or sector defects. Direct orbital injury may cause short-lived blurred vision for close objects due to reversible iridoplegia. Diplopia limited to downward gaze and corrected when the head is tilted away from the side of the affected eye indicates trochlear (fourth nerve) nerve damage. It occurs frequently as an isolated problem after minor head injury or may develop for unknown reasons after a delay of several days. Facial nerve injury caused by a basilar fracture is present immediately in up to 3% of severe injuries; it may also be delayed for 5–7 days. Fractures through the petrous bone, particularly the less common transverse type, are liable to produce facial palsy. Delayed facial palsy occurring up to a week after injury, the mechanism of which is unknown, has a good prognosis. Injury to the eighth cranial nerve from a fracture of the petrous bone causes loss of hearing, vertigo, and nystagmus immediately after injury. Deafness from eighth nerve injury is rare and must be distinguished from blood in the middle ear or disruption of the middle ear ossicles. Dizziness, tinnitus, and high-tone hearing loss occur from cochlear concussion.

SEIZURES

Convulsions are surprisingly uncommon immediately after TBI, but a brief period of tonic extensor posturing or a few clonic movements of the limbs just after the moment of impact can occur. However, the cortical scars that evolve from contusions are highly epileptogenic and may later manifest as seizures, even after many months or years **(Chap. 436)**. The severity of injury roughly determines the risk of future seizures. It has been estimated that 17% of individuals with brain contusion, subdural hematoma, or prolonged LOC will develop a seizure disorder and that this risk extends for an indefinite period of time, whereas the risk is ≤2% after mild injury. The majority of convulsions in the latter group occur within 5 years of injury but may be delayed for decades. Penetrating injuries have a much higher rate of subsequent epilepsy.

CLINICAL SYNDROMES AND TREATMENT OF HEAD INJURY

CONCUSSION/MILD TBI

The patient who has briefly lost consciousness or been stunned after a minor head injury usually becomes fully alert and attentive within minutes but may complain of headache, dizziness, faintness, nausea, a single episode of emesis, difficulty with concentration, a brief amnestic period, or slight blurring of vision. This typical concussion syndrome has a good prognosis with little risk of subsequent deterioration. Children are particularly prone to drowsiness, vomiting, and irritability, symptoms that are sometimes delayed for several hours after apparently minor injuries. Vasovagal syncope that follows injury may cause undue concern. Generalized or frontal headache is common in the following days. It may be migrainous (throbbing and hemicranial) in nature or aching and bilateral. After several hours of observation, patients with minor injury may be accompanied home and observed for a day by a family member or friend, with written instructions to return if symptoms worsen.

Persistent severe headache and repeated vomiting in the context of normal alertness and no focal neurologic signs is usually benign, but CT should be obtained and a longer period of observation is appropriate. The decision to perform imaging tests also depends on clinical signs that indicate that the impact was severe (e.g., persistent confusion, repeated vomiting, palpable skull fracture); the presence of other serious bodily injuries, an underlying coagulopathy, or age >65 years; and on the degree of surveillance that can be anticipated after discharge. Guidelines have also indicated that older age (>65 years), two or more episodes of vomiting, >30 min of retrograde or persistent anterograde amnesia, seizure, and concurrent drug or alcohol intoxication are sensitive (but not specific) indicators of intracranial hemorrhage that justify CT scanning.

Though not incorporated into conventional clinical practice guidelines, growing evidence suggests that MRI improves sensitivity for detection of small intracranial hemorrhages and other lesions in mild TBI patients, particular among those with negative findings on CT. Specifically, intracranial abnormalities are fairly common on MRI (27%) in CT-negative patients. Further, acute MRI findings have prognostic utility in predicting recovery and outcome after mTBI/concussion (e.g., risk of functional impairment, time to return to activity).

Blood-based (serum and plasma) biomarkers of astrocyte damage/astrogliosis (glial fibrillary acidic protein [GFAP]) and neuronal injury (ubiquitin carboxy-terminal hydrolase L1 [UCHL1]) also hold promise in improving detection and outcome prediction across the full spectrum of TBI. With development and regulatory approval of new rapid assay systems, these biomarkers can now be used for real-time point-of-care assessment; GFAP in particular has high discriminant ability to detect intracranial abnormalities, as well as potential to differentiate CT+, CT–/MRI+, and CT–/MRI– patients. Similar to MRI, emerging biomarkers appear to have not only diagnostic but also prognostic utility in predicting the trajectory of recovery and functional impairments weeks and months after TBI.

SPORT-RELATED CONCUSSION

Concussion is a frequent injury in contact and collision sports (e.g., football, hockey, wrestling) at all levels of participation, including youth sports. Head injury associated with sport and recreational activity accounts for 45% of TBI-related emergency department visits in children age 17 years and under. Over the last decade, data from the Centers for Disease Control and Prevention indicate a 27% decrease in emergency department visits for sport- and recreation-related TBI in the United States between 2012 and 2018, with a specific decline in contact sport–related visits by 32%. Given that national and state surveillance systems continue to report increased sport-related concussion rates over the same time period, it could be inferred that diagnosis and management of sport-related concussion outside of the emergency department have increased.

The natural history of clinical recovery following sport-related concussion has been a subject of substantial ongoing research. Recent large prospective studies have reinforced earlier indications that the acute recovery is favorable. For example, a longitudinal study of over 34,000 collegiate athletes (1751 who experienced concussion) from 22 institutions found that median time to symptom resolution was 6.4 days and median time for return to sport was 12.8 days. By 1 month after injury, 92% of athletes had experienced resolution of symptoms and 85% had been cleared to return to sport. Across several studies, postinjury symptom burden is the most robust predictor of recovery and risk of prolonged symptoms. Other injury/postinjury factors associated with longer return to sport time were continued play following injury and access to health care providers. Several other prospective studies have replicated that the overwhelming majority of athletes across ages (pediatric to adult) achieve a complete recovery in symptoms, cognitive functioning, postural stability, and other functional impairments over a period of 1–4 weeks following concussion.

There continues to be a growing focus toward a more rapid return to activity and early rehabilitation following injury. Specifically, while experts agree that initial rest after injury is beneficial for recovery, extended inactivity beyond 5 days can be detrimental and increase risk for protracted recovery. Rather, active rehabilitation involving supervised subthreshold exercise has been shown to decrease the duration of symptoms and reduce risk of a protracted recovery. Cervicovestibular rehabilitation has been recently recommended for those who experience neck pain, dizziness, or headaches for >10 days after injury.

Preliminary evidence suggests that earlier return to learn/school is associated with faster injury recovery, and there has been an increased focus on facilitating a faster and optimal return to learn/school through accommodations. This could include, but is not limited to, a shortened schedule or built-in breaks for fatigue, opportunity for a quiet work

environment to prevent headaches or attentional difficulties, and setting expectations for course work to reduce anxiety, among other accommodations. Most patients (>90%) experience a full return to learn without accommodations by 10 days.

There are a small, select percentage of athletes who remain symptomatic or impaired on functional testing well beyond the window of recovery commonly reported in group studies. The greatest challenge arguably still facing sport medicine clinicians and public health experts is how to most effectively manage and reduce risk in this subset of athletes who do not follow the "typical" course of recovery. The precise likelihood that an athlete will not follow the typical course of rapid, spontaneous recovery and instead exhibit prolonged postconcussive symptoms or other functional impairments after concussion remains unclear. In addition to the injury-related or postinjury factors identified above, a preinjury mental health disorder, migraine, and prior concussion have been consistently associated with the potential for prolonged recovery.

Following acute concussion, multimodal advanced neuroimaging has demonstrated a variety of changes, including decreased cerebral blood flow, increased global and local functional connectivity, and alterations in white matter microstructure reflecting axonal organization. In general, these metrics correlate with measures of injury severity, and resolution of these changes tends to parallel clinical recovery. However, a number of studies have shown that slight changes on advanced multimodal imaging can persist even after symptoms have fully resolved, supporting the concept that the "tail" of neurobiologic recovery may extend beyond the time course of apparent clinical recovery.

In the current absence of adequate data, a commonsense approach to athletic concussion has been to remove the individual from play immediately and avoid contact sports for at least several days after a mild injury, and for a longer period if there are more severe injuries or if there are protracted neurologic symptoms such as headache and difficulty concentrating. No individual should return to play unless all concussion-related symptoms have resolved and an assessment has been made by a health care professional who has experience with treatment of concussion. Validated symptom inventories, such as the Rivermead Post-Concussion Symptom Questionnaire **(Table 454-2)**, have been developed to aid clinicians with recording and quantifying the diverse range of physical, cognitive, and behavioral symptoms that can occur following concussion. In addition to characterizing the constellation of acute symptoms and their severity, symptom inventories can be beneficial to track the course and resolution of symptoms through recovery. Differentiating concussion-related symptoms from factors that may be also influencing endorsement (e.g., preinjury mood disorders) is an important component of managing recovery from sport-related concussion. Once cleared, the individual can then begin a graduated program of increasing activity. These guidelines are designed in part to avoid a perpetuation of symptoms but also to prevent the rare *second-impact syndrome*, in which diffuse and fatal cerebral swelling follows a second minor head injury.

TABLE 454-2 Review of Concussion Symptoms

PHYSICAL	COGNITIVE	BEHAVIORAL
Headaches	Forgetfulness or poor memory	Being irritable, easily angered
Dizziness	Poor concentration	Feeling depressed or tearful
Nausea and/or vomiting	Taking longer to think	Feeling frustrated or impatient
Noise sensitivity		Restlessness
Sleep disturbance		
Fatigue		
Blurred vision		
Light sensitivity		
Double vision		

Note: Items were adapted from the Rivermead Post-Concussion Symptom Questionnaire. Each item is rated on a 5-point Likert scale (0–4), as follows: 0 = Not experienced at all; 1 = No more of a problem now than preinjury; 2 = A mild problem; 3 = A moderate problem; 4 = A severe problem. Total scores can range from 0–64.

POSTCONCUSSIVE STATES

There has been a recent paradigm shift from the term *postconcussion syndrome* (PCS) to *persistent postconcussion symptoms* (PPCS) in an effort to avoid classifying prolonged sequelae under a nonspecific diagnostic label and a shifting focus toward identifying and targeting treatment toward direct areas of persistent difficulty. PPCS following mild TBI could include symptoms of fatigue, dizziness, headache, and/or difficulty in concentration. Management is difficult and generally requires identification and management of the specific problem or problems that are most troubling to the individual. A clear explanation and education around the symptoms that may follow concussion have been shown to reduce subsequent complaints. Care is taken to avoid prolonged use of drugs that produce dependence. Headache may initially be treated with acetaminophen and small doses of amitriptyline. Vestibular exercises **(Chap. 24)** and small doses of vestibular suppressants such as promethazine (Phenergan) may be helpful when dizziness is the main problem. After mild or moderate injury, patients who have difficulty with memory or with complex cognitive tasks at work may be reassured to know that these problems usually improve over several months, and a reduced workload or other accommodations may be prescribed in the interim. For select cases, speech and language therapy intervention may be appropriate.

For the vast majority of individuals with mTBI, symptoms of PPCS subside and resolve within a few weeks of injury. For a subset of individuals with mTBI, however, complaints of postconcussion symptoms persist beyond the expectation derived from TBI severity markers. Subtypes of PPCS have been proposed to improve characterization of specific symptoms or types of sequelae following mTBI. These include neurologic, cognitive, behavioral, or somatic complaints that continue beyond the acute and subacute periods, becoming chronic and often operationalized as persisting beyond 3 months. Although the overall risk of experiencing PPCS following mTBI is low, the frequency of mTBI patients who present in a clinical setting is believed to be higher.

mTBI patients with PPCS frequently present to the outpatient clinics of primary care physicians, physiatrists, or neurologists seeking relief for lingering related symptoms. While some patients will have already received an initial medical workup to rule out a more serious brain injury during the acute phase, many patients will have had no prior contact with health care specialists. A medical workup ordered in the outpatient setting for PPCS-related complaints is typically unremarkable for any identifiable neurologic cause to account for the persisting symptoms reported by the patient. The development of uniform decision trees or "standard of care" treatment regimens for PPCS has been limited by the diversity of symptoms that patients experience, even within mTBI subgroups that have sustained very similar injury patterns. While some patients experience somatic symptoms, others complain of subjective cognitive or behavioral changes. Symptom inventories (Table 454-2) can be helpful in documenting the broad range of these symptoms and serve as a metric for improvement following symptom-based treatment.

Active rehabilitation for the treatment of PPCS involving subthreshold exercise has increased in popularity over recent years and has gained empirical support for its effectiveness as a useful intervention for protracted recovery.

PPCS are often influenced by diverse cognitive, emotional, medical, psychosocial, and motivational factors. Because of this complexity, treatments targeting persistent and refractory symptoms should be tailored to the needs and expectations of the individual patient, with referrals to specialists as needed for assistance with management of headache, neck and back pain, dizziness and vertigo, and other persisting symptoms. A comprehensive review of concussion and persisting symptoms, presented in Table 454-2, allows for development of an individualized approach that leverages currently available treatment for those sequelae that are most bothersome to the patient (e.g., vestibular or cervicovestibular rehabilitation therapy for vertigo, melatonin

for sleep disturbance). Patients are frequently referred to behavioral health providers such as neuropsychologists, rehabilitation psychologists, health psychologists, and/or psychiatrists for a variety of reasons, but particularly when they are experiencing persistent cognitive, emotional, or behavioral changes. Patients with mood disorders (e.g., depression), anxiety disorders (e.g., posttraumatic stress disorder), or adjustment reactions may benefit from psychiatric consultation for appropriate medication trials or from time-limited psychotherapy such as cognitive behavioral therapy.

Due to the complexity of presentation and varying diagnostic criteria, there are limited studies regarding overall prognosis of PPCS. However, treatment targeted to the individual's specific persisting difficulties can improve functional outcomes and patient-rated quality of life. Further, collaborative care has been shown to improve outcomes among patients experiencing PPCS. These improved outcomes are likely due to a multidisciplinary team's ability to simultaneously address the diverse set of difficulties that can occur with PPCS.

INJURY OF INTERMEDIATE SEVERITY

Patients who are not fully alert or have persistent confusion, behavioral changes, extreme dizziness, or focal neurologic signs such as hemiparesis should be admitted to the hospital and undergo a cerebral imaging study. A cerebral contusion or hematoma will usually be found. Common syndromes include (1) delirium with a disinclination to be examined or moved, expletive speech, and resistance if disturbed (anterior temporal lobe contusions); (2) a quiet, disinterested, slowed mental state (abulia) alternating with irascibility (inferior frontal and frontopolar contusions); (3) a focal deficit such as aphasia or mild hemiparesis (due to subdural hematoma or convexity contusion or, less often, carotid artery dissection); (4) confusion and inattention, poor performance on simple mental tasks, and fluctuating orientation (associated with several types of injuries, including those described above, and with medial frontal contusions and interhemispheric subdural hematoma); (5) repetitive vomiting, nystagmus, drowsiness, and unsteadiness (labyrinthine concussion, but occasionally due to a posterior fossa subdural hematoma or vertebral artery dissection); and (6) diabetes insipidus (damage to the median eminence or pituitary stalk). Injuries of this degree can be complicated by drug or alcohol intoxication, and clinically inapparent cervical spine injury may be present. Blast injuries are often accompanied by rupture of the tympanic membranes.

After surgical removal of hematomas, patients in this category improve over weeks to months. During the first week, the state of alertness, memory, and other cognitive functions often fluctuate, and agitation and somnolence are common. Behavioral changes tend to be worse at night, as with many other encephalopathies, and may be treated with small doses of antipsychotic medications. Subtle abnormalities of attention, intellect, spontaneity, and memory return toward normal weeks or months after the injury, sometimes abruptly. However, the full extent of recovery may not be realized for several years. Persistent cognitive problems are discussed below.

SEVERE INJURY

Patients who are comatose from the moment of injury require immediate neurologic attention and resuscitation. After intubation, with care taken to immobilize the cervical spine, the depth of coma, pupillary size and reactivity, limb movements, and Babinski responses are assessed. As soon as vital functions permit and cervical spine x-rays and a CT scan have been obtained, the patient should be transported to a critical care unit. Hypoxia should be reversed, and normal saline used as the resuscitation fluid in preference to albumin. The finding of an epidural or subdural hematoma or large intracerebral hemorrhage is usually an indication for prompt surgery and intracranial decompression in an otherwise salvageable patient. Measurement of ICP with a ventricular catheter or fiberoptic device in order to guide treatment has been favored by many units but has not improved outcome. Similarly, induced hypothermia has shown no benefit. Hyperosmolar intravenous solutions are used in various regimens to limit intracranial pressure. Prophylactic antiepileptic medications are recommended for 7 days and should be discontinued unless there are multiple seizures after injury. Management of raised ICP, a frequent feature of severe head injury, is discussed in **Chap. 318**.

Despite the improvement in mortality for severe TBI over the past few decades, a great deal of therapeutic nihilism persists in TBI. The common use of a 6-month outcome for TBI clinical studies reinforces this misconception. The recovery from severe TBI can take years. Furthermore, the ability to predict long-term outcome is limited and frequently incorrect. Best-practice guidelines recommend, in the absence of brain death, that aggressive therapy be instituted for at least 72 h in the acute injury period.

LONG-TERM OUTCOMES IN TBI

Continued follow-up of prospective studies has increased awareness of TBI as a chronic condition with evolving changes and needs over several years after injury. While the majority of individuals remain broadly stable, clinically meaningful improvement and decline across multiple domains (psychiatric, cognitive, and functional outcomes) have been observed from 2 to 7 years after injury, regardless of initial TBI severity. The direction of the changes beyond 1 year after injury can be variable (may decline and improve later, or vice versa). Collectively, this indicates that functional status remains dynamic beyond 1 year after injury, a conventionally considered plateau of recovery. Future investigation is required to better understand which factors are associated with improvement and decline beyond 1 year after injury. Regardless, there is growing awareness that TBI is an evolving condition that requires ongoing monitoring, rehabilitation, and support to address individual patient needs.

Chronic difficulties associated with TBI (characterized above), as opposed to level of risk for Alzheimer's disease and related dementias (ADRD), is an important distinction in determining long-term outcomes of TBI. TBI (aggregated mild to severe) is associated with a 63–96% increased risk of all-cause dementia. The degree of risk for dementia ranges along the gradient of TBI severity (i.e., greatest risk among severe injuries). There is some evidence that repeated mTBI or sport-related concussions may be associated with elevated risk as well. To date, however, investigations have less reliably established mTBI as a robust risk factor for dementia, likely due to methodologic heterogeneity (e.g., use of different diagnostic criteria, exposure misclassification, self-report vs physician diagnoses of TBI or dementia).

Though an identified risk factor for all-cause dementia, pathophysiologic and epidemiologic factors that underlie the association between TBI and risk of specific neurodegenerative pathologies and dementia subtypes are not well understood. As a result, associations between TBI and clinical syndromes (e.g., Alzheimer's disease, Parkinson's disease, amyotrophic lateral sclerosis) or distinct neuropathologies (e.g., beta-amyloid, Lewy bodies, transactive response DNA-binding protein 43) have been inconsistently reported in the literature. In a large study involving clinical and neuropathologic data from three pooled prospective studies of community-based cohorts, a significant relationship was found between TBI with LOC >1 h and subsequent Parkinson's disease diagnosis, progression rate of parkinsonism, and Lewy body accumulation at postmortem examination. Positron emission tomography (PET) studies have allowed for in vivo investigation of neuropathologic deposition and have failed to consistently observe associations between remote TBI (mild through severe) and amyloid or tau deposition.

Among former contact and collision sport athletes, exposure to repetitive head impacts (RHI) involving external blows that do not produce signs and symptoms of mTBI/concussion is common. The brains of these patients with substantial RHI exposure may display a characteristic deposition of tau protein in neurons located in the superficial cortical layers and perivascular regions and particularly in the depths of sulci. This pattern has been defined as the pathognomonic lesion of *chronic traumatic encephalopathy* (CTE). The degree to which this neuropathologic finding is present in nonathlete populations with potential RHI exposure (e.g., former military service members and veterans, victims of intimate partner violence) is uncertain, although the prevalence was found to be low in a large autopsy study of military service members.

A variety of neurodegenerative pathologies are commonly found in the presence of CTE, adding to the complexity of diagnosis. Furthermore, the dynamic interplay between RHI and mTBI history is not well understood. While staging criteria for this neuropathologic entity have yet to be established, a consensus meeting to define the neuropathologic criteria for CTE proposed an algorithm assessing CTE as "low" or "high" in severity. Overall, its contribution, if any, to late-life dementia and parkinsonism in former athletes, soldiers, or others who have sustained repeated concussive injuries is unknown.

Research criteria for the clinical diagnosis of CTE have been proposed. The criteria generally require substantial exposure to RHI, cognitive impairment (primarily in the domains of episodic memory and executive function) and/or neurobehavioral dysregulation, progressive course, and the absence of an alternative explanation for symptoms. Multiple studies have suggested that these proposed criteria lack specificity (i.e., they are frequent in other conditions and non-CTE cases). As such, CTE remains a postmortem diagnosis.

Investigations have not observed robust or consistent in vivo brain-related changes associated with years of contact sport/football exposure (a commonly used proxy measure for RHI) using advanced MRI, PET imaging, or blood-based biomarkers. For example, associations between years of participation and amyloid deposition or white matter hyperintensity volume have not been observed. Studies of brain morphometry (volumetric and structural changes) and tau deposition have been more variable, though evidence suggests that conventionally employed PET tracers and blood biomarkers may be limited in their specificity for CTE p-tau. Impairment of neuropsychological and neuropsychiatric function is most commonly observed in those with polypathology, particularly amyloid. Taken together, further study is required to better refine the clinical and postmortem diagnostic criteria of CTE, enhance clinicopathologic correlation, and ultimately improve patient care and management. **CTE is also discussed in Chap. 435.**

455 Multiple Sclerosis

Bruce A. C. Cree, Stephen L. Hauser

Multiple sclerosis (MS) is an autoimmune disease of the central nervous system (CNS) characterized by chronic inflammation, demyelination, gliosis (plaques or scarring), and neuronal loss; the course can be relapsing or progressive. MS plaques typically develop at different times and in different CNS locations (i.e., MS is said to be disseminated in time and space). One million individuals in the United States, and millions worldwide, are affected. The clinical course is extremely variable, ranging from a relatively benign condition to a rapidly evolving and incapacitating disease requiring profound lifestyle adjustments. The past decade has seen tremendous progress in understanding basic disease mechanisms underlying MS and in developing highly effective therapies especially for the relapsing form of the disease. These advances have dramatically improved the long-term outcome for patients.

CLINICAL MANIFESTATIONS

Onset is typically between 20 and 40 years (slightly later in men than in women), but the disease can present across the lifespan. Women are affected approximately three times more often than men. Early symptoms may be severe or seem so trivial that a patient may not seek medical attention for months or years. On occasion, MS lesions are located exclusively in noneloquent regions of the nervous system, and in such instances, clinical manifestations can be largely or entirely absent. Autopsy series identified MS in some individuals (~0.1% of cases) who were seemingly asymptomatic during life, and magnetic resonance imaging (MRI) scans obtained for unrelated reasons also showed evidence of asymptomatic MS, an incidental finding termed a *radiologically isolated syndrome* (RIS; see below).

Specific symptoms of MS are varied and reflect the location and severity of lesions within the CNS **(Table 455-1)**. Moreover, neurologic examination often reveals unexpected findings in addition to the anticipated ones. For example, a patient may present with symptoms in one leg but signs in both.

Sensory symptoms include both paresthesias (e.g., tingling, prickling sensations, "pins and needles," formications, or painful burning) and hypesthesia (e.g., reduced sensation, numbness, or a "dead" feeling). Unpleasant sensations (e.g., feelings that body parts are swollen, wet, raw, or tightly wrapped) are also common. Sensory impairment of the trunk and legs below a horizontal line on the torso (a sensory level) indicates that the spinal cord is the site of the disturbance. It is often accompanied by a bandlike sensation of tightness around the torso. Pain is a common symptom of MS, experienced by >50% of patients. Pain can occur anywhere on the body and can change locations over time.

Optic neuritis (ON) presents as diminished visual acuity, dimness, or decreased color perception (desaturation) in the central field of vision. These symptoms can be mild or may progress to severe visual loss. Rarely, there is complete loss of light perception. Visual symptoms are generally monocular but may be bilateral. Periorbital pain (aggravated by eye movement) typically precedes or accompanies the visual loss. An afferent pupillary defect **(Chap. 34)** is usually present. Fundoscopic examination may be normal or reveal optic disc swelling (papillitis). Pallor of the optic disc (optic atrophy) commonly follows ON. Uveitis is uncommon and should raise the possibility of alternative diagnoses such as sarcoidosis or lymphoma.

TABLE 455-1 Initial Symptoms of Multiple Sclerosis (MS)

SYMPTOM	PERCENTAGE OF CASES	SYMPTOM	PERCENTAGE OF CASES
Sensory loss	37	Lhermitte	3
Optic neuritis	36	Pain	3
Weakness	35	Dementia	2
Paresthesias	24	Visual loss	2
Diplopia	15	Facial palsy	1
Ataxia	11	Impotence	1
Vertigo	6	Myokymia	1
Paroxysmal attacks	4	Epilepsy	1
Bladder	4	Falling	1

Source: Data from RJ Swingler, DA Compston: The morbidity of multiple sclerosis. Q J Med 83:325, 1992.

Weakness of the limbs can manifest as loss of strength, speed, or dexterity; as fatigue; or as a disturbance of gait. Exercise-induced weakness is a characteristic symptom of MS. The weakness is of the upper motor neuron type **(Chap. 26)** and is usually accompanied by other pyramidal signs such as spasticity, hyperreflexia, and extensor plantar responses. Occasionally, a tendon reflex may be lost (simulating a peripheral nerve lesion) if an MS lesion disrupts the afferent reflex fibers in the spinal cord **(see Fig. 26-2)**.

Facial weakness due to a lesion in the pons may resemble idiopathic Bell's palsy **(Chap. 452)**. Unlike Bell's palsy, facial weakness in MS is usually not associated with ipsilateral loss of taste sensation or retroauricular pain.

Spasticity **(Chap. 26)** is commonly associated with spontaneous and movement-induced muscle spasms, especially in the legs. This can be accompanied by painful spasms interfering with ambulation, work, or self-care. Occasionally, spasticity provides support for the body weight during ambulation, and in these cases, treatment of spasticity may actually do more harm than good.

Visual blurring in MS may result from ON or diplopia (double vision); if the symptom resolves when either eye is covered, the cause is diplopia. *Diplopia* may be caused by internuclear ophthalmoplegia (INO) or palsy of the sixth cranial nerve (rarely the third or fourth). An INO consists of impaired adduction of one eye due to a lesion in the ipsilateral medial longitudinal fasciculus **(Chaps. 34 and V3)**. Prominent nystagmus is often observed in the abducting eye, along with a small skew deviation. A bilateral INO is particularly suggestive of MS. Other common gaze disturbances in MS include (1) a horizontal gaze palsy, (2) a "one and a half" syndrome (horizontal gaze palsy plus an INO), and (3) acquired pendular nystagmus.

Ataxia usually manifests as cerebellar tremors **(Chap. 450)**. Ataxia may also involve the head and trunk or the voice, producing a characteristic cerebellar dysarthria (scanning speech).

Vertigo may appear suddenly from a brainstem lesion, superficially resembling acute labyrinthitis **(Chap. 24)**. *Hearing loss* **(Chap. 36)** may also occur in MS but is uncommon.

ANCILLARY SYMPTOMS

Paroxysmal symptoms are distinguished by their brief duration (10 s to 2 min), high frequency (5–40 episodes per day), lack of any alteration of consciousness or change in background electroencephalogram during episodes, and a self-limited course (generally lasting weeks to months). They may be precipitated by hyperventilation or movement. Manifestations can include Lhermitte's symptom; tonic contractions of a limb, face, or trunk (tonic seizures); paroxysmal dysarthria and ataxia; paroxysmal sensory disturbances; and several other less well-characterized syndromes. Paroxysmal symptoms probably result from spontaneous discharges arising at the edges of demyelinated plaques and spreading to adjacent white matter tracts.

Lhermitte's symptom is an electric shock–like sensation (typically induced by flexion or other movements of the neck) that radiates down the back into the legs. Rarely, it radiates into the arms. It is generally self-limited but may persist for years. Lhermitte's symptom can also occur with other disorders of the cervical spinal cord (e.g., cervical spondylosis).

Trigeminal neuralgia, hemifacial spasm, and glossopharyngeal neuralgia **(Chap. 452)** can occur when the demyelinating lesion involves the root entry (or exit) zone of the fifth, seventh, and ninth cranial nerve, respectively. Trigeminal neuralgia (tic douloureux) is a very brief lancinating facial pain often triggered by an afferent input from the face or teeth. Most cases of trigeminal neuralgia are not MS related; however, atypical features such as onset before age 50 years, bilateral symptoms, objective sensory loss, or nonparoxysmal pain should raise the possibility that MS could be responsible.

Facial myokymia consists of either persistent rapid flickering contractions of the facial musculature (especially the lower portion of the orbicularis oculus) or a contraction that slowly spreads across the face. It results from lesions of the corticobulbar tracts or brainstem course of the facial nerve.

Heat sensitivity refers to neurologic symptoms produced by an elevation of the body's core temperature. For example, unilateral visual blurring may occur during a hot shower or with physical exercise (*Uhthoff's symptom*). It is also common for MS symptoms to worsen transiently, sometimes dramatically, during febrile illnesses. Such heat-related symptoms probably result from transient conduction block.

Bladder dysfunction is ultimately present in most MS patients. During normal reflex voiding, relaxation of the bladder sphincter (α-adrenergic innervation) is coordinated with contraction of the detrusor muscle in the bladder wall (muscarinic cholinergic innervation). *Detrusor hyperreflexia*, due to impairment of suprasegmental inhibition, causes urinary frequency, urgency, nocturia, and uncontrolled bladder emptying. *Detrusor sphincter dyssynergia*, due to loss of synchronization between detrusor and sphincter muscles, causes difficulty in initiating and/or stopping the urinary stream, producing hesitancy, urinary retention, overflow incontinence, and recurrent infection.

Constipation occurs in some patients, especially with advanced disease. Fecal urgency or *bowel incontinence* is less common than urinary symptoms but can be socially debilitating.

Sexual dysfunction may manifest as decreased libido, impaired genital sensation, impotence in men, and diminished vaginal lubrication or adductor spasms in women.

Cognitive dysfunction is often mild when present, but can include memory loss; impaired attention; difficulties in executive functioning, memory, and problem solving; slowed information processing; and problems shifting between cognitive tasks. Euphoria (elevated mood) or emotional lability (pseudobulbar palsy) was once thought to be characteristic of MS but is actually relatively uncommon. Cognitive dysfunction sufficient to impair activities of daily living is rare.

Depression, experienced by approximately half of patients, can be reactive, endogenous, or part of the illness itself and can contribute to fatigue.

Fatigue **(Chap. 25)** is experienced by most MS patients and is the most common reason for work-related disability in MS. Fatigue can be exacerbated by elevated temperatures, depression, expending exceptional effort to accomplish basic activities of daily living, or sleep disturbances (e.g., from frequent nocturnal awakenings to urinate).

DISEASE COURSE

In the traditional model of MS, the disease was considered to have three principal clinical forms, designated relapsing-remitting, secondary progressive, and primary progressive. Relapses were thought to be caused by inflammation, while progression was the consequence of neurodegeneration. More recently, these categories were supplanted by a unitary view of the disease, in which inflammation and neurodegeneration are present in most patients throughout the disease course. The concept that all MS is a single disease is also supported by findings from genetics, epidemiology, immunology, and pathology. Nonetheless, from a clinical perspective, it is still often useful to apply the classical subtype scheme to assessment and management of patients.

1. *Relapsing-remitting or bout onset MS* (RRMS) accounts for 90% of MS cases and is characterized by discrete attacks of neurologic dysfunction that generally evolve over days to weeks (rarely over hours). In early MS, there is often substantial or complete recovery over the ensuing weeks to months. However, as attacks continue, recovery may be less evident. Between attacks, patients were earlier thought to be neurologically stable; however, it is now clear that most if not all patients with RRMS experience subtle "silent" progression even when relapse-free **(Fig. 455-1)**. The category *relapsing MS* (RMS) is used to identify all relapsing patients, both RRMS as well as secondary progressive patients who continue to experience attacks.
2. *Secondary progressive MS* (SPMS) always begins as RRMS. At some point, however, the clinical course changes so that the patient experiences progressive deterioration in function unassociated with acute attacks. SPMS produces a greater amount of fixed neurologic disability than RRMS. A practical definition for SPMS is a patient who has developed some level of permanent walking disability not due exclusively to relapses. The Extended Disability Status Score (EDSS) is a widely used measure of neurologic impairment in MS

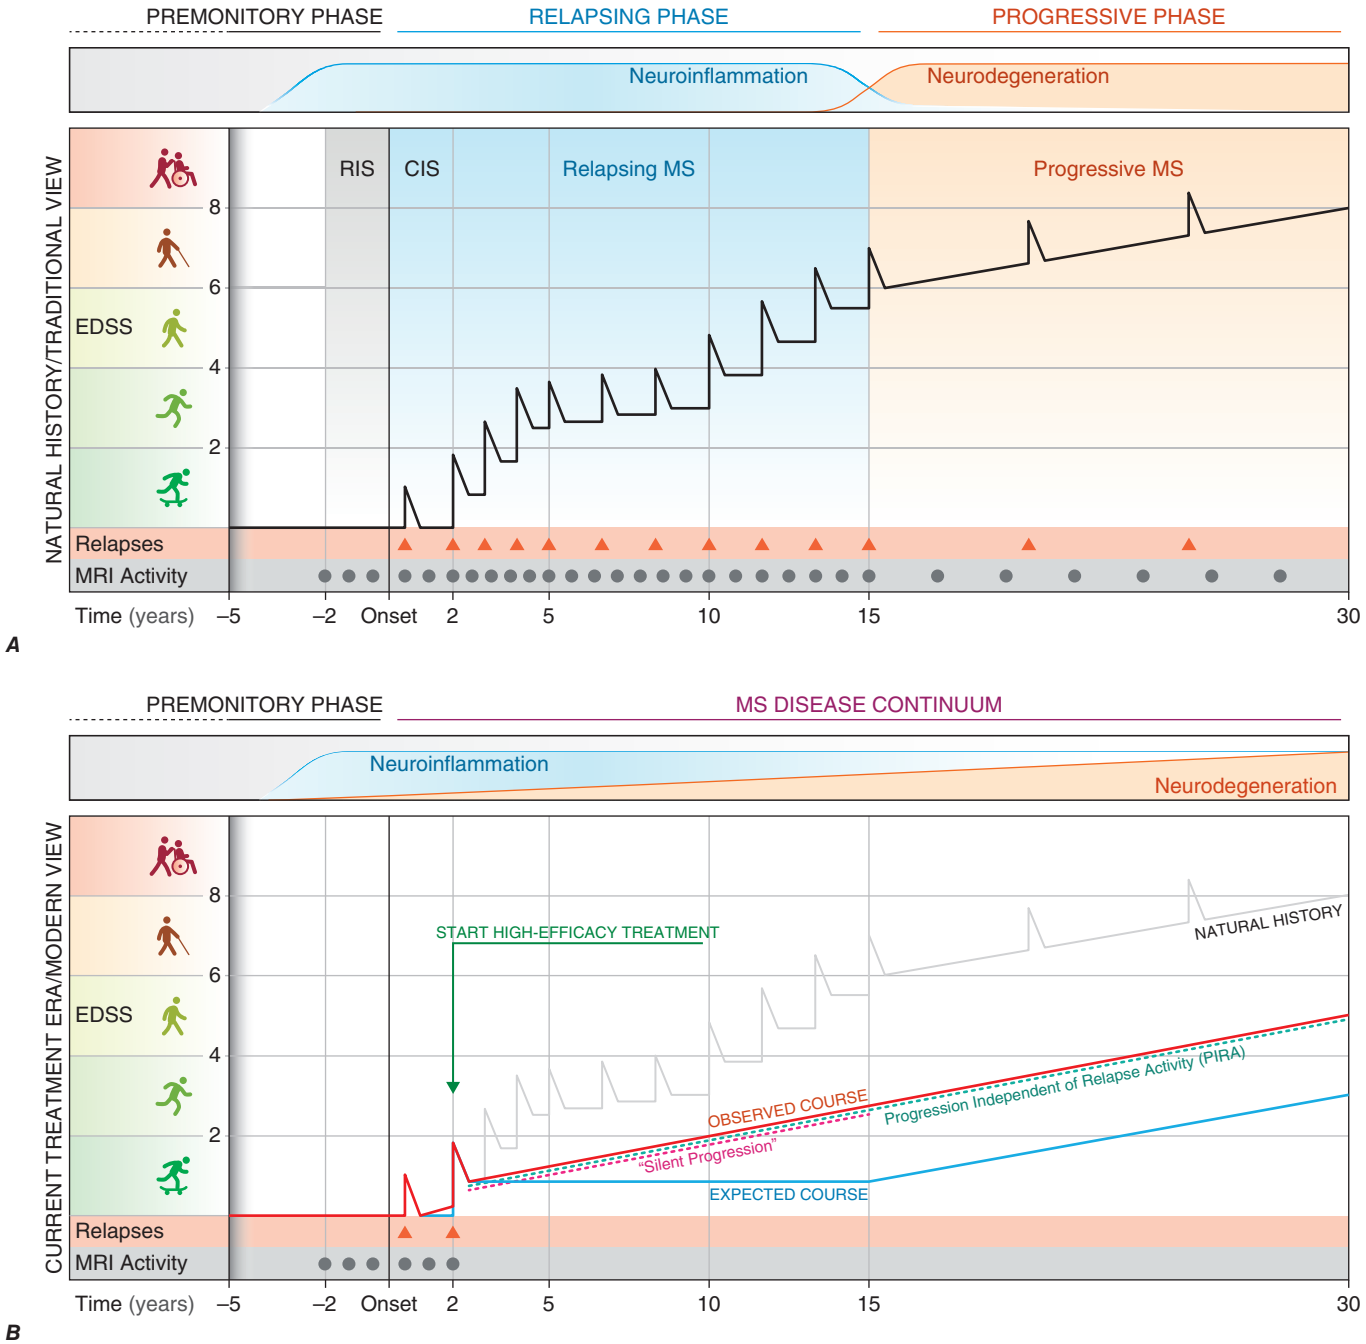

FIGURE 455-1 The clinical course of multiple sclerosis (MS) in the current treatment era. The top half of the figure illustrates the traditional view of the natural history of relapse-onset MS in the pretreatment era. During the relapsing phase, disability accumulation was thought to result from incomplete recovery from relapses, until relapse-independent disability, designated SPMS, supervened. In the bottom half of the figure, the "new" natural history of MS in the current treatment era is shown. With use of highly effective therapies, attacks are abolished in most patients, but insidious progression independent of relapse activity, termed "silent progression," is now evident during the relapsing phase. CIS, clinically isolated syndrome; EDSS, Extended Disability Status Score; MRI, magnetic resonance imaging; RIS, radiologically isolated syndrome; SPMS, secondary progressive multiple sclerosis.

(Table 455-2); an EDSS of 4 or greater, plus a Functional Status Scale (FSS) motor system score of 2 or greater, can support a diagnosis of SPMS. For a patient with RRMS, in the pretreatment era, the risk of developing SPMS was ~3% each year, meaning that the great majority of RRMS would ultimately evolve into SPMS. However, more recent case series have indicated a much lower rate of evolution to SPMS, estimated at <1% each year, likely due to widespread use of increasingly effective therapies for MS.

3. *Primary progressive MS* (PPMS) accounts for ~10% of cases. These patients do not experience attacks but rather steadily decline in function from disease onset. Compared to RRMS, the sex distribution is more even, the disease begins later in life (mean age ~40 years), and disability develops faster relative to the onset of the first clinical symptom. As noted above, despite these differences PPMS appears to represent the same underlying illness as RRMS and SPMS, and some PPMS patients experience relapses over the course of their illness. The term *active progressive MS* is used to categorize progressive MS patients (both SPMS and PPMS) who experience relapses or are found to have new lesions on serial MRI scans.

Disability in MS is thought to accumulate as either a consequence of limited recovery following an acute relapse, a process also known as *relapse associated worsening* (RAW), or from presumed underlying neurodegeneration in the absence of clinical relapse, a process termed *progression independent of relapsing activity* (PIRA). Although RAW was once thought to be the primary driver of disability accumulation in RRMS, it is now clear that PIRA is the cause of disability accumulation in RRMS, SPMS, and PPMS. That PIRA events can occur "silently,"

TABLE 455-2 Scoring Systems for Multiple Sclerosis (MS)

Expanded Disability Status Scale (EDSS)

0.0 = Normal neurologic examination (all grade 0 in functional status [FS])
1.0 = No disability, minimal signs in one FS (i.e., grade 1)
1.5 = No disability, minimal signs in more than one FS (more than one grade 1)
2.0 = Minimal disability in one FS (one FS grade 2, others 0 or 1)
2.5 = Minimal disability in two FS (two FS grade 2, others 0 or 1)
3.0 = Moderate disability in one FS (one FS grade 3, others 0 or 1) or mild disability in three or four FS (three/four FS grade 2, others 0 or 1) although fully ambulatory
3.5 = Fully ambulatory but with moderate disability in one FS (one grade 3) and one or two FS grade 2; or two FS grade 3; or five FS grade 2 (others 0 or 1)
4.0 = Ambulatory without aid or rest for ~500 m
4.5 = Ambulatory without aid or rest for ~300 m
5.0 = Ambulatory without aid or rest for ~200 m
5.5 = Ambulatory without aid or rest for ~100 m
6.0 = Unilateral assistance required to walk about 100 m with or without resting
6.5 = Constant bilateral assistance required to walk about 20 m without resting
7.0 = Unable to walk beyond about 5 m even with aid; essentially restricted to wheelchair; wheels self and transfers alone
7.5 = Unable to take more than a few steps; restricted to wheelchair; may need aid to transfer
8.0 = Essentially restricted to bed or chair or perambulated in wheelchair, but out of bed most of day; retains many self-care functions; generally has effective use of arms
8.5 = Essentially restricted to bed much of the day; has some effective use of arm(s); retains some self-care functions
9.0 = Helpless bed patient; can communicate and eat
9.5 = Totally helpless bed patient; unable to communicate or eat
10.0 = Death due to MS

Functional Status (FS) Score

A. Pyramidal functions
0 = Normal
1 = Abnormal signs without disability
2 = Minimal disability
3 = Mild or moderate paraparesis or hemiparesis, or severe monoparesis
4 = Marked paraparesis or hemiparesis, moderate quadriparesis, or monoplegia
5 = Paraplegia, hemiplegia, or marked quadriparesis
6 = Quadriplegia

B. Cerebellar functions
0 = Normal
1 = Abnormal signs without disability
2 = Mild ataxia
3 = Moderate truncal or limb ataxia
4 = Severe ataxia all limbs
5 = Unable to perform coordinated movements due to ataxia

C. Brainstem functions
0 = Normal
1 = Signs only
2 = Moderate nystagmus or other mild disability
3 = Severe nystagmus, marked extraocular weakness, or moderate disability of other cranial nerves
4 = Marked dysarthria or other marked disability
5 = Inability to swallow or speak

D. Sensory functions
0 = Normal
1 = Vibration or figure-writing decrease only, in 1 or 2 limbs
2 = Mild decrease in touch or pain or position sense, and/or moderate decrease in vibration in 1 or 2 limbs, or vibratory decrease alone in 3 or 4 limbs
3 = Moderate decrease in touch or pain or position sense, and/or essentially lost vibration in 1 or 2 limbs, or mild decrease in touch or pain, and/or moderate decrease in all proprioceptive tests in 3 or 4 limbs
4 = Marked decrease in touch or pain or loss of proprioception, alone or combined, in 1 or 2 limbs or moderate decrease in touch or pain and/or severe proprioceptive decrease in >2 limbs
5 = Loss (essentially) of sensation in 1 or 2 limbs or moderate decrease in touch or pain and/or loss of proprioception for most of the body below the head
6 = Sensation essentially lost below the head

E. Bowel and bladder functions
0 = Normal
1 = Mild urinary hesitancy, urgency, or retention
2 = Moderate hesitancy, urgency, retention of bowel or bladder, or rare urinary incontinence
3 = Frequent urinary incontinence
4 = In need of almost constant catheterization
5 = Loss of bladder function
6 = Loss of bowel and bladder function

F. Visual (or optic) functions
0 = Normal
1 = Scotoma with visual acuity (corrected) better than 20/30
2 = Worse eye with scotoma with maximal visual acuity (corrected) of 20/30 to 20/59
3 = Worse eye with large scotoma, or moderate decrease in fields, but with maximal visual acuity (corrected) of 20/60 to 20/99
4 = Worse eye with marked decrease of fields and maximal acuity (corrected) of 20/100 to 20/200; grade 3 plus maximal acuity of better eye of 20/60 or less
5 = Worse eye with maximal visual acuity (corrected) <20/200; grade 4 plus maximal acuity of better eye of ≤20/60
6 = Grade 5 plus maximal visual acuity of better eye of ≤20/60

G. Cerebral (or mental) functions
0 = Normal
1 = Mood alteration only (does not affect EDSS score)
2 = Mild decrease in mentation
3 = Moderate decrease in mentation
4 = Marked decrease in mentation
5 = Chronic brain syndrome—severe or incompetent

Source: Adapted from JF Kurtzke: Rating neurologic impairment in multiple sclerosis: An expanded disability status scale (EDSS). Neurology 33:1444, 1983.

meaning so insidiously that neither the patient nor the provider recognizes their occurrence at the time of gradual worsening, raises the important question as to whether there is a meaningful distinction between RRMS and SPMS. If any confirmed PIRA event is considered to be indicative of SPMS, then the SPMS onset begins much earlier in the disease course when patients still experience relapses but have only accumulated relative minor disability.

EPIDEMIOLOGY

Geographic gradients are consistently observed in MS, with the highest prevalence generally found in temperate zones; in tropical regions, the prevalence is often 10-fold to 20-fold less. In addition, a north-south gradient was observed in numerous national and regional studies, with decreasing rates as one moves equatorially.

The prevalence of MS also increased steadily in several regions around the world over the past half-century, presumably reflecting the impact of some environmental shift, improved diagnosis, and/or a longer lifespan. Moreover, this increase appears to have occurred to a greater degree in women than men and in nonwhite populations. In the United States, there is a slightly higher prevalence in white compared with black individuals, with lower estimates in Hispanics, followed by Asians.

Multiple lines of evidence incriminate a role for infection with the Epstein-Barr virus (EBV) in MS. Individuals who have never been EBV infected (~5% of the population globally) have a very low MS risk, ~20-fold lower than in EBV-positive individuals, and a history of infectious mononucleosis (associated with initial exposure to EBV during adolescence or later in life) increases risk more than twofold higher yet. Higher antibody titers to EBV nuclear antigens were repeatedly associated with MS risk, and studies from longitudinal biobank collections showed that serologic conversion to EBV is a near-universal prerequisite for development of MS. Following primary EBV infection, a lifelong infection is established in most individuals, with latent EBV exclusively present in very small numbers (~$1:10^{-6}$) of B lymphocytes. EBV-infected B cells were not consistently identified in the nervous system of MS patients. It is possible that ongoing lytic cycles by very few infected B cells residing within the CNS could produce bursts of inflammation and MS lesions; however, it is more likely that pathology could be triggered by B cell–mediated antigen presentation of EBV peptides that cross-react with MS autoantigens via molecular mimicry (see "Immunology," below).

A history of cigarette smoking is also associated with MS risk. Interestingly, in an animal model of MS, the lung was identified as a critical site for activation of pathogenic T lymphocytes responsible for autoimmune demyelination.

Finally, vitamin D deficiency has been repeatedly associated with MS. Immunoregulatory effects of vitamin D could explain these apparent relationships. Exposure of the skin to ultraviolet B (UVB) radiation from the sun is essential for the biosynthesis of vitamin D, and this endogenous production is the most important source of vitamin D in most individuals. A diet rich in fatty fish represents another source of vitamin D. At higher latitudes, the amount of UVB radiation reaching the earth's surface is often insufficient, particularly during winter months, and consequently, low serum levels of vitamin D are frequent in temperate zones. The common practice to avoid direct sun exposure and the widespread use of sunblock would be expected to exacerbate any population-wide vitamin D deficiency.

GENETIC CONSIDERATIONS

MS aggregates within some families, and adoption, half-sibling, twin, and spousal studies indicate that familial aggregation is primarily due to genetic factors. Importantly, family studies also support a contribution of environment, as fraternal twins of MS patients are at higher risk than nontwin siblings **(Table 455-3)**.

Susceptibility to MS is polygenic, with each gene contributing a relatively small amount to overall risk. The strongest susceptibility signal genome-wide maps to the human leukocyte antigen (HLA)-DRB1 gene in the class II region of the major histocompatibility complex (MHC) and specifically to HLA-DRB1*1501 (formerly designated DR2), and this association accounts for ~10% of the disease risk. This HLA association, first described in the early 1970s, suggests that MS, at its core, is an autoimmune disease. Whole-genome association studies have identified >230 other MS susceptibility variants, each of which individually has only a very small effect on MS risk. Many of these MS-associated genes have known roles in the adaptive and innate immune system, for example, the genes for the interleukin (IL) 7 receptor (CD127), IL-2 receptor (CD25), and T-cell costimulatory molecule LFA-3 (CD58); some variants also influence susceptibility to other autoimmune diseases in addition to MS. The variants identified so far all lack specificity and sensitivity for MS; thus, at present, they are not useful for diagnosis and have no meaningful effect on the clinical course of MS once it begins. For many years, identification of genes that influence disease expression was elusive, but recently, the first loci for MS severity were identified; unlike risk genes, these variants appear to operate in the nervous system rather than immune system, and one signal reaching genome-wide significance, located in the region of dysferlin and a zinc finger gene (ZNF638), confers a 7-year acceleration of progression to wheelchair-dependent status.

TABLE 455-3 Risk of Developing Multiple Sclerosis (MS)

1 in 3	If an identical twin has MS
1 in 15	If a fraternal twin has MS
1 in 25	If a sibling has MS
1 in 50	If a parent or half-sibling has MS
1 in 100	If a first cousin has MS
1 in 1000	If a spouse has MS
1 in 1000	If no one in the family has MS

PATHOGENESIS

PATHOLOGY

Demyelination New MS lesions begin with perivenular cuffing by inflammatory mononuclear cells, predominantly T cells and macrophages, which also infiltrate the surrounding white matter. At sites of inflammation, the blood-brain barrier (BBB) is disrupted, but unlike vasculitis, the vessel wall is preserved. At the leading edge of lesions, cytotoxic CD8 cells are found. Involvement of the humoral immune system is also evident; B lymphocytes infiltrate the nervous system, myelin-specific autoantibodies are present on degenerating myelin sheaths, and complement is activated.

Sharply demarcated areas of demyelination are the pathologic hallmark of MS lesions, and evidence of myelin degeneration is found at the earliest time points of tissue injury. Although relative sparing of axons is typical, partial or total axonal destruction can also occur, especially within highly inflammatory lesions. In some lesions, surviving oligodendrocytes or those that differentiate from precursor cells partially remyelinate the surviving axons, producing so-called *shadow plaques*. However, in many lesions, oligodendrocyte precursor cells are present but fail to differentiate into mature myelin-producing cells. Therefore, promoting remyelination to protect axons remains an important therapeutic goal. As lesions evolve, there is prominent astrocytic proliferation (gliosis), and the term *sclerosis* refers to these gliotic plaques that have a rubbery or hardened texture at autopsy.

Neurodegeneration Cumulative axonal and neuronal loss is the most important contributor to irreversible neurologic disability and progressive symptoms. With paraplegia due to MS, as many as 70% of axons are ultimately lost from the lateral corticospinal (e.g., motor) tracts. Demyelination can reduce trophic support for axons, redistribute ion channels, and destabilize action potential membrane potentials. Axons can adapt initially to these injuries, but over time, distal and retrograde degeneration ("dying-back" axonopathy) occurs.

Multiple pathologies appear to contribute to progressive symptoms. *Chronic active plaques* are preexisting white matter lesions that show evidence of persistent inflammation, progressive axonal loss, and gradual concentric expansion, with large numbers of microglial cells at the leading edge of enlarging lesions without BBB disruption. Also important is a primary injury to the cerebral cortex. Cortical plaques are frequent in MS but are generally not well visualized by MRI; these can extend upward from adjacent white matter lesions or may be located entirely within the cortex or underneath the pia. *Ectopic lymphoid follicles* are aggregates of B, T, and plasma cells located in the superficial meninges, especially overlying deep cortical sulci; similar clusters are also present in perivascular spaces. Ectopic lymphoid follicles are associated with underlying demyelination and neuronal loss in the cerebral cortex, and diffusible factors from these lymphoid cells appear to mediate subpial cortical demyelination and neurodegeneration. Cux2-positive neurons in layer 2 and 3 of the neocortex appear to be particularly vulnerable. Neuronal and axonal death may result from glutamate-mediated excitotoxicity, oxidative injury, iron accumulation, and/or mitochondrial failure.

In relapsing MS, inflammation is characterized by focal perivenular infiltration of lymphocytes and monocytes, BBB disruption, and active demyelination. By contrast, inflammation in progressive MS is more diffuse, with widespread microglial proliferation across large areas of white matter, accompanied by infiltration of CD8 T cells and plasmablasts/plasma cells. Reduced myelin staining and axonal injury ("dirty

white matter") are associated with these chronic pathologies. Astrogliosis has long been known to be a prominent feature of MS pathology, and activated astrocytes likely contribute directly to neuronal and myelin injury (Chap. 435). Ongoing inflammation occurs behind an intact BBB in many patients with progressive MS, possibly accounting for the failure of immunotherapies not capable of crossing the BBB to benefit patients with progressive MS.

IMMUNOLOGY

An autoimmune response directed against components of CNS myelin, and perhaps other neural elements as well, remains the cornerstone of current concepts of MS pathogenesis. However, specific antigenic targets in MS have never been conclusively identified.

B Lymphocytes and Antibodies B cells are centrally involved in the development of demyelinating lesions, as evidenced by the efficacy of B cell–based treatments in all forms of MS (see "Treatment" below). Clonally restricted populations of activated, antigen-experienced, memory B cells and plasma cells are present in MS lesions, in meningeal lymphoid follicle-like structures overlying the cerebral cortex, and in cerebrospinal fluid (CSF). They produce the oligoclonal immunoglobulins and increased antibody synthesis rates in the CSF long useful in the diagnosis of MS. Myelin-specific autoantibodies, some directed against an extracellular myelin protein, myelin oligodendrocyte glycoprotein (MOG), have been detected bound to degenerating myelin in MS plaques. However, many more antibodies derived from these B cells appear to be directed against a diverse array of ubiquitous intracellular proteins seemingly unrelated to MS pathogenesis. Furthermore, the specific targets are different in each patient. Therefore, although these highly restricted CNS antibodies are characteristic of MS, their role in disease remains uncertain.

More likely, the antigen-presenting cell (APC) function of B cells explains their role in MS pathogenesis. Fragments of self-peptides derived from HLA-DR2 proteins themselves were found to bind intact DRB1*1501 molecules on B cells and serve as antigens for presentation to T cells. Memory CD4+ T cells derived from CSF responded to these self-peptides bound to DR2 molecules, and in some cases, these self-peptides were cross-reactive with several myelin antigens, as well as proteins derived from EBV, *Akkermansia muciniphila* (a commensal gut bacterium associated with dysbiosis in MS patients), and RAS guanyl-releasing protein 2 (RASGRP2), previously found to be a possible T-cell autoantigen in MS. Thus, MS-associated HLA proteins contain fragments that might trigger autoimmunity through molecular mimicry with viral, bacterial, or normal host antigens.

Autoreactive T Lymphocytes Autoreactive T cells may be triggered and sustained via B-cell antigen presentation. Myelin basic protein (MBP), an intracellular protein involved in myelin compaction, is an important T-cell antigen in experimental allergic encephalomyelitis (EAE), a laboratory model for MS. Activated MBP-reactive T cells have been identified in the blood, in CSF, and within MS lesions. The MS-associated HLA-DRB1*1501 protein binds with high affinity to a fragment of MBP (spanning amino acids 89–96), potentially stimulating T-cell responses to this self-protein. Several different populations of proinflammatory T cells are likely to mediate autoimmunity in MS. T-helper type 1 (T_H1) cells producing interferon γ (IFN-γ) are one key effector population; T_H1 cytokines, including IL-2, tumor necrosis factor (TNF)-α, and IFN-γ, play key roles in activating and maintaining autoimmune responses, and TNF-α and IFN-γ may directly injure oligodendrocytes or the myelin membrane. B cells from MS patients are also known to be high producers of TNF-α. As noted above, CD8 cytotoxic T cells are present at the active edges of expanding MS lesions, and activated CD8 cells also appear to be enriched for reactivity against myelin antigens in MS patients.

Microglial Activation Widespread microglial activation is a hallmark of progressive MS pathology. Activated microglia are found in cortical plaques in the absence of macrophage and leukocyte infiltrates. Some cortical plaques are found adjacent to sites of meningeal inflammation in which tertiary lymphoid follicles are found. As discussed above, these meningeal lymphoid structures are a hallmark of MS pathology. Microglial activation in MS is thought to be triggered by proinflammatory B and T lymphocytes or in response to tissue injury signals via toll-like receptor signaling. Although once thought to exist in either proinflammatory or anti-inflammatory states, microglia are now understood to have varied and context-dependent transcriptional states.

PHYSIOLOGY

Nerve conduction in myelinated axons occurs in a saltatory manner, with the nerve impulse jumping from one node of Ranvier to the next without depolarization of the axonal membrane underlying the myelin sheath between nodes (Fig. 455-2*A*). This produces faster conduction velocities (~70 m/s) than the slow velocities (~1 m/s) produced by continuous propagation in unmyelinated nerves. Conduction block occurs when the nerve impulse is unable to traverse the demyelinated segment. This can happen when the resting axon membrane becomes hyperpolarized due to exposure of voltage-dependent potassium channels that are normally buried underneath the myelin sheath. A temporary conduction block often follows a demyelinating event before sodium channels (originally concentrated at the nodes) redistribute along the naked axon (Fig. 455-2*B*). This redistribution ultimately allows continuous propagation of nerve action potentials through the demyelinated segment. Conduction block may be incomplete, affecting high- but not low-frequency volleys of impulses. Variable conduction block can also occur with raised body temperature or metabolic alterations. These factors may explain clinical fluctuations that vary from hour to hour or appear with fever or exercise. Conduction slowing occurs when the demyelinated segments of the axonal membrane are reorganized to support continuous (slow) nerve impulse propagation.

DIAGNOSIS

There is no single diagnostic test for MS. Diagnostic criteria for clinically definite MS require two or more episodes of symptoms and two or more signs that reflect pathology in anatomically noncontiguous white matter tracts of the CNS (Table 455-4). Symptoms must last for >24 h and occur as distinct episodes separated by a month or more. In patients who have only one of the two required signs on neurologic examination, the second may be documented by abnormal tests such as MRI or evoked potentials (EPs). Similarly, in the most recent diagnostic scheme, the second clinical event (in time) may be supported solely by MRI findings, consisting of either the development of new focal white matter lesions on MRI or the simultaneous presence of both an enhancing lesion and a nonenhancing lesion in an asymptomatic location. In patients whose course is progressive from onset for ≥6 months

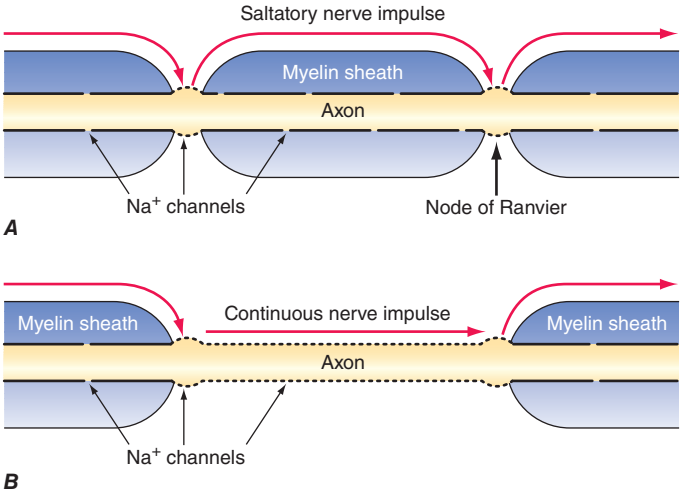

FIGURE 455-2 Nerve conduction in myelinated and demyelinated axons. ***A.*** Saltatory nerve conduction in myelinated axons occurs with the nerve impulse jumping from one node of Ranvier to the next. Sodium channels (*shown as breaks in the solid black line*) are concentrated at the nodes where axonal depolarization occurs. ***B.*** Following demyelination, additional sodium channels are redistributed along the axon itself, thereby allowing continuous propagation of the nerve action potential despite the absence of myelin.

TABLE 455-4 Diagnostic Criteria for Multiple Sclerosis (MS)

CLINICAL PRESENTATION	ADDITIONAL DATA NEEDED FOR MS DIAGNOSIS
2 or more attacks; objective clinical evidence of 2 or more lesions or objective clinical evidence of 1 lesion with reasonable historical evidence of a prior attack	None
2 or more attacks; objective clinical evidence of 1 lesion	Dissemination in space, demonstrated by ≥1 T2 lesion on MRI in at least 2 out of 4 MS-typical regions of the CNS (periventricular, juxtacortical, infratentorial, or spinal cord) OR • Await a further clinical attack implicating a different CNS site
1 attack; objective clinical evidence of 2 or more lesions	Dissemination in time, demonstrated by • Simultaneous presence of asymptomatic gadolinium-enhancing and nonenhancing lesions at any time OR • A new T2 and/or gadolinium-enhancing lesion(s) on follow-up MRI, irrespective of its timing with reference to a baseline scan OR • Await a second clinical attack
1 attack; objective clinical evidence of 1 lesion (clinically isolated syndrome)	Dissemination in space and time, demonstrated by: For dissemination in space • ≥1 T2 lesion in at least 2 out of 4 MS-typical regions of the CNS (periventricular, juxtacortical, infratentorial, or spinal cord) OR • Await a second clinical attack implicating a different CNS site AND • For dissemination in time • Simultaneous presence of asymptomatic gadolinium-enhancing and nonenhancing lesions at any time OR • A new T2 and/or gadolinium-enhancing lesion(s) on follow-up MRI, irrespective of its timing with reference to a baseline scan OR • Await a second clinical attack
Insidious neurologic progression suggestive of MS (PPMS)	1 year of disease progression (retrospectively or prospectively determined) PLUS 2 out of the 3 following criteria: • Evidence for dissemination in space in the brain based on ≥1 T2+ lesions in the MS-characteristic periventricular, juxtacortical, or infratentorial regions • Evidence for dissemination in space in the spinal cord based on ≥2 T2+ lesions in the cord • Positive CSF (isoelectric focusing evidence of oligoclonal bands and/or elevated IgG index)

Abbreviations: CNS, central nervous system; CSF, cerebrospinal fluid; MRI, magnetic resonance imaging; PPMS, primary progressive multiple sclerosis.

without superimposed relapses, documentation of intrathecal IgG synthesis may be used to support a diagnosis of PPMS.

DIAGNOSTIC TESTS

MAGNETIC RESONANCE IMAGING

MRI has revolutionized the diagnosis and management of MS (**Fig. 455-3**); characteristic abnormalities are found in >95% of patients, although the majority of lesions visualized by MRI are asymptomatic. An increase in vascular permeability from a breakdown of the BBB is detected by leakage of intravenous gadolinium (Gd) into the parenchyma. Such leakage occurs early in the development of an MS lesion and serves as a marker of inflammation. Gd enhancement typically persists for <1 month, and the residual MS plaque remains visible indefinitely as a focal area of hyperintensity (a lesion) on T2-weighted images. Lesions are frequently oriented perpendicular to the ventricular surface, corresponding to a pattern of perivenous demyelination (Dawson's fingers; **Fig. 455-3*B***). Lesions are multifocal within the brain, brainstem, and spinal cord. Lesions >6 mm located in the corpus callosum, periventricular white matter, brainstem, cerebellum, or spinal cord are particularly helpful diagnostically. Also useful diagnostically is a *central vein sign* within plaques visualized with susceptibility-weighted (such as T2*) sequences **(Chap. 434)**. Criteria for the use of MRI in diagnosis of MS are shown in Table 455-4.

Serial MRI studies in RRMS reveal that bursts of focal inflammatory disease activity occur far more frequently than would have been predicted by the frequency of relapses. Thus, early in MS, most disease activity is clinically silent.

The total volume of T2-weighted signal abnormality (the "burden of disease") shows a significant (albeit weak) correlation with clinical disability. Quantitative measures of brain and especially spinal cord atrophy provide evidence of diffuse tissue injury and correlate more strongly with measures of disability or progressive MS. Serial MRI studies also indicate that progressive brain atrophy occurs even in very early MS and continues throughout the disease course. Approximately one-third of T2-weighted lesions appear as hypointense lesions (*black holes*) on T1-weighted imaging. Black holes are markers of irreversible demyelination and axonal loss, although even this measure depends on the timing of the image acquisition (e.g., most acute Gd-enhancing T2 lesions are T1 dark, and in chronic lesions, there is progressive T1 darkening over time).

CEREBROSPINAL FLUID

CSF changes in MS include a mononuclear cell pleocytosis and an increased level of intrathecally synthesized IgG. The total CSF protein is usually normal or only mildly elevated. Various formulas distinguish intrathecally synthesized IgG from IgG that entered the CNS passively from the serum. The CSF IgG index expresses the ratio of IgG to albumin in the CSF divided by the same ratio in the serum. The IgG synthesis rate uses serum and CSF IgG and albumin measurements to calculate the rate of CNS IgG synthesis. The measurement of oligoclonal bands (OCBs) by agarose gel electrophoresis of the CSF assesses intrathecal production of specific IgG clones separated by differences in charge. Two or more discrete OCBs, not present in a paired serum sample, are found in >90% of patients with MS. OCBs may be absent at the onset of MS, and in individual patients, the number of bands may increase over time.

A mild CSF pleocytosis (>5 cells/μL) is present in ~25% of cases, usually in young patients with RMS. A pleocytosis of >75 cells/μL, the presence of polymorphonuclear leukocytes, or a protein concentration >1 g/L (>100 mg/dL) in CSF should raise concern that the patient may not have MS. Because of its utility to rule in and also rule out MS, CSF examination is highly recommended as part of the routine MS workup, and especially when the diagnosis is uncertain.

EVOKED POTENTIALS

EP testing assesses function in afferent (visual, auditory, and somatosensory) or efferent (motor) CNS pathways. EPs use computer averaging to measure CNS electric potentials evoked by repetitive stimulation of selected peripheral nerves or of the brain. These tests provide the most information when the pathways studied are clinically uninvolved. For example, in a patient with a relapsing spinal cord syndrome with sensory deficits in the legs, an abnormal somatosensory EP following posterior tibial nerve stimulation provides little new information. By contrast, an abnormal visual EP in this circumstance would permit a diagnosis of clinically definite MS (Table 455-4). Abnormalities on one or more EP modalities occur in 80–90% of MS patients. EP abnormalities are not specific to MS, although a marked delay in the latency of a

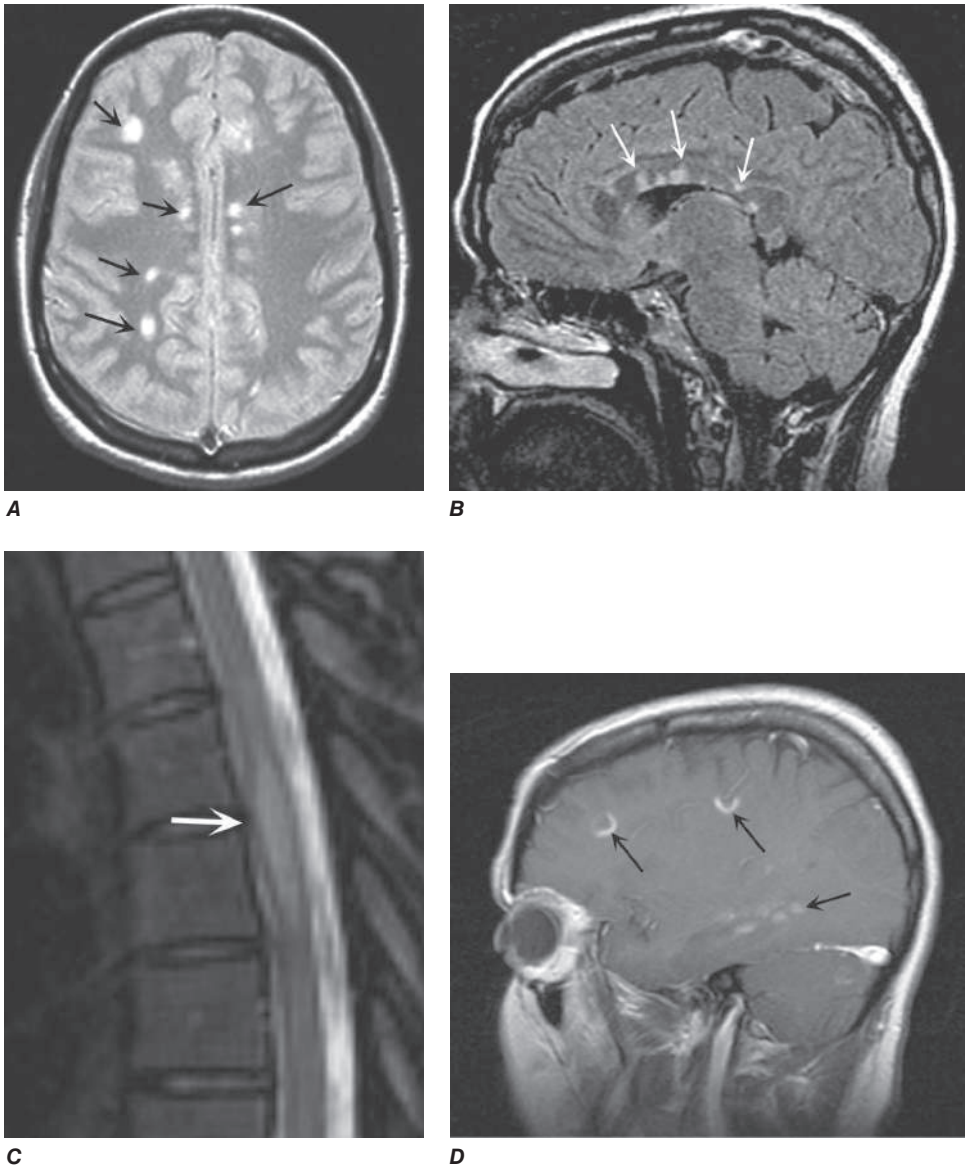

FIGURE 455-3 Magnetic resonance imaging findings in multiple sclerosis (MS). ***A.*** Axial first-echo image from T2-weighted sequence demonstrates multiple bright signal abnormalities in white matter, typical for MS. ***B.*** Sagittal T2-weighted fluid-attenuated inversion recovery (FLAIR) image in which the high signal of cerebrospinal fluid (CSF) has been suppressed. CSF appears dark, whereas areas of brain edema or demyelination appear high in signal, as shown here in the corpus callosum (*arrows*). Lesions in the anterior corpus callosum are frequent in MS and rare in vascular disease. ***C.*** Sagittal T2-weighted fast spin echo image of the thoracic spine demonstrates a fusiform high-signal-intensity lesion in the midthoracic spinal cord. ***D.*** Sagittal T1-weighted image obtained after the intravenous administration of gadolinium diethylene triamine pentaacetic acid (DTPA) reveals focal areas of blood-brain barrier disruption, identified as high-signal-intensity regions (*arrows*).

specific EP component (as opposed to a reduced amplitude or distorted wave shape) suggests demyelination.

DIFFERENTIAL DIAGNOSIS

The possibility of an alternative diagnosis should always be considered **(Table 455-5)**, particularly when (1) symptoms are localized exclusively to the posterior fossa, craniocervical junction, or spinal cord; (2) the patient is <15 or >60 years of age; (3) the clinical course is progressive from onset; (4) the patient has never experienced visual, sensory, or bladder symptoms; or (5) laboratory findings (e.g., MRI, CSF, or EPs) are atypical. Similarly, symptoms that are uncommon or rare in MS (e.g., aphasia, parkinsonism, chorea, isolated dementia, severe muscular atrophy, peripheral neuropathy, episodic loss of consciousness, fever, headache, seizures, or coma) favor an alternative diagnosis. Diagnosis can be particularly difficult in patients with a rapid or explosive (stroke-like) onset or those with mild symptoms and a normal neurologic examination. Rarely, intense inflammation and swelling may produce a mass lesion that mimics a primary or metastatic tumor. Disorders possibly mistaken for MS include neuromyelitis optica (NMO) and the more recently identified myelin oligodendrocyte protein-associated disease (MOGAD) and glial fibrillary acid protein (GFAP) disorders **(Chap. 456)**; these should be considered in patients who present with bilateral and/or severe optic neuritis or severe transverse myelitis. With hyperacute or postinfectious presentations, another consideration is acute disseminated encephalomyelitis (ADEM; **Chap. 456**). Other possibilities include Sjögren's syndrome, sarcoidosis, vascular disorders (antiphospholipid syndrome and vasculitis), rarely CNS lymphoma, and still more rarely infections such as syphilis or Lyme disease. The specific tests required to exclude alternative diagnoses will vary with each clinical situation; however, an erythrocyte sedimentation rate, serum B_{12} level, antinuclear antibodies, and treponemal antibody should probably be obtained in all patients with suspected MS.

TREATMENT

Therapy for MS can be divided into several categories: (1) treatment of acute attacks, (2) treatment with disease-modifying agents that reduce the biologic activity of MS, and (3) symptomatic therapy. Treatments that promote remyelination or neural repair do not currently exist, but several promising approaches are being actively investigated.

TABLE 455-5 Disorders That Can Mimic Multiple Sclerosis (MS)
Acute disseminated encephalomyelitis (ADEM)
Antiphospholipid antibody syndrome
Behçet's disease
Cerebral autosomal-dominant arteriopathy, subcortical infarcts, and leukoencephalopathy (CADASIL)
Congenital leukodystrophies (e.g., adrenoleukodystrophy, metachromatic leukodystrophy)
Glial Fibrillary Acidic Protein (GFAP) Autoimmunity
Human immunodeficiency virus (HIV) infection
Ischemic optic neuropathy (arteritic and nonarteritic)
Lyme disease
Mitochondrial encephalopathy with lactic acidosis and stroke (MELAS)
Myelin oligodendrocyte glycoprotein-associated disease (MOGAD)
Neoplasms (e.g., lymphoma, glioma, meningioma)
Neuromyelitis optica
Sarcoidosis
Sjögren's syndrome
Stroke and ischemic cerebrovascular disease
Syphilis
Systemic lupus erythematosus and related collagen vascular disorders
Tropical spastic paraparesis (HTLV-1/2 infection)
Vascular malformations (especially spinal dural AV fistulas)
Vasculitis (primary CNS or other)
Vitamin B_{12} deficiency

Abbreviations: AV, arteriovenous; CNS, central nervous system; HTLV, human T-cell lymphotropic virus.

As noted above, the EDSS is a widely used measure of neurologic impairment in MS (Table 455-2). Most patients with EDSS scores <3.5 walk normally and are generally not disabled; by contrast, patients with EDSS scores >4.0 have progressive MS (SPMS or PPMS), are gait-impaired, and often are occupationally disabled.

ACUTE ATTACKS OR INITIAL DEMYELINATING EPISODES

When patients experience acute deterioration, it is important to consider whether this change reflects new disease activity or a "pseudoexacerbation" resulting from an increase in ambient temperature, fever, or an infection. When the clinical change is thought to reflect a pseudoexacerbation, glucocorticoid treatment is inappropriate. Glucocorticoids are used to manage first attacks and exacerbations that are moderate to severe in severity. They provide short-term clinical benefit by reducing the degree and duration of attacks. Whether treatment provides any long-term benefit on the course of the illness is less clear. Therefore, mild attacks are often not treated. Physical and occupational therapy can help with mobility and manual dexterity.

Glucocorticoid treatment is usually administered as intravenous methylprednisolone, 500–1000 mg/d for 3–5 days, either without a taper or followed by a course of oral prednisone beginning at a dose of 60–80 mg/d and gradually tapered over 2 weeks. Orally administered methylprednisolone, prednisone, or dexamethasone (in equivalent dosages) can be substituted for the intravenous portion of the therapy. Outpatient treatment is almost always possible.

Side effects of short-term glucocorticoid therapy include fluid retention, potassium loss, weight gain, gastric disturbances, acne, and emotional lability. Concurrent use of a low-salt, potassium-rich diet and avoidance of potassium-wasting diuretics are advisable. Lithium carbonate (300 mg orally bid) may help manage emotional lability and insomnia associated with glucocorticoid therapy. Patients with a history of peptic ulcer disease may require cimetidine (400 mg bid) or ranitidine (150 mg bid). Proton pump inhibitors such as pantoprazole (40 mg orally bid) may reduce the likelihood of gastritis, especially when large doses are administered orally. Plasma exchange (five to seven exchanges: 40–60 mL/kg per exchange, every other day for 14 days) may benefit patients with fulminant attacks of demyelination that are unresponsive to glucocorticoids.

DISEASE-MODIFYING THERAPIES FOR MS

RMS More than a dozen immunomodulatory and immunosuppressive agents are in use for treatment of RMS **(Table 455-6)**. In phase 3 clinical trials, each was shown to reduce the frequency of clinical relapses and evolution of new brain MRI lesions. Each can also be used in SPMS patients who continue to experience attacks, both because SPMS can be difficult to distinguish from RRMS and because the available clinical trials, although not all definitive, suggest that such patients may sometimes derive therapeutic benefit. Moreover, regulators now consider patients with recent relapses to be a "relapsing form of MS" (i.e., RMS), regardless of whether these patients previously had progressive disability independent from relapses. It is important to note that the relative efficacy of the different agents has not been directly tested in head-to-head studies and that cross-trial comparisons are inaccurate. However, given the increasingly complex landscape of therapeutics for MS, for convenience, the presentation of these agents was divided by an estimate of their relative (high, moderate, or modest) perceived level of efficacy. These are meant to serve as a general guide, with the caveat that considerable variance exists in practice patterns, as well as availability of these agents, in different parts of the world.

Therapy should be initiated in all patients diagnosed with RMS and those presenting with a first demyelinating event who are at high risk for MS (sometimes termed as a clinically isolated syndrome [CIS]). We favor use of the most highly effective disease-modifying therapies as first-line options for most patients. This recommendation is based on evidence from long-term prospective trials and real-world data indicating that initial treatment with highly effective agents provides outstanding control against relapsing disease, maximum protection against relapse-independent progression, and long-term outcomes, and is safe. We typically begin with an anti-CD20 B-cell-targeting drug (ocrelizumab, ofatumumab, or ublituximab) or, if these approved treatments are unavailable, with rituximab or a biosimilar. In JCV-negative patients, we begin with the cell-trafficking inhibitor natalizumab. Anti-CD20 agents are particularly attractive given their high level of efficacy, relative ease of use, favorable safety profile, and absence of rebound following discontinuation. For patients who prefer oral treatment, either an S1P modulator or a fumarate is also reasonable for first-line therapy.

First-line treatment with high-efficacy therapy has supplanted the alternative approach in which a treatment of modest or moderate effectiveness was first used and therapy advanced to a more effective agent when breakthrough disease (evident clinically or by MRI) occurred. Older first-generation therapies, such as IFN-βor glatiramer acetate, are often continued in patients who are doing well on these agents but are less commonly used today for patients with new-onset MS. Irrespective of the agent used, a change in therapy may be required in patients with suboptimal responses, such as those experiencing relapses and/or active MRI scans while on treatment, or for adverse events that may be drug-related. Pregnancy-related management is discussed later in this chapter.

Some patients, especially those with a mild initial RRMS course—e.g., a normal examination or minimal impairment (EDSS ≤2.5) and low disease activity by MRI—may initially decline therapy with a potent immunosuppressive drug. In these situations, either an oral (fumarates, S1P modulators, or teriflunomide) or injectable (IFN-β or glatiramer acetate) agent can be considered. The injectable agents (IFN-β and glatiramer acetate) have a superb long-term track record for safety but have a high nuisance factor due to the need for frequent injections, as well as bothersome side effects that reduce adherence.

As noted above, multiple lines of evidence indicate that institution of effective therapy can improve the long-term outcome of MS, including a prolongation of the time to reach disability outcomes (e.g., SPMS and requiring assistance to ambulate) and reduction in MS-related mortality. These benefits seem most conspicuous when treatment is begun early in the relapsing stage of the illness. It may be reasonable to delay initiating treatment in some patients with (1) normal neurologic

TABLE 455-6 Disease-Modifying Therapies for Multiple Sclerosis

CATEGORY AND MECHANISM OF ACTION	GENERIC NAME (TRADE NAME)	DOSE AND INTERVAL	CHARACTERISTICS	COMMENTS (USE, ADVERSE EFFECTS, ETC.)
Highly Effective				
Anti-CD20 B cell MAbs: Depletes B lymphocytes, especially motile B cells in peripheral blood; B cells in lymphoid organs variably protected; plasma cells preserved	Ocrelizumab (Ocrevus)	600-mg infusion q6 months (first dose given as two 300-mg infusions 14 days apart)	Humanized ADCC > complement	Infusion reactions usually mild; outstanding efficacy and safety in long-term RMS extension trials; also approved for PPMS
	Ofatumumab (Kesimpta)	20-mg subcutaneous injections monthly (after 3 weekly 20-mg loading doses)	Fully human Complement > ADCC	Advantage of home-based treatment; only very minor injection- related reactions
	Ublituximab (Briumvi)	450-mg infusion q6 months (first dose given as 150-mg, followed 14 days later by 450-mg, infusions)	Chimeric ADCC > Complement	
	Rituximab (Rituxan and biosimilars)	1000-mg infusion q6 months (dose used in phase 2 trial in RMS); some clinicians use 500 mg IV q6 months	Chimeric Complement > ADCC	Formally tested only in preliminary (phase 2) study
Anti-α4 subunit of $\alpha4\beta1$ integrin (adhesion molecule) MAb: Prevents lymphocytes from binding to endothelial cells and entering the CNS	Natalizumab (Tysabri)	300-mg monthly infusion	Humanized	Hypersensitivity Rxns (<10%) including anaphylaxis; NAbs in ~6%; major risk is PML (0.4%); can be given safely only if serum antibodies to JC virus are absent (~50% of patients); repeat testing q6 months with ongoing treatment; risk of rebound disease activity after cessation
Anti-CD52 MAb: Depletes lymphocytes and monocytes	Alemtuzumab (Lemtrada)	12 mg/m^2 infusion for 5 consecutive days; a second 3-day course administered 1 year later	Long-lasting benefits but serious risks limit use; approval in United States only for patients who have failed at least two other drugs	Multiple autoimmune complications including thyroid (~25%) and ITP (1–3%), malignancies, infection risk
Moderately Effective				
Sphingosine-1-phosphate (S1P) modulators: Prevents egress of lymphocytes from secondary lymphoid organs Pretreatment CBC, LFTs, ECG, eye exam required; vaccinate for VZV in seronegative patients	Fingolimod (Gilenya)	0.5 mg oral once daily	Binds to S1P1, S1P3, S1P4, and S1P5 receptors	Heart block or bradycardia can occur with first dose; a 6-h period of initial observation with ECG monitoring required; LFT abnormalities, macular edema; rare VZV or cryptococcal infections; risk of rebound disease activity after cessation for all agents in this class
	Ozanimod (Zeposia)	1 mg oral once daily	S1P1- and S1P5-selective inhibitor (cardiac receptors are mostly S1P3 and only weakly engaged by ozanimod)	Up-titration regimen used to begin treatment; first-dose monitoring not required for most patients
	Ponesimod (Ponvory)	20 mg oral once daily	S1P1-selective modulator	Up-titration regimen used to begin treatment; initial dose requires 4-h cardiac monitoring for patients with heart rate <55 beats/min
	Siponimod (Mayzent)	Based on CYP2C9 genotype. 1 mg oral daily for pts with CYP2C9 1/*3 or 2/*3 Dose reduced in patients with the CYP2C9 *3/*3 genotype (<0.5% of the population) due to substantially elevated drug levels	S1P1- and S1P5-selective modulator	Approved for SPMS with active disease (relapses or new focal MRI lesions); first-dose monitoring only for patients with sinus bradycardia, heart block, or prior myocardial infarction or heart failure
Fumarate: Immunomodulator; reduces proinflammatory and increases regulatory cytokines; inhibits degradation of Nrf2, increasing natural antioxidants	Dimethyl fumarate (Tecfidera)	240 mg oral twice daily (half-dose for first 7 days)	Metabolized to active compound monomethyl fumarate	Gastrointestinal side effects, flushing; these may improve over time; monitor for LFT abnormalities and for lymphopenia (which can persist after drug cessation); rare PML cases
	Diroximel fumarate (Vumerity)	262 mg oral twice daily	Metabolized to active compound monomethyl fumarate	Similar side effect profile as dimethyl fumarate
2-Chlorodeoxyadenosine: Lymphocytotoxic; possibly followed by reconstitution by nonpathogenic immune cells	Cladribine (Mavenclad)	Weight-based oral dosing (3.5 mg/kg) divided over 4–5 days, repeated 23–27 days later; a second identical course is administered 1 year later	Purine analogue prodrug phosphorylated in lymphocytes and incorporated into DNA, triggering apoptosis; long-lasting	Long-lasting benefits but use limited by risks of malignancy, teratogenicity, and infection including PML

(*Continued*)

TABLE 455-6 Disease-Modifying Therapies for Multiple Sclerosis (Continued)

CATEGORY AND MECHANISM OF ACTION	GENERIC NAME (TRADE NAME)	DOSE AND INTERVAL	CHARACTERISTICS	COMMENTS (USE, ADVERSE EFFECTS, ETC.)
Modestly Effective				
Glatiramer acetate: Immunomodulator; reduces proinflammatory and increases regulatory cytokines; induces antigen-specific suppressor T cells; binds MHC molecules	Glatiramer acetate (Copaxone)	Subcutaneous injection 20 mg daily, or alternatively, 40 mg three times weekly	Synthetic random polypeptide of four amino acids (L-glutamic acid, L-lysine, L-alanine, L-tyrosine)	Well tolerated; injection site reactions; ~15% of patients experience one (or less often more than one) episode of flushing, chest tightness, dyspnea, palpitations, anxiety
Interferon (IFN)-β: Immunomodulator; reduces proinflammatory and increases regulatory cytokines; interferes with antigen presentation, T-cell proliferation, lymphocyte trafficking	Interferon-β-1a (Avonex)	Intramuscular injections 30 mg once weekly	Neutralizing antibodies in 2–10% (can decrease over time with all IFN preparations)	With all IFN preparations: flu-like symptoms (fever, chills, myalgias) common; managed with NSAIDs; mild lab abnormalities (LFTs, lymphopenia); rare cases of severe hepatotoxicity
	Interferon-β-1a (Rebif)	Subcutaneous injections 44 mg three times per week	Neutralizing antibodies in 15–25%	
	Interferon-β-1b (Betaseron or Extavia)	Subcutaneous injections 250 mg every other day	Neutralizing antibodies in 30–40%	
	Pegylated interferon-β-1a (Plegridy)	Subcutaneous injections 125 mg every 14 days	Pegylation increases half-life; neutralizing antibodies in <1%	
Teriflunomide: Anti-inflammatory; limits proliferation of rapidly dividing B and T lymphocytes	Teriflunomide (Aubagio)	14 mg oral daily	Inhibits mitochondrial enzyme dihydro-orotate dehydrogenase involved in de novo pyrimidine synthesis; cytostatic rather than cytotoxic	Hair thinning, gastrointestinal toxicity (nausea and diarrhea), rarely toxic epidermal necrolysis or Stevens-Johnson syndrome; long-lasting teratogenicity (elimination protocol with cholestyramine or activated charcoal)

Abbreviations: ADCC, antibody-dependent cell-mediated cytotoxicity; CBC, complete blood count; CNS, central nervous system; ECG, electrocardiogram; ITP, immune thrombocytopenia; LFT, liver function test; MAbs, monoclonal antibodies; MHC, major histocompatibility complex; MRI, magnetic resonance imaging; NAb, neutralizing antibody; NSAID, nonsteroidal anti-inflammatory drug; PML, progressive multifocal leukoencephalopathy; PPMS, primary progressive multiple sclerosis; RMS, relapsing multiple sclerosis; Rxn, reaction; SPMS, secondary progressive multiple sclerosis; VZV, varicella-zoster virus.

examinations, (2) a single attack or a low attack frequency, and (3) a low burden of disease as assessed by brain MRI. Untreated patients, however, should be followed closely with periodic brain MRI scans; the need for therapy is reassessed if scans reveal evidence of ongoing, subclinical disease. Finally, vitamin D deficiency should be corrected in all patients with MS, and generally this requires oral supplementation with vitamin D_3, 4000 IU daily. Several clinical trials showed that supplementation with vitamin D in relapsing MS patients reduces MRI measures of disease activity and may also reduce the relapse frequency in patients actively treated with either IFN or glatiramer acetate.

SPMS For patients with active SPMS, either ocrelizumab or siponimod is a reasonable first-line option. Ocrelizumab is approved for active SPMS despite not having been specifically studied in this patient population. Siponimod in a single pivotal study reduced the risk of progression in SPMS; however, subgroup analysis showed that patients with a relapse in the 2 years prior to treatment and those with contrast-enhancing lesions on brain MRI received the most therapeutic benefit. Regulatory bodies also approved cladribine and ponesimod for active SPMS despite neither having been specifically studied in this MS subgroup.

PPMS Ocrelizumab was shown to reduce progression of clinical disability in PPMS by 25% and also improve other clinical and MRI markers of inflammatory and degenerative disease activity. Although the magnitude of the effect in PPMS is lower than in RMS, for the average patient with PPMS, these data translate to the expectation that >7 years of wheelchair-independent function is gained on average. Ocrelizumab is the only agent convincingly shown to modify the course of PPMS.

OTHER OFF-LABEL TREATMENT OPTIONS

Autologous hematopoietic stem cell transplantation appears to be highly effective in reducing relapses and may improve disability in relapsing MS. It appears to be largely ineffective for patients with progressive MS. Stem cell transplantation also carries significant risk, however, including toxicities from chemotherapy-conditioning regimens. Ongoing clinical trials should help to better position this procedure with respect to available pharmacologic interventions.

Intravenous immunoglobulin (IVIg), administered in monthly pulses (up to 1 g/kg) for up to 2 years, appears to reduce annual exacerbation rates. However, its use is limited because of its high cost, questions about optimal dose, and uncertainty about any impact on long-term disability. It can be considered when the risks of immunosuppression preclude use of other MS agents.

Numerous clinical trials of promising experimental therapies are currently underway. These include studies testing higher doses of ocrelizumab; Bruton's tyrosine kinase (BTK) inhibitors to selectively deplete B cells, plasma cells, and microglia; CD19-targeted chimeric antigen receptor (CAR) T cells; and molecules to promote remyelination.

THERAPIES TO AVOID

Many purported treatments for MS have never been subjected to scientific scrutiny. These include dietary therapies (e.g., the Swank diet, the Paleo diet, the Wahls diet), megadose vitamins, calcium orotate, bee stings, cow colostrum, hyperbaric oxygen, procarin (a combination of histamine and caffeine), chelation, acupuncture, acupressure, various Chinese herbal remedies, and removal of mercury-amalgam tooth fillings, among others. Although infections with EBV, human herpesvirus (HHV) 6, or other agents are plausibly involved in MS, treatment with antiviral agents or antibiotics is not recommended. A chronic cerebrospinal insufficiency (CCSVI) was proposed as a cause of MS, and surgical intervention with vascular repair was recommended; however, multiple studies failed to confirm the initial claims. A double-blind trial of high-dose biotin to improve disability in progressive forms of MS also found no benefit. Patients should avoid costly or potentially hazardous unproven treatments, many of which also lack biologic plausibility.

SYMPTOMATIC THERAPIES

For all patients, it is important to encourage attention to a healthy lifestyle, including maintaining an optimistic outlook, a healthy diet, and regular exercise as tolerated (swimming is often well-tolerated because of the cooling effect of cold water). It is reasonable also to correct vitamin D deficiency with oral vitamin D and consider dietary supplementation with long-chain fatty acids (such as omega-3 oil tablets) due to their mild immunomodulatory effects.

Bladder dysfunction management is best guided by urodynamic testing because symptoms correlate poorly with the specific pathophysiology, which can also change over time as the disease evolves. The underlying cause can be bladder hyperreflexia, atony, or dyssynergia between the detrusor and the external sphincter muscle.

Detrusor hyperreflexia can be initially managed with evening fluid restriction or frequent voluntary voiding. If these methods fail, beta-3 adrenergic agonists such mirabegron (25–50 mg/d) and vibegron (75 mg/d) that relax bladder smooth muscle should be tried. Beta-3 adrenergic agonists are preferred over anticholinergic agents such as oxybutynin (5–15 mg/d), propantheline bromide (10–15 mg/d), tolterodine tartrate (2–4 mg/d), or solifenacin (5–10 mg/d) because anticholinergic side effects can worsen other MS symptoms including cognitive dysfunction. Co-administration of pseudoephedrine (30–60 mg) with anticholinergics is sometimes beneficial. Detrusor muscle injections of botulinum toxin (e.g., onabotulinumtoxinA 200 IU) can be useful when anticholinergics are ineffective or produce side effects such as cognitive dysfunction or fatigue.

An *atonic bladder* due to loss of reflex bladder wall contraction may respond to bethanechol (30–150 mg/d), and *detrusor/sphincter dyssynergia* may respond to phenoxybenzamine (10–20 mg/d) or terazosin hydrochloride (1–20 mg/d). However, both conditions often require catheterization.

Urinary tract infections should be treated promptly. Patients with postvoid residual urine volumes >200 mL are predisposed to infections. Prevention by urine acidification (with cranberry juice or vitamin C) inhibits some bacteria. Prophylactic administration of antibiotics is sometimes necessary but may lead to colonization by resistant organisms. Intermittent catheterization may help to prevent recurrent infections and reduce overflow incontinence.

Treatment of *constipation* includes high-fiber diets and fluids. Natural or other laxatives may help. *Fecal incontinence* may respond to a reduction in dietary fiber.

Spasticity and *spasms* may improve with physical therapy, regular exercise, and stretching. Avoidance of triggers (e.g., infections, fecal impactions, bed sores) is extremely important. Effective medications include baclofen (20–120 mg/d), diazepam (2–40 mg/d), tizanidine (8–32 mg/d), dantrolene (25–400 mg/d), and cyclobenzaprine hydrochloride (10–60 mg/d). For severe spasticity, a baclofen pump (delivering medication directly into the CSF) can provide substantial relief.

Weakness can sometimes be improved with the use of potassium channel blockers such as 4-aminopyridine (20 mg/d) and 3,4-diaminopyridine (40–80 mg/d), particularly in the setting where lower-extremity weakness interferes with the patient's ability to ambulate. Extended-release 4-aminopyridine (10 mg twice daily) can be obtained either as dalfampridine (Ampyra) or through a compounding pharmacy. The principal concern with the use of these agents is the possibility of inducing seizures at high doses.

Ataxia/tremor is often intractable. Clonazepam (0.5–2 mg/d), primidone (50–250 mg/d), propranolol (40–200 mg/d), or ondansetron (8–16 mg/d) may help. Wrist weights occasionally reduce tremor in the arm or hand. Thalamotomy and deep-brain stimulation have been tried with mixed success.

Pain is treated with anticonvulsants (gabapentin [300–3600 mg/d]; pregabalin [50–300 mg/d]; carbamazepine [100–1000 mg/d]; phenytoin [300–600 mg/d]); tricyclic antidepressants (amitriptyline [25–100 mg/d], nortriptyline [25–100 mg/d], desipramine [100–300 mg/d]); serotonin-norepinephrine reuptake inhibitors (duloxetine [20–120 mg/d] or venlafaxine [75–225 mg/d]); or antiarrhythmics (mexiletine, 300–900 mg/d). If these approaches fail, patients should be referred to a comprehensive pain-management program.

Depression should be actively treated. Useful drugs include the selective serotonin reuptake inhibitors (escitalopram [10–20 mg/d], fluoxetine [20–80 mg/d], or sertraline [50–200 mg/d]), tricyclic antidepressants (amitriptyline [25–150 mg/d], nortriptyline [25–150 mg/d], or desipramine [100–300 mg/d]) and mixed norepinephrine/serotonin reuptake inhibitors (duloxetine [20–120 mg/d] or venlafaxine [75–225 mg/d]).

Fatigue may improve with assistive devices, help in the home, or successful management of spasticity. Careful attention to medications that could contribute to fatigue is often helpful. For example, patients who require anticholinergic medication for nocturia may benefit from dosing at bedtime only. Excessive daytime somnolence caused by MS may respond to methylphenidate (5–25 mg/d), modafinil (100–400 mg/d), or armodafinil (150–250 mg/d).

Cognitive problems may respond marginally to lisdexamfetamine (40 mg/d).

Paroxysmal symptoms respond dramatically to low-dose anticonvulsants (acetazolamide [200–600 mg/d], carbamazepine [50–400 mg/d], phenytoin [50–300 mg/d], or gabapentin [600–1800 mg/d]).

Heat sensitivity may respond to heat avoidance, air-conditioning, or cooling garments.

Sexual dysfunction may be helped by lubricants to aid in genital stimulation and sexual arousal. Management of pain, spasticity, fatigue, and bladder/bowel dysfunction may also help. Sildenafil (50–100 mg), tadalafil (5–20 mg), or vardenafil (5–20 mg), taken 1–2 h before sex, are standard treatments for erectile dysfunction.

PROGNOSIS

Historically, most patients with MS ultimately experienced progressive neurologic disability. In older studies conducted before disease-modifying therapies for MS were available, 15 years after onset, only 20% of patients had no functional limitation, and between one-third and one-half of RMS patients progressed to SPMS and required assistance with ambulation; furthermore, 25 years after onset, ~80% of MS patients reached this level of disability. Long-term studies from the early treatment era indicated clearly that prognosis had improved substantially, with a two- to threefold slowing of transition from RMS to SPMS. And currently with high-efficacy therapy widely available, the prognosis continues to improve; relapses are largely eliminated and relapse-independent progression has been further slowed. For example, the ocrelizumab extension trials revealed that after 10 years of continuous treatment, nearly 80% of patients with RMS experienced no disease worsening and more patients had improved than worsened, and in PPMS, more than one-third had experienced no worsening and more than 80% were still ambulatory. As noted above, the long-term course may improve further as highly efficacious agents are increasingly employed early in the disease course. However, many patients with progressive MS still continue to worsen despite best available therapy, and for these patients, more effective therapies are sorely needed.

Natural history studies from the pretreatment era indicated that certain clinical features suggest a more favorable prognosis. These include ON or sensory symptoms at onset; fewer than two relapses in the first year of illness; and minimal impairment after 5 years. Predictors of an early aggressive course of the illness include an older age at symptom onset, male gender, greater disability, and the appearance of motor signs during the first year of the illness. Importantly, some MS patients, estimated at <10%, have a benign variant of MS and never develop neurologic disability even when untreated.

PREGNANCY-RELATED ISSUES

Pregnant MS patients experience fewer attacks during gestation (especially in the last trimester) but more attacks in the first 3 months postpartum. When considering the pregnancy year as a whole (i.e., 9 months of pregnancy plus 3 months postpartum), the overall disease course is unaffected. Disease-modifying therapy is generally discontinued during pregnancy, and special care needs to be taken with agents (natalizumab and the S1P drugs) that have risk of rebound disease activity following discontinuation. Replacement of these agents with an anti-CD20 B-cell therapy such as ocrelizumab before conception appears to mitigate this risk and also provide long-lasting protection that extends throughout the pregnancy and immediate postpartum period. Intravenously administered B-cell therapies also provide an attractive management option for many patients contemplating pregnancy, and our practice is to advise patients to stop receiving infusions 3–4 months prior to attempting to conceive. Earlier studies raised concerns that drugs used for fertility treatments might worsen MS disease

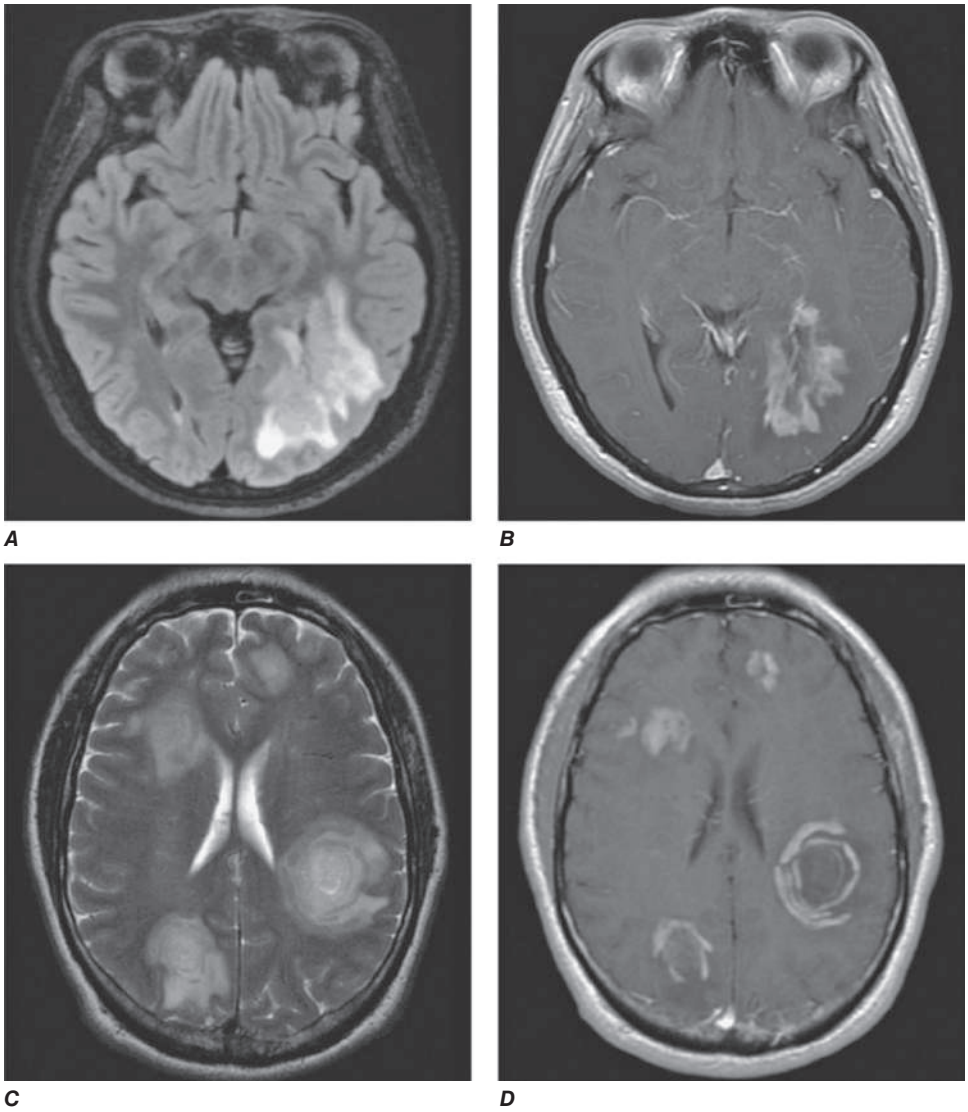

FIGURE 455-4 Magnetic resonance imaging findings in variants of MS. ***A*** and ***B***. Acute tumefactive MS. In ***A***, a sagittal T2-weighted fluid-attenuated inversion recovery (FLAIR) image of a large solitary right parieto-occipital white matter lesion is shown, with effacement of overlying cortical sulci consistent with mass effect. In ***B***, T1-weighted image obtained after the intravenous administration of gadolinium diethylene triamine pentaacetic acid (DTPA) reveals a large serpiginous area of blood-brain barrier disruption consistent with acute inflammation. ***C*** and ***D***. Balo's concentric sclerosis. In ***C***, an axial T2-weighted sequence shows multiple areas of abnormal ovoid bright signal in the supratentorial white matter bilaterally; some lesions reveal concentric layers, typical of Balo's concentric sclerosis. In ***D***, T1-weighted magnetic resonance images after gadolinium demonstrate abnormal enhancement of all lesions with some lesions demonstrating concentric ring enhancement.

activity, but more recent studies indicate that these produce little if any additional risk.

CLINICAL VARIANTS OF MS

Acute or fulminant MS (*Marburg's variant*) is an aggressive demyelinating process that in some cases progresses inexorably to death within 1–2 years. Typically, there are no remissions. Marburg's variant does not seem to follow infection or vaccination, and it is unclear whether this syndrome represents an extreme form of MS or another disease altogether. When an acute demyelinating syndrome presents as a solitary expansile lesion, a brain tumor is often suspected **(Fig. 455-4*A, B*)**. Such cases are designated tumefactive MS, and a brain biopsy may be required to establish the diagnosis. *Balo's concentric sclerosis* is another fulminant demyelinating syndrome characterized by concentric brain or spinal cord lesions with alternating spheres of demyelination and remyelination **(Fig. 455-4*C, D*)**. For these fulminant demyelinating states, no controlled trials of therapy exist; high-dose glucocorticoids and plasma exchange are often used, with uncertain benefit.

456 Neuromyelitis Optica

Bruce A. C. Cree, Stephen L. Hauser

Neuromyelitis optica (NMO) is an aggressive, antibody-mediated, inflammatory disorder characterized by recurrent attacks of optic neuritis (ON) and myelitis; the more inclusive term *NMO spectrum disorder* (NMOSD) was proposed to incorporate individuals with partial forms and those with involvement of additional structures in the central nervous system **(Table 456-1)**. NMO is more frequent in women than men (9:1) and typically begins in adulthood (40-year mean age of onset) but can arise at any age. An important consideration, especially early in its presentation, is distinguishing between NMO and multiple sclerosis (MS; **Chap 455**). In patients with NMO, attacks of ON can be bilateral and produce severe vision loss (uncommon in MS); myelitis can be severe and transverse (rare in MS) and is typically longitudinally extensive **(Fig. 456-1)** involving three or more contiguous vertebral segments. In contrast to MS, progressive symptoms only rarely occur in NMO, and accumulation of disability is caused by attack-related injury. The brain magnetic resonance imaging (MRI) was earlier thought to be normal in NMO, but it is now recognized that in many cases brain lesions are present, including areas of nonspecific signal change as well as lesions associated with specific syndromes such as the area postrema in the lower medulla presenting as intractable hiccoughs or vomiting; the hypothalamus causing a sleep disorder or endocrinopathy; or the cerebral hemispheres producing focal symptoms, encephalopathy, or seizures. Large MRI lesions in the cerebral hemispheres can be asymptomatic, sometimes have a "cloud-like" appearance, and unlike MS lesions, are often not destructive and can resolve completely. Spinal cord MRI lesions typically consist of focal enhancing areas of swelling and tissue destruction, extending over three or more spinal cord segments, and on axial sequences, these are centered on the gray matter of the cord. Cerebrospinal fluid (CSF) findings include pleocytosis greater than that observed in MS, with neutrophils and eosinophils present in many acute cases; oligoclonal bands (OCBs) are uncommon, occurring in <20% of NMO patients. The pathology of NMO is a distinctive astrocytopathy with inflammation, loss of astrocytes, and an absence of staining of the water channel protein aquaporin-4 (AQP4) by immunohistochemistry, plus thickened blood vessel walls, demyelination, and deposition of antibody and complement.

TABLE 456-1 Diagnostic Criteria for Neuromyelitis Optica Spectrum Disorder (NMOSD)

Diagnostic Criteria for NMOSD with AQP4-IgG
1. At least one core clinical characteristic
2. Positive test for AQP4-IgG using best available detection method (cell-based assay strongly recommended)
3. Exclusion of alternative diagnoses
Diagnostic Criteria for NMOSD without AQP4-IgG or NMOSD with Unknown AQP4-IgG Status
1. At least two core clinical characteristics occurring as a result of one or more clinical attacks and meeting all of the following requirements:
a. At least one core clinical characteristic must be optic neuritis, acute myelitis with LETM, or area postrema syndrome
b. Dissemination in space (two or more different clinical characteristics)
c. Fulfillment of additional MRI requirements, as applicable
2. Negative test for AQP4-IgG using best available detection method or testing unavailable
3. Exclusion of alternative diagnoses
Core Clinical Characteristics
1. Optic neuritis
2. Acute myelitis
3. Area postrema syndrome: episode of otherwise unexplained hiccups or nausea or vomiting
4. Acute brainstem syndrome
5. Symptomatic narcolepsy or acute diencephalic clinical syndrome (hypothalamic dysfunction) with NMOSD-typical diencephalic MRI lesions
6. Symptomatic cerebral syndrome with NMOSD-typical brain lesions
Additional MRI Requirements for NMOSD without AQP4-IgG and NMOSD with Unknown AQP4-IgG Status
1. Acute optic neuritis: requires brain MRI showing (a) normal findings or only nonspecific white matter lesions, OR (b) optic nerve MRI with T2-hyperintense lesion of T1-weighted gadolinium-enhancing lesion extending over >1/2 optic nerve length or involving optic chiasm
2. Acute myelitis: requires associated intramedullary MRI lesion extending ≥3 contiguous segments (LETM) OR ≥3 contiguous segments of focal spinal cord atrophy in patients with history compatible with acute myelitis
3. Area postrema syndrome requires associated dorsal medulla/area postrema lesions
4. Acute brainstem syndrome requires periependymal brainstem lesions

Abbreviations: AQP4, aquaporin-4; LETM, longitudinally extensive transverse myelitis; MRI, magnetic resonance imaging.

NMO is an autoimmune disease associated with a highly specific autoantibody directed against the water channel protein AQP4 that is present in the sera of ~90% of affected patients. AQP4 is localized to the foot processes of astrocytes in close apposition to endothelial surfaces, as well as at paranodal regions near nodes of Ranvier. Pathologic studies in NMO show loss of AQP4 associated with antibody and complement deposition and cytolysis of astrocytes within NMO lesions. It is likely that AQP4 antibodies are pathogenic because passive transfer of AQP4 antibodies into laboratory animals can reproduce histologic features of the disease. Both complement fixation and antibody-dependent cell-mediated cytotoxicity (ADCC) are thought to contribute to astrocyte injury. Proinflammatory T lymphocytes of the T_H17 type recognize an immunodominant epitope of AQP4 and may also contribute to pathogenesis. Recent data have identified a population of B lymphocytes in the thymus that constitutively express AQP4 and interact with AQP4-specific T cells to produce antigen-specific tolerance; this interaction might be impaired in NMO. During acute attacks of myelitis, CSF levels of interleukin-6 (IL-6; a proinflammatory cytokine) and glial fibrillary acidic protein (GFAP; an astrocyte protein) are markedly elevated, consistent with active inflammation and astrocyte injury. Because of the high specificity of the antibody, its presence is diagnostic when found in conjunction with a typical clinical presentation. Anti-AQP4 seropositive patients have a high risk for future attacks; more than half will relapse within 1 year if untreated.

CLINICAL COURSE

NMO is typically a recurrent disease; the course is monophasic in <10% of patients. Individuals who test negative for AQP4 antibodies are somewhat more likely to have a monophasic course. Untreated NMO is usually severely disabling over time; in one series, respiratory failure from cervical myelitis was present in one-third of patients, and 8 years after onset, 60% of patients were blind and more than half had permanent paralysis of one or more limbs. Observational data suggest that the long-term course of NMO has been substantially improved since the development of therapies to treat acute attacks and prevent relapses. The 5-year survival rate appears to have increased from 68–75% around 1999 to 91–98% as of 2017, a change presumably due to improved diagnosis and widespread use of immune-suppressing therapies.

GLOBAL CONSIDERATIONS

The incidence and prevalence of NMO shows considerable variation between populations and geographic regions, with prevalence estimates that range from <1 to >4 per 100,000. Although NMO can occur in people of any ethnic background, individuals of Asian and African origin are disproportionately affected, with the highest reported prevalence in Martinique. Among white populations, MS **(Chap. 455)** is far more common than NMO.

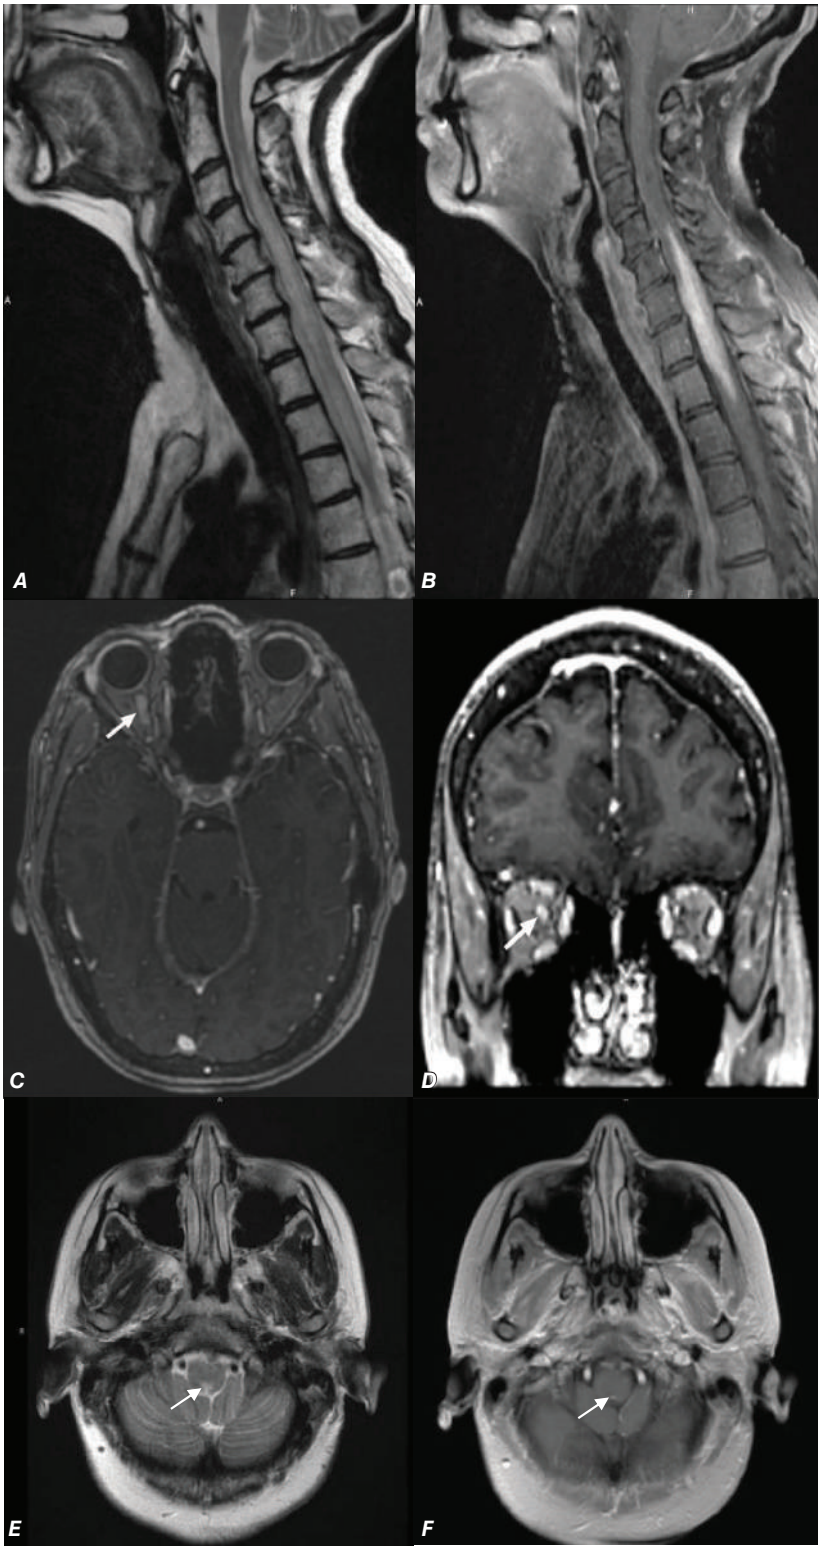

FIGURE 456-1 Imaging findings in neuromyelitis optica: longitudinally extensive transverse myelitis, optic neuritis, and brainstem involvement. ***A.*** Sagittal fluid-attenuated inversion recovery (FLAIR) cervical spine MRI showing an area of increased signal change on T2-weighted imaging spanning more than three vertebral segments in length. ***B.*** Sagittal T1-weighted cervical spine MRI following gadolinium-diethylene triamine pentaacetic acid (DPTA) infusion showing enhancement. ***C and D.*** Axial and coronal brain MRI following gadolinium DPTA infusion shows enhancement of the right optic nerve. ***E.*** Axial brain MRI shows an area of hyperintense signal on T2-weighted imaging within the area postrema (*arrow*). ***F.*** Axial T1-weighted brain MRI following gadolinium-DPTA infusion shows punctate enhancement of the area postrema (arrow).

Interestingly, when MS affects individuals of African or Asian ancestry, there is a propensity for demyelinating lesions in some individuals to involve predominantly the optic nerve and spinal cord, an MS subtype termed *opticospinal MS*. Some patients with opticospinal MS are seropositive for AQP4 antibodies, indicating that they represent NMOSD.

ASSOCIATED CONDITIONS

Up to 40% of NMO patients have a systemic autoimmune disorder, such as systemic lupus erythematosus, Sjögren's syndrome, perinuclear antineutrophil cytoplasmic antibody (p-ANCA)–associated vasculitis, myasthenia gravis, Hashimoto's thyroiditis, or mixed connective tissue disease. This is another feature distinct from MS; MS patients rarely

have other comorbid autoimmune diseases other than hypothyroidism. In some NMO cases, onset may be associated with acute infection with varicella-zoster virus, Epstein-Barr virus, HIV, or tuberculosis. Rare cases appear to be paraneoplastic and associated with breast, lung, or other cancers.

TREATMENT

Neuromyelitis Optica

ACUTE ATTACKS

Acute attacks are usually treated with high-dose glucocorticoids (e.g., methylprednisolone 1 g/d for 5–10 days followed by a prednisone taper). Plasma exchange (typically 5–7 exchanges of 1.5 plasma volumes/exchange) is used empirically for acute episodes that do not respond to glucocorticoids.

PROPHYLAXIS AGAINST RELAPSES

Given the unfavorable natural history of untreated NMO, prophylaxis against relapses is recommended for nearly all patients. Four monoclonal antibody medications are approved for attack prevention in NMO: an anti-CD19 B-cell depleter (inebilizumab), an IL-6 receptor blocker (satralizumab), and two terminal complement inhibitors (eculizumab and ravulizumab) **(Table 456-2)**. It is our general practice to begin therapy with either inebilizumab or satralizumab and to use complement inhibitors as second-line treatment for nonresponders. None of the U.S. Food and Drug Administration–approved medications are approved for AQP4-negative patients, and in practice, obtaining these medications for seronegative patients is challenging from a payer perspective. In AQP4-seronegative patients, the risk of a relapse is lower (approximately half of patients have only a single attack), and in these patients, our practice is to begin treatment with empiric therapies such as rituximab or mycophenolate mofetil. Because AQP4-seronegative patients require involvement of both optic neuritis and longitudinally extensive myelitis to meet criteria for seronegative NMOSD, the majority of AQP4-seronegative patients will have had more than one attack.

Inebilizumab (Uplizna) Inebilizumab is a humanized affinity-optimized, afucosylated monoclonal antibody that binds to the B-cell surface antigen CD19 and depletes a wide range of B cells including pre-B cells and some plasmablasts. Expression of CD19 starts at an earlier stage of B-cell development than CD20, and in contrast to CD20, which is absent from plasmablasts and mature plasma cells, CD19 is expressed on plasmablasts, as well as a proportion of plasma cells in secondary lymphoid organs and bone marrow. In the pivotal clinical trial that included individuals both positive and negative for AQP4, inebilizumab reduced the time to the first attack by 77% compared to placebo (hazard ratio, 0.23; p <.0001). Inebilizumab-treated participants also had reduced rates of hospitalizations, disability worsening, and new MRI lesions.

Inebilizumab is dosed as an initial 300-mg IV infusion followed 2 weeks later by a second 300-mg IV infusion, with subsequent doses of 300-mg infusions every 6 months thereafter. Inebilizumab is associated with a dose dependent decline in serum IgG levels and with neutropenia in some patients.

TABLE 456-2 Attack Risk Reductions of Approved Neuromyelitis Optica Spectrum Disorder (NMOSD) Treatments

	RISK REDUCTION IN AQUAPORIN-4–SEROPOSITIVE NMOSD
Eculizumab (add-on to immune suppression)	94%, p <.001
Ravulizumab (add-on to immune suppression)	100%, p <.001
Inebilizumab (monotherapy)	78%, p = .01
Satralizumab (monotherapy)	77%, p <.001
Satralizumab (add-on to immune suppression)	74%, p = .001

Satralizumab (Enspryng) Satralizumab is a monoclonal antibody that binds to the IL-6 receptor, blocking engagement of IL-6, a proinflammatory cytokine that is upregulated in the CSF during acute NMO attacks. Satralizumab was investigated in NMOSD in two registration trials: one as monotherapy and the other as add-on therapy. Both AQP4-seropositive and AQP4-seronegative participants were enrolled. In the monotherapy study, the risk of attack was reduced by 74% with satralizumab (p = .014), and in the add-on study, the risk of attack was reduced by 78% (p = .014). Although both studies recruited substantial numbers of AQP4-seronegative participants, there was no clinically meaningful impact of satralizumab in seronegative participants.

Satralizumab is administered as a loading dosage of 120 mg by subcutaneous injection at weeks 0, 2, and 4, followed by a maintenance dose of 120 mg every 4 weeks. Screening for hepatitis B virus, tuberculosis, and liver transaminase elevations is required before starting satralizumab. Aspartate aminotransferase (AST) and alanine aminotransferase (ALT) should be monitored during treatment for transaminase elevations and complete blood count (CBC) monitored for neutropenia. Satralizumab is also associated with weight gain; body weight increases of at least 7% from baseline occurred in 30% of satralizumab-treated participants compared to 8% of those treated with placebo.

Eculizumab (Soliris) The monoclonal antibody eculizumab binds with high affinity to the complement protein C5, inhibiting its cleavage into C5a and C5b and thereby preventing generation of the terminal complement attack complex C5b-9. Eculizumab was investigated as an add-on therapy in AQP4-seropositive NMO. The time to first attack was longer in patients treated with eculizumab compared to placebo (relative risk reduction, 94%; hazard ratio, 0.058; p <.0001) Eculizumab-treated patients also had a 96% relative reduction in the annualized attack rate, as well as dramatically reduced rates of hospitalizations and need for glucocorticoids or plasma exchange for acute attacks. Eculizumab is dosed as follows: 900 mg weekly for the first 4 weeks, followed by 1200 mg for the fifth dose 1 week later, and then 1200 mg every 2 weeks thereafter.

Because of its toxicity profile, eculizumab is available only through a restricted program under a Risk Evaluation and Mitigation Strategy (REMS). Life-threatening and fatal meningococcal infections have occurred (boxed warning). Eculizumab-treated patients must be immunized with meningococcal vaccines (MenACWY two doses at least 8 weeks apart plus either MenB-4C [two doses at least 1 month apart] or MenB-FHbp [three doses over 6 months]) at least 2 weeks prior to administering the first dose unless the risks of delaying eculizumab therapy outweigh the risks of developing a meningococcal infection. The MenACWY vaccine requires revaccination every 5 years, and the MenB-4C/MenB-FHbp requires a booster 1 year after vaccination and then every 2–3 years with ongoing treatment. Vaccination reduces, but does not eliminate, the risk of meningococcal infections. Eculizumab-treated patients must be monitored closely for early signs of meningococcal infections and evaluated immediately if infection is suspected.

Ravulizumab (Ultomiris) Like eculizumab, ravulizumab is a terminal complement inhibitor. Ravulizumab was developed using antibody recycling technology to increase its half-life, thereby allowing less frequent administration than its parent compound eculizumab. In a single-arm, open-label study of ravulizumab in NMOSD, ravulizumab-treated participants did not experience any attacks during 50 weeks of observation. A historical control arm from the eculizumab PREVENT clinical trial was used for comparison. Ravulizumab-treated patients also require vaccination for meningococcal infections. It seems likely that ravulizumab produces even more potent complement inhibition than eculizumab, resulting in apparently greater efficacy but also a higher risk of meningococcal infection. Ravulizumab is administered intravenously with a weight-based loading dose followed by maintenance dosing every 8 weeks.

OTHER TREATMENTS

Prior to the approval of disease-modifying therapies for NMO, several empiric regimens were commonly used including mycophenolate mofetil (1000 mg bid); rituximab, a B-cell-depleting anti-CD20 monoclonal antibody (2 g IV every 6 months); or a combination of glucocorticoids (500 mg IV methylprednisolone daily for 5 days, then oral prednisone 1 mg/kg per day for 2 months, followed by slow taper) plus azathioprine (2 mg/kg per day started on week 3).

Plasma cell–targeted therapy with anti–B-cell maturation antigen (BCMA) chimeric antigen receptor (CAR) T cells has shown promise in an early clinical study of patients with NMOSD who failed to respond to other treatments.

Importantly, some therapies with proven efficacy in MS do not appear to be useful for NMO. Available evidence suggests that interferon beta is ineffective and paradoxically may increase the risk of NMO relapses, and based on limited data, glatiramer acetate, fingolimod, natalizumab, and alemtuzumab also appear to be ineffective. These distinctions highlight the need for efficient diagnosis of NMO.

MYELIN OLIGODENDROCYTE GLYCOPROTEIN ANTIBODY–ASSOCIATED DISEASE

Although long considered to be a likely target for antibody-mediated demyelination, anti–myelin oligodendrocyte glycoprotein (MOG) antibodies detected by a cell-based assay that enables recognition of MOG epitopes in a lipid bilayer were only recently found to be associated with cases of acute disseminated encephalomyelitis (ADEM) in children and then with cases of AQP4-seronegative NMO. Further studies showed that patients who are seropositive for anti-MOG antibodies are at risk for bilateral, synchronous optic neuritis and myelitis and meningoencephalitis **(Table 456-3)**. A clinical feature that can help distinguish ON associated with MOG antibody–associated disease (MOGAD) from NMO or MS is the presence of papillitis seen by fundoscopy or orbital MRI, a finding that is common in MOGAD, rare in NMO, and variable but usually unilateral in MS. ON associated with MOGAD is typically longitudinally extensive on MRI, and brain MRI can be normal or show fluffy areas of increased signal change in white or gray matter structures, similar to NMO. MRI lesions that are typical for MS, including finger-like lesions oriented perpendicular to the ventricular surface (Dawson fingers) and T1 hypointense lesions, are uncommon. Spinal cord lesions can be longitudinally extensive or short and sometimes involve the conus medullaris. Demyelination associated with MOGAD is sometimes monophasic, as in ADEM, but can also be recurrent. The CSF may show a pleocytosis with occasional neutrophils. Elevated intrathecal synthesis of gamma globulins is atypical: oligoclonal bands are present in only ~6–13% of cases. A small percentage of patients who present with syndromes suggestive of MOGAD but test negative (or only weakly positive) for serum anti-MOG antibodies have detectable antibodies restricted to the CSF; thus, in these seronegative cases, CSF anti-MOG antibody testing should be pursued. The mechanism of central nervous system (CNS) injury in MOGAD is not established and could involve MOG-reactive cytotoxic T cells in addition to anti-MOG antibodies. Studies in MOG-induced experimental autoimmune encephalomyelitis, an animal model, suggest that anti-MOG antibodies may opsonize traces of MOG protein in secondary lymphoid tissues, triggering a peripheral immune response against MOG.

Acute episodes are managed with high-dose glucocorticoids followed by a prednisone taper and sometimes by plasmapheresis, as with NMO. Brain lesions associated with MOGAD often respond rapidly to treatment with glucocorticoids and may resolve entirely. Some patients experience disease recurrence following discontinuation of prednisone and can become glucocorticoid dependent. Clinical trials in MOGAD are underway with satralizumab (the IL-6 receptor blocker indicated for AQP4-seropositive NMO) and rozanolixizumab (Rystiggo; a humanized monoclonal antibody that binds the neonatal Fc receptor). There are limited data on use of other immune-suppressing medications typically used in NMO. Off-label empiric treatments include daily prednisone, IV immunoglobulin, rituximab, and mycophenolate mofetil. Anti-MOG antibody titers appear to decline either spontaneously or in the setting of treatment.

TABLE 456-3 Diagnostic Criteria for Myelin Oligodendrocyte Glycoprotein Antibody–Associated Disease (MOGAD)

Diagnostic Criteria for MOGAD
1. At least one core clinical event:
Optic neuritis
Myelitis
ADEM
Cerebral monofocal or polyfocal deficits
Brainstem or cerebellar deficits
Cerebral or cortical encephalitis often with seizures
2. Positive MOG IgG test (cell-based assay)
Clear positive – no additional requirements
Low positive, or positive without titer or CSF positive only – Must be AQP4 seronegative and have one or more of the following supporting features
Supporting clinical or radiographic features:
Optic neuritis – bilateral synchronous, >50% of length of optic nerve involvement, perineural optic nerve sheath enhancement, disc edema
Myelitis – longitudinally extensive, central cord involvement or "H sign," conus involvement
Brain/brainstem/cerebellar – ill-defined lesions, deep gray matter involvement, cortical lesions with or without overlying meningeal enhancement
3. Exclusion of better diagnoses including MS

Abbreviations: ADEM, acute disseminated encephalomyelitis; AQP4, aquaporin 4; CSF, cerebrospinal fluid; MOG, myelin oligodendrocyte glycoprotein; MS, multiple sclerosis.

Source: Adapted from B Banwell et al: Lancet Neurol 22:268, 2023.

GLIAL FIBRILLARY ACIDIC PROTEIN (GFAP) AUTOIMMUNITY

Autoimmunity against the astrocyte protein GFAP presents with a range of symptoms referable to meningismus, encephalitis, myelitis, and optic neuritis. Some cases follow a viral prodrome, and fever and headache are commonly present. The clinical syndrome can also include a movement disorder reflecting involvement of deep gray matter structures. MRI shows characteristic patterns of gadolinium enhancement localized to GFAP-enriched CNS regions including venous structures in a periventricular radial orientation, the leptomeninges, the periependymal spinal cord, and a striking serpiginous pattern involving brain parenchyma. Longitudinally extensive spinal cord involvement can also be present. These patterns share similarities with those observed in neurosarcoidosis, and their presence should prompt consideration for either condition. A lymphocytic pleocytosis is commonly present in the CSF. Antibodies against GFAP can be measured in the serum or CSF. GFAP autoimmunity is found as a paraneoplastic syndrome in ~25% of cases, most commonly associated with ovarian teratoma, and can coexist with anti-*N*-methyl-D-aspartate receptor (NMDAR) encephalitis or NMO. T cells are implicated in pathophysiology based on histopathology and association with checkpoint inhibitor treatment for cancer or in the setting of HIV. GFAP autoimmunity is generally glucocorticoid responsive. Early recognition with prompt intervention is associated with more favorable outcomes. Relapses occur in ~20% of patients and require use of immune suppression therapy.

ACUTE DISSEMINATED ENCEPHALOMYELITIS

ADEM has a monophasic course and is often associated with an antecedent infection (postinfectious encephalomyelitis); historically, a small number of ADEM cases have followed immunization (postvaccinal encephalomyelitis). ADEM is far more common in children than adults, and many adult cases initially thought to represent ADEM subsequently experience late relapses qualifying as either MS or

another chronic inflammatory disorder such as vasculitis, sarcoidosis, or lymphoma. Many cases previously thought to represent ADEM are now recognized as MOGAD. The hallmark of ADEM is the presence of widely scattered foci of perivenular inflammation and demyelination that can involve both white matter and gray matter structures, in contrast to larger confluent white matter lesions typical of MS. In the most explosive form of ADEM, acute hemorrhagic leukoencephalitis, the lesions are vasculitic and hemorrhagic, and the clinical course is devastating.

Postinfectious encephalomyelitis is most frequently associated with the viral exanthems of childhood. Infection with measles virus is the most common antecedent (1 in 1000 cases). Worldwide, measles encephalomyelitis is still common, although use of the live measles vaccine has dramatically reduced its incidence. In developed countries, ADEM is now most frequently associated with varicella (chickenpox) infections (1 in 4000–10,000 cases). It may also follow infection with rubella, mumps, influenza, parainfluenza, Epstein-Barr virus, human herpesvirus-6, HIV, dengue, Zika, other viruses, and *Mycoplasma pneumoniae*. Cases have also been described in association with SARS-CoV-2 infection. Some patients may have a nonspecific upper respiratory infection or no known antecedent illness. Modern vaccines appear to pose no meaningful risk for ADEM; one large study (Vaccine Safety Datalink) of 24 different vaccines in >9 million individuals (64 million doses in total) revealed no excess risk for ADEM, with the possible exception of Tdap (tetanus, diphtheria, acellular pertussis) vaccine estimated at less than one case per million doses.

All forms of ADEM presumably result from a cross-reactive immune response to the infectious agent that then triggers an inflammatory demyelinating response. Autoantibodies to MBP and other myelin antigens have been detected in the CSF from some patients with ADEM, and as noted above, ADEM cases with serum or CSF antibodies against MOG are now considered to be MOGAD.

CLINICAL MANIFESTATIONS

In severe cases, onset is abrupt and progression rapid (hours to days). In postinfectious ADEM, the neurologic syndrome generally begins late in the course of the viral illness as the exanthem is fading. Fever reappears, and headache, meningismus, and lethargy progressing to coma may develop. Seizures are common. Signs of disseminated neurologic disease are consistently present (e.g., hemiparesis or quadriparesis, extensor plantar responses, lost or hyperactive tendon reflexes, sensory loss, and brainstem involvement). In ADEM due to chickenpox, cerebellar involvement is often conspicuous. CSF protein is modestly elevated (0.5–1.5 g/L [50–150 mg/dL]). Lymphocytic pleocytosis, generally ≥200 cells/μL, occurs in 80% of patients. Occasional patients have higher counts or a mixed polymorphonuclear-lymphocytic pattern during the initial days of the illness. Transient CSF oligoclonal banding was reported in a minority of cases. MRI usually reveals extensive changes in the brain and spinal cord, consisting of white matter hyperintensities on T2 and fluid-attenuated inversion recovery (FLAIR) sequences with gadolinium enhancement on T1-weighted sequences.

DIAGNOSIS

The diagnosis is most reliably established when there is a history of a recent infectious illness. In severe cases with predominantly cerebral involvement, acute encephalitis due to infection with herpes simplex or other viruses including HIV may be difficult to exclude; other considerations include hypercoagulable states including the antiphospholipid antibody syndrome, autoimmune (paraneoplastic) limbic encephalitis, vasculitis, sarcoidosis, primary CNS lymphoma, or metastatic cancer. An explosive presentation of MS can mimic ADEM, and especially in adults, it may not be possible to distinguish these conditions acutely. The simultaneous onset of disseminated symptoms and signs is common in ADEM and rare in MS. Similarly, meningismus, encephalopathy (drowsiness, stupor or coma), and seizures suggest ADEM rather than MS. Unlike MS, in ADEM, optic nerve involvement is generally bilateral and transverse myelopathy complete. MRI findings that favor ADEM include extensive and relatively symmetric white matter abnormalities, basal ganglia or cortical gray matter lesions, and gadolinium enhancement of all abnormal areas. In contrast, OCBs in the CSF are more common in MS. In one study of adult patients initially thought to have ADEM, 30% experienced additional relapses over a follow-up period of 3 years, and they were reclassified as having MS. Other patients initially classified as ADEM are subsequently found to have NMO, MOGAD, or GFAP autoimmunity. Occasional patients with "recurrent ADEM" have also been reported, especially children; however, it is not possible to distinguish this entity from atypical MS. Because of the clinical overlap at presentation between ADEM and MS, it is important that routine surveillance imaging be performed following recovery from ADEM so that subclinical disease activity due to MS can be recognized and treatment for MS initiated.

TREATMENT

Initial therapy is with high-dose glucocorticoids; depending on the response, treatment may need to be continued for 8 weeks. Patients who fail to respond within a few days may benefit from a course of plasma exchange or IV immunoglobulin. The prognosis reflects the severity of the underlying acute illness. In modern case series of presumptive ADEM in adults, mortality rates of 5–20% are reported, and many survivors have permanent neurologic sequelae.

Section 3 Nerve and Muscle Disorders

457 Peripheral Neuropathy

Anthony A. Amato, Richard J. Barohn

Peripheral nerves are composed of sensory, motor, and autonomic elements. Diseases can affect the cell body of a neuron or its peripheral processes, namely the axons or the encasing myelin sheaths. Most peripheral nerves are mixed and contain sensory and motor as well as autonomic fibers. Nerves can be subdivided into three major

classes: large myelinated, small myelinated, and small unmyelinated. Motor axons are usually large myelinated fibers that conduct rapidly (~50 m/s). Sensory fibers may be any of the three types. Large-diameter sensory fibers conduct proprioception and vibratory sensation to the brain, while the smaller-diameter myelinated and unmyelinated fibers transmit pain and temperature sensation. Autonomic nerves are also small in diameter. Thus, peripheral neuropathies can impair sensory, motor, or autonomic function, either singly or in combination. Peripheral neuropathies are further classified into those that primarily affect the cell body (e.g., neuronopathy or ganglionopathy), myelin (myelinopathy), and the axon (axonopathy). These different classes of peripheral neuropathies have distinct clinical and electrophysiologic features. This chapter discusses the clinical approach to a patient suspected of having a peripheral neuropathy, as well as specific neuropathies, including hereditary and acquired neuropathies. **The inflammatory neuropathies are discussed in Chap. 458.**

GENERAL APPROACH

In approaching a patient with a neuropathy, the clinician has three main goals: (1) identify where the lesion is, (2) identify the cause, and (3) determine the proper treatment. The first goal is accomplished by obtaining a thorough history, neurologic examination, and electrodiagnostic and other laboratory studies **(Fig. 457-1)**. While gathering this information, seven key questions are asked **(Table 457-1)**, the answers to which help identify the pattern of involvement and the cause of the neuropathy **(Table 457-2)**. Despite an extensive evaluation, in approximately half of patients, no etiology is ever found; these patients typically have a predominately sensory polyneuropathy and have been labeled as having idiopathic or cryptogenic sensory and sensorimotor polyneuropathy (CSPN).

INFORMATION FROM THE HISTORY AND PHYSICAL EXAMINATION: SEVEN KEY QUESTIONS (TABLE 457-1)

1. What Systems Are Involved? It is important to determine if the patient's symptoms and signs are motor, sensory, autonomic, or a combination of these. If the patient has only weakness without any evidence of sensory or autonomic dysfunction, a motor neuropathy, neuromuscular junction abnormality, or myopathy should be considered. Some peripheral neuropathies are associated with significant autonomic nervous system dysfunction. Symptoms of autonomic involvement include fainting spells or orthostatic lightheadedness; heat intolerance; or any bowel, bladder, or sexual dysfunction **(Chap. 451)**. There will typically be an orthostatic fall in blood pressure without an appropriate increase in heart rate. Autonomic dysfunction in the absence of diabetes should alert the clinician to the possibility of amyloid polyneuropathy. Rarely, a pandysautonomic syndrome can be the only manifestation of a peripheral neuropathy without other motor or sensory findings. The majority of neuropathies are predominantly sensory in nature.

2. What Is the Distribution of Weakness? Delineating the pattern of weakness, if present, is essential for diagnosis, and in this regard, two additional questions should be answered: (1) Does the weakness only involve the distal extremity, or is it both proximal and distal? and (2) Is the weakness focal and asymmetric, or is it symmetric? Symmetric proximal and distal weakness is the hallmark of acquired immune demyelinating polyneuropathies, both the acute form (Guillain-Barré syndrome [GBS]) and the chronic form (chronic inflammatory demyelinating polyneuropathy [CIDP]) **(Chap. 458)**. The importance of finding symmetric proximal and distal weakness in a patient who presents with both motor and sensory symptoms cannot

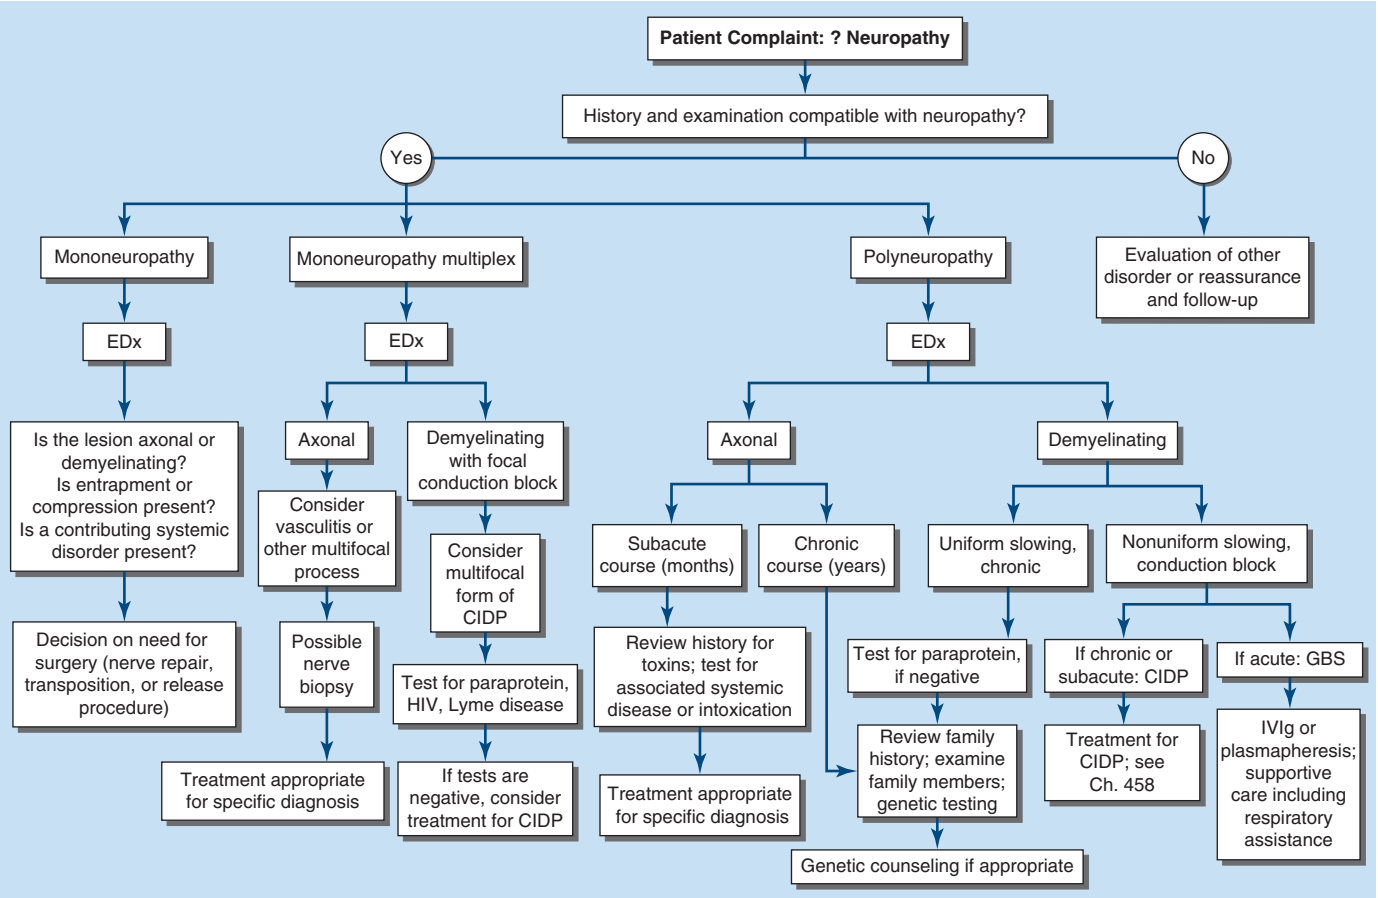

FIGURE 457-1 Approach to the evaluation of peripheral neuropathies. CIDP, chronic inflammatory demyelinating polyradiculoneuropathy; EDx, electrodiagnostic; GBS, Guillain-Barré syndrome; IVIg, intravenous immunoglobulin.

TABLE 457-1 Approach to Neuropathic Disorders: Seven Key Questions

1. **What systems are involved?**
   - Motor, sensory, autonomic, or combinations
2. **What is the distribution of weakness?**
   - Only distal versus proximal and distal
   - Focal/asymmetric versus symmetric
3. **What is the nature of the sensory involvement?**
   - Temperature loss or burning or stabbing pain (e.g., small fiber)
   - Vibratory or proprioceptive loss (e.g., large fiber)
4. **Is there evidence of upper motor neuron involvement?**
   - Without sensory loss
   - With sensory loss
5. **What is the temporal evolution?**
   - Acute (days to 4 weeks)
   - Subacute (4–8 weeks)
   - Chronic (>8 weeks)
   - Monophasic, progressive, or relapsing-remitting
6. **Is there evidence for a hereditary neuropathy?**
   - Family history of neuropathy
   - Lack of sensory symptoms despite sensory signs
7. **Are there any associated medical conditions?**
   - Cancer, diabetes mellitus, connective tissue disease or other autoimmune diseases, infection (e.g., HIV, Lyme disease, leprosy)
   - Medications including over-the-counter drugs that may cause a toxic neuropathy
   - Preceding events, drugs, toxins

be overemphasized because this identifies the important subset of patients who may have a treatable acquired demyelinating neuropathic disorder (i.e., GBS or CIDP).

Findings of an asymmetric or multifocal pattern of weakness narrow the differential diagnosis. Some neuropathic disorders may present with unilateral extremity weakness. In the absence of sensory symptoms and signs, such weakness evolving over weeks or months would be worrisome for motor neuron disease (e.g., amyotrophic lateral sclerosis [ALS]), but it would be important to exclude multifocal motor neuropathy that may be treatable **(Chap. 458)**. In a patient presenting with asymmetric subacute or acute sensory and motor symptoms and signs, radiculopathies, plexopathies, compressive mononeuropathies, or multiple mononeuropathies (e.g., mononeuropathy multiplex) must be considered.

ALS **(Chap. 448)** can produce prominent neck extensor weakness (head drop), tongue and pharyngeal weakness (dysarthria and dysphagia), or shortness of breath. These focal symmetric weakness patterns can also be seen in neuromuscular junction disorders (myasthenia gravis, Lambert-Eaton myasthenic syndrome [LEMS] **[Chap. 459]**) and some myopathies, particularly isolated neck extensor myopathy **(Chap. 460)**.

3. What Is the Nature of the Sensory Involvement? The patient may have loss of sensation (numbness), altered sensation to touch (hyperpathia or allodynia), or uncomfortable spontaneous sensations (tingling, burning, or aching) **(Chap. 27)**. Neuropathic pain can be burning, dull, and poorly localized (protopathic pain), presumably transmitted by polymodal C nociceptor fibers, or sharp and lancinating (epicritic pain), relayed by A-delta fibers. If pain and temperature perception are lost, while vibratory and position sense are preserved along with muscle strength, deep tendon reflexes, and normal nerve conduction studies (NCS), a small-fiber neuropathy is likely. The most likely causes of small-fiber neuropathies, when one is identified, are diabetes mellitus (DM) or glucose intolerance. Amyloid neuropathy should be considered as well in such cases, but most of these small-fiber neuropathies remain idiopathic despite extensive evaluation.

Severe proprioceptive loss also narrows the differential diagnosis. Affected patients will note imbalance, especially in the

TABLE 457-2 Patterns of Neuropathic Disorders

Pattern 1: Symmetric proximal and distal weakness with sensory loss
Consider: inflammatory demyelinating polyneuropathy (GBS and CIDP)

Pattern 2: Symmetric distal sensory loss with or without distal weakness
Consider: cryptogenic or idiopathic sensory polyneuropathy (CSPN), diabetes mellitus and other metabolic disorders, drugs, toxins, familial (HSAN), CMT, amyloidosis, CANVAS, SORD neuropathy, and others

Pattern 3: Asymmetric distal weakness with sensory loss
With involvement of multiple nerves
Consider: multifocal CIDP, vasculitis, cryoglobulinemia, amyloidosis, sarcoid, infectious (leprosy, Lyme, hepatitis B, C, or E, HIV, CMV), HNPP, tumor infiltration
With involvement of single nerves/regions
Consider: may be any of the above but also could be compressive mononeuropathy, plexopathy, or radiculopathy

Pattern 4: Asymmetric proximal and distal weakness with sensory loss
Consider: polyradiculopathy or plexopathy due to diabetes mellitus, meningeal carcinomatosis or lymphomatosis, sarcoid, amyloid, hereditary plexopathy (HNPP, HNA), idiopathic

Pattern 5: Asymmetric distal weakness without sensory loss
With upper motor neuron findings
Consider: motor neuron disease
Without upper motor neuron findings
Consider: progressive muscular atrophy, juvenile monomelic amyotrophy (Hirayama's disease), multifocal motor neuropathy, multifocal acquired motor axonopathy

Pattern 6: Symmetric sensory loss and distal areflexia with upper motor neuron findings
Consider: vitamin B_{12}, vitamin E, and copper deficiency with combined system degeneration with peripheral neuropathy, chronic liver disease, hereditary leukodystrophies (e.g., adrenomyeloneuropathy), HSP-plus

Pattern 7: Symmetric weakness without sensory loss
With proximal and distal weakness
Consider: SMA
With distal weakness
Consider: hereditary motor neuropathy ("distal" SMA) or atypical CMT

Pattern 8: Focal midline proximal symmetric weakness
Neck extensor weakness
Consider: ALS
Bulbar weakness
Consider: ALS/PLS, isolated bulbar ALS (IBALS), Kennedy's syndrome (X-linked, bulbospinal SMA), bulbar presentation GBS
Diaphragm weakness (SOB)
Consider: ALS

Pattern 9: Asymmetric proprioceptive sensory loss without weakness
Consider causes of a sensory neuronopathy (ganglionopathy):
Cancer (paraneoplastic)
CANVAS
Sjögren's syndrome
Idiopathic sensory neuronopathy (possible GBS variant)
Cisplatin and other chemotherapeutic agents
Vitamin B_6 toxicity
HIV-related sensory neuronopathy

Pattern 10: Autonomic symptoms and signs
Consider neuropathies associated with prominent autonomic dysfunction:
Hereditary sensory and autonomic neuropathy
Amyloidosis (familial and acquired)
Diabetes mellitus
GBS
Idiopathic pandysautonomia (may be a variant of GBS)
Porphyria
HIV-related autonomic neuropathy
Vincristine and other chemotherapeutic agents

Abbreviations: ALS, amyotrophic lateral sclerosis; CIDP, chronic inflammatory demyelinating polyneuropathy; CANVAS, cerebellar ataxia, neuropathy, and vestibular areflexia syndrome; CMT, Charcot-Marie-Tooth disease; CMV, cytomegalovirus; GBS, Guillain-Barré syndrome; HIV, human immunodeficiency virus; HNA, hereditary neuralgic amyotrophy; HNPP, hereditary neuropathy with liability to pressure palsies; HSAN, hereditary sensory and autonomic neuropathy; HSP-plus, hereditary spastic paraplegia plus neuropathy; PLS, primary lateral sclerosis; SMA, spinal muscular atrophy; SOB, shortness of breath; SORD, sorbitol dehydrogenase deficiency.

dark. A neurologic examination revealing a dramatic loss of proprioception with vibration loss and normal strength should alert the clinician to consider a sensory neuronopathy/ganglionopathy (Pattern 9, Table 457-2). In particular, if this loss is asymmetric or affects the arms more than the legs, this pattern suggests a non-length-dependent process as seen in sensory neuronopathies.

4. Is There Evidence of Upper Motor Neuron Involvement? If the patient presents with symmetric distal sensory symptoms and signs suggestive of a distal sensory neuropathy, but there is additional evidence of symmetric upper motor neuron involvement **(Chap. 26)**, the physician should consider a combined system degeneration with neuropathy. The most common cause for this pattern is vitamin B_{12} deficiency, but other etiologies should also be considered (e.g., copper deficiency, human immunodeficiency virus [HIV] infection, severe hepatic disease, adrenomyeloneuropathy [AMN]), and hereditary spastic paraplegia plus a neuropathy.

5. What Is the Temporal Evolution? It is important to determine the onset, duration, and evolution of symptoms and signs. Does the disease have an acute (days to 4 weeks), subacute (4–8 weeks), or chronic (>8 weeks) course? Is the course monophasic, progressive, or relapsing? Most neuropathies are insidious and slowly progressive in nature. Neuropathies with acute and subacute presentations include GBS, vasculitis, and radiculopathies related to diabetes or Lyme disease. A relapsing course can be present in CIDP and porphyria.

6. Is There Evidence for a Hereditary Neuropathy? In patients with slowly progressive distal weakness over many years with few sensory symptoms yet significant sensory deficits on clinical examination, the clinician should consider a hereditary neuropathy (e.g., Charcot-Marie-Tooth disease [CMT]). On examination, the feet may show high or flat arches or hammer toes, and scoliosis may be present. In suspected cases, it may be necessary to perform neurologic and electrophysiologic studies on family members in addition to the patient.

7. Does the Patient Have Any Other Medical Conditions? It is important to inquire about associated medical conditions (e.g., DM, systemic lupus erythematosus [SLE]); preceding or concurrent infections (e.g. diarrheal illness preceding GBS); surgeries (e.g., gastric bypass and nutritional neuropathies); medications (toxic neuropathy), including over-the-counter vitamin preparations (B_6); alcohol; dietary habits; and use of dentures (e.g., fixatives contain zinc that can lead to copper deficiency).

PATTERN RECOGNITION APPROACH TO NEUROPATHIC DISORDERS

Based on the answers to the seven key questions, neuropathic disorders can be classified into several patterns based on the distribution or pattern of sensory, motor, and autonomic involvement (Table 457-2). Each pattern has a limited differential diagnosis, and information from laboratory studies usually permits a final diagnosis to be established.

ELECTRODIAGNOSTIC STUDIES

The electrodiagnostic (EDx) evaluation of patients with a suspected peripheral neuropathy consists of NCS and needle electromyography (EMG). In addition, studies of autonomic function can be valuable. The electrophysiologic data can confirm whether the neuropathic disorder is a mononeuropathy, multiple mononeuropathy (mononeuropathy multiplex), radiculopathy, plexopathy, or generalized polyneuropathy. Similarly, EDx evaluation can ascertain whether the process involves only sensory fibers, motor fibers, autonomic fibers, or a combination of these. Finally, the electrophysiologic data can help distinguish axonopathies from myelinopathies as well as axonal degeneration secondary to ganglionopathies from the more common length-dependent axonopathies.

NCS are most helpful in classifying a neuropathy as due to axonal degeneration or segmental demyelination **(Table 457-3)**. In general, low-amplitude potentials with relatively preserved distal latencies, conduction velocities, and late potentials, along with fibrillations on needle EMG, suggest an axonal neuropathy. On the other hand, slow conduction velocities, prolonged distal latencies and late potentials, relatively preserved amplitudes, and the absence of fibrillations on needle EMG imply a primary demyelinating neuropathy. The presence of nonuniform slowing of conduction velocity, conduction block, or temporal dispersion further suggests an acquired demyelinating neuropathy (e.g., GBS or CIDP) as opposed to a hereditary demyelinating neuropathy (e.g., CMT type 1).

Autonomic studies are used to assess small myelinated (A-delta) or unmyelinated (C) nerve fiber involvement. Such testing includes heart rate response to deep breathing, heart rate and blood pressure response to both the Valsalva maneuver and tilt-table testing, and quantitative sudomotor axon reflex testing **(Chap. 451)**. These studies are particularly useful in patients who have pure small-fiber neuropathy or autonomic neuropathy in which routine NCS are normal.

TABLE 457-3 Electrophysiologic Features: Axonal Degeneration versus Segmental Demyelination

	AXONAL DEGENERATION	SEGMENTAL DEMYELINATION
Motor Nerve Conduction Studies		
CMAP amplitude	Decreased	Normal (except with CB or distal dispersion)
Distal latency	Normal	Prolonged
Conduction velocity	Normal	Slow
Conduction block	Absent	Present
Temporal dispersion	Absent	Present
F wave	Normal or absent	Prolonged or absent
H reflex	Normal or absent	Prolonged or absent
Sensory Nerve Conduction Studies		
SNAP amplitude	Decreased	Normal or decreased
Distal latency	Normal	Prolonged
Conduction velocity	Normal	Slow
Needle EMG		
Spontaneous activity		
Fibrillations	Present	Absent
Fasciculations	Present	Absent
Motor unit potentials		
Recruitment	Decreased	Decreased
Morphology	Long duration, large amplitude, polyphasic (if there is reinnervation)	Normal

Abbreviations: CB, conduction block; CMAP, compound motor action potential; EMG, electromyography; SNAP, sensory nerve action potential.

OTHER IMPORTANT LABORATORY INFORMATION

In patients with generalized symmetric peripheral neuropathy, a standard laboratory evaluation should include a complete blood count, basic chemistries including serum electrolytes and tests of renal and hepatic function, fasting blood glucose (FBS), hemoglobin (Hb) A_{1c}, thyroid function tests, B_{12}, folate, erythrocyte sedimentation rate (ESR), rheumatoid factor, antinuclear antibodies (ANA), serum protein electrophoresis (SPEP) and immunoelectrophoresis or immunofixation, and free light chains in serum and urine. Quantification of the concentration of serum-free light chains and the kappa/lambda ratio is more sensitive than SPEP, immunoelectrophoresis, or immunofixation to detect a monoclonal gammopathy and therefore should be done if amyloidosis is suspected. A skeletal survey should be performed in patients with acquired demyelinating neuropathies and M-spikes to look for osteosclerotic or lytic lesions. Patients with monoclonal gammopathy should also be referred to a hematologist for consideration of a bone marrow biopsy. An oral glucose tolerance test is indicated in patients with painful sensory neuropathies even if FBS and HbA_{1c} are normal, as the test is abnormal in about one-third of such patients. In addition to the above tests, patients with a mononeuropathy multiplex

pattern of involvement should have a vasculitis workup, including antineutrophil cytoplasmic antibodies (ANCAs), cryoglobulins, hepatitis serology, Western blot for Lyme disease, HIV, and occasionally a cytomegalovirus (CMV) titer.

There are many autoantibody panels (various antiganglioside antibodies) marketed for screening routine neuropathy patients for a treatable condition. These autoantibodies have no proven clinical utility or added benefit beyond the information obtained from a complete clinical examination and detailed EDx. A heavy metal screen is also not necessary as a screening procedure, unless there is a history of possible exposure or suggestive features on examination (e.g., severe painful sensorimotor and autonomic neuropathy and alopecia—thallium; severe painful sensorimotor neuropathy with or without gastrointestinal [GI] disturbance and Mee's lines—arsenic; wrist or finger extensor weakness and anemia with basophilic stippling of red blood cells—lead).

In patients with suspected GBS or CIDP, a lumbar puncture is indicated to look for an elevated cerebrospinal fluid (CSF) protein. In idiopathic cases of GBS and CIDP, CSF pleocytosis is usually absent. If cells are present, one should consider HIV infection, Lyme disease, sarcoidosis, or lymphomatous or leukemic infiltration of nerve roots. Recently, serum IgG4 antibodies to neurofascin and contactin-2 have been discovered in CIDP with severe sensory ataxia, tremor, and distal weakness **(Chap. 458)**. These cases are difficult to treat with standard immunotherapies but may respond to rituximab. Some patients with GBS and CIDP have abnormal liver function tests. In these cases, it is important to also check for hepatitis B and C, HIV, CMV, and Epstein-Barr virus (EBV) infection. In patients with an axonal GBS (by EMG/NCS) or those with a suspicious coinciding history (e.g., unexplained abdominal pain, psychiatric illness, significant autonomic dysfunction), it is reasonable to screen for porphyria.

In patients with a severe sensory ataxia, a sensory ganglionopathy or neuronopathy should be considered. The most common causes of sensory ganglionopathies are Sjögren's syndrome **(Chap. 373)** and a paraneoplastic neuropathy **(Chap. 99)**. Neuropathy can be the initial manifestation of Sjögren's syndrome. Thus, one should always inquire about dry eyes and mouth in patients with sensory signs and symptoms. Further, some patients can manifest sicca complex without other manifestations of Sjögren's syndrome. Thus, patients with sensory ataxia should be tested for antibodies to SS-A/Ro and SS-B/La, in addition to the routine ANA. To evaluate a possible paraneoplastic sensory ganglionopathy, antineuronal nuclear antibodies (e.g., anti-Hu antibodies) should be obtained. These antibodies are most commonly seen in patients with small-cell carcinoma of the lung but are also present with breast, ovarian, lymphoma, and other cancers. Importantly, the paraneoplastic neuropathy can precede the detection of the cancer, and detection of these autoantibodies should lead to a search for malignancy.

NERVE BIOPSIES

Nerve biopsies are now rarely performed in the evaluation of neuropathies. The primary indication for nerve biopsy is suspicion for amyloid neuropathy or vasculitis. In most instances, the abnormalities present on biopsies do not help distinguish one form of peripheral neuropathy from another (beyond what is already apparent by clinical examination and the NCS). Nerve biopsies should only be performed when the NCS are abnormal. The sural nerve is most commonly biopsied because it is a pure sensory nerve and biopsy will not result in loss of motor function. In suspected vasculitis, a combination biopsy of a superficial peroneal nerve (pure sensory) and the underlying peroneus brevis muscle obtained from a single small incision increases the diagnostic yield. Tissue can be analyzed to assess for evidence of inflammation, vasculitis, or amyloid deposition. Semithin plastic sections, teased fiber preparations, and electron microscopy are used to assess the morphology of the nerve fibers and to distinguish axonopathies from myelinopathies.

SKIN BIOPSIES

Skin biopsies are sometimes used to diagnose a small-fiber neuropathy. Following a punch biopsy of the skin in the distal lower extremity, immunologic staining can be used to measure the density of small unmyelinated fibers. The density of these nerve fibers is reduced in patients with small-fiber neuropathies in whom NCS and routine nerve biopsies are often normal. This technique may allow for an objective measurement in patients with mainly subjective symptoms. However, it often adds little to what one already knows from the clinical examination and EDx.

SPECIFIC DISORDERS

HEREDITARY NEUROPATHIES

CMT disease is the most common type of hereditary neuropathy (Pattern 2, Table 457-2). Rather than one disease, CMT is a syndrome of many genetically distinct disorders **(Table 457-4)**. The various subtypes of CMT are classified according to the nerve conduction velocities (NCVs) and predominant pathology (e.g., demyelination or axonal degeneration), inheritance pattern (autosomal dominant, autosomal recessive, or X-linked), and the specific mutated genes. Type 1 CMT (or CMT1) refers to inherited demyelinating sensorimotor neuropathies, whereas the axonal sensory neuropathies are classified as CMT2. By definition, motor conduction velocities in the arms are slowed to <38 m/s in CMT1 and are >38 m/s in CMT2. However, most cases of CMT1 actually have motor NCVs between 20 and 25 m/s. CMT1 and CMT2 usually begin in childhood or early adult life; however, onset later in life can occur, particularly in CMT2. Both are inherited in an autosomal dominant fashion, with a few exceptions. There are no medical therapies for any of the CMTs, but physical and occupational therapy can be beneficial, as can bracing (e.g., ankle-foot orthotics for foot drop) and other orthotic devices.

CMT1

CMT1 is the most common form of hereditary neuropathy. Affected individuals usually present in the first to third decade of life with distal leg weakness (e.g., foot drop), although patients may remain asymptomatic even late in life. People with CMT generally do not complain of numbness or tingling, which can be helpful in distinguishing CMT from acquired forms of neuropathy in which sensory symptoms usually predominate. Although usually asymptomatic, reduced sensation to all modalities is apparent on examination. Muscle stretch reflexes are unobtainable or reduced throughout. There is often atrophy of the muscles below the knee (particularly the anterior compartment), leading to so-called inverted champagne bottle legs.

Motor NCVs are generally in the 20–25 m/s range. Nerve biopsies usually are not performed on patients suspected of having CMT1, because the diagnosis usually can be made by less invasive testing (e.g., NCS and genetic studies). However, when done, the biopsies reveal reduced numbers of myelinated nerve fibers with a predilection for loss of large-diameter fibers and Schwann cell proliferation around thinly or demyelinated fibers, forming so-called onion bulbs.

CMT1A is the most common subtype of CMT1, representing 70% of cases, and is caused by a 1.5-megabase (Mb) duplication within chromosome 17p11.2-12 encoding the gene for peripheral myelin protein-22 (PMP-22). This results in patients having three copies of the PMP-22 gene rather than two. This protein accounts for 2–5% of myelin protein and is expressed in compact regions of the peripheral myelin sheath. Approximately 20% of patients with CMT1 have CMT1B, caused by mutations in the myelin protein zero (MPZ). CMT1B is for the most part clinically, electrophysiologically, and histologically indistinguishable from CMT1A. MPZ is an integral myelin protein and accounts for more than half of the myelin protein in peripheral nerves. Other forms of CMT1 are much less common and also indistinguishable from one another clinically and electrophysiologically (Table 457-4).

CMT2

CMT2 occurs approximately half as frequently as CMT1, and CMT2 tends to present later in life. Affected individuals usually become symptomatic in the second decade; some cases present earlier in childhood, whereas others remain asymptomatic into late adult life. Clinically, CMT2 is for the most part indistinguishable from CMT1. NCS are helpful in this regard; in contrast to CMT1, the velocities are normal or

Abbreviations: AARS, alanyl-tRNA synthetase; AD, autosomal dominant; AR, autosomal recessive; ATL, atlastin; CANVAS, cerebellar ataxia, neuropathy, and vestibular areflexia syndrome; CMT, Charcot-Marie-Tooth; DNMT1, DNA methyltransferase 1; DYS, dystonin; DYNC1HI, cytoplasmic dynein 1 heavy chain 1; ELP1, elongator complex protein 1; ERG2, early growth response-2 protein; FAM134B, family with sequence similarity 134, member B; FIG4, FDG1-related F actin-binding protein; GDAP1, ganglioside-induced differentiation-associated protein-1; HK1, hexokinase 1; HMSN-P, hereditary motor and sensory neuropathy proximal; HNA, hereditary neuralgic amyotrophy; HNPP, hereditary neuropathy with liability to pressure palsies; HSAN, hereditary sensory and autonomic neuropathy; IFN2, inverted formin-2; IKBKAP, $_{k}$B kinase complex-associated protein; LGMD, limb girdle muscular dystrophy; LITAF, lipopolysaccharide-induced tumor necrosis factor α factor; LRSAM1, E3 ubiquitin-protein ligase; MED25, mediator 25; MFN2, mitochondrial fusion protein mitofusin 2 gene; MPZ, myelin protein zero protein; MTMR2, myotubularin-related protein-2; NDRG1, N-myc downstream regulated 1; NGF, Beta-nerve growth factor; NTRK, 1trkA/NGF receptor; PMP-22, peripheral myelin protein-22; PRKWNK1, protein kinase, lysine deficient 1; PRPS1, phosphoribosylpyrophosphate synthetase 1; RAB7, Ras-related protein 7; RFC1, replication factor C subunit 1; SEPT9, septin 9; SH3TC2, SH3 domain and tetratricopeptide repeats 2; SMA, spinal muscular atrophy; SORD, sorbitol dehydrogenase; SPTLC, serine palmitoyltransferase long-chain base; TFG, TRK-fused gene; TrkA/NGF, tyrosine kinase A/nerve growth factor; tRNA, transfer ribonucleic acid; TRPV4, transient receptor potential cation channel, subfamily V, member 4; WNK1, WNK lysine deficient; YARS, tyrosyl-tRNA synthetase.

Source: Modified from AA Amato, J Russell: *Neuromuscular Disorders,* 2nd ed. New York, McGraw-Hill, 2016, Table 11-1, pp. 265–266.

only slightly slowed. The most common cause of CMT2 is a mutation in the gene for mitofusin 2 (MFN2), which accounts for ~20–30% of CMT2 cases overall. MFN2 localizes to the outer mitochondrial membrane, where it regulates the mitochondrial network architecture by participating in mitochondrial fusion. The other genes associated with CMT2 are much less common (Table 457-4).

CMT DOMINANT AND RECESSIVE INTERMEDIATE

In CMT dominant-intermediate (CMT-DI) and CMT recessive-intermediate (CMT-RI), the NCVs are faster than usually seen in CMT1 (e.g., >38 m/s) but slower than in CMT2 (Table 457-4).

CMT3

CMT3 was originally described by Dejerine and Sottas as a hereditary demyelinating sensorimotor polyneuropathy presenting in infancy or early childhood. Affected children are severely weak. Motor NCVs are markedly slowed, typically ≤5–10 m/s. Most cases of CMT3 are caused by point mutations in the genes for PMP-22, MPZ, or ERG-2, which are also the genes responsible for CMT1. The term *CMT3* is no longer recommended, but rather, the neuropathy is classified as CMT1 if autosomal dominant or as CMT4 in cases of autosomal recessive inheritance.

CMT4

CMT4 is extremely rare and is characterized by a severe, childhood-onset sensorimotor polyneuropathy that is usually inherited in an autosomal recessive fashion. Electrophysiologic and histologic evaluations can show demyelinating or axonal features. CMT4 is genetically heterogeneous (Table 457-4).

CMTX

There are several forms of X-linked CMT, the most common type is CMTX1 (Table 457-4). This shares clinical features similar to CMT1 and CMT2, except that the neuropathy is much more severe in males than in females. CMT1X accounts for ~10–15% of CMT overall. Males usually present in the first two decades of life with atrophy and weakness of the distal arms and legs, areflexia, pes cavus, and hammer toes. Obligate female carriers are frequently asymptomatic but can develop signs and symptoms of CMT. Onset in females is usually after the second decade of life, and the neuropathy is milder in severity.

NCS reveal features of both demyelination and axonal degeneration. In males, motor NCVs in the arms and legs are moderately slowed (in the low to mid 30-m/s range). About 50% of males with CMTX1 have motor NCVs between 15 and 35 m/s with ~80% of these falling between 25 and 35 m/s (intermediate slowing). In contrast, ~80% of females with CMTX1 have NCVs in the normal range and 20% have NCVs in the intermediate range. CMT1X is caused by mutations in *GJB1*, which encodes for gap junction protein-beta or connexin-32. Connexins are gap junction structural proteins that are important in cell-to-cell communication.

Hereditary Neuropathy with Liability to Pressure Palsies (HNPP) HNPP is an autosomal dominant disorder related to CMT1A. While CMT1A is usually associated with a 1.5-Mb duplication in chromosome 17p11.2 that results in an extra copy of the PMP-22 gene, HNPP is caused by inheritance of the chromosome with the corresponding 1.5-Mb deletion of this segment, and thus, affected individuals have only one copy of the PMP-22 gene. Patients usually manifest in the second or third decade of life with painless numbness and weakness in the distribution of single peripheral nerves, although multiple mononeuropathies can occur (Pattern 3, Table 457-2). Symptomatic mononeuropathy or multiple mononeuropathies are often precipitated by trivial compression of nerve(s) as can occur with wearing a backpack, leaning on the elbows, or crossing one's legs for even a short period of time. These pressure-related mononeuropathies may take weeks or months to resolve. In addition, some affected individuals manifest with a progressive or relapsing, generalized and symmetric, sensorimotor peripheral neuropathy that resembles CMT.

Hereditary Neuralgic Amyotrophy (HNA) HNA is an autosomal dominant disorder characterized by recurrent attacks of pain, weakness, and sensory loss in the distribution of the brachial plexus often beginning in childhood (Pattern 4, Table 457-2). These attacks are similar to those seen with idiopathic brachial plexitis (see below). Attacks may occur in the postpartum period, following surgery, or at other times of stress. Most patients recover over several weeks or months. Slightly dysmorphic features, including hypotelorism, epicanthal folds, cleft palate, syndactyly, micrognathia, and facial asymmetry, are evident in some individuals. EDx demonstrate an axonal process. HNA is genetically heterogeneous but can be caused by mutations in septin 9 (*SEPT9*). Septins may be important in formation of the neuronal cytoskeleton and have a role in cell division, but it is not known how mutations in *SEPT9* lead to HNA.

Hereditary Sensory and Autonomic Neuropathy (HSAN) The HSANs are a very rare group of hereditary neuropathies in which sensory and autonomic dysfunction predominates over muscle weakness, unlike CMT, in which motor findings are most prominent (Pattern 2, Table 457-2; Table 457-4). Nevertheless, affected individuals can develop motor weakness, and there can be overlap with CMT. There are no medical therapies available to treat these neuropathies, other than prevention and treatment of mutilating skin and bone lesions.

Of the HSANs, only HSAN1 typically presents in adults. HSAN1 is the most common of the HSANs and is inherited in an autosomal dominant fashion. Affected individuals usually manifest in the second through fourth decades of life. HSAN1 is associated with the degeneration of small myelinated and unmyelinated nerve fibers leading to severe loss of pain and temperature sensation, deep dermal ulcerations, recurrent osteomyelitis, Charcot joints, bone loss, gross foot and hand deformities, and amputated digits. Although most people with HSAN1 do not complain of numbness, they often describe burning, aching, or lancinating pains. Autonomic neuropathy is not a prominent feature, but bladder dysfunction and reduced sweating in the feet may occur. HSAN1A, which is most common, is caused by mutations in the serine palmitoyltransferase long-chain base 1 (*SPTLC1*) gene.

OTHER HEREDITARY NEUROPATHIES (TABLE 457-5)

SORBITAL DEHYDROGENASE DEFICIENCY WITH PERIPHERAL NEUROPATHY

Sorbitol dehydrogenase deficiency with peripheral neuropathy (SORD) is a newly reported entity that is very important as it appears to be the most common autosomal recessive inherited form of neuropathy. It presents as a slowly progressive, length-dependent, axonal motor greater than sensory polyneuropathy or pure motor neuropathy. Age of onset is usually in the late teens. It is caused by pathogenic mutations in the *SORD* gene. SORD is the second enzyme of the two-step polyol pathway whereby glucose is metabolized into sorbitol, and then SORD oxidizes sorbitol into fructose. Sorbitol is a relatively nonmetabolizable sugar, and levels are markedly increased.

FABRY'S DISEASE

Fabry's disease (angiokeratoma corporis diffusum) is an X-linked dominant disorder. Although men are more commonly and severely affected, women can also manifest symptoms and signs of the disease. Angiokeratomas are reddish-purple maculopapular lesions that are usually found around the umbilicus, scrotum, inguinal region, and perineum. Burning or lancinating pain in the hands and feet often develops in males in late childhood or early adult life (Pattern 2, Table 457-2). However, the neuropathy is usually overshadowed by complications arising from an associated premature atherosclerosis (e.g., hypertension, renal failure, cardiac disease, and stroke) that often lead to death by the fifth decade of life. Some patients also manifest primarily with a dilated cardiomyopathy.

Fabry's disease is caused by mutations in the α-galactosidase gene that lead to the accumulation of ceramide trihexoside in nerves and

blood vessels. A decrease in α-galactosidase activity is evident in leukocytes and cultured fibroblasts. Glycolipid granules may be appreciated in ganglion cells of the peripheral and sympathetic nervous systems and in perineurial cells. Enzyme replacement therapy (ERT) may improve the neuropathy if patients are treated early, before irreversible nerve fiber loss develops. Current U.S. Food and Drug Administration (FDA)-approved recombinant ERTs are agalsidase-α (Replagal; 0.2 mg/kg body weight) and agalsidase-β (Fabrazyme; 1 mg/kg body weight) and pegunigalsidase (Elfabrio), which are each given intravenously every 2 weeks. In addition, migalastat is an oral pharmacologic chaperone that increases the enzyme activity of "amenable" mutations (defined as those mutations in the catalytic domain of the enzyme that lead to misfolding of the enzyme but otherwise would not significantly impair its function). Such mutations occur in ~50% of patients. Migalastat had been shown to reduce left ventricular mass and stabilize kidney function, but studies have not assessed if the neuropathy improves or stabilizes.

ADRENOLEUKODYSTROPHY/ ADRENOMYELONEUROPATHY

Adrenoleukodystrophy (ALD) and AMN are allelic X-linked dominant disorders caused by mutations in the peroxisomal transmembrane adenosine triphosphate-binding cassette (ABC) transporter gene. Patients with ALD manifest with central nervous system (CNS) abnormalities. However, ~30% of patients with mutations in this gene present with the AMN phenotype that typically manifests in the third to fifth decade of life as mild to moderate peripheral neuropathy combined with progressive spastic paraplegia (Pattern 6, Table 457-2) **(Chap. 453)**. Rare patients present with an adult-onset spinocerebellar ataxia or only with adrenal insufficiency.

EDx is suggestive of a primary axonopathy with secondary demyelination. Nerve biopsies demonstrate a loss of myelinated and unmyelinated nerve fibers with lamellar inclusions in the cytoplasm of Schwann cells. Very-long-chain fatty acid (VLCFA) levels (C24, C25, and C26) are increased in the urine. Laboratory evidence of adrenal insufficiency is evident in approximately two-thirds of patients. The diagnosis can be confirmed by genetic testing.

Adrenal insufficiency is managed by replacement therapy; however, there is no proven effective therapy for the neurologic manifestations of ALD/AMN. Diets low in VLCFAs and supplemented with Lorenzo's oil (erucic and oleic acids) reduce the levels of VLCFAs and increase the levels of C22 in serum, fibroblasts, and liver; however, several large, open-label trials of Lorenzo's oil failed to demonstrate efficacy. Although allogeneic bone marrow transplantation and gene therapy have been successful in slowing progression of cognitive decline in some patients with ALD treated early in their disease, these approaches are ineffective for the myelopathy or neuropathy.

REFSUM'S DISEASE

Refsum's disease can manifest in infancy to early adulthood with the classic tetrad of (1) peripheral neuropathy, (2) retinitis pigmentosa, (3) cerebellar ataxia, and (4) elevated CSF protein concentration. Most affected individuals develop progressive distal sensory loss and weakness in the legs leading to foot drop by their twenties (Pattern 2, Table 457-2). Subsequently, the proximal leg and arm muscles may become weak. Patients may also develop sensorineural hearing loss, cardiac conduction abnormalities, ichthyosis, and anosmia.

Serum phytanic acid levels are elevated. Sensory and motor NCS reveal reduced amplitudes, prolonged latencies, and slowed conduction velocities. Nerve biopsy demonstrates a loss of myelinated nerve fibers, with remaining axons often thinly myelinated and associated with onion bulb formation.

Refsum's disease is genetically heterogeneous but autosomal recessive in nature. Classical Refsum's disease with childhood or early adult onset is caused by mutations in the gene that encodes for phytanoyl-CoA α-hydroxylase (*PAHX*). Less commonly, mutations in the gene encoding peroxin 7 receptor protein (PRX7) are responsible. These mutations lead to the accumulation of phytanic acid in the central and peripheral nervous systems. Treatment is removal of phytanic precursors (phytols: fish oils, dairy products, and ruminant fats) from the diet.

TANGIER DISEASE

Tangier disease is a rare autosomal recessive disorder that can present as (1) asymmetric multiple mononeuropathies, (2) a slowly progressive symmetric polyneuropathy predominantly in the legs, or (3) a pseudo-syringomyelia pattern with dissociated sensory loss (i.e., abnormal pain/temperature perception but preserved position/vibration in the arms **[Chap. 453]**). The tonsils may appear swollen and yellowish-orange in color, and there may also be splenomegaly and lymphadenopathy.

Tangier disease is caused by mutations in the ATP-binding cassette transporter 1 (*ABC1*) gene, which leads to markedly reduced levels of high-density lipoprotein (HDL) cholesterol levels, whereas triacylglycerol levels are increased. Nerve biopsies reveal axonal degeneration with demyelination and remyelination. Electron microscopy demonstrates abnormal accumulation of lipid in Schwann cells, particularly those encompassing unmyelinated and small myelinated nerves. There is no specific treatment.

PORPHYRIA

Porphyria is a group of inherited disorders caused by defects in heme biosynthesis **(Chap. 428)**. Three forms of porphyria are associated with peripheral neuropathy: acute intermittent porphyria (AIP), hereditary coproporphyria (HCP), and variegate porphyria (VP). The acute neurologic manifestations are similar in each, with the exception that a photosensitive rash is seen with HCP and VP but not in AIP. Attacks of porphyria can be precipitated by certain drugs (usually those metabolized by the P450 system), hormonal changes (e.g., pregnancy, menstrual cycle), and dietary restrictions.

An acute attack of porphyria may begin with sharp abdominal pain. Subsequently, patients may develop agitation, hallucinations, or

seizures. Several days later, back and extremity pain followed by weakness ensues, mimicking GBS (Pattern 1, Table 457-2). Weakness can involve the arms or the legs and can be asymmetric, proximal, or distal in distribution, as well as affecting the face and bulbar musculature. Dysautonomia and signs of sympathetic overactivity are common (e.g., pupillary dilation, tachycardia, and hypertension). Constipation, urinary retention, and incontinence can also be seen.

The CSF protein is typically normal or mildly elevated. Liver function tests and hematologic parameters are usually normal. Some patients are hyponatremic due to inappropriate secretion of antidiuretic hormone **(Chap. 390)**. The urine may appear brownish in color secondary to the high concentration of porphyrin metabolites. Accumulation of intermediary precursors of heme (i.e., d-aminolevulinic acid, porphobilinogen, uroporphobilinogen, coproporphyrinogen, and protoporphyrinogen) is found in urine. Specific enzyme activities can also be measured in erythrocytes and leukocytes. The primary abnormalities on EDx are marked reductions in compound motor action potential (CMAP) amplitudes and signs of active axonal degeneration on needle EMG.

The porphyrias are inherited in an autosomal dominant fashion. AIP is associated with porphobilinogen deaminase deficiency, HCP is caused by defects in coproporphyrin oxidase, and VP is associated with protoporphyrinogen oxidase deficiency. The pathogenesis of the neuropathy is not completely understood. Treatment with glucose and hematin may reduce the accumulation of heme precursors. Intravenous glucose is started at a rate of 10–20 g/h. If there is no improvement within 24 h, intravenous hematin 2–5 mg/kg per day for 3–14 days should be administered. Givosiran is a small interfering RNA (siRNA) that neutralizes excess aminolevulinic acid (ALA) mRNA in hepatocytes for patients with recurrent attacks of acute intermittent porphyria. In clinical trials, givosiran 2.5 mg/kg subcutaneously per month led to reduced attack frequency, better daily pain scores for pain, improved quality of life, lower levels of urinary ALA and porphobilinogen, and fewer days of hematin compared with placebo.

CEREBELLAR ATAXIA, NEUROPATHY, AND VESTIBULAR AREFLEXIA SYNDROME (CANVAS)

Cerebellar ataxia, neuropathy, and vestibular areflexia syndrome (CANVAS) appears to be the most common cause of autosomal recessive ataxia. It usually manifests in middle adult life with a sensory neuropathy/neuronopathy that progresses over the course of 10–15 years to cerebellar and vestibular dysfunction, as well as a dry cough. Examination reveals loss of large-fiber sensory modalities with a sensory ataxia as well as cerebellar ataxia. The clinical spectrum is quite broad, however, and some patients manifest with upper and low motor neuron involvement (spasticity, brisk reflexes, muscle atrophy, and fasciculations) similar to amyotrophic lateral sclerosis. CANVAS can also present with dysautonomia and features of parkinsonism. NCS reveal low-amplitude or absent sensory responses that are in a non-length-dependent pattern, and EMG can show signs of active denervation and chronic reinnervation. Brain magnetic resonance imaging (MRI) scans can reveal cerebellar atrophy. Sural nerve biopsies have shown loss of large myelinated axons, and autopsy studies demonstrate degeneration of the dorsal root ganglia and posterior columns. In most cases, CANVAS is associated with biallelic $(AAGGG)_n$ repeat expansions in the second intron of the replication factor complex subunit 1 (*RFC1*). The is a DNA polymerase accessory protein required for the coordinated synthesis of both DNA strands during replication and after DNA damage.

FAMILIAL AMYLOID POLYNEUROPATHY

Familial amyloid polyneuropathy (FAP) is phenotypically and genetically heterogeneous and is caused by mutations in the genes for transthyretin (TTR), apolipoprotein A1, or gelsolin **(Chap. 117)**. The majority of patients with FAP have mutations in the TTR gene. Amyloid deposition may be evident in abdominal fat pad, rectal, or nerve biopsies. The clinical features, histopathology, and EDx reveal abnormalities consistent with a generalized or multifocal, predominantly axonal but occasionally demyelinating, polyneuropathy.

Patients with TTR-related FAP usually develop insidious onset of numbness and painful paresthesias in the distal lower limbs in the third to fourth decade of life, although some patients develop the disorder later in life (Pattern 2, Table 457-2). Carpal tunnel syndrome (CTS) is common. Autonomic involvement can be severe, leading to postural hypotension, constipation or persistent diarrhea, erectile dysfunction, and impaired sweating (Pattern 10, Table 457-2). Amyloid deposition also occurs in the heart, kidneys, liver, and corneas. Patients usually die 10–15 years after the onset of symptoms from cardiac failure or complications from malnutrition. Because the liver produces much of the body's TTR, liver transplantation has been used to treat FAP related to TTR mutations. Serum TTR levels decrease after transplantation, and improvement in clinical and EDx features has been reported. Both tafamidis meglumine (20 mg daily) and diflunisal (250 mg twice daily), which prevent misfolding and deposition of mutated TTR, appear to slow the rate of deterioration in patients with TTR-related FAP. Several forms of gene therapy are also now available. Randomized, placebo-controlled trials of antisense oligonucleotides, patisiran 0.3 mg/kg intravenous every 3 weeks, vutrisiran 25 mg subcutaneous every 3 months, and eplontersen 45 mg subcutaneous every 4 weeks, as well as the siRNA inotersen 300 mg subcutaneous weekly, have been shown to be effective in FAP related to TTR mutations. These drugs block expression of both mutant and wild-type TTR, reducing amyloid precursor protein synthesis.

Patients with apolipoprotein A1–related FAP (Van Allen type) usually present in the fourth decade with numbness and painful dysesthesias in the distal limbs. Gradually, the symptoms progress, leading to proximal and distal weakness and atrophy. Although autonomic neuropathy is not severe, some patients develop diarrhea, constipation, or gastroparesis. Most patients die from systemic complications of amyloidosis (e.g., renal failure) 12–15 years after the onset of the neuropathy.

Gelsolin-related amyloidosis (Finnish type) is characterized by the combination of lattice corneal dystrophy and multiple cranial neuropathies that usually begin in the third decade of life. Over time, a mild generalized sensorimotor polyneuropathy develops. Autonomic dysfunction does not occur.

ACQUIRED NEUROPATHIES

PRIMARY OR AL AMYLOIDOSIS (SEE CHAP. 117)

Besides FAP, amyloidosis can also be acquired. In primary or AL amyloidosis, the abnormal protein deposition is composed of immunoglobulin light chains. AL amyloidosis occurs in the setting of multiple myeloma (MM), Waldenström's macroglobulinemia, lymphoma, other plasmacytomas, or lymphoproliferative disorders, or without any other identifiable disease.

Approximately 30% of patients with AL primary amyloidosis present with a polyneuropathy, most typically painful dysesthesias and burning sensations in the feet (Pattern 2, Table 457-2). However, the trunk can be involved, and some patients manifest with a mononeuropathy multiplex pattern. CTS occurs in 25% of patients and may be the initial manifestation. The neuropathy is slowly progressive, and eventually, weakness develops along with large-fiber sensory loss. Most patients develop autonomic involvement with postural hypertension, syncope, bowel and bladder incontinence, constipation, impotence, and impaired sweating (Pattern 10, Table 457-2). Patients generally die from their systemic illness (renal failure, cardiac disease).

The monoclonal protein may be composed of IgG, IgA, IgM, or only free light chain. Lambda (λ) is more common than κ light chain (>2:1) in AL amyloidosis. The CSF protein is often increased (with normal cell count), and thus, the neuropathy may be mistaken for CIDP **(Chap. 458)**. Nerve biopsies reveal axonal degeneration and amyloid deposition in either a globular or diffuse pattern infiltrating the perineurial, epineurial, and endoneurial connected tissue and in blood vessel walls.

The median survival of patients with primary amyloidosis is <2 years, with death usually from progressive congestive heart failure or renal failure. Chemotherapy with melphalan, prednisone, and colchicine, to

reduce the concentration of monoclonal proteins, and autologous stem cell transplantation may prolong survival, but whether the neuropathy improves is controversial.

DIABETIC NEUROPATHY

DM is the most common cause of peripheral neuropathy in developed countries. DM is associated with several types of polyneuropathy: distal symmetric sensory or sensorimotor polyneuropathy, autonomic neuropathy, diabetic neuropathic cachexia, polyradiculoneuropathies, cranial neuropathies, and other mononeuropathies. Risk factors for the development of neuropathy include long-standing, poorly controlled DM and the presence of retinopathy and nephropathy.

Diabetic Distal Symmetric Sensory and Sensorimotor Polyneuropathy (DSPN) DSPN is the most common form of diabetic neuropathy and manifests as sensory loss beginning in the toes that gradually progresses over time up the legs and into the fingers and arms (Pattern 2, Table 457-2). When severe, a patient may develop sensory loss in the trunk (chest and abdomen), initially in the midline anteriorly and later extending laterally. Tingling, burning, deep aching pains may also be apparent. NCS usually show reduced amplitudes and mild to moderate slowing of conduction velocities. Nerve biopsy reveals axonal degeneration, endothelial hyperplasia, and, occasionally, perivascular inflammation. Tight control of glucose may reduce the risk of developing neuropathy or improve the underlying neuropathy. A variety of medications have been used with variable success to treat painful symptoms associated with DSPN, including anticonvulsants, antidepressants, sodium channel blockers, and other analgesics (Table 457-6).

Diabetic Autonomic Neuropathy Autonomic neuropathy is typically seen in combination with DSPN. The autonomic neuropathy can manifest as abnormal sweating, dysfunctional thermoregulation, dry eyes and mouth, pupillary abnormalities, cardiac arrhythmias, postural hypotension, GI abnormalities (e.g., gastroparesis, postprandial bloating, chronic diarrhea, or constipation), and genitourinary dysfunction (e.g., impotence, retrograde ejaculation, incontinence) (Pattern 10, Table 457-2). Tests of autonomic function are generally abnormal, including sympathetic skin responses and quantitative sudomotor axon reflex testing. Sensory and motor NCS generally demonstrate features described above with DSPN.

Diabetic Radiculoplexus Neuropathy (Diabetic Amyotrophy or Bruns-Garland Syndrome) Diabetic radiculoplexus neuropathy is the presenting manifestation of DM in approximately one-third of patients. Typically, patients present with severe pain in the low back, hip, and thigh in one leg. Rarely, the diabetic polyradiculoneuropathy begins in both legs at the same time (Pattern 4, Table 457-2). Atrophy and weakness of proximal and distal muscles in the affected leg become apparent within a few days or weeks. The neuropathy is often accompanied or heralded by severe weight loss. Weakness usually progresses over several weeks or months but can continue to progress for 18 months or more. Subsequently, there is slow recovery, but many are left with residual weakness, sensory loss, and pain. In contrast to the more typical lumbosacral radiculoplexus neuropathy, some patients develop thoracic radiculopathy or, even less commonly, a cervical polyradiculoneuropathy. CSF protein is usually elevated, while the cell count is normal. ESR is often increased. EDx reveals evidence of active denervation in affected proximal and distal muscles in the limbs and in paraspinal muscles. Nerve biopsies may demonstrate axonal degeneration along with perivascular inflammation. Patients with severe pain are sometimes treated in the acute period with glucocorticoids, although a randomized controlled trial has yet to be performed, and the natural history of this neuropathy is gradual improvement.

Diabetic Mononeuropathies or Multiple Mononeuropathies The most common mononeuropathies are median neuropathy at the wrist and ulnar neuropathy at the elbow, but peroneal neuropathy at the fibular head and sciatic, lateral femoral, cutaneous, or cranial neuropathies also occur (Pattern 3, Table 457-2). In regard to cranial mononeuropathies, seventh nerve palsies are relatively common but may have other, nondiabetic etiologies. In diabetics, a third nerve palsy is most common, followed by sixth nerve and, less frequently, fourth nerve palsies. Diabetic third nerve palsies are characteristically pupil-sparing (Chap. 34).

HYPOTHYROIDISM

Hypothyroidism is more commonly associated with a proximal myopathy, but some patients develop a neuropathy, most typically CTS. Rarely, a generalized sensory polyneuropathy characterized by painful paresthesias and numbness in both the legs and hands can occur. Treatment is correction of the hypothyroidism.

TABLE 457-6 Treatment of Painful Sensory Neuropathies

THERAPY	ROUTE	DOSE	SIDE EFFECTS
First-Line			
Lidoderm 5% patch	Apply to painful area	Up to 3 patches qd	Skin irritation
Tricyclic antidepressants (e.g., amitriptyline, nortriptyline)	PO	10–100 mg qhs	Cognitive changes, sedation, dry eyes and mouth, urinary retention, constipation
Gabapentin	PO	300–1200 mg tid	Cognitive changes, sedation, peripheral edema
Pregabalin	PO	50–100 mg tid	Cognitive changes, sedation, peripheral edema
Duloxetine	PO	30–60 mg qd	Cognitive changes, sedation, dry eyes, diaphoresis, nausea, diarrhea, constipation
Second-Line			
Carbamazepine	PO	200–400 mg q 6–8 h	Cognitive changes, dizziness, leukopenia, liver dysfunction
Phenytoin	PO	200–400 mg qhs	Cognitive changes, dizziness, liver dysfunction
Venlafaxine	PO	37.5–150 mg/d	Asthenia, sweating, nausea, constipation, anorexia, vomiting, somnolence, dry mouth, dizziness, nervousness, anxiety, tremor, and blurred vision as well as abnormal ejaculation/orgasm and impotence
Tramadol	PO	50 mg qid	Cognitive changes, gastrointestinal upset
Third-Line			
Mexiletine	PO	200–300 mg tid	Arrhythmias
Other Agents			
EMLA cream	Apply cutaneously	qid	Local erythema
2.5% lidocaine			
2.5% prilocaine			
Capsaicin 0.025–0.075% cream	Apply cutaneously	qid	Painful burning skin

Source: Modified from AA Amato, J Russell: *Neuromuscular Disorders,* 2nd ed. New York, McGraw-Hill, 2016, Table 22-3, p. 485.

SJÖGREN'S SYNDROME

Sjögren's syndrome, characterized by the sicca complex of xerophthalmia, xerostomia, and dryness of other mucous membranes, can be complicated by neuropathy (Chap. 373). Most common is a length-dependent axonal sensorimotor neuropathy characterized mainly by sensory loss in the distal extremities (Pattern 2, Table 457-2). A pure small-fiber neuropathy or a cranial neuropathy, particularly involving the trigeminal nerve, can also be seen. Sjögren's syndrome is also associated with sensory neuronopathy/ganglionopathy. Patients with sensory ganglionopathies develop progressive numbness and tingling of the limbs, trunk, and face in a non-length-dependent manner such that symptoms can involve the face or arms more than the legs. The onset can be acute or insidious. Sensory examination demonstrates severe vibratory and proprioceptive loss leading to sensory ataxia.

Patients with neuropathy due to Sjögren's syndrome may have ANAs, SS-A/Ro, and SS-B/La antibodies in the serum, but most do not. NCS demonstrate reduced amplitudes of sensory studies in the affected limbs. Nerve biopsy demonstrates axonal degeneration. Nonspecific perivascular inflammation may be present, but only rarely is there necrotizing vasculitis. There is no specific treatment for neuropathies related to Sjögren's syndrome. When vasculitis is suspected, immunosuppressive agents may be beneficial. Occasionally, the sensory neuronopathy/ganglionopathy stabilizes or improves with immunotherapy, such as intravenous immunoglobulin.

RHEUMATOID ARTHRITIS

Peripheral neuropathy occurs in at least 50% of patients with rheumatoid arthritis (RA) and may be vasculitic in nature (Chap. 370). Vasculitic neuropathy can present with a mononeuropathy multiplex (Pattern 3, Table 457-2), a generalized symmetric pattern of involvement (Pattern 2, Table 457-2), or a combination of these patterns (Chap. 375). Neuropathies may also result from drugs used to treat RA (e.g., tumor necrosis blockers, leflunomide). Nerve biopsy often reveals thickening of the epineurial and endoneurial blood vessels as well as perivascular inflammation or vasculitis, with transmural inflammatory cell infiltration and fibrinoid necrosis of vessel walls. The neuropathy is usually responsive to immunomodulating therapies.

SYSTEMIC LUPUS ERYTHEMATOSUS

Between 2 and 27% of individuals with SLE develop a peripheral neuropathy (Chap. 368). Affected patients typically present with a slowly progressive sensory loss beginning in the feet. Some patients develop burning pain and paresthesias with normal reflexes, and NCS suggest a pure small-fiber neuropathy (Pattern 2, Table 457-2). Less common are multiple mononeuropathies presumably secondary to necrotizing vasculitis (Pattern 3, Table 457-2). Rarely, a generalized sensorimotor polyneuropathy meeting clinical, laboratory, electrophysiologic, and histologic criteria for either GBS or CIDP may occur. Immunosuppressive therapy may be beneficial in SLE patients with neuropathy due to vasculitis. Immunosuppressive agents are less likely to be effective in patients with a generalized sensory or sensorimotor polyneuropathy without evidence of vasculitis. Patients with a GBS or CIDP-like neuropathy should be treated accordingly (Chap. 458).

SYSTEMIC SCLEROSIS (SCLERODERMA)

A distal symmetric, mainly sensory polyneuropathy complicates 5–67% of scleroderma cases (Pattern 2, Table 457-2) (Chap. 372). Cranial mononeuropathies can also develop, most commonly of the trigeminal nerve, producing numbness and dysesthesias in the face. Multiple mononeuropathies also occur (Pattern 3, Table 457-2). The EDx and histologic features of nerve biopsy are those of an axonal sensory greater than motor polyneuropathy.

MIXED CONNECTIVE TISSUE DISEASE

A mild distal axonal sensorimotor polyneuropathy occurs in ~10% of patients with mixed connective tissue disease.

SARCOIDOSIS

The peripheral nervous system or CNS is involved in ~5% of patients with sarcoidosis (Chap. 379). The most common cranial nerve involved is the seventh nerve, which can be affected bilaterally. Some patients develop radiculopathy or polyradiculopathy (Pattern 4, Table 457-2). With a generalized root involvement, the clinical presentation can mimic GBS or CIDP. Patients can also present with multiple mononeuropathies (Pattern 3, Table 457-2) or a generalized, slowly progressive, sensory greater than motor polyneuropathy (Pattern 2, Table 457-2). Some have features of a pure small-fiber neuropathy. EDx reveals an axonal neuropathy. Nerve biopsy can reveal noncaseating granulomas infiltrating the endoneurium, perineurium, or epineurium along with lymphocytic necrotizing angiitis. Neurosarcoidosis may respond to treatment with glucocorticoids or other immunosuppressive agents.

HYPEREOSINOPHILIC SYNDROME

Hypereosinophilic syndrome is characterized by eosinophilia associated with various skin, cardiac, hematologic, and neurologic abnormalities. A generalized peripheral neuropathy or a mononeuropathy multiplex occurs in 6–14% of patients (Pattern 2, Table 457-2).

CELIAC DISEASE (GLUTEN-INDUCED ENTEROPATHY OR NONTROPICAL SPRUE)

Neurologic complications, particularly ataxia and peripheral neuropathy, are estimated to occur in 10% of patients with celiac disease (Chap. 336). A generalized sensorimotor polyneuropathy, pure motor neuropathy, multiple mononeuropathies, autonomic neuropathy, small-fiber neuropathy, and neuromyotonia have all been reported in association with celiac disease or antigliadin/antiendomysial antibodies (Patterns 2, 3, and 9; Table 457-2). Nerve biopsy may reveal a loss of large myelinated fibers. The neuropathy may be secondary to malabsorption of vitamins B_{12} and E. However, some patients have no appreciable vitamin deficiencies. The pathogenic basis for the neuropathy in these patients is unclear but may be autoimmune in etiology. The neuropathy does not appear to respond to a gluten-free diet. In patients with vitamin B_{12} or vitamin E deficiency, replacement therapy may improve or stabilize the neuropathy.

INFLAMMATORY BOWEL DISEASE

Ulcerative colitis and Crohn's disease may be complicated by GBS, CIDP, generalized axonal sensory or sensorimotor polyneuropathy, small-fiber neuropathy, or mononeuropathy (Patterns 2 and 3, Table 457-2) (Chap. 337). These neuropathies may be autoimmune, nutritional (e.g., vitamin B_{12} deficiency), treatment related (e.g., metronidazole), or idiopathic in nature. An acute neuropathy with demyelination resembling GBS, CIDP, or multifocal motor neuropathy may occur in patients treated with tumor necrosis factor α blockers.

UREMIC NEUROPATHY

Approximately 60% of patients with renal failure develop a polyneuropathy characterized by length-dependent numbness, tingling, allodynia, and mild distal weakness (Pattern 2, Table 457-2). Rarely, a rapidly progressive weakness and sensory loss very similar to GBS can occur that improves with an increase in the intensity of renal dialysis or with transplantation (Pattern 1, Table 457-2). Mononeuropathies can also occur, the most common of which is CTS. Ischemic monomelic neuropathy (see below) can complicate arteriovenous shunts created in the arm for dialysis (Pattern 3, Table 457-2). EDx in uremic patients reveals features of a length-dependent, primarily axonal, sensorimotor polyneuropathy. Sural nerve biopsies demonstrate a loss of nerve fibers (particularly large myelinated nerve fibers), active axonal degeneration, and segmental and paranodal demyelination. The sensorimotor polyneuropathy can be stabilized by hemodialysis and improved with successful renal transplantation.

CHRONIC LIVER DISEASE

A generalized sensorimotor neuropathy characterized by numbness, tingling, and minor weakness in the distal aspects of primarily the lower limbs commonly occurs in patients with chronic liver failure. EDx studies are consistent with a sensory greater than motor axonopathy. Occasionally patients with severe liver disease develop a combined neuropathy and myopathy. Sural nerve biopsy reveals both segmental

demyelination and axonal loss. It is not known if hepatic failure in isolation can cause peripheral neuropathy, as the majority of patients have liver disease secondary to other disorders, such as alcoholism or viral hepatitis, which can also cause neuropathy.

CRITICAL ILLNESS POLYNEUROPATHY

The most common causes of acute generalized weakness leading to admission to a medical intensive care unit (ICU) are GBS and myasthenia gravis (Pattern 1, Table 457-2) **(Chaps. 458 and 459)**. However, weakness developing in critically ill patients while in the ICU is usually caused by critical illness polyneuropathy (CIP) or critical illness myopathy (CIM) or, much less commonly, by prolonged neuromuscular blockade. From a clinical and EDx standpoint, it can be quite difficult to distinguish these disorders. Most specialists believe that CIM is more common. Both CIM and CIP develop as a complication of sepsis and multiple organ failure. They usually present as an inability to wean a patient from a ventilator. A coexisting encephalopathy may limit the neurologic examination, in particular the sensory examination. Muscle stretch reflexes are absent or reduced.

Serum creatine kinase (CK) is usually normal; an elevated serum CK would point to CIM as opposed to CIP. NCS reveal absent or markedly reduced amplitudes of motor and sensory studies in CIP, whereas sensory studies are relatively preserved in CIM. Needle EMG usually reveals profuse positive sharp waves and fibrillation potentials, and it is not unusual in patients with severe weakness to be unable to recruit motor unit action potentials. The pathogenic basis of CIP is not known. Perhaps circulating toxins and metabolic abnormalities associated with sepsis and multiorgan failure impair axonal transport or mitochondrial function, leading to axonal degeneration.

LEPROSY (HANSEN'S DISEASE)

Leprosy, caused by the acid-fast bacteria *Mycobacterium leprae*, is the most common cause of peripheral neuropathy in Southeast Asia, Africa, and South America **(Chap. 184)**. Clinical manifestations range from tuberculoid leprosy at one end of the spectrum to lepromatous leprosy at the other end, with borderline leprosy in between. Neuropathies are most common in patients with borderline leprosy. Superficial cutaneous nerves of the ears and distal limbs are commonly affected. Mononeuropathies, multiple mononeuropathies, or a slowly progressive symmetric sensorimotor polyneuropathy may develop (Patterns 2 and 3, Table 457-2). Sensory NCS are usually absent in the lower limb and are reduced in amplitude in the arms. Motor NCS may demonstrate reduced amplitudes in affected nerves but occasionally can reveal demyelinating features. Leprosy is usually diagnosed by skin lesion biopsy. Nerve biopsy can also be diagnostic, particularly when there are no apparent skin lesions. The tuberculoid form is characterized by granulomas, and bacilli are not seen. In contrast, with lepromatous leprosy, large numbers of infiltrating bacilli, T_H2 lymphocytes, and organism-laden, foamy macrophages with minimal granulomatous infiltration are evident. The bacilli are best appreciated using the Fite stain, where they can be seen as red-staining rods often in clusters free in the endoneurium, within macrophages, or within Schwann cells.

Patients are generally treated with multiple drugs: dapsone, rifampin, and clofazimine. Other medications that are used include thalidomide, pefloxacin, ofloxacin, sparfloxacin, minocycline, and clarithromycin. Patients are generally treated for 2 years. Treatment is sometimes complicated by the so-called reversal reaction, particularly in borderline leprosy. The reversal reaction can occur at any time during treatment and develops because of a shift to the tuberculoid end of the spectrum, with an increase in cellular immunity during treatment. The cellular response is upregulated as evidenced by an increased release of tumor necrosis factor α, interferon γ, and interleukin 2, with new granuloma formation. This can result in an exacerbation of the rash and the neuropathy as well as in appearance of new lesions. High-dose glucocorticoids blunt this adverse reaction and may be used prophylactically at treatment onset in high-risk patients. Erythema nodosum leprosum (ENL) is also treated with glucocorticoids or thalidomide.

LYME DISEASE

Lyme disease is caused by infection with *Borrelia burgdorferi*, a spirochete usually transmitted by the deer tick *Ixodes dammini* **(Chap. 191)**. Neurologic complications may develop during the second and third stages of infection. Facial neuropathy is most common and is bilateral in about half of cases, which is rare for idiopathic Bell's palsy. Involvement of nerves is frequently asymmetric. Some patients present with a polyradiculoneuropathy or multiple mononeuropathies (Pattern 3 or 4, Table 457-2). EDx is suggestive of a primary axonopathy. Nerve biopsies can reveal axonal degeneration with perivascular inflammation. Treatment is with antibiotics.

DIPHTHERITIC NEUROPATHY

Diphtheria is caused by the bacteria *Corynebacterium diphtheriae* **(Chap. 155)**. Infected individuals present with flu-like symptoms of generalized myalgias, headache, fatigue, low-grade fever, and irritability within a week to 10 days of the exposure. Between 20 and 70% of patients develop a peripheral neuropathy caused by a toxin released by the bacteria. Three to 4 weeks after infection, patients may note decreased sensation in their throat and begin to develop dysphagia, dysarthria, hoarseness, and blurred vision due to impaired accommodation. A generalized polyneuropathy may manifest 2 or 3 months following the initial infection, characterized by numbness, paresthesias, and weakness of the arms and legs and occasionally ventilatory failure (Pattern 1, Table 457-2). CSF protein can be elevated with or without lymphocytic pleocytosis. EDx suggests a diffuse axonal sensorimotor polyneuropathy. Antitoxin and antibiotics should be given within 48 h of symptom onset. Although early treatment reduces the incidence and severity of some complications (i.e., cardiomyopathy), it does not appear to alter the natural history of the associated peripheral neuropathy. The neuropathy usually resolves after several months.

COVID-19

GBS **(Chap. 458)** has been reported in the setting of acute COVID-19 infection though a causal relationship has not been clearly established. There does appear to be an increased risk of GBS with adenovirus-vector vaccines but not the messenger RNA vaccines.

HUMAN IMMUNODEFICIENCY VIRUS

HIV infection can result in a variety of neurologic complications, including peripheral neuropathies **(Chap. 208)**. Approximately 20% of HIV-infected individuals develop a neuropathy as a direct result of the virus itself or as a result of other associated viral infections (e.g., CMV) or neurotoxicity secondary to antiviral medications (see below). The major presentations of peripheral neuropathy associated with HIV infection include (1) distal symmetric polyneuropathy (DSP), (2) inflammatory demyelinating polyneuropathy (including both GBS and CIDP), (3) multiple mononeuropathies (e.g., vasculitis, CMV-related), (4) polyradiculopathy (usually CMV-related), (5) autonomic neuropathy, and (6) sensory ganglionitis.

HIV-Related Distal Symmetric Polyneuropathy DSP is the most common form of peripheral neuropathy associated with HIV infection and usually is seen in patients with AIDS. It is characterized by numbness and painful paresthesias involving the distal extremities (Pattern 2, Table 457-2). The pathogenic basis for DSP is unknown but is not due to actual infection of the peripheral nerves. The neuropathy may be immune mediated, perhaps caused by the release of cytokines from surrounding inflammatory cells. Vitamin B_{12} deficiency may contribute in some instances but is not a major cause of most cases of DSP. Older antiretroviral agents (e.g., dideoxycytidine, dideoxyinosine, stavudine) are also neurotoxic and can cause a painful sensory neuropathy.

HIV-Related Inflammatory Demyelinating Polyradiculoneuropathy Both acute inflammatory demyelinating polyneuropathy (AIDP) and CIDP can occur as a complication of HIV infection (Pattern 1, Table 457-2). AIDP usually develops at the time of seroconversion, whereas CIDP can occur any time in the course of the infection. Clinical and EDx features are indistinguishable from idiopathic AIDP

or CIDP (Chap. 458). In addition to elevated protein levels, lymphocytic pleocytosis is evident in the CSF, a finding that helps distinguish this HIV-associated polyradiculoneuropathy from idiopathic AIDP/CIDP.

HIV-Related Progressive Polyradiculopathy An acute, progressive lumbosacral polyradiculoneuropathy usually secondary to CMV infection can develop in patients with AIDS (Pattern 4, Table 457-2). Patients present with severe radicular pain, numbness, and weakness in the legs, which is usually asymmetric. CSF is abnormal, demonstrating a high protein level, along with a reduced glucose concentration and notably a neutrophilic pleocytosis. EDx studies reveal features of active axonal degeneration. The polyradiculoneuropathy may improve with antiviral therapy.

HIV-Related Multiple Mononeuropathies Multiple mononeuropathies can also develop in patients with HIV infection, usually in the context of AIDS. Weakness, numbness, paresthesias, and pain occur in the distribution of affected nerves (Pattern 3, Table 457-2). Nerve biopsies can reveal axonal degeneration with necrotizing vasculitis or perivascular inflammation. Glucocorticoid treatment is indicated for vasculitis directly due to HIV infection.

HIV-Related Sensory Neuronopathy/Ganglionopathy Dorsal root ganglionitis is a very rare complication of HIV infection, and neuronopathy can be the presenting manifestation. Patients develop sensory ataxia similar to idiopathic sensory neuronopathy/ganglionopathy (Pattern 9, Table 457-2). NCS reveal reduced amplitudes or absence of sensory nerve action potentials (SNAPs).

HERPES VARICELLA-ZOSTER VIRUS

Peripheral neuropathy from herpes varicella-zoster (HVZ) infection results from reactivation of latent virus or from a primary infection (Chap. 198). Two-thirds of infections in adults are characterized by dermal zoster in which severe pain and paresthesias develop in a dermatomal region followed within a week or two by a vesicular rash in the same distribution (Pattern 3, Table 457-2). Weakness in muscles innervated by roots corresponding to the dermatomal distribution of skin lesions occurs in 5–30% of patients. Approximately 25% of affected patients have continued pain (postherpetic neuralgia [PHN]). A large clinical trial demonstrated that vaccination against zoster reduces the incidence of HVZ among vaccine recipients by 51% and reduces the incidence of PHN by 67%. Treatment of PHN is symptomatic (Table 457-6).

CYTOMEGALOVIRUS

CMV can cause an acute lumbosacral polyradiculopathy and multiple mononeuropathies in patients with HIV infection and in other immune deficiency conditions (Pattern 4, Table 457-2) (Chap. 200).

EPSTEIN-BARR VIRUS

EBV infection has been associated with GBS, cranial neuropathies, mononeuropathy multiplex, brachial plexopathy, lumbosacral radiculoplexopathy, and sensory neuronopathies (Patterns 1, 3, 4, and 9, Table 457-2) (Chap. 199).

HEPATITIS VIRUSES

Hepatitis B and C can cause multiple mononeuropathies related to vasculitis, AIDP, or CIDP (Patterns 1 and 3, Table 457-2) (Chap. 352).

NEUROPATHIES ASSOCIATED WITH MALIGNANCY

Patients with malignancy can develop neuropathies due to (1) a direct effect of the cancer by invasion or compression of the nerves, (2) remote or paraneoplastic effect, (3) a toxic effect of treatment, or (4) as a consequence of immune compromise caused by immunosuppressive medications. The most common associated malignancy is lung cancer, but neuropathies also complicate carcinoma of the breast, ovaries, stomach, colon, rectum, and other organs, including the lymphoproliferative system.

PARANEOPLASTIC SENSORY NEURONOPATHY/GANGLIONOPATHY

Paraneoplastic encephalomyelitis/sensory neuronopathy (PEM/SN) usually complicates small-cell lung carcinoma (Chap. 99). Patients usually present with numbness and paresthesias in the distal extremities that are often asymmetric. The onset can be acute or insidiously progressive. Prominent loss of proprioception leads to sensory ataxia (Pattern 9; Table 457-2). Weakness can be present, usually secondary to an associated myelitis, motor neuronopathy, or concurrent LEMS. Many patients also develop confusion, memory loss, depression, hallucinations or seizures, or cerebellar ataxia. Polyclonal antineuronal antibodies (IgG) directed against a 35- to 40-kDa protein or complex of proteins, the so-called Hu antigen, are found in the sera or CSF in the majority of patients with paraneoplastic PEM/SN. CSF may be normal or may demonstrate mild lymphocytic pleocytosis and elevated protein. PEM/SN is probably the result of antigenic similarity between proteins expressed in the tumor cells and neuronal cells, leading to an immune response directed against both cell types. Treatment of the underlying cancer generally does not affect the course of PEM/SN. However, occasional patients may improve following treatment of the tumor. Unfortunately, plasmapheresis, intravenous immunoglobulin, and immunosuppressive agents have not shown benefit.

NEUROPATHY SECONDARY TO TUMOR INFILTRATION

Malignant cells, in particular leukemia and lymphoma, can infiltrate cranial and peripheral nerves, leading to mononeuropathy, mononeuropathy multiplex, polyradiculopathy, plexopathy, or even a generalized symmetric distal or proximal and distal polyneuropathy (Patterns 1, 2, 3, and 4; Table 457-2). Neuropathy related to tumor infiltration is often painful; it can be the presenting manifestation of the cancer or the heralding symptom of a relapse. The neuropathy may improve with treatment of the underlying leukemia or lymphoma or with glucocorticoids.

NEUROPATHY AS A COMPLICATION OF BONE MARROW TRANSPLANTATION

Neuropathies may develop in patients who undergo bone marrow transplantation (BMT) because of the toxic effects of chemotherapy, radiation, infection, or an autoimmune response directed against the peripheral nerves. Peripheral neuropathy in BMT is often associated with graft-versus-host disease (GVHD). Chronic GVHD shares many features with a variety of autoimmune disorders, and it is possible that an immune-mediated response directed against peripheral nerves is responsible. Patients with chronic GVHD may develop cranial neuropathies, sensorimotor polyneuropathies, multiple mononeuropathies, and severe generalized peripheral neuropathies resembling AIDP or CIDP (Patterns 1, 2, and 3; Table 457-2). The neuropathy may improve by increasing the intensity of immunosuppressive or immunomodulating therapy and resolution of the GVHD.

LYMPHOMA

Lymphomas may cause neuropathy by infiltration or direct compression of nerves or by a paraneoplastic process. The neuropathy can be purely sensory or motor but most commonly is sensorimotor. The pattern of involvement may be symmetric, asymmetric, or multifocal, and the course may be acute, gradually progressive, or relapsing and remitting (Patterns 1, 2, and 3; Table 457-2). EDx can be compatible with either an axonal or demyelinating process. CSF may reveal lymphocytic pleocytosis and an elevated protein. Nerve biopsy may demonstrate endoneurial inflammatory cells in both the infiltrative and the paraneoplastic etiologies. A monoclonal population of cells favors lymphomatous invasion. The neuropathy may respond to treatment of the underlying lymphoma or immunomodulating therapies.

MULTIPLE MYELOMA

MM usually presents in the fifth to seventh decade of life with fatigue, bone pain, anemia, and hypercalcemia (Chap. 116). Clinical and EDx features of neuropathy occur in as many as 40% of patients. The most common pattern is that of a distal, axonal, sensory, or sensorimotor

polyneuropathy (Pattern 2; Table 457-2). Less frequently, a chronic demyelinating polyradiculoneuropathy may develop (Pattern 1; Table 457-2) (see POEMS, **Chap. 458**). MM can be complicated by amyloid polyneuropathy and should be considered in patients with painful paresthesias, loss of pinprick and temperature discrimination, and autonomic dysfunction (suggestive of a small-fiber neuropathy) and CTS. Expanding plasmacytomas can compress cranial nerves and spinal roots as well. A monoclonal protein, usually composed of γ or μ heavy chains or κ light chains, may be identified in the serum or urine. EDx usually shows reduced amplitudes with normal or only mildly abnormal distal latencies and conduction velocities. A superimposed median neuropathy at the wrist is common. Abdominal fat pad, rectal, or sural nerve biopsy can be performed to look for amyloid deposition. Unfortunately, the treatment of the underlying MM does not usually affect the course of the neuropathy.

NEUROPATHIES ASSOCIATED WITH MONOCLONAL GAMMOPATHY OF UNCERTAIN SIGNIFICANCE (SEE CHAP. 458)

Toxic Neuropathies Secondary to Chemotherapy Many of the commonly used chemotherapy agents can cause a toxic neuropathy (**Table 457-7**). The mechanisms by which these agents cause toxic neuropathies vary, as does the specific type of neuropathy produced. The risk of developing a toxic neuropathy or more severe neuropathy appears to be greater in patients with a preexisting neuropathy (e.g., CMT disease, diabetic neuropathy) and those who also take other potentially neurotoxic drugs (e.g., nitrofurantoin, isoniazid, disulfiram, pyridoxine). Chemotherapeutic agents usually cause a sensory greater than motor length-dependent axonal neuropathy or neuronopathy/ganglionopathy (Patterns 2 and 9; Table 457-2).

OTHER TOXIC NEUROPATHIES

Neuropathies can develop as complications of toxic effects of various drugs and other environmental exposures (**Table 457-8**). The more common neuropathies associated with these agents are discussed here.

CHLOROQUINE AND HYDROXYCHLOROQUINE

Chloroquine and hydroxychloroquine can cause a toxic myopathy characterized by slowly progressive, painless, proximal weakness and atrophy, which is worse in the legs than the arms. In addition, neuropathy can also develop with or without the myopathy leading to sensory loss and distal weakness. The "neuromyopathy" usually appears in patients taking 500 mg daily for a year or more but has been reported with doses as low as 200 mg/d. Serum CK levels are usually elevated due to the superimposed myopathy. NCS reveal mild slowing of motor and sensory NCVs with a mild to moderate reduction in the amplitudes, although NCS may be normal in patients with only the myopathy. EMG demonstrates myopathic muscle action potentials (MUAPs), increased insertional activity in the form of positive sharp waves, fibrillation potentials, and occasionally myotonic potentials, particularly in the proximal muscles. Neurogenic MUAPs and reduced recruitment are found in more distal muscles. Nerve biopsy demonstrates autophagic vacuoles within Schwann cells. Vacuoles may also be evident in muscle biopsies. The pathogenic basis

TABLE 457-7 Toxic Neuropathies Secondary to Chemotherapy

DRUG	MECHANISM OF NEUROTOXICITY	CLINICAL FEATURES	NERVE HISTOPATHOLOGY	EMG/NCS
Vinca alkaloids (vincristine, vinblastine, vindesine, vinorelbine)	Interfere with axonal microtubule assembly; impairs axonal transport	Symmetric, S-M, large-/small-fiber PN; autonomic symptoms common; infrequent cranial neuropathies	Axonal degeneration of myelinated and unmyelinated fibers; regenerating clusters, minimal segmental demyelination	Axonal sensorimotor PN; distal denervation on EMG; abnormal QST, particularly vibratory perception
Cisplatin	Preferential damage to dorsal root ganglia: ? binds to and cross-links DNA ? inhibits protein synthesis ? impairs axonal transport	Predominant large-fiber sensory neuronopathy; sensory ataxia	Loss of large > small myelinated and unmyelinated fibers; axonal degeneration with small clusters of regenerating fibers; secondary segmental demyelination	Low-amplitude or unobtainable SNAPs with normal CMAPs and EMG; abnormal QST, particularly vibratory perception
Taxanes (paclitaxel, docetaxel)	Promotes axonal microtubule assembly; interferes with axonal transport	Symmetric, predominantly sensory PN; large-fiber modalities affected more than small-fiber	Loss of large > small myelinated and unmyelinated fibers; axonal degeneration with small clusters of regenerating fibers; secondary segmental demyelination	Axonal sensorimotor PN; distal denervation on EMG; abnormal QST, particularly vibratory perception
Suramin				
Axonal PN	Unknown;? inhibition of neurotrophic growth factor binding;? neuronal lysosomal storage	Symmetric, length-dependent, sensory-predominant PN	None described	Abnormalities consistent with an axonal S-M PN
Demyelinating PN	Unknown;? immunomodulating effects	Subacute, S-M PN with diffuse proximal and distal weakness; areflexia; increased CSF protein	Loss of large and small myelinated fibers with primary demyelination and secondary axonal degeneration; occasional epi- and endoneurial inflammatory cell infiltrates	Features suggestive of an acquired demyelinating sensorimotor PN (e.g., slow CVs, prolonged distal latencies and F-wave latencies, conduction block, temporal dispersion)
Cytarabine (ARA-C)	Unknown;? selective Schwann cell toxicity;? immunomodulating effects	GBS-like syndrome; pure sensory neuropathy; brachial plexopathy	Loss of myelinated nerve fibers; axonal degeneration; segmental demyelination; no inflammation	Axonal, demyelinating, or mixed S-M PN; denervation on EMG
Etoposide (VP-16)	Unknown;? selective dorsal root ganglia toxicity	Length-dependent, sensory-predominant PN; autonomic neuropathy	None described	Abnormalities consistent with an axonal S-M PN
Bortezomib (Velcade)	Unknown	Length-dependent, sensory, predominantly small-fiber PN	Not reported	Abnormalities consistent with an axonal sensory neuropathy with early small-fiber involvement (abnormal autonomic studies)

Abbreviations: CMAP, compound motor action potential; CSF, cerebrospinal fluid; CVs, conduction velocities; EMG, electromyography; GBS, Guillain-Barré syndrome; NCS, nerve conduction studies; PN, polyneuropathy; QST, quantitative sensory testing; S-M, sensorimotor; SNAP, sensory nerve action potential.

TABLE 457-8 Toxic Neuropathies

DRUG	MECHANISM OF NEUROTOXICITY	CLINICAL FEATURES	NERVE HISTOPATHOLOGY	EMG/NCS
Misonidazole	Unknown	Painful paresthesias and loss of large- and small-fiber sensory modalities and sometimes distal weakness in length-dependent pattern	Axonal degeneration of large, myelinated fibers; axonal swellings; segmental demyelination	Low-amplitude or unobtainable SNAPs with normal or only slightly reduced CMAP amplitudes
Metronidazole	Unknown	Painful paresthesias and loss of large- and small-fiber sensory modalities and sometimes distal weakness in length-dependent pattern	Axonal degeneration	Low-amplitude or unobtainable SNAPs with normal CMAPs
Chloroquine and hydroxychloroquine	Amphiphilic properties may lead to drug-lipid complexes that are indigestible and result in accumulation of autophagic vacuoles	Loss of large- and small-fiber sensory modalities and distal weakness in length-dependent pattern; superimposed myopathy may lead to proximal weakness	Axonal degeneration with autophagic vacuoles in nerves as well as muscle fibers	Low-amplitude or unobtainable SNAPs with normal or reduced CMAP amplitudes; distal denervation on EMG; irritability and myopathic-appearing MUAPs proximally in patients with superimposed toxic myopathy
Amiodarone	Amphiphilic properties may lead to drug-lipid complexes that are indigestible and result in accumulation of autophagic vacuoles	Paresthesias and pain with loss of large- and small-fiber sensory modalities and distal weakness in length-dependent pattern; superimposed myopathy may lead to proximal weakness	Axonal degeneration and segmental demyelination with myeloid inclusions in nerves and muscle fibers	Low-amplitude or unobtainable SNAPs with normal or reduced CMAP amplitudes; can also have prominent slowing of CVs; distal denervation on EMG; irritability and myopathic-appearing MUAPs proximally in patients with superimposed toxic myopathy
Colchicine	Inhibits polymerization of tubulin in microtubules and impairs axoplasmic flow	Numbness and paresthesias with loss of large-fiber modalities in a length-dependent fashion; superimposed myopathy may lead to proximal in addition to distal weakness	Nerve biopsy demonstrates axonal degeneration; muscle biopsy reveals fibers with vacuoles	Low-amplitude or unobtainable SNAPs with normal or reduced CMAP amplitudes; irritability and myopathic-appearing MUAPs proximally in patients with superimposed toxic myopathy
Podophyllin	Binds to microtubules and impairs axoplasmic flow	Sensory loss, tingling, muscle weakness, and diminished muscle stretch reflexes in length-dependent pattern; autonomic neuropathy	Axonal degeneration	Low-amplitude or unobtainable SNAPs with normal or reduced CMAP amplitudes
Thalidomide	Unknown	Numbness, tingling, and burning pain and weakness in a length-dependent pattern	Axonal degeneration; autopsy studies reveal degeneration of dorsal root ganglia	Low-amplitude or unobtainable SNAPs with normal or reduced CMAP amplitudes
Disulfiram	Accumulation of neurofilaments and impaired axoplasmic flow	Numbness, tingling, and burning pain in a length-dependent pattern	Axonal degeneration with accumulation of neurofilaments in the axons	Low-amplitude or unobtainable SNAPs with normal or reduced CMAP amplitudes
Dapsone	Unknown	Distal weakness that may progress to proximal muscles; sensory loss	Axonal degeneration and segmental demyelination	Low-amplitude or unobtainable CMAPs with normal or reduced SNAP amplitudes
Leflunomide	Unknown	Paresthesias and numbness in a length-dependent pattern	Unknown	Low-amplitude or unobtainable SNAPs with normal or reduced CMAP amplitudes
Nitrofurantoin	Unknown	Numbness, painful paresthesias, and severe weakness that may resemble GBS	Axonal degeneration; autopsy studies reveal degeneration of dorsal root ganglia and anterior horn cells	Low-amplitude or unobtainable SNAPs with normal or reduced CMAP amplitudes
Pyridoxine (vitamin B_6)	Unknown	Dysesthesias and sensory ataxia; impaired large-fiber sensory modalities on examination	Marked loss of sensory axons and cell bodies in dorsal root ganglia	Reduced amplitudes or absent SNAPs
Isoniazid	Inhibits pyridoxal phosphokinase leading to pyridoxine deficiency	Dysesthesias and sensory ataxia; impaired large-fiber sensory modalities on examination	Marked loss of sensory axons and cell bodies in dorsal root ganglia and degeneration of the dorsal columns	Reduced amplitudes or absent SNAPs and, to a lesser extent, CMAPs
Ethambutol	Unknown	Numbness with loss of large-fiber modalities on examination	Axonal degeneration	Reduced amplitudes or absent SNAPs
Antinucleosides	Unknown	Dysesthesia and sensory ataxia; impaired large-fiber sensory modalities on examination	Axonal degeneration	Reduced amplitudes or absent SNAPs
Phenytoin	Unknown	Numbness with loss of large-fiber modalities on examination	Axonal degeneration and segmental demyelination	Low-amplitude or unobtainable SNAPs with normal or reduced CMAP amplitudes
Lithium	Unknown	Numbness with loss of large-fiber modalities on examination	Axonal degeneration	Low-amplitude or unobtainable SNAPs with normal or reduced CMAP amplitudes

(*Continued*)

TABLE 457-8 Toxic Neuropathies (Continued)

DRUG	MECHANISM OF NEUROTOXICITY	CLINICAL FEATURES	NERVE HISTOPATHOLOGY	EMG/NCS
Acrylamide	Unknown; may be caused by impaired axonal transport	Numbness with loss of large-fiber modalities on examination; sensory ataxia; mild distal weakness	Degeneration of sensory axons in peripheral nerves and posterior columns, spinocerebellar tracts, mammillary bodies, optic tracts, and corticospinal tracts in the CNS	Low-amplitude or unobtainable SNAPs with normal or reduced CMAP amplitudes
Carbon disulfide	Unknown	Length-dependent numbness and tingling with mild distal weakness	Axonal swellings with accumulation of neurofilaments	Low-amplitude or unobtainable SNAPs with normal or reduced CMAP amplitudes
Ethylene oxide	Unknown; may act as alkylating agent and bind DNA	Length-dependent numbness and tingling; may have mild distal weakness	Axonal degeneration	Low-amplitude or unobtainable SNAPs with normal or reduced CMAP amplitudes
Organophosphates	Bind and inhibit neuropathy target esterase	Early features are those of neuromuscular blockade with generalized weakness; later axonal sensorimotor PN ensues	Axonal degeneration along with degeneration of gracile fasciculus and corticospinal tracts	Early: repetitive firing of CMAPs and decrement with repetitive nerve stimulation; late: axonal sensorimotor PN
Hexacarbons	Unknown; may lead to covalent cross-linking between neurofilaments	Acute, severe sensorimotor PN that may resemble GBS	Axonal degeneration and giant axons swollen with neurofilaments	Features of a mixed axonal and/or demyelinating sensorimotor axonal PN—reduced amplitudes, prolonged distal latencies, conduction block, and slowing of CVs
Lead	Unknown; may interfere with mitochondria	Encephalopathy; motor neuropathy (often resembles radial neuropathy with wrist and finger drop); autonomic neuropathy; bluish-black discoloration of gums	Axonal degeneration of motor axons	Reduction of CMAP amplitudes with active denervation on EMG
Mercury	Unknown; may combine with sulfhydryl groups	Abdominal pain and nephrotic syndrome; encephalopathy; ataxia; paresthesias	Axonal degeneration; degeneration of dorsal root ganglia, calcarine, and cerebellar cortex	Low-amplitude or unobtainable SNAPs with normal or reduced CMAP amplitudes
Thallium	Unknown	Encephalopathy; painful sensory symptoms; mild loss of vibration; distal or generalized weakness may also develop; autonomic neuropathy; alopecia	Axonal degeneration	Low-amplitude or unobtainable SNAPs with normal or reduced CMAP amplitudes
Arsenic	Unknown; may combine with sulfhydryl groups	Abdominal discomfort, burning pain, and paresthesias; generalized weakness; autonomic insufficiency; can resemble GBS	Axonal degeneration	Low-amplitude or unobtainable SNAPs with normal or reduced CMAP amplitudes; may have demyelinating features: prolonged distal latencies and slowing of CVs
Gold	Unknown	Distal paresthesias and reduction of all sensory modalities	Axonal degeneration	Low-amplitude or unobtainable SNAPs

Abbreviations: CMAP, compound motor action potential; CVs, conduction velocities; EMG, electromyography; GBS, Guillain-Barré syndrome; MUAP, muscle action potential; NCS, nerve conduction studies; PN, polyneuropathy; S-M, sensorimotor; SNAP, sensory nerve action potential.

of the neuropathy is not known but may be related to the amphiphilic properties of the drug. These agents contain both hydrophobic and hydrophilic regions that allow them to interact with the anionic phospholipids of cell membranes and organelles. The drug-lipid complexes may be resistant to digestion by lysosomal enzymes, leading to the formation of autophagic vacuoles filled with myeloid debris that may in turn cause degeneration of nerves and muscle fibers. The signs and symptoms of the neuropathy and myopathy are usually reversible following discontinuation of medication.

AMIODARONE

Amiodarone can cause a neuromyopathy similar to chloroquine and hydroxychloroquine. The neuromyopathy typically appears after patients have taken the medication for 2–3 years. Nerve biopsy demonstrates a combination of segmental demyelination and axonal loss. Electron microscopy reveals lamellar or dense inclusions in Schwann cells, pericytes, and endothelial cells. The inclusions in muscle and nerve biopsies have persisted as long as 2 years following discontinuation of the medication.

COLCHICINE

Colchicine can also cause a neuromyopathy. Patients usually present with proximal weakness and numbness and tingling in the distal extremities. EDx reveals features of an axonal polyneuropathy. Muscle biopsy reveals a vacuolar myopathy, whereas sensory nerves demonstrate axonal degeneration. Colchicine inhibits the polymerization of tubulin into microtubules. The disruption of the microtubules probably leads to defective intracellular movement of important proteins, nutrients, and waste products in muscle and nerves.

THALIDOMIDE

Thalidomide is an immunomodulating agent used to treat MM, GVHD, leprosy, and other autoimmune disorders. Thalidomide is associated with severe teratogenic effects as well as peripheral neuropathy that can be dose-limiting. Patients develop numbness, painful tingling, and burning discomfort in the feet and hands and less commonly muscle weakness and atrophy. Even after stopping the drug for 4–6 years, as many as 50% patients continue to have significant symptoms. NCS demonstrate reduced amplitudes or complete absence of SNAPs, with preserved conduction velocities when obtainable. Motor

NCS are usually normal. Nerve biopsy reveals a loss of large-diameter myelinated fibers and axonal degeneration. Degeneration of dorsal root ganglion cells has been reported at autopsy.

PYRIDOXINE (VITAMIN B_6) TOXICITY

Pyridoxine is an essential vitamin that serves as a coenzyme for transamination and decarboxylation. However, at high doses (116 mg/d), patients can develop a severe sensory neuropathy with dysesthesias and sensory ataxia. NCS reveal absent or markedly reduced SNAP amplitudes with relatively preserved CMAPs. Nerve biopsy reveals axonal loss of fiber at all diameters. Loss of dorsal root ganglion cells with subsequent degeneration of both the peripheral and central sensory tracts have been reported in animal models.

ISONIAZID

One of the most common side effects of isoniazid (INH) is peripheral neuropathy. Standard doses of INH (3–5 mg/kg per day) are associated with a 2% incidence of neuropathy, whereas neuropathy develops in at least 17% of patients taking in excess of 6 mg/kg per d. The elderly, malnourished, and "slow acetylators" are at increased risk for developing the neuropathy. INH inhibits pyridoxal phosphokinase, resulting in pyridoxine deficiency and the neuropathy. Prophylactic administration of pyridoxine 100 mg/d can prevent the neuropathy from developing.

ANTIRETROVIRAL AGENTS

The nucleoside analogues zalcitabine (dideoxycytidine or ddC), didanosine (dideoxyinosine or ddI), stavudine (d4T), lamivudine (3TC), and antiretroviral nucleoside reverse transcriptase inhibitor (NRTI) are used to treat HIV infection. One of the major dose-limiting side effects of these medications is a predominantly sensory, length-dependent, symmetrically painful neuropathy (Pattern 2; Table 457-2). Zalcitabine (ddC) is the most extensively studied of the nucleoside analogues, and at doses >0.18 mg/kg per d, it is associated with a subacute onset of severe burning and lancinating pains in the feet and hands. NCS reveal decreased amplitudes of the SNAPs with normal motor studies. The nucleoside analogues inhibit mitochondrial DNA polymerase, which is the suspected pathogenic basis for the neuropathy. Because of a "coasting effect," patients can continue to worsen even 2–3 weeks after stopping the medication. Following dose reduction, improvement in the neuropathy is seen in most patients after several months (mean time ~10 weeks).

HEXACARBONS (*n*-HEXANE, METHYL *n*-BUTYL KETONE)/GLUE SNIFFER'S NEUROPATHY

n-Hexane and methyl *n*-butyl ketone are water-insoluble industrial organic solvents that are also present in some glues. Exposure through inhalation, accidentally or intentionally (glue sniffing), or through skin absorption can lead to a profound subacute sensory and motor polyneuropathy (Pattern 2; Table 457-2). NCS demonstrate decreased amplitudes of the SNAPs and CMAPs with slightly slow conduction velocities. Nerve biopsy reveals a loss of myelinated fibers and giant axons that are filled with 10-nm neurofilaments. Hexacarbon exposure leads to covalent cross-linking between axonal neurofilaments that results in their aggregation, impaired axonal transport, swelling of the axons, and eventual axonal degeneration.

LEAD

Lead neuropathy is uncommon, but it can be seen in children who accidentally ingest lead-based paints in older buildings and in industrial workers exposed to lead-containing products. The most common presentation of lead poisoning is an encephalopathy; however, symptoms and signs of a primarily motor neuropathy can also occur. The neuropathy is characterized by an insidious and progressive onset of weakness usually beginning in the arms, in particular involving the wrist and finger extensors, resembling a radial neuropathy. Sensation is generally preserved; however, the autonomic nervous system can be affected (Patterns 2, 3, and 10; Table 457-2). Laboratory investigation can reveal a microcytic hypochromic anemia with basophilic stippling of erythrocytes, an elevated serum lead level, and an elevated serum coproporphyrin level. A 24-h urine collection demonstrates elevated levels of lead excretion. The NCS may reveal reduced CMAP amplitudes, while the SNAPs are typically normal. The pathogenic basis may be related to abnormal porphyrin metabolism. The most important principle of management is to remove the source of the exposure. Chelation therapy with calcium disodium ethylene-diaminetetraacetic acid (EDTA), British anti-Lewisite (BAL), and penicillamine also demonstrates variable efficacy.

MERCURY

Mercury toxicity may occur as a result of exposure to either organic or inorganic mercurials. Mercury poisoning presents with paresthesias in hands and feet that progress proximally and may involve the face and tongue. Motor weakness can also develop. CNS symptoms often overshadow the neuropathy. EDx shows features of a primarily axonal sensorimotor polyneuropathy. The primary site of neuromuscular pathology appears to be the dorsal root ganglia. The mainstay of treatment is removing the source of exposure.

THALLIUM

Thallium can exist in a monovalent or trivalent form and is primarily used as a rodenticide. The toxic neuropathy usually manifests as burning paresthesias of the feet, abdominal pain, and vomiting. Increased thirst, sleep disturbances, and psychotic behavior may be noted. Within the first week, patients develop pigmentation of the hair, an acne-like rash in the malar area of the face, and hyperreflexia. By the second and third weeks, autonomic instability with labile heart rate and blood pressure may be seen. Hyporeflexia and alopecia also occur but may not be evident until the third or fourth week following exposure. With severe intoxication, proximal weakness and involvement of the cranial nerves can occur. Some patients require mechanical ventilation due to respiratory muscle involvement. The lethal dose of thallium is variable, ranging from 8 to 15 mg/kg body weight. Death can result in <48 h following a particularly large dose. NCS demonstrate features of a primarily axonal sensorimotor polyneuropathy. With acute intoxication, potassium ferric ferrocyanide II may be effective in preventing absorption of thallium from the gut. However, there may be no benefit once thallium has been absorbed. Unfortunately, chelating agents are not very efficacious. Adequate diuresis is essential to help eliminate thallium from the body without increasing tissue availability from the serum.

ARSENIC

Arsenic is another heavy metal that can cause a toxic sensorimotor polyneuropathy. The neuropathy manifests 5–10 days after ingestion of arsenic and progresses for several weeks, sometimes mimicking GBS. The presenting symptoms are typically an abrupt onset of abdominal discomfort, nausea, vomiting, pain, and diarrhea followed within several days by burning pain in the feet and hands. Examination of the skin can be helpful in the diagnosis as the loss of the superficial epidermal layer results in patchy regions of increased or decreased pigmentation on the skin several weeks after an acute exposure or with chronic low levels of ingestion. Mee's lines, which are transverse lines at the base of the fingernails and toenails, do not become evident until 1 or 2 months after the exposure. Multiple Mee's lines may be seen in patients with long fingernails who have had chronic exposure to arsenic. Mee's lines are not specific for arsenic toxicity as they can also be seen following thallium poisoning. Because arsenic is cleared from blood rapidly, the serum concentration of arsenic is not diagnostically helpful. However, arsenic levels are increased in the urine, hair, and fingernails of patients exposed to arsenic. Anemia with stippling of erythrocytes is common, and occasionally, pancytopenia and aplastic anemia can develop. Increased CSF protein levels without pleocytosis can be seen; this can lead to misdiagnosis as GBS. NCS are usually suggestive of an axonal sensorimotor polyneuropathy; however, demyelinating features can be present. Chelation therapy with BAL has yielded inconsistent results; therefore, it is not generally recommended.

NUTRITIONAL NEUROPATHIES

COBALAMIN (VITAMIN B_{12})

Pernicious anemia is the most common cause of cobalamin deficiency. Other causes include dietary avoidance (vegetarians), gastrectomy, gastric bypass surgery, inflammatory bowel disease, pancreatic

insufficiency, bacterial overgrowth, and possibly histamine-2 blockers and proton pump inhibitors. An underappreciated cause of cobalamin deficiency is food-cobalamin malabsorption. This typically occurs in older individuals and results from an inability to adequately absorb cobalamin in food protein. No apparent cause of deficiency is identified in a significant number of patients with cobalamin deficiency. The use of nitrous oxide as an anesthetic agent or as a recreational drug can produce acute cobalamin deficiency neuropathy and subacute combined degeneration.

Complaints of numb hands typically appear before lower extremity paresthesias are noted. A preferential large-fiber sensory loss affecting proprioception and vibration with sparing of small-fiber modalities is present; an unsteady gait reflects sensory ataxia. These features, coupled with diffuse hyperreflexia and absent Achilles reflexes, should always focus attention on the possibility of cobalamin deficiency (Patterns 2 and 6; Table 457-2). Optic atrophy and, in severe cases, behavioral changes ranging from mild irritability and forgetfulness to severe dementia and frank psychosis may appear. The full clinical picture of subacute combined degeneration is uncommon. CNS manifestations, especially pyramidal tract signs, may be missing, and in fact, some patients may only exhibit symptoms of peripheral neuropathy.

EDx shows an axonal sensorimotor neuropathy. CNS involvement produces abnormal somatosensory and visual evoked potential latencies. The diagnosis is confirmed by finding reduced serum cobalamin levels. In up to 40% of patients, anemia and macrocytosis are lacking. Serum methylmalonic acid and homocysteine, the metabolites that accumulate when cobalamin-dependent reactions are blocked, are elevated. Antibodies to intrinsic factor are present in ~60% and antiparietal cell antibodies in ~90% of individuals with pernicious anemia.

Cobalamin deficiency can be treated with various regimens of cobalamin. One typical regimen consists of 1000 μg cyanocobalamin IM weekly for 1 month and monthly thereafter. Patients with food cobalamin malabsorption can absorb free cobalamin and therefore can be treated with oral cobalamin supplementation. An oral cobalamin dose of 1000 μg/d should be sufficient. Treatment for cobalamin deficiency usually does not completely reverse the clinical manifestations, and at least 50% of patients exhibit some permanent neurologic deficit.

THIAMINE DEFICIENCY

Thiamine (vitamin B_1) deficiency is an uncommon cause of peripheral neuropathy in developed countries. It is now most often seen as a consequence of chronic alcohol abuse, recurrent vomiting, total parenteral nutrition, and bariatric surgery. Thiamine deficiency polyneuropathy can occur in normal, healthy young adults who do not abuse alcohol but who engage in inappropriately restrictive diets. Thiamine is water-soluble. It is present in most animal and plant tissues, but the greatest sources are unrefined cereal grains, wheat germ, yeast, soybean flour, and pork. Beriberi means "I can't, I can't" in Singhalese, the language of natives of what was once part of the Dutch East Indies (now Sri Lanka). *Dry beriberi* refers to neuropathic symptoms. The term *wet beriberi* is used when cardiac manifestations predominate (in reference to edema). Beriberi was relatively uncommon until the late 1800s when it became widespread among people for whom rice was a dietary mainstay. This epidemic was due to a new technique of processing rice that removed the germ from the rice shaft, rendering the so-called polished rice deficient in thiamine and other essential nutrients.

Symptoms of neuropathy follow prolonged deficiency. These begin with mild sensory loss and/or burning dysesthesias in the toes and feet and aching and cramping in the lower legs. Pain may be the predominant symptom. With progression, patients develop features of a nonspecific generalized polyneuropathy, with distal sensory loss in the feet and hands.

Blood and urine assays for thiamine are not reliable for diagnosis of deficiency. Erythrocyte transketolase activity and the percentage increase in activity (in vitro) following the addition of thiamine pyrophosphate (TPP) may be more accurate and reliable. EDx shows nonspecific findings of an axonal sensorimotor polyneuropathy. When a diagnosis of thiamine deficiency is made or suspected, thiamine replacement should be provided until proper nutrition is restored. Thiamine is usually given intravenously or intramuscularly at a dose of 100 mg/d. Although cardiac manifestations show a striking response to thiamine replacement, neurologic improvement is usually more variable and less dramatic.

VITAMIN E DEFICIENCY

The term *vitamin E* is usually used for α-tocopherol, the most active of the four main types of vitamin E. Because vitamin E is present in animal fat, vegetable oils, and various grains, deficiency is usually due to factors other than insufficient intake. Vitamin E deficiency usually occurs secondary to lipid malabsorption or in uncommon disorders of vitamin E transport. One hereditary disorder is abetalipoproteinemia, a rare autosomal dominant disorder characterized by steatorrhea, pigmentary retinopathy, acanthocytosis, and progressive ataxia. Patients with cystic fibrosis may also have vitamin E deficiency secondary to steatorrhea. There are genetic forms of isolated vitamin E deficiency not associated with lipid malabsorption. Vitamin E deficiency may also occur as a consequence of various cholestatic and hepatobiliary disorders as well as short-bowel syndromes resulting from the surgical treatment of intestinal disorders.

Clinical features may not appear until many years after the onset of deficiency. The onset of symptoms tends to be insidious, and progression is slow. The main clinical features are spinocerebellar ataxia and polyneuropathy, thus resembling Friedreich's ataxia or other spinocerebellar ataxias. Patients manifest progressive ataxia and signs of posterior column dysfunction, such as impaired joint position and vibratory sensation. Because of the polyneuropathy, there is hyporeflexia, but plantar responses may be extensor as a result of the spinal cord involvement (Patterns 2 and 6; Table 457-2). Other neurologic manifestations may include ophthalmoplegia, pigmented retinopathy, night blindness, dysarthria, pseudoathetosis, dystonia, and tremor. Vitamin E deficiency may present as an isolated polyneuropathy, but this is very rare. The yield of checking serum vitamin E levels in patients with isolated polyneuropathy is extremely low, and this test should not be part of routine practice.

Diagnosis is made by measuring α-tocopherol levels in the serum. EDx shows features of an axonal neuropathy. Treatment is replacement with oral vitamin E, but high doses are not needed. For patients with isolated vitamin E deficiency, treatment consists of 1500–6000 IU/d in divided doses.

VITAMIN B_6 DEFICIENCY

Vitamin B_6, or pyridoxine, can produce neuropathic manifestations from both deficiency and toxicity. Vitamin B_6 toxicity was discussed above. Vitamin B_6 deficiency is most commonly seen in patients treated with isoniazid or hydralazine. The polyneuropathy of vitamin B_6 is nonspecific, manifesting as a generalized axonal sensorimotor polyneuropathy. Vitamin B_6 deficiency can be detected by direct assay. Vitamin B_6 supplementation with 50–100 mg/d is suggested for patients being treated with isoniazid or hydralazine. This same dose is appropriate for replacement in cases of nutritional deficiency.

PELLAGRA (NIACIN DEFICIENCY)

Pellagra is produced by deficiency of niacin. Although pellagra may be seen in alcoholics, this disorder has essentially been eradicated in most Western countries by means of enriching bread with niacin. Nevertheless, pellagra continues to be a problem in a number of underdeveloped regions, particularly in Asia and Africa, where corn is the main source of carbohydrate. Neurologic manifestations are variable; abnormalities can develop in the brain and spinal cord as well as peripheral nerves. When peripheral nerves are involved, the neuropathy is usually mild and resembles beriberi. Treatment is with niacin 40–250 mg/d.

COPPER DEFICIENCY

A syndrome that has only recently been described is myeloneuropathy secondary to copper deficiency **(see also Chap. 453)**. Most patients present with lower limb paresthesias, weakness, spasticity, and gait difficulties (Pattern 6; Table 457-2). Large-fiber sensory function is impaired, reflexes are brisk, and plantar responses are extensor. In some

cases, light touch and pinprick sensation are affected, and NCS indicate sensorimotor axonal polyneuropathy in addition to myelopathy.

Hematologic abnormalities are a known complication of copper deficiency; these can include microcytic anemia, neutropenia, and occasionally pancytopenia. Because copper is absorbed in the stomach and proximal jejunum, many cases of copper deficiency occur in the setting of prior gastric surgery. Excess zinc is an established cause of copper deficiency. Zinc upregulates enterocyte production of metallothionine, which results in decreased absorption of copper. Excessive dietary zinc supplements or denture cream containing zinc can produce this clinical picture. Other potential causes of copper deficiency include malnutrition, prematurity, total parenteral nutrition, and ingestion of copper-chelating agents.

Following oral or IV copper replacement, some patients show neurologic improvement, but this may take many months or not occur at all. Replacement consists of oral copper sulfate or gluconate 2 mg one to three times a day. If oral copper replacement is not effective, elemental copper in the copper sulfate or copper chloride forms can be given as 2 mg IV daily for 3–5 days, then weekly for 1–2 months until copper levels normalize. Thereafter, oral daily copper therapy can be resumed. In contrast to the neurologic manifestations, most of the hematologic indices normalize in response to copper replacement therapy.

NEUROPATHY ASSOCIATED WITH GASTRIC SURGERY

Polyneuropathy may occur following gastric surgery for ulcer, cancer, or weight reduction. This usually occurs in the context of rapid, significant weight loss and recurrent, protracted vomiting. The clinical picture is one of acute or subacute sensory loss and weakness. Neuropathy following weight loss surgery usually occurs in the first several months after surgery. Weight reduction surgical procedures include gastrojejunostomy, gastric stapling, vertical banded gastroplasty, and gastrectomy with Roux-en-Y anastomosis. The initial manifestations are usually numbness and paresthesias in the feet (Pattern 2; Table 457-2). In many cases, no specific nutritional deficiency factor is identified.

Management consists of parenteral vitamin supplementation, especially including thiamine. Improvement has been observed following supplementation, parenteral nutritional support, and reversal of the surgical bypass. The duration and severity of deficits before identification and treatment of neuropathy are important predictors of final outcome.

CRYPTOGENIC (IDIOPATHIC) SENSORY AND SENSORIMOTOR POLYNEUROPATHY

Cryptogenic (idiopathic) sensory and sensorimotor polyneuropathy (CSPN) is a diagnosis of exclusion, established after a careful medical, family, and social history; neurologic examination; and directed laboratory testing. Despite extensive evaluation, the cause of polyneuropathy in as many as 50% of all patients is idiopathic. CSPN should be considered a distinct diagnostic subset of peripheral neuropathy. The onset of CSPN is predominantly in the sixth and seventh decades. Patients complain of distal numbness, tingling, and often burning pain that invariably begins in the feet and may eventually involve the fingers and hands ("burning feet syndrome"). Patients exhibit a distal sensory loss to pinprick, touch, and vibration in the toes and feet, and occasionally in the fingers (Pattern 2; Table 457-2). It is uncommon to see significant proprioception deficits, even though patients may complain of gait unsteadiness. However, tandem gait may be abnormal in a minority of cases. Neither subjective nor objective evidence of weakness is a prominent feature. Most patients have evidence of both large- and small-fiber loss on neurologic examination and EDx. Approximately 10% of patients have only evidence of small-fiber involvement. The ankle muscle stretch reflex is frequently absent, but in cases with predominantly small-fiber loss, this may be preserved. The EDx findings range from isolated SNAP abnormalities (usually with loss of amplitude), to evidence for an axonal sensorimotor neuropathy, to a completely normal study (if primarily small fibers are involved). Therapy primarily involves the control of neuropathic pain (Table 457-6) if present. A large comparative effectiveness study in CSPN showed that the drugs nortriptyline and duloxetine outperformed pregabalin and mexiletine. These drugs should not be used if the patient has only numbness and tingling but no pain.

Although no treatment is available that can reverse an idiopathic distal peripheral neuropathy, the prognosis is good. Progression often does not occur or is minimal, with sensory symptoms and signs progressing proximally up to the knees and elbows. The disorder does not lead to significant motor disability over time. The relatively benign course of this disorder should be explained to patients.

MONONEUROPATHIES/PLEXOPATHIES/RADICULOPATHIES (PATTERN 3; TABLE 457-2)

MEDIAN NEUROPATHY

CTS is a compression of the median nerve in the carpal tunnel at the wrist. The median nerve enters the hand through the carpal tunnel by coursing under the transverse carpal ligament. The symptoms of CTS consist of numbness and paresthesias variably in the thumb, index, middle, and half of the ring finger. At times, the paresthesias can include the entire hand and extend into the forearm or upper arm or can be isolated to one or two fingers. Pain is another common symptom and can be located in the hand and forearm and, at times, in the proximal arm. CTS is common and often misdiagnosed as thoracic outlet syndrome. The signs of CTS are decreased sensation in the median nerve distribution; reproduction of the sensation of tingling when a percussion hammer is tapped over the wrist (Tinel sign) or the wrist is flexed for 30–60 s (Phalen sign); and weakness of thumb opposition and abduction. EDx is extremely sensitive and shows slowing of sensory and, to a lesser extent, motor median potentials across the wrist. Ultrasound can show focal swelling of the median nerve at the wrist. Treatment options consist of avoidance of precipitating activities; control of underlying systemic-associated conditions if present; nonsteroidal anti-inflammatory medications; neutral (volar) position wrist splints, especially for night use; glucocorticoid/anesthetic injection into the carpal tunnel; and surgical decompression by dividing the transverse carpal ligament. The surgical option should be considered if there is a poor response to nonsurgical treatments; if there is thenar muscle atrophy and/or weakness; and if there are significant denervation potentials on EMG.

Other proximal median neuropathies are very uncommon and include the pronator teres syndrome and anterior interosseous neuropathy. These often occur as a partial form of brachial plexitis.

ULNAR NEUROPATHY AT THE ELBOW—"CUBITAL TUNNEL SYNDROME"

The ulnar nerve passes through the condylar groove between the medial epicondyle and the olecranon. Symptoms consist of paresthesias, tingling, and numbness in the medial hand and half of the fourth and the entire fifth fingers, pain at the elbow or forearm, and weakness. Signs consist of decreased sensation in an ulnar distribution, Tinel's sign at the elbow, and weakness and atrophy of ulnar-innervated hand muscles. The Froment sign indicates thumb adductor weakness and consists of flexion of the thumb at the interphalangeal joint when attempting to oppose the thumb against the lateral border of the second digit. EDx may show slowing of ulnar motor NCV across the elbow with prolonged ulnar sensory latencies. Ultrasound can show swelling of the ulnar nerve around the elbow as well. Treatment consists of avoiding aggravating factors, using elbow pads, and surgery to decompress the nerve in the cubital tunnel. Ulnar neuropathies can also rarely occur at the wrist in the ulnar (Guyon) canal or in the hand, usually after trauma.

RADIAL NEUROPATHY

The radial nerve winds around the proximal humerus in the spiral groove and proceeds down the lateral arm and enters the forearm, dividing into the posterior interosseous nerve and superficial nerve. The symptoms and signs consist of wrist drop; finger extension weakness; thumb abduction weakness; and sensory loss in the dorsal web between the thumb and index finger. Triceps and brachioradialis

strength is often normal, and triceps reflex is often intact. Most cases of radial neuropathy are transient compressive (neuropraxic) injuries that recover spontaneously in 6–8 weeks. If there has been prolonged compression and severe axonal damage, it may take several months to recover. Treatment consists of cock-up wrist and finger splints, avoiding further compression, and physical therapy to avoid flexion contracture. If there is no improvement in 2–3 weeks, an EDx study is recommended to confirm the clinical diagnosis and determine the degree of severity.

LATERAL FEMORAL CUTANEOUS NEUROPATHY (MERALGIA PARESTHETICA)

The lateral femoral cutaneous nerve arises from the upper lumbar plexus (spinal levels L2/3), crosses through the inguinal ligament near its attachment to the iliac bone, and supplies sensation to the anterior lateral thigh. The neuropathy affecting this nerve is also known as meralgia paresthetica. Symptoms and signs consist of paresthesias, numbness, and occasionally pain in the lateral thigh. Symptoms are increased by standing or walking and are relieved by sitting. There is normal strength, and knee reflexes are intact. The diagnosis is clinical, and further tests usually are not performed. EDx is only needed to rule out lumbar plexopathy, radiculopathy, or femoral neuropathy. If the symptoms and signs are classic, EMG is not necessary. Symptoms often resolve spontaneously over weeks or months, but the patient may be left with permanent numbness. Treatment consists of weight loss and avoiding tight belts. Analgesics in the form of a lidocaine patch, nonsteroidal agents, and occasionally medications for neuropathic pain can be used (Table 457-6). Rarely, locally injecting the nerve with an anesthetic can be tried. There is no role for surgery.

FEMORAL NEUROPATHY

Femoral neuropathies can arise as complications of retroperitoneal hematoma, lithotomy positioning, hip arthroplasty or dislocation, iliac artery occlusion, femoral arterial procedures, infiltration by hematogenous malignancy, penetrating groin trauma, pelvic surgery including hysterectomy and renal transplantation, and diabetes (a partial form of lumbosacral diabetic plexopathy); some cases are idiopathic. Patients with femoral neuropathy have difficulty extending their knee and flexing the hip. Sensory symptoms occurring either on the anterior thigh and/or medial leg occur in only half of reported cases. A prominent painful component is the exception rather than the rule, may be delayed, and is often self-limited in nature. The quadriceps (patellar) reflex is diminished.

SCIATIC NEUROPATHY

Sciatic neuropathies commonly complicate hip arthroplasty, pelvic procedures in which patients are placed in a prolonged lithotomy position, trauma, hematomas, tumor infiltration, and vasculitis. In addition, many sciatic neuropathies are idiopathic. Weakness may involve all motions of the ankles and toes as well as flexion of the leg at the knee; abduction and extension of the thigh at the hip are spared. Sensory loss occurs in the entire foot and the distal lateral leg. The ankle jerk and, on occasion, the internal hamstring reflex are diminished or more typically absent on the affected side. The peroneal subdivision of the sciatic nerve is typically involved disproportionately to the tibial counterpart. Thus, patients may have only ankle dorsiflexion and eversion weakness with sparing of knee flexion, ankle inversion, and plantar flexion; these features can lead to misdiagnosis of a common peroneal neuropathy.

PERONEAL NEUROPATHY

The sciatic nerve divides at the distal femur into the tibial and peroneal nerve. The common peroneal nerve passes posterior and laterally around the fibular head, under the fibular tunnel. It then divides into the superficial peroneal nerve, which supplies the ankle evertor muscles and sensation over the anterolateral distal leg and dorsum of the foot, and the deep peroneal nerve, which supplies ankle dorsiflexors and toe extensor muscles and a small area of sensation dorsally in the area of the first and second toes.

Symptoms and signs consist of foot drop (ankle dorsiflexion, toe extension, and ankle eversion weakness) and variable sensory loss, which may involve the superficial and deep peroneal pattern. There is usually no pain. Onset may be on awakening in the morning. Peroneal neuropathy needs to be distinguished from L5 radiculopathy. In L5 radiculopathy, ankle invertors and evertors are weak and needle EMG reveals denervation. EDx can help localize the lesion. Peroneal motor conduction velocity shows slowing and amplitude drop across the fibular head. Management consists of rapid weight loss and avoiding leg crossing. Foot drop is treated with an ankle brace. A knee pad can be worn over the lateral knee to avoid further compression. Most cases spontaneously resolve over weeks or months.

RADICULOPATHIES

Radiculopathies are most often due to compression from degenerative joint disease and herniated disks, but there are a number of unusual etiologies (Table 457-9). **Degenerative spine disease affects a number of different structures, which narrow the diameter of the neural foramen or canal of the spinal column and compromise nerve root integrity; these are discussed in detail in Chaps. 18 and 19.**

PLEXOPATHIES (PATTERN 4; TABLE 457-2)

BRACHIAL PLEXUS

The brachial plexus is composed of three trunks (upper, middle, and lower), with two divisions (anterior and posterior) per trunk (Fig. 457-2). Subsequently, the trunks divide into three cords (medial, lateral, and posterior), and from these, arise the multiple terminal nerves innervating the arm. The anterior primary rami of C5 and C6 fuse to form the upper trunk; the anterior primary ramus of C7 continues as the middle trunk, while the anterior rami of C8 and T1 join to form the lower trunk. There are several disorders commonly associated with brachial plexopathy.

Immune-Mediated Brachial Plexus Neuropathy Immune-mediated brachial plexus neuropathy (IBPN) goes by various terms, including *acute brachial plexitis, neuralgic amyotrophy*, and *Parsonage-Turner syndrome*. IBPN usually presents with an acute onset of severe pain in the shoulder region. The intense pain usually lasts several days to a few weeks, but a dull ache can persist. Individuals who are affected may not appreciate weakness of the arm early in the course because the pain limits movement. However, as the pain dissipates, weakness and often sensory loss are appreciated. Attacks can occasionally recur.

Clinical findings are dependent on the distribution of involvement (e.g., specific trunk, divisions, cords, or terminal nerves). The most

TABLE 457-9 Causes of Radiculopathy

- Herniated nucleus pulposus
- Degenerative joint disease
- Rheumatoid arthritis
- Trauma
- Vertebral body compression fracture
- Pott's disease (tuberculosis)
- Compression by extradural mass (e.g., meningioma, metastatic tumor, hematoma, abscess)
- Primary nerve tumor (e.g., neurofibroma, schwannoma, neurinoma)
- Carcinomatous meningitis
- Perineurial spread of tumor (e.g., prostate cancer)
- Acute inflammatory demyelinating polyradiculopathy
- Chronic inflammatory demyelinating polyradiculopathy
- Sarcoidosis
- Amyloidoma
- Diabetic radiculopathy
- Infection (Lyme disease, herpes zoster, HIV, cytomegalovirus, syphilis, schistosomiasis, *Strongyloides*)
- Arachnoiditis (e.g., postsurgical)
- Radiation

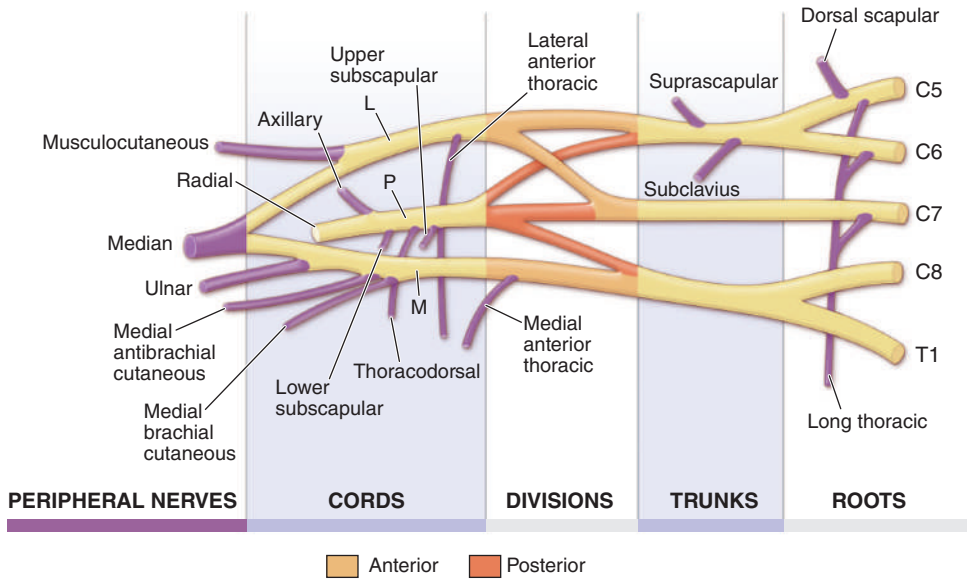

FIGURE 457-2 Brachial plexus anatomy. L, lateral; M, medial; P, posterior. *(Reproduced with permission J Goodgold: Anatomical Correlates of Clinical Electromyography. Baltimore, Williams and Wilkins, 1974.)*

common pattern of IBPN involves the upper trunk or a single or multiple mononeuropathies primarily involving the suprascapular, long thoracic, or axillary nerves. Additionally, the phrenic and anterior interosseous nerves may be concomitantly affected. Any of these nerves may also be affected in isolation. EDx is useful to confirm and localize the site(s) of involvement. Empirical treatment of severe pain with glucocorticoids is often used in the acute period.

Brachial Plexopathies Associated with Neoplasms Neoplasms involving the brachial plexus may be primary nerve tumors, local cancers expanding into the plexus (e.g., Pancoast lung tumor or lymphoma), and metastatic tumors. Primary brachial plexus tumors are less common than the secondary tumors and include schwannomas, neurinomas, and neurofibromas. Secondary tumors affecting the brachial plexus are more common and are always malignant. These may arise from local tumors, expanding into the plexus. For example, a Pancoast tumor of the upper lobe of the lung may invade or compress the lower trunk, whereas a primary lymphoma arising from the cervical or axillary lymph nodes may also infiltrate the plexus. Pancoast tumors typically present as an insidious onset of pain in the upper arm, sensory disturbance in the medial aspect of the forearm and hand, and weakness and atrophy of the intrinsic hand muscles along with an ipsilateral Horner's syndrome. Chest computed tomography (CT) scans or MRI can demonstrate extension of the tumor into the plexus. Metastatic involvement of the brachial plexus may occur with spread of breast cancer into the axillary lymph nodes and local spread into the nearby nerves.

Perioperative Plexopathies (Median Sternotomy) The most common surgical procedures associated with brachial plexopathy as a complication are those that involve median sternotomies (e.g., open-heart surgeries and thoracotomies). Brachial plexopathies occur in as many as 5% of patients following a median sternotomy and typically affect the lower trunk. Thus, individuals manifest with sensory disturbance affecting the medial aspect of forearm and hand along with weakness of the intrinsic hand muscles. The mechanism is related to the stretch of the lower trunk, so most individuals who are affected recover within a few months.

Lumbosacral Plexus The lumbar plexus arises from the ventral primary rami of the first to the fourth lumbar spinal nerves (Fig. 457-3). These nerves pass downward and laterally from the vertebral column within the psoas major muscle. The femoral nerve derives from the dorsal branches of the second to the fourth lumbar ventral rami. The obturator nerve arises from the ventral branches of the same lumbar rami. The lumbar plexus communicates with the sacral plexus by the lumbosacral trunk, which contains some fibers from the fourth and all of the fibers from the fifth lumbar ventral rami (Fig. 457-4).

The sacral plexus is the part of the lumbosacral plexus that is formed by the union of the lumbosacral trunk with the ventral rami of the first to fourth sacral nerves. The plexus lies on the posterior and posterolateral wall of the pelvis with its components converging toward the sciatic notch. The lateral trunk of the sciatic nerve (which forms the common peroneal nerve) arises from the union of the dorsal branches of the lumbosacral trunk (L4, L5) and the dorsal branches of the S1 and S2 spinal nerve ventral rami. The medial trunk of the sciatic nerve (which forms the tibial nerve) derives from the ventral branches of the same ventral rami (L4-S2).

LUMBOSACRAL PLEXOPATHIES

Plexopathies are typically recognized when motor, sensory, and if applicable, reflex deficits occur in multiple nerve and segmental distributions confined to one extremity. If localization within the lumbosacral plexus can be accomplished, designation as a lumbar plexopathy, a sacral plexopathy, a lumbosacral trunk lesion, or a panplexopathy is the best localization that can be expected. Although lumbar plexopathies may be bilateral, usually occurring in a stepwise and chronologically dissociated manner, sacral plexopathies are more likely to behave in this manner due to their closer anatomic proximity. The differential diagnosis of plexopathy includes disorders of the conus medullaris and cauda equina (polyradiculopathy). If there is a paucity of pain and sensory involvement, motor neuron disease should be considered as well.

The causes of lumbosacral plexopathies are listed in Table 457-10. Diabetic radiculopathy (discussed above) is a fairly common cause of painful leg weakness. Lumbosacral plexopathies are a well-recognized complication of retroperitoneal hemorrhage. Various primary and metastatic malignancies can affect the lumbosacral plexus as well; these include carcinoma of the cervix, endometrium, and ovary; osteosarcoma; testicular cancer; MM; lymphoma; acute myelogenous leukemia; colon cancer; squamous cell carcinoma of the rectum; adenocarcinoma of unknown origin; and intraneural spread of prostate cancer.

RECURRENT NEOPLASTIC DISEASE OR RADIATION-INDUCED PLEXOPATHY

The treatment for various malignancies is often radiation therapy, the field of which may include parts of the brachial plexus. It can be difficult in such situations to determine if a new brachial or lumbosacral plexopathy is related to tumor within the plexus or from

- Benign neoplasm
- Radiation
- Amyloid
- Diabetic radiculoplexus neuropathy
- Idiopathic radiculoplexus neuropathy
- Sarcoidosis
- Aortic occlusion/surgery
- Lithotomy positioning
- Hip arthroplasty
- Pelvic fracture
- Obstetric injury

radiation-induced nerve damage. Radiation can be associated with microvascular abnormalities and fibrosis of surrounding tissues, which can damage the axons and the Schwann cells. Radiation-induced plexopathy can develop months or years following therapy and is dose dependent.

Tumor invasion is usually painful and more commonly affects the lower trunk, whereas radiation injury is often painless and affects the upper trunk. Imaging studies such as MRI and CT scans are useful but can be misleading, especially when there is small microscopic invasion of the plexus. EMG can be informative if myokymic discharges are appreciated, as this finding strongly suggests radiation-induced damage.

EVALUATION AND TREATMENT OF PLEXOPATHIES

Most patients with plexopathies will undergo both imaging with MRI and EDx evaluations. Severe pain from acute idiopathic lumbosacral plexopathy may respond to a short course of glucocorticoids.

458 Guillain-Barré Syndrome and Other Immune-Mediated Neuropathies

Stephen L. Hauser, Anthony A. Amato

GUILLAIN-BARRÉ SYNDROME

Guillain-Barré syndrome (GBS) is an acute, frequently severe, and fulminant polyradiculoneuropathy that is autoimmune in nature. It occurs year-round at a rate of between 10 and 20 cases per million annually; in the United States, ~5000–6000 cases occur per year. Males are at slightly higher risk for GBS than females, and in Western countries, adults are more frequently affected than children.

Clinical Manifestations GBS manifests as a rapidly evolving areflexic motor paralysis with or without sensory disturbance. The usual pattern is an ascending paralysis that may be first noticed as rubbery legs. Weakness typically evolves over hours to a few days and is frequently accompanied by tingling dysesthesias in the extremities. The legs are usually more affected than the arms, and facial diparesis is present in 50% of affected individuals. The lower cranial nerves are also frequently involved, causing bulbar weakness with difficulty handling secretions and maintaining an airway; the diagnosis in these patients may initially be mistaken for brainstem ischemia. Pain in the neck, shoulder, back, or diffusely over the spine is also common in the early stages of GBS, occurring in ~50% of patients. Most patients require hospitalization, and in different series, up to 30% require ventilatory assistance at some time during the illness. The need for mechanical ventilation is associated with more severe weakness on admission, a rapid tempo of progression, and the presence of facial and/or bulbar weakness during the first week of symptoms. Fever and constitutional symptoms are absent at the onset and, if present, cast doubt on the diagnosis. Deep tendon reflexes attenuate or disappear within the first few days of onset. Cutaneous sensory deficits (e.g., loss of pain and temperature sensation) are usually relatively mild, but functions subserved by large sensory fibers, such as deep tendon reflexes and proprioception, are more severely affected. Bladder dysfunction may occur in severe cases but is usually transient. If bladder dysfunction is a prominent feature and comes early in the course or there is a sensory level on examination, diagnostic possibilities other than GBS should be considered, particularly spinal cord disease **(Chap. 453)**. Once clinical worsening stops and the patient reaches a plateau (almost always within 4 weeks of onset), further progression is unlikely.

Autonomic involvement is common and may occur even in patients whose GBS is otherwise mild. The usual manifestations are loss of vasomotor control with wide fluctuations in blood pressure, postural hypotension, and cardiac dysrhythmias. These features require close monitoring and management and can be fatal. Pain is another common feature of GBS; in addition to the acute pain described above, a deep aching pain may be present in weakened muscles that patients liken to having overexercised the previous day. Other pains in GBS include dysesthetic pain in the extremities as a manifestation of sensory nerve fiber involvement. These pains are self-limited and often respond to standard analgesics **(Chap. 14)**.

Several subtypes of GBS are recognized, as determined primarily by electrodiagnostic (EDx) and pathologic distinctions **(Table 458-1)**. The most common variant is acute inflammatory demyelinating polyneuropathy (AIDP). Additionally, there are two "axonal" or "nodal/paranodal" variants, which are often clinically severe: the acute motor axonal neuropathy (AMAN) and acute motor sensory axonal neuropathy (AMSAN) subtypes. In addition, a range of limited or regional GBS syndromes are also encountered. Notable among these is the Miller Fisher syndrome (MFS), which presents as rapidly evolving ataxia and areflexia of limbs without weakness, and ophthalmoplegia, often with pupillary paralysis. The MFS variant accounts for ~5% of all cases and is strongly associated with antibodies to the ganglioside GQ1b (see "Immunopathogenesis," below). Other regional variants of GBS include (1) pure sensory forms; (2) ophthalmoplegia with anti-GQ1b antibodies as part of severe motor-sensory GBS; (3) GBS with severe bulbar and facial paralysis, sometimes associated with antecedent cytomegalovirus (CMV) infection and anti-GM2 antibodies; and (4) acute pandysautonomia **(Chap. 451)**.

Antecedent Events Approximately 70% of cases of GBS occur 1–3 weeks after an acute infectious process, usually respiratory or gastrointestinal. Culture and seroepidemiologic techniques show that 20–30% of all cases occurring in North America, Europe, and Australia are preceded by infection or reinfection with *Campylobacter jejuni*. A similar proportion is preceded by a human herpes virus infection, often CMV or Epstein-Barr virus. Other viruses (e.g., HIV, hepatitis E, Zika) and also *Mycoplasma pneumoniae* have been identified as agents involved in antecedent infections. Cases of GBS have been reported in association with SARS-CoV-2 infection during the COVID-19 pandemic, but a causal relationship has not been established.

C. jejuni has also been implicated in summer outbreaks of AMAN among children and young adults exposed to chickens in rural China, as has infection by Zika virus in the increased incidence of GBS in Brazil and other endemic regions.

Recent immunizations have also been implicated in GBS. The swine influenza vaccine, administered widely in the United States in 1976, is the most notable example. Influenza vaccines in use from 1992 to 1994, however, resulted in only one additional case of GBS per million persons vaccinated, and the more recent seasonal influenza vaccines appear to confer a GBS risk of <1 per million. Epidemiologic studies looking at H1N1 vaccination demonstrated at most only a slight increased risk of GBS. There appears to be an increased risk of GBS with SARS-CoV-2 vaccines using adenovirus vectors, but not the messenger RNA vaccines. Meningococcal vaccinations (Menactra) do not appear to carry an increased risk. Older-type rabies vaccine, prepared in nervous system tissue, is implicated as a trigger of GBS in developing countries where it is still used; the mechanism is presumably immunization against neural antigens.

TABLE 458-1 Subtypes of Guillain-Barré Syndrome (GBS)

SUBTYPE	FEATURES	ELECTRODIAGNOSIS	PATHOLOGY
Acute inflammatory demyelinating polyneuropathy (AIDP)	Adults affected more than children; 90% of cases in Western world; recovery rapid; anti-GM1 antibodies (<50%)	Demyelinating	First attack on Schwann cell surface; widespread myelin damage, macrophage activation, and lymphocytic infiltration; variable secondary axonal damage
Acute motor axonal neuropathy (AMAN)	Children and young adults; prevalent in China and Mexico; may be seasonal; recovery rapid; anti-GD1a antibodies	Axonal	First attack at motor nodes of Ranvier; macrophage activation, few lymphocytes, frequent periaxonal macrophages; extent of axonal damage highly variable
Acute motor sensory axonal neuropathy (AMSAN)	Mostly adults; uncommon; recovery slow, often incomplete; closely related to AMAN	Axonal	Same as AMAN, but also affects sensory nerves and roots; axonal damage usually severe
Miller Fisher syndrome (MFS)	Adults and children; ophthalmoplegia, ataxia, and areflexia; anti-GQ1b antibodies (90%)	Axonal or demyelinating	Few cases examined; resembles AIDP

GBS also occurs more frequently than can be attributed to chance alone in patients with lymphoma (including Hodgkin's disease), in HIV-seropositive individuals, and in patients with systemic lupus erythematosus (SLE) and possibly Sjogren's syndrome. GBS, other inflammatory neuropathies, and myositis can also occur as a complication of immune checkpoint inhibitors used to treat various cancers.

Immunopathogenesis Several lines of evidence support an autoimmune basis for AIDP, the most common and best-studied type of GBS; the concept extends to all of the subtypes of GBS (Table 458-1).

It is likely that both cellular and humoral immune mechanisms contribute to tissue damage in AIDP. AIDP is also closely analogous to an experimental T cell–mediated immunopathy designated *experimental allergic neuritis* (EAN). EAN is induced in laboratory animals by immune sensitization against protein fragments derived from peripheral nerve proteins and, in particular, against the P2 protein. Based on analogy to EAN, it was initially thought that AIDP was also likely to have a T cell–mediated pathogenesis, and consistent with this concept, autoreactive T cells against several peripheral myelin proteins have recently been identified in peripheral blood, cerebrospinal fluid (CSF), and infiltrating nerves from AIDP patients. However, abundant data also indicate that autoantibodies directed against T cell–independent nonprotein determinants may be the central mediators in many cases. Involvement of the humoral arm of the immune system in AIDP is supported by the demonstration of terminal complement complex on Schwann cells in autopsy series and induction of complement-dependent demyelination and conduction block following injection of serum from patients with GBS into nerves of animals. In AMAN, there is deposition of IgG and complement activation products on the nodal and internodal axolemma of motor fibers.

Circumstantial evidence suggests that all GBS results from immune responses to nonself antigens (infectious agents, vaccines) that misdirect to host nerve tissue through a resemblance-of-epitope (molecular mimicry) mechanism **(Fig. 458-1)**. The neural targets are likely to be glycoconjugates, specifically gangliosides **(Table 458-2; Fig. 458-2)**. Gangliosides are complex glycosphingolipids that contain one or more sialic acid residues; various gangliosides participate in cell-cell interactions (including those between axons and glia), modulation of receptors, and regulation of growth. They are typically exposed on the plasma membrane of cells, rendering them susceptible to an antibody-mediated attack. Gangliosides and other glycoconjugates are present in large quantity in human nervous tissues and in key sites, such as nodes of Ranvier. Antiganglioside antibodies, most frequently to GM1, are common in GBS (20–50% of cases), particularly in AMAN and AMSAN, and in those cases, they are preceded by *C. jejuni* infection. Some AIDP autoantibodies may recognize glycolipid heterocomplexes, rather than single species, present on cell membranes. Furthermore, isolates of *C. jejuni* from stool cultures of patients with GBS have surface glycolipid structures that antigenically cross react with gangliosides, including GM1, concentrated in human nerves. Sialic acid residues from pathogenic *C. jejuni* strains can also trigger activation of dendritic cells via signaling through Toll-like receptor 4 (TLR4), promoting B-cell differentiation and further amplifying humoral autoimmunity. Another line of evidence implicating humoral autoimmunity is derived from cases of GBS that followed intravenous administration of bovine brain gangliosides for treatment of various neuropathies; 5–15 days after injection, some recipients developed AMAN with high titers of anti-GM1 antibodies that recognized epitopes at nodes of Ranvier and motor endplates. Experimentally, anti-GM1 antibodies can trigger complement-mediated injury at paranodal axon-glial junctions, disrupting the clustering of sodium channels and likely contributing to conduction block (see "Pathophysiology," below).

Anti-GQ1b IgG antibodies are found in >90% of patients with MFS (Table 458-2; Fig. 458-2), and titers of IgG are highest early in

Subtypes and variants	IgG autoantibodies to
Guillain-Barré syndrome	
Acute inflammatory demyelinating polyneuropathy	None
Facial variant: Facial diplegia and paresthesia	None
Acute motor axonal neuropathy	GM1, GD1a
More and less extensive forms	
Acute motor-sensory axonal neuropathy	GM1, GD1a
Acute motor-conduction-block neuropathy	GM1, GD1a
Pharyngeal-cervical-brachial weakness	GT1a>GQ1b>>GD1a
Miller Fisher syndrome	GQ1b, GT1a
Incomplete forms	
Acute ophthalmoparesis (without ataxia)	GQ1b, GT1a
Acute ataxic neuropathy (without ophthalmoplegia)	GQ1b, GT1a
CNS variant: Bickerstaff's brainstem encephalitis	GQ1b, GT1a

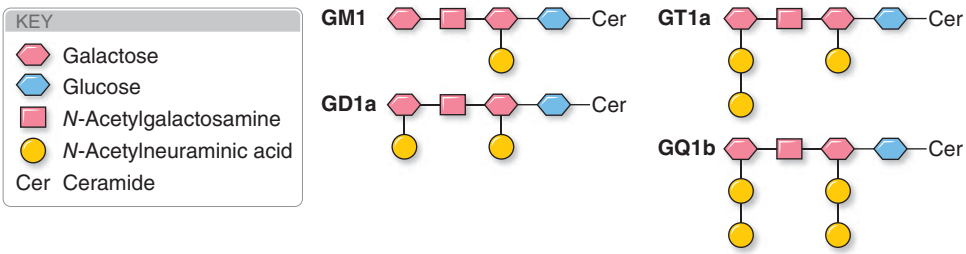

FIGURE 458-1 Spectrum of disorders in Guillain-Barré syndrome and associated antiganglioside antibodies. IgG autoantibodies against GM1 or GD1a are strongly associated with acute motor axonal neuropathy (AMAN), as well as the more extensive acute motor-sensory axonal neuropathy (AMSAN), and the less extensive acute motor-conduction-block neuropathy. IgG anti-GQ1b antibodies, which cross-react with GT1a, are strongly associated with Miller Fisher syndrome, its incomplete forms (acute ophthalmoparesis [without ataxia] and acute ataxic neuropathy [without ophthalmoplegia]), and its more extensive form, Bickerstaff's brainstem encephalitis. Pharyngeal-cervical-brachial weakness is categorized as a localized form of acute motor axonal neuropathy or an extensive form of Miller Fisher syndrome. Half of patients with pharyngeal-cervical-brachial weakness have IgG anti-GT1a antibodies, which often cross-react with GQ1b. IgG anti-GD1a antibodies have also been detected in a small percentage of patients. The anti-GQ1b antibody syndrome includes Miller Fisher syndrome, acute ophthalmoparesis, acute ataxic neuropathy, Bickerstaff's brainstem encephalitis, and pharyngeal-cervical-brachial weakness. The presence of clinical overlap also indicates that Miller Fisher syndrome is part of a continuous spectrum with these conditions. Patients who have had Guillain-Barré syndrome overlapped with Miller Fisher syndrome or with its related conditions have IgG antibodies against GM1 or GD1a as well as against GQ1b or GT1a, supporting a link between AMAN and anti-GQ1b syndrome. *(From N Yuki, H-P Hartung: Guillain-Barré syndrome. N Engl J Med 366:2294, 2012. Copyright © 2012 Massachusetts Medical Society. Reprinted with permission from Massachusetts Medical Society.)*

TABLE 458-2 Principal Antiglycolipid Antibodies Implicated in Immune Neuropathies

CLINICAL PRESENTATION	ANTIBODY TARGET	USUAL ISOTYPE
Acute Immune Neuropathies (Guillain-Barré Syndrome)		
Acute inflammatory demyelinating polyneuropathy (AIDP)	No clear patterns GM1 most common	IgG (polyclonal)
Acute motor axonal neuropathy (AMAN)	GD1a, GM1, GM1b, GalNAc–GD1a (<50% for any)	IgG (polyclonal)
Miller Fisher syndrome (MFS)	GQ1b (>90%)	IgG (polyclonal)
Acute pharyngeal cervicobrachial neuropathy (APCBN)	GT1a (? most)	IgG (polyclonal)
Chronic Immune Neuropathies		
Chronic inflammatory demyelinating polyneuropathy (CIDP) (75%)	Rarely to P0, myelin P2 protein, or PMP22	IgG, IgA
CIDP-M (MGUS associated) (25%)	Neural binding sites	IgG, IgA (monoclonal)
Anti-MAG neuropathy	SGPG, SGLPG (on MAG) (50%) Uncertain (50%)	IgM (monoclonal) IgM (monoclonal)
Nodal/paranodal neuropathies	Approximately 10% to CNTN1 or NF155, less often to NF140/186 and Caspr1	IgG4 with CNTN1, NF155, NF140/186, Caspr1 Rare IgM with NF155
Multifocal motor neuropathy (MMN)	GM1, GalNAc–GD1a, others (25–50%)	IgM (polyclonal, monoclonal)
Chronic sensory ataxic neuropathy	GD1b, GQ1b, and other b-series gangliosides	IgM (monoclonal)

Abbreviations: CIDP-M, CIDP with a monoclonal gammopathy; Caspr1, contactin associated protein-1; CNTN1, contactin-1; MAG, myelin-associated glycoprotein; MGUS, monoclonal gammopathy of undetermined significance; NF140/186, neurofascin 140/186; NF155, neurofascin 155; SGPG, sulfoglucuronyl paragloboside; SGLPG, sulfoglucuronyl lactosaminyl paragloboside.

the course. Anti-GQ1b antibodies are not found in other forms of GBS unless there is extraocular motor nerve involvement. A possible explanation for this association is that extraocular motor nerves are enriched in GQ1b gangliosides in comparison to limb nerves. In addition, a monoclonal anti-GQ1b antibody raised against *C. jejuni* isolated from a patient with MFS blocked neuromuscular transmission experimentally.

Taken together, these observations provide strong but still inconclusive evidence that autoantibodies play an important pathogenic role in GBS. Although antiganglioside antibodies have been studied most intensively, other antigenic targets may also be important. Proof that these antibodies are pathogenic requires that they be capable of mediating disease following direct passive transfer to naïve hosts; this has not yet been demonstrated, although one case of possible maternal-fetal transplacental transfer of GBS has been described.

In AIDP, an early step in the induction of tissue damage appears to be complement deposition along the outer surface of the Schwann cell. Activation of complement initiates a characteristic vesicular disintegration of the myelin sheath and also leads to recruitment of activated macrophages, which participate in damage to myelin and axons. In AMAN, the pattern is different in that complement is deposited along with IgG at the nodes of Ranvier along large motor axons. Interestingly, in cases of AMAN, antibodies against GD1a appear to have a fine specificity that favors binding to motor rather than sensory nerve roots, even though this ganglioside is expressed on both fiber types.

Pathophysiology In the demyelinating forms of GBS (AIDP), the basis for flaccid paralysis and sensory disturbance is conduction block. This finding, demonstrable electrophysiologically, implies that the axonal connections remain intact. Hence, recovery can take place rapidly as remyelination occurs. In severe cases of demyelinating GBS, secondary axonal degeneration usually occurs; its extent can be estimated electrophysiologically. More secondary axonal degeneration correlates with a slower rate of recovery and a greater degree of residual disability. With AMAN and AMSAN, a primary axonal pattern is encountered electrophysiologically (low-amplitude compound muscle action potentials). The implication has been that axons have degenerated and become disconnected from their targets, specifically the neuromuscular junctions, and must therefore regenerate for recovery to take place. However, the rapid recovery in many cases suggests the low amplitudes are often from reversible conduction block due to binding of antibodies to ion channel proteins in the nodes and paranodes. In severe cases, axonal degeneration can occur, and it is in these cases that recovery is much slower.

Laboratory Features CSF findings are distinctive, consisting of an elevated CSF protein level (1–10 g/L [100–1000 mg/dL]) without accompanying pleocytosis. The CSF is often normal when symptoms have been present for ≤48 h; by the end of the first week, the level of protein is usually elevated. A transient increase in the CSF white cell count (10–100/μL) occurs on occasion in otherwise typical GBS; however, a sustained CSF pleocytosis suggests an alternative diagnosis (viral myelitis) or a concurrent diagnosis such as unrecognized HIV infection, leukemia or lymphoma with infiltration of nerves, or neurosarcoidosis. EDx features are mild or absent in the early stages of GBS and lag behind the clinical evolution. In AIDP, the earliest features are prolonged F-wave latencies, prolonged distal latencies, and reduced amplitudes of compound muscle action potentials (CMAPs), probably owing to the predilection for involvement of nerve roots and distal motor nerve terminals early in the course. Later, slowing of conduction velocity, conduction block, and temporal dispersion may be appreciated (Table 458-1). Occasionally, sensory nerve action potentials (SNAPs) may be normal in the feet (e.g., sural nerve) when abnormal in the arms. This is also a sign that the patient does not have one of the more typical "length-dependent" polyneuropathies. As mentioned, in AMAN and AMSAN, the principal EDx finding is reduced amplitude of CMAPs (and also SNAPs with AMSAN) without conduction slowing or prolongation of distal latencies, which early on is caused by conduction block but later can be due to axonal degeneration.

Diagnosis GBS is a descriptive entity. The diagnosis of AIDP is made by recognizing the pattern of rapidly evolving paralysis with areflexia, absence of fever or other systemic symptoms, and characteristic antecedent events. In 2011, the Brighton Collaboration developed a new set of case definitions for GBS in response to needs of epidemiologic studies of vaccination and assessing risks of GBS **(Table 458-3)**. These criteria have subsequently been validated. Other disorders that may enter into the differential diagnosis include acute myelopathies (especially with prolonged back pain and sphincter disturbances); diphtheria (early oropharyngeal disturbances); Lyme polyradiculitis and other tick-borne paralyses; porphyria (abdominal pain, seizures, psychosis); vasculitic neuropathy (check erythrocyte sedimentation rate, described below); poliomyelitis and acute flaccid myelitis (wild-type poliovirus, West Nile virus, enterovirus D68, enterovirus A71, Japanese encephalitis virus, and the wild-type poliovirus); CMV polyradiculitis (in immunocompromised patients); critical illness neuropathy or myopathy; neuromuscular junction disorders such as myasthenia gravis and botulism (pupillary reactivity lost early); poisonings with organophosphates, thallium, or arsenic; paralytic shellfish poisoning; or severe hypophosphatemia (rare). Cases of acute flaccid myelitis may pose particular challenges in distinguishing these from GBS because sphincter disturbances may be absent.

Laboratory tests are helpful primarily to exclude mimics of GBS. CSF pleocytosis is seen with poliomyelitis, acute flaccid myelitis, and Lyme and CMV polyradiculitis. EDx features may be minimal early in GBS, and the CSF protein level may not rise until the end of the first

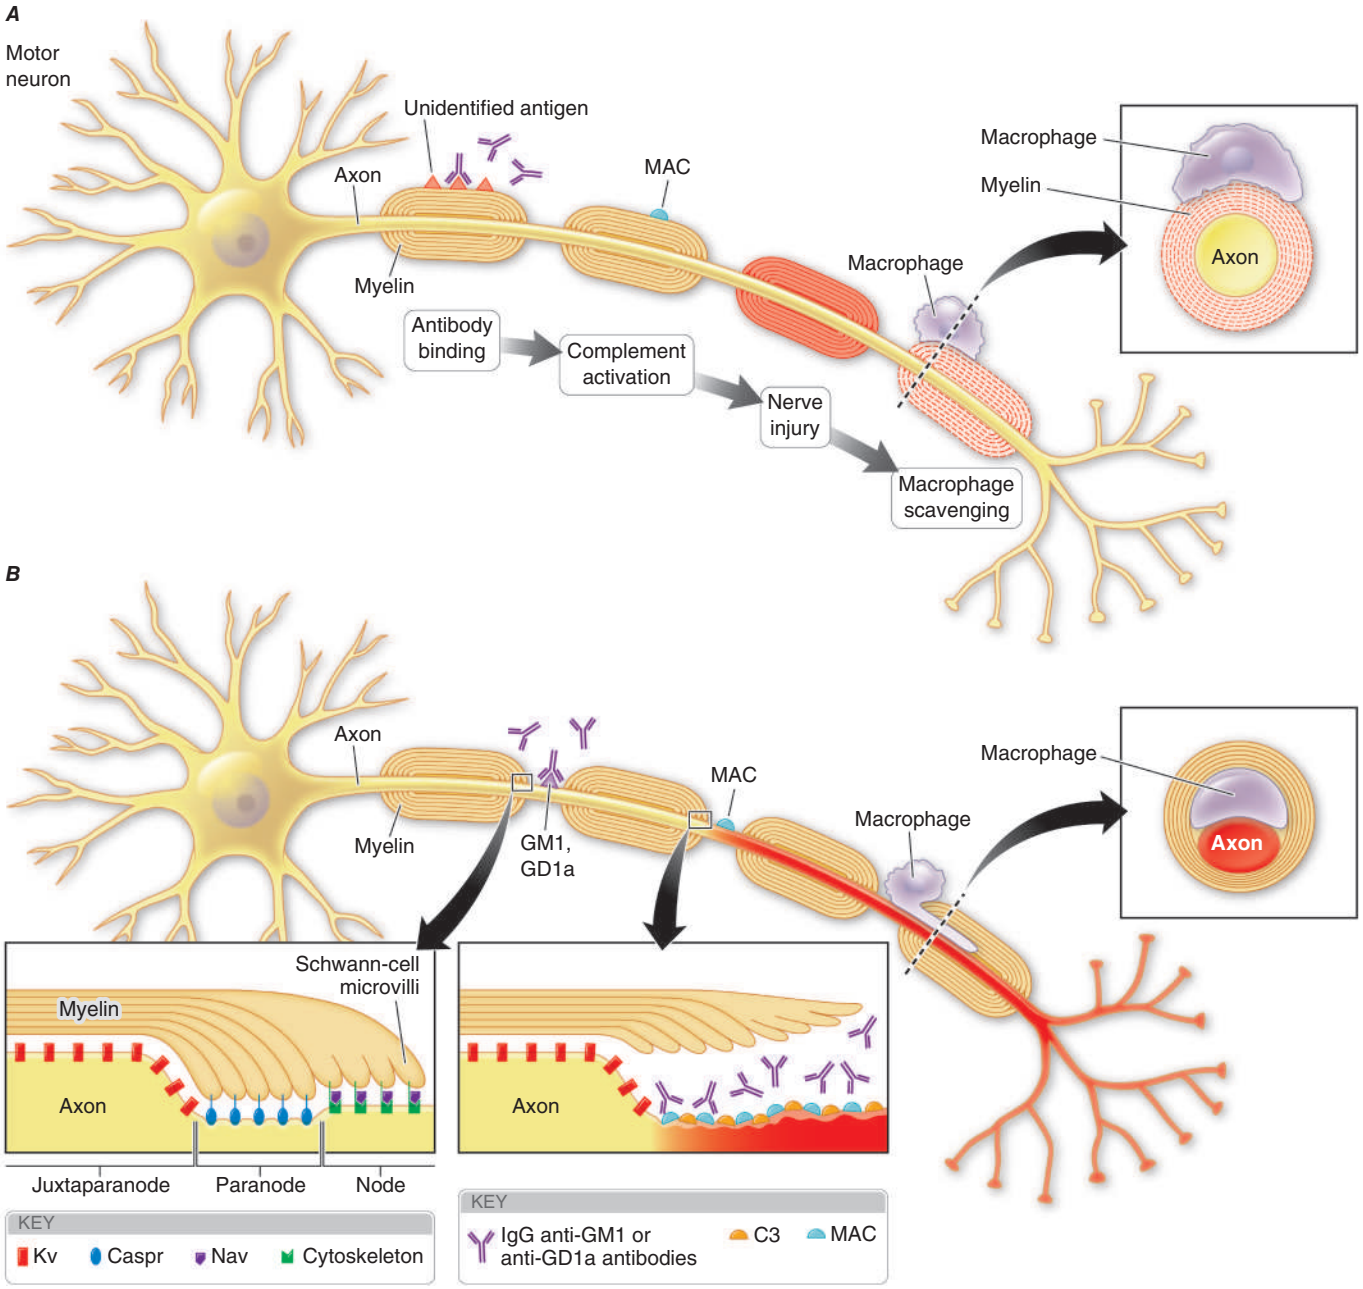

FIGURE 458-2 Possible immune mechanisms in Guillain-Barré syndrome (GBS). Panel ***A*** shows the immunopathogenesis of AIDP. Although autoantigens have yet to be unequivocally identified, autoantibodies may bind to myelin antigens and activate complement. This is followed by the formation of membrane-attack complex (MAC) on the outer surface of Schwann cells and the initiation of vesicular degeneration. Macrophages subsequently invade myelin and act as scavengers to remove myelin debris. Panel ***B*** shows the immunopathogenesis of acute axonal forms of GBS (acute motor axonal neuropathy [AMAN] and acute motor-sensory axonal neuropathy [AMSAN]). Myelinated axons are divided into four functional regions: the nodes of Ranvier, paranodes, juxtaparanodes, and internodes. Gangliosides GM1 and GD1a are strongly expressed at the nodes of Ranvier, where the voltage-gated sodium (Nav) channels are localized. Contactin-associated protein (Caspr) and voltage-gated potassium (Kv) channels are respectively present at the paranodes and juxtaparanodes. IgG anti-GM1 or anti-GD1a autoantibodies bind to the nodal axolemma, leading to MAC formation. This results in the disappearance of Nav clusters and the detachment of paranodal myelin, which can lead to nerve-conduction failure and muscle weakness. Axonal degeneration may follow at a later stage. Macrophages subsequently invade from the nodes into the periaxonal space, scavenging the injured axons. *(From N Yuki, H-P Hartung: Guillain-Barré syndrome. N Engl J Med 366:2294, 2012. week. If the diagnosis is strongly suspected, treatment should be initiated without waiting for evolution of the characteristic EDx and CSF findings to occur. GBS patients with risk factors for HIV or with CSF pleocytosis should have a serologic test for HIV.

TREATMENT

Guillain-Barré Syndrome

In the vast majority of patients with GBS, treatment should be initiated as soon after diagnosis as possible. Each day counts; ~2 weeks after the first motor symptoms, it is not known whether immunotherapy is still effective. If the patient has already reached the plateau stage, then treatment probably is no longer indicated, unless the patient has severe motor weakness and one cannot exclude the possibility that an immunologic attack is still ongoing. Either high-dose intravenous immune globulin (IVIg) or plasmapheresis (PLEX) can be initiated, as they are equally effective for typical GBS. A combination of the two therapies is not significantly better than either alone. IVIg is often the initial therapy chosen because of its ease of administration and good safety record. IVIg is usually administered as five daily infusions for a total dose of 2 g/kg body weight. There is some evidence that GBS autoantibodies are neutralized by anti-idiotypic antibodies present in IVIg

TABLE 458-3 Brighton Criteria for Diagnosis of Guillain-Barré Syndrome (GBS) and Miller Fisher Syndrome

Clinical case definitions for diagnosis of GBS

Level 1 of diagnostic certainty

Bilateral AND flaccid weakness of the limbs
AND
Decreased or absent deep tendon reflexes in weak limbs
AND
Monophasic illness pattern and interval between onset and nadir of weakness between 12 h and 28 days and subsequent clinical plateau
AND
Electrophysiologic findings consistent with GBS
AND
Cytoalbuminologic dissociation (i.e., elevation of CSF protein level above laboratory normal value AND CSF total white cell count <50 cells/μL)
AND
Absence of an identified alternative diagnosis for weakness

Level 2 of diagnostic certainty

Bilateral AND flaccid weakness of the limbs
AND
Decreased or absent deep tendon reflexes in weak limbs
AND
Monophasic illness pattern and interval between onset and nadir of weakness between 12 h and 28 days and subsequent clinical plateau
AND
CSF total white cell count <50 cells/μL (with or without CSF protein elevation above laboratory normal value)
OR
If CSF not collected or results not available, electrophysiologic studies consistent with GBS
AND
Absence of identified alternative diagnosis for weakness

Level 3 of diagnostic certainty

Bilateral and flaccid weakness of the limbs
AND
Decreased or absent deep tendon reflexes in weak limbs
AND
Monophasic illness pattern and interval between onset and nadir of weakness between 12 h and 28 days and subsequent clinical plateau
AND
Absence of identified alternative diagnosis for weakness

Clinical case definitions for diagnosis of Miller Fisher syndrome

Level 1 of diagnostic certainty

Bilateral ophthalmoparesis and bilateral reduced or absent tendon reflexes, and ataxia
AND
Absence of limb weakness
AND
Monophasic illness pattern and interval between onset and nadir of weakness between 12 h and 28 days and subsequent clinical plateau
AND
Cytoalbuminologic dissociation (i.e., elevation of cerebrospinal protein above the laboratory normal and total CSF white cell count <50 cells/μL)
AND
Nerve conduction studies are normal, OR indicate involvement of sensory nerves only
AND
No alterations in consciousness or corticospinal tract signs
AND
Absence of identified alternative diagnosis

Level 2 of diagnostic certainty

Bilateral ophthalmoparesis and bilateral reduced or absent tendon reflexes and ataxia
AND
Absence of limb weakness
AND
Monophasic illness pattern and interval between onset and nadir of weakness between 12 h and 28 days and subsequent clinical plateau
AND
CSF with a total white cell count <50 cells/μL) (with or without CSF protein elevation above laboratory normal value)
OR
Nerve conduction studies are normal, OR indicate involvement of sensory nerves only
AND
No alterations in consciousness or corticospinal tract signs
AND
Absence of identified alternative diagnosis

Level 3 of diagnostic certainty

Bilateral ophthalmoparesis and bilateral reduced or absent tendon reflexes and ataxia
AND
Absence of limb weakness
AND
Monophasic illness pattern and interval between onset and nadir of weakness between 12 h and 28 days and subsequent clinical plateau
AND
No alterations in consciousness or corticospinal tract signs
AND
Absence of identified alternative diagnosis

Abbreviation: CSF, cerebrospinal fluid.

preparations, perhaps accounting for the therapeutic effect. A course of PLEX usually consists of ~40–50 mL/kg plasma exchange (PE) 4–6 times over 7–12 days. Meta-analysis of randomized clinical trials indicates that treatment reduces the need for mechanical ventilation by nearly half (from 27 to 14% with PLEX) and increases the likelihood of full recovery at 1 year (from 55 to 68%). Functionally significant improvement may occur toward the end of the first week of treatment or may be delayed for several weeks. The lack of noticeable improvement following a course of IVIg or PLEX is not an indication to treat with the alternate treatment. However, there are occasional patients who are treated early in the course of GBS and improve, who then relapse within a month. Brief retreatment with the original therapy is usually effective in such cases. Glucocorticoids have not been found to be effective in GBS. Occasional patients with very mild forms of GBS, especially those who appear to have already reached a plateau when initially seen, may be managed conservatively without IVIg or PLEX.

In the worsening phase of GBS, most patients require monitoring in a critical care setting, with particular attention to vital capacity, heart rhythm, blood pressure, nutrition, deep-vein thrombosis prophylaxis, cardiovascular status, early consideration (after 2 weeks of intubation) of tracheotomy, and chest physiotherapy. As noted, ~30% of patients with GBS require ventilatory assistance, sometimes for prolonged periods of time (several weeks or longer). Frequent turning and assiduous skin care are important, as are daily range-of-motion exercises to avoid joint contractures and daily reassurance as to the generally good outlook for recovery.

Prognosis and Recovery Approximately 85% of patients with GBS achieve a full functional recovery within several months to a year, although minor findings on examination (such as areflexia) may persist and patients often complain of continued symptoms, including fatigue. The mortality rate is <5% in optimal settings; death usually results from secondary pulmonary complications. The outlook is worst

in patients with severe proximal motor and sensory axonal damage. Such axonal damage may be either primary or secondary in nature (see "Pathophysiology," above), but in either case, successful regeneration cannot occur. Other factors that worsen the outlook for recovery are advanced age, a fulminant or severe attack, and a delay in the onset of treatment. Elevated serum levels of neurofilament light (Nfl) chains and high titers of serum anti-GM1 antibodies are both associated with more axonal involvement in GBS and poor recovery. Between 5 and 10% of patients with typical GBS have one or more late relapses; many of these cases are then classified as chronic inflammatory demyelinating polyneuropathy (CIDP).

CHRONIC INFLAMMATORY DEMYELINATING POLYNEUROPATHY

CIDP is distinguished from GBS by its chronic course. In other respects, this neuropathy shares many features with the common demyelinating form of GBS, including elevated CSF protein levels and the EDx findings of acquired demyelination. Most cases occur in adults, and males are affected slightly more often than females. The incidence of CIDP is lower than that of GBS, but due to the protracted course, the prevalence is greater. As with GBS, CIDP and its variants can be triggered by use of immune checkpoint inhibitors used to treat various cancers.

Clinical Manifestations Onset is usually gradual over a few months or longer, but in a few cases, the initial attack is indistinguishable from that of GBS. An acute-onset form of CIDP may mimic GBS but should be considered if it deteriorates >9 weeks after onset or relapses at least three times. Symptoms are both motor and sensory in most cases. Weakness of the limbs is usually symmetric but can be strikingly asymmetric in multifocal acquired demyelinating sensory and motor (MADSAM) neuropathy variant (Lewis-Sumner syndrome) in which discrete peripheral nerves are involved. There is considerable variability from case to case. Some patients experience a chronic progressive course, whereas others, usually younger patients, have a relapsing and remitting course. A small proportion have cranial nerve findings, including external ophthalmoplegia. Some have only motor findings, and a small proportion present with a relatively pure syndrome of sensory ataxia. The latter can be seen in the chronic inflammatory sensory polyradiculopathy (CISP) variant of CIDP in which demyelination predominantly occurs at the sensory roots or with the distal acquired demyelinating symmetric (DADS) variant. Some patients with CISP have mild motor involvement, and these cases are termed CISP-plus. New European Academy of Neurology/Peripheral Nerve Society (EAN/PNS) criteria for CIDP considers CISP as a separate entity, but we and others still feel it belongs as a subcategory of CIDP as the histopathology and response to treatment are similar. CIDP tends to ameliorate over time with treatment; the result is that many years after onset, nearly 75% of patients have reasonable functional status. Death from CIDP is uncommon.

Diagnosis The diagnosis rests on characteristic clinical, CSF, and electrophysiologic findings. The CSF is usually acellular with an elevated protein level, sometimes several times normal. As with GBS, a CSF pleocytosis should lead to the consideration of HIV infection, leukemia or lymphoma, and neurosarcoidosis. EDx findings reveal variable degrees of conduction slowing, prolonged distal latencies, distal and temporal dispersion of CMAPs, and conduction block as the principal features. In particular, the presence of conduction block is a certain sign of an acquired demyelinating process. Evidence of axonal loss, presumably secondary to demyelination, is present in >50% of patients. Serum protein electrophoresis with immunofixation is indicated to search for monoclonal gammopathy and associated conditions (see "Monoclonal Gammopathy of Undetermined Significance," below). Magnetic resonance imaging (MRI) can demonstrate enlarged nerves, clumping of cauda equina, and enhancement. Ultrasound is cheaper and often more readily available and can likewise show enlargement of nerves at the roots or more distally. Studies have shown that imaging complements EDx findings and increases sensitivity. In all patients with presumptive CIDP, it is also reasonable to exclude vasculitis, collagen vascular disease (especially SLE), chronic hepatitis, HIV infection, amyloidosis, and diabetes mellitus. Other associated conditions include inflammatory bowel disease and lymphoma.

Pathogenesis Biopsy in typical CIDP reveals little inflammation and onion-bulb changes (imbricated layers of attenuated Schwann cell processes surrounding an axon) that result from recurrent demyelination and remyelination (Fig. 458-1). The response to therapy suggests that CIDP is immune-mediated; CIDP responds to glucocorticoids, whereas GBS does not. Passive transfer of demyelination into experimental animals has been accomplished using IgG purified from the serum of some patients with CIDP, lending support for a humoral autoimmune pathogenesis. A minority of patients have serum antibodies against P0, myelin P2 protein, or PMP22 (proteins whose genes are mutated in certain forms of hereditary Charcot-Marie-Tooth neuropathy).

As many as 25% of patients with clinical features of CIDP also have a monoclonal gammopathy of undetermined significance (MGUS), discussed below. Cases associated with monoclonal IgA or IgG kappa usually respond to treatment as favorably as cases without a monoclonal gammopathy. Patients with IgM-kappa monoclonal gammopathy and antibodies directed against myelin-associated glycoprotein (MAG) have a distinct demyelinating polyneuropathy with more sensory findings, usually only distal weakness, and a poor response to immunotherapy.

TREATMENT

Chronic Inflammatory Demyelinating Polyneuropathy

Most authorities initiate treatment for CIDP when progression is rapid or walking is compromised. If the disorder is mild, management can be expectant, awaiting spontaneous remission. Controlled studies have shown that high-dose IVIg, subcutaneous Ig (scIg), PLEX, and glucocorticoids are all more effective than placebo. Initial therapy is usually with IVIg, administered as 2.0 g/kg body weight given in divided doses over 2–5 days; three monthly courses are generally recommended before concluding a patient has failed treatment. If the patient responds, the infusion intervals can be gradually increased or the dosage decreased (e.g., starting at 1 g/kg every 3–4 weeks). Patients who require more frequent IVIg, experience side effects with IVIg (headaches), have poor venous access, or find it more convenient are treated with scIg (2–3 times a week such that the total dosage per month is the same or slightly higher than the monthly dosage of IVIg). PLEX, which appears to be as effective as IVIg, is initiated at 2–3 treatments per week for 6 weeks; periodic retreatment may also be required. Treatment with glucocorticoids is another option (60–80 mg prednisone PO daily for 1–2 months, followed by a gradual dose reduction of 10 mg per month as tolerated), but long-term adverse effects including bone demineralization, gastrointestinal bleeding, and cushingoid changes are problematic. As many as one-third of patients with CIDP fail to respond adequately to the initial therapy chosen; a different treatment should then be tried. Patients who fail therapy with IVIg, scIg, PLEX, and glucocorticoids may benefit from treatment with immunosuppressive agents such as azathioprine, methotrexate, cyclosporine, and cyclophosphamide, either alone or as adjunctive therapy. Use of these therapies requires periodic reassessment of their risks and benefits. A trial of efgartigimod alfa, a human neonatal Fc antibody fragment approved for myasthenia gravis (Chap. 457), demonstrated effectiveness in preventing relapses in CIDP; however, the medication will need to be compared with other more established options to determine its place in the CIDP treatment algorithm. In patients with a CIDP-like neuropathy who fail to respond to treatment, it is important to evaluate for a nodopathy, paranodopathy, or POEMS syndrome (*p*olyneuropathy, *o*rganomegaly, *e*ndocrinopathy, *m*onoclonal gammopathy, *s*kin changes; see below).

NODOPATHIES AND PARANODOPATHIES

Approximately 10% of patients previously considered to have CIDP have autoantibodies targeting antigens residing in nodal and paranodal regions that are responsible for the positioning and anchoring of ion channels and myelin folds in strategic locations along the axolemma. The EAN/PNS criteria now consider these separate from CIDP, and they are called nodopathies and paranodopathies. These neuropathies are associated with IgG4 isotype antibodies directed against nodal or paranodal antibodies including contactin-1 (CNTN1) or neurofascin 155 (NF155) and, less commonly, IgM anti-NF140/186. Patients typically manifest with progressive symmetric, distally predominant weakness, sensory ataxia, and postural and intention tremor. Renal failure and nephrotic syndrome from membranous glomerulonephritis are associated with CNTN1 neuropathy. Of note, the CNTN1 protein is also present on podocytes on kidneys, and antibodies that deposit along the glomerular basement membrane are visible on renal biopsy. Other antibodies have less clinical specificity. Anti-contactin associated protein-1 (Caspr1) antibodies are associated with severe neuropathic pain. Passive transfer of IgG4 CNTN1 antibodies produces paranodal damage and ataxia in rodents. Electrophysiology is indistinguishable from typical CIDP.

Importantly, as these nodopathies and paranodopathies are usually associated with IgG4 antibodies, they are less responsive to IVIg. However, they can respond to rituximab.

MULTIFOCAL MOTOR NEUROPATHY

Multifocal motor neuropathy (MMN) is a distinctive but uncommon neuropathy that presents with slowly progressive motor weakness and atrophy evolving over years in the distribution of selected nerve trunks, associated with sites of persistent focal motor conduction block in the same nerve trunks. Sensory fibers are relatively spared. The arms are affected more frequently than the legs, and >75% of all patients are male. Some cases have been confused with lower motor neuron forms of amyotrophic lateral sclerosis **(Chap. 448)**. Less than 50% of patients present with high titers of polyclonal IgM antibody to the ganglioside GM1. It is uncertain how this finding relates to the discrete foci of persistent motor conduction block, but high concentrations of GM1 gangliosides are normal constituents of nodes of Ranvier in peripheral nerve fibers. Pathology reveals demyelination and mild inflammatory changes at the sites of conduction block.

Most patients with MMN respond to high-dose IVIg or scIg (dosages as for CIDP, above); periodic retreatment is required (usually at least monthly) to maintain the benefit. Some refractory patients have responded to rituximab or cyclophosphamide. Glucocorticoids and PE are not effective.

NEUROPATHIES WITH MONOCLONAL GAMMOPATHY

MULTIPLE MYELOMA

Clinically overt polyneuropathy occurs in ~5% of patients with the commonly encountered type of multiple myeloma, which exhibits either lytic or diffuse osteoporotic bone lesions. These neuropathies are sensorimotor, are usually mild and slowly progressive but may be severe, and generally do not reverse with successful suppression of the myeloma. In most cases, EDx and pathologic features are consistent with a process of axonal degeneration.

In contrast, myeloma with osteosclerotic features, although representing only 3% of all myelomas, is associated with polyneuropathy in one-half of cases. These neuropathies, which may also occur with solitary plasmacytoma, are distinct because they (1) are demyelinating or mixed axonal and demyelinating by EDx, have elevated CSF protein, and clinically resemble CIDP; (2) often respond to radiation therapy or removal of the primary lesion; (3) are associated with different monoclonal proteins and light chains (almost always lambda as opposed to primarily kappa in the lytic type of multiple myeloma); (4) are typically refractory to standard treatments of CIDP; and (5) may occur in association with other systemic findings including thickening of the skin, hyperpigmentation, hypertrichosis, organomegaly, endocrinopathy, anasarca, and clubbing of fingers. These are features of POEMS syndrome. Levels of vascular endothelial growth factor (VEGF) are increased in the serum, and this factor is thought to somehow play a pathogenic role in this syndrome. Treatment of the neuropathy is best directed at the osteosclerotic myeloma using surgery, radiotherapy, chemotherapy, or autologous peripheral blood stem cell transplantation.

Neuropathies are also encountered in other systemic conditions with gammopathy, including Waldenström macroglobulinemia, primary systemic amyloidosis, and cryoglobulinemic states (mixed essential cryoglobulinemia, some cases of hepatitis C).

MONOCLONAL GAMMOPATHY OF UNDETERMINED SIGNIFICANCE

Chronic polyneuropathies occurring in association with MGUS are usually associated with the immunoglobulin isotypes IgG, IgA, and IgM. Most patients present with isolated sensory symptoms in their distal extremities and have EDx features of an axonal sensory or sensorimotor polyneuropathy. These patients otherwise resemble idiopathic sensory polyneuropathy, and the MGUS might just be coincidental. They usually do not respond to immunotherapies designed to reduce the concentration of the monoclonal protein. Some patients, however, present with generalized weakness and sensory loss and EDx studies indistinguishable from CIDP without monoclonal gammopathy (see "Chronic Inflammatory Demyelinating Polyneuropathy," above), and their response to immunosuppressive agents is also similar. An exception is the syndrome of IgM-kappa monoclonal gammopathy associated with an indolent, long-standing, sometimes static sensory neuropathy, frequently with tremor and sensory ataxia. Most patients are men and aged >50 years. In the majority, the monoclonal IgM immunoglobulin binds to a normal peripheral nerve constituent, MAG, found in the paranodal regions of Schwann cells. Binding appears to be specific for a polysaccharide epitope that is also found in other normal peripheral nerve myelin glycoproteins, P0 and PMP22, and also in other normal nerve-related glycosphingolipids (Fig. 458-1). In the MAG-positive cases, IgM paraprotein is incorporated into the myelin sheaths of affected patients and widens the spacing of the myelin lamellae, thus producing a distinctive ultrastructural pattern. Demyelination and remyelination are the hallmarks of the lesions, but axonal loss develops over time. These anti-MAG polyneuropathies are typical refractory to immunotherapy. In a small proportion of patients (30% at 10 years), MGUS will in time evolve into frankly malignant conditions such as multiple myeloma or lymphoma.

VASCULITIC NEUROPATHY

Peripheral nerve involvement is common in polyarteritis nodosa (PAN), appearing in half of all cases clinically and in 100% of cases at postmortem studies **(Chap. 375)**. The most common pattern is multifocal (asymmetric) motor-sensory neuropathy (mononeuropathy multiplex) due to ischemic lesions of nerve trunks and roots; however, some cases of vasculitic neuropathy present as a distal, symmetric sensorimotor polyneuropathy. Symptoms of neuropathy are a common presenting complaint in patients with PAN. The EDx findings are those of an axonal process. Small- to medium-sized arteries of the vasa nervorum, particularly the epineural vessels, are affected in PAN, resulting in a widespread ischemic neuropathy. A high frequency of neuropathy occurs in eosinophilic granulomatosis with polyangiitis (Churg-Strauss syndrome [CSS]).

Systemic vasculitis should always be considered when a subacute or chronically evolving mononeuropathy multiplex occurs in conjunction with constitutional symptoms (fever, anorexia, weight loss, loss of energy, malaise, and nonspecific pains). Diagnosis of suspected vasculitic neuropathy is made by a combined nerve and muscle biopsy, with serial section or skip-serial techniques.

Approximately one-third of biopsy-proven cases of vasculitic neuropathy are "nonsystemic" in that the vasculitis appears to affect only peripheral nerves. Constitutional symptoms are absent, and the course is more indolent than that of PAN. The erythrocyte sedimentation rate may be elevated, but other tests for systemic disease are negative.

Nevertheless, clinically silent involvement of other organs is likely, and vasculitis is frequently found in muscle biopsied at the same time as nerve.

Vasculitic neuropathy may also be seen as part of the vasculitis syndrome occurring in the course of other connective tissue disorders. The most frequent is rheumatoid arthritis, but ischemic neuropathy due to involvement of vasa nervorum may also occur in mixed cryoglobulinemia, Sjögren's syndrome, granulomatosis with polyangiitis (formerly known as Wegener's), hypersensitivity angiitis, SLE, and progressive systemic sclerosis.

Some vasculitides are associated with antineutrophil cytoplasmic antibodies (ANCAs), which in turn are subclassified as cytoplasmic (cANCA) or perinuclear (pANCA). cANCAs are directed against proteinase 3 (PR3), whereas pANCAs target myeloperoxidase (MPO). PR3/cANCAs are associated with eosinophilic granulomatosis with polyangiitis, whereas MPO/pANCAs are typically associated with microscopic polyangiitis, CSS, and less commonly PAN. Of note, MPO/pANCA has also been seen in minocycline-induced vasculitis.

Management of these neuropathies, including the "nonsystemic" vasculitic neuropathy, consists of treatment of the underlying condition as well as the aggressive use of glucocorticoids and cyclophosphamide. Use of these immunosuppressive agents has resulted in dramatic improvements in outcome, with 5-year survival rates now >80%. Clinical trials found that the combination of rituximab and glucocorticoids is not inferior to cyclophosphamide and glucocorticoids. Thus, combination therapy with glucocorticoids and rituximab is recommended as the standard initial treatment, particularly for ANCA-associated vasculitis. Mepolizumab, an anti–interleukin 5 monoclonal antibody, when added to standard care, is also effective for treatment of eosinophilic granulomatosis with polyangiitis.

ANTI-Hu PARANEOPLASTIC NEUROPATHY

(Chap. 99) This uncommon immune-mediated disorder manifests as a sensory neuronopathy (i.e., selective damage to sensory nerve bodies in dorsal root ganglia). The onset is often asymmetric with dysesthesias and sensory loss in the limbs that soon progress to affect all limbs, the torso, and the face. Marked sensory ataxia, pseudoathetosis, and inability to walk, stand, or even sit unsupported are frequent features and are secondary to the extensive deafferentation. Subacute sensory neuronopathy may be idiopathic, but more than half of cases are paraneoplastic, primarily related to lung cancer, and most of those are small-cell lung cancer (SCLC). Diagnosis of the underlying SCLC requires awareness of the association, testing for the paraneoplastic antibody, and often positron emission tomography (PET) scanning for the tumor. The target antigens are a family of RNA-binding proteins (HuD, HuC, and Hel-N1) that in normal tissues are only expressed by neurons. The same proteins are usually expressed by SCLC, triggering in some patients an immune response characterized by antibodies and cytotoxic T cells that cross-react with the Hu proteins of the dorsal root ganglion neurons, resulting in immune-mediated neuronal destruction. An encephalomyelitis may accompany the sensory neuronopathy and presumably has the same pathogenesis. Neurologic symptoms usually precede, by ≤6 months, the identification of SCLC. The sensory neuronopathy runs its course in a few weeks or months and stabilizes, leaving the patient disabled. Most cases are unresponsive to treatment with glucocorticoids, IVIg, PE, or immunosuppressant drugs.

459 Myasthenia Gravis and Other Diseases of the Neuromuscular Junction

Anthony A. Amato, Amanda C. Guidon

Myasthenia gravis (MG) is a neuromuscular junction (NMJ) disorder characterized by weakness and fatigability of skeletal muscles. The underlying defect is a decrease in the number of available acetylcholine receptors (AChRs) at NMJs due to an antibody-mediated autoimmune attack. Available treatments for MG are highly effective, although side effects can limit their use and a cure has remained elusive.

PATHOPHYSIOLOGY

At the NMJ **(Fig. 459-1, Video 459-1)**, acetylcholine (ACh) is synthesized in the motor nerve terminal and stored in vesicles (quanta). When an action potential travels down a motor nerve and reaches the nerve terminal, ACh from 150 to 200 vesicles is released and combines with AChRs that are densely packed at the crests of postsynaptic folds on skeletal muscle. The AChR consists of five subunits (2α, 1β, 1δ, 1γ, or ε) arranged around a central pore. When ACh combines with the binding sites on α subunits of the AChR, the channel in the AChR opens, permitting the rapid entry of cations, chiefly sodium, which produces depolarization at the end-plate region of the muscle fiber. If the depolarization is sufficiently large, it initiates an action potential that is propagated along the muscle fiber, triggering muscle contraction. This process is rapidly terminated by hydrolysis of ACh by acetylcholinesterase, which is present within the synaptic cleft, and by diffusion of ACh away from the receptor.

Muscle-specific tyrosine kinase (MuSK) is a postsynaptic transmembrane protein that helps stabilize postsynaptic clustering of AChRs. Agrin is released from the presynaptic motor nerve terminal and binds low-density lipoprotein receptor-related protein 4 (LRP4). This agrin-LRP4 complex activates MuSK. This facilitates recruitment of cytoplasmic proteins, including downstream of tyrosine kinase 7 (DOK7) and rapsyn, to assist in clustering AChR. These various proteins are important in the pathogenesis of not only MG but also some of the hereditary congenital myasthenic syndromes.

In MG, the fundamental defect is a decrease in the number of available AChRs at the postsynaptic muscle membrane. In addition, the postsynaptic folds are flattened, or "simplified." These changes result in decreased efficiency of neuromuscular transmission. Therefore, although ACh is released normally, it produces small end-plate

potentials that may fail to trigger muscle action potentials. Failure of transmission results in muscle weakness.

The amount of ACh released per impulse normally declines on repeated activity (termed *presynaptic rundown*). In myasthenic patients, reduced efficiency of neuromuscular transmission, combined with this normal rundown, results in activation of fewer and fewer muscle fibers by successive nerve impulses, and hence increasing weakness, or *myasthenic fatigue*. This mechanism also accounts for the decremental response to repetitive nerve stimulation seen on electrodiagnostic testing.

MG is an autoimmune disorder most commonly caused by anti-AChR antibodies. The anti-AChR antibodies reduce the number of available AChRs at NMJs by three distinct mechanisms: (1) accelerated turnover of AChRs by a mechanism involving cross-linking and rapid endocytosis of the receptors; (2) damage to the postsynaptic muscle membrane through antibody-mediated complement activation; and (3) blockade of the active site of the AChR (i.e., the site that normally binds ACh). An immune response to MuSK, a protein involved in AChR clustering at the NMJ (as noted above), also results in MG, with reduction of AChRs demonstrated experimentally. Anti-MuSK antibody occurs in ~10% of patients (~40% of AChR antibody–negative patients with generalized MG), whereas 1–3% have antibodies to another protein at the NMJ—LRP4—that, as mentioned, is also important for clustering of AChRs. These pathogenic antibodies are IgG and are T-cell dependent. Thus, immunotherapeutic strategies directed against either the antibody-producing B cells or helper T cells, directly reducing the pathogenic antibodies, or blocking complement-mediated destruction of the AChRs are all effective in anti-AChR-positive MG. MuSK antibodies exert their pathogenic effect by directly inhibiting binding between MuSK and LRP4, leading to loss of AChRs and other functions of MuSK. Of note, MuSK antibodies are of the IgG4 subtype and, as such, do not activate complement. As a result, anti-MuSK-positive MG does not respond to complement inhibition. LRP4 antibodies are of the IgG1 subclass and also cause complement-mediated destruction, similar to AChR antibodies, and possibly interrupt agrin-induced MuSK activation.

Although MG is caused by autoantibodies, a significant contribution exists from T cells, including T regulatory (Treg) cells. These Tregs are critical in suppressing activation of other immune cells that have escaped negative selection in the thymus. Because these other cells have not been deleted by negative selection or suppressed in the periphery, they attack "self" antigens. Deficiency or dysfunction of Tregs contributes to the pathogenesis not only of MG but of many other autoimmune diseases. The primary source of Treg cells is the thymus, which

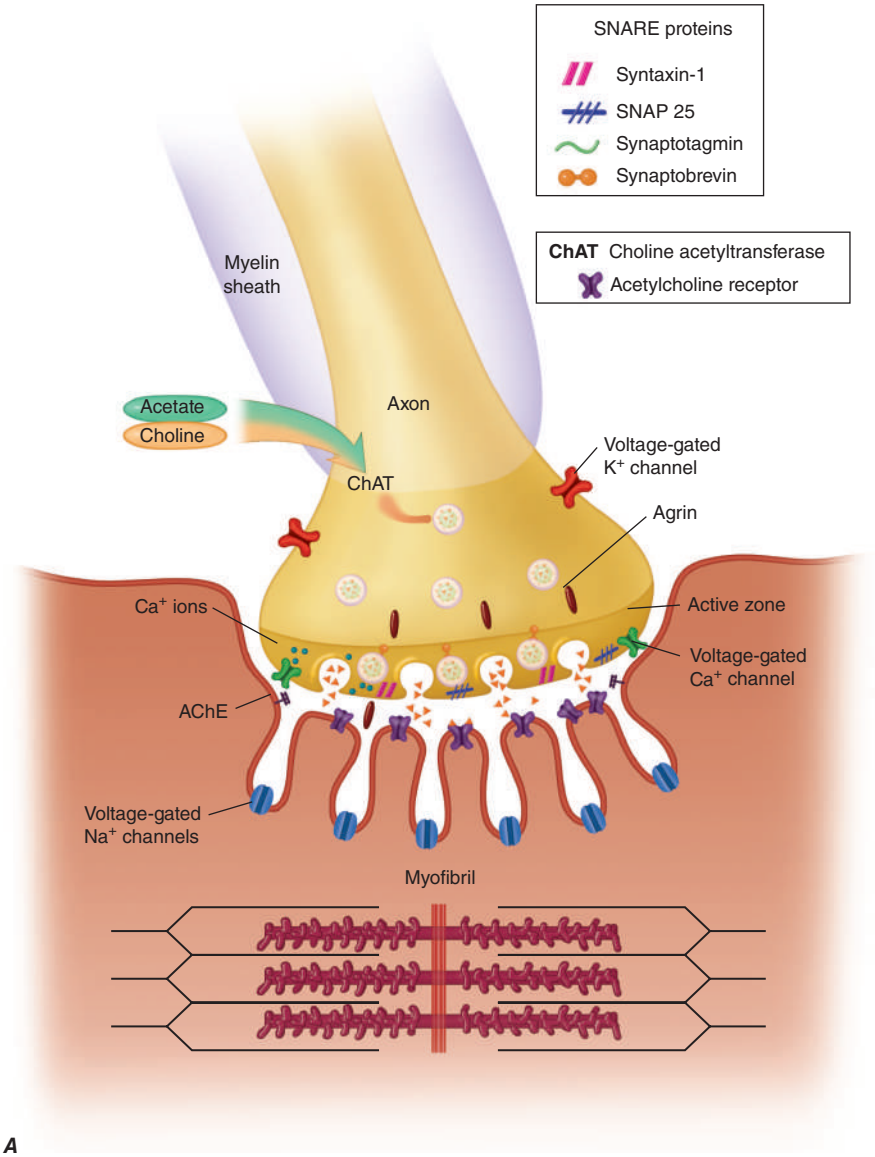

FIGURE 459-1 Illustrations of (*A*) a normal presynaptic neuromuscular junction, (*B*) a normal postsynaptic terminal, and (*C*) a myasthenic neuromuscular junction. AChE, acetylcholinesterase. See text for description of normal neuromuscular transmission. The myasthenia gravis (MG) junction demonstrates a reduced number of acetylcholine receptors (AChRs); flattened, simplified postsynaptic folds; and a widened synaptic space. See Video 459-1 also. *(Reproduced with permission from AA Amato, J Russell: Neuromuscular Disorders, 2nd ed. New York, McGraw-Hill; 2016.)*

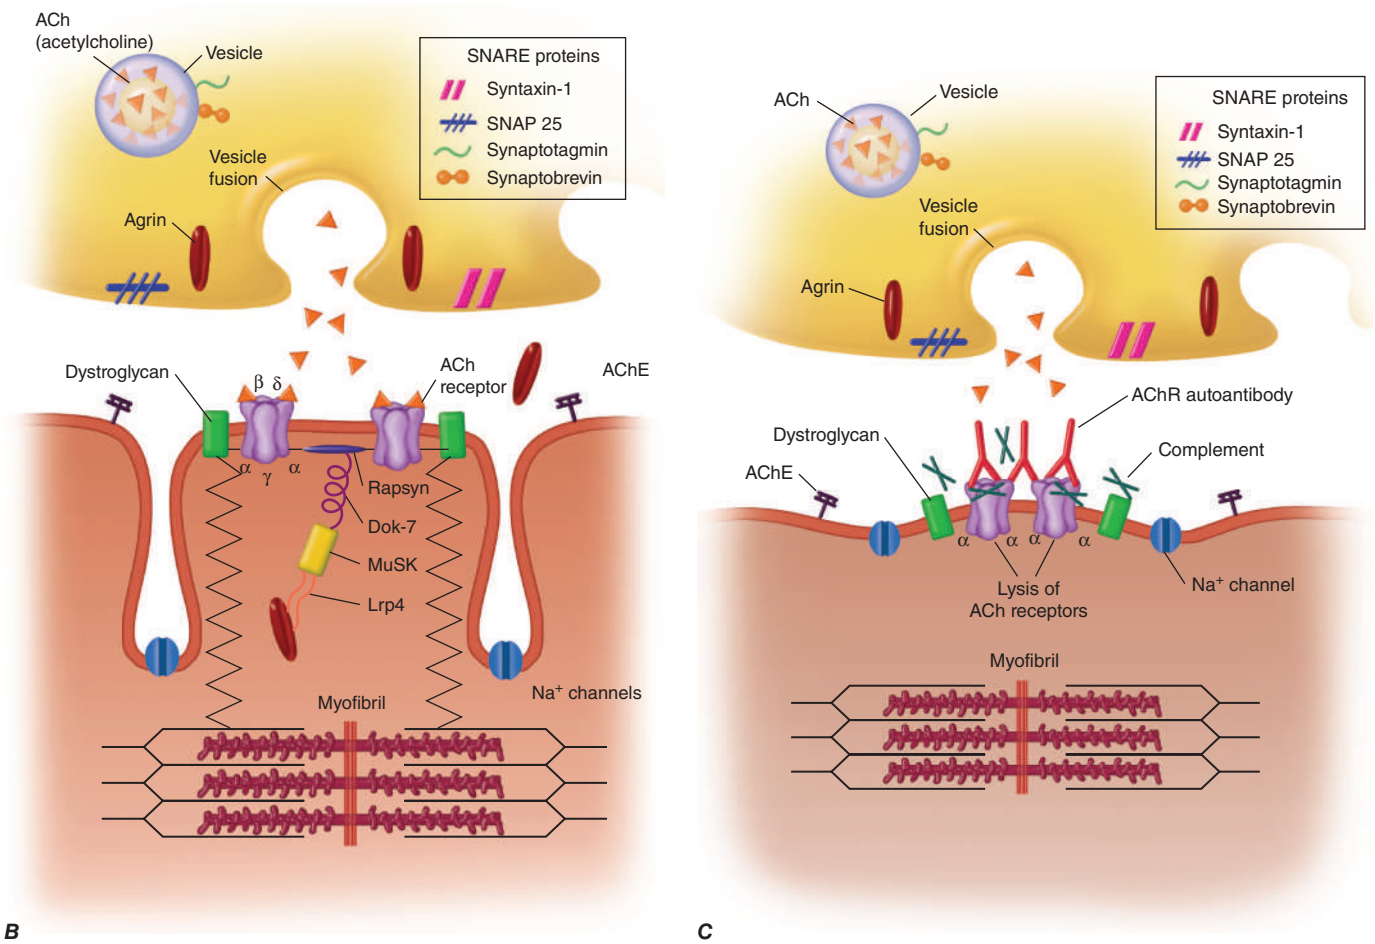

FIGURE 459-1 (*Continued*)

is abnormal in ~75% of patients with AChR antibody–positive MG. In ~65%, the thymus is "hyperplastic," with the presence of active germinal centers detected histologically. The hyperplastic thymus may be but is not necessarily enlarged. An additional 10% of patients have thymic tumors (thymomas). Muscle-like cells within the thymus (myoid cells), which express AChRs on their surface, may serve as a source of autoantigen and trigger the autoimmune reaction within the thymus gland.

CLINICAL FEATURES

MG has an incidence ranging from 6.3 to 29 per million and a prevalence ranging from 100 to 361 per million. It affects individuals in all age groups, but peak incidence occurs in women in their twenties and thirties and in men in their fifties and sixties. Overall, women are affected more frequently than men, in a ratio of ~3:2. Cardinal features are *weakness* and *fatigability* of muscles. Myasthenic weakness often worsens during repeated use (fatigue) and/or late in the day and may improve following rest or sleep. The course of MG is variable. Exacerbations and remissions may occur, particularly during the first 1–3 years after disease onset. In ~85% of patients, myasthenic weakness becomes generalized, affecting facial, bulbar, axial, or limb muscles in addition to ocular muscles. If weakness remains restricted to ocular muscles for 3 years, future generalization is unlikely, and these patients are said to have *ocular MG*. However, we have seen rare patients generalize >5 years after onset of ocular MG. Unrelated infections, systemic disorders, or tapering of MG therapies can lead to increased myasthenic weakness and may precipitate myasthenic exacerbation or "crisis" (see below). Some exacerbations occur without any identifiable precipitating factors.

The distribution of muscle weakness often has a characteristic pattern. Cranial muscles, particularly extraocular and eyelid muscles, are frequently involved early in the course of MG; diplopia and ptosis are common initial symptoms. Facial weakness produces a "snarling" expression when the patient attempts to smile. Weakness in chewing is most noticeable after prolonged effort or chewing hard or tough foods like meat. Speech may have a nasal timbre caused by weakness of the palate or a dysarthric "mushy" quality due to tongue weakness. Hoarseness can occur from laryngeal weakness. Difficulty in swallowing (dysphagia) may occur as a result of weakness of the palate, tongue, or pharynx, giving rise to nasal regurgitation or aspiration of liquids or food. Bulbar, neck, and ventilatory weakness can be especially prominent in MuSK antibody–positive MG. Weakness in neck extensor muscles can lead to head drop. Limb weakness in MG is often proximal and may be asymmetric. Nonetheless, some patients manifest with mainly distal weakness (finger and wrist drop or foot drop). Deep tendon reflexes are typically preserved. Sensory symptoms, sensory loss, and pain are absent. If ventilatory weakness necessitates intubation or noninvasive ventilation to avoid intubation, the patient is said to be in *MG crisis*. All other worsening is termed *exacerbation*.

DIAGNOSIS AND EVALUATION (TABLE 459-1)

The diagnosis is suspected based on weakness and fatigability in the typical distribution described above, without loss of deep tendon reflexes or sensory signs or symptoms or abnormality of other neurologic functions. The suspected diagnosis should be confirmed definitively before treatment is undertaken; this is essential because (1) other treatable conditions may closely resemble MG and (2) the treatment of MG may involve surgery and the prolonged use of drugs with potential side effects.

Ice-Pack Test If a patient has ptosis, application of a pack of ice over a ptotic eye for 2 min often results in improvement if the ptosis is due to an NMJ defect. A lid rise of 2 mm following this cooling is considered a positive result. This is hypothesized to be due to less depletion of quanta of AChR in the cold and reduced activity of

TABLE 459-1 Diagnosis of Myasthenia Gravis (MG)

History
Diplopia, ptosis, dysarthria, dysphagia, dyspnea
Weakness in characteristic distribution: proximal limbs, neck extensors, generalized
Fluctuation and fatigue: worse with repeated activity, improved by rest
Effects of previous treatments
Physical examination
Evaluation for ptosis at rest and following 1 min of exercise, extraocular muscles and subjective diplopia, orbicularis oculi and oris strength, jaw opening and closure
Assessment of muscle strength in neck and extremities
Weakness following repeated shoulder abduction
Vital capacity measurement
Absence of other neurologic signs
Laboratory testing
Anti-AChR radioimmunoassay: ~85% positive in generalized MG; 50% in ocular MG; definite diagnosis if positive; negative result does not exclude MG; ~40% of AChR antibody–negative patients with generalized MG have anti-MuSK antibodies and ~2% have LRP4 antibodies
Repetitive nerve stimulation: decrement of >10% at 3 Hz: highly probable
Single-fiber electromyography: blocking and jitter, with normal fiber density; confirmatory, but not specific
Edrophonium chloride (Enlon) 2 mg + 8 mg IV; highly probable diagnosis if unequivocally positive
Ice-pack test looking for improvement in ptosis is very sensitive
For ocular or cranial MG: exclude intracranial lesions by CT or MRI

Abbreviations: AChR, acetylcholine receptor; CT, computed tomography; LRP4, lipoprotein receptor-related protein 4; MRI, magnetic resonance imaging; MuSK, muscle-specific tyrosine kinase.

acetylcholinesterase at the NMJ. It is a quick and easy test to do in the clinic or at the bedside of a hospitalized patient.

Autoantibodies Associated with MG As previously mentioned, anti-AChR antibodies are detectable in the serum of ~85% of all myasthenic patients but in only ~50% of patients with weakness confined to the ocular muscles. The presence of anti-AChR antibodies is virtually diagnostic of MG, but a negative test does not exclude the disease. The measured level of anti-AChR antibody does not correspond well with the severity of MG in different patients. Antibodies to MuSK are present in up to 40% of AChR antibody–negative patients with generalized MG depending on the population. MuSK antibodies are rarely present in AChR antibody–positive patients or in patients with MG limited to ocular muscles. A small proportion of MG patients without antibodies to AChR or MuSK have antibodies to LRP4. Sending LRP4 antibodies has a low specificity. As such, we only check them in patients with clear MG by phenotype and electrodiagnostic testing but absent AChR and MuSK antibodies. Additionally, antibodies against agrin also have been found in rare patients with MG, but it is unclear if they are pathogenic, and they are not currently tested in clinical practice. Additionally, anti-striated muscle antibodies directed against titin and other skeletal muscle components have been identified in some patients. However, they are not pathogenic, and their presence does not confirm the diagnosis of MG or the presence of a thymoma. Given their limited utility and potential for misinterpretation, we do not order them. Furthermore, antibodies directed against Caspr2 (contactin-associated protein-like 2) may coexist primarily in patients with thymoma who have MG and neuromyotonia or Morvan's syndrome. The presence of these antibodies can help confirm the diagnosis of a second paraneoplastic syndrome in these clinical situations.

Electrodiagnostic Testing Repetitive nerve stimulation may provide helpful diagnostic evidence of MG. Medications that inhibit acetylcholinesterase should be stopped 12–24 h or for as long as possible before testing. It is best to test weak muscles or proximal muscle groups. Electrical stimulation is delivered at a rate of two or three per second to the appropriate nerves, and action potentials are recorded from the muscles. In normal individuals, the amplitude of the evoked muscle action potentials does not change by >10% at these rates of stimulation. However, in myasthenic patients, there is a rapid reduction of >10% in the amplitude of the evoked responses. If repetitive nerve stimulation is normal and/or symptoms are exclusively ocular, single-fiber electromyography (EMG), a specialized more sensitive test typically done at MG referral centers, is performed.

Anticholinesterase Test Drugs that inhibit the enzyme acetylcholinesterase allow ACh to interact repeatedly with the limited number of AChRs in MG, producing improvement in muscle strength. Edrophonium was most commonly used historically for diagnostic testing because of the rapid onset (30 s) and short duration (~5 min) of its effect, with an objective endpoint such as ptosis typically measured. Edrophonium is no longer used due to potential for side effects and lack of availability.

Pulmonary Function Tests (Chap. 295) Measurements of ventilatory function are valuable because of the frequency and seriousness of respiratory impairment in myasthenic patients.

Differential Diagnosis Other conditions that cause weakness of the cranial and/or somatic musculature include nonautoimmune congenital myasthenia, drug-induced myasthenia, Lambert-Eaton myasthenic syndrome (LEMS), hyperthyroidism (Graves' disease), botulism, intracranial mass lesions, oculopharyngeal dystrophy, and mitochondrial myopathy (Kearns-Sayre syndrome, progressive external ophthalmoplegia). Treatment with immune checkpoint inhibitors (ICIs) for cancer may also result in autoimmune MG. Myositis and myocarditis are also often found in combination with MG as a complication of ICIs (Chap. 377). Symptoms typically begin after the first or second cycle of treatment, with ptosis, diplopia, bulbar, neck, extremity weakness, and respiratory weakness. ICI-related myositis without disordered neuromuscular transmission can mimic MG, itself causing a similar pattern of weakness including ocular and bulbar weakness, which is uncommon in other autoimmune myopathies. Patients usually improve when the ICI is discontinued and a short course of glucocorticoids is given, with intravenous immunoglobulin (IVIg) or plasma exchange depending on severity; however, with fulminant disease, the fatality rate remains high, mainly due to the concurrent myocarditis. Treatment with penicillamine (used for scleroderma or rheumatoid arthritis) has also been associated with MG. Aminoglycoside, quinolone and macrolide antibiotics, intravenous magnesium, or procainamide can also cause exacerbation of weakness in myasthenic patients; very large doses can cause neuromuscular weakness in normal individuals. Botulinum toxin injections should be avoided in MG patients.

The *congenital myasthenic syndromes (CMS)* comprise a rare heterogeneous group of disorders of the NMJ that are not autoimmune but rather are due to mutations in >30 identified genes. Virtually any component of the NMJ may be affected. Alterations in function of the presynaptic nerve terminal, in the various subunits of the AChR, acetylcholinesterase, or the other molecules involved in end-plate development or maintenance, have been identified in the different forms of CMS. These disorders share many of the clinical features of autoimmune MG, including weakness and fatigability of proximal or distal extremity muscles and often involving extraocular and eyelid muscles similar to the distribution in autoimmune MG. CMS is most often suspected when symptoms of myasthenia began in infancy or childhood; however, some patients initially present in adulthood. As in autoimmune MG, repetitive nerve stimulation is often associated with a decremental response. Some forms of CMS (e.g., acetylcholinesterase deficiency, prolonged open channel syndrome) have a feature of afterdischarges that are not seen in MG. An additional clue is the absence of AChR and MuSK antibodies, although these are absent in ~10% of generalized MG patients (so-called double seronegative MG).

The prevalence of CMS is estimated at ~3.8 per 100,000. The most common genetic defects occur in the ε subunit of the AChR, accounting for ~50% of CMS cases, with mutations in the genes encoding for rapsin, COLQ, DOK7, agrin, and GFPT together accounting for ~40%.

In most of the recessively inherited forms of CMS, the mutations are heteroallelic; that is, different mutations affecting each of the two alleles are present. Features of the most common forms of CMS are summarized in **Table 459-2**. Molecular analysis is required for precise elucidation of the defect; this may lead to helpful treatment as well as genetic counseling. Some forms of CMS improve with acetylcholinesterase inhibitors, while others (e.g., slow channel syndrome, acetylcholinesterase deficiency, DOK7-related CMS) actually worsen. Fluoxetine and quinidine can be useful for slow channel syndrome, and albuterol for mutations affecting acetylcholinesterase, DOK7, rapsyn, and agrin. Additionally, ephedrine and 3,4-diaminopyridine (3,4-DAP) may be of benefit in some forms of CMS.

LEMS is a presynaptic disorder of the NMJ that causes skeletal muscle weakness; however, the pattern of involvement differs from that in MG. The proximal muscles of the lower limbs are most commonly affected, although other muscles may be involved as well. Cranial and bulbar weakness, including ptosis of the eyelids, diplopia, dysarthria, and dysphagia may occur but are not typically the presenting or prominent symptoms. However, LEMS can be further distinguished from MG because patients with LEMS often have depressed or absent reflexes and experience autonomic symptoms such as dry mouth, orthostasis, and impotence **(Chap. 451)**. Nerve stimulation produces an initial low-amplitude compound muscle action potential and, at low rates of repetitive stimulation (2–3 Hz), a decremental response as seen in MG; however, at high rates (20–50 Hz) or following brief exercise, incremental responses occur. LEMS is caused by autoantibodies directed against P/Q-type calcium channels at the presynaptic motor nerve terminals detected in ~85% of LEMS patients. These autoantibodies impair the release of ACh from nerve terminals. In young adults, particularly women, LEMS is less commonly associated with an underlying cancer. However, in older adults, LEMS is associated with malignancy, most commonly small-cell lung cancer (SCLC), and virtually all of these patients have P/Q-type calcium channel autoantibodies. The tumor cells may express calcium channels that stimulate the autoimmune response. Initial management requires comprehensive evaluation for malignancy and reassessment if the initial malignancy evaluation is negative. Treatment of LEMS symptoms involves therapy first with 3,4-DAP and pyridostigmine. 3,4-DAP acts by blocking potassium channels, which results in prolonged depolarization of the motor nerve terminals, thus enhancing ACh release. Pyridostigmine prolongs the action of ACh, allowing repeated interactions with AChRs. If symptoms are severe or life-threatening or if symptomatic therapy is insufficient, immunomodulatory therapy including IVIg or plasma exchange can be used.

Botulism **(Chap. 158)** is due to potent bacterial toxins produced by any of eight different strains of *Clostridium botulinum*. The toxins enzymatically cleave specific proteins essential for the release of ACh from the motor nerve terminal, thereby interfering with neuromuscular transmission. Most commonly, botulism is caused by ingestion of improperly prepared food containing toxin. Rarely, the nearly ubiquitous spores of *C. botulinum* may germinate in wounds. In infants, the spores may germinate in the gastrointestinal (GI) tract and release toxin, causing muscle weakness. Patients present with myasthenia-like bulbar weakness (e.g., diplopia, dysarthria, dysphagia) and lack sensory symptoms and signs. Weakness may generalize to the limbs and may result in respiratory failure. Reflexes are present early, but they may be diminished as the disease progresses. Mentation is normal. Autonomic findings include paralytic ileus, constipation, urinary retention, dilated or poorly reactive pupils, and dry mouth. The demonstration of toxin in serum by bioassay is definitive, but the results usually take a relatively long time to be completed and may be negative. Nerve stimulation studies reveal reduced compound muscle action potential (CMAP) amplitudes that increase following high-frequency repetitive stimulation. Treatment includes ventilatory support and aggressive inpatient supportive care (e.g., nutrition, deep-vein thrombosis prophylaxis) as needed. Antitoxin should be given as early as possible to be effective and can be obtained through the Centers for Disease Control and Prevention. A preventive vaccine is available for laboratory workers or other highly exposed individuals.

Hyperthyroidism is readily diagnosed or excluded by tests of thyroid function, which should be carried out routinely in patients with suspected MG. Abnormalities of thyroid function (hyper- or hypothyroidism) may increase myasthenic weakness. Diplopia resembling that in MG may occasionally be due to an intracranial mass lesion that compresses nerves to the extraocular muscles (e.g., sphenoid ridge meningioma), but magnetic resonance imaging (MRI) of the head and orbits usually reveals the lesion.

Progressive external ophthalmoplegia is a rare condition resulting in weakness of the extraocular muscles and often symmetric ptosis, which may be accompanied by weakness of the proximal muscles of the limbs and other systemic features. Most patients with this condition have mitochondrial disorders that can be detected by genetic testing or with muscle biopsy **(Chap. 460)**.

Search for Associated Conditions (Table 459-3) Myasthenic patients have an increased incidence of several associated disorders. Thymic abnormalities occur in ~75% of AChR antibody–positive patients, as noted above. Neoplastic change (thymoma) may produce enlargement of the thymus, which is detected by chest computed tomography (CT) or MRI. A thymic shadow on CT scan may normally be present through young adulthood, but enlargement of the thymus in a patient age >40 years is highly suspicious for thymoma. Approximately 10–15% of patients with MG have thymoma, and therefore, chest imaging to evaluate this possibility is performed at diagnosis.

Hyperthyroidism occurs in 3–8% of patients and may aggravate the myasthenic weakness. Thyroid function tests should be obtained in all patients with suspected MG. Other autoimmune disorders, most commonly systemic lupus erythematosus and rheumatoid arthritis, can coexist with MG; associations also occur with neuromyelitis optica, multiple sclerosis, neuromyotonia, Morvan's syndrome (encephalitis, insomnia, confusion, hallucinations, autonomic dysfunction, and neuromyotonia), rippling muscle disease, granulomatous myositis/myocarditis, and chronic inflammatory demyelinating polyneuropathy.

An infection of any kind can exacerbate typical MG and should be sought carefully in patients with relapses. Because of the side effects of glucocorticoids and other immunotherapies used in the treatment of MG, a thorough medical investigation should be undertaken, searching specifically for evidence of chronic or latent infection (such as tuberculosis or hepatitis), hypertension, diabetes, renal disease, and glaucoma.

TREATMENT

Myasthenia Gravis

The prognosis of MG has improved strikingly as a result of advances in treatment. Nearly all myasthenic patients can be returned to full productive lives with proper therapy. Common treatments for MG include anticholinesterase medications, glucocorticoids and other immunosuppressive agents, thymectomy, plasmapheresis, IVIg, rituximab, and the recently approved complement inhibitors and neonatal Fc receptor (FcRn) antagonists **(Fig. 459-2)**.

ANTICHOLINESTERASE MEDICATIONS

Anticholinesterase medication produces at least partial improvement in most myasthenic patients, although improvement is complete in only a few. Patients with anti-MuSK MG generally obtain less benefit from anticholinesterase agents than those with AChR antibodies and may actually worsen. Pyridostigmine is the most widely used anticholinesterase drug and is initiated at a dosage of 30–60 mg three to four times daily. The beneficial action of oral pyridostigmine begins within 15–30 min and lasts for 3–4 h, but individual responses vary. The frequency and amount of the dose should be tailored to the patient's individual requirements throughout the day. For example, patients with weakness in chewing and swallowing may benefit by taking the medication before meals so that peak strength coincides with mealtimes. Long-acting pyridostigmine may occasionally be useful to get the patient through the night but should not be used for daytime medication because of variable absorption. The maximum useful dose of pyridostigmine

TABLE 459-2 Congenital Myasthenic Syndromes (CMS)

CMS SUBTYPE	GENE	CLINICAL FEATURES	ELECTROPHYSIOLOGIC FEATURES	RESPONSE TO ACHE INHIBITORS	TREATMENT
Presynaptic Disorders					
CMS with paucity of ACh release	*CHAT; CHT*	AR; early onset, respiratory failure at birth, episodic apnea, improvement with age	Decremental response to RNS	Improve	AChE inhibitors; 3,4-DAP
Synaptic Disorders					
AChE deficiency	*COLQ*	AR; early onset; variable severity; axial weakness with scoliosis; apnea; +/– EOM involvement, slow or absent pupillary responses	After discharges on nerve stimulation and decrement on RNS	Worsen	Albuterol; ephedrine; 3,4-DAP; avoid AChE inhibitors
Postsynaptic Disorders Involving AChR Deficiency or Kinetics					
Primary AChR deficiency	AChR subunit genes	AR; early onset; variable severity; fatigue; typical MG features	Decremental response to RNS	Improve	AChE inhibitors; 3,4-DAP
AChR kinetic disorder: slow channel syndrome	AChR subunit genes	AD; onset childhood to early adult; weak forearm extensors and neck; respiratory weakness; variable severity	After discharges on nerve stimulation and decrement on RNS	Worsen	Fluoxetine and quinidine; avoid AChE inhibitors
AChR kinetic disorder: fast channel syndrome	AChR subunit genes	AR; early onset; mild to severe; ptosis, EOM involvement; weakness and fatigue	Decremental response to RNS	Improve	AChE inhibitors; caution with 3,4-DAP
Postsynaptic Disorders Involving Abnormal Clustering/Function of AChR					
	DOK 7	AR; limb girdle weakness with ptosis but no EOM involvement	Decremental response to RNS	Variable	Albuterol; ephedrine; may worsen with AChE inhibitors
	Rapsyn	AR; early onset with hypotonia, respiratory failure, and arthrogryposis at birth to early adult onset resembling MG	Decremental response to RNS	Variable	Albuterol
	Agrin	AR; limb girdle or distal weakness, apnea	Decremental response to RNS	Variable	Albuterol; may worsen with AChE inhibitors
	MuSK	AR; congenital or childhood onset of ptosis, EOM and progressive limb girdle weakness	Decremental response to RNS	Variable	Variable response to AChE inhibitors and 3,4-DAP Positive response to albuterol
	LRP4	AR; congenital onset with hypotonia; ventilatory failure, mild ptosis, and EOM weakness	Decremental response to RNS	Worsen	Worsen with AChE inhibitors
Other Postsynaptic Disorders					
Limb-girdle CMS with tubular aggregates	*GFPT1; DPAGT1; ALG2; ALG14; DPAGT1*	AR; limb-girdle weakness usually without ptosis or EOM weakness; onset in infancy or early adult	Decremental response to RNS	Variable	Albuterol; ephedrine; variable response to AChE inhibitors and 3,4-DAP; albuterol
Congenital muscular dystrophy with myasthenia	*Plectin*	AR; infantile or childhood onset of generalized weakness including ptosis and EOM; epidermolysis bullosa simplex; elevated CK	Decremental response to RNS	Variable	No response to AChE and 3,4-DAP

Abbreviations: ACh, acetylcholine; AChE, acetylcholinesterase; AChR, acetylcholine receptor; AD, autosomal dominant; AR, autosomal recessive; CHAT, choline acetyl transferase; CHT, sodium-dependent high-affinity choline transport 1; CK, creatine kinase; CMA, congenital myasthenic syndrome; COLQ, collaganic tail of endplate acetylcholinesterase; 3,4-DAP, 3,4-diaminopyridine; Dok7, downstream of tyrosine kinase 7; DPAGT1, UDP-N-acetylglucosamine-dolichyl-phosphate N-acetylglucosamine phosphotransferase; EOM, extraocular muscle; GFPT1, glutamine-fructose-6-phosphate aminotransferase 1; LRP4, lipoprotein receptor-related protein 4; MG, myasthenia gravis; MuSK, muscle specific kinase; RNS, repetitive nerve stimulation.

rarely exceeds 360–480 mg daily. Overdosage with anticholinesterase medication may cause increased weakness and other side effects. In some patients, muscarinic side effects of the anticholinesterase medication (diarrhea, abdominal cramps, excess salivation, nausea) may limit the dose tolerated. Atropine/diphenoxylate or loperamide is useful for the treatment of gastrointestinal symptoms.

THYMECTOMY

Two separate issues should be distinguished: (1) surgical removal of thymoma, and (2) thymectomy as a treatment for MG. Surgical removal of a thymoma is necessary because of the possibility of local tumor spread, although most thymomas are histologically benign. A large international study (the MGTX trial) of extended transsternal thymectomy in nonthymomatous, AChR antibody–positive, generalized MG demonstrated that participants who underwent thymectomy had improved strength and function, required less prednisone and fewer additions of second-line agents (e.g., azathioprine), and had fewer hospitalizations for exacerbations lasting at least 5 years. Whether or not less invasive thymectomy provides identical benefit is unknown; however, less invasive techniques are now used in most thymectomies at many institutions. Importantly, patients with ocular myasthenia, MuSK-positive, and seronegative MG were all excluded from the MGTX study; retrospective and anecdotal evidence suggests that these patients may not benefit from thymectomy. Thymectomy should never be carried out as an emergency procedure, but only when the patient is adequately prepared. If necessary, treatment with IVIg or plasmapheresis may be used before surgery to maximize strength in weak patients.

IMMUNOTHERAPY

The choice of immunotherapy should be guided by the relative benefits and risks for the individual patient and the urgency of treatment. It is helpful to develop a treatment plan based on short-term, intermediate-term, and long-term objectives. For example,

TABLE 459-3 Disorders Associated with Myasthenia Gravis and Recommended Laboratory Tests

Associated disorders
Disorders of the thymus: thymoma, hyperplasia
Other autoimmune neurologic disorders: chronic inflammatory demyelinating polyneuropathy, neuromyelitis optica
Other autoimmune disorders: Hashimoto's thyroiditis, Graves' disease, rheumatoid arthritis, systemic lupus erythematosus, skin disorders, family history of autoimmune disorder
Disorders or circumstances that may exacerbate myasthenia gravis: hyperthyroidism or hypothyroidism, occult infection, medical treatment for other conditions (see Table 459-5)
Disorders that may interfere with therapy: tuberculosis, diabetes, peptic ulcer, gastrointestinal bleeding, renal disease, hypertension, asthma, osteoporosis, obesity
Recommended laboratory tests or procedures
CT or MRI of chest
Tests for antinuclear antibodies, rheumatoid factor
Thyroid function tests
Testing for tuberculosis
Fasting blood glucose, hemoglobin A_{1c}
Pulmonary function tests
Bone densitometry

Abbreviations: CT, computed tomography; MRI, magnetic resonance imaging.

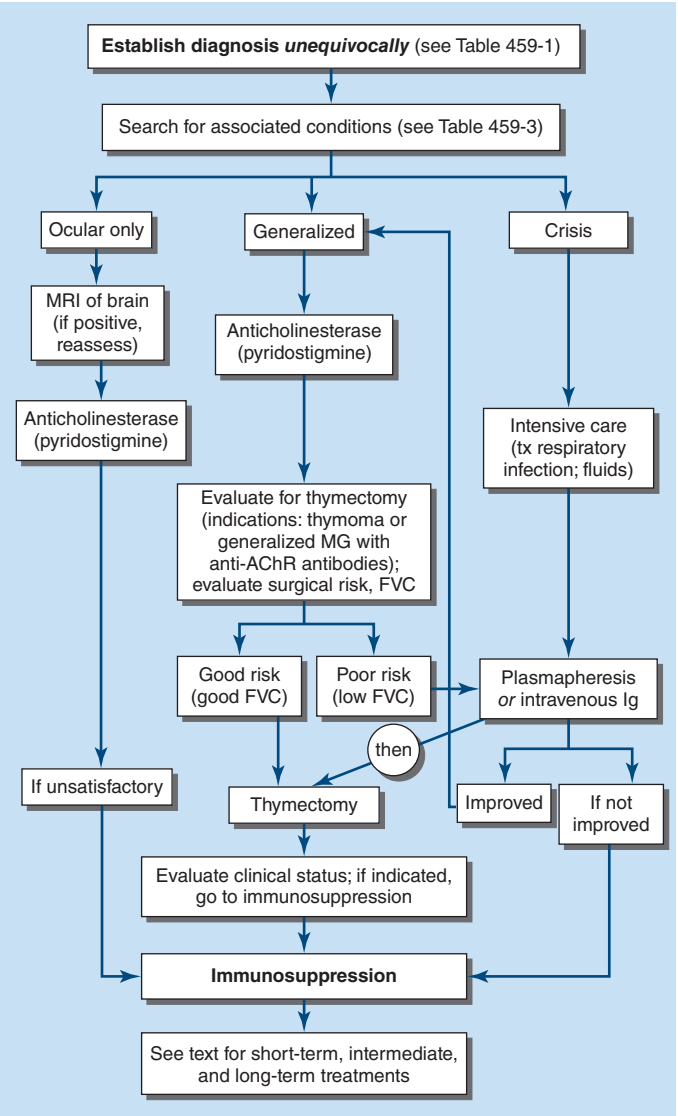

FIGURE 459-2 Algorithm for the management of myasthenia gravis. FVC, forced vital capacity; MRI, magnetic resonance imaging.

if immediate improvement is essential typically because of the severity of weakness, IVIg should be administered or plasmapheresis should be undertaken as "rescue" therapy. For the intermediate term, glucocorticoids, cyclosporine or tacrolimus, rituximab, and the newer complement inhibitors and FcRn antagonists generally produce clinical improvement within a period of 1–3 months. They can be used for bridging until other immunotherapies become effective or in refractory patients. The beneficial effects of other nonsteroidal immunosuppressive therapies, azathioprine and mycophenolate mofetil, usually begin after many months (and as long as 1–1.5 years), However, these drugs have advantages over glucocorticoids for the long-term treatment of patients with MG. Rituximab is highly effective in patients with MuSK antibody–positive MG.

Glucocorticoid Therapy Glucocorticoids, when used properly, produce improvement in myasthenic weakness in the great majority of patients. To minimize adverse side effects, prednisone should be given in a single morning dose rather than in divided doses throughout the day. In patients with only ocular or mild generalized weakness, the initial dose can be relatively low (15–25 mg/d). The dose is increased stepwise, as tolerated by the patient (usually by 5 mg/d at 7- to 14-day intervals), until there is marked clinical improvement or a dose of 50–60 mg/d is reached. The full effect of a particular dose of prednisone often takes 2–3 weeks to observe. In patients with more severe weakness and those already in the hospital and/or intubated, starting at a high dose is reasonable, typically after pretreatment with IVIg or plasma exchange to protect against early steroid-associated worsening. Patients are maintained for about a month on the dose that controls their symptoms, and then the dosage is slowly tapered (no faster than 10 mg a month until on 20 mg daily and then by 2.5–5 mg every 1–3 months until on 10 mg daily, and more slowly thereafter) to determine the minimum effective dose. Close monitoring both for side effects and for efficacy is essential. Some patients can be managed without the addition of other immunotherapies. Patients on long-term glucocorticoid therapy must be followed carefully to prevent or treat adverse side effects. The most common errors include (1) an insufficient duration or dose of prednisone—improvement may be delayed and gradual; (2) tapering the dosage too early, too rapidly, or excessively; and (3) lack of attention to prevention and treatment of side effects.

Other Immunotherapies Mycophenolate mofetil, azathioprine, cyclosporine, tacrolimus, rituximab, and rarely, cyclophosphamide are effective in many patients, either alone or in various combinations.

Mycophenolate mofetil is widely used because of its presumed effectiveness and relative lack of side effects. A dose of 1–1.5 g bid is recommended. Its mechanism of action involves inhibition of purine synthesis by the de novo pathway. Since lymphocytes have only the de novo pathway, but lack the alternative salvage pathway that is present in all other cells, mycophenolate inhibits proliferation of lymphocytes but not proliferation of other cells. It does not kill or eliminate preexisting autoreactive lymphocytes, and therefore, clinical improvement may be delayed for many months to a year, until the preexisting autoreactive lymphocytes die spontaneously. The advantage of mycophenolate lies in its relative paucity of adverse side effects. The primary side effect is diarrhea or other GI symptoms. Rare side effects are development of leukopenia and very small risks of malignancy or progressive multifocal leukoencephalopathy inherent in nearly all immunosuppressive treatments. Although two published studies did not show positive outcomes, most experts attribute the negative results to flaws in the trial designs, and mycophenolate is widely used and supported in many guidelines for long-term treatment of myasthenic patients.

Azathioprine has long been used for MG, and a randomized, clinical trial demonstrated that it was effective in reducing the dosage of prednisone necessary to control MG symptoms. However, the beneficial effect can take a year or more to become evident.

Approximately 10–15% of patients are unable to tolerate azathioprine because of idiosyncratic reactions consisting of flulike symptoms (e.g., fever and malaise, abdominal pain), bone marrow suppression, or abnormalities of liver function. An initial dose of 50 mg/d is given for about a week to test for these side effects. If this dose is tolerated, it is increased by 50 mg weekly to 150 mg daily. Some patients require additional increases to reach a dose of ~2–3 mg/kg of total body weight or until the white blood count falls to 3000–4000/μL. Allopurinol should never be used in combination with azathioprine because the two drugs share a common degradation pathway; the result may be severe bone marrow suppression due to increased effects of the azathioprine.

The calcineurin inhibitors cyclosporine and tacrolimus are effective in MG and work more rapidly than azathioprine and mycophenolate. However, both, and cyclosporin in particular, are associated with more frequent severe side effects including hypertension, nephrotoxicity, and drug interactions. The usual dose of cyclosporine is 4–5 mg/kg per d, and the average dose of tacrolimus is 0.07–0.1 mg/kg per d, given in two equally divided doses. "Trough" blood levels are measured 12 h after the evening dose. The therapeutic range for the trough level of cyclosporine is 150–200 ng/L, and for tacrolimus, it is 5–15 ng/L.

Rituximab is a monoclonal antibody that binds to the CD20 molecule on B lymphocytes. It is widely used for the treatment of B-cell lymphomas and has also proven successful in the treatment of several autoimmune diseases including rheumatoid arthritis, pemphigus, and some IgM-related neuropathies. Rituximab can induce prolonged remissions in MuSK antibody–positive MG, which was previously more difficult to treat than anti-AChR–positive MG. We treat MuSK antibody–positive MG patients with 1 g IV on two occasions 2 weeks apart. Periodically, a repeat course needs to be administered; some MuSK patients can go up to 2–3 years between infusions.

A large National Institutes of Health–sponsored randomized trial of rituximab in AChR antibody–positive generalized MG failed to demonstrate efficacy, but many of the participants had long-standing MG that failed other therapies. However, a more recent randomized, placebo-controlled trial from Sweden of new-onset MG (<1 year) reported that a single infusion of 500 mg IV rituximab resulted in greater likelihood of participants achieving minimal MG manifestations and reduced need for rescue medications compared with placebo at 48 weeks. Further studies are needed, however, to determine how long this improvement may last and the need for retreatment.

For the rare refractory MG patient, a course of high-dose cyclophosphamide may induce long-lasting benefit. At high doses, cyclophosphamide eliminates mature lymphocytes but spares hematopoietic precursors (stem cells), because they express the enzyme aldehyde dehydrogenase, which hydrolyzes cyclophosphamide. This procedure is reserved for refractory patients and should be administered only in a facility fully familiar with this approach. Maintenance immunotherapy after treatment is usually required to sustain the beneficial effect.

NEWLY APPROVED TREATMENTS

Special attention needs to be given to the newly approved therapies for MG. Complement inhibitors and FcRn inhibitors have revolutionized treatment of patients with MG **(Table 459-4)**. Because they work quickly in most patients, they may be used as bridge therapies until other immunotherapies can "kick in" or in those who are refractory to standard treatments.

Complement Inhibitors Currently, three complement inhibitors are U.S. Food and Drug Administration (FDA) approved for AChR antibody–positive generalized MG based on positive clinical trial results. Most patients who will improve on these agents will do so within the first 12 weeks, and improvement is appreciated in many within the first 1–4 weeks. These drugs each work by inhibiting the cleavage of C5 in the terminal complement cascade. Eculizumab was shown to be effective in a positive phase 3 study, which led to FDA approval in 2017. Subsequently, ravulizumab was approved in 2021. Both eculizumab and ravulizumab are monoclonal antibodies given intravenously; ravulizumab has a longer effect. Zilucoplan is the latest complement inhibitor and was approved in 2023. Unlike eculizumab and ravulizumab, zilucoplan is a subcutaneously administered macrocyclic peptide inhibitor of C5. Because it is not a monoclonal antibody like eculizumab and ravulizumab, it can be coadministered with plasma exchange, IVIg, or FcRn antagonists. An additional benefit is that patients can self-administer zilucoplan with a prefilled syringe. In practice, we typically reassess efficacy at 12 weeks in patients treated with C5 inhibitors and decide whether or not to continue treatment.

Complement inhibition increases the risk of meningococcal infection. Therefore, a first series of vaccinations with both quadrivalent and MenB vaccines is given at least 14 days prior to initiation of treatment and then again 1–2 months later. Those patients in whom treatment needs to be started sooner than this initial vaccination series is complete should receive antibiotic prophylaxis (penicillin). Vaccination reduces, but does not eliminate, the risk of meningitis. Physicians must enroll in drug-specific risk evaluation and mitigation strategy programs for all complement inhibitors and counsel patients regarding the risk and signs and symptoms of meningitis. Patients are recommended to carry a safety/alert wallet card.

Neonatal Fc Receptor (FcRn) Antagonists FcRns on endothelial cells salvage IgG and albumin from degradation by lysosomes, leading to longer IgG half-lives. Blocking the FcRn results in increased catabolism of IgG, thereby reducing IgG (and pathogenic antibody) levels. The potential benefits over plasma exchange include the ease of administration, increased availability, and reduced risk in patients with coagulopathies or limited peripheral venous access. Efgartigimod and rozanolixizumab are now approved for clinical use based on their efficacy in clinical trials (Table 459-4). Efgartigimod can be given intravenously or subcutaneously, whereas rozanolixizumab is given via a subcutaneous infusion. Importantly, only rozanolixizumab is approved for both anti-AChR and anti-MuSK generalized myasthenia. As with complement inhibitors, the FcRn inhibitors usually are effective within the first 3 months of treatment, again often within the first month. Side effects are somewhat variable and include increased risk of respiratory and urinary infections, headaches (including aseptic meningitis with rozanolixizumab), and hypoalbuminemia (FcRn also prevents lysosomes from degrading albumin). Comparative efficacy with one another or with complement inhibitors cannot be readily ascertained with existing clinical trial data. One potential benefit of FcRn antagonists over complement inhibitors is that guidance from clinical trials exists on how to ramp up or ramp down administration frequency based on clinical response.

PLASMAPHERESIS AND INTRAVENOUS IMMUNOGLOBULIN

Plasmapheresis has long been used therapeutically in MG. Plasma, which contains the pathogenic antibodies, is mechanically separated from the blood cells, which are then returned to the patient. A course of five or six exchanges (3–4 L per exchange) is generally administered over a 10- to 14-day period. Plasmapheresis produces a short-term reduction in anti-AChR antibodies, with clinical improvement in many patients. It is most useful as a temporary treatment in severely affected patients or to improve the patient's condition prior to surgery (e.g., thymectomy).

The indications for the use of IVIg are the same as those for plasma exchange: to produce rapid improvement to help the patient through a difficult period of myasthenic weakness or prior to surgery. This treatment has the advantages of not requiring special equipment or large-bore venous access. The usual dose is 2 g/kg, which is typically administered over 2–5 days. Improvement occurs in ~70% of patients, beginning during treatment or within a week and continuing for weeks to months. The exact mechanism of

TABLE 459-4 Comparison of New Complement Inhibitors and FcRn Inhibitors for Generalized Myasthenia

DRUG/MECHANISM	TRIAL(S)	FDA APPROVED DOSING	CLINICAL TRIAL POPULATION	NOTES
Approved Complement Inhibitors				
Eculizumab (humanized monoclonal Ab anti-C5, inhibits terminal complement/MAC activation)	Phase 2 REGAIN : 26 weeks REGAIN open-label extension: 22.7 months (median), up to 3 years	Loading: 900 mg IV weekly × 4 Maintenance: 1200 mg IV on week 5 then q2 weeks	AChR ab + gMG (class II–IV) Refractory (at least 2 NSISTs or at least 1 NSIST and PLEX/IVIg) MGADL score ≥6	Did not reach statistical significance for primary MGADL endpoint Reached significance for multiple secondary endpoints Requires meningococcal vaccination
Ravulizumab (humanized monoclonal Ab anti-C5, inhibits terminal complement/MAC activation)	Phase 2 CHAMPION MG: 26 weeks CHAMPION MG open-label extension	Actual body weight–based dosing Loading: 40 to <60 kg: 2400 mg IV; 60 to <100 kg: 2700 mg IV; ≥100 kg: 3000 mg IV Maintenance (14 days after loading and then q8 weeks): 40 to <60 kg: 3000 mg IV; 60 to <100 kg: 3300 mg IV; ≥100 kg: 3600 mg IV	Adults with AChR ab + gMG (class II–IV) MGADL score ≥6	Requires meningococcal vaccination
Zilucoplan (synthetic macrocyclic peptide targeting C5/C5b, inhibits terminal complement/MAC activation)	Phase 2 RAISE: 12 weeks RAISE-XT open-label extension	Phase 3 dosing 0.3 mg/kg SC daily Label dosing (prefilled syringes): Actual body weight–based daily SC injections <56 kg: 16.6 mg daily; 56 kg to <77 kg: 23 mg; ≥77 kg: 32.4 mg	Adults with AChR ab + gMG (class II–IV) MGADL score ≥6 QMG ≥12	Requires meningococcal vaccination Self-administered SC
Approved FcRn Inhibitors				
Efgartigimod IV/SC (human anti-FcRn IgG1 Fc fragment; reduces autoantibody levels and IgG recycling)	Phase 2 ADAPT: 26 weeks ADAPT open-label extension: up to 3 years ADAPT-SC noninferiority study, open-label parallel-group: 12 weeks with open-label extension	Weight-based IV: 10 mg/kg IV (up to 1200 mg) weekly × 4 = 1 cycle Fixed dose SC: 1,008 mg SC weekly × 4 = 1 cycle	Adults with gMG regardless of Ab status, MGADL at least 5 with 50% nonocular	ADAPT was designed to observe wearing off – cycles repeated at return of symptoms and no sooner than every 8 weeks Number of infusions per cycle and time between cycles can be individualized (as was done in the open-label extension) Efgartigimod SC is not currently approved for self-injection; health care provider administered; refrigeration required
Rozanolixizumab (human anti-FcRn IgG4 monoclonal antibody; reduces autoantibody levels and IgG recycling)	Phase 2 MycarinG: 18 weeks Open-label extension: completed	Phase 3 included 7 and 10 mg/kg given as SC infusion weekly for 6 weeks followed by 8 weeks off. Patients averaged 4 treatment cycles per year (range 1–7) Clinical dosing: <50 kg: 420 mg; 50 to <100 kg: 560 mg; ≥100 kg: 840 mg given as a weekly health care provider–administered SC infusion for 6 weeks (1 cycle)	Adults with AChR or MuSK Ab + gMG (11% of participants) MGADL score ≥3 QMG score ≥11	Headache occurred in 38–45% of treatment group and 19% of placebo, including rare aseptic meningitis Infection rate higher in 10 mg/kg dosing group; efficacy equivalent Shorter mean disease duration than other phase 3 trials (5–6 years) Hypoalbuminemia and peripheral edema

action of IVIg in MG is unknown; the treatment has no consistent long-term effect on the measurable amount of circulating AChR antibody. Adverse reactions are generally not serious but may include headache, fluid overload, and rarely aseptic meningitis, renal failure, hemolytic anemia, and embolic or thrombotic events. IVIg or plasma exchange is occasionally used in combination with other immunosuppressive therapy for maintenance treatment of difficult MG, though this is less common in the contemporary era since the advent of C5 inhibitors and FcRn antagonists.

INVESTIGATIONAL TREATMENTS

Several trials of different complement and FcRn inhibitors are underway. Inhibitors of interleukin 6 and CD19 targets on B cells are also being studied. Notably, CD19-targeting chimeric antigen receptor (CAR) therapy and chimeric autoantibody receptor T (CAART) therapy targeting the antibody ligand on T cells are also in clinical trials for MG.

MANAGEMENT OF MYASTHENIC CRISIS

Myasthenic crisis is defined as an exacerbation of weakness sufficient to endanger life; it usually includes ventilatory failure caused by diaphragmatic and intercostal muscle weakness. Treatment should be carried out in intensive care units staffed with teams experienced in the management of MG. The possibility that deterioration could be due to excessive anticholinesterase medication ("cholinergic crisis") is unlikely given that very high doses of cholinesterase inhibitors are rarely used but is considered in the differential. The most common cause of crisis is intercurrent

infection. This should be treated immediately because the mechanical and immunologic defenses of the patient can be assumed to be compromised. The myasthenic patient with fever and early infection should be treated like other immunocompromised patients. Early and effective antibiotic therapy, ventilatory assistance, and pulmonary physiotherapy are essentials of the treatment program. As discussed above, plasmapheresis or IVIg is frequently helpful in hastening recovery.

MANAGEMENT OF MYASTHENIA ASSOCIATED WITH IMMUNE CHECKPOINT INHIBITOR THERAPY

MG is a rare complication of ICI therapy for cancer. It can develop de novo or as an exacerbation of preexisting diagnosed or undiagnosed disease. Patients usually manifest with ocular, bulbar, neck, and respiratory weakness within the first one to four cycles of ICI therapy. Compared to idiopathic MG, ICI-associated MG is more likely to be seronegative and overlap with myositis and myocarditis. The mortality rate is 20–50%, most often because of severe myocarditis. Importantly, ICI-associated myositis is more common than immune-related MG. It can resemble MG clinically, with prominent or exclusively ocular weakness but without evidence for a decrementing response on repetitive nerve stimulation. The mainstay of treatment for ICI-associated MG is glucocorticoids, including IV solumedrol (which differs from idiopathic MG), and with plasma exchange or IVIg added for severe weakness. Complement inhibitors have recently been reported as effective in AChR antibody–positive ICI-associated MG with myositis and myocarditis.

DRUGS TO AVOID IN MYASTHENIC PATIENTS

Many drugs can potentially exacerbate weakness in patients with MG **(Table 459-5)**. As a rule, the listed drugs should be avoided whenever possible.

TABLE 459-5 Drugs with Interactions in Myasthenia Gravis (MG)

Drugs That May Exacerbate Weakness in Patients with MG
Antibiotics
Aminoglycosides: e.g., streptomycin, tobramycin, kanamycin
Quinolones: e.g., ciprofloxacin, levofloxacin, ofloxacin, gatifloxacin
Macrolides: e.g., erythromycin, azithromycin
Nondepolarizing muscle relaxants for surgery
D-Tubocurarine (curare), pancuronium, vecuronium, atracurium
Beta-blocking agents
Propranolol, atenolol, metoprolol
Local anesthetics and related agents
Procaine, Xylocaine in large amounts
Procainamide (for arrhythmias)
Botulinum toxin
Botox exacerbates weakness
Quinine derivatives
Quinine, quinidine, chloroquine, mefloquine (Lariam)
Magnesium
Decreases acetylcholine release
Penicillamine
May cause MG
Checkpoint inhibitors
May cause MG and other autoimmune neuromuscular disorders (e.g., myositis, inflammatory neuropathy)
Drugs with Important Interactions in MG
Cyclosporine and tacrolimus
Broad range of drug interactions, which may raise or lower levels
Azathioprine
Avoid allopurinol—combination may result in myelosuppression

PATIENT ASSESSMENT

To evaluate the effectiveness of treatment as well as drug-induced side effects, it is important to assess the patient's clinical status systematically at baseline and on repeated interval examinations. Following the patient with spirometry with determination of forced vital capacity and mean inspiratory and expiratory pressures is important.

PROGNOSIS

Approximately 20% of patients with MG achieve a sustained remission and can be tapered off all immunotherapies. There does not appear to be a correlation between disease severity and likelihood of remission. Thymectomy may increase the chance of achieving remission in anti-AChR MG, but the large, randomized MGTX trial was too short in duration to examine this endpoint; rather, the results revealed only that thymectomy was efficacious and led to less use of glucocorticoids and second-line agents. Mortality from MG diminished greatly during the twentieth century, changing from a "grave" illness with mortality of nearly 70% a century ago, to 2–30% by the 1950s, with contemporary estimates in the 1–5% range. Anti-MuSK patients generally were more difficult to treat than anti-AChR MG in the past. However, recent series suggest that rituximab is effective in this subgroup, thereby reducing these risks and improving the prognosis. Nonparaneoplastic LEMS is usually responsive to immunotherapy and symptomatic treatment with pyridostigmine and 3,4-DAP. In older adults, LEMS is most often paraneoplastic, and screening for an underlying tumor is indicated **(Chap. 99)**. Recent studies suggest that survival in patients with LEMS has improved, for uncertain reasons and likely not due to earlier diagnosis and treatment of the tumor. There is wide variability in age of onset, severity, and prognosis of the many types of CMS.

GLOBAL ISSUES

The incidence of MG and its subtypes varies in different populations, for example, occurring in ~2–10/10^6 individuals in the United States and the Netherlands and up to 20/10^6 individuals in Spain. Estimates of prevalence in different parts of the world range widely from 2–360/10^6. The age of onset may also be influenced by geographic and/or ethnic differences. Juvenile-onset MG is uncommon in Western populations but may represent more than half of cases in Asians. MuSK MG appears to be more common in the Mediterranean area of Europe than in northern Europe and is also more common in the northern regions of East Asia than in the southern regions. A concern during the COVID-19 pandemic is whether MG patients on immunosuppressive therapies might be at increased risk of infection or developing a more severe course. Furthermore, flares of MG can be triggered by infection, and contracting COVID-19 may lead to an exacerbation, including MG crisis. We have not reduced the dosage of immunosuppressive medications in MG patients who are doing well but have been more likely to manage worsening disease by treating with IVIg rather than increasing the dosage of, or adding new, immunosuppressive agents. Patients are strongly advised to receive the COVID-19 vaccine, wear masks, and maintain social distancing, particularly when infection levels are high in their communities. An international panel published guidelines for management of MG patients during the pandemic.

460 Muscular Dystrophies and Other Muscle Diseases

Anthony A. Amato, Robert H. Brown, Jr.

Myopathies are disorders with structural changes or functional impairment of muscle and can be differentiated from other diseases of the motor unit (e.g., lower motor neuron or neuromuscular junction pathologies) by characteristic clinical and laboratory findings. **Myasthenia gravis and related disorders are discussed in Chap. 459; inflammatory myopathies are discussed in Chap. 377.**

CLINICAL FEATURES

The most important aspect of assessing individuals with neuromuscular disorders is taking a thorough history of the patient's symptoms, disease progression, and past medical and family history, as well as performing a detailed neurologic examination. Based on this and additional laboratory workup (e.g., serum creatine kinase [CK], electromyography [EMG]), one can usually localize the site of the lesion to muscle (as opposed to motor neurons, peripheral nerves, or neuromuscular junction) and the pattern of muscle involvement. It is this pattern of muscle involvement that is most useful in narrowing the differential diagnosis **(Table 460-1)**. Most myopathies present with proximal, symmetric limb weakness with preserved reflexes and sensation. However, asymmetric and predominantly distal weakness can be seen in some myopathies. An associated sensory loss suggests a peripheral neuropathy or a central nervous system (CNS) abnormality (e.g., myelopathy) rather than a myopathy. On occasion, disorders affecting the motor nerve cell bodies in the spinal cord (anterior horn cell disease), the neuromuscular junction, or peripheral nerves can mimic findings of myopathy.

Muscle Weakness Symptoms of muscle weakness can be either intermittent or persistent. Disorders causing *intermittent weakness* (Table 460-1 and **Fig. 460-1**) include myasthenia gravis, periodic paralyses (hypokalemic or hyperkalemic), and metabolic energy deficiencies of glycolysis (especially myophosphorylase deficiency), fatty acid utilization (carnitine palmitoyltransferase [CPT] deficiency), and some mitochondrial myopathies. The states of energy deficiency cause activity-related muscle breakdown accompanied by myoglobinuria.

Most muscle disorders cause *persistent weakness* (Table 460-1 and **Fig. 460-2**). In the majority of these, including most types of muscular dystrophy and inflammatory myopathies, the proximal muscles are weaker than the distal and are symmetrically affected, and the facial muscles are spared, a pattern referred to as *limb-girdle weakness*. The differential diagnosis is more restricted for other patterns of weakness. Facial weakness (difficulty with eye closure and impaired smile) and scapular winging **(Fig. 460-3)** are characteristic of facioscapulohumeral dystrophy (FSHD). Facial and distal limb weakness associated with hand grip myotonia is virtually diagnostic of myotonic dystrophy type 1. When other cranial nerve muscles are weak, causing ptosis or extraocular muscle weakness, the most important disorders to consider include neuromuscular junction disorders, oculopharyngeal muscular dystrophy, mitochondrial myopathies, or some of the congenital myopathies (Table 460-1). A pathognomonic pattern characteristic of inclusion body myositis is atrophy and weakness of the flexor forearm (e.g., wrist and finger flexors) and quadriceps muscles that is often asymmetric. Less frequently seen, but important diagnostically, are the axial myopathies that predominantly affect the paraspinal muscles and include dropped head syndrome indicative of selective neck extensor muscle weakness. The most important neuromuscular diseases associated with this axial muscle weakness include myasthenia gravis, amyotrophic lateral sclerosis, sporadic late-onset nemaline rod myopathy (SLONM), late-onset ryanodine receptor 1 (RyR1) myopathies, hyperparathyroidism, focal myositis, and some forms of inclusion body myopathy. A final pattern, recognized because of preferential distal extremity weakness, is seen in the distal myopathies.

It is important to examine functional capabilities to help disclose certain patterns of weakness (Table 460-1 and **Table 460-2**). The Gower sign **(Fig. 460-4)** is particularly useful. Observing the gait of an individual may disclose a hyperlordotic posture caused by combined trunk and hip weakness, frequently exaggerated by toe walking **(Fig. 460-5)**. A waddling gait is caused by the inability of weak hip muscles to prevent hip drop or hip dip. Hyperextension of the knee (genu recurvatum or back-kneeing) is characteristic of quadriceps muscle weakness, and a steppage gait, due to foot drop, accompanies distal weakness.

Any disorder causing muscle weakness may be accompanied by *fatigue*, referring to an inability to maintain or sustain a force (pathologic fatigability). This condition must be differentiated from asthenia, a type of fatigue caused by excess tiredness or lack of energy. Associated symptoms may help differentiate asthenia and pathologic fatigability. Asthenia is often accompanied by a tendency to avoid physical activities, complaints of daytime sleepiness, necessity for frequent naps, and difficulty concentrating on activities such as reading. There may be feelings of overwhelming stress and depression. In contrast, pathologic fatigability occurs in disorders of neuromuscular transmission and in disorders altering energy production, including defects in glycolysis, lipid metabolism, or mitochondrial energy production. Pathologic fatigability also occurs in chronic myopathies because of difficulty accomplishing a task with less muscle. Pathologic fatigability is accompanied by abnormal clinical or laboratory findings. Fatigue without those supportive features almost never indicates a primary muscle disease.

Muscle Pain (Myalgias), Cramps, and Stiffness Some myopathies can be associated with muscle pain, cramps, contractures, stiff or rigid muscles, or inability to relax the muscles (e.g., myotonia) (Table 460-1). *Muscle cramps* are abrupt in onset, short in duration, triggered by voluntary muscle contraction, and may cause abnormal posturing of the joint. Muscle cramps often occur in neurogenic disorders, especially motor neuron disease **(Chap. 448)**, radiculopathies, and polyneuropathies **(Chap. 457)**, but are not a feature of most primary muscle diseases.

A *muscle contracture* is different from a muscle cramp. In both conditions, the muscle becomes hard, but a contracture is associated with energy failure in glycolytic disorders. The muscle is unable to relax after an active muscle contraction. The EMG shows electrical silence. Confusion is created because contracture also refers to a muscle that cannot be passively stretched to its proper length (fixed contracture)

TABLE 460-1 Myopathies by Pattern of Weakness/Muscle Involvement

Proximal (Limb-Girdle) Weakness

- Most dystrophies (e.g., dystrophinophies, limb-girdle, myofibrillar myopathy, myotonic dystrophy type 2, rare FSHD)
- Congenital myopathies (e.g., central core, multiminicore, centronuclear, nemaline rod)
- Metabolic myopathies (e.g., glycogen and lipid storage diseases)
- Mitochondrial myopathies
- Inflammatory myopathies (DM, PM, IMNM, anti-synthetase syndrome)
- Toxic myopathies (see Table 460-6)
- Endocrine myopathies
- Neuromuscular junction disorders (myasthenia gravis, LEMS, congenital myasthenia, botulism, **see Chap. 459**)
- SLONM

Distal Weakness

- Distal muscular dystrophies/myofibrillar myopathy (see Table 460-5)
- Congenital myopathies (e.g., late-onset centronuclear and nemaline rod myopathies)
- Oculopharyngeal distal myopathy
- Metabolic
  - Glycogen storage disease (e.g., brancher and debrancher deficiency, rarely McArdle disease)
  - Lipid storage disease (e.g., neutral lipid storage myopathy, multiacyldehydrogenase deficiency)
- NMJ disorders (e.g., rare myasthenia gravis and congenital myasthenia)

Proximal Arm/Distal Leg Weakness (Scapuloperoneal or Humeroperonal) Weakness

- Facioscapulohumeral muscular dystrophy (FSHD)
- Scapuloperoneal myopathy and neuropathy
- Myofibrillar myopathies
- Emery-Dreifuss muscular dystrophy (EDMD)
- Bethlem myopathy

Distal Arm/Proximal Leg Weakness

- Inclusion body myositis (usually wrist and finger flexors in arms, hip flexors and knee extensors in legs, and asymmetric)
- Myotonic dystrophy (uncommon presentation)

Axial Muscle Weakness

- Inflammatory (cervicobrachial myositis)
- sIBM and hIBM
- Myotonic dystrophy 2
- Isolated neck extensor myopathy/bent spine syndrome
- FSHD
- Late-onset central core (*RYR1* mutations)
- SLONM
- Metabolic (late-onset Pompe, McArdle disease, lipid storage, mitochondrial)
- Hyperparathyroidism/osteomalacia/vitamin D deficiency
- Myasthenia gravis

Eye Muscle Weakness (Ptosis/Ophthalmoparesis)

- Ptosis without ophthalmoparesis
  - Myotonic dystrophy
  - Congenital myopathies
  - Neuromuscular junction disorders
- Ptosis with ophthalmoparesis
  - Oculopharyngeal dystrophy
  - Oculopharygeal distal myopathy
  - Mitochondrial myopathy
  - hIBM type 3
  - Neuromuscular junction disorders

Episodic Weakness or Myoglobinuria

- Related to exercise
  - Glycogenoses (e.g., McArdle disease, etc.)
  - Lipid disorders (e.g., CPT2 deficiency)
  - Mitochondrial myopathies (e.g., cytochrome B deficiency)
- Not related to exercise
  - *RYR1* mutations can cause malignant hyperthermia, episodic rhabdomyolysis/myoglobinuria, and atypical periodic paralysis
  - Other causes of malignant hyperthermia
- Drugs/toxins (e.g., statins)
  - Prolonged/intensive eccentric exercise
  - Inflammatory (e.g., PM/DM—rare, viral/bacterial infections)
- Delayed or unrelated to exercise
  - Periodic paralysis (e.g., hereditary hyper- or hypokalemic, thyrotoxic, associated renal tubular acidosis, acquired electrolyte imbalance)
  - NMJ disorders

Muscle Stiffness/Decreased Ability to Relax

- Myotonic dystrophy 1 and 2
- Myotonia congenita
- Paramyotonia congenita
- Hyperkalemic periodic paralysis with myotonia
- Potassium aggravated myotonia
- Schwartz-Jampel syndrome
- Other: rippling muscle disease (acquired and hereditary), acquired neuromyotonia (Isaacs' syndrome), stiff-person syndrome, Brody's disease

Abbreviations: DM, dermatomyositis; hIBM, hereditary inclusion body myopathy; IMNM, immune-mediated necrotizing myopathy; LEMS, Lambert-Eaton myasthenic syndrome; NMJ, neuromuscular junction; PM, polymyositis; sIBM, sporadic inclusion body myositis; SLONM, sporadic late-onset nemaline myopathy.

because of fibrosis. In some muscle disorders, especially in Emery-Dreifuss muscular dystrophy (EDMD) and Bethlem myopathy, fixed contractures occur early and represent distinctive features of the disease.

Myotonia is a condition of prolonged muscle contraction followed by slow muscle relaxation. It always follows muscle activation (action myotonia), usually voluntary, but may be elicited by mechanical stimulation (percussion myotonia) of the muscle. Myotonia typically causes difficulty in releasing objects after a firm grasp. In myotonic muscular dystrophy type 1 (DM1), distal weakness usually accompanies myotonia, whereas in DM2, proximal muscles are more affected. Myotonia also occurs with *myotonia congenita* (a chloride channel disorder), but in this condition, muscle weakness is usually not prominent. Myotonia may also be seen in individuals with sodium channel mutations (*hyperkalemic periodic paralysis* or *potassium-sensitive myotonia*). Another sodium channelopathy, *paramyotonia congenita* (PC), also is associated with muscle stiffness. In contrast to other disorders associated with myotonia in which the myotonia is eased by repetitive activity, PC is named for a paradoxical phenomenon whereby the myotonia worsens with repetitive activity. Potassium-aggravated myotonia is an allelic disorder in which myotonia is brought on by consumption of too much potassium-containing foods.

Muscle stiffness can refer to different phenomena. Some patients with inflammation of joints and periarticular surfaces feel stiff. This condition is different from the disorders of hyperexcitable motor nerves causing stiff or rigid muscles. In *stiff-person syndrome*, spontaneous discharges of the motor neurons of the spinal cord cause involuntary muscle contractions mainly involving the axial (trunk) and proximal lower extremity muscles. The gait becomes stiff and labored, with hyperlordosis of the lumbar spine. Superimposed episodic muscle spasms are precipitated by sudden movements, unexpected noises, and emotional upset. The muscles relax during sleep. Serum antibodies against glutamic acid decarboxylase are present in approximately two-thirds of cases. In *acquired neuromyotonia* (*Isaacs' syndrome*), there is hyperexcitability of the peripheral nerves manifesting as continuous muscle fiber activity in the form of widespread fasciculations and myokymia with impaired muscle relaxation. Muscles of the leg are stiff,

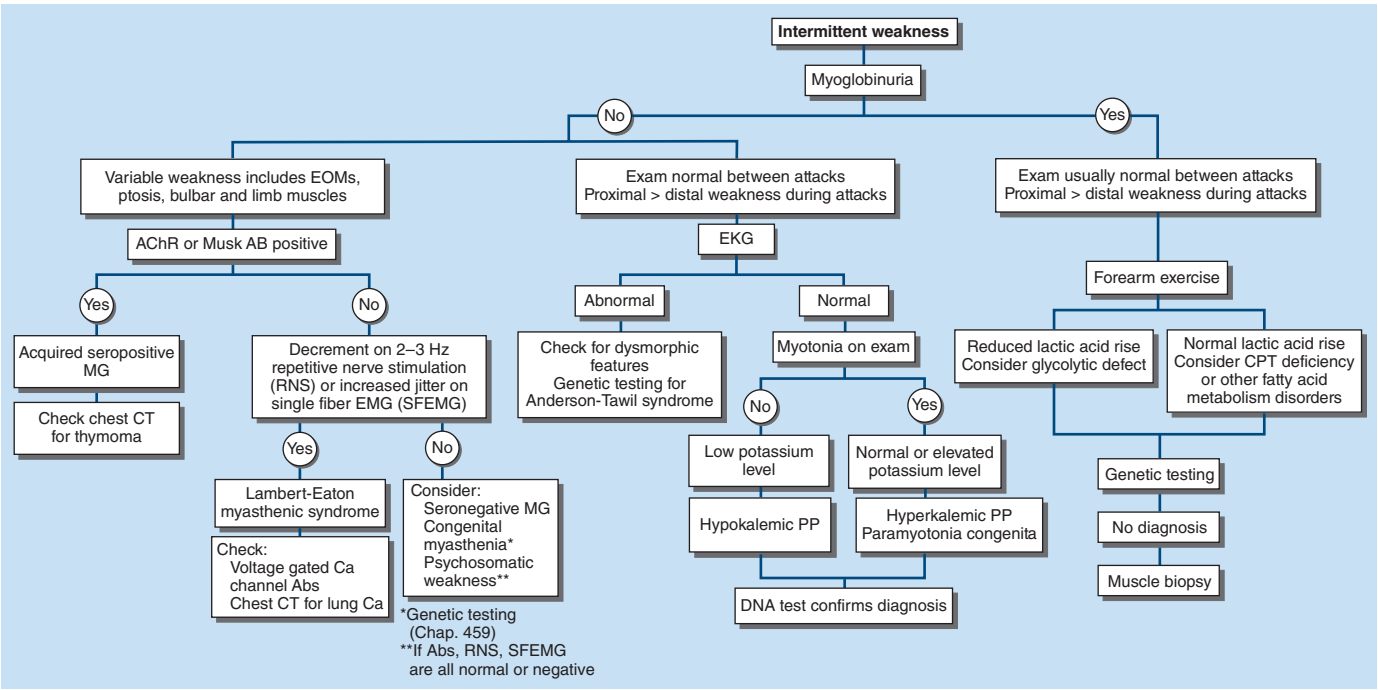

FIGURE 460-1 Diagnostic evaluation of intermittent weakness. AChR AB, acetylcholine receptor antibody; CPT, carnitine palmitoyltransferase; EKG, electrocardiogram; EMG, electromyogram; EOMs, extraocular muscles; MG, myasthenia gravis; PP, periodic paralysis.

and the constant contractions of the muscle cause increased sweating of the extremities. This peripheral nerve hyperexcitability is mediated by antibodies that target voltage-gated potassium channels.

There are two painful muscle conditions of particular importance, neither of which is associated with muscle weakness. *Fibromyalgia* is a common, yet poorly understood myofascial pain syndrome in which patients complain of severe muscle pain and tenderness, severe fatigue, and often poor sleep. Serum CK, erythrocyte sedimentation rate (ESR), EMG, and muscle biopsy are normal **(Chap. 385)**. *Polymyalgia rheumatica* occurs mainly in patients aged >50 years and is characterized by stiffness and pain in the shoulders, lower back, hips, and thighs **(Chap. 375)**. The ESR and CRP are elevated, while serum CK, EMG, and muscle biopsy are normal.

Muscle Enlargement and Atrophy In most myopathies, muscle tissue is replaced by fat and connective tissue, but the size of the muscle is usually not affected. However, in many limb-girdle muscular dystrophies, enlarged calf muscles are typical. The enlargement represents true muscle hypertrophy; thus, the term *pseudohypertrophy* should be avoided when referring to these patients. The calf muscles remain very strong even late in the course of these disorders. Muscle enlargement can also result from infiltration by sarcoid granulomas, amyloid deposits, bacterial and parasitic infections, and focal myositis.

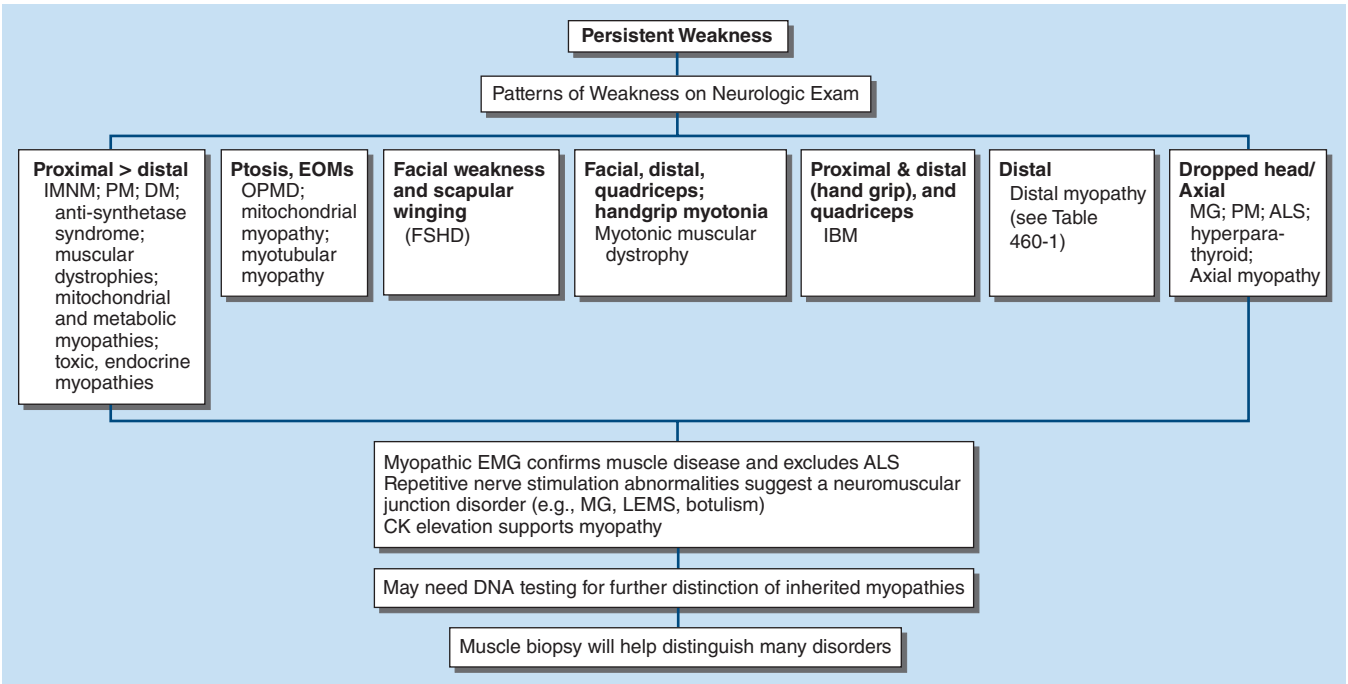

FIGURE 460-2 Diagnostic evaluation of persistent weakness. Examination reveals one of seven patterns of weakness. The pattern of weakness in combination with the laboratory evaluation leads to a diagnosis. ALS, amyotrophic lateral sclerosis; CK, creatine kinase; DM, dermatomyositis; EMG, electromyography; EOMs, extraocular muscles; FSHD, facioscapulohumeral dystrophy; IBM, inclusion body myositis; IMNM, immune-mediated necrotizing myopathy; MG, myasthenia gravis; OPMD, oculopharyngeal muscular dystrophy; PM, polymyositis.

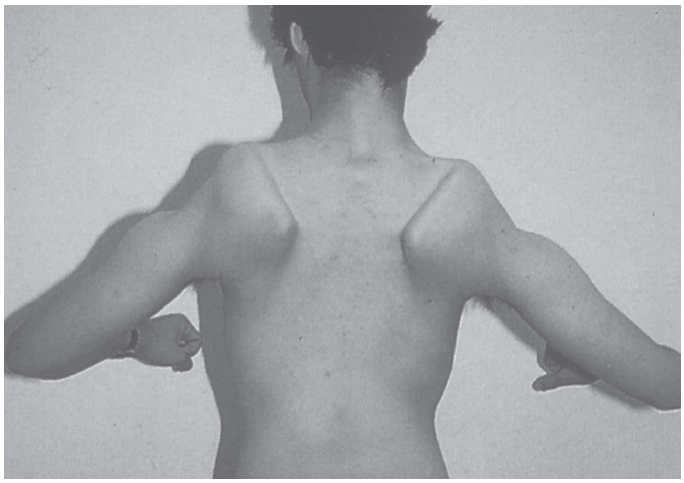

FIGURE 460-3 Facioscapulohumeral dystrophy with prominent scapular winging.

In contrast, muscle atrophy is characteristic of other myopathies. In Miyoshi myopathy, which can be caused by mutations in the genes that encode for dysferlin and anoctamin 5, there is a predilection for early atrophy of the gastrocnemius muscles, particularly the medial aspect. Atrophy of the humeral muscles is characteristic of FSHD and EDMD.

LABORATORY EVALUATION

Various tests can be used to evaluate a suspected myopathy, including CK levels, endocrine studies (e.g., thyroid function tests, parathyroid hormone and vitamin D levels), autoantibodies (associated with myositis and systemic disorders), forearm exercise test, muscle biopsy, and genetic testing. Electrodiagnostic studies can be useful to differentiate myopathies from other neuromuscular disorders (motor neuron disease, peripheral neuropathies, neuromuscular junction disorders) but, in most instances, do not help distinguish the specific type of myopathy.

Serum Enzymes CK is the most sensitive measure of muscle damage. The MM isoenzyme predominates in skeletal muscle, whereas CK-myocardial bound (CK-MB) is the marker for cardiac muscle. Serum CK can be elevated in normal individuals without provocation, presumably on a genetic basis or after strenuous activity, trauma, a prolonged muscle cramp, or a generalized seizure. Aspartate aminotransferase (AST), alanine aminotransferase (ALT), aldolase, and lactate dehydrogenase (LDH) are enzymes sharing an origin in both muscle and liver. Problems arise when the levels of these enzymes are found to be elevated in a routine screening battery, leading to the erroneous assumption that liver disease is present when in fact muscle could be the cause. An elevated γ-glutamyl transferase (GGT) helps to establish a liver origin because this enzyme is not found in muscle. Rarely, aldose can be elevated in an inflammatory myopathy when CK, AST, and ALT are normal, signifying that the inflammation predominantly affects the perimysium (dermatomyositis, graft-versus-host disease) or the surrounding fascia (fasciitis).

TABLE 460-2 Observations on Examination That Disclose Muscle Weakness

FUNCTIONAL IMPAIRMENT	MUSCLE WEAKNESS
Inability to forcibly close eyes	Upper facial muscles
Impaired pucker	Lower facial muscles
Inability to raise head from prone position	Neck extensor muscles
Inability to raise head from supine position	Neck flexor muscles
Inability to raise arms above head	Proximal arm muscles (may be only scapular stabilizing muscles)
Inability to walk without hyperextending knee (back-kneeing or genu recurvatum)	Knee extensor muscles
Inability to walk with heels touching the floor (toe walking)	Shortening of the Achilles tendon
Inability to lift foot while walking (steppage gait or foot drop)	Anterior compartment of leg
Inability to walk without a waddling gait	Hip muscles
Inability to get up from the floor without climbing up the extremities (Gowers' sign)	Hip, thigh, and trunk muscles
Inability to get up from a chair without using arms	Hip muscles

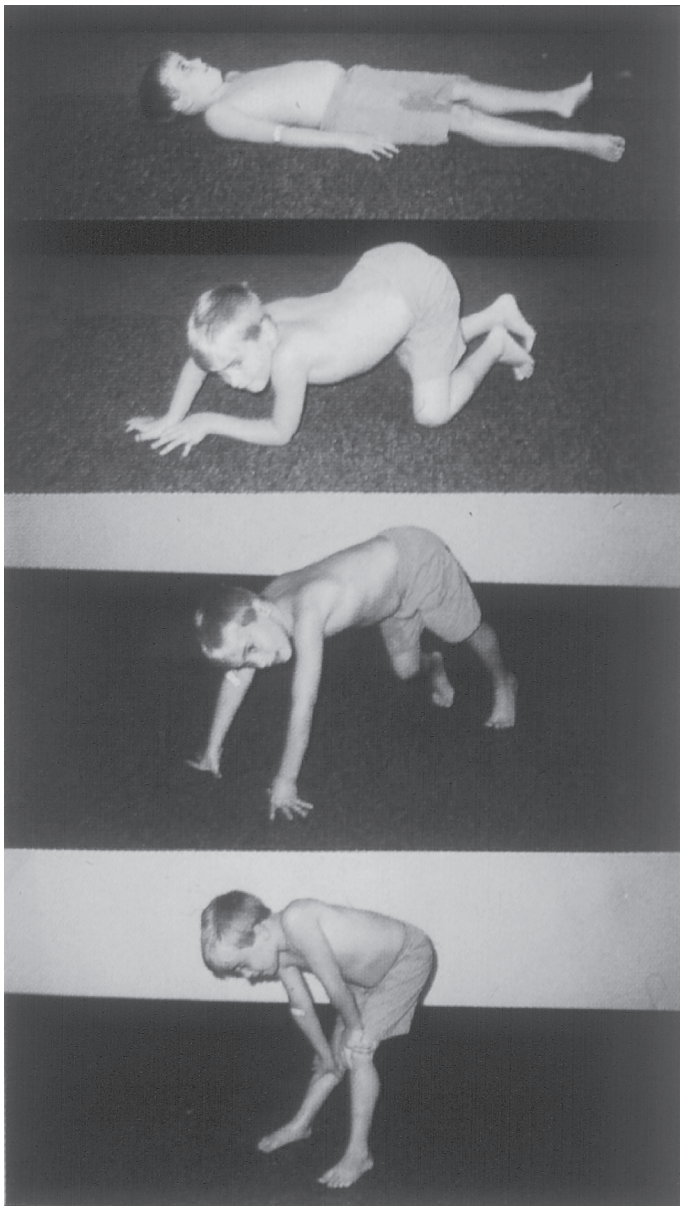

FIGURE 460-4 Gower sign showing a patient using his arms to climb up the legs in attempting to get up from the floor.

Electrodiagnostic Studies EMG, repetitive nerve stimulation, and nerve conduction studies (NCS) **(Chap. 457)** are helpful in differentiating myopathies from motor neuron disease, neuropathies, and neuromuscular junction diseases. Routine NCS are typically normal in myopathies, but reduced amplitudes of compound muscle action potentials may be seen in atrophied muscles. The needle EMG may reveal irritability on needle insertion and spontaneously that is suggestive of a myopathy with active necrosis or muscle membrane instability (inflammatory myopathies, dystrophies, toxic myopathies, myotonic myopathies), whereas a lack of irritability is characteristic of long-standing myopathic disorders (muscular dystrophies with severe fibrofatty replacement, endocrine myopathies, disuse atrophy, and many of the metabolic myopathies between bouts of rhabdomyolysis). In addition, the EMG may demonstrate myotonic discharges that will narrow the differential diagnosis (Table 460-1). Another important

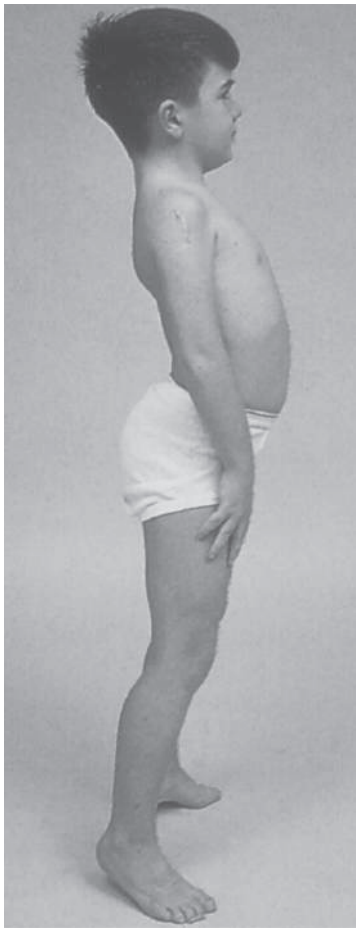

FIGURE 460-5 Hyperlordotic posture, exaggerated by standing on toes, associated with trunk and hip weakness.

EMG finding is the presence of short-duration, small-amplitude, polyphasic motor unit action potentials (MUAPs). In myopathies, the MUAPs fire early but at a normal rate to compensate for the loss of individual muscle fibers, whereas in neurogenic disorders, the MUAPs fire faster. An EMG is usually normal in steroid or disuse myopathy, both of which are associated with type 2 fiber atrophy; this is because the EMG preferentially assesses the physiologic function of type 1 fibers. The EMG can supplement the clinical examination in choosing an appropriately affected muscle to biopsy.

Imaging Studies Skeletal magnetic resonance imaging (MRI) and ultrasound are increasingly utilized to assess the pattern of muscle involvement, which can help in narrowing the diagnosis, and are often more sensitive than the clinical examination and EMG, particularly early in a disease course. For example, there is early predilection of the vastus lateralis and medialis muscles with relative sparing of the rectus femoris muscles on imaging of thigh muscles in patients with inclusion body myositis, and this can be appreciated on imaging prior to weakness being detected on manual muscle testing. MRI can also demonstrate fasciitis when the clinical examination and EMG are normal. Imaging can also be used to help guide what muscle to biopsy in patients with weakness on manual muscle testing and EMG abnormalities only in muscles that are not typically biopsied (e.g., paraspinal or hip girdle). We have found imaging helpful in patients with presumed muscular dystrophy when the muscle biopsy is not diagnostic and genetic testing shows only a variation of unclear significance. In this situation, the pattern of muscle involvement on imaging can support the known pattern of muscle involvement of a specific hereditary myopathy. The cost and availability of MRI preclude routine use in some settings, but ultrasound is more readily available and less expensive.

Genetic Testing This is increasingly available and is the gold standard for diagnosing patients with hereditary myopathies. Next-generation sequencing panels are increasing utilized, but clinicians need to know their limitations; large deletions and duplications can be missed, as can mutations in noncoding (intronic) regions. Furthermore, testing often reveals sequence alterations of unclear significance.

Forearm Exercise Test With exercise-induced muscle pain and myoglobinuria, there may be a defect in glycolysis. For safety, the test should not be performed under ischemic conditions to avoid an unnecessary insult to the muscle, causing rhabdomyolysis. The test is performed by placing a small indwelling catheter into an antecubital vein. A baseline blood sample is obtained for lactic acid and ammonia. The forearm muscles are exercised by asking the patient to vigorously open and close the hand for 1 min. Blood is then obtained at intervals of 1, 2, 4, 6, and 10 min for comparison with the baseline sample. A three- to fourfold rise of lactic acid is typical. The simultaneous measurement of ammonia serves as a control because it should also rise with exercise. In patients with myophosphorylase deficiency and certain other glycolytic defects, the lactic acid rise will be absent or below normal, while the rise in ammonia will reach control values. If there is lack of effort, neither lactic acid nor ammonia will rise. Patients with selective failure to increase ammonia may have myoadenylate deaminase deficiency. This condition has been reported to be a cause of myoglobinuria, but deficiency of this enzyme in asymptomatic individuals makes interpretation controversial.

Muscle Biopsy Muscle biopsy is extremely helpful in evaluation of acquired myopathies but is performed less frequently in suspected hereditary myopathies as genetic testing has become more widely available. However, muscle biopsy can be helpful in cases of suspected hereditary myopathy in which genetic testing was nondiagnostic. Almost any superficial muscle can be biopsied, but it is important to biopsy one that is affected clinically but not too severely (for example, grade 4 out of 5 strength or movement against moderate resistance by manual muscle testing) **(Chap. 433)**. A specific diagnosis can be established in many disorders.

HEREDITARY MYOPATHIES

Muscular dystrophy refers to a group of hereditary progressive diseases, each with unique phenotypic and genetic features **(Tables 460-3 through 460-6 and Fig. 460-6)**. The prognosis of dystrophies is slow progressive weakness, though the severity and course are variable between and even within subtypes. Some are associated with cardiac and ventilatory muscle involvement, which are the leading causes of mortality. Unfortunately, there are no specific medical therapies for most of the muscular dystrophies, and treatment is aimed at maintaining function with physical and occupational therapy. Noninvasive ventilation and tracheostomy may be warranted. Those with cardiomyopathy may require afterload reduction, antiarrhythmic agents, pacemakers or intracardiac defibrillators, and occasionally cardiac transplantation. We will focus primarily on those that manifest in adulthood.

DUCHENNE AND BECKER MUSCULAR DYSTROPHY (DMD AND BMD)

DMD and BMD are X-linked recessive muscular dystrophies caused by mutations in the *dystrophin* gene. Affecting 1 in 3000 male births, DMD is the most common mutational disease affecting boys. The incidence of BMD is ~5 per 100,000.

Clinical Features Proximal muscles, especially of the lower extremities, are prominently involved in both disorders. This becomes evident in DMD very early; boys with DMD have difficulty climbing stairs and never run well. As the disease progresses, weakness becomes more generalized. Hypertrophy of muscles, particularly in the calves, is an early and prominent finding. Most patients with BMD first experience difficulties between ages 5 and 15 years, although onset in the third or fourth decade or even later can occur. Life expectancy for DMD and BMD is reduced, but most BMD cases survive into the fourth or fifth decade. Intellectual disability may occur in both disorders but is less common in BMD. Cardiac involvement is common in both DMD and BMD and may result in heart failure; some BMD

TABLE 460-3 Autosomal Dominant (AD) Limb-Girdle Muscular Dystrophies (LGMDs)

patients manifest with only heart failure. Other less common presentations of dystrophinopathy are asymptomatic hyper-CK-emia, myalgias without weakness, and myoglobinuria.

Laboratory Features Serum CK levels are usually elevated. Muscle biopsies demonstrate dystrophic features. Western blot analysis of muscle biopsy samples demonstrates absent dystrophin in DMD or reduction in levels or size of dystrophin in BMD. In both disorders, mutations can be established using DNA from peripheral blood leukocytes. In most cases, muscle biopsies are no longer performed when DMD or BMD is suspected, as genetic testing is less invasive, less costly, and routinely available. Deletions within or duplications of the *dystrophin* gene are common in both DMD and BMD; in ~95% of cases, the mutation does not alter the translational reading frame of messenger RNA. These "in-frame" mutations allow for production of some dystrophin, which accounts for the presence of altered rather than absent dystrophin on Western blot analysis and a milder clinical phenotype.

TREATMENT

Duchenne and Becker Muscular Dystrophy

Glucocorticoids slow progression in DMD, but their use has not been adequately studied in BMD. Physical and occupational therapy are important in helping maintain function. As death is often from the associated cardiomyopathy, it is important to follow patients with a cardiologist and treat appropriately. Small studies suggest that there may be a clinical benefit in selected cases of DMD from short oligonucleotides that permit skipping of mutant exons, leading to expression of a short but nonetheless functional dystrophin protein. In parallel, other studies suggest that small molecules may permit read-through of protein-truncating mutations in some DMD cases. Gene therapy studies have not as yet been conducted in BMD.

LIMB-GIRDLE MUSCULAR DYSTROPHY

The limb-girdle muscular dystrophies (LGMDs) are a genetically heterogenous group of dystrophies in which males and females are affected equally, with typical onset ranging from late in the first decade to the fourth decade. The LGMDs usually manifest with progressive weakness of pelvic and shoulder girdle musculature and are often clinically indistinguishable from DMD and BMD. Respiratory insufficiency from weakness of the diaphragm may occur, as may cardiomyopathy. Serum CKs are elevated, and the EMG is myopathic. Muscle biopsies reveal dystrophic features, but the findings are not specific to differentiate subtypes from one another unless immunohistochemistry is employed (e.g., immunostaining for various sarcoglycans, dysferlin, alpha-dystroglycan) or there are features to suggest one of the myofibrillar myopathies. Nonetheless, definitive diagnosis requires genetic testing.

The traditional classification of LGMD is based on autosomal dominant (LGMD1) and autosomal recessive (LGMD2) inheritance. Superimposed on the backbone of LGMD1 and LGMD2, the classification uses a sequential alphabetical lettering system (LGMD1A, LGMD2A, etc.) based on genotype. However, ever-expanding discoveries of new genes have outgrown the alphabet. The European Neuromuscular Centre (ENMC) proposed a new nomenclature in which autosomal dominant cases are termed LGMD "D" and autosomal recessive as LGMD "R," followed by a numerical number based on genotype. Furthermore, this new classification only includes cases in which at least two unrelated families have been reported, the predominant weakness at onset was proximal, independent ambulation was achieved at some time, CK is elevated, and muscle biopsies or imaging revealed dystrophic features. Thus, mutations in the *CPN3* gene leading to a deficiency in calpain-3, which traditionally were classified as LGMD2A, are classified as LGMDR1 by this new system. In contrast, mutations in myotilin (LGMD1A) and desmin (LGMD1E and LGMD2R) and that often have more distal weakness and have biopsy features of a myofibrillar myopathy are not classified as a LGMD in this new scheme but rather as subtypes of myofibrillar myopathy. Likewise, laminopathies (LGMD1B) are considered a subtype of EDMD rather than an LGMD. The myofibrillar myopathies are now considered as being separate from LGMD. This new classification of LGMD and distal muscular dystrophies is summarized in Tables 460-3 and 460-4.

A recent metanalysis reported the prevalence of LGMD to be 1.63 per 100,000 (range, 0.56–5.75 per 100,000), while estimated prevalences

TABLE 460-6 Myofibrillary Myopathies (MFM)

MYOFIBRILLAR MYOPATHY	INHERITANCE	GENE	AFFECTED PROTEIN

Abbreviations: AD, autosomal dominant; AR, autosomal recessive.

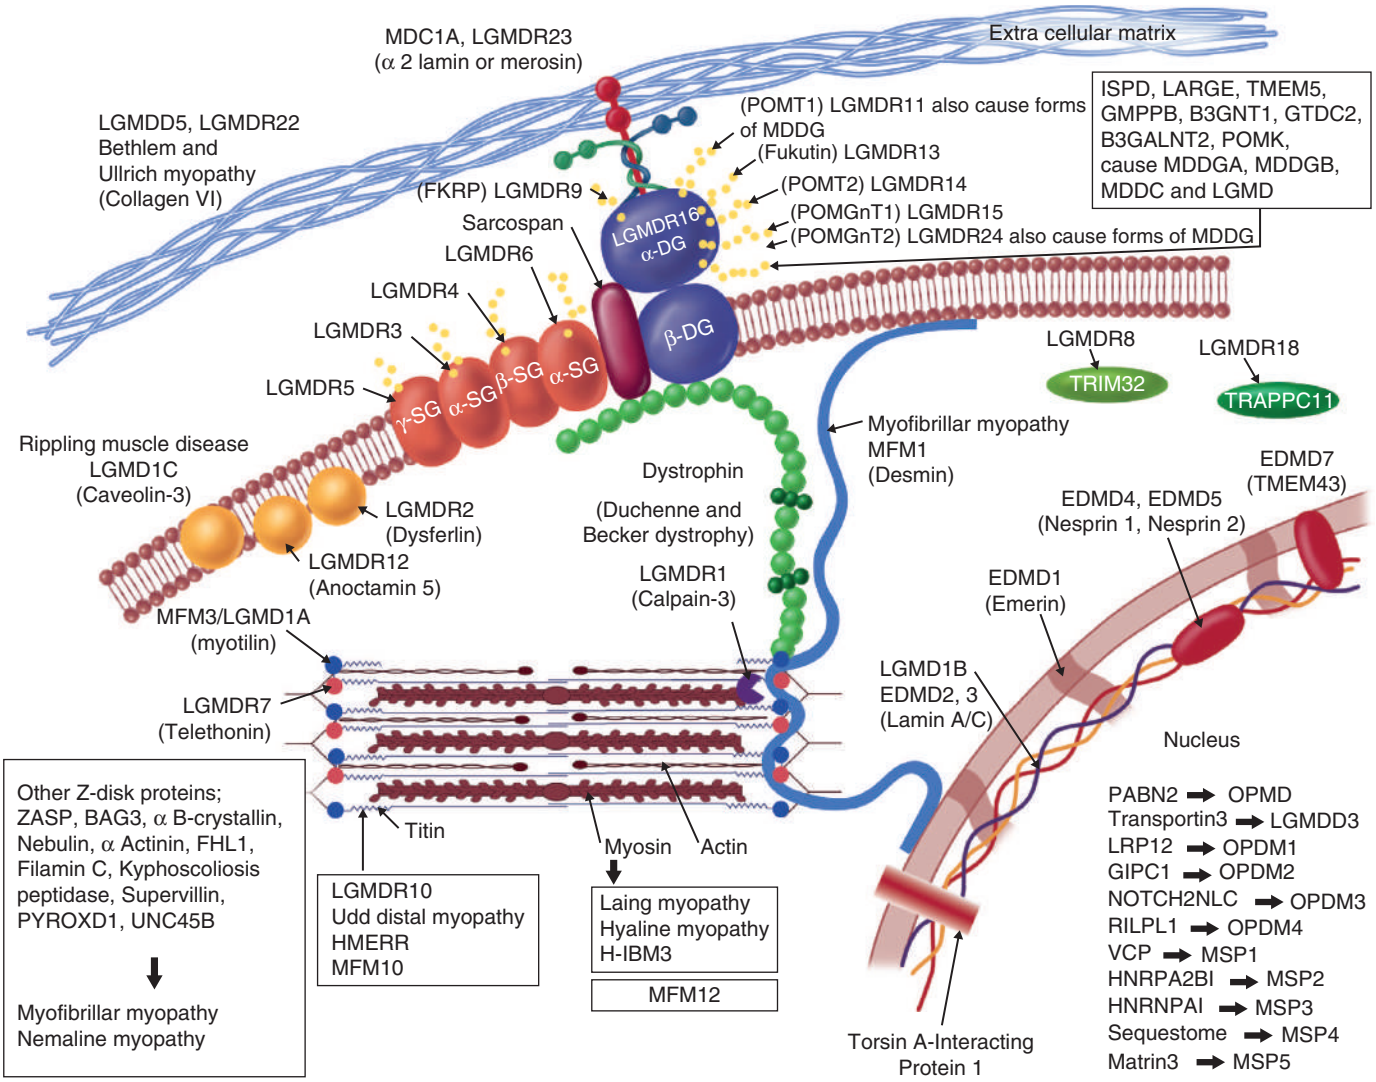

FIGURE 460-6 Proteins involved in the muscular dystrophies. This schematic shows the location of various sarcolemmal, sarcomeric, nuclear, and enzymatic proteins associated with muscular dystrophies. The diseases associated with mutations in the genes responsible for encoding these proteins are shown in boxes. Dystrophin, via its interaction with the dystroglycan complex, connects the actin cytoskeleton to the extracellular matrix. Extracellularly, the sarcoglycan complex interacts with biglycan, which connects this complex to the dystroglycan complex and the extracellular matrix collagen. Various enzymes are important in the glycosylation of the α-dystroglycan and mediate its binding to the extracellular matrix and usually cause a congenital muscular dystrophy with severe brain and eye abnormalities but may cause milder limb-girdle muscular dystrophy (LGMD) phenotype. Mutations in genes that encode for sarcomeric and Z-disk proteins cause forms of LGMD and distal myopathies (including myofibrillar myopathy, forms of hereditary inclusion body myopathy) as well as nemaline rod myopathy and other "congenital" myopathies. Mutations affecting nuclear membrane proteins are responsible for most forms of Emery-Dreifuss muscular dystrophy (EDMD). Mutations in other nuclear genes cause other forms of dystrophy. *(Reproduced with permission from AA Amato et al (eds): Amato and Russell's Neuromuscular disorders, 3rd ed. New York: McGraw Hill; 2025.)*

of individual specific subtypes of LGMDs vary. The most common types of adult-onset LGMD are calpainopathy (LGMD2A/LGMDR1), fukutin-related protein (FKRP) deficiency (LGMD2I/LGMDR9), and anoctaminopathy (LGMD2L/LGMDR12). Calpainopathy (LGMD2A/LGMDR1), the most common cause of LGMD in those with ancestry from Spain, France, Italy, and Great Britain, is associated with marked scapular winging, lack of calf muscle hypertrophy, and lack of cardiac and lung involvement. Of note, autosomal dominant mutations in an intron of the calpain-3 gene is responsible for LGMD1I/LGMDD4. LGMD2I/LGMDR9 is more common in individuals with northern European ancestry, is associated with calf muscle hypertrophy, and can have cardiac and lung involvement out of proportion to extremity weakness. LGMD2L/LGMDR12 accounts for ~7% of LGMD in the United States, and the prevalence is higher in northern Europe; as seen in dysferlinopathies (LGMD2B/LGMDR2 and Miyoshi myopathy type 1), anoctaminopathy has an early predilection for medial calf atrophy and weakness.

Importantly, immune-mediated necrotizing myopathies can mimic LGMD clinically and histopathologically (Chap. 377). Anyone suspected of having an LGMD but without definite pathogenic mutation(s) identified on genetic testing should be screened for the presence of serum antibodies against HMGCR and SRP to assess for a treatable autoimmune cause.

EMERY-DREIFUSS MUSCULAR DYSTROPHY

There are at least seven subtypes of EDMD that have been associated with mutations in *EMD* (EDMD1), *LMNA* (EDMD2 and EDMD3), *SYNE1* (EDMD4), *SYNE2* (EDMD5), *FHL1* (EDMD6), and *TMEM43* (EDMD7), encoding emerin, lamin A/C, nesprin-1, nesprin-2, FHL1, and LUMA, respectively. Mutations in *EMD* and *FHL* produce X-linked inheritance, whereas the others can be autosomal dominant (*LMNA, SYNE1, SYNE2, LUMA*) or autosomal recessive (*LMNA1*). The clinical phenotypes are quite similar.

Clinical Features Prominent contractures can be recognized in early childhood and teenage years, often preceding muscle weakness. The contractures persist throughout the course of the disease and are present at the elbows, ankles, and neck. Muscle weakness affects humeral and peroneal muscles at first and later spreads to a limb-girdle distribution (Table 460-1). The cardiomyopathy is potentially life threatening and may result in sudden death. A spectrum of atrial rhythm and conduction defects includes atrial fibrillation,

atrial standstill, and atrioventricular heart block. Some patients have a dilated cardiomyopathy. Female carriers of the X-linked variant may manifest with a cardiomyopathy.

Laboratory Features Serum CK is usually slightly elevated, and the EMG is myopathic. Muscle biopsy usually shows nonspecific dystrophic features, although cases associated with *FHL1* mutations have features of myofibrillar myopathy. Immunohistochemistry reveals absent emerin staining of myonuclei in X-linked EDMD due to *emerin* mutations. Electrocardiograms (ECGs) demonstrate atrial and atrioventricular rhythm disturbances.

X-linked EDMD usually arises from defects in the *emerin* gene encoding a nuclear envelope protein. *FHL1* mutations are also a cause of X-linked scapuloperoneal dystrophy but can also present with an X-linked form of EDMD. The autosomal dominant disease can be caused by mutations in the *LMNA* gene encoding Lamin A/C; in the synaptic nuclear envelope protein 1 (*SYNE1*) or 2 (*SYNE2*) encoding nesprin-1 and nesprin-2, respectively; and in *TMEM43* encoding LUMA. These proteins are essential components of the filamentous network underlying the inner nuclear membrane. Loss of structural integrity of the nuclear envelope from defects in emerin, Lamin A/C, nesprin-1, nesprin-2, and LUMA accounts for overlapping phenotypes.

TREATMENT

Emery-Dreifuss Muscular Dystrophy

Supportive care should be offered for neuromuscular disability, including ambulatory aids, if necessary. Stretching of contractures is difficult. Management of cardiomyopathy and arrhythmias (e.g., early use of a defibrillator or cardiac pacemaker) may be lifesaving.

MYOTONIC DYSTROPHY

There are two distinct forms of myotonic dystrophy (*dystrophia myotonica* [DM]), namely myotonic dystrophy type 1 (DM1) and myotonic dystrophy type 2 (DM2), also called *proximal myotonic myopathy* (PROMM).

Clinical Features The clinical expression of DM1 varies widely and involves many systems other than muscle. Affected patients may have a "hatchet-faced" appearance due to temporalis, masseter, and facial muscle atrophy and weakness. Frontal baldness is frequent. Weakness of wrist and fingers occurs early, as does foot drop. Proximal muscles are less affected. Palatal, pharyngeal, and tongue involvement can lead to dysarthria and dysphagia. Some patients have diaphragm and intercostal muscle weakness, resulting in ventilatory insufficiency. Myotonia is usually apparent by the age of 5 years and is best demonstrable by percussion of the thenar eminence or asking patients to close their fingers very tightly and then relax.

ECG abnormalities include first-degree heart block and more extensive conduction system involvement. Complete heart block and sudden death can occur. Congestive heart failure occurs infrequently but may result from cor pulmonale secondary to respiratory failure. Other associated features include intellectual impairment, hypersomnia, posterior subcapsular cataracts, gonadal atrophy, insulin resistance, and decreased esophageal and colonic motility.

Congenital myotonic dystrophy is a more severe form of DM1 and occurs in ~25% of infants of affected mothers. It is characterized by severe facial and bulbar weakness, transient neonatal respiratory insufficiency, and intellectual disability.

DM2 or PROMM involves mainly proximal muscles. Other features of the disease overlap with DM1, including cataracts, testicular atrophy, insulin resistance, constipation, hypersomnia, and cognitive defects. Cardiac conduction defects occur but are less common. The hatchet face and frontal baldness are also less consistent features. A very striking difference is the failure to clearly identify a congenital form of DM2.

Laboratory Features The diagnosis of myotonic dystrophy can usually be made on the basis of clinical findings. Serum CK levels may be normal or mildly elevated. EMG evidence of myotonia is present in most cases of DM1 but is more patchy in DM2. Muscle biopsy is not typically performed for diagnosis but is sometimes done when the clinical features and electrophysiologic features are not recognized. The major histopathologic features in both DM1 and DM2 are numerous internalized nuclei in individual muscle fibers combined with many atrophic fibers with pyknotic nuclear clumps.

DM1 and DM2 are autosomal dominant disorders. DM1 is transmitted by an intronic mutation consisting of an unstable expansion of a CTG trinucleotide repeat in a serine-threonine protein kinase gene (named *DMPK*). An increase in the severity of the disease phenotype in successive generations (genetic anticipation) is accompanied by an increase in the number of trinucleotide repeats. The unstable triplet repeat in myotonic dystrophy can be used for prenatal diagnosis. Congenital disease occurs almost exclusively in infants born to affected mothers.

DM2 is caused by a DNA expansion mutation consisting of a CCTG repeat in intron 1 of the *CNBP* gene encoding the CCHC-type zinc finger nucleic acid binding protein. The DNA expansions in DM1 and DM2 impair muscle function by a toxic gain of function of the mutant mRNA. In both DM1 and DM2, the mutant RNA appears to form intranuclear inclusions composed of aberrant RNA. These RNA inclusions sequester RNA-binding proteins essential for proper splicing of a variety of other mRNAs. This leads to abnormal transcription of multiple proteins in a variety of tissues/organ systems, in turn causing the systemic manifestations of DM1 and DM2.

TREATMENT

Myotonic Dystrophy

The myotonia in DM1 and DM2 is usually not so bothersome to warrant treatment, but when it is, mexiletine may be helpful. A cardiac pacemaker or implantable cardioverter defibrillator should be considered for patients with significant arrhythmia. Molded ankle-foot orthoses help stabilize gait in patients with foot drop. Excessive daytime somnolence with or without sleep apnea is not uncommon. Sleep studies, noninvasive respiratory support (biphasic positive airway pressure [BiPAP]), and treatment with modafinil may be beneficial.

FACIOSCAPULOHUMERAL (FSHD) MUSCULAR DYSTROPHY

There are two forms of FSHD that have similar pathogenesis. Most patients have FSHD type 1 (95%), whereas ~5% have FSHD2. Both forms are clinically and histopathologically identical. The prevalence FSHD is ~5 per 100,000 individuals.

Clinical Features FSHD typically presents in childhood or young adulthood. In most cases, facial weakness is the initial manifestation, appearing as an inability to smile, whistle, or fully close the eyes. Loss of scapular stabilizer muscles makes arm elevation difficult. Scapular winging (Fig. 460-3) becomes apparent with attempts at abduction and forward movement of the arms. Biceps and triceps muscles may be severely affected, with relative sparing of the deltoid muscles. Weakness is invariably worse for wrist extension than for wrist flexion, and weakness of the anterior compartment muscles of the legs may lead to foot drop. In 20% of patients, weakness progresses to involve the pelvic muscles, and severe functional impairment and possible wheelchair dependency result. The heart is not involved, but there can be ventilatory muscle weakness in 5% of affected individuals. There is an increased incidence of nerve deafness. *Coats' disease*, a disorder consisting of telangiectasia, exudation, and retinal detachment, also occurs.

Laboratory Features The serum CK level may be normal or mildly elevated. EMG and muscle biopsy show nonspecific abnormalities but on occasion can reveal a prominent inflammatory infiltrate leading to an incorrect diagnosis of myositis (Chap. 377).

FSHD1 is associated with deletions of tandem 3.3-kb repeats at 4q35. The deletion reduces the number of repeats to a fragment of <35 kb in most patients. Within these repeats lies the *DUX4* gene, which usually is not expressed after early muscle development. In

patients with FSHD1, these deletions in the setting of a specific polymorphism lead to hypomethylation of the region and toxic expression of the *DUX4* gene. In cases of FSHD2, there is no deletion, but rather mutations in three different genes have been identified, each of which interestingly leads to hypomethylation of the DUX4 region and the permissive expression of the *DUX4* gene. Dominant mutations in the structural maintenance of chromosomes hinge domain 1 (*SMCHD1*) gene are the most common cause of FSHD2, but heterozygous mutations in the DNA methyltransferase 3B (*DNMT3B*) gene and homozygous mutations in the ligand-dependent nuclear receptor-interacting factor 1 (*LRIF1*) gene also cause autosomal recessive FSHD2. These proteins normally interact with SMCHD1, and mutations lead to hypomethylation of DUX4. As in FSHD1, this leads to an overexpression of the *DUX4* transcript that encodes for double homeobox 4, which itself is a transcription factor controlling the expression of other genes. In turn, this likely results in the altered expression of additional genes.

TREATMENT

Facioscapulohumeral Muscular Dystrophy

No specific treatment is available, though clinical trials assessing the safety and efficacy of reducing DUX4 expression are ongoing. Physical and occupational therapy are the current mainstays of treatment. Ankle-foot orthoses are helpful for foot drop. Scapular stabilization procedures improve scapular winging and function.

OCULOPHARYNGEAL DYSTROPHY (OPMD)

OPMD represents one of several disorders characterized by progressive external ophthalmoplegia, which consists of slowly progressive ptosis and limitation of eye movements with sparing of pupillary reactions for light and accommodation. Patients usually do not complain of diplopia, in contrast to patients having conditions with a more acute onset of ocular muscle weakness (e.g., myasthenia gravis).

Clinical Features OPMD has a late onset; it usually presents in the fourth to sixth decade with ptosis or dysphagia. The extraocular muscle impairment is less prominent in the early phase but may become severe over time. The swallowing problem may lead to aspiration. Weakness of the neck and proximal extremities can develop but is usually mild in degree.

Laboratory Features The serum CK level may be two to three times normal. EMG can identify myopathic changes in weak muscles. Muscle biopsies are no longer necessary for diagnosis in most cases but, when performed, demonstrate muscle fibers with rimmed vacuoles. On electron microscopy, a distinctive feature of OPMD is the presence of 8.5-nm tubular filaments in some muscle cell nuclei.

OPMD is an autosomal dominant disorder that has a high incidence in certain populations (e.g., French-Canadians, individuals of Spanish ancestry, and Ashkenazi Jews). The molecular defect in OPMD is an expansion of a polyalanine repeat tract in a poly-RNA-binding protein (*PABP2*) gene. *PABP2* is involved in polyadenylation of mRNAs and their transport through the nuclei pores into the cytoplasm. The expansion of the GCG repeats results in abnormal folding of the polyalanine domains of *PABP2* and its resistance to nuclear proteasomal degradation. This in turn may result in (1) direct toxicity of the intranuclear aggregates; (2) intranuclear sequestration of essential transcription factors, molecular chaperones, RNA binding proteins, and RNAs by these intranuclear aggregates; or (3) suppression of the normal function of the wild-type protein.

TREATMENT

Oculopharyngeal Dystrophy

Dysphagia can lead to significant undernourishment and aspiration. Cricopharyngeal myotomy may improve swallowing. Eyelid crutches can improve vision when obstructed by ptosis; candidates for ptosis surgery must be carefully selected—those with severe facial weakness are not suitable.

OCULOPHARYNGEAL DISTAL MYOPATHY (OPDM)

Clinical Features OPDM is characterized by adult-onset ptosis, external ophthalmoplegia, facial muscle weakness, distal limb muscle weakness and atrophy, and pharyngeal involvement, resulting in dysphagia and dysarthria. Some patients manifest with only ptosis without pharyngeal or distal weakness.

Laboratory Features Serum CK levels are normal or only mildly elevated. EMG is myopathic. Muscle biopsies reveal dystrophic features including muscle fibers with rimmed vacuoles. Intramyonuclear inclusions immunostaining with anti-phospho-p62/SQSTM1 antibodies are evident. Similar intranuclear inclusions are found on skin biopsies.

OPDM is a genetically heterogeneous autosomal disorder caused by trinucleotide repeat expansions (CTG) in the 5′ untranslated region (UTR) regions of *LRP12* (OPDM1), *G1PC1* (OPDM2), *NOTCH2NLC* (OPDM3), and *RILPL1* (OPMD4). Notably, the CGG repeat expansion in *NOTCH2NLC* is also the cause of neuronal intranuclear hyaline inclusion disease and other neurodegenerative diseases affecting the brain. These repeat expansion disorders lead to RNA-mediated sequestration of RNA-binding proteins and altered translation of proteins.

TREATMENT

Oculopharyngeal Distal Myopathy

Treatment of dysphagia and ptosis is similar to that noted with OPMD.

DISTAL MYOPATHIES/DYSTROPHIES

The distal myopathies are notable for their preferential distal distribution of muscle weakness in contrast to most muscle conditions associated with proximal weakness. The major distal myopathies are summarized in Tables 460-1, 460-5, and 460-6.

Clinical Features *Welander, Udd*, and *Markesbery-Griggs type distal myopathies* are all late-onset, dominantly inherited disorders of distal limb muscles, usually beginning after age 40 years. Welander distal myopathy preferentially involves the wrist and finger extensors, whereas the others are associated with anterior tibial weakness leading to progressive foot drop. *Laing distal myopathy* is also a dominantly inherited disorder heralded by tibial weakness; however, it is distinguished by onset in childhood or early adult life. GNE myopathy (previously known as *Nonaka distal myopathy* and autosomal recessive hereditary inclusion body myopathy) and *Miyoshi myopathy* are distinguished by autosomal recessive inheritance and onset in the late teens or twenties. GNE and Williams myopathy produce prominent anterior tibial weakness, whereas Miyoshi myopathy is unique in that gastrocnemius muscles are preferentially affected at onset. Finally, the *myofibrillar myopathies* (MFMs) are a clinically and genetically heterogeneous group of muscular dystrophies that can be associated with prominent distal or proximal weakness; they can be inherited in an autosomal dominant or recessive pattern (Table 460-6).

Laboratory Features Serum CK levels are markedly elevated in Miyoshi myopathy, but in the other conditions, serum CK is only slightly increased. EMGs are myopathic and can be irritable with myotonic discharges in MFM. Muscle biopsy shows nonspecific dystrophic features and, with the exception of Laing and Miyoshi myopathies, often shows rimmed vacuoles. MFM is associated with the accumulation of dense inclusions and amorphous material best seen on Gomori trichrome staining along with myofibrillar disruption on electron microscopy. Immune staining sometimes demonstrates accumulation of desmin and other proteins in MFM, large deposits of myosin heavy chain in the subsarcolemmal region of type 1 muscle fibers in Laing myopathy, and reduced or absent dysferlin in Miyoshi myopathy type 1.

TREATMENT

Distal Myopathies

Occupational therapy is offered for loss of hand function; ankle-foot orthoses can support distal lower limb muscles. The MFMs can be associated with cardiomyopathy (congestive heart failure or arrhythmias) and respiratory failure that may require medical management. Laing-type distal myopathy can also be associated with a cardiomyopathy.

MULTISYSTEM PROTEINOPATHIES (MSP)

The multisystem proteinopathies (MSPs) are genetically heterogenous disorders featured by hereditary inclusion body myopathy (IBM), amyotrophic lateral sclerosis, parkinsonism, frontotemporal dementia, and Paget disease of bone. Some forms have also been referred to as IBMPFD for some of the above major clinical features. Patients present in adulthood with progressive proximal or distal weakness. Serum CK is usually mildly elevated. EMG shows features of an irritable myopathy but also neurogenic features as well. Muscle biopsies in patients with myopathy show rimmed vacuoles, inclusions that immunostain with ubiquitin, and TDP-43 extrusion from myonuclei. Most are caused by mutations in genes that encode for RNA-binding proteins or proteins involved in the elimination of other aged proteins. There are at least five types of MSP (Table 460-7).

SPORADIC LATE-ONSET NEMALINE MYOPATHY

Clinical Features Sporadic late onset nemaline myopathy (SLONM) should not be confused with congenital forms of nemaline myopathy, which usually are congenital and/or hereditary in nature. SLONM is not a genetic disorder and usually presents after the age of 40 years with proximal extremity weakness. Some patients may present with an axial myopathy, isolated head drop, or bent spine syndrome from paraspinal muscle weakness. Ventilatory muscle involvement and cardiomyopathy may develop. Additionally, SLONM can complicate HIV infection.

Laboratory Features Serum CK is usually normal or mildly elevated and can be lower than normal. EMG reveals signs of an irritable myopathy. About 50% of cases are associated with a monoclonal gammopathy of undetermined significance (IgG or IgA). Muscle biopsies can reveal inflammatory cell infiltrates, trabeculated or lobulated fibers, many atrophic muscle fibers, and fibers with nemaline rods. The rods are often smaller than ones seen in the hereditary nemaline myopathies and may be missed on routine light microscopy if thickness of the sections is >3 μm. However, the rods are almost always appreciated on electron microscopy, and on immunohistochemistry, the rods are usually immunoreactive to anti-α-actinin antibody.

TREATMENT

SLONM

Some patients with SLONM respond to intravenous immunoglobulin or other immunosuppressive therapies. Autologous stem cell transplantation has been beneficial in some patients with SLONM and a monoclonal gammopathy.

TABLE 460-7 Multisystem Proteinopathies

MULTISYSTEM PROTEINOPATHY	INHERITANCE	GENE	AFFECTED PROTEIN
MSP1 / IBMPFD1	AD	*VCP*	Valosin-containing protein
MSP2 / IBMPFD2	AD	*HNRPA2B1*	HNRPA2B1
MSP3 / IBMPFD3	AD	*HNRNPA1*	HNRNPA1
MSP4	AD	*SQTM1*	Sequestome
MSP5	AD	*MTR3*	Matrin 3

Abbreviations: AD, autosomal dominant; HNRNPA1, heterogeneous nuclear ribonucleoprotein A1; HNRPA2B1, heterogeneous nuclear ribonucleoprotein A2/B1; IBMPFD, inclusion body myopathy, Paget disease, frontotemporal dementia; MSP, multisystem proteinopathy.

DISORDERS OF MUSCLE ENERGY METABOLISM

There are two principal sources of energy for skeletal muscle—fatty acids and glucose. Abnormalities in either glucose or lipid utilization can be associated with distinct clinical presentations that can range from an acute, painful syndrome with rhabdomyolysis and myoglobinuria to a chronic, progressive muscle weakness simulating muscular dystrophy (Table 460-1). As with the muscular dystrophies, there are no specific medical treatments available.

GLYCOGEN STORAGE AND GLYCOLYTIC DEFECTS

Disorders of Glycolysis Causing Exercise Intolerance Several glycolytic defects are associated with recurrent myoglobinuria. The most common is *McArdle disease* caused by mutations in the *PYGM* gene leading to *myophosphorylase deficiency*. Symptoms of muscle pain and stiffness usually begin in adolescence. With severe episodes, myoglobinuria can occur.

Certain features help distinguish some enzyme defects. In McArdle disease, exercise tolerance can be enhanced by a slow induction phase (warm-up) or brief periods of rest, allowing for the start of the "second-wind" phenomenon (switching to utilization of fatty acids). Varying degrees of hemolytic anemia accompany deficiencies of both phosphofructokinase (mild) and phosphoglycerate kinase (severe). In phosphoglycerate kinase deficiency, the usual clinical presentation is a seizure disorder associated with intellectual disability; exercise intolerance is an infrequent manifestation.

In all of these conditions, the serum CK levels fluctuate widely and may be elevated even during symptom-free periods. CK levels >100 times normal are expected accompanying myoglobinuria. A forearm exercise test reveals a blunted rise in venous lactate with a normal rise in ammonia. A definitive diagnosis of glycolytic disease can be made by muscle biopsy with appropriate staining and enzyme assays, but genetic testing is now done in lieu of biopsy in most cases.

Training may enhance exercise tolerance, perhaps by increasing perfusion to muscle. Dietary intake of free glucose or fructose prior to activity may improve function, but care must be taken to avoid obesity from ingesting too many calories.

Disorders of Glycogen Storage Causing Progressive Weakness • α-GLUCOSIDASE, OR ACID MALTASE, DEFICIENCY (POMPE DISEASE) Three clinical forms of α-glucosidase, or acid maltase, deficiency (*type II glycogenosis*) can be distinguished. The infantile form is the most common, with onset of symptoms in the first 3 months of life. Infants develop severe muscle weakness, cardiomegaly, hepatomegaly, and respiratory insufficiency. Glycogen accumulation in motor neurons of the spinal cord and brainstem contributes to muscle weakness. Death usually occurs by 1.5 years of age. In the childhood form, the picture resembles DMD with delayed motor milestones resulting from proximal limb muscle weakness and involvement of respiratory muscles. The heart may be involved, but the liver and brain are unaffected. The adult form usually begins in the third or fourth decade but can present as late as the seventh decade. Ventilatory weakness can be the initial and only manifestation in 20–30% of late-onset cases.

The serum CK level is 2–10 times normal in infantile or childhood-onset Pompe disease but can be normal in adult-onset cases. EMG can demonstrate muscle membrane irritability, particularly in the paraspinal muscles. The muscle biopsy in infants typically reveals vacuoles containing glycogen and the lysosomal enzyme acid phosphatase. Electron microscopy reveals membrane-bound and free tissue glycogen. However, muscle biopsies in late-onset Pompe disease may demonstrate only nonspecific abnormalities. Enzyme analysis of dried blood spots is a sensitive technique to screen for Pompe disease. A definitive diagnosis is established by genetic testing.

Pompe disease is inherited as an autosomal recessive disorder caused by mutations of the α-*glucosidase* gene. Enzyme replacement therapy (ERT) with IV recombinant human α-glucosidase is beneficial in infantile-onset Pompe disease. In late-onset cases, ERT has a more modest benefit.

OTHER GLYCOGEN STORAGE DISEASES WITH PROGRESSIVE WEAKNESS In *debranching enzyme deficiency* (*type III glycogenosis*), a slowly progressive form of muscle weakness can develop after puberty. Rarely, myoglobinuria may be seen. Patients are usually diagnosed in infancy, however, because of hypotonia and delayed motor milestones; hepatomegaly, growth retardation, and hypoglycemia are other manifestations. *Branching enzyme deficiency* (*type IV glycogenosis*) is a rare and fatal glycogen storage disease characterized by failure to thrive and hepatomegaly. Hypotonia and muscle wasting may be present, but the skeletal muscle manifestations are minor compared to liver failure. An autosomal dominant glycogen storage disease was reported in a single family that was due to a mutation in the *PYGM* gene that typically causes autosomal recessive McArdle disease. Affected individuals presented with progressive proximal weakness, no exercise intolerance, normal CK, and a normal lactic acid increase with exercise.

LIPID AS AN ENERGY SOURCE AND ASSOCIATED DEFECTS

Lipid is an important muscle energy source during rest and during prolonged, submaximal exercise. Oxidation of fatty acids occurs in the mitochondria. To enter the mitochondria, a fatty acid must first be converted to an "activated fatty acid," acyl-CoA. The acyl-CoA must be linked with carnitine by the enzyme CPT for transport into the mitochondria.

Carnitine Palmitoyltransferase 2 (CPT2) Deficiency CPT2 deficiency is the most common recognizable cause of recurrent myoglobinuria. Onset is usually in the teenage years or early twenties. Muscle pain and myoglobinuria typically occur after prolonged exercise but can also be precipitated by fasting or infections; up to 20% of patients do not exhibit myoglobinuria, however. Strength is normal between attacks. In contrast to disorders caused by defects in glycolysis, in which muscle cramps follow short, intense bursts of exercise, the muscle pain in CPT2 deficiency does not occur until the limits of utilization have been exceeded and muscle breakdown has already begun.

Serum CK levels and EMG findings are both usually normal between episodes. A normal rise of venous lactate during forearm exercise distinguishes this condition from glycolytic defects. Muscle biopsy does not show lipid accumulation and is usually normal between attacks. The diagnosis requires direct measurement of muscle CPT or genetic testing. Attempts to improve exercise tolerance with frequent meals and a low-fat, high-carbohydrate diet, or by substituting medium-chain triglycerides in the diet, have not proven to be beneficial.

MITOCHONDRIAL MYOPATHIES

Mitochondria play a key role in energy production. Oxidation of the major nutrients derived from carbohydrate, fat, and protein leads to the generation of reducing equivalents. The latter are transported through the respiratory chain in the process known as *oxidative phosphorylation*. The energy generated by the oxidation-reduction reactions of the respiratory chain is stored in an electrochemical gradient coupled to ATP synthesis.

A novel feature of mitochondria is their genetic composition. Each mitochondrion possesses a DNA genome that is distinct from that of the nuclear DNA. Human mitochondrial DNA (mtDNA) consists of a double-strand, circular molecule comprising 16,569 base pairs (bp). It codes for 22 transfer RNAs, 2 ribosomal RNAs, and 13 polypeptides of the respiratory chain enzymes. The genetics of mitochondrial diseases differ from the genetics of chromosomal disorders. The DNA of mitochondria is directly inherited from the cytoplasm of the gametes, mainly from the oocyte. The sperm contributes very little of its mitochondria to the offspring at the time of fertilization. Thus, mitochondrial genes are derived almost exclusively from the mother, accounting for maternal inheritance of some mitochondrial disorders.

Patients with mitochondrial myopathies have clinical manifestations that usually fall into three groups: chronic progressive external ophthalmoplegia (CPEO), skeletal muscle–CNS syndromes, and pure myopathy simulating muscular dystrophy or metabolic myopathy. Unfortunately, no specific medical therapies are clearly beneficial, although coenzyme Q10 supplements are often prescribed.

Kearns-Sayre Syndrome (KSS) This is a widespread multiorgan system disorder with a defined triad of clinical findings: onset before age 20, CPEO, and pigmentary retinopathy, plus one or more of the following features: complete heart block, cerebrospinal fluid (CSF) protein >1 g/L (100 mg/dL), or cerebellar ataxia. The cardiac disease includes syncopal attacks and cardiac arrest related to the abnormalities in the cardiac conduction system: prolonged intraventricular conduction time, bundle branch block, and complete atrioventricular block. Death attributed to heart block occurs in ~20% of the patients. Varying degrees of progressive limb muscle weakness and easy fatigability affect activities of daily living. Many affected individuals have intellectual disabilities. Endocrine abnormalities are also common, including gonadal dysfunction in both sexes with delayed puberty, short stature, and infertility. Diabetes mellitus occurs in ~13% of KSS patients. Other less common endocrine disorders include thyroid disease, hyperaldosteronism, Addison's disease, and hypoparathyroidism.

Serum CK and lactate levels are normal or slightly elevated. Serum levels of fibroblast growth factor 21 (FGF-21) and growth and differentiation factor 15 (GDF-15) are often elevated in mitochondrial disorders with muscle weakness. EMG is often myopathic. NCS may be abnormal related to an associated neuropathy. Muscle biopsies reveal ragged red fibers and cytochrome oxidase (COX)–negative fibers. By electron microscopy, there are increased numbers of mitochondria that often appear enlarged and contain paracrystalline inclusions.

KSS is a sporadic disorder caused by single mtDNA deletions that are presumed to arise spontaneously in the ovum or zygote. The most common deletion, occurring in about one-third of patients, removes 4977 bp of contiguous mtDNA. Monitoring for cardiac conduction defects is critical. Prophylactic pacemaker implantation is indicated when ECGs demonstrate a bifascicular block.

Progressive External Ophthalmoplegia (PEO) PEO can be caused by nuclear DNA mutations affecting mtDNA and thus inherited in a Mendelian fashion or by mutations in mtDNA. Onset is usually after puberty. Fatigue, exercise intolerance, dysphagia, and complaints of muscle weakness are typical. The neurologic examination confirms the ptosis and ophthalmoplegia, usually asymmetric in distribution. Patients do not complain of diplopia. Mild facial, neck flexor, and proximal weakness is typical. Rarely, respiratory muscles may be progressively affected and may be the direct cause of death.

Serum CK and lactate can be normal or mildly elevated. The EMG can be myopathic. Ragged red and COX-negative fibers are prominently displayed in the muscle biopsy.

This autosomal dominant form of CPEO is most commonly caused by mutations in the genes encoding adenine nucleotide translocator 1 (*ANT1*), twinkle gene (*C10orf2*), and mtDNA polymerase 1 (*POLG1*). Autosomal recessive PEO can also be caused by mutations in *POLG1*. Point mutations have been identified within various mitochondrial tRNA (Leu, Ile, Asn, Trp) genes in families with maternal inheritance of PEO.

There is no specific medical treatment available; exercise may improve function, but this will depend on the patient's ability to participate.

Myoclonic Epilepsy with Ragged Red Fibers (MERRF) The onset of MERRF is variable, ranging from late childhood to middle adult life. Characteristic features include myoclonic epilepsy, cerebellar ataxia, and progressive proximal muscle weakness. The seizure disorder is an integral part of the disease and may be the initial symptom. Cerebellar ataxia precedes or accompanies epilepsy. Other more variable features include dementia, peripheral neuropathy, optic atrophy, hearing loss, and diabetes mellitus.

Serum CK levels and lactate may be normal or elevated. EMG is myopathic, and in some patients, NCS show a neuropathy. The electroencephalogram is abnormal, corroborating clinical findings of epilepsy. Typical ragged red fibers are seen on muscle biopsy. MERRF is caused by maternally inherited point mutations of mitochondrial

tRNA genes. The most common mutation found in 80% of MERRF patients is an A to G substitution at nucleotide 8344 of tRNA lysine (A8344G $tRNA^{lys}$). Only supportive treatment is possible, with special attention to epilepsy.

Mitochondrial Myopathy, Encephalopathy, Lactic Acidosis, and Stroke-like Episodes (MELAS) MELAS is the most common mitochondrial encephalomyopathy. The term *stroke-like* is appropriate because the cerebral lesions do not conform to a strictly vascular distribution. The onset in the majority of patients is before age 20. Seizures, usually partial motor or generalized, are common and may represent the first clearly recognizable sign of disease. The cerebral insults that resemble strokes cause hemiparesis, hemianopia, and cortical blindness. A presumptive stroke occurring before age 40 should place this mitochondrial encephalomyopathy high in the differential diagnosis. Associated conditions include hearing loss, diabetes mellitus, hypothalamic pituitary dysfunction causing growth hormone deficiency, hypothyroidism, and absence of secondary sexual characteristics. In its full expression, MELAS leads to dementia, a bedridden state, and a fatal outcome. Serum lactic acid is typically elevated.

The CSF protein is also increased but is usually ≤1 g/L (100 mg/dL). Muscle biopsies show ragged red fibers. Neuroimaging demonstrates basal ganglia calcification in a high percentage of cases. Focal lesions that mimic infarction are present predominantly in the occipital and parietal lobes. Strict vascular territories are not respected, and cerebral angiography fails to demonstrate lesions of the major cerebral blood vessels.

MELAS is usually caused by maternally inherited point mutations of mitochondrial tRNA genes. The A3243G point mutation in $tRNA^{Leu(UUR)}$ is the most common, occurring in ~80% of MELAS cases. No specific treatment is available. Supportive treatment is essential for the stroke-like episodes, seizures, and endocrinopathies.

Mitochondrial DNA Depletion Syndromes Mitochondrial DNA depletion syndrome (MDS) is a heterogeneous group of disorders that are inherited in an autosomal recessive fashion and can present in infancy or in adults. MDS can be caused by mutations in several genes (*TK2*, *DGUOK*, *RRM2B*, *TYMP*, *SUCLA1*, and *SUCLA2*) that lead to depletion of mitochondrial deoxyribonucleotides (dNTP) necessary for mtDNA replication. The other major cause of MDS is a set of mutations in genes essential for mtDNA replication (e.g., *POLG1* and *C10orf2*). The clinical phenotypes associated with MDS vary. Patients may develop a severe encephalopathy (e.g., Leigh's syndrome), PEO, an isolated myopathy, myo-neuro-gastrointestinal encephalopathy (MNGIE), and a sensory neuropathy with ataxia.

DISORDERS OF MUSCLE MEMBRANE EXCITABILITY

Muscle membrane excitability is affected in a group of disorders referred to as *channelopathies*. These disorders usually present with episodic muscle weakness (periodic paralysis) and sometimes myotonia or paramyotonia (Table 460-1).

CALCIUM CHANNEL DISORDERS OF MUSCLE

Hypokalemic Periodic Paralysis (HypoKPP) This is an autosomal dominant disorder with onset in adolescence. Males are more often affected because of decreased penetrance in females. Episodic weakness with onset after age 25 is almost never due to periodic paralyses, with the exception of thyrotoxic periodic paralysis. Attacks are often provoked by meals high in carbohydrates or sodium and may accompany rest following prolonged exercise. Weakness usually affects proximal limb muscles more than distal. Ocular and bulbar muscles are less likely to be affected. Respiratory muscles are usually spared, but when they are involved, the condition may prove fatal. Weakness may take as long as 24 h to resolve. Life-threatening cardiac arrhythmias related to hypokalemia may occur during attacks. As a late complication, patients commonly develop severe, disabling proximal lower extremity weakness.

Attacks of thyrotoxic periodic paralysis resemble those of primary HypoKPP. Despite a higher incidence of thyrotoxicosis in women, men, particularly those of Asian descent, are more likely to manifest this complication. Attacks abate with treatment of the underlying thyroid condition.

A low serum potassium level during an attack, excluding secondary causes, establishes the diagnosis. In the midst of an attack of weakness, motor conduction studies may demonstrate reduced amplitudes, whereas EMG may show electrical silence in severely weak muscles. In between attacks, the EMG and routine NCS are normal. However, a long exercise NCS test may demonstrate decrementing amplitudes.

HypoKPP type 1 is the most common form and is caused by mutations in the voltage-sensitive, skeletal muscle calcium channel gene, *CALCL1A3*. Approximately 10% of cases are HypoKPP type 2, arising from mutations in the voltage-sensitive sodium channel gene (*SCN4A*). In both forms, the mutations lead to an abnormal gating pore current that predisposes the muscle cell to depolarize when potassium levels are low.

TREATMENT

Hypokalemic Periodic Paralysis

Mild attacks usually do not require medical treatment. However, severe attacks of weakness can be improved by the administration of potassium. Oral KCl (0.2–0.4 mmol/kg) can be given every 30 min. Only rarely is IV therapy necessary (e.g., when swallowing problems or vomiting is present). The long-term goal of therapy is to avoid attacks. Patients should be made aware of the importance of a low-carbohydrate, low-sodium diet and consequences of intense exercise. Prophylactic administration of acetazolamide or dichlorphenamide can reduce attacks of periodic weakness. However, in patients with HypoKPP type 2, attacks of weakness can be exacerbated with these medications.

SODIUM CHANNEL DISORDERS OF MUSCLE

Hyperkalemic Periodic Paralysis (HyperKPP) The term *hyperkalemic* is misleading because patients are often normokalemic during attacks. That attacks are precipitated by potassium administration best defines the disease. The onset is usually in the first decade; males and females are affected equally. Attacks are brief and mild, usually lasting 30 min to several hours. Weakness affects proximal muscles, sparing bulbar muscles. Attacks are precipitated by rest following exercise and fasting.

Potassium may be slightly elevated or normal during an attack. As in HypoKPP, NCS in HyperKPP muscle may demonstrate reduced motor amplitudes and the EMG may be silent in very weak muscles. A long exercise NCS test can reveal diminished amplitudes as well. The EMG may demonstrate myotonic discharges. HyperKPP is caused by mutations of the voltage-gated sodium channel *SCN4A* gene. Acetazolamide or dichlorphenamide can reduce the frequency and severity of attacks. Mexiletine may be helpful in patients with significant clinical myotonia.

Paramyotonia Congenita In PC, the attacks of weakness are cold-induced or occur spontaneously and are mild. Myotonia is a prominent feature but worsens with muscle activity (paradoxical myotonia). This is in contrast to classic myotonia in which exercise alleviates the condition. Attacks of weakness are seldom severe enough to require emergency room treatment. Over time, patients develop inter-attack weakness as they do in other forms of periodic paralysis.

Serum CK is usually mildly elevated. Routine NCS are normal. Short exercise NCS tests may be abnormal, however, and cooling of the muscle often dramatically reduces the amplitude of the compound muscle action potentials. EMG reveals diffuse myotonic potentials in

PC. Upon local cooling of the muscle, the myotonic discharges disappear as the patient becomes unable to activate MUAPs.

PC is inherited as an autosomal dominant condition; voltage-gated sodium channel mutations are responsible, and thus, this disorder is allelic with HyperKPP. Mexiletine is reported to be helpful in reducing the myotonia.

POTASSIUM CHANNEL DISORDERS

Andersen-Tawil Syndrome This rare disease is characterized by episodic weakness, cardiac arrhythmias, and dysmorphic features (short stature, scoliosis, clinodactyly, hypertelorism, small or prominent low-set ears, micrognathia, and broad forehead). The cardiac arrhythmias are potentially serious and life threatening. They include long QT, ventricular ectopy, bidirectional ventricular arrhythmias, and tachycardia. The disease is most commonly caused by mutations of the inwardly rectifying potassium channel (*Kir 2.1*) gene that heighten muscle cell excitability. The episodes of weakness may differ between patients because of potassium variability. Acetazolamide may decrease the attack frequency and severity.

CHLORIDE CHANNEL DISORDERS

Two forms of this disorder, autosomal dominant (*Thomsen disease*) and autosomal recessive (*Becker disease*), are both caused by mutations in the chloride channel 1 gene (*CLCN1*). Symptoms are noted in infancy and early childhood. The severity lessens in the third to fourth decade. Myotonia is worsened by cold and improved by activity. The gait may appear slow and labored at first but improves with walking. In Thomsen disease, muscle strength is normal, but in Becker disease, which is usually more severe, there may be muscle weakness. Muscle hypertrophy is usually present. Myotonic discharges are prominently displayed by EMG recordings. Serum CK is normal or mildly elevated. Mexiletine is helpful in relieving the myotonia.

ENDOCRINE AND METABOLIC MYOPATHIES

Endocrinopathies can cause weakness, but fatigue is more common than true weakness. The serum CK level is often normal (except in hypothyroidism), and the muscle histology is characterized by atrophy rather than destruction of muscle fibers. Nearly all endocrine myopathies respond to treatment.

THYROID DISORDERS

Hypothyroidism (Chap. 395) Patients with hypothyroidism have frequent muscle complaints, and about one-third have proximal muscle weakness. Muscle cramps, pain, and stiffness are common. Some patients have enlarged muscles. Features of slow muscle contraction and relaxation occur in 25% of patients; the relaxation phase of muscle stretch reflexes is characteristically prolonged and best observed at the ankle or biceps brachii reflexes. The serum CK level is often elevated (up to 10 times normal). EMG is typically normal. Muscle biopsy shows no distinctive morphologic abnormalities.

Hyperthyroidism (Chap. 396) Patients who are thyrotoxic commonly have proximal muscle weakness, but they rarely complain of myopathic symptoms. Activity of deep tendon reflexes may be enhanced. Fasciculations may be apparent and, when coupled with increased muscle stretch reflexes, may lead to an erroneous diagnosis of amyotrophic lateral sclerosis. A form of hypokalemic periodic paralysis can occur in patients who are thyrotoxic. Mutations in the *KCNJ18* gene that encodes for the inwardly rectifying potassium channel, Kir 2.6, have been discovered in up to a third of cases.

PARATHYROID DISORDERS (SEE ALSO CHAP. 422)

Hyperparathyroidism Proximal muscle weakness, muscle wasting, and brisk muscle stretch reflexes are the main features of this endocrinopathy. Some patients develop neck extensor weakness (part of the dropped head syndrome). Serum CK levels are usually normal or slightly elevated. Serum parathyroid hormone levels are elevated, while vitamin D and calcium levels are usually reduced. Muscle biopsies show only mild type 2 fiber atrophy.

Hypoparathyroidism An overt myopathy due to hypocalcemia rarely occurs. Neuromuscular symptoms are usually related to localized or generalized tetany. Serum CK levels may be increased secondary to muscle damage from sustained tetany. Hyporeflexia or areflexia is usually present and contrasts with the hyperreflexia in hyperparathyroidism.

ADRENAL DISORDERS (SEE ALSO CHAP. 398)

Conditions associated with glucocorticoid excess cause a myopathy; steroid myopathy is the most commonly diagnosed endocrine muscle disease. Proximal muscle weakness combined with a cushingoid appearance are the key clinical features. Serum CK and EMG are normal. Muscle biopsy, not typically done for diagnostic purposes, reveals type 2b muscle fiber atrophy. In primary hyperaldosteronism (*Conn's syndrome*), neuromuscular complications are due to potassium depletion. The clinical picture is one of persistent muscle weakness. Long-standing hyperaldosteronism may lead to proximal limb weakness and wasting. Serum CK levels may be elevated, and a muscle biopsy may demonstrate necrotic fibers. These changes relate to hypokalemia and are not a direct effect of aldosterone on skeletal muscle.

PITUITARY DISORDERS (SEE ALSO CHAP. 392)

Patients with acromegaly usually have mild proximal weakness. Muscles often appear enlarged but exhibit decreased force generation. The duration of acromegaly, rather than the serum growth hormone levels, correlates with the degree of myopathy.

DIABETES MELLITUS (SEE ALSO CHAP. 417)

Neuromuscular complications of diabetes mellitus are most often related to neuropathy. The only notable myopathy is ischemic infarction of leg muscles, usually involving one of the thigh muscles but on occasion affecting the distal leg. This condition occurs in patients with poorly controlled diabetes and presents with the abrupt onset of pain, tenderness, and edema of a thigh or calf. The area of muscle infarction is hard and indurated. The muscles most often affected include the vastus lateralis, thigh adductors, and biceps femoris. Computed tomography (CT) or MRI can demonstrate focal abnormalities in the affected muscle. Diagnosis by imaging is preferable to muscle biopsy, if possible, as hemorrhage into the biopsy site can occur.

MYOPATHIES OF SYSTEMIC ILLNESS

Systemic illnesses such as chronic respiratory, cardiac, or hepatic failure are frequently associated with severe muscle wasting and complaints of weakness. Fatigue is usually a more significant problem than weakness, which is typically mild.

DRUG-INDUCED OR TOXIC MYOPATHIES

The most common toxic myopathies are caused by the cholesterol-lowering agents and glucocorticoids. Others impact practice to a lesser degree but are important to consider in specific situations. **Table 460-8** provides a comprehensive list of drug-induced myopathies with their distinguishing features.

MYOPATHY FROM LIPID-LOWERING AGENTS

All classes of lipid-lowering agents have been implicated in muscle toxicity, including HMG-CoA reductase inhibitors (statins) and, to a much lesser extent, fibrates, niacin, and ezetimibe. Myalgia and elevated CKs are the most common manifestations. Rarely, patients exhibit proximal weakness or myoglobinuria. Concomitant use of statins with fibrates and cyclosporine increases the risk of severe

TABLE 460-8 Drug-Induced Myopathies

DRUGS	MAJOR TOXIC REACTION
Lipid-lowering agents HMG-CoA reductase inhibitors Fibric acid derivatives Niacin (nicotinic acid)	Drugs belonging to all three of the major classes of lipid-lowering agents can produce a spectrum of toxicity: asymptomatic serum creatine kinase elevation, myalgias, exercise-induced pain, rhabdomyolysis, and myoglobinuria.
Glucocorticoids	Acute, high-dose glucocorticoid treatment can cause acute quadriplegic myopathy. These high doses of steroids are often combined with nondepolarizing neuromuscular blocking agents, but the weakness can occur without their use. Chronic steroid administration produces predominantly proximal weakness.
Nondepolarizing neuromuscular blocking agents	Acute quadriplegic myopathy can occur with or without concomitant glucocorticoids.
Zidovudine	Mitochondrial myopathy with ragged red fibers.
Drugs of abuse Alcohol Amphetamines Cocaine Heroin Phencyclidine Meperidine	All drugs in this group can lead to widespread muscle breakdown, rhabdomyolysis, and myoglobinuria. Local injections cause muscle necrosis, skin induration, and limb contractures.
Autoimmune myopathy Statins Checkpoint inhibitors D-Penicillamine	Use of statins may cause an immune-mediated necrotizing myopathy associated with HMG-CoA reductase antibodies. Checkpoint inhibitors can be complicated by myositis, myocarditis, myasthenia gravis, and immune-mediated neuropathies. Myasthenia gravis has also been reported with penicillamine.
Amphophilic cationic drugs Amiodarone Chloroquine Hydroxychloroquine	All amphophilic drugs have the potential to produce painless, proximal weakness associated with necrosis and autophagic vacuoles in the muscle biopsy.
Antimicrotubular drugs Colchicine	This drug produces painless, proximal weakness especially in the setting of renal failure. Muscle biopsy shows necrosis and fibers with autophagic vacuoles.

myotoxicity. EMG demonstrates irritability, and myopathic units and muscle biopsies reveal necrotic muscle fibers in weak muscles. Severe myalgia, weakness, marked elevations in serum CK (>3–5 times baseline), and myoglobinuria are indications for stopping the drug. Patients usually improve with drug cessation, although this may take several weeks. Rare cases continue to progress after the offending agent is discontinued. It is possible that in such cases the statin may have triggered an immune-mediated necrotizing myopathy, as these individuals require immunotherapy (e.g., intravenous immunoglobulin or immunosuppressive agents) to improve and often relapse when these therapies are discontinued **(Chap. 377)**. Autoantibodies directed against HMG-CoA reductase have been identified in many of these cases.

GLUCOCORTICOID-RELATED MYOPATHIES

Glucocorticoid myopathy occurs with chronic treatment or as "acute quadriplegic" myopathy secondary to high-dose IV glucocorticoid use. Chronic administration produces proximal weakness accompanied by cushingoid manifestations, which can be quite debilitating; the chronic use of prednisone at a daily dose of ≥30 mg/d is most often associated with toxicity. Patients taking fluorinated glucocorticoids (triamcinolone, betamethasone, dexamethasone) appear to be at especially high risk for myopathy. In chronic steroid myopathy, the serum CK is usually normal. Serum potassium may be low. The muscle biopsy in chronic cases shows preferential type 2 muscle fiber atrophy; this is not reflected in the EMG, which is usually normal.

Patients receiving high-dose IV glucocorticoids for status asthmaticus, chronic obstructive pulmonary disease, organ transplantation, or other indications may develop severe generalized weakness (critical illness myopathy). This myopathy, also known as acute quadriplegic myopathy, can also occur in the setting of sepsis. Involvement of the diaphragm and intercostal muscles causes ventilatory muscle weakness and is usually appreciated when patients are unable to be weaned off a ventilatory in the intensive care unit. NCS demonstrate reduced compound muscle action potentials in the setting of relatively preserved sensory potentials. EMG can demonstrate abnormal insertional and spontaneous activity and early recruitment of myopathic appearing units in those muscles that can be activated. Muscle biopsy can show a distinctive loss of thick filaments (myosin) by electron microscopy. Treatment is withdrawal of glucocorticoids and physical therapy, but the recovery is slow. Patients require supportive care and rehabilitation.

OTHER DRUG-INDUCED MYOPATHIES

Certain drugs produce painless, largely proximal muscle weakness. These drugs include the amphophilic cationic drugs (amiodarone, chloroquine, hydroxychloroquine) and antimicrotubular drugs (colchicine) (Table 460-6). Muscle biopsy can be useful in the identification of toxicity because autophagic vacuoles are prominent pathologic features of these toxins.

GLOBAL ISSUES

As previously discussed, certain dystrophies have an increased prevalence in different parts of the world. LGMD2A/LGMDR1 is the most common LGMD in individuals from Spain, France, Italy, and Great Britain; LGMD2I/LGMDR9 is more common in those with northern European ancestry. GNE myopathy is the most common form of distal myopathy in Japan but is also prevalent in the Ashkenazi population. OPMD is most common in those with ancestry from Spain and French-Canada as well as among Ashkenazi. Epidemiologic studies are lacking regarding other forms of myopathy and their prevalence in different areas of the world.

Section 4 Syndromes Associated with Chronic Fatigue

461 Myalgic Encephalomyelitis/ Chronic Fatigue Syndrome

Elizabeth R. Unger, Jin-Mann S. Lin, Jeanne Bertolli

Myalgic encephalomyelitis/chronic fatigue syndrome (ME/CFS) is a chronic complex illness with multisystem manifestations and long-term impact on functional impairment comparable to multiple sclerosis, rheumatoid arthritis, and congestive heart failure. The hallmark of ME/CFS is persistent and unexplained fatigue resulting in significant impairment in daily functioning, along with worsening symptoms following physical or mental exertion that would have been tolerated before illness (postexertional malaise). Besides intense fatigue, many patients report concomitant symptoms such as pain, cognitive dysfunction, and unrefreshing sleep. Additional symptoms can include headache, sore throat, tender lymph nodes, muscle aches, joint aches, feverishness, difficulty sleeping, psychiatric problems, allergies, and abdominal cramps. The recognition that ME/CFS is one diagnosable condition in Long COVID has raised clinical awareness about this poorly understood illness, although patients still face stigma and misunderstanding among health care providers.

The condition has been known by many names, and debate about the name and case definition continues. The composite name ME/CFS was adopted by the U.S. Department of Health and Human Services in recognition of the limitations of either ME (absence of definitive inflammation in brain and spinal cord) or CFS (trivializes an often devastating illness through confusion with fatigue that everyone experiences).

EPIDEMIOLOGY

Determining how frequently ME/CFS occurs and characteristics of those affected has been complicated by variability in study design and application of case definitions. In the absence of a simple diagnostic test, evaluation by an experienced clinician is required for case identification. Clinic-based studies most accurately identify patients with ME/CFS but overrepresent higher socioeconomic groups with access to ME/CFS clinics. Population-based studies with or without a clinical evaluation estimated that between 836,000 and 3.3 million Americans have ME/CFS. However, studies indicate that ≥80% of those meeting criteria for ME/CFS had not been diagnosed by a health care provider. The illness costs the U.S. economy between $18 and $51 billion annually in medical costs and lost income. ME/CFS is three to four times more common in women than men. The highest prevalence is among those 40–50 years of age, but the age range is broad and includes children and adolescents. Persons of all races and ethnicities are affected, and there is some evidence that socioeconomically disadvantaged groups are at increased risk.

RISK FACTORS AND PATHOPHYSIOLOGY

A wide variety of infectious agents have been reported to be associated with a postinfectious fatiguing illness resembling ME/CFS. These include both viral and nonviral pathogens, such as Epstein-Barr virus, Ross River virus, *Coxiella burnetti* (Q fever), Ebola virus, SARS-CoV-1, and *Giardia*. While recovery from these infections is the rule, ~10% of those infected remain ill for ≥6 months. Most recently, published reports suggest that SARS-CoV-2 infection is also associated with prolonged fatiguing illness. Host and pathogen factors associated with recovery versus persistent disease remain elusive. In addition to infectious insults,

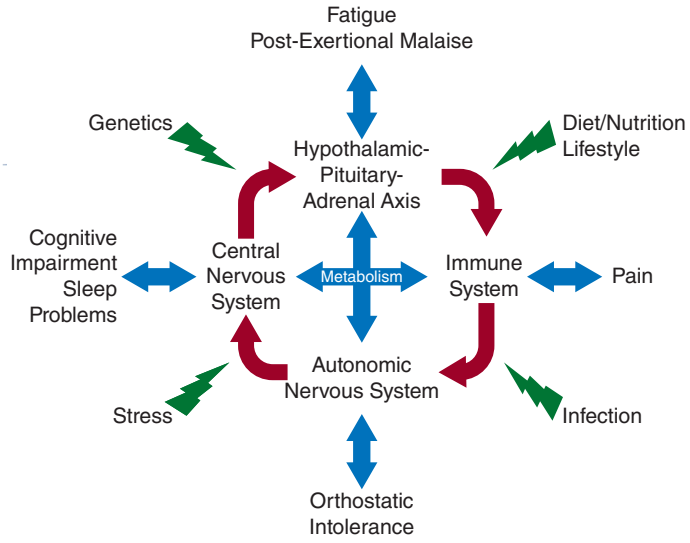

FIGURE 461-1 A multisystem model for myalgic encephalomyelitis/chronic fatigue syndrome (ME/CFS). An example of a unifying model for ME/CFS demonstrating the interactions of multiple organ systems and environmental, genetic, and behavioral factors contributing to symptoms.

a variety of stressors, including toxins, physical trauma, adverse events, and allostatic load (or "wear and tear" on the body), have been found to be associated with ME/CFS. Twin studies and family histories suggest a role for shared environment as well as genetic factors.

Evidence for immunologic dysfunction is inconsistent. Modest elevations in titers of antinuclear antibodies, reductions in immunoglobulin subclasses, deficiencies in mitogen-driven lymphocyte proliferation, reductions in natural killer cell activity, disturbances in cytokine production, and altered T-cell metabolism have been described. None of these immune findings has been firmly established and none of these changes appear in most patients. In theory, symptoms of ME/CFS could result from excessive production of a cytokine, such as interleukin 1 or interferon α, which induces fatigue and other flulike symptoms; however, compelling data in support of this hypothesis are lacking.

Other studies have reported various nonspecific changes in regional brain structures estimated by magnetic resonance imaging; dysfunction of the autonomic nervous system; abnormalities in the hypothalamic-pituitary-adrenal (HPA) axis; altered metabolism; and dysbiosis of the intestinal microbiome. Confirmatory studies are needed, and none of the findings are consistent enough to be used for diagnosis. It is clear that ME/CFS represents a complex disorder with alterations in multiple interrelated homeostatic systems. A variety of unifying models for the illness have been proposed, and discoveries about the pathophysiology of ME/CFS hold promise for elucidating novel mechanisms and interactions important in other illnesses (Fig. 461-1).

APPROACH TO THE PATIENT

Myalgic Encephalomyelitis/Chronic Fatigue Syndrome

DIAGNOSIS

A diagnosis of ME/CFS is made based on patient-reported symptoms that fit a characteristic profile. After a careful review of the literature and symptom-based case definitions for ME, CFS, or ME/CFS, the Institute of Medicine (IOM) committee recommended in 2015 straightforward diagnostic criteria (Table 461-1). This includes the symptoms consistently noted in prior consensus case definitions: fatigue limiting the patient's ability to participate in their usual pre-illness activities, sleep problems, and postexertional malaise (PEM). PEM is a relapse in symptoms triggered by physical, emotional, or mental exertion that would not have been problematic for the patient before onset of ME/CFS. The relapse lasts more than a day and sometimes weeks. In addition, either difficulty

TABLE 461-1 2015 Institute of Medicine Diagnostic Criteria for Myalgic Encephalomyelitis/Chronic Fatigue Syndrome

Substantial reduction or impairment in the ability to engage in pre-illness levels of activity (occupational, educational, social, or personal life) that: • lasts for >6 months • is accompanied by fatigue that is often profound, of new or definite onset (not lifelong), not the result of ongoing excessive exertion, and is not substantially alleviated by rest
Postexertional malaise (PEM)[a]—worsening of symptoms after physical, mental, or emotional exertion that would not have caused a problem before the illness
Unrefreshing sleep[a]
Cognitive impairment or **orthostatic intolerance**[a]

[a]Frequency and severity of symptoms should be assessed; should be present at least half of the time and with at least moderate intensity.

thinking and concentrating (often referred to by patients as "brain fog") or orthostatic intolerance should be present.

Patients with ME/CFS may experience a wide range of other symptoms not specified in the IOM diagnostic criteria **(Table 461-2)**. As a result, patients meeting ME/CFS criteria could have very different clinical features based on the type, frequency, and severity of their symptoms. Patients may describe a precipitating cause for their illness, such as a known or presumed infection, but frequently no initiating factor is recognized. The symptoms may occur suddenly within a day or week or may occur gradually.

While the diagnostic criteria specifies that illness must be present at least 6 months, the possibility of ME/CFS should be considered for patients with consistent symptoms persisting >1 month, and evaluation and supportive care can begin as early as 4–6 weeks after onset. Listening to patients' descriptions of what they are experiencing is important. Asking questions can help patients accurately describe their experience with fatigue and PEM. These include asking about current activity levels compared with before they became ill, what happens when they are as active as they were pre-illness, and how long it takes to recover after exertion. Whereas patients recognize relapses, the relation of relapse to activity level may not be apparent, and as a result, PEM may not be recognized. Patients may also appear well during an office visit, only to relapse afterward from exertion surrounding the consultation.

Although the 2015 IOM ME/CFS criteria do not list medical or psychological conditions that exclude the diagnosis of ME/CFS, a careful clinical evaluation is required to identify and treat other illnesses that could explain or contribute to the patient's symptoms. The initial evaluation also requires reviewing family history, medical history (including infections, traumas/surgeries, and occupational exposure to environmental toxins), and medications and supplements; performing a physical examination, including lean test for postural orthostatic tachycardia syndrome (POTS; **Chap. 451**); a mental health assessment (screen for depression and anxiety); and routine screening laboratory tests (if recent results are not on record). As routine laboratory tests are usually within normal limits, their role is in identifying other illnesses, and the specific panel of tests should be adjusted based on the patient's presentation. Typically the tests include complete blood count, erythrocyte sedimentation rate, electrolytes, fasting glucose, renal function tests (blood urea nitrogen, glomerular filtration rate), calcium, phosphate, liver function (bilirubin, alanine aminotransferase, alkaline phosphatase, aspartate aminotransferase, gamma-glutamyl transferase, total protein, albumin/globulin ratio), C-reactive protein, thyroid function (thyroid-stimulating hormone, free thyroxine), iron studies to assess both iron overload and iron deficiency (serum iron, transferrin saturation, ferritin), celiac disease screening tests, and urinalysis.

DIFFERENTIAL DIAGNOSIS AND COMORBID CONDITIONS

While the differential diagnosis for fatigue is quite broad **(Chap. 25)**, further workups and referrals should be chosen carefully based on the patient's history, symptoms (particularly those that are new, worsening, or unusual), and results of initial laboratory tests. Conditions reported to occur in association with ME/CFS **(Table 461-3)** should be kept in mind during the evaluation and follow-up, as management and treatment modalities for these comorbidities could contribute to an improved quality of life.

MANAGEMENT

While there are no approved drugs to treat or cure ME/CFS, patients benefit from receiving a diagnosis and an individualized plan that addresses the symptoms that are most problematic for the patient. Some symptoms, in particular, disturbed sleep **(Chap. 33)** and pain **(Chap. 14)**, may improve with nonpharmacologic therapies (e.g., sleep hygiene, massage, acupuncture, hot or cold packs) or medications. Any medications should be started at lower doses than usual and only slowly increased. Patients with ME/CFS have been reported to be more sensitive to medications than the general population, and benefits with fewer toxicities may be achieved at lower doses. Narcotics should be avoided, and referral to sleep centers or other specialists may be required.

Controlled therapeutic trials have not established significant benefit for patients with ME/CFS from acyclovir, fludrocortisone, galantamine, modafinil, and IV immunoglobulin, among other agents. These studies have been limited by small numbers and lack power to investigate benefit in patient subgroups. Preliminary small studies reported the possible effectiveness of the B-cell-targeting anti-CD20 monoclonal antibody rituximab in ME/CFS, but a subsequent large, well-designed, prospective, double-blind study found no benefit. Numerous anecdotes circulate regarding other traditional and nontraditional therapies. It is important to guide patients away from therapeutic modalities that are toxic, expensive, or unreasonable.

Educating the patient and family about PEM can be helpful in avoiding the harmful cycle of overexertion during "good days" followed by relapse that can negate any functional gains. This is often referred to as "push and crash." Recognizing limits and using activity management (pacing) can help limit PEM. It is important to maintain tolerated activity levels to minimize deconditioning. Activity may be advanced very gradually as tolerated.

TABLE 461-2 Additional Symptoms Experienced by Patients with Myalgic Encephalomyelitis/Chronic Fatigue Syndrome

Joint pain without swelling or redness
Muscle aches
New headaches
Tender lymph nodes
Sensitivity to sensory stimuli (e.g., light, noise, smells)
Sore throat
Shortness of breath
Irregular heartbeat
Alcohol intolerance
Difficulties with temperature regulation (feeling feverish or chilled)

TABLE 461-3 Myalgic Encephalomyelitis/Chronic Fatigue Syndrome Comorbid Conditions

Chronic overlapping pain conditions: fibromyalgia (FM), chronic migraine, temporomandibular joint disease (TMJ), irritable bowel syndrome (IBS), endometriosis, vulvodynia, urologic chronic pelvic pain syndromes (UCPPS)
Postural orthostatic tachycardia syndrome (POTS)
Allergies
Sjögren's syndrome
Ehlers-Danlos syndrome
Mast cell activation syndrome (MCAS)
Dysautonomia
Multiple chemical sensitivities

Counseling may help patients and their families cope with the long-term consequences of living with a chronic illness. Consultation with a physical or occupational therapist may identify energy-saving strategies for activities of daily living as well as needed accommodations, such as a wheelchair for activities that require walking longer distances or prolonged standing.

COURSE AND PROGNOSIS

The illness severity varies from mild or moderate, with patients retaining varying degrees of pre-illness function, to severe, with patients essentially homebound. Most patients experience some improvement and stabilize, although return to their prior level of function is unusual. A continued decline in function should prompt evaluation for other illnesses. Patients should be re-evaluated at scheduled intervals to adjust treatments and detect any intercurrent disease. New or changing symptoms should be worked up to identify any new illnesses. Given the social isolation and loss of hope associated with a debilitating chronic illness, serious depression and an increased risk of suicide are reported for patients with ME/CFS. Clinicians should be prepared to screen for this and refer patients as needed.

Section 5 Psychiatric and Addiction Disorders

462 Biology of Psychiatric Disorders

Robert O. Messing, Eric J. Nestler, Matthew W. State

Psychiatric disorders are central nervous system diseases characterized by disturbances in emotion, cognition, motivation, and socialization. They are highly heritable, with genetic risk comprising 20–90% of disease vulnerability depending on the syndrome. As a result of their prevalence, early onset, and persistence, they contribute substantially to the burden of illness worldwide. All psychiatric disorders are broad heterogeneous syndromes that currently lack well-defined neuropathology and bona fide biologic markers. Therefore, diagnoses continue to be made solely from clinical observations using criteria in the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition *(DSM-5)*, of the American Psychiatric Association **(see Chap. 463)**.

There is increasing agreement that the classification of psychiatric illnesses in the *DSM* does not accurately reflect their underlying biology. Uncertainties in diagnosis complicate efforts to study the genetic basis and attendant neurobiological mechanisms underlying mental illness, though recent technologic advances along with the consolidation of very large patient cohorts have, for multiple disorders, led to significant progress in these realms. In addition, there have been efforts to address the limitations of a categorical nosology directly through the development of an alternative diagnostic scheme, termed Research Domain Criteria (RDoC). This system classifies mental illness on the basis of core behavioral abnormalities shared across several syndromes—such as psychosis (loss of reality) or anhedonia (decreased ability to experience pleasure)—and the associated brain circuitry that controls these behavioral domains. Such classifications may assist in defining the biologic basis of key symptoms. Other factors that have impeded progress in understanding mental illness include the lack of access to pathologic brain tissue except upon death and inherent limitations of animal models for disorders defined largely by behavioral abnormalities (e.g., hallucinations, delusions, guilt, suicidality) that are inaccessible in animals.

Despite these limitations, the past decade has been marked by real progress. Neuroimaging methods are beginning to provide evidence of brain pathology; genome-wide association studies and high-throughput sequencing are reliably identifying genes and genomic loci that confer risk for severe forms of mental illness; and investigations of better-validated animal models, leveraging a host of new methods to study molecular, cellular, and circuit-level processes, are offering new insight into disease pathogenesis. There is also excitement in the utility of neurons, glia, and brain organoids induced in vitro from patient-derived pluripotent stem cells, providing novel ways to study disease pathophysiology and screen for new treatments. There is consequently justified optimism that the field of psychiatry will better integrate behaviorally defined syndromes with an understanding of biological substrates in a way that will drive the development of improved treatments and eventually cures and preventive measures. This chapter describes several examples of recent discoveries in basic neuroscience and genetics that have informed our current understanding of disease mechanisms in psychiatry.

NEUROGENETICS

Because the human brain can only be examined indirectly during life, genome analyses have been extremely important for obtaining molecular clues about the pathogenesis of psychiatric disorders. Moreover, the identification of germline risk alleles and mutations provides potential traction on the question of cause versus effect. In other types of cross-sectional studies, it may be impossible to determine whether a phenotype or biomarker observed in affected humans or model systems reflects an etiologic factor or a compensatory response. In contrast, germline genetic risk is present before the brain develops—at least theoretically allowing for experiments to address temporal sequencing.

A wealth of new information has been made possible by two decades of advances subsequent to the sequencing of the human genome. These have enabled affordable, very large-scale genome-wide association and high-throughput sequencing studies. A striking example of the impact of these developments has been progress in the genetics of autism spectrum disorders (ASDs), a phenotypically heterogeneous neurodevelopmental syndrome characterized by impaired social communication and restricted, repetitive patterns of behavior. ASDs are highly heritable. Concordance rates in monozygotic twins range from 60–90%, a four- to sixfold increase compared to dizygotic twins and siblings. ASDs are also highly genetically heterogeneous and, like many psychiatric conditions, are mainly inherited in a polygenic fashion,

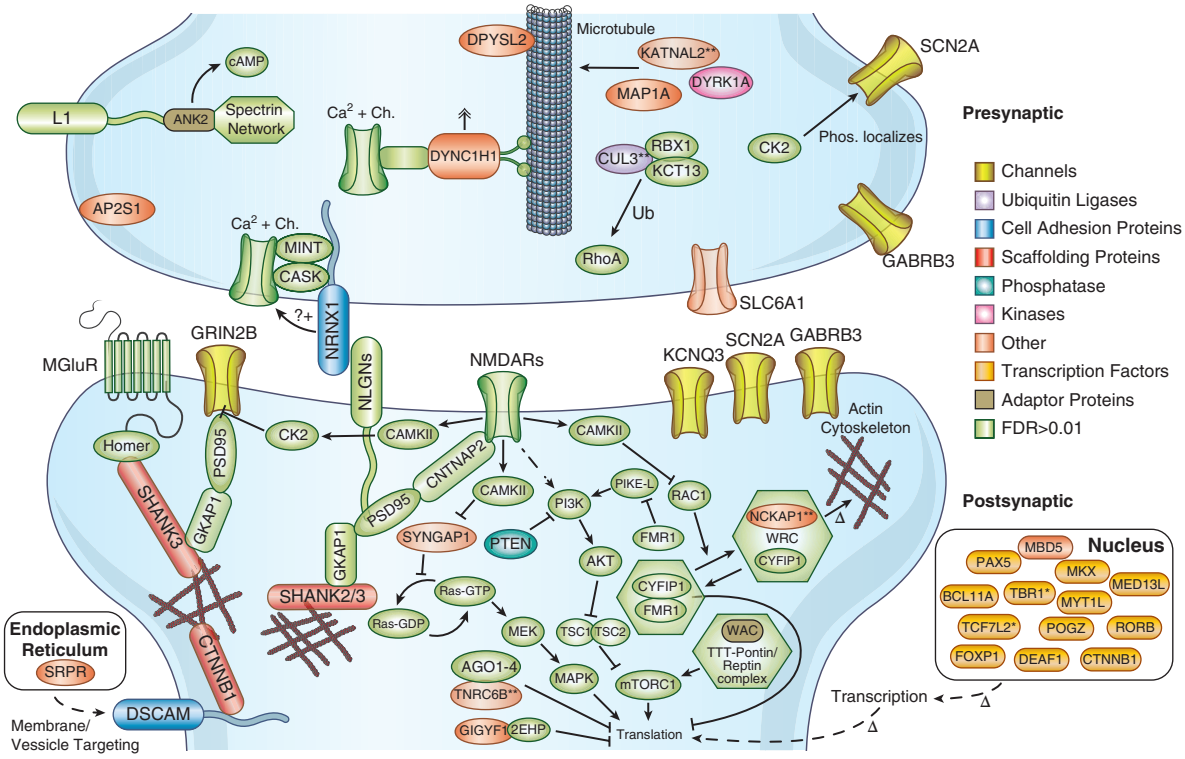
conferred by a conspiracy of alleles that are common in the population and carry small individual effects. Indeed, the increments of increased risk for any common ASD risk allele are so modest that studies of tens of thousands of individuals have identified only a handful of associations meeting gold-standard genome-wide statistical thresholds. However, with increasingly large cohorts and an associated increase in statistical power, the number of identified risk loci is destined to continue to grow.

At the same time, the development of next-generation DNA sequencing has identified a substantial minority of ASD patients who carry rare, often spontaneous (de novo), heterozygous, protein-damaging mutations. This latter group has served as a powerful resource for the identification of specific ASD risk genes of very large effect **(Fig. 462-1)**. To date, about 70–250 ASD genes have been identified by high-throughput sequencing analyses based on false discovery rates ranging from <0.001 to <0.1, respectively. In addition, approximately 10% of ASD-affected individuals carry rare, typically de novo, submicroscopic gains or losses of chromosomal material, known as copy number variations (CNVs), that also confer very large risks. All told, these mutations in individual genes or gene-rich genomic regions account for ~20–30% of cases of ASD seen in clinic, although none individually account for >1%. Importantly, as gene discovery in ASD has progressed, considerable overlap, both phenotypically and genetically, has been found among ASD, epilepsy, and well-established intellectual disability syndromes. For example, individuals with *fragile X syndrome* or *tuberous sclerosis* **(Chap. 95)** show elevated rates of ASD, and mutations in the causal genes may be found in patients who present with otherwise idiopathic ASD.

The discovery of very large-effect ASD risk genes that are vulnerable to protein-damaging mutations has provided important opportunities to delve into pathologic mechanisms. From the earliest successes in gene discovery, several common biological themes have emerged. For instance, many of the identified pathogenic rare mutations are in genes that encode proteins involved in synaptic structure or function or in transcriptional and chromatin regulation (Fig. 462-1). More recently, studies of high-confidence ASD risk mutations in model systems have confirmed these predictions and pointed to neurogenesis and neuronal migration as additional shared pathological mechanisms. Moreover, the availability of increasingly comprehensive maps of human brain gene expression has enabled studies of when and where ASD risk genes converge. These transcriptomic studies have repeatedly pointed to glutamatergic neurons in the mid-fetal human cortex (Fig. 462-1) as one of several regions and cell types enriched for ASD genetic vulnerability. Given that many autism risk genes are biologically pleiotropic—that is, they serve multiple different functions—the identification of anatomic and temporal dimensions of risk should help narrow in on pathophysiologic mechanisms and potential therapeutic targets. Moreover, as the number of large-effect ASD risk genes grows and the scale of transcriptomic, epigenomic, and proteomic mapping of human brain development expands, points of pathogenic convergence promise to be identifiable at single-cell resolution.

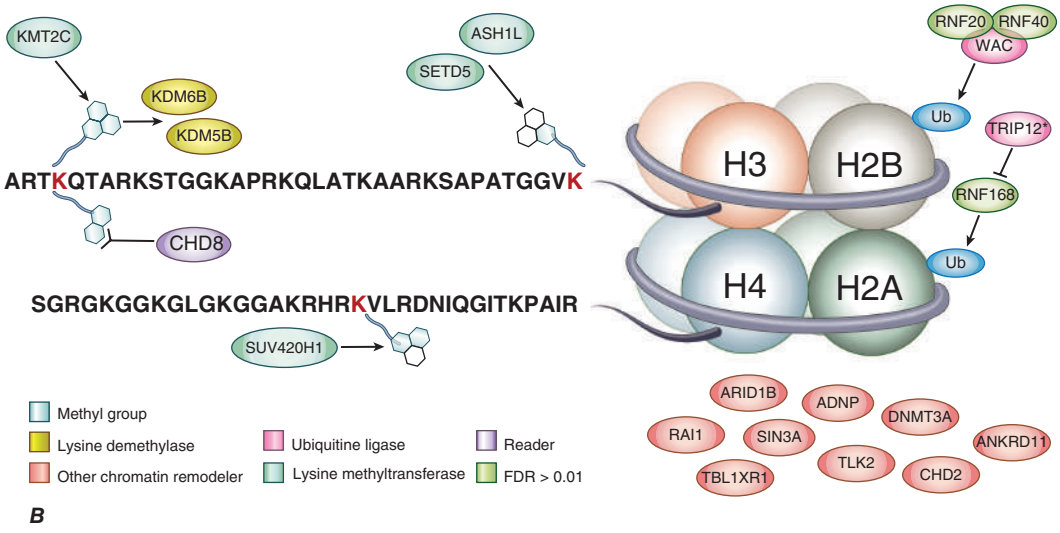
A deeper understanding of disease pathogenesis and the identification of genetic subtypes is ultimately aimed at developing more effective, rational, and personalized therapies, particularly for those who are most severely affected. In this regard, in humans, increasing attention has turned to nucleic acid targeting to treat severe phenotypes in cases in which a highly penetrant coding mutation is present, for example, with CRISPR-based therapies or the use of antisense oligonucleotides (ASOs). Remarkable success with very early intervention in spinal muscular atrophy using these strategies has piqued interest in their utility in a range of brain-based conditions. Currently, among neurodevelopmental disorders, these approaches are being actively pursued for well-known intellectual disability syndromes that may also manifest core features of or elevated risk for ASD, such as Angelman syndrome and SHANK3 deletion/Phelan-McDermid syndrome. If successful, such efforts would be transformational, and potentially not only for the individuals carrying mutations that may be amenable to nucleic acid–targeting approaches.

The ability to catalog common genetic variants and assay them on array-based platforms and carry out whole exome sequencing has also allowed investigators to leverage large patient cohorts to reliably detect risk loci for schizophrenia and bipolar disorder. In contrast to ASD, where the lion's share of early success resulted from the study of rare, large-effect, de novo mutations, much of gene discovery for these syndromes has resulted from genome-wide association studies of common inherited polymorphisms. To date, several hundred distinct genomic regions, marked by associated single nucleotide polymorphisms, have been identified in schizophrenia, some of which show risk as well for bipolar disorder. Several identified genes are parts of molecular complexes, such as voltage-gated calcium channels (in particular, *CACNA1C* and *CACNB2*) and the postsynaptic density of excitatory synapses. Notably, as the scale of high-throughput sequencing studies has expanded, rare large-effect mutations have also been identified in schizophrenia. To date, 10 high-confidence genes have been identified.



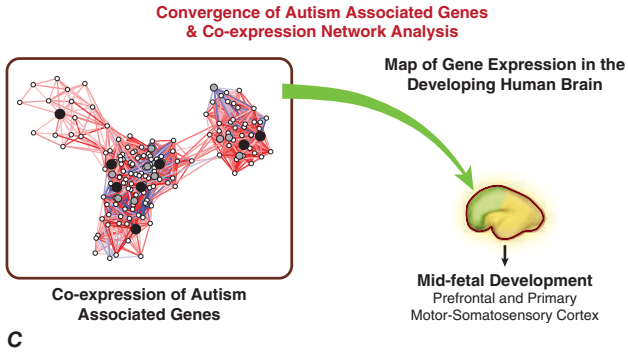
Genes that promote risk for addiction and depression have also begun to emerge from large studies. One susceptibility locus for addiction is the *CHRNA5-A3-B4* nicotinic acetylcholine receptor gene cluster on chromosome 15 associated with nicotine and alcohol addiction. Genome-wide association studies of depression and addiction have required hundreds of thousands of cases and controls to identify the first statistically significant loci using state-of-the-art approaches. For example, a meta-analysis of >1 million individuals was able to identify 110 unique genetic variants associated with problematic alcohol use. Such findings collectively point to the tremendous heterogeneity of these disorders as well as the very small biological effects conferred by any individual common allele.

A recurrent theme in genetic studies of psychiatric disorders is phenotypic pleiotropy, namely, that individual risk genes may be associated with multiple psychiatric and neurodevelopmental syndromes. For example, functionally identical heterozygous deletions of the gene *NRXN1* are associated with ASD, schizophrenia, intellection disability, epilepsy, and other neurodevelopmental phenotypes. Common polymorphisms in *CACNA1C* are associated with both schizophrenia and bipolar disorder. Rare mutations in this same gene may lead to severe neurodevelopmental syndromes and congenital heart disease, including Timothy syndrome, which may include autistic features. Likewise, there is striking overlap among the phenotypes associated with large-effect CNVs, including ASD, schizophrenia, and bipolar disorder, as well as epilepsy and intellectual disability. For example, duplication of chromosome 16p is associated with both schizophrenia and autism, whereas deletions in the DiGeorge's (velocardiofacial) syndrome region are associated with schizophrenia, autism, and bipolar disorder. These findings attest to the complexity of psychiatric disorders, the very large gap between molecular mechanisms and the current categorical diagnostic schemes, and the influence of additional factors that combine to specify the ultimate phenotype. The latter might include polygenic "background," stochastic events, epigenetic effects, and environmental factors. This pleiotropy of consequences for a given genetic mutation in psychiatry is akin to the pleiotropy seen for neurodegenerative disorders as well as for many cancer-causing mutations, where the same mutation can lead to very different disorders across the population.



SIGNAL TRANSDUCTION

Studies of signal transduction disturbances in psychiatric disorders have provided insight into development of new therapeutic agents. For example, lithium is a highly effective drug for bipolar disorder and competes with magnesium to inhibit numerous magnesium-dependent enzymes, including GSK3β and several enzymes involved in phosphoinositide signaling that lead to activation of protein kinase C. These findings have led to discovery programs focused on developing GSK3β or protein kinase C inhibitors as potential novel treatments for mood disorders, although none have demonstrated clinical efficacy to date.



The observations that tricyclic antidepressants (e.g., imipramine) inhibit serotonin and/or norepinephrine reuptake and that monoamine oxidase inhibitors (e.g., tranylcypromine) are effective antidepressants initially led to the view that depression is caused by a deficiency of these monoamines. However, this hypothesis has not

FIGURE 462-1 Functional characteristics and developmental convergence of autism spectrum disorder (ASD) associated genes. A representative selection of genes associated with ASD based on recurrent rare coding mutations is shown in ***A*** and ***B***. Those genes encoding proteins with a false discovery rate (FDR) <0.01 in Sanders et al, *Neuron* 2015, and Satterstrom et al, *Cell* 2020, are highlighted with respect to their putative functions. Genes meeting the highest confidence criteria in Sanders et al 2015 and showing either an FDR >0.01 or an FDR >0.3 in Satterstrom are noted (* and **, respectively). Additional interacting and functionally related molecules that do not meet the above criteria are shown in *green*. *FMR1*, *TSC1*, and *TSC2* are syndromic ASD genes included in the figure (***A***). Multiple gene ontology analyses of ASD genes have highlighted both pre- and postsynaptic molecules (***A***) and chromatin modifiers (***B***) as points of enrichment. In ***C***, an alternative strategy for grouping ASD risk genes is highlighted (Willsey et al, *Cell* 2013), based on their spatiotemporal expression patterns as opposed to putative functions. One analytic strategy, illustrated in ***C***, leveraged only high-confidence ASD genes and examined their developmental expression patterns using the BrainSpan data set. Convergence for ASD risk was identified in deep layer (V and VI) excitatory neurons in mid-fetal human cortex. Multiple analyses have similarly found glutamatergic neurons in mid-fetal prefrontal cortex as one point of convergence, with somewhat less agreement on layer specificity and potential additional spatiotemporal points of convergence.

been substantiated. A cardinal feature of these drugs is that long-term (weeks to months) administration is needed for their antidepressant effects. This means that their short-term actions, namely promotion of serotonin or norepinephrine function, are not per se antidepressant but rather induce a cascade of adaptations in the brain that underlie their slowly developing clinical effects. The nature of these therapeutic drug-induced adaptations has not been identified with certainty. A subset of depressed patients display upregulation of the hypothalamic-pituitary-adrenal (HPA) axis characterized by increased secretion of corticotropin-releasing factor (CRF) and glucocorticoids. One hypothesis posits that in these patients excessive glucocorticoids cause atrophy of hippocampal neurons, which is associated with reduced hippocampal volumes seen clinically. Chronic antidepressant administration might reverse this atrophy by increasing brain-derived neurotrophic factor (BDNF) or a host of other neurotrophic factors in the hippocampus. A role for stress-induced decreases in the generation of newly born hippocampal granule cell neurons, and its reversal by antidepressants through BDNF or other growth factors, has also been suggested.

A major advance in recent years has been the identification of several rapidly acting antidepressants with non–monoamine-based mechanisms of action. The best established is ketamine, a noncompetitive antagonist of *N*-methyl-D-aspartate (NMDA) glutamate receptors among other actions, which exerts rapid (hours) and robust antidepressant effects in severely depressed patients who have not responded to other treatments. Ketamine, which at higher doses is psychotomimetic and anesthetic, exerts these antidepressant effects at lower doses with minimal side effects. However, the response to ketamine is transient, which has led to several approaches to maintain treatment response, such as repeated ketamine delivery. The mechanism underlying ketamine's antidepressant action is not known, and its action as an NMDA receptor antagonist has recently been called into question. Nevertheless, ketamine's striking clinical efficacy has stimulated animal research on the role of glutamate neurotransmission and synaptic plasticity in key limbic regions. Recent evidence supports a role for TORC1 or BDNF activation, as blockade of either blocks the antidepressant-like effects of ketamine in animal models. Mechanisms by which ketamine activates these signaling cascades are currently an active area of investigation.

Another area of great interest is the potential clinical utility of psychedelic drugs and 3,4-methylenedioxy-methamphetamine (MDMA or ecstasy). Psychedelic drugs are thought to act as partial agonists of serotonin 5-HT_{2A} receptors, whereas MDMA promotes serotonin release from nerve terminals. Both are being studied for treatment of depression and posttraumatic stress disorder, although much additional clinical research is needed to establish their efficacy, safety, and mechanism of action.

A major goal in the field of substance use disorders has been to identify neuroadaptive mechanisms that lead from recreational use to addiction. Such research has determined that repeated intake of abused drugs induces specific changes in cellular signal transduction, leading to changes in synaptic strength (long-term potentiation or depression) and neuronal structure (altered dendritic branching or cell soma size) within the brain's reward circuitry. These drug-induced modifications are mediated in part by changes in gene expression, achieved by regulation of transcription factors (e.g., CREB [cAMP response element-binding protein] and ΔFOSB [a FOS family protein]) and their target genes. Such alterations in gene expression are associated with lasting alterations in epigenetic modifications, including histone acetylation and methylation and DNA methylation. These adaptations provide opportunities for developing treatments targeted to drug-addicted individuals. The fact that the spectrum of these adaptations differs in part depending on the particular addictive substance used raises hope that treatments could be developed that are specific for different classes of addictive drugs and less likely to disturb basic mechanisms that govern normal motivation and reward.

Increasingly, causal relationships are being established between individual molecular and cellular adaptations and specific behavioral abnormalities that characterize the addicted state. For example, acute activation of μ-opioid receptors by morphine or other opioids activates

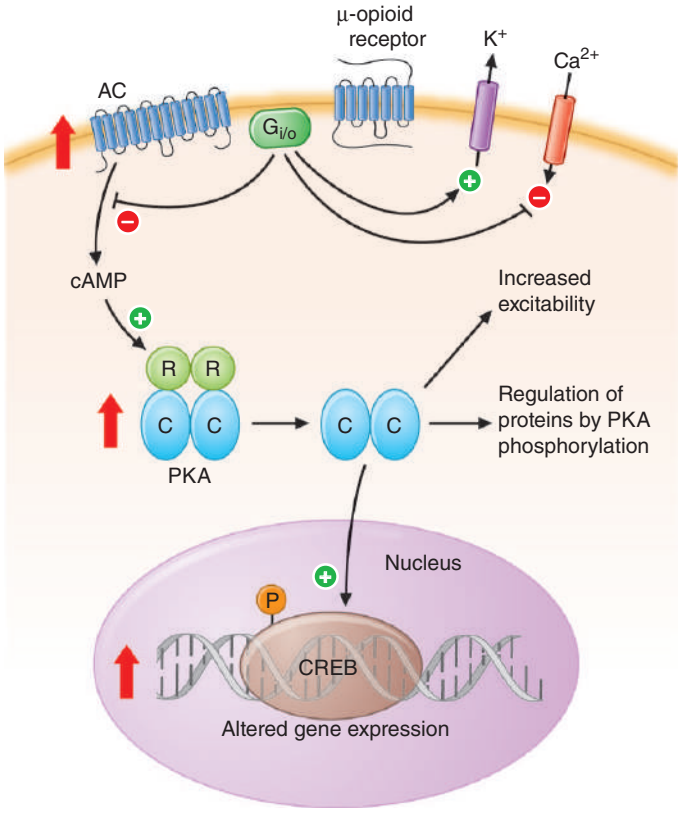

FIGURE 462-2 Opioid action in the locus coeruleus (LC). Binding of opioid agonists to μ-opioid receptors on LC neurons catalyzes nucleotide exchange on G_i and G_o proteins, leading to inhibition of adenylyl cyclase (AC), neuronal hyperpolarization via activation of K^+ channels, and perhaps inhibition of Ca^{2+} channels. Inhibition of AC reduces protein kinase A (PKA) activity and phosphorylation of several PKA substrate proteins, thereby altering their function. For example, opioids reduce phosphorylation of the cAMP response element-binding protein (CREB), which initiates longer term changes in neuronal function. Chronic administration of opioids increases levels of AC isoforms, PKA catalytic (C) and regulatory (R) subunits, and the phosphorylation of several proteins, including CREB (indicated by *red arrows*). These changes contribute to the altered phenotype of the drug-addicted state. For example, the excitability of LC neurons is increased by enhanced cAMP signaling. Activation of CREB causes upregulation of AC isoforms and tyrosine hydroxylase, the rate-limiting enzyme in catecholamine biosynthesis.

$G_{i/o}$ proteins, leading to inhibition of adenylyl cyclase (AC), resulting in reduced cyclic AMP (cAMP) production, protein kinase A (PKA) activation, and activation of the transcription factor CREB. Repeated administration of these drugs **(Fig. 462-2)** evokes a homeostatic response involving upregulation of ACs and PKA and increased activation of CREB. Such upregulation of cAMP-CREB signaling has been identified in the locus coeruleus (LC), periaqueductal gray, ventral tegmental area (VTA), nucleus accumbens (NAc), and several other central nervous system (CNS) regions and contributes to opioid craving and signs of opioid withdrawal. The fact that endogenous opioid peptides do not produce tolerance and dependence, while morphine and related drugs do, may relate to the observation that, unlike endogenous opioids, morphine and like drugs are weak inducers of μ-opioid receptor desensitization and endocytosis. Therefore, these drugs cause prolonged receptor activation and inhibition of ACs, which provides a powerful stimulus for the upregulation of cAMP-CREB signaling that characterizes the opioid-dependent state.

SYSTEMS NEUROSCIENCE

The study of interconnected brain circuits that drive behavior has been greatly advanced through newer methods in brain imaging that have documented abnormalities in neural function and connectivity in psychiatric disorders. Electroceutical devices, which use electrical or magnetic stimulation to control neuronal activity, have had some success in depression, obsessive-compulsive disorder, pain, and addiction. The past decade has also witnessed the development of revolutionary new

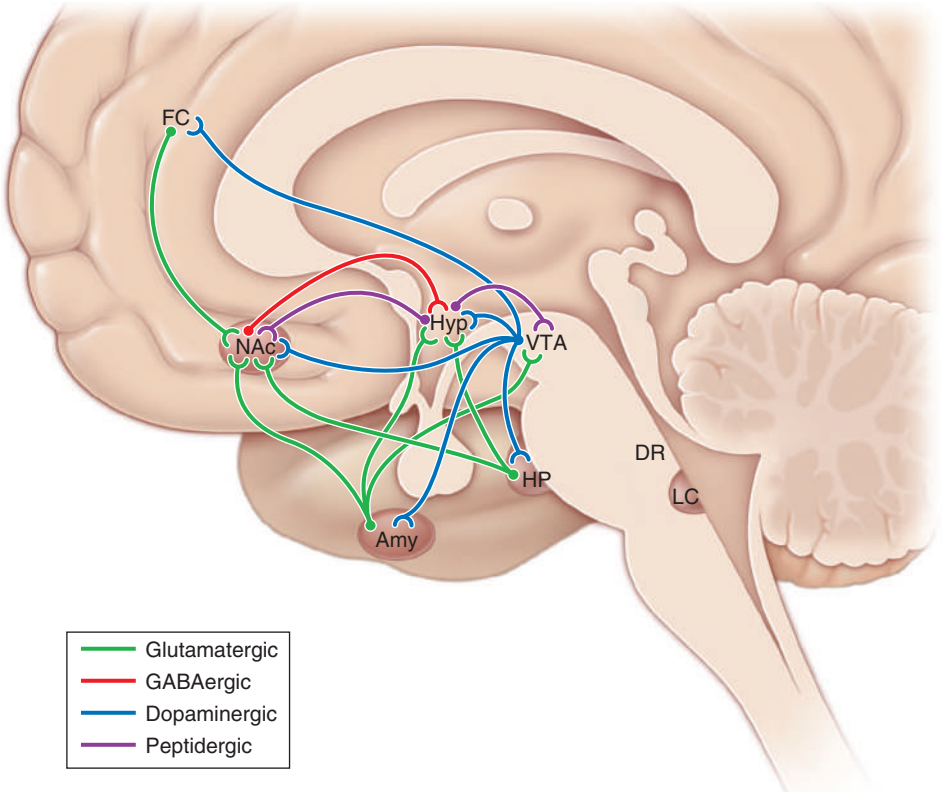

FIGURE 462-3 Neural circuitry of depression and addiction. The figure shows a simplified summary of a series of limbic circuits in the brain that regulate mood and motivation and are implicated in depression and addiction. Shown in the figure are the hippocampus (HP) and amygdala (Amy) in the temporal lobe, regions of prefrontal cortex, nucleus accumbens (NAc), and hypothalamus (Hyp). Only a subset of the known interconnections among these brain regions is shown. Also shown is the innervation of several of these brain regions by monoaminergic neurons. The ventral tegmental area (VTA) provides dopaminergic input to each of the limbic structures. Norepinephrine (from the locus coeruleus [LC]) and serotonin (from the dorsal raphe [DR] and other raphe nuclei) innervate all of the regions shown. In addition, there are strong connections between the hypothalamus and the VTA-NAc pathway. Important peptidergic projections from the hypothalamus include those from the arcuate nucleus that release β-endorphin and melanocortin and from the lateral hypothalamus that release orexin.

techniques—optogenetics, designer receptors, and ligands—that provide unprecedented temporal and spatial control of neural circuits. The development of genetically encoded calcium detectors and of high-density electrode arrays has allowed in vivo monitoring of thousands of neurons in multiple brain regions simultaneously. Advances in histology and microscopy now permit three-dimensional imaging of specific proteins in the intact brain, while advances in endoscopic microscopy allow imaging of hundreds of neurons within deep brain structures in awake, freely moving animals. Together with recent advances in machine learning and artificial intelligence for analysis of large complex datasets, these new methods are revolutionizing our ability to understand the circuit basis of brain function.

Positron emission tomography (PET), diffusion tensor imaging (DTI), and functional magnetic resonance imaging (fMRI) have identified neural circuits that contribute to psychiatric disorders, for example, defining the neural circuitry of mood within the brain's limbic system **(Fig. 462-3)**. Integral to this system are the NAc (important also for brain reward—see below), amygdala, hippocampus, and regions of prefrontal cortex. Recent optogenetic research in animals, where the activity of specific types of neurons in defined circuits can be controlled with light, has confirmed the importance of this limbic circuitry in controlling depression-related behavioral abnormalities. Given that many symptoms of depression (so-called neurovegetative symptoms) involve physiologic functions, a key role for the hypothalamus is presumed as well. A subset of depressed individuals shows a small reduction in hippocampal size, as noted above. In addition, brain imaging investigations have revealed increased activation of the amygdala by negative stimuli and reduced activation of the NAc by rewarding stimuli. There is also evidence for altered activity in prefrontal cortex, such as hyperactivity of subgenual area 25 in anterior cingulate cortex. Such findings have led to trials of deep brain stimulation (DBS) of either the NAc or subgenual area 25 **(see Fig. 32-1)**, which appears to be therapeutic in some severely depressed individuals.

In schizophrenia, structural and functional imaging studies have confirmed earlier pathologic studies that show enlargement of the ventricular system and reduction of cortical and subcortical gray matter in frontal and temporal lobes and in the limbic system. Functional imaging studies show reduced metabolic (presumably neural) activity in the dorsolateral prefrontal cortex at rest and when performing tests of executive function, including working memory. There is also evidence for impaired structural and task-related functional connectivity, mainly in frontal and temporal lobes. The reduction in cortical thickness seen in schizophrenia is associated with increased cell packing density and reduced neuropil (defined as axons, dendrites, and glial cell processes) without an apparent change in neuronal cell number. Specific classes of interneurons in prefrontal cortex consistently show reduced expression of the gene encoding the enzyme glutamic acid decarboxylase 1 (*GAD1*), which synthesizes γ-aminobutyric acid (GABA), the principal inhibitory neurotransmitter in the brain. Recently, results from well-powered genome-wide association studies point to synaptic pruning, including the involvement of microglia, as a potential contributing mechanism. In the region of the genome most strongly associated with schizophrenia risk, variations in the relative expression of two isotypes of complement component 4, C4A and C4B, have been found to account for a significant proportion of this genetic signal. Studies of loss of C4 in mice show deficient synaptic pruning, leading to the hypothesis that increased expression of C4A in humans may result in excessive synaptic pruning. Such results point to the potential for a gene-driven understanding of pathophysiology; however, the findings also leave some important questions unanswered. The strongest effect haplotype in humans still only accounts for a very small increase in risk, with an odds ratio of <1.3. In contrast, having a sibling with schizophrenia increases risk approximately tenfold. In short, whether this allele reflects a driving pathophysiologic mechanism remains to be determined. Moreover, humans have diverged at the C4 locus compared with rodents such that only a single C4 isotype is present in the mouse, preventing any analysis of the putative effects of changing the ratio of C4A to C4B—the phenomenon associated with disease risk in humans. Nonetheless, all the aforementioned findings support the notion that schizophrenia is a developmental neurodegenerative disorder with some evidence pointing to loss of cortical interneurons in frontal and temporal lobes.

Work in rodent and nonhuman primate models of addiction has established the brain's reward regions as key neural substrates for the acute actions of drugs of abuse and for addiction induced in vulnerable individuals by repeated drug administration (Fig. 462-3). Midbrain dopamine neurons in the VTA function normally as rheostats of reward: they are activated by natural rewards (food, sex, social interaction) or even by the expectation of such rewards, and many are suppressed by the absence of an expected reward or by aversive

TABLE 462-1 Initial Actions of Drugs of Abuse

DRUG	NEUROTRANSMITTER AFFECTED	DRUG TARGET (ACTION)
Opioids	Endorphins, enkephalins	μ- and δ-opioid receptors (agonist)
Psychostimulants (cocaine, amphetamine, methamphetamine)	Dopamine	Dopamine transporter (antagonist—cocaine; reverse transport—amphetamine, methamphetamine)
Nicotine	Acetylcholine	Nicotinic cholinergic receptors (agonist)
Ethanol	GABA	$GABA_A$ receptors (positive allosteric modulator)
	Glutamate	NMDA glutamate receptors (antagonist)
	Acetylcholine	Nicotinic cholinergic receptors (allosteric modulator)
	Serotonin	$5\text{-}HT_3$ receptor (positive allosteric modulator)
	Others	Calcium-activated K^+ channel (activator)
Marijuana	Endocannabinoids (anandamide, 2-arachidonoylglycerol)	CB_1 receptor (agonist)
Phencyclidine	Glutamate	NMDA glutamate receptor (antagonist)

Abbreviations: GABA, γ-aminobutyric acid; NMDA, *N*-methyl-D-aspartate.

stimuli. These neurons thereby transmit crucial survival signals to the rest of the limbic brain to promote reward-related behavior, including motor responses to seek and obtain the rewards (NAc), memories of reward-related cues and contexts (amygdala, hippocampus), and executive control of obtaining rewards (prefrontal cortex).

Drugs of abuse alter neurotransmission through initial actions at different classes of ion channels, neurotransmitter receptors, or neurotransmitter transporters **(Table 462-1)**. Studies in animal models have demonstrated that although the initial targets differ, the actions of these drugs converge on the brain's reward circuitry by promoting dopamine neurotransmission in the NAc and other limbic targets of the VTA. In addition, some drugs promote activation of opioid and cannabinoid receptors, which modulate this reward circuitry. By these mechanisms, drugs of abuse produce powerful rewarding signals, which, after repeated drug administration, corrupt a vulnerable brain's reward circuitry in ways that promote addiction. Three major pathologic adaptations have been described. First, drugs produce tolerance in reward circuits and increased activity in limbic stress circuits, which promote escalating drug intake and a negative emotional state during drug withdrawal that promotes relapse. Second, sensitization to the rewarding effects of the drugs and associated cues is seen during prolonged abstinence and also triggers relapse. Third, executive function is impaired in such a way as to increase impulsivity and compulsivity, both of which promote relapse.

Imaging studies in humans confirm that addictive drugs, as well as craving for them, activate the brain's reward circuitry. In addition, patients who abuse alcohol or psychostimulants show reduced gray matter in the prefrontal cortex as well as reduced activity in anterior cingulate and orbitofrontal cortex during tasks of attention and inhibitory control. It is thought that damage to these cortical areas contributes to addiction by impairing decision-making and increasing impulsivity.

NEUROINFLAMMATION

There is increasing evidence for the involvement of nonneuronal cell types and inflammatory mechanisms in a wide range of psychiatric syndromes. For example, a subset of depressed patients displays elevated blood levels of interleukin 6 (IL-6), tumor necrosis factor α (TNF-α), and other proinflammatory cytokines. Moreover, rodents exposed to chronic stress exhibit similar increases in peripheral levels of these cytokines, and peripheral or central delivery of those cytokines to normal rodents increases their susceptibility to chronic stress. These findings have led to the novel idea of using peripheral cytokines as biomarkers of a subtype of depression and the potential utility of developing new antidepressants that oppose the actions of specific cytokines.

Recent evidence has also linked proinflammatory signaling in the brain to addiction, particularly to alcohol. Alcohol use disorder is associated with impaired innate immunity, increases in circulating proinflammatory cytokines, and increases in brain expression of several immune-related genes. Many of these genes are expressed by astrocytes and microglia and by neurons under certain pathologic conditions, where they play important roles in modifying neuronal function and plasticity. For example, cytokine monocyte chemotactic protein-1 (MCP-1) modulates the release of certain neurotransmitters and, when administered into the VTA, increases neuronal excitability, promotes dopamine release, and increases locomotor activity. Gene expression studies of alcohol drinking in mice have identified a network of regulated neuroimmune proteins in brain, and a role in regulation of alcohol consumption has been validated for several, including chemokines MCP-1 and chemokine (C-C motif) ligand 3 (CCL3), beta-2 microglobulin, CD14, IL-1 receptor antagonist, toll-like receptors 3 (TLR3) and 7 (TLR7), and cathepsins S and F. This work has led to discovery of anti-inflammatory medications that reduce alcohol intake in animals, such as antagonists of phosphodiesterase 4, which regulates cAMP availability, or agonists of peroxisome proliferator-activated receptors (PPARs), which are transcription factors that repress key inflammatory signaling molecules such as nuclear factor-κB (NF-κB) and nuclear factor of activated T cells (NFAT). A major focus of current research is to define the sites and mechanisms by which proinflammatory cytokines impair brain function to elicit a depressive episode or promote drug abuse, including a role for astrocytes and microglia.

CONCLUSIONS

This brief narrative illustrates the substantial progress that is being made in understanding the genetic and neurobiological basis of mental illness. It is anticipated that biologic measures will be used increasingly to more accurately diagnose and subtype psychiatric disorders and that targeted therapeutics will become available for these complex conditions.

463 Psychiatric Disorders

Victor I. Reus

Psychiatric disorders are common in medical practice and may present either as a primary disorder or as a comorbid condition. The prevalence of mental or substance use disorders in the United States is ~30%, but only one-third of affected individuals are currently receiving treatment. Global burden of disease statistics indicates that 4 of the 10 most important causes of morbidity and attendant health care costs worldwide are psychiatric in origin.

Changes in health care delivery underscore the need for primary care physicians to assume responsibility for the initial diagnosis and treatment of the most common mental disorders. Prompt diagnosis is essential to ensure that patients have access to appropriate medical services and to maximize the clinical outcome. Validated patient-based questionnaires have been developed that systematically probe for signs and symptoms associated with the most prevalent psychiatric diagnoses and guide the clinician into targeted assessment. The Primary Care Evaluation of Mental Disorders (PRIME-MD; and a self-report form, the Patient Health Questionnaire) and the Symptom-Driven Diagnostic System for Primary Care (SDDS-PC) are inventories that require only 10 min to complete and link patient responses to the formal diagnostic criteria of anxiety, mood, somatoform, and eating disorders and to alcohol abuse or dependence. A variety of smart phone apps for assessment and monitoring of psychiatric conditions and for psychological and pharmacologic treatment interventions are also available.

A physician who refers patients to a psychiatrist should know not only when doing so is appropriate but also how to refer because societal misconceptions and the stigma of mental illness impede the process. Primary care physicians should base referrals to a psychiatrist on the presence of signs and symptoms of a mental disorder and not simply on the absence of a physical explanation for a patient's complaint. The physician should discuss with the patient the reasons for requesting the referral or consultation and provide reassurance that they will continue to provide medical care and work collaboratively with the mental health professional. Consultation with a psychiatrist or transfer of care is appropriate when physicians encounter evidence of psychotic symptoms, mania, severe depression, or anxiety; symptoms of posttraumatic stress disorder (PTSD); suicidal or homicidal preoccupation; or a failure to respond to first-order treatment. This chapter reviews the clinical assessment and treatment of some of the most common mental disorders presenting in primary care and is based on the *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, Text Revision (DSM-5-TR), the framework for categorizing psychiatric illness used in the United States. **Eating disorders are discussed later in this chapter, and the biology of psychiatric and addictive disorders is discussed in Chap. 462.**

GLOBAL CONSIDERATIONS

The DSM-5-TR and the tenth revision of the International Classification of Diseases (ICD-10-CM), which is used more commonly worldwide, have taken somewhat differing approaches to the diagnosis of mental illness, but considerable effort has been expended to provide an operational translation between the two nosologies. Both systems are in essence purely descriptive and emphasize clinical pragmatism, in distinction to the Research Domain Criteria (RDOC) proposed by the National Institute of Mental Health, which aspires to provide a causal framework for classification of behavioral disturbance. More recently, an alternative approach, based on a hierarchy of dimensions generated by factor analytic techniques, HiTOP (Hierarchical Taxonomy of Psychopathology) has been put forward as a possible improvement over DSM-5-TR for clinical usage, although it too lacks validity and is prone to diagnostic error. None of these diagnostic systems has as yet achieved adequate validation, and large-scale genetic investigations have revealed that differing psychiatric disorders overlap in their genetic risk variants and phenotypic symptoms. The Global Burden of Disease Study (2019), using available epidemiologic data, nevertheless has reinforced the conclusion that, regardless of nosologic differences, mental and substance abuse disorders are the major cause of life-years lost to disability among all medical illnesses, affecting >300 million individuals worldwide. There is general agreement that high-income countries will need to build capacity in professional training in low- and middle-income countries in order to provide an adequate balanced care model for the delivery of evidence-based therapies for mental disorders. Recent surveys that indicate a dramatic increase in mental disorder prevalence in rapidly developing countries, such as China, may reflect both an increased recognition of the issue and also the consequence of social turmoil, stigma, and historically inadequate resources. A salient example of the ways in which societal disruption and isolation may contribute to exacerbating already unmet mental health needs can be seen in the COVID-19 pandemic, which resulted in an increased incidence of diagnosed psychiatric disorders in both affected and unaffected individuals, as well as caregivers. The need for improved prevention strategies and for more definitive and effective interventional treatments remains a global concern.

ANXIETY DISORDERS

Anxiety disorders, the most prevalent psychiatric illnesses in the general community, are present in 15–20% of medical clinic patients. Anxiety, defined as a subjective sense of unease, dread, or foreboding, can indicate a primary psychiatric condition or can be a component of, or reaction to, a primary medical disease. The primary anxiety disorders are classified according to their duration and course and the existence and nature of precipitants.

When evaluating the anxious patient, the clinician must first determine whether the anxiety antedates or postdates a medical illness or is due to a medication side effect. Approximately one-third of patients presenting with anxiety have a medical etiology for their psychiatric symptoms, but an anxiety disorder can also present with somatic symptoms in the absence of a diagnosable medical condition.

PANIC DISORDER

Clinical Manifestations Panic disorder is defined by the presence of recurrent and unpredictable panic attacks, which are distinct episodes of intense fear and discomfort associated with a variety of physical symptoms, including palpitations, sweating, trembling, shortness of breath, chest pain, dizziness, and a fear of impending doom or death. Paresthesias, gastrointestinal distress, and feelings of unreality are also common. Diagnostic criteria require at least 1 month of concern or worry about the attacks or a change in behavior related to them. The lifetime prevalence of panic disorder is 2–3%. Panic attacks have a sudden onset, developing within 10 min and usually resolving over the course of an hour, and can occur in an unexpected fashion, such as when waking from sleep. The frequency and severity of panic attacks vary, ranging from once a week to clusters of attacks separated by months of well-being. The first attack is usually outside the home, and onset is typically in late adolescence to early adulthood. In some individuals, anticipatory anxiety develops over time and results in a generalized fear and a progressive avoidance of places or situations in which a panic attack might recur. *Agoraphobia*, which occurs commonly in patients with panic disorder, is an acquired irrational fear of being in places where one might feel trapped or unable to escape. It may, however, be diagnosed even if panic disorder is not present. Typically, it leads the patient into a progressive restriction in lifestyle and, in a literal sense, in geography. Frequently, patients are embarrassed that they are housebound and dependent on the company of others to go out into the world and do not volunteer this information; thus, physicians will fail to recognize the syndrome if direct questioning is not pursued.

Differential Diagnosis A diagnosis of panic disorder is made after a medical etiology for the panic attacks has been ruled out. A variety of cardiovascular, respiratory, endocrine, and neurologic conditions can present with anxiety as the chief complaint. Patients with true panic disorder will often focus on one specific feature to the exclusion

of others. For example, 20% of patients who present with syncope as a primary medical complaint have a primary diagnosis of a mood, anxiety, or substance abuse disorder, the most common being panic disorder. The differential diagnosis of panic disorder is complicated by a high rate of comorbidity with other psychiatric conditions, especially alcohol and benzodiazepine abuse, which patients initially use in an attempt at self-medication. Some 75% of panic disorder patients will also satisfy criteria for major depression at some point in their illness.

When the history is nonspecific, physical examination and focused laboratory testing must be used to rule out anxiety states resulting from medical disorders such as pheochromocytoma, thyrotoxicosis, or hypoglycemia. Electrocardiogram (ECG) and echocardiogram may detect some cardiovascular conditions associated with panic, such as paroxysmal atrial tachycardia and mitral valve prolapse. In two studies, panic disorder was the primary diagnosis in 43% of patients with chest pain who had normal coronary angiograms and was present in 9% of all outpatients referred for cardiac evaluation. Panic disorder has also been diagnosed in many patients referred for pulmonary function testing or with symptoms of irritable bowel syndrome.

Etiology and Pathophysiology The etiology of panic disorder is unknown but appears to involve a genetic predisposition, altered autonomic responsivity, and social learning. Panic disorder shows familial aggregation; the disorder is concordant in 30–45% of monozygotic twins, and genome-wide screens have identified suggestive risk loci. Acute panic attacks appear to be associated with increased noradrenergic discharges in the locus coeruleus. Intravenous infusion of sodium lactate evokes an attack in two-thirds of panic disorder patients, as do the α_2-adrenergic antagonist yohimbine, cholecystokinin tetrapeptide (CCK-4), and carbon dioxide inhalation. It is hypothesized that each of these stimuli activates a pathway involving noradrenergic neurons in the locus coeruleus and serotonergic neurons in the dorsal raphe. Resting-state functional magnetic resonance imaging (fMRI) has identified abnormalities in the default mode network involving the medial temporal lobe, with greater activation in the sensorimotor cortex in panic disorder and in amygdala-frontal connectivity in social anxiety disorder.

TREATMENT

Panic Disorder

Patients with panic disorder have a heightened sensitivity to somatic symptoms, which triggers increasing arousal, setting off the panic attack; accordingly, therapeutic intervention involves altering the patient's cognitive interpretation of anxiety-producing experiences, as well as preventing the attack itself.

Achievable goals of treatment are to decrease the frequency of panic attacks and to reduce their intensity. The cornerstone of drug therapy is antidepressant medication **(Tables 463-1 through 463-3)**. Selective serotonin reuptake inhibitors (SSRIs) benefit the majority of panic disorder patients and do not have the adverse effects of tricyclic antidepressants (TCAs). Fluoxetine, paroxetine, sertraline, and the selective serotonin-norepinephrine reuptake inhibitor (SNRI) venlafaxine have received approval from the U.S. Food and Drug Administration (FDA) for this indication. These drugs should be started at one-third to one-half of their usual antidepressant dose (e.g., 5–10 mg fluoxetine, 25–50 mg sertraline, 10 mg paroxetine, venlafaxine 37.5 mg). Monoamine oxidase inhibitors (MAOIs) are also effective and may specifically benefit patients who have comorbid features of atypical depression (i.e., hypersomnia and weight gain). Insomnia, orthostatic hypotension, and the need to maintain a low-tyramine diet (avoidance of cheese and wine) have limited their use, however. Antidepressants typically take 2–6 weeks to become effective, and doses may need to be adjusted based on the clinical response.

Because of anticipatory anxiety and the need for immediate relief of panic symptoms, benzodiazepines are useful early in the course of treatment and sporadically thereafter **(Table 463-4)**. FDA-approved agents include alprazolam and clonazepam. A recent Cochrane review found no difference between antidepressants and benzodiazepines in response rate, with desipramine and alprazolam ranked highest in achieving remission and clonazepam and alprazolam in reducing frequency of panic attacks. In treatment-resistant cases, short-term augmentation with aripiprazole, divalproex sodium, or pindolol has some evidence for efficacy. There also is no clear difference in short-term efficacy between psychological therapies and antidepressant or benzodiazepine treatment, alone or in combination.

Early psychotherapeutic intervention and education aimed at symptom control enhance the effectiveness of drug treatment. Patients can be taught breathing techniques, be educated about physiologic changes that occur with panic, and learn to expose themselves voluntarily to precipitating events in a treatment program spanning 12–15 sessions. Homework assignments and monitored compliance are important components of successful treatment. Once patients have achieved a satisfactory response, drug treatment should be maintained for 1–2 years to prevent relapse. Controlled trials indicate a success rate of 75–85%, although the likelihood of complete remission is somewhat lower.

GENERALIZED ANXIETY DISORDER

Clinical Manifestations Patients with generalized anxiety disorder (GAD) have persistent, excessive, and/or unrealistic worry associated with muscle tension, impaired concentration, autonomic arousal, feeling "on edge" or restless, and insomnia **(Table 463-5)**. Onset is usually before age 20 years, and a history of childhood fears and social inhibition may be present. The lifetime prevalence of GAD is 5–6%; the risk is higher in first-degree relatives of patients with the diagnosis. Interestingly, family studies indicate that GAD and panic disorder segregate independently. More than 80% of patients with GAD also suffer from major depression, dysthymia, or social phobia. Comorbid substance abuse is common in these patients, particularly alcohol and/or sedative/hypnotic abuse. Patients with GAD worry excessively over minor matters, with life-disrupting effects; unlike panic disorder, complaints of shortness of breath, palpitations, and tachycardia are relatively rare.

Etiology and Pathophysiology Most anxiogenic and anxiolytic agents act on the γ-aminobutyric acid $(GABA)_A$ receptor/chloride ion channel complex, implicating this neurotransmitter system in pathogenesis. Benzodiazepines are thought to bind two separate $GABA_A$ receptor sites: type I, which has a broad neuroanatomic distribution, and type II, which is concentrated in the hippocampus, striatum, and neocortex. The antianxiety effects of the various benzodiazepines are influenced by their relative binding to alpha 2 and 3 subunits of the $GABA_A$ receptor, and sedation and memory impairment to the alpha 1 subunit. Serotonin (5-hydroxytryptamine [5-HT]) and 3α-reduced neuroactive steroids (allosteric modulators of $GABA_A$) also appear to have a role in anxiety, and buspirone, a partial $5\text{-}HT_{1A}$ receptor agonist, and certain $5\text{-}HT_{2A}$ and $5\text{-}HT_{2C}$ receptor antagonists (e.g., mirtazapine and nefazodone) may have beneficial effects.

TREATMENT

Generalized Anxiety Disorder

A combination of pharmacologic and psychotherapeutic interventions is most effective in GAD, but complete symptomatic relief is rare. A short course of a benzodiazepine is usually indicated, preferably lorazepam, oxazepam, clonazepam, or alprazolam, although only the last two are FDA approved. (The first two of these agents are metabolized via conjugation rather than oxidation and thus do not accumulate if hepatic function is impaired; the latter also has limited active metabolites.) Treatment should be initiated at the lowest dose possible and prescribed on an as-needed basis as symptoms warrant. Benzodiazepines differ in their milligram per kilogram potency, half-life, lipid solubility, metabolic pathways, and presence of active metabolites. Agents that are absorbed rapidly and

TABLE 463-1 Antidepressants

NAME	USUAL DAILY DOSE (mg)	SIDE EFFECTS	COMMENTS
SSRIs			
Fluoxetine (Prozac)	10–80	Headache; nausea and other GI effects; jitteriness; insomnia; sexual dysfunction; can affect plasma levels of other medicines (except sertraline); akathisia rare	Once-daily dosing, usually in the morning; fluoxetine has very long half-life; must not be combined with MAOIs
Sertraline (Zoloft)	50–200		
Paroxetine (Paxil)	20–60		
Fluvoxamine (Luvox)	100–300		
Citalopram (Celexa)	20–60		
Escitalopram (Lexapro)	10–30		
TCAs and Tetracyclics			
Amitriptyline (Elavil)	150–300	Anticholinergic (dry mouth, tachycardia, constipation, urinary retention, blurred vision); sweating; tremor; postural hypotension; cardiac conduction delay; sedation; weight gain	Once-daily dosing, usually qhs; blood levels of most TCAs available; can be lethal in overdose (lethal dose = 2 g); nortriptyline best tolerated, especially by elderly
Nortriptyline (Pamelor)	50–200		
Imipramine (Tofranil)	150–300		
Desipramine (Norpramin)	150–300		
Doxepin (Sinequan)	150–300	Nausea, anxiety, dry mouth	FDA-approved for OCD
Clomipramine (Anafranil)	150–300		
Maprotiline (Ludiomil)	25–150		
Protriptyline (Vivactil)	15–40		
Trimipramine (Surmontil)	75–200	Drowsiness, constipation, dry mouth	tid or qid dosing required
Amoxapine (Asendin)	100–300		Lethality in OD, EPS possible
Mixed Serotonin-Norepinephrine Reuptake Inhibitors (SNRI) and Receptor Blockers			
Venlafaxine (Effexor), XR	75–375	Nausea; dizziness; dry mouth; headaches; increased blood pressure; anxiety and insomnia	bid–tid dosing (extended-release available); lower potential for drug interactions than SSRIs; contraindicated with MAOIs
Desvenlafaxine (Pristiq)	50–400	Nausea, dizziness, insomnia	Primary metabolite of venlafaxine; no increased efficacy with higher dosing
Duloxetine (Cymbalta)	40–60	Nausea, dizziness, headache, insomnia, constipation	May have utility in treatment of neuropathic pain and stress incontinence
Mirtazapine (Remeron)	15–45	Somnolence, weight gain; neutropenia rare	Once-a-day dosing; 5-HT_3 antagonist
Vilazodone (Viibryd)	40	Nausea, diarrhea, headache; dosage adjustment if given with CYP3A4 inhibitor/stimulator	Also 5-HT_{1A} receptor partial agonist
Vortioxetine (Trintellix)	5–20	Nausea, diarrhea, sweating, headache; low incidence of sedation or weight gain	No specific p450 effects; 5-HT_{3A} and 5-HT_7 receptor antagonist, 5-HT_{1B} partial agonist, and 5-HT_{1A} agonist
Levomilnacipran (Fetzima)	40–120	Nausea, constipation, sweating; rare increase in blood pressure/pulse	Most noradrenergic of SNRIs
Mixed-Action Drugs			
Bupropion (Wellbutrin), CR, XR	250–450	Jitteriness; flushing; seizures in at-risk patients; anorexia; tachycardia; psychosis	tid dosing, but sustained-release also available; fewer sexual side effects than SSRIs or TCAs; may be useful for adult ADD
Trazodone (Desyrel)	200–600	Sedation; dry mouth; ventricular irritability; postural hypotension; priapism rare	Useful in low doses for sleep because of sedating effects with no anticholinergic side effects
Trazodone extended-release (Oleptro)	150–375	Daytime somnolence, dizziness, nausea	
Nefazodone	300–600	Headache, nausea, dizziness	Rare risk of liver failure, priapism
Gepirone extended-release (Exxua)	18.2–72.6	Dizziness, nausea, insomnia	Partial agonist/5-HT_{1A}; 5-HT_{2A} antagonist
Esketamine (Spravato)	56–84 1–2 times a week	Sedation, dissociation, respiratory depression	Ketamine isomer for treatment-resistant depression and/or suicidal risk
Zuranolone (Zurzuvae)	50 qhs for 14 days	Somnolence, confusion, dizziness	Oral neuroactive steroid for postpartum depression
Dextromethorphan-bupropion (Auvelity)	45/105 bid	Dizziness, headache, diarrhea	Possible increased speed of response
MAOIs			
Phenelzine (Nardil)	45–90	Insomnia; hypotension; edema; anorgasmia; weight gain; neuropathy; hypertensive crisis; toxic reactions with SSRIs; narcotics	May be more effective in patients with atypical features or treatment-refractory depression
Tranylcypromine (Parnate)	20–50		
Isocarboxazid (Marplan)	20–60		Less weight gain and hypotension than phenelzine
Transdermal selegiline (Emsam)	6–12	Local skin reaction, hypertension	No dietary restrictions with 6-mg dose

Abbreviations: ADD, attention-deficit disorder; EPS, extrapyramidal symptoms; FDA, U.S. Food and Drug Administration; GI, gastrointestinal; MAOIs, monoamine oxidase inhibitors; OCD, obsessive-compulsive disorder; OD, overdose; SSRIs, selective serotonin reuptake inhibitors; TCAs, tricyclic antidepressants.

TABLE 463-2 Management of Antidepressant Side Effects

SYMPTOMS	COMMENTS AND MANAGEMENT STRATEGIES
Gastrointestinal	
Nausea, loss of appetite	Usually short-lived and dose-related; consider temporary dose reduction or administration with food and antacids
Diarrhea	Famotidine, 20–40 mg/d
Constipation	Wait for tolerance; try diet change, stool softener, exercise; avoid laxatives
Sexual dysfunction	Consider dose reduction; drug holiday
Anorgasmia/ impotence; impaired ejaculation	Bethanechol, 10–20 mg, 2 h before activity, or cyproheptadine, 4–8 mg, 2 h before activity, or bupropion, 100 mg bid, or amantadine, 100 mg bid/tid
Orthostasis	Tolerance unlikely; increase fluid intake, use calf exercises/support hose; fludrocortisone, 0.025 mg/d
Anticholinergic	Wait for tolerance
Dry mouth, eyes	Maintain good oral hygiene; use artificial tears, sugar-free gum
Tremor/jitteriness	Antiparkinsonian drugs not effective; use dose reduction/ slow increase; lorazepam, 0.5 mg bid, or propranolol, 10–20 mg bid
Insomnia	Schedule all doses for the morning; trazodone, 50–100 mg qhs
Sedation	Caffeine; schedule all dosing for bedtime; bupropion, 75–100 mg in afternoon
Headache	Evaluate diet, stress, other drugs; try dose reduction; amitriptyline, 50 mg/d
Weight gain	Decrease carbohydrates; exercise; consider fluoxetine
Loss of therapeutic benefit over time	Related to tolerance? Increase dose or drug holiday; add amantadine, 100 mg bid, buspirone, 10 mg tid, or pindolol, 2.5 mg bid

TABLE 463-3 Possible Drug Interactions with Selective Serotonin Reuptake Inhibitors

AGENT	EFFECT
Monoamine oxidase inhibitors	Serotonin syndrome—absolute contraindication
Serotonergic agonists, e.g., tryptophan, fenfluramine, triptans	Potential serotonin syndrome
Drugs that are metabolized by P450 isoenzymes: tricyclics, other SSRIs, antipsychotics, beta blockers, codeine, triazolobenzodiazepines, calcium channel blockers	Delayed metabolism resulting in increased blood levels and potential toxicity
Drugs that are bound tightly to plasma proteins, e.g., warfarin	Increased bleeding secondary to displacement
Drugs that inhibit the metabolism of SSRIs by P450 isoenzymes, e.g., quinidine	Increased SSRI side effects

Abbreviation: SSRIs, selective serotonin reuptake inhibitors.

are lipid soluble, such as diazepam, have a rapid onset of action and a higher abuse potential. Benzodiazepines should generally not be prescribed for >4–6 weeks because of the development of tolerance and the serious risk of abuse and dependence. Withdrawal must be closely monitored as relapses can occur. It is important to warn patients that concomitant use of alcohol or other sedating drugs may exacerbate side effects and impair their ability to function. An optimistic approach that encourages the patient to clarify environmental precipitants, anticipate their reactions, and plan effective response strategies is an essential element of therapy.

Adverse effects of benzodiazepines generally parallel their relative half-lives. Longer-acting agents, such as diazepam, chlordiazepoxide, flurazepam, and clonazepam, tend to accumulate active metabolites, with resultant sedation, impairment of cognition, and poor psychomotor performance. Shorter-acting compounds, such as alprazolam, lorazepam, and oxazepam, can produce daytime anxiety, early-morning insomnia, and, with discontinuation, rebound anxiety and insomnia. Although patients develop tolerance to the sedative effects of benzodiazepines, they are less likely to habituate to the adverse psychomotor effects. Withdrawal from the longer half-life benzodiazepines can be accomplished through gradual, stepwise dose reduction (by 10% every 1–2 weeks) over 6–12 weeks. It is usually more difficult to taper patients off shorter-acting benzodiazepines. Physicians may need to switch the patient to a benzodiazepine with a longer half-life or use an adjunctive medication such as a beta blocker or carbamazepine, before attempting to discontinue the benzodiazepine. Withdrawal reactions vary in severity and duration; they can include depression, anxiety, lethargy, diaphoresis, autonomic arousal, and, rarely, seizures.

Buspirone is a nonbenzodiazepine anxiolytic agent. It is nonsedating, does not produce tolerance or dependence, does not interact

TABLE 463-4 Anxiolytics

NAME	EQUIVALENT PO DOSE (mg)	ONSET OF ACTION	HALF-LIFE (h)	COMMENTS
Benzodiazepines				
Diazepam (Valium)	5	Fast	20–70	Active metabolites; quite sedating
Flurazepam (Dalmane)	15	Fast	30–100	Flurazepam is a prodrug; metabolites are active; quite sedating
Triazolam (Halcion)	0.25	Intermediate	1.5–5	No active metabolites; can induce confusion and delirium, especially in elderly
Lorazepam (Ativan)	1	Intermediate	10–20	No active metabolites; direct hepatic glucuronide conjugation; quite sedating; FDA-approved for anxiety with depression
Alprazolam (Xanax)	0.5	Intermediate	12–15	Active metabolites; not too sedating; FDA-approved for panic disorder and anxiety with depression; tolerance and dependence develop easily; difficult to withdraw
Chlordiazepoxide (Librium)	10	Intermediate	5–30	Active metabolites; moderately sedating
Oxazepam (Serax)	15	Slow	5–15	No active metabolites; direct glucuronide conjugation; not too sedating
Temazepam (Restoril)	15	Slow	9–12	No active metabolites; moderately sedating
Clonazepam (Klonopin)	0.5	Slow	18–50	No active metabolites; moderately sedating; FDA-approved for panic disorder
Clorazepate (Tranxene)	15	Fast	40–200	Low sedation; unreliable absorption
Prazepam (Centrax)	10–60	Fast	29–224	Less sedating than diazepam
Nonbenzodiazepines				
Buspirone (BuSpar)	7.5	2 weeks	2–3	Active metabolites; tid dosing—usual daily dose 10–20 mg tid; nonsedating; no additive effects with alcohol; useful for controlling agitation in demented or brain-injured patients

Abbreviation: FDA, U.S. Food and Drug Administration.

TABLE 463-5 Diagnostic Criteria for Generalized Anxiety Disorder

A. Excessive anxiety and worry (apprehensive expectation), occurring more days than not for at least 6 months, about a number of events or activities (such as work or school performance).

B. The individual finds it difficult to control the worry.

C. The anxiety and worry are associated with three (or more) of the following six symptoms (with at least some symptoms having been present for more days than not for the past 6 months):

Note: Only one item is required in children.

1. Restlessness or feeling keyed up or on edge.
2. Being easily fatigued.
3. Difficulty concentrating or mind going blank.
4. Irritability.
5. Muscle tension.
6. Sleep disturbance (difficulty falling or staying asleep, or restless, unsatisfying sleep).

D. The anxiety, worry, or physical symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

E. The disturbance is not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication) or another medical condition (e.g., hyperthyroidism).

F. The disturbance is not better explained by another mental disorder (e.g., anxiety or worry about having panic attacks in panic disorder, negative evaluation in social anxiety disorder, contamination or other obsessions in obsessive-compulsive disorder, separation from attachment figures in separation anxiety disorder, reminders of traumatic events in posttraumatic stress disorder, gaining weight in anorexia nervosa, physical complaints in somatic symptom disorder, perceived appearance flaws in body dysmorphic disorder, having a serious illness in illness anxiety disorder, or the content of delusional beliefs in schizophrenia or delusional disorder).

with benzodiazepine receptors or alcohol, and has no abuse or disinhibition potential. However, it requires several weeks to take effect and requires thrice-daily dosing. Patients who were previously responsive to a benzodiazepine are unlikely to rate buspirone as equally effective, but patients with head injury or dementia who have symptoms of anxiety and/or agitation may do well with this agent. Escitalopram, paroxetine, duloxetine, and venlafaxine are FDA approved for the treatment of GAD, usually at doses that are comparable to their efficacy in major depression, and may be preferable to usage of benzodiazepines in the treatment of chronic anxiety. Benzodiazepines are contraindicated during pregnancy and breast-feeding.

Anticonvulsants with GABAergic properties may also be effective against anxiety. Gabapentin, oxcarbazepine, tiagabine, pregabalin, and divalproex have all shown some degree of benefit in a variety of anxiety-related syndromes in off-label usage.

PHOBIC DISORDERS

Clinical Manifestations The cardinal feature of phobic disorders is a marked and persistent fear of objects or situations, exposure to which results in an immediate anxiety reaction. The patient avoids the phobic stimulus, and this avoidance usually impairs occupational or social functioning. Panic attacks may be triggered by the phobic stimulus or may occur spontaneously. Unlike patients with other anxiety disorders, individuals with phobias usually experience anxiety only in specific situations. Common phobias include fear of closed spaces (claustrophobia), fear of blood, and fear of flying. Social phobia is distinguished by a specific fear of social or performance situations in which the individual is exposed to unfamiliar individuals or to possible examination and evaluation by others. Examples include having to converse at a party, using public restrooms, or meeting strangers. In each case, the affected individual is aware that the experienced fear is excessive and unreasonable given the circumstance. The specific content of a phobia may vary across gender, ethnic, and cultural boundaries.

Phobic disorders are common, affecting ~7–9% of the population. Twice as many females are affected than males. Full criteria for diagnosis are usually satisfied first in early adulthood, but behavioral avoidance of unfamiliar people, situations, or objects dating from early childhood is common.

In one study of female twins, concordance rates for agoraphobia, social phobia, and animal phobia were found to be 23% for monozygotic twins and 15% for dizygotic twins. A twin study of fear conditioning, a model for the acquisition of phobias, demonstrated a heritability of 35–45%. Animal studies of fear conditioning have indicated that processing of the fear stimulus occurs through the lateral nucleus of the amygdala, extending through the central nucleus and projecting to the periaqueductal gray region, lateral hypothalamus, and paraventricular hypothalamus.

TREATMENT

Phobic Disorders

Beta blockers (e.g., propranolol, 20–40 mg orally 2 h before the event) are particularly effective in the treatment of "performance anxiety" (but not general social phobia) and appear to work by blocking the peripheral manifestations of anxiety such as perspiration, tachycardia, palpitations, and tremor. MAOIs alleviate social phobia independently of their antidepressant activity, and paroxetine, sertraline, fluvoxamine CR, and venlafaxine XR have received FDA approval for treatment of social anxiety. Benzodiazepines can be helpful in reducing fearful avoidance, but the chronic nature of phobic disorders limits their usefulness.

Behaviorally focused psychotherapy is an important component of treatment because relapse rates are high when medication is used as the sole treatment. Cognitive-behavioral strategies are based on the finding that distorted perceptions and interpretations of fear-producing stimuli play a major role in perpetuation of phobias. Individual and group therapy sessions teach the patient to identify specific negative thoughts associated with the anxiety-producing situation and help to reduce the patient's fear of loss of control. In desensitization therapy, hierarchies of feared situations are constructed, and the patient is encouraged to pursue and master gradual exposure to the anxiety-producing stimuli.

Patients with social phobia, in particular, have a high rate of comorbid alcohol abuse, as well as of other psychiatric conditions (e.g., eating disorders), necessitating the need for parallel management of each disorder if anxiety reduction is to be achieved.

STRESS DISORDERS

Clinical Manifestations Patients may develop anxiety after exposure to extreme traumatic events such as the threat of personal death or injury or the death of a loved one. The reaction may occur shortly after the trauma (*acute stress disorder*) or be delayed and subject to recurrence (PTSD) **(Table 463-6)**. In both syndromes, individuals experience associated symptoms of detachment and loss of emotional responsivity. The patient may feel depersonalized and unable to recall specific aspects of the trauma, although typically, it is reexperienced through intrusions in thought, dreams, or flashbacks, particularly when cues of the original event are present. Patients often actively avoid stimuli that precipitate recollections of the trauma and demonstrate a resulting increase in vigilance, arousal, and startle response. Patients with stress disorders are at risk for the development of other disorders related to anxiety, mood, and substance abuse (especially alcohol). Between 5 and 10% of Americans will at some time in their life satisfy criteria for PTSD, with women more likely to be affected than men. A validated four-item screen for PTSD (PC-PTSD) is available.

Risk factors for the development of PTSD include a past psychiatric history and personality characteristics of high neuroticism and extroversion. Twin studies show a substantial genetic influence on all symptoms associated with PTSD, with less evidence for an environmental effect.

TABLE 463-6 Diagnostic Criteria for Posttraumatic Stress Disorder

Posttraumatic Stress Disorder in Individuals Older Than 6 Years

Note: The following criteria apply to adults, adolescents, and children older than 6 years.

For children 6 years and younger, see corresponding criteria below.

A. Exposure to actual or threatened death, serious injury, or sexual violence in one (or more) of the following ways:

1. Directly experiencing the traumatic event(s). 2. Witnessing, in person, the event(s) as it occurred to others. 3. Learning that the traumatic event(s) occurred to a close family member or close friend. In cases of actual or threatened death of a family member or friend, the event(s) must have been violent or accidental. 4. Experiencing repeated or extreme exposure to aversive details of the traumatic event(s) (e.g., first responders collecting human remains; police officers repeatedly exposed to details of child abuse).

Note: Criterion A4 does not apply to exposure through electronic media, television, movies, or pictures, unless this exposure is work related.

B. Presence of one (or more) of the following intrusion symptoms associated with the traumatic event(s), beginning after the traumatic event(s) occurred:

1. Recurrent, involuntary, and intrusive distressing memories of the traumatic event(s).

Note: In children older than 6 years, repetitive play may occur in which themes or aspects of the traumatic event(s) are expressed.

2. Recurrent distressing dreams in which the content and/or affect of the dream are related to the traumatic event(s).

Note: In children, there may be frightening dreams without recognizable content.

3. Dissociative reactions (e.g., flashbacks) in which the individual feels or acts as if the traumatic event(s) were recurring. (Such reactions may occur on a continuum, with the most extreme expression being a complete loss of awareness of present surroundings.)

Note: In children, trauma-specific reenactment may occur in play.

4. Intense or prolonged psychological distress at exposure to internal or external cues that symbolize or resemble an aspect of the traumatic event(s). 5. Marked physiological reactions to internal or external cues that symbolize or resemble an aspect of the traumatic event(s).

C. Persistent avoidance of stimuli associated with the traumatic event(s), beginning after the traumatic event(s) occurred, as evidenced by one or both of the following:

1. Avoidance of or efforts to avoid distressing memories, thoughts, or feelings about or closely associated with the traumatic event(s). 2. Avoidance of or efforts to avoid external reminders (people, places, conversations, activities, objects, situations) that arouse distressing memories, thoughts, or feelings about or closely associated with the traumatic event(s).

D. Negative alterations in cognitions and mood associated with the traumatic event(s), beginning or worsening after the traumatic event(s) occurred, as evidenced by two (or more) of the following:

1. Inability to remember an important aspect of the traumatic event(s) (typically due to dissociative amnesia and not to other factors such as head injury, alcohol, or drugs). 2. Persistent and exaggerated negative beliefs or expectations about oneself, others, or the world (e.g., "I am bad," "No one can be trusted," "The world is completely dangerous," "My whole nervous system is permanently ruined"). 3. Persistent, distorted cognitions about the cause or consequences of the traumatic event(s) that lead the individual to blame himself/herself or others. 4. Persistent negative emotional state (e.g., fear, horror, anger, guilt, or shame). 5. Markedly diminished interest or participation in significant activities. 6. Feelings of detachment or estrangement from others. 7. Persistent inability to experience positive emotions (e.g., inability to experience happiness, satisfaction, or loving feelings).

E. Marked alterations in arousal and reactivity associated with the traumatic event(s), beginning or worsening after the traumatic event(s) occurred, as evidenced by two (or more) of the following:

1. Irritable behavior and angry outbursts (with little or no provocation) typically expressed as verbal or physical aggression toward people or objects. 2. Reckless or self-destructive behavior. 3. Hypervigilance. 4. Exaggerated startle response. 5. Problems with concentration. 6. Sleep disturbance (e.g., difficulty falling or staying asleep or restless sleep).

F. Duration of the disturbance (Criteria B, C, D, and E) is more than 1 month.

G. The disturbance causes clinically significant distress or impairment in social, occupational, or other important areas of functioning.

H. The disturbance is not attributable to the physiological effects of a substance (e.g., medication, alcohol) or another medical condition.

Specify whether:

With dissociative symptoms: The individual's symptoms meet the criteria for posttraumatic stress disorder, and in addition, in response to the stressor, the individual experiences persistent or recurrent symptoms of either of the following:

1. 1. **Depersonalization:** Persistent or recurrent experiences of feeling detached from, and as if one were an outside observer of, one's mental processes or body (e.g., feeling as though one were in a dream; feeling a sense of unreality of self or body or of time moving slowly).
   2. **Derealization:** Persistent or recurrent experiences of unreality of surroundings (e.g., the world around the individual is experienced as unreal, dreamlike, distant, or distorted).
2. **Note:** To use this subtype, the dissociative symptoms must not be attributable to the physiological effects of a substance (e.g., blackouts, behavior during alcohol intoxication) or another medical condition (e.g., complex partial seizures).

Specify if:

With delayed expression: If the full diagnostic criteria are not met until at least 6 months after the event (although the onset and expression of some symptoms may be immediate).

Posttraumatic Stress Disorder in Children 6 Years and Younger

A. In children 6 years and younger, exposure to actual or threatened death, serious injury, or sexual violence in one (or more) of the following ways:

1. Directly experiencing the traumatic event(s). 2. Witnessing, in person, the event(s) as it occurred to others, especially primary caregivers. 3. Learning that the traumatic event(s) occurred to a parent or caregiving figure.

B. Presence of one (or more) of the following intrusion symptoms associated with the traumatic event(s), beginning after the traumatic event(s) occurred:

1. Recurrent, involuntary, and intrusive distressing memories of the traumatic event(s).

Note: Spontaneous and intrusive memories may not necessarily appear distressing and may be expressed as play reenactment.

2. Recurrent distressing dreams in which the content and/or affect of the dream are related to the traumatic event(s).

Note: It may not be possible to ascertain that the frightening content is related to the traumatic event.

3. Dissociative reactions (e.g., flashbacks) in which the child feels or acts as if the traumatic event(s) were recurring. (Such reactions may occur on a continuum, with the most extreme expression being a complete loss of awareness of present surroundings.) Such trauma-specific reenactment may occur in play. 4. Intense or prolonged psychological distress at exposure to internal or external cues that symbolize or resemble an aspect of the traumatic event(s). 5. Marked physiological reactions to reminders of the traumatic event(s).

C. One (or more) of the following symptoms, representing either persistent avoidance of stimuli associated with the traumatic event(s) or negative alterations in cognitions and mood associated with the traumatic event(s), must be present, beginning after the event(s) or worsening after the event(s):

Persistent Avoidance of Stimuli

1. Avoidance of or efforts to avoid activities, places, or physical reminders that arouse recollections of the traumatic event(s). 2. Avoidance of or efforts to avoid people, conversations, or interpersonal situations that arouse recollections of the traumatic event(s).

(*Continued*)

TABLE 463-6 Diagnostic Criteria for Posttraumatic Stress Disorder (Continued)

Negative Alterations in Cognitions

3. Substantially increased frequency of negative emotional states (e.g., fear, guilt, sadness, shame, confusion). 4. Markedly diminished interest or participation in significant activities, including constriction of play. 5. Socially withdrawn behavior. 6. Persistent reduction in expression of positive emotions.

D. Alterations in arousal and reactivity associated with the traumatic event(s), beginning or worsening after the traumatic event(s) occurred, as evidenced by two (or more) of the following:

1. Irritable behavior and angry outbursts (with little or no provocation) typically expressed as verbal or physical aggression toward people or objects (including extreme temper tantrums). 2. Hypervigilance. 3. Exaggerated startle response. 4. Problems with concentration. 5. Sleep disturbance (e.g., difficulty falling or staying asleep or restless sleep).

E. The duration of the disturbance is more than 1 month.

F. The disturbance causes clinically significant distress or impairment in relationships with parents, siblings, peers, or other caregivers or with school behavior.

G. The disturbance is not attributable to the physiological effects of a substance (e.g., medication or alcohol) or another medical condition.

Specify whether:

With dissociative symptoms: The individual's symptoms meet the criteria for posttraumatic stress disorder, and the individual experiences persistent or recurrent symptoms of either of the following:

1. Depersonalization: Persistent or recurrent experiences of feeling detached from, and as if one were an outside observer of, one's mental processes or body (e.g., feeling as though one were in a dream; feeling a sense of unreality of self or body or of time moving slowly). 2. Derealization: Persistent or recurrent experiences of unreality of surroundings (e.g., the world around the individual is experienced as unreal, dreamlike, distant, or distorted).

Note: To use this subtype, the dissociative symptoms must not be attributable to the physiological effects of a substance (e.g., blackouts) or another medical condition (e.g., complex partial seizures).

Specify if:

With delayed expression: If the full diagnostic criteria are not met until at least 6 months after the event (although the onset and expression of some symptoms may be immediate).

Etiology and Pathophysiology It is hypothesized that in PTSD there is excessive release of norepinephrine from the locus coeruleus in response to stress and increased noradrenergic activity at projection sites in the hippocampus and amygdala. These changes theoretically facilitate the encoding of fear-based memories. Greater sympathetic responses to cues associated with the traumatic event occur in PTSD, although pituitary adrenal responses are blunted. In addition to fear learning, changes in threat detection (insula overactivity), executive function, emotional regulation, and contextual learning have been documented. Predictive biomarkers include increased heart rate and serum lactate, decreased coagulation, insulin resistance, and alterations in glycolysis and fatty acid uptake.

TREATMENT

Stress Disorders

Acute stress reactions are usually self-limited, and treatment typically involves the short-term use of benzodiazepines and supportive/expressive psychotherapy. The chronic and recurrent nature of PTSD, however, requires a more complex approach using drug and behavioral treatments. PTSD is highly correlated with peritraumatic dissociative symptoms and the development of an acute stress disorder at the time of the trauma. Attempts to prevent or ameliorate PTSD through usage of agents such as escitalopram, hydrocortisone, and intranasal oxytocin in the acute stress period have proven equivocal. The SSRIs (paroxetine and sertraline are FDA approved for PTSD), venlafaxine, fluoxetine, and topiramate can all reduce anxiety, symptoms of intrusion, and avoidance behaviors. Recently, the psychedelic agent MDMA (3,4-methylenedioxymethamphetamine) demonstrated efficacy as an adjunct to intensive psychotherapeutic intervention, as did stellate ganglion block. Low-dose trazodone and mirtazapine, sedating antidepressants, are frequently used at night to help with insomnia. Benzodiazepines and SSRIs, however, should not be given in the early aftermath of trauma. Psychotherapeutic strategies for PTSD help the patient overcome avoidance behaviors and demoralization and master fear of recurrence of the trauma; therapies that encourage the patient to dismantle avoidance behaviors through stepwise focusing on the experience of the traumatic event, such as trauma-focused cognitive-behavioral and eye movement desensitization and reprocessing (EMDR) therapies and prolonged exposure therapy utilizing augmented or virtual reality are the most effective. Debriefing after the traumatic event does not prevent PTSD and may exacerbate symptoms.

OBSESSIVE-COMPULSIVE DISORDER

Clinical Manifestations Obsessive-compulsive disorder (OCD) is characterized by obsessive thoughts and compulsive behaviors that impair everyday functioning. Fears of contamination and germs are common, as are handwashing, counting behaviors, and having to check and recheck such actions as whether a door is locked. The degree to which the disorder is disruptive for the individual varies, but in all cases, obsessive-compulsive activities take up >1 h per day and are undertaken to relieve the anxiety triggered by the core fear. Patients often conceal their symptoms, usually because they are embarrassed by the content of their thoughts or the nature of their actions. Physicians must ask specific questions regarding recurrent thoughts and behaviors, particularly if physical clues such as chafed and reddened hands or patchy hair loss (from repetitive hair pulling, or trichotillomania) are present. Comorbid conditions are common, the most frequent being depression, other anxiety disorders, eating disorders, and tics. OCD has a lifetime prevalence of 2–3% worldwide. Onset is usually gradual, beginning in early adulthood, but childhood onset is not rare. The disorder usually has a waxing and waning course, but some cases may show a steady deterioration in psychosocial functioning.

Etiology and Pathophysiology A genetic contribution to OCD is suggested by twin studies, but no susceptibility gene for OCD has been identified to date. Insulin signaling has been implicated in some recent reports. Family studies show an aggregation of OCD with Tourette's disorder, and both are more common in males and in first-born children.

The anatomy of obsessive-compulsive behavior is thought to include the orbital frontal cortex, caudate nucleus, and globus pallidus. The caudate nucleus appears to be involved in the acquisition and maintenance of habit and skill learning, and interventions that are successful in reducing obsessive-compulsive behaviors also decrease metabolic activity in the caudate.

TREATMENT

Obsessive-Compulsive Disorder

Clomipramine, fluoxetine, fluvoxamine, paroxetine, and sertraline are approved for the treatment of OCD in adults (and all but paroxetine are also approved for children). Clomipramine is a TCA that is often tolerated poorly owing to anticholinergic and sedative side effects at the doses required to treat the illness (25–250 mg/d); its efficacy in OCD is unrelated to its antidepressant activity.

Fluoxetine (5–60 mg/d), fluvoxamine (25–300 mg/d), paroxetine (40–60 mg/d), and sertraline (50–150 mg/d) are as effective as clomipramine and have a more benign side effect profile. Venlafaxine and duloxetine also have shown efficacy but are not FDA approved. Only 50–60% of patients with OCD show adequate improvement with pharmacotherapy alone. In treatment-resistant cases, augmentation with other serotonergic agents such as buspirone, or with a neuroleptic or benzodiazepine, may be beneficial, or alternatively, high-dose theta burst repetitive transcranial magnetic stimulation (rTMS). In severe cases, closed loop deep-brain stimulation has been found to be effective. When a therapeutic response is achieved, long-duration maintenance therapy is usually indicated.

For many individuals, particularly those with time-consuming compulsions, behavior therapy and exposure response prevention will result in as much improvement as that afforded by medication. Effective techniques include the gradual increase in exposure to stressful situations, maintenance of a diary to clarify stressors, and homework assignments that substitute new activities for compulsive behaviors.

MOOD DISORDERS

Mood disorders are characterized by a disturbance in the regulation of mood, behavior, and affect. Mood disorders are subdivided into (1) depressive disorders, (2) bipolar disorders, and (3) depression in association with medical illness or alcohol and substance abuse **(Chaps. 464 through 468)**. Major depressive disorder (MDD) is differentiated from bipolar disorder by the absence of a manic or hypomanic episode. The relationship between pure depressive syndromes and bipolar disorders is not well understood; MDD is more frequent in families of bipolar individuals, but the reverse is not true. In the most recent Global Burden of Disease Study conducted by the World Health Organization (2019), depression was the single largest factor contributing to disability, which had increased 61% as measured by disability-adjusted life-years (DALYs) since 1990. In the United States, lost productivity directly related to mood disorders has been estimated at $55.1 billion per year.

DEPRESSION IN ASSOCIATION WITH MEDICAL ILLNESS

Depression occurring in the context of medical illness is difficult to evaluate. Depressive symptomatology may reflect the psychological stress of coping with the disease, may be caused by the disease process itself or by the medications used to treat it, or may simply coexist in time with the medical diagnosis.

Virtually every class of *medication* includes some agent that can induce depression. Antihypertensive drugs, anticholesterolemic agents, and antiarrhythmic agents are common triggers of depressive symptoms. Iatrogenic depression should also be considered in patients receiving glucocorticoids, antimicrobials, systemic analgesics, antiparkinsonian medications, and anticonvulsants. To decide whether a causal relationship exists between pharmacologic therapy and a patient's change in mood, it may sometimes be necessary to undertake an empirical trial of an alternative medication.

Between 20 and 30% of *cardiac* patients manifest a depressive disorder; an even higher percentage experience depressive symptomatology when self-reporting scales are used. Depressive symptoms following unstable angina, myocardial infarction, cardiac bypass surgery, or heart transplant impair rehabilitation and are associated with higher rates of mortality and medical morbidity. Depressed patients often show decreased variability in heart rate (an index of reduced parasympathetic nervous system activity), which may predispose individuals to ventricular arrhythmia and increased morbidity. Depression also appears to increase the risk of coronary heart disease, possibly through increased platelet aggregation. TCAs are contraindicated in patients with bundle branch block, and TCA-induced tachycardia is an additional concern in patients with congestive heart failure. SSRIs appear not to induce ECG changes or adverse cardiac events and thus are reasonable first-line drugs for patients at risk for TCA-related complications. SSRIs may interfere with hepatic metabolism of anticoagulants, however, causing increased anticoagulation.

In patients with *cancer*, the mean prevalence of depression is 25%, but depression occurs in 40–50% of patients with cancers of the pancreas or oropharynx. This association is not due to the effect of cachexia alone, as the higher prevalence of depression in patients with pancreatic cancer persists when compared to those with advanced gastric cancer. Initiation of antidepressant medication in cancer patients has been shown to improve quality of life as well as mood. Psychotherapeutic approaches, particularly group therapy, may have some effect on short-term depression, anxiety, and pain symptoms.

Depression occurs frequently in patients with *neurologic disorders*, particularly cerebrovascular disorders, Parkinson's disease, dementia, multiple sclerosis, and traumatic brain injury. One in five patients with left-hemisphere stroke involving the dorsolateral frontal cortex experiences major depression. Late-onset depression in otherwise cognitively normal individuals increases the risk of a subsequent diagnosis of Alzheimer's disease. All classes of antidepressant agents are effective against these depressions, as are, in some cases, stimulant compounds. SNRIs such as duloxetine or levomilnacipran may be more effective in depression associated with chronic pain.

The reported prevalence of depression in patients with *diabetes mellitus* varies from 8 to 27%, with the severity of the mood state correlating with the level of hyperglycemia and the presence of diabetic complications. Treatment of depression may be complicated by effects of antidepressive agents on glycemic control. MAOIs can induce hypoglycemia and weight gain, whereas TCAs can produce hyperglycemia and carbohydrate craving. SSRIs and SNRIs, like MAOIs, may reduce fasting plasma glucose but are easier to use and may also improve dietary and medication compliance.

Hypothyroidism is frequently associated with features of depression, most commonly depressed mood and memory impairment. Hyperthyroid states may also present in a similar fashion, usually in geriatric populations. Improvement in mood usually follows normalization of thyroid function, but adjunctive antidepressant medication is sometimes required. Patients with subclinical hypothyroidism can also experience symptoms of depression and cognitive difficulty that respond to thyroid replacement.

The lifetime prevalence of depression in *HIV-positive* individuals has been estimated at 22–45%. The relationship between depression and disease progression is multifactorial and likely to involve psychological and social factors, alterations in immune function, and central nervous system (CNS) disease. Chronic hepatitis C infection is also associated with depression, which may worsen with interferon-α treatment.

Some chronic disorders of uncertain etiology, such as chronic fatigue syndrome **(Chap. 461)** and fibromyalgia **(Chap. 385)**, are strongly associated with depression and anxiety; patients may benefit from antidepressant treatment or anticonvulsant agents such as pregabalin.

DEPRESSIVE DISORDERS

Clinical Manifestations Major depression is defined as depressed mood on a daily basis for a minimum duration of 2 weeks **(Table 463-7)**. An episode may be characterized by sadness, indifference, apathy, or irritability and is usually associated with changes in sleep patterns, appetite, and weight; motor agitation or retardation; fatigue; impaired concentration and decision-making; feelings of shame or guilt; and thoughts of death or dying. Patients with depression have a profound loss of pleasure in all enjoyable activities, exhibit early-morning awakening, feel that the dysphoric mood state is qualitatively different from sadness, and often notice a diurnal variation in mood (worse in morning hours). Patients experiencing bereavement or grief may exhibit many of the same signs and symptoms of major depression, although the emphasis is usually on feelings of emptiness and loss, rather than anhedonia and loss of self-esteem, and the duration is usually limited. In certain cases, however, the diagnosis of major depression may be warranted even in the context of a significant loss.

Approximately 15% of the population experiences a major depressive episode at some point in life, and 6–8% of all outpatients in

TABLE 463-7 Criteria for a Major Depressive Episode

A. Five (or more) of the following symptoms have been present during the same 2-week period and represent a change from previous functioning; at least one of the symptoms is either (1) depressed mood or (2) loss of interest or pleasure.

Note: Do not include symptoms that are clearly attributable to another medical condition.

1. Depressed mood most of the day, nearly every day, as indicated by either subjective report (e.g., feels sad, empty, hopeless) or observation made by others (e.g., appears tearful). (**Note:** In children and adolescents, can be irritable mood.)
2. Markedly diminished interest or pleasure in all, or almost all, activities most of the day, nearly every day (as indicated by either subjective account or observation).
3. Significant weight loss when not dieting or weight gain (e.g., a change of more than 5% of body weight in a month), or decrease or increase in appetite nearly every day. (Note: In children, consider failure to make expected weight gain.)
4. Insomnia or hypersomnia nearly every day.
5. Psychomotor agitation or retardation nearly every day (observable by others, not merely subjective feelings of restlessness or being slowed down).
6. Fatigue or loss of energy nearly every day.
7. Feelings of worthlessness or excessive or inappropriate guilt (which may be delusional) nearly every day (not merely self-reproach or guilt about being sick).
8. Diminished ability to think or concentrate, or indecisiveness, nearly every day (either by subjective account or as observed by others).
9. Recurrent thoughts of death (not just fear of dying), recurrent suicidal ideation without a specific plan, or a suicide attempt or a specific plan for committing suicide.

B. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

C. The episode is not attributable to the physiological effects of a substance or another medical condition.

Note: Criteria A–C represent a major depressive episode.

Note: Responses to a significant loss (e.g., bereavement, financial ruin, losses from a natural disaster, a serious medical illness or disability) may include the feelings of intense sadness, rumination about the loss, insomnia, poor appetite, and weight loss noted in Criterion A, which may resemble a depressive episode.

Although such symptoms may be understandable or considered appropriate to the loss, the presence of a major depressive episode in addition to the normal response to a significant loss should also be carefully considered. This decision inevitably requires the exercise of clinical judgment based on the individual's history and the cultural norms for the expression of distress in the context of loss.[1]

D. At least one major depressive episode is not better explained by schizoaffective disorder and is not superimposed on schizophrenia, schizophreniform disorder, delusional disorder, or other specified and unspecified schizophrenia spectrum and other psychotic disorders.

E. There has never been a manic episode or a hypomanic episode.

Note: This exclusion does not apply if all of the manic-like or hypomanic-like episodes are substance-induced or are attributable to the physiological effects of another medical condition.

[1]In distinguishing grief from a major depressive episode (MDE), it is useful to consider that in grief the predominant affect is feelings of emptiness and loss, while in an MDE it is persistent depressed mood and the inability to anticipate happiness or pleasure. The dysphoria in grief is likely to decrease in intensity over days to weeks and occurs in waves, the so-called pangs of grief. These waves tend to be associated with thoughts or reminders of the deceased. The depressed mood of an MDE is more persistent and not tied to specific thoughts or preoccupations. The pain of grief may be accompanied by positive emotions and humor that are uncharacteristic of the pervasive unhappiness and misery characteristic of an MDE. The thought content associated with grief generally features a preoccupation with thoughts and memories of the deceased, rather than the self-critical or pessimistic ruminations seen in an MDE. In grief, self-esteem is generally preserved, whereas in an MDE feelings of worthlessness and self-loathing are common. If self-derogatory ideation is present in grief, it typically involves perceived failings vis-à-vis the deceased (e.g., not visiting frequently enough, not telling the deceased how much he or she was loved). If a bereaved individual thinks about death and dying, such thoughts are generally focused on the deceased and possibly about "joining" the deceased, whereas in an MDE such thoughts are focused on ending one's own life because of feeling worthless, undeserving of life, or unable to cope with the pain of depression.

primary care settings satisfy diagnostic criteria for the disorder. Depression is often undiagnosed and, even more frequently, is treated inadequately. If a physician suspects the presence of a major depressive episode, the initial task is to determine whether it represents unipolar or bipolar depression or is one of the 10–15% of cases that are secondary to general medical illness or substance abuse. Physicians should also assess the risk of suicide by direct questioning, as patients are often reluctant to verbalize such thoughts without prompting. If specific plans are uncovered or if significant risk factors exist (e.g., a past history of suicide attempts, profound hopelessness, concurrent medical illness, substance abuse, or social isolation), the patient must be referred to a mental health specialist for immediate care. The physician should specifically probe each of these areas in an empathic and hopeful manner, being sensitive to denial and possible minimization of distress. The presence of anxiety, panic, or agitation significantly increases near-term suicidal risk. Approximately 4–5% of all depressed patients will commit suicide; most will have sought help from physicians within 1 month of their deaths.

In some depressed patients, the mood disorder does not appear to be episodic and is not clearly associated with either psychosocial dysfunction or change from the individual's usual experience in life. Persistent depressive disorder (*dysthymic disorder*) consists of a pattern of chronic (at least 2 years), ongoing depressive symptoms that are usually less severe and/or less numerous than those found in major depression, but the functional consequences may be equivalent to or even greater; the two conditions are sometimes difficult to separate and can occur together ("double depression"). Many patients who exhibit a profile of pessimism, disinterest, and low self-esteem respond to antidepressant treatment. Persistent and chronic depressive disorders occur in ~2% of the general population.

Depression is approximately twice as common in women as in men, and the incidence increases with age in both sexes. Twin studies indicate that the liability to major depression of early onset (before age 25 years) is largely genetic in origin. Negative life events can precipitate and contribute to depression, but genetic factors influence the sensitivity of individuals to these stressful events. In most cases, both biologic and psychosocial factors are involved in the precipitation and unfolding of depressive episodes. The most potent stressors appear to involve death of a relative, assault, or severe marital or relationship problems.

Unipolar depressive disorders usually begin in early adulthood and recur episodically over the course of a lifetime. The best predictor of future risk is the number of past episodes; 50–60% of patients who have a first episode have at least one or two recurrences. Some patients experience multiple episodes that become more severe and frequent over time. The duration of an untreated episode varies greatly, ranging from a few months to ≥1 year. The pattern of recurrence and clinical progression in a developing episode are also variable. Within an individual, the nature of episodes (e.g., specific presenting symptoms, frequency, and duration) may be similar over time. In a minority of patients, a severe depressive episode can progress to a psychotic state, and in elderly patients, depressive symptoms can be associated with cognitive deficits mimicking dementia ("pseudodementia"). A seasonal pattern of depression, called *seasonal affective disorder*, may manifest with onset and remission of episodes at predictable times of the year. This disorder is more common in women, with symptoms of anergy, fatigue, weight gain, hypersomnia, and episodic carbohydrate craving. The prevalence increases with distance from the equator, and improvement may occur by altering light exposure.

Etiology and Pathophysiology Although evidence for genetic transmission of unipolar depression is not as strong as in bipolar disorder, monozygotic twins have a higher concordance rate (46%) than dizygotic siblings (20%), with little support for any effect of a shared family environment. Large-scale genome-wide association studies (GWAS) involving hundreds of thousands of cases and controls have identified several hundred loci across the genome, some of which are unique to major depression, but others of which overlap with findings from disparate psychiatric disorders, indicating possible pleiotropy. Epigenetic changes are also likely to contribute to risk.

Neuroendocrine abnormalities that reflect the neurovegetative signs and symptoms of depression include increased cortisol and corticotropin-releasing hormone (CRH) secretion, a decreased inhibitory response of glucocorticoids to dexamethasone, and a blunted response of thyroid-stimulating hormone (TSH) level to infusion of thyroid-releasing hormone (TRH). Antidepressant treatment leads to normalization of these abnormalities. Major depression is also associated with changes in levels of proinflammatory cytokines and neurotrophins, an increase in measures of oxidative stress and cellular aging, telomere shortening, epigenetic changes, and mitochondrial dysfunction. Alterations in the gut microbiome may also be involved.

Diurnal variations in symptom severity and alterations in circadian rhythmicity of a number of neurochemical and neurohumoral factors suggest that a primary defect may be present in regulation of biologic rhythms. Patients with major depression show consistent findings of a decrease in rapid eye movement (REM)–sleep onset (REM latency), an increase in REM density, and, in some subjects, a decrease in stage IV delta slow-wave sleep.

Although antidepressant drugs inhibit neurotransmitter uptake within hours, their therapeutic effects typically emerge over several weeks, implicating adaptive changes in second messenger systems and neurotrophic and transcription factors as possible mechanisms of action.

TREATMENT

Depressive Disorders

Treatment planning requires coordination of short-term strategies to induce remission combined with longer-term maintenance designed to prevent recurrence. The most effective intervention for achieving remission and preventing relapse is medication, but combined treatments, incorporating psychotherapy to help the patient cope with decreased self-esteem and demoralization, improve outcomes, as do self-help strategies such as exercise **(Fig. 463-1)**. Approximately 40% of primary care patients with depression drop out of treatment and discontinue medication if symptomatic improvement is not noted within a month, unless additional support is provided. Outcome improves with (1) increased intensity and frequency of visits during the first 4–6 weeks of treatment, (2) supplemental educational materials, and (3) psychiatric consultation as indicated. Despite the widespread use of SSRIs and other second-generation antidepressant drugs, there is no convincing evidence that these classes of antidepressants are more efficacious than TCAs. Between 60 and 70% of all depressed patients respond to any drug chosen, if it is given in a sufficient dose for 6–8 weeks.

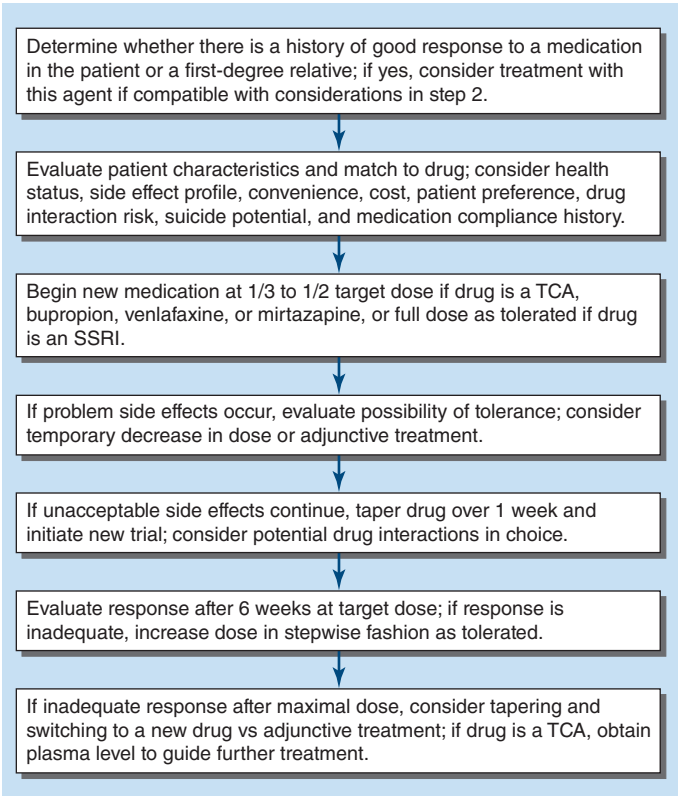

FIGURE 463-1 A guideline for the medical management of major depressive disorder. SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant.

A rational approach to selecting which antidepressant to use (Table 463-1) involves matching the patient's preference and medical history with the metabolic and side effect profile of the drug (Tables 463-2 and 463-3). A previous response, or a family history of a positive response, to a specific antidepressant often suggests that drug should be tried first. Before initiating antidepressant therapy, the physician should evaluate the possible contribution of comorbid illnesses and consider their specific treatment. In individuals with suicidal ideation, particular attention should be paid to choosing a drug with low toxicity if taken in overdose. Newer antidepressant drugs are distinctly safer in this regard; nevertheless, the advantages of TCAs have not been completely superseded. The existence of generic equivalents makes TCAs relatively cheap, and for secondary tricyclics, particularly nortriptyline and desipramine, well-defined relationships among dose, plasma level, and therapeutic response exist. The steady-state plasma level achieved for a given drug dose can vary more than tenfold between individuals, and plasma levels may help in interpreting apparent resistance to treatment and/or unexpected drug toxicity. The principal side effects of TCAs are antihistaminergic (sedation) and anticholinergic (constipation, dry mouth, urinary hesitancy, blurred vision). TCAs are contraindicated in patients with serious cardiovascular risk factors, and overdoses of tricyclic agents can be lethal, with desipramine carrying the greatest risk. It is judicious to prescribe only a 10-day supply when suicide is a risk. Most patients require a daily dose of 150–200 mg of imipramine or amitriptyline or its equivalent to achieve a therapeutic blood level of 150–300 ng/mL and a satisfactory remission; some patients show a partial effect at lower doses. Geriatric patients may require a low starting dose and slow escalation. Ethnic differences in drug metabolism are significant, with Hispanic, Asian, and black patients generally requiring lower doses to achieve a comparable blood level.

Second-generation antidepressants are similar to tricyclics in their effect on neurotransmitter reuptake, although some also have specific actions on catecholamine and indolamine receptors as well. Amoxapine is a dibenzoxazepine derivative that blocks norepinephrine and serotonin reuptake and has a metabolite that shows a degree of dopamine blockade. Long-term use of this drug carries a risk of tardive dyskinesia. Maprotiline is a potent noradrenergic reuptake blocker that has little anticholinergic effect but may produce seizures. Bupropion is a novel antidepressant whose mechanism of action is thought to involve enhancement of noradrenergic function. It has no anticholinergic, sedating, or orthostatic side effects and has a low incidence of sexual side effects. It may, however, be associated with stimulant-like side effects, may lower seizure threshold, and has an exceptionally short half-life, requiring frequent dosing. An extended-release preparation is available, as is a version combining it with dextromethorphan, an *N*-methyl-D-aspartate (NMDA) receptor agonist, that is proposed to result in a more rapid therapeutic response.

SSRIs such as fluoxetine, sertraline, paroxetine, citalopram, and escitalopram cause a lower frequency of anticholinergic, sedating, and cardiovascular side effects but a possibly greater incidence of gastrointestinal complaints, sleep impairment, and sexual dysfunction than do TCAs. Akathisia, involving an inner sense of restlessness and anxiety in addition to increased motor activity, may also be more common, particularly during the first week of treatment. One concern is the risk of "serotonin syndrome," which is thought to result from hyperstimulation of brainstem 5-HT_{1A} receptors and is characterized by myoclonus, agitation, abdominal cramping, hyperpyrexia,

hypertension, and potentially death. Serotonergic agonists taken in combination should be monitored closely for this reason. Considerations such as half-life, compliance, toxicity, and drug-drug interactions may guide the choice of a particular SSRI. Fluoxetine and its principal active metabolite, norfluoxetine, for example, have a combined half-life of almost 7 days, resulting in a delay of 5 weeks before steady-state levels are achieved and a similar delay for complete drug excretion once their use is discontinued; paroxetine appears to incur a greater risk of withdrawal symptoms with abrupt discontinuation. All the SSRIs may impair sexual function, resulting in diminished libido, impotence, or difficulty in achieving orgasm. Sexual dysfunction frequently results in noncompliance and should be asked about specifically. Sexual dysfunction can sometimes be ameliorated by lowering the dose, by instituting weekend drug holidays (two or three times a month), or by treatment with amantadine (100 mg tid), bethanechol (25 mg tid), buspirone (10 mg tid), or bupropion (100–150 mg/d). Paroxetine appears to be more anticholinergic than either fluoxetine or sertraline, and sertraline carries a lower risk of producing an adverse drug interaction than the other two. Rare side effects of SSRIs include angina due to vasospasm and prolongation of the prothrombin time. Escitalopram is the most specific of currently available SSRIs and appears to have no significant inhibitory effects on the P450 system.

Venlafaxine, desvenlafaxine, duloxetine, and levomilnacipran block the reuptake of both norepinephrine and serotonin but produce relatively little in the way of traditional tricyclic side effects. Vortioxetine, also a 5-HT_{1A} agonist, and vilazodone block reuptake of serotonin but have negligible effects on norepinephrine reuptake, although vortioxetine may increase norepinephrine levels through wide effects on serotonergic receptors, as a 5-HT_{1A} agonist, 5-HT_{1B} partial agonist, and a 5-HT_{1D}, 5-HT_3, and 5-HT_7 antagonist. Unlike the SSRIs, venlafaxine and vortioxetine have relatively linear dose-response curves. Patients on immediate-release venlafaxine should be monitored for a possible increase in diastolic blood pressure, and multiple daily dosing is required because of the drug's short half-life. An extended-release form is available and has a somewhat lower incidence of gastrointestinal side effects. Mirtazapine is a tetracyclic that has a unique spectrum of activity, as it increases noradrenergic and serotonergic neurotransmission through a blockade of central α_2-adrenergic receptors and postsynaptic 5-HT_2 and 5-HT_3 receptors. It is also strongly antihistaminic and, as such, may produce sedation. Levomilnacipran is the most noradrenergic of the SNRIs and theoretically may be appropriate for patients with more severe fatigue and anergia. Gepirone, an older drug recently approved, is a partial 5-HT_{1A} agonist and 5-HT_{2A} antagonist.

With the exception of citalopram and escitalopram, each of the SSRIs may inhibit one or more cytochrome P450 enzymes. Depending on the specific isoenzyme involved, the metabolism of a number of concomitantly administered medications can be dramatically affected. Fluoxetine and paroxetine, for example, by inhibiting 2D6, can cause dramatic increases in the blood level of type 1C antiarrhythmics, whereas sertraline, by acting on 3A4, may alter blood levels of carbamazepine or digoxin. Depending on drug specificity for a particular CYP enzyme for its own metabolism, concomitant medications or dietary factors, such as grapefruit juice, may in turn affect the efficacy or toxicity of the SSRI.

The MAOIs are highly effective, particularly in atypical depression, but the risk of hypertensive crisis following intake of tyramine-containing food or sympathomimetic drugs makes them inappropriate as first-line agents. Transdermal selegiline may avert this risk at low dose. Common side effects include orthostatic hypotension, weight gain, insomnia, and sexual dysfunction. MAOIs should not be used concomitantly with SSRIs, because of the risk of serotonin syndrome, or with TCAs, because of possible hyperadrenergic effects.

Electroconvulsive therapy is at least as effective as medication, but its use is reserved for treatment-resistant cases and delusional depressions. rTMS is approved for treatment-resistant depression and has been shown to have efficacy in several controlled trials. Vagus nerve stimulation (VNS) has also recently been approved for treatment-resistant depression, but its degree of efficacy is controversial. Some meta-analyses of low-intensity transcranial current stimulation (tCS) have shown a positive benefit over sham treatment, but whether this is comparable to or synergistic with antidepressant treatment is unclear. In off-label usage, intravenous ketamine, a dissociative anesthetic, and intranasal esketamine (an isomer that has FDA approval in treatment-resistant cases) have been shown to have short-term antidepressant efficacy, often after a single administration, and may decrease suicidality. Questions remain, however, about the risk/benefit ratio over the longer term. Psilocybin, a hallucinogen, has also shown some potential benefit in controlled administration. Lastly, deep brain stimulation of the ventral anterior limb of the internal capsule and of the subcallosal cingulate region has demonstrable efficacy in randomized experimental trials of treatment-resistant depression.

Postpartum depression may respond to any of the above interventions, but a neuroactive steroid, brexanolone (Zulresso), administered in a continuous intravenous infusion over 60 h, can provide symptomatic relief for at least 30 days. Sedation and loss of consciousness are possible adverse effects. An oral version, zuranolone (Zurzuvae), can be given on an outpatient basis.

Regardless of the treatment undertaken, the response should be evaluated after ~2 months. Three-quarters of patients show improvement by this time, but if remission is inadequate, the patient should be questioned about compliance, and an increase in medication dose should be considered if side effects are not troublesome. If this approach is unsuccessful, referral to a mental health specialist is advised. Strategies for treatment resistance include selection of an alternative drug, combinations of antidepressants, and/or adjunctive treatment with other classes of drugs, including lithium, thyroid hormone, L-methylfolate, *S*-adenosylmethionine, *N*-acetyl cysteine, atypical antipsychotic agents, and dopamine agonists. In switching to a different monotherapy, other drugs from the same class appear to be as likely to be efficacious as choosing a drug from a different class. A large randomized trial (STAR-D) was unable to show preferential efficacy, but the addition of certain atypical antipsychotic drugs (quetiapine extended-release; aripiprazole; brexpiprazole) has received FDA approval, as has usage of a combined medication, olanzapine and fluoxetine (Symbyax). Patients whose response to an SSRI wanes over time may benefit from the addition of buspirone (10 mg tid) or pindolol (2–5 mg tid) or small amounts of a TCA such as nortriptyline (25 mg bid or tid). Most patients will show some degree of response, but aggressive treatment should be pursued until remission is achieved, and drug treatment should be continued for at least 6–9 months to prevent relapse. In patients who have had two or more episodes of depression, indefinite maintenance treatment should be considered. Pharmacogenomic testing focusing on cytochrome p450 allelic variation may sometimes be helpful in identifying individuals who are poor or rapid metabolizers, but assessing pharmacodynamic gene variants has not been shown to be cost-effective or affect clinical outcomes.

It is essential to educate patients both about depression and the benefits and side effects of medications they are receiving. Advice about stress reduction and cautions that alcohol may exacerbate depressive symptoms and impair drug response are helpful. Patients should be given time to describe their experience, their outlook, and the impact of the depression on them and their families. Occasional empathic silence may be as helpful for the treatment alliance as verbal reassurance. Controlled trials have shown that cognitive-behavioral and interpersonal therapies are effective in improving psychological and social adjustment and that a combined treatment approach is more successful than medication alone for many patients.

BIPOLAR DISORDER

Clinical Manifestations Bipolar disorder is characterized by unpredictable swings in mood from mania (or hypomania) to

depression. Some patients suffer only from recurrent attacks of *mania*, which in its pure form is associated with increased psychomotor activity; excessive social extroversion; decreased need for sleep; impulsivity and impaired judgment; and expansive, elated, grandiose, and sometimes irritable mood **(Table 463-8)**. In severe mania, patients may experience delusions and paranoid thinking indistinguishable from schizophrenia. One-half of patients with bipolar disorder present not with euphoria but with a mixture of psychomotor agitation and activation, accompanied by dysphoria, anxiety, and irritability. It may be difficult to distinguish such a mixed state from agitated depression. In some bipolar patients (*bipolar II disorder*), the full criteria for mania are lacking, and the requisite recurrent depressions are separated by periods of mild activation and increased energy (hypomania). In *cyclothymic disorder*, there are numerous hypomanic periods, usually of relatively short duration, alternating with clusters of depressive symptoms that fail, either in severity or duration, to meet the criteria of major depression. The mood fluctuations are chronic and should be present for at least 2 years before the diagnosis is made.

Manic episodes typically emerge over a period of days to weeks, but onset within hours is possible, usually in the early-morning hours. An untreated episode of either depression or mania can be as short as several weeks or last as long as 8–12 months, and rare patients have an unremitting chronic course. The term *rapid cycling* is used for patients who have four or more episodes of either depression or mania in a given year. This pattern occurs in 15% of all patients, most of whom are women. In some cases, rapid cycling is linked to an underlying thyroid dysfunction, and in others, it is iatrogenically triggered by prolonged antidepressant treatment. Approximately one-half of patients have sustained difficulties in work performance and psychosocial functioning, with depressive phases being more responsible for impairment than mania.

Bipolar disorder is common, affecting ~1.5% of the population in the United States. Onset is typically between 20–30 years of age, but many individuals report premorbid symptoms in late childhood or early adolescence. The prevalence is similar for men and women; women are likely to have more depressive and men more manic episodes over a lifetime. Recognizing a bipolar diathesis in an individual who presents with a depressive episode but no history of mania is difficult but essential in optimizing treatment planning, because antidepressants may be contraindicated and result in symptom worsening and cycle acceleration. Suggestive features of bipolarity include a childhood onset, a history of antidepressant treatment failure, atypical features of hypersomnolence and weight gain, and marked irritability or impulsivity.

Differential Diagnosis The differential diagnosis of mania includes secondary mania induced by stimulant or sympathomimetic drugs, hyperthyroidism, AIDS, neurologic disorders such as Huntington's or Wilson's disease, frontotemporal dementia, and cerebrovascular accidents. Comorbidity with alcohol and substance abuse is common, either because of shared genetic risk, poor judgment, and increased impulsivity or because of an attempt to self-treat the underlying mood symptoms and sleep disturbances.

Etiology and Pathophysiology Genetic predisposition to bipolar disorder is evident from family studies; the concordance rate for monozygotic twins approaches 80%. A number of risk genes that have been identified to date overlap with those conveying risk for other psychiatric disorders, such as schizophrenia and autism, implying some degree of shared pathophysiology. Replicated loci include the alpha subunit of the L-type calcium channel (*CACNA1C*), teneurin transmembrane protein 4 (*ODZ4*), ankyrin 3 (*ANK3*), neurocan (*NCAN*), and tetratricopeptide repeat and ankyrin repeat containing 1 (*TRANK1*). Common variants convey little individual risk but collectively account for 25% of heritability. A few rarer, more penetrant variants have also been reported, but no causative mutations have as yet been confirmed. Similarly, no clear biomarkers have been identified, but there is evidence for circadian rhythm and calcium dysregulation and oxidative stress, and mitochondrial, microRNA, and endoplasmic reticulum abnormalities. Reported MRI findings include gray matter thinning in frontal, temporal, and parietal cortex.

TREATMENT

Bipolar Disorder

(Table 463-9) Lithium carbonate is the mainstay of treatment in bipolar disorder, although paradoxically underutilized. Sodium valproate and carbamazepine, as well as a number of second-generation antipsychotic agents (e.g., aripiprazole, asenapine, cariprazine, olanzapine, quetiapine, risperidone, ziprasidone), also have FDA approval for the treatment of acute mania. Oxcarbazepine is not FDA approved but appears to enjoy carbamazepine's spectrum of efficacy. The response rate to lithium carbonate is 70–80% in acute mania, with beneficial effects appearing in 1–2 weeks. Lithium also has a prophylactic effect in prevention of recurrent mania and, to a lesser extent, in the prevention of recurrent depression, which is more difficult to treat than unipolar depression. A simple cation, lithium is rapidly absorbed from the gastrointestinal tract and remains unbound to plasma or tissue proteins. Some 95% of a given dose is excreted unchanged through the kidneys within 24 h.

Serious side effects from lithium are rare, but minor complaints such as gastrointestinal discomfort, nausea, diarrhea, polyuria, weight gain, skin eruptions, alopecia, and edema are common. Over time, urine-concentrating ability may be decreased, but significant nephrotoxicity is relatively rare. Lithium exerts an antithyroid effect by interfering with the synthesis and release of thyroid hormones. More serious side effects include tremor, poor concentration and memory, ataxia, dysarthria, and incoordination.

In the treatment of acute mania, lithium is initiated at 300 mg bid or tid, and the dose is then increased by 300 mg every 2–3 days to achieve blood levels of 0.8–1.2 meq/L. Because the therapeutic effect of lithium may not appear until after 7–10 days of treatment, adjunctive usage of lorazepam (1–2 mg every 4 h) or clonazepam (0.5–1 mg every 4 h) may be beneficial to control agitation. Antipsychotics are indicated in patients with severe agitation who respond only partially to benzodiazepines. Patients using lithium should be monitored closely, because the blood levels required to achieve a therapeutic benefit are close to those associated with toxicity.

Valproic acid may be more effective than lithium for patients who experience rapid cycling (i.e., more than four episodes a year) or who present with a mixed or dysphoric mania. Tremor and weight gain are the most common side effects; hepatotoxicity and pancreatitis are rare toxicities.

The recurrent nature of bipolar mood disorder necessitates maintenance treatment. A sustained blood lithium level of at least 0.8 meq/L is important for optimal prophylaxis and has been shown to reduce the risk of suicide, a finding not yet apparent for other mood stabilizers. Decrease in acute suicidal risk may also result from treatment with parenteral ketamine or intranasal esketamine. Combinations of mood stabilizers together or with atypical antipsychotic drugs are sometimes required to maintain mood stability. Quetiapine extended release, olanzapine, risperidone, and lamotrigine have been approved for maintenance treatment as sole agents, in combination with lithium and with aripiprazole and ziprasidone as adjunctive drugs. Lurasidone, olanzapine/fluoxetine, and quetiapine are also approved to treat acute depressive episodes in bipolar disorder. Compliance is frequently an issue and often requires enlistment and education of concerned family members. Efforts to identify and modify psychosocial factors that may trigger episodes are important, as is an emphasis on lifestyle regularity (social rhythm therapy). Mobile apps for smartphones that alert the individual and clinician to changes in activity and speech are proving useful in early detection of behavioral change and in delivering clinical interventions and education. Antidepressant medications are sometimes required for the treatment of severe breakthrough depressions, but their use should generally be avoided during maintenance treatment because of the risk of precipitating mania or accelerating the cycle frequency. Alternative off-label agents for bipolar depression include pramipexole, modafinil, omega-3 fatty acids, and *N*-acetyl cysteine; interventions such as electroconvulsive

TABLE 463-8 Criteria for Bipolar I Disorder

For a diagnosis of bipolar I disorder, it is necessary to meet the following criteria for a manic episode. The manic episode may have been preceded by and may be followed by hypomanic or major depressive episodes.

Manic Episode

A. A distinct period of abnormally and persistently elevated, expansive, or irritable mood and abnormally and persistently increased activity or energy, lasting at least 1 week and present most of the day, nearly every day (or any duration if hospitalization is necessary).

B. During the period of mood disturbance and increased energy or activity, three (or more) of the following symptoms (four if the mood is only irritable) are present to a significant degree and represent a noticeable change from usual behavior:
   1. Inflated self-esteem or grandiosity.
   2. Decreased need for sleep (e.g., feels rested after only 3 hours of sleep).
   3. More talkative than usual or pressure to keep talking.
   4. Flight of ideas or subjective experience that thoughts are racing.
   5. Distractibility (i.e., attention too easily drawn to unimportant or irrelevant external stimuli), as reported or observed.
   6. Increase in goal-directed activity (either socially, at work or school, or sexually) or psychomotor agitation (i.e., purposeless non-goal-directed activity).
   7. Excessive involvement in activities that have a high potential for painful consequences (e.g., engaging in unrestrained buying sprees, sexual indiscretions, or foolish business investments).

C. The mood disturbance is sufficiently severe to cause marked impairment in social or occupational functioning or to necessitate hospitalization to prevent harm to self or others, or there are psychotic features.

D. The episode is not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication, other treatment) or another medical condition.

Note: A full manic episode that emerges during antidepressant treatment (e.g., medication, electroconvulsive therapy) but persists at a fully syndromal level beyond the physiological effect of that treatment is sufficient evidence for a manic episode and, therefore, a bipolar I diagnosis.

Note: Criteria A–D constitute a manic episode. At least one lifetime manic episode is required for the diagnosis of bipolar I disorder.

Hypomanic Episode

A. A distinct period of abnormally and persistently elevated, expansive, or irritable mood and abnormally and persistently increased activity or energy, lasting at least 4 consecutive days and present most of the day, nearly every day.

B. During the period of mood disturbance and increased energy and activity, three (or more) of the following symptoms (four if the mood is only irritable) have persisted, represent a noticeable change from usual behavior, and have been present to a significant degree:
   1. Inflated self-esteem or grandiosity.
   2. Decreased need for sleep (e.g., feels rested after only 3 hours of sleep).
   3. More talkative than usual or pressure to keep talking.
   4. Flight of ideas or subjective experience that thoughts are racing.
   5. Distractibility (i.e., attention too easily drawn to unimportant or irrelevant external stimuli), as reported or observed.
   6. Increase in goal-directed activity (either socially, at work or school, or sexually) or psychomotor agitation.
   7. Excessive involvement in activities that have a high potential for painful consequences (e.g., engaging in unrestrained buying sprees, sexual indiscretions, or foolish business investments).

C. The episode is associated with an unequivocal change in functioning that is uncharacteristic of the individual when not symptomatic.

D. The disturbance in mood and the change in functioning are observable by others.

E. The episode is not severe enough to cause marked impairment in social or occupational functioning or to necessitate hospitalization. If there are psychotic features, the episode is, by definition, manic.

F. The episode is not attributable to the physiological effects of a substance (e.g., a drug of abuse, a medication, other treatment) or another medical condition.

Note: A full hypomanic episode that emerges during antidepressant treatment (e.g., medication, electroconvulsive therapy) but persists at a fully syndromal level beyond the physiological effect of that treatment is sufficient evidence for a hypomanic episode diagnosis. However, caution is indicated so that one or two symptoms (particularly increased irritability, edginess, or agitation following antidepressant use) are not taken as sufficient for diagnosis of a hypomanic episode, nor necessarily indicative of a bipolar diathesis.

Note: Criteria A–F constitute a hypomanic episode. Hypomanic episodes are common in bipolar I disorder but are not required for the diagnosis of bipolar I disorder.

Major Depressive Episode

A. Five (or more) of the following symptoms have been present during the same 2-week period and represent a change from previous functioning; at least one of the symptoms is either (1) depressed mood or (2) loss of interest or pleasure.

Note: Do not include symptoms that are clearly attributable to another medical condition.
   1. Depressed mood most of the day, nearly every day, as indicated by either subjective report (e.g., feels sad, empty, or hopeless) or observation made by others (e.g., appears tearful). (**Note:** In children and adolescents, can be irritable mood.)
   2. Markedly diminished interest or pleasure in all, or almost all, activities most of the day, nearly every day (as indicated by either subjective account or observation).
   3. Significant weight loss when not dieting or weight gain (e.g., a change of more than 5% of body weight in a month), or decrease or increase in appetite nearly every day. (**Note:** In children, consider failure to make expected weight gain.)
   4. Insomnia or hypersomnia nearly every day.
   5. Psychomotor agitation or retardation nearly every day (observable by others, not merely subjective feelings of restlessness or being slowed down).
   6. Fatigue or loss of energy nearly every day.
   7. Feelings of worthlessness or excessive or inappropriate guilt (which may be delusional) nearly every day (not merely self-reproach or guilt about being sick).
   8. Diminished ability to think or concentrate, or indecisiveness, nearly every day (either by subjective account or as observed by others).
   9. Recurrent thoughts of death (not just fear of dying); recurrent suicidal ideation without a specific plan; a specific suicide plan; or a suicide attempt.

B. The symptoms cause clinically significant distress or impairment in social, occupational, or other important areas of functioning.

C. The episode is not attributable to the physiological effects of a substance or another medical condition.

Note: Criteria A–C constitute a major depressive episode. Major depressive episodes are common in bipolar I disorder but are not required for the diagnosis of bipolar I disorder.

Note: Responses to a significant loss (e.g., bereavement, financial ruin, losses from a natural disaster, a serious medical illness or disability) may include the feelings of intense sadness, rumination about the loss, insomnia, poor appetite, and weight loss noted in Criterion A, which may resemble a depressive episode. Although such symptoms may be understandable or considered appropriate to the loss, the presence of a major depressive episode in addition to the normal response to a significant loss should also be carefully considered. This decision inevitably requires the exercise of clinical judgment based on the individual's history and the cultural norms for the expression of distress in the context of loss.

Bipolar I Disorder

A. Criteria have been met for at least one manic episode (Criteria A–D under "Manic Episode" above).

B. At least one manic episode is not better explained by schizoaffective disorder and is not superimposed on schizophrenia, schizophreniform disorder, delusional disorder, or other specified or unspecified schizophrenia spectrum and other psychotic disorder.

TABLE 463-9 Clinical Pharmacology of Mood Stabilizers

AGENT AND DOSING	SIDE EFFECTS AND OTHER EFFECTS
Lithium	**Common Side Effects**
Starting dose: 300 mg bid or tid Therapeutic blood level: 0.8–1.2 meq/L	Nausea/anorexia/diarrhea, fine tremor, thirst, polyuria, fatigue, weight gain, acne, folliculitis, neutrophilia, hypothyroidism Blood level is increased by thiazides, tetracyclines, and NSAIDs Blood level is decreased by bronchodilators, verapamil, and carbonic anhydrase inhibitors *Rare side effects:* Neurotoxicity, renal toxicity, hypercalcemia, ECG changes
Valproic Acid	**Common Side Effects**
Starting dose: 250 mg tid Therapeutic blood level: 50–125 µg/mL	Nausea/anorexia, weight gain, sedation, tremor, rash, alopecia Inhibits hepatic metabolism of other medications *Rare side effects:* Pancreatitis, hepatotoxicity, Stevens-Johnson syndrome
Carbamazepine/ Oxcarbazepine	**Common Side Effects**
Starting dose: 200 mg bid for carbamazepine, 150 mg bid for oxcarbazepine Therapeutic blood level: 4–12 µg/mL for carbamazepine	Nausea/anorexia, sedation, rash, dizziness/ataxia Carbamazepine, but not oxcarbazepine, induces hepatic metabolism of other medications *Rare side effects:* Hyponatremia, agranulocytosis, Stevens-Johnson syndrome
Lamotrigine	**Common Side Effects**
Starting dose: 25 mg/d	Rash, dizziness, headache, tremor, sedation, nausea *Rare side effect*: Stevens-Johnson syndrome

Abbreviations: ECG, electrocardiogram; NSAIDs, nonsteroidal anti-inflammatory drugs.

therapy, light therapy, and rTMS may also be effective. Loss of efficacy over time may be observed with any of the mood-stabilizing agents. In such situations, an alternative agent or combination therapy is usually helpful.

SOMATIC SYMPTOM DISORDER

Many patients presenting in general medical practice, perhaps as many as 5–7%, will experience a somatic symptom(s) as particularly distressing and preoccupying, to the point that it comes to dominate their thoughts, feelings, and beliefs and interferes to a varying degree with everyday functioning. Although the absence of a medical explanation for these complaints was historically emphasized as a diagnostic element, it has been recognized that the patient's interpretation and elaboration of the experience is the critical defining factor and that patients with well-established medical causation may qualify for the diagnosis. Multiple complaints are typical, but severe single symptoms can occur as well. Comorbidity with depressive and anxiety disorders is common and may affect the severity of the experience and its functional consequences. Personality factors may be a significant risk factor, as may a low level of educational or socioeconomic status or a history of recent stressful life events. Cultural factors are relevant as well and should be incorporated into the evaluation. Individuals who have persistent preoccupations about having or acquiring a serious illness, but who do not have a specific somatic complaint, may qualify for a related diagnosis—illness anxiety disorder. The diagnosis of conversion disorder (functional neurologic symptom disorder) is used to specifically identify individuals whose somatic complaints involve one or more symptoms of altered voluntary motor or sensory function that cannot be medically explained and that cause significant distress or impairment or require medical evaluation.

In *factitious illnesses*, the patient consciously and voluntarily produces physical symptoms of illness. The term *Munchausen's syndrome* is reserved for individuals with particularly dramatic, chronic, or severe factitious illness. In true factitious illness, the sick role itself is gratifying. A variety of signs, symptoms, and diseases have been either simulated or caused by factitious behavior, the most common including chronic diarrhea, fever of unknown origin, intestinal bleeding or hematuria, seizures, and hypoglycemia. Factitious disorder is usually not diagnosed until 5–10 years after its onset, and it can produce significant social and medical costs. In *malingering*, the fabrication derives from a desire for some external reward such as a narcotic medication or disability reimbursement.

TREATMENT

Somatic Symptom Disorder and Related Disorders

Patients with somatic symptom disorder are frequently subjected to many diagnostic tests and exploratory surgeries in an attempt to find their "real" illness. Such an approach is doomed to failure and does not address the core issue. Successful treatment is best achieved through behavior modification, in which access to the physician is tightly regulated and adjusted to provide a sustained and predictable level of support that is less clearly contingent on the patient's level of presenting distress. Visits can be brief and should not be associated with a need for a diagnostic or treatment action. Although the literature is limited, some patients may benefit from antidepressant treatment.

Any attempt to confront the patient usually creates a sense of humiliation and causes the patient to abandon treatment from that caregiver. A better strategy is to introduce psychological causation as one of a number of possible explanations in the differential diagnoses that are discussed. Without directly linking psychotherapeutic intervention to the diagnosis, the patient can be offered a face-saving means by which the pathologic relationship with the health care system can be examined and alternative approaches to life stressors developed. Specific medical treatments also may be indicated and effective in treating some of the functional consequences of conversion disorder.

FEEDING AND EATING DISORDERS

CLINICAL MANIFESTATIONS

Feeding and eating disorders constitute a group of conditions in which there is a persistent disturbance of eating or associated behaviors that significantly impair an individual's physical health or psychosocial functioning. In DSM-5-TR, the described categories (with the exception of pica) are defined to be mutually exclusive in a given episode, based on the understanding that although they are phenotypically similar in some ways, they differ in course, prognosis, and effective treatment interventions.

PICA

Pica is diagnosed when the individual, aged >2 years, eats one or more nonnutritive, nonfood substances for a month or more and requires medical attention as a result. There is usually no specific aversion to food in general but a preferential choice to ingest substances such as clay, starch, soap, paper, or ash. The diagnosis requires the exclusion of specific culturally approved practices and has not been commonly found to be caused by a specific nutritional deficiency. Onset is most common in childhood, but the disorder can occur in association with other major psychiatric conditions in adults. An association with pregnancy has been observed, but the condition is only diagnosed when medical risks are increased by the behavior.

RUMINATION DISORDER

In this condition, individuals who have no demonstrable associated gastrointestinal or other medical condition repeatedly regurgitate their food after eating and then either rechew or swallow it or spit it out. The behavior typically occurs on a daily basis and must persist for at least 1 month. Weight loss and malnutrition are common sequelae, and individuals may attempt to conceal their behavior, either by covering

their mouth or through social avoidance while eating. In infancy, the onset is typically between 3 and 12 months of age, and the behavior may remit spontaneously, although in some, it appears to be recurrent.

AVOIDANT/RESTRICTIVE FOOD INTAKE DISORDER

The cardinal feature of this disorder is avoidance or restriction of food intake, usually stemming from a lack of interest in or distaste of food and associated with weight loss, nutritional deficiency, dependency on nutritional supplementation, or marked impairment in psychosocial functioning, either alone or in combination. Culturally approved practices, such as fasting or a lack of available food, must be excluded as possible causes. The disorder is distinguished from anorexia nervosa by the presence of emotional factors, such as a fear of gaining weight and distortion of body image in the latter condition. Onset is usually in infancy or early childhood, but avoidant behaviors may persist into adulthood. The disorder is equally prevalent in males and females and is frequently comorbid with anxiety and cognitive and attention-deficit disorders and situations of familial stress. Developmental delay and functional deficits may be significant if the disorder is long-standing and unrecognized.

ANOREXIA NERVOSA

Individuals are diagnosed with anorexia nervosa if they restrict their caloric intake to a degree that their body weight deviates significantly from age, gender, health, and developmental norms and if they also exhibit a fear of gaining weight and an associated disturbance in body image. The condition is further characterized by differentiating those who achieve their weight loss predominantly through restricting intake or by excessive exercise (restricting type) from those who engage in recurrent binge eating and/or subsequent purging, self-induced vomiting, and usage of enemas, laxatives, or diuretics (binge-eating/purging type). Such subtyping is more state- than trait-specific, as individuals may transition from one profile to the other over time. Determination of whether an individual satisfies the primary criterion of significant low weight is complex and must be individualized, using all available historical information and comparison of body habitus to international body-mass norms and guidelines.

Individuals with anorexia nervosa frequently lack insight into their condition and are in denial about possible medical consequences; they often are not comforted by their achieved weight loss and persist in their behaviors despite having met previously self-designated weight goals. Alterations in the circuitry of reward sensitivity and executive function have been reported in anorexia, implicating disturbances in frontal cortex and anterior insula regulation of interoceptive awareness of satiety and hunger. Neurochemical findings, including the role of ghrelin, remain controversial.

Onset is most common in adolescence, although onset in later life can occur. Many more females than males are affected, with a lifetime prevalence in women of up to 4%. The disorder appears most prevalent in postindustrialized and urbanized countries and is frequently comorbid with preexisting anxiety disorders. The medical consequences of prolonged anorexia nervosa are multisystemic and can be life-threatening in severe presentations. Changes in laboratory values may be present, including leukopenia with lymphocytosis, elevations in blood urea nitrogen, and metabolic alkalosis and hypokalemia when purging is present. History and physical examination may reveal amenorrhea in females, skin abnormalities (petechiae, lanugo hair, dryness), and signs of hypometabolic function, including hypotension, hypothermia, and sinus bradycardia. Endocrine effects include hypogonadism, growth hormone resistance, and hypercortisolemia. Osteoporosis is a longer-term concern.

The course of the disorder is variable, with some individuals recovering after a single episode, while others exhibit recurrent episodes or a chronic course. Untreated anorexia has a mortality of 5.1/1000, the highest among psychiatric conditions. Maudsley Anorexia Nervosa Treatment for Adults (MANTRA) and eating disorder–focused cognitive-behavior therapy have proven to be effective therapies, with strict behavioral contingencies used when weight loss becomes critical. No pharmacologic intervention has proven to be specifically beneficial, but comorbid depression and anxiety should be treated. Weight gain should be undertaken gradually with a goal of 0.5–1 pound per week to prevent refeeding syndrome. Most individuals are able to achieve remission within 5 years of the original diagnosis.

BULIMIA NERVOSA

Bulimia nervosa describes individuals who engage in recurrent and frequent (at least once a week for 3 months) periods of binge eating and who then resort to compensatory behaviors, such as self-induced purging, enemas, use of laxatives, or excessive exercise, to avoid weight gain. Binge eating itself is defined as excessive food intake in a prescribed period of time, usually <2 h. As in anorexia nervosa, disturbances in body image occur and promote the behavior, but unlike in anorexia, individuals are of normal weight or even somewhat overweight. Subjects typically describe a loss of control and express shame about their actions, and often relate that their episodes are triggered by feelings of negative self-esteem or social stresses. The lifetime prevalence in women is ~2%, with a 10:1 female-to-male ratio. The disorder typically begins in adolescence and may be persistent over a number of years. Transition to anorexia occurs in only 10–15% of cases. Many of the medical risks associated with bulimia nervosa parallel those of anorexia nervosa and are a direct consequence of purging, including fluid and electrolyte disturbances and cardiac conduction abnormalities. Physical examination often results in no specific findings, but dental erosion and parotid gland enlargement may be present. Effective treatment approaches include SSRI antidepressants, usually in combination with cognitive-behavioral, emotion regulation, or interpersonal-based psychotherapies.

BINGE-EATING DISORDER

Binge-eating disorder is distinguished from bulimia nervosa by the absence of compensatory behaviors to prevent weight gain after an episode and by a lack of effort to restrict weight gain between episodes. Other features are similar, including distress over the behavior and the experience of loss of control, resulting in eating more rapidly or in greater amounts than intended or eating when not hungry. The 12-month prevalence in females is 1.6%, with a much lower female-to-male ratio than bulimia nervosa. Little is known about the course of the disorder, given its recent categorization, but its prognosis is markedly better than for other eating disorders, both in terms of its natural course and response to treatment. Transition to other eating disorder conditions is thought to be rare.

PERSONALITY DISORDERS

CLINICAL MANIFESTATIONS

Personality disorders are characteristic patterns of thinking, feeling, and interpersonal behavior that are relatively inflexible and cause significant functional impairment or subjective distress for the individual. The observed behaviors are not secondary to another mental disorder, nor are they precipitated by substance abuse or a general medical condition. This distinction is often difficult to make in clinical practice, because personality change may be the first sign of serious neurologic, endocrine, or other medical illness. Patients with frontal-lobe tumors, for example, can present with changes in motivation and personality while the results of the neurologic examination remain within normal limits. Individuals with personality disorders are often regarded as "difficult patients" in clinical medical practice because they are seen as excessively demanding and/or unwilling to follow recommended treatment plans. Although DSM-5-TR portrays personality disorders as qualitatively distinct categories, there is an alternative and emerging perspective that personality characteristics vary as a continuum between normal functioning and formal mental disorder, the essential features being moderate or greater impairment in self/interpersonal functioning and one or more pathological personality traits.

Personality disorders have been grouped into three overlapping clusters. *Cluster A* includes paranoid, schizoid, and schizotypal personality disorders. It includes individuals who are odd and eccentric and who maintain an emotional distance from others. Individuals have a restricted emotional range and remain socially isolated. Patients with schizotypal personality disorder frequently have unusual perceptual

experiences and express magical beliefs about the external world. The essential feature of paranoid personality disorder is a pervasive mistrust and suspiciousness of others to an extent that is unjustified by available evidence. *Cluster B* disorders include antisocial, borderline, histrionic, and narcissistic types and describe individuals whose behavior is impulsive, excessively emotional, and erratic. *Cluster C* incorporates avoidant, dependent, and obsessive-compulsive personality types; enduring traits are anxiety and fear. The boundaries between cluster types are to some extent artificial, and many patients who meet criteria for one personality disorder also meet criteria for aspects of another. The risk of a comorbid major mental disorder is increased in patients who qualify for a diagnosis of personality disorder.

ETIOLOGY AND PATHOPHYSIOLOGY

Genetic studies have increasingly suggested a genetic contribution to the development of personality disorders. One study of 106,000 subjects identified nine loci significantly linked to aspects of neuroticism.

TREATMENT

Personality Disorders

Dialectical behavior therapy (DBT) is a cognitive-behavioral approach that focuses on behavioral change while providing acceptance, compassion, and validation of the patient. Several randomized trials have demonstrated the efficacy of DBT in the treatment of personality disorders. Antidepressant medications and low-dose antipsychotic drugs have some efficacy in cluster A personality disorders, whereas anticonvulsant mood-stabilizing agents and MAOIs may be considered for patients with cluster B diagnoses who show marked mood reactivity, behavioral dyscontrol, and/or rejection hypersensitivity. Anxious or fearful cluster C patients often respond to medications used for axis I anxiety disorders (see above). It is important that the physician and the patient have reasonable expectations vis-à-vis the possible benefit of any medication used and its side effects. Improvement may be subtle and observable only over time.

SCHIZOPHRENIA

CLINICAL MANIFESTATIONS

Schizophrenia is a heterogeneous syndrome characterized by perturbations of language, perception, thinking, social activity, affect, and volition. There are no pathognomonic features. The syndrome commonly begins in late adolescence, has an insidious (and less commonly, acute) onset, and, often, a poor outcome, progressing from social withdrawal and perceptual distortions to recurrent delusions and hallucinations. Patients may present with positive symptoms (such as conceptual disorganization, delusions, or hallucinations) or negative symptoms (loss of function, anhedonia, decreased emotional expression, impaired concentration, and diminished social engagement) and must have at least two of these for a 1-month period and continuous signs for at least 6 months to meet formal diagnostic criteria. Disorganized thinking or speech and grossly disorganized motor behavior, including catatonia, may also be present. As individuals age, positive psychotic symptoms tend to attenuate, and some measure of social and occupational function may be regained. "Negative" symptoms predominate in one-third of the schizophrenic population and are associated with a poor long-term outcome and a poor response to drug treatment. However, marked variability in the course and individual character of symptoms is typical.

The term *schizophreniform disorder* describes patients who meet the symptom requirements but not the duration requirements for schizophrenia, and *schizoaffective disorder* is used for those who manifest symptoms of schizophrenia and independent periods of mood disturbance. The terms *schizotypal* and *schizoid* refer to specific personality disorders and are discussed in that section. The diagnosis of delusional disorder is used for individuals who have delusions of various content for at least 1 month but who otherwise do not meet criteria for schizophrenia. Patients who experience a sudden onset of a brief (<1 month) alteration in thought processing, characterized by delusions, hallucinations, disorganized speech, or gross motor behavior, are most appropriately designated as having a brief psychotic disorder. Catatonia is recognized as a nonspecific syndrome that can occur as a consequence of other severe psychiatric/medical disorders and is diagnosed by the documentation of three or more of a cluster of motor and behavioral symptoms, including stupor, cataplexy, mutism, waxy flexibility, and stereotypy, among others. Prognosis depends not on symptom severity but on the response to antipsychotic medication. A permanent remission without recurrence does occasionally occur. About 10% of schizophrenic patients commit suicide.

Schizophrenia is present in 0.85% of individuals worldwide, with a lifetime prevalence of ~1–1.5%. An estimated 300,000 episodes of acute schizophrenia occur annually in the United States, resulting in direct and indirect costs of $155.7 billion.

DIFFERENTIAL DIAGNOSIS

The diagnosis is principally one of exclusion, requiring the absence of significant associated mood symptoms, any relevant medical condition, and substance abuse. Drug reactions that cause hallucinations, paranoia, confusion, or bizarre behavior may be dose-related or idiosyncratic; parkinsonian medications, clonidine, quinacrine, and procaine derivatives are the most common prescription medications associated with these symptoms. Drug causes should be ruled out in any case of newly emergent psychosis. The general neurologic examination in patients with schizophrenia is usually normal, but motor rigidity, tremor, and dyskinesias are noted in one-quarter of untreated patients.

EPIDEMIOLOGY AND PATHOPHYSIOLOGY

Epidemiologic surveys identify several risk factors for schizophrenia, including genetic susceptibility, early developmental insults, winter birth, and increasing parental age. Genetic factors are involved in at least a subset of individuals who develop schizophrenia. Schizophrenia is observed in ~6.6% of all first-degree relatives of an affected proband. If both parents are affected, the risk for offspring is 40%. The concordance rate for monozygotic twins is 50%, compared to 10% for dizygotic twins. Schizophrenia-prone families are also at risk for other psychiatric disorders, including schizoaffective disorder and *schizotypal* and *schizoid personality disorders*, the latter terms designating individuals who show a lifetime pattern of social and interpersonal deficits characterized by an inability to form close interpersonal relationships, eccentric behavior, and mild perceptual distortions. Large-scale GWASs have identified several hundred small effect risk loci and a few larger effect copy number variants, along with epigenetic effects, and have led to initial exploration in the clinical use of polygenic risk scores in diagnosis and prognosis. Pathways identified include ones involved in immunity, inflammation, and cell signaling. There is also recent evidence that brain gene expression in schizophrenia is similar to that seen in older aging adults without the disorder, implicating parallel mechanisms for cognitive deterioration.

TREATMENT

Schizophrenia

Antipsychotic agents **(Table 463-10)** are the cornerstone of acute and maintenance treatment of schizophrenia and are effective in the treatment of hallucinations, delusions, and thought disorders, regardless of etiology. The mechanism of action involves, at least in part, binding to dopamine D_2/D_3 receptors in the ventral striatum; the clinical potencies of traditional antipsychotic drugs parallel their affinities for the D_2 receptor, and even the newer "atypical" agents exert some degree of D_2 receptor blockade. All current neuroleptics induce expression of the immediate-early gene c-*fos* in the nucleus accumbens, a dopaminergic site connecting prefrontal and limbic cortices. The development of newer atypical neuroleptics, however, is increasingly focusing on different targets: D_3, 5-HT_{1A}, 5-HT_7, mGlu2/3, and muscarinic acetylcholine (M1, M4) receptors; α_1- and α_2-noradrenergic activity; and altering the relationship between 5-HT_2 and D_2 receptor activity, resulting in faster dissociation of D_2 binding and effects on neuroplasticity.

TABLE 463-10 Antipsychotic Agents

NAME	USUAL PO DAILY DOSE (mg)	SIDE EFFECTS	SEDATION	COMMENTS
First-Generation Antipsychotics				
Low potency				
Chlorpromazine (Thorazine)	100–1000	Anticholinergic effects; orthostasis; photosensitivity; cholestasis; QT prolongation	+++	EPSEs usually not prominent; can cause anticholinergic delirium in elderly patients
Thioridazine (Mellaril)	100–600			
Midpotency				
Trifluoperazine (Stelazine)	2–50	Fewer anticholinergic side effects	++	Well tolerated by most patients
Perphenazine (Trilafon)	4–64	Fewer EPSEs than with higher-potency agents	++	
Loxapine (Loxitane)	30–100	Frequent EPSEs	++	
Molindone (Moban)	30–100	Frequent EPSEs	0	Little weight gain
High potency				
Haloperidol (Haldol)	5–20	No anticholinergic side effects; EPSEs often prominent	0/+	Often prescribed in doses that are too high; long-acting injectable forms of haloperidol and fluphenazine available
Fluphenazine (Prolixin)	1–20	Frequent EPSEs	0/+	
Thiothixene (Navane)	2–50	Frequent EPSEs	0/+	
Second-Generation Antipsychotics				
Clozapine (Clozaril)	150–600	Agranulocytosis (1%); weight gain; seizures; drooling; hyperthermia	+ +	Requires weekly WBC count for first 6 months, then biweekly if stable
Risperidone (Risperdal)	2–8	Orthostasis	+	Requires slow titration; EPSEs observed with doses >6 mg qd
Olanzapine (Zyprexa)	10–30	Weight gain	++	Mild prolactin elevation
Quetiapine (Seroquel)	350–800	Sedation; weight gain; anxiety	+++	bid dosing
Ziprasidone (Geodon)	120–200	Orthostatic hypotension	+/++	Minimal weight gain; increases QT interval
Aripiprazole (Abilify)	10–30	Nausea, anxiety, insomnia	0/+	Mixed agonist/antagonist; extended-release available
Paliperidone (Invega)	3–12	Restlessness, EPSEs, increased prolactin, headache	+	Active metabolite of risperidone
Iloperidone (Fanapt)	12–24	Dizziness, hypotension	0/+	Requires dose titration; long-acting injectable available
Asenapine (Saphris)	10–20	Dizziness, anxiety, EPSEs, minimal weight gain	++	Sublingual tablets; bid dosing
Lurasidone (Latuda)	40–80	Nausea, EPSEs	++	Uses CYP3A4
Brexpiprazole (Rexulti)	1–4	Anxiety, dizziness, fatigue	++	CYP3A4 and 2D6 interactions
Pimavanserin (Nuplazid)	34	Edema, confusion, sedation	++	Approved for Parkinson's disease psychosis
Cariprazine (Vraylar)	1.5–6	EPSEs, vomiting	++	Preferential D_3 receptor affinity
Lumateperone (Caplyta)	42	Fatigue, dry mouth; no apparent metabolic/motor effects	++	5-HT_A > D_2 receptor affinity

Abbreviations: EPSEs, extrapyramidal side effects; WBC, white blood cell.

Conventional neuroleptics differ in their potency and side effect profile. Older agents, such as chlorpromazine and thioridazine, are more sedating and anticholinergic and more likely to cause orthostatic hypotension, whereas higher-potency antipsychotics, such as haloperidol, perphenazine, and thiothixene, are more likely to induce extrapyramidal side effects. The model "atypical" antipsychotic agent is clozapine, a dibenzodiazepine that has a greater potency in blocking the 5-HT_2 than the D_2 receptor and a much higher affinity for the D_4 than the D_2 receptor. Its principal disadvantage is a risk of blood dyscrasias. Paliperidone is a metabolite of risperidone and shares many of its properties. Unlike other antipsychotics, clozapine does not cause a rise in prolactin levels. Approximately 30% of patients who do not benefit from conventional antipsychotic agents will have a better response to this drug, which also has a demonstrated superiority to other antipsychotic agents in preventing suicide; however, its side effect profile makes it most appropriate for treatment-resistant cases. Risperidone, a benzisoxazole derivative, is more potent at 5-HT_2 than D_2 receptor sites, like clozapine, but it also exerts significant α_2 antagonism, a property that may contribute to its perceived ability to improve mood and increase motor activity. Risperidone is not as effective as clozapine in treatment-resistant cases but does not carry a risk of blood dyscrasias. Olanzapine is similar neurochemically to clozapine but has a significant risk of inducing weight gain. Quetiapine is distinct in having a weak D_2 effect but potent α_1 and histamine blockade. Ziprasidone causes minimal weight gain and is unlikely to increase prolactin but may increase QT prolongation. Aripiprazole also has little risk of weight gain or prolactin increase but may increase anxiety, nausea, and insomnia as a result of its partial agonist properties. Asenapine is associated with minimal weight gain and anticholinergic effect but may have a higher than expected risk of extrapyramidal symptoms (EPSs). Cariprazine, a D_2/D_3 partial agonist, has no QT or prolactin elevation risk but can result in EPS as well.

Antipsychotic agents are effective in 70% of patients presenting with a first episode. Improvement may be observed within hours or days, but full remission usually requires 6–8 weeks. The choice of agent depends principally on the side effect profile and cost of treatment or on a past personal or family history of a favorable response to the drug in question. Atypical agents appear to be more effective in treating negative symptoms and improving cognitive function. An equivalent treatment response can usually be achieved with relatively low doses of any drug selected (i.e., 4–6 mg/d of haloperidol, 10–15 mg of olanzapine, or 4–6 mg/d of risperidone). Doses in this range result in >80% D_2 receptor blockade, and there is little evidence that higher doses increase either the rapidity or degree of response. Maintenance treatment requires careful attention to the possibility of relapse and monitoring for the development of a movement disorder. Intermittent

drug treatment is less effective than regular dosing, but gradual dose reduction is likely to improve social functioning in many schizophrenic patients who have been maintained at high doses. If medications are completely discontinued, however, the relapse rate is 60% within 6 months. Long-acting injectable (LAI) preparations (risperidone, paliperidone, olanzapine, aripiprazole) are considered when noncompliance with oral therapy leads to relapses but should not be considered interchangeable because the agents differ in their indications, injection intervals and sites/volumes, and possible adverse reactions, among other factors. Extended treatment studies indicate a significant decrease in relapse with LAI usage. In treatment-resistant patients, a transition to clozapine usually results in rapid improvement, but a prolonged delay in response in some cases necessitates a 6- to 9-month trial for maximal benefit to occur.

Antipsychotic medications can cause a broad range of side effects, including lethargy, weight gain, postural hypotension, constipation, and dry mouth. Extrapyramidal symptoms such as dystonia, akathisia, and akinesia are also frequent with first-generation agents and may contribute to poor adherence if not specifically addressed. Anticholinergic and parkinsonian symptoms respond well to trihexyphenidyl, 2 mg bid, or benztropine mesylate, 1–2 mg bid. Akathisia may respond to beta blockers. In rare cases, more serious and occasionally life-threatening side effects may emerge, including hyperprolactinemia, ventricular arrhythmias, gastrointestinal obstruction, retinal pigmentation, obstructive jaundice, and neuroleptic malignant syndrome (characterized by hyperthermia, autonomic dysfunction, muscular rigidity, and elevated creatine phosphokinase levels). The most serious adverse effects of clozapine are agranulocytosis, which has an incidence of 1%, and induction of seizures, which has an incidence of 10%. Weekly white blood cell counts are required, particularly during the first 3 months of treatment.

The risk of type 2 diabetes mellitus appears to be increased in schizophrenia, and second-generation agents as a group, with the exception of lumateperone, produce greater adverse effects on glucose regulation, independent of effects on obesity, than traditional agents. Clozapine, olanzapine, and quetiapine seem more likely to cause hyperglycemia, weight gain, and hypertriglyceridemia than other atypical antipsychotic drugs. Close monitoring of plasma glucose and lipid levels is indicated with the use of these agents.

A serious side effect of long-term use of first-generation and, to a lesser extent, second-generation antipsychotic agents is tardive dyskinesia, characterized by repetitive, involuntary, and potentially irreversible movements of the tongue and lips (buccolinguo-masticatory triad) and, in approximately half of cases, choreoathetosis. Tardive dyskinesia has an incidence of 2–4% per year of exposure and a prevalence of 20% in chronically treated patients. The prevalence increases with age, total dose, and duration of drug administration and may involve formation of free radicals and perhaps mitochondrial energy failure. Valbenazine (Ingrezza), a vesicular monoamine transporter 2 inhibitor that depletes presynaptic dopamine, is approved for treatment of tardive dyskinesia.

The CATIE study, a large-scale investigation of the effectiveness of antipsychotic agents in "real-world" patients, revealed a high rate of discontinuation of treatment after >18 months. Olanzapine showed greater effectiveness than quetiapine, risperidone, perphenazine, or ziprasidone but also a higher discontinuation rate due to weight gain and metabolic effects. Surprisingly, perphenazine, a first-generation agent, showed little evidence of inferiority to newer drugs.

Drug treatment of schizophrenia is by itself insufficient. Educational efforts directed toward families and relevant community resources have proved to be necessary to maintain stability and optimize outcome. A collaborative treatment model using social cognition interventions and involving a multidisciplinary case-management team that seeks out and closely follows the patient in the community has proved particularly effective. Attempts to prevent schizophrenia through early identification and treatment (both psychosocial and psychopharmacologic) of high-risk children and adolescents are currently being evaluated.

ASSESSMENT AND EVALUATION OF VIOLENCE

Primary care physicians may encounter situations in which family, domestic, or societal violence is discovered or suspected. Such an awareness can carry legal and moral obligations; many state laws mandate reporting of child, spousal, and elder abuse. Physicians are frequently the first point of contact for both victim and abuser. Approximately 2 million older Americans and 1.5 million U.S. children are thought to experience some form of physical maltreatment each year. Spousal abuse is believed to be even more prevalent. An interview study of 24,000 women in 10 countries found a lifetime prevalence of physical or sexual violence that ranged from 15–71%; these individuals are more likely to suffer from depression, anxiety, and substance abuse and to have attempted suicide. In addition, abused individuals frequently express low self-esteem, vague somatic symptomatology, social isolation, and a passive feeling of loss of control. Although it is essential to treat these elements in the victim, the first obligation is to ensure that the perpetrator has taken responsibility for preventing any further violence. Substance abuse and/or dependence and serious mental illness in the abuser may contribute to the risk of harm and require direct intervention. Depending on the situation, law enforcement agencies, community resources such as support groups and shelters, and individual and family counseling can be appropriate components of a treatment plan. A safety plan should be formulated with the victim, in addition to providing information about abuse, its likelihood of recurrence, and its tendency to increase in severity and frequency. Antianxiety and antidepressant medications may sometimes be useful in treating the acute symptoms, but only if independent evidence for an appropriate psychiatric diagnosis exists.

464 Alcohol and Alcohol Use Disorders

Marc A. Schuckit

Most patients drink alcohol, including many who take this drug at levels that can adversely affect their medical conditions or interfere with the effects of prescribed medications. Therefore, it is important to note that this chapter presents information relevant to all patients, not just those with alcohol problems. Alcohol (beverage ethanol) has diverse and widespread effects on the body and impacts directly or indirectly on almost every neurochemical system in the brain. At even relatively low doses, this drug can exacerbate most medical problems and affect medications metabolized in the liver, and at higher doses, it can temporarily mimic many medical (e.g., diabetes) and psychiatric (e.g., depression) conditions. Frequent and heavier drinking is also associated with the treatable but life-threatening condition of alcohol use disorder (the modern term for alcoholism). Physicians from all specialties play an important role in *screening*, using *brief interventions*, and treating or *referring for treatment* individuals with repetitive alcohol problems, a process abbreviated as SBIRT.

The lifetime risk for repetitive serious alcohol problems (e.g., alcohol use disorder) in patients is at least 20% for men and 10% for women, regardless of a person's education or income, and U.S. yearly costs for these disorders exceed $249 billion. Although low doses of alcohol might have healthful benefits, drinking more than three standard drinks per day enhances the risk for cancer and vascular disease, and alcohol use disorders decrease the life span by ~10 years. Unfortunately, most clinicians have had only limited training in identifying and treating alcohol-related disorders.

PHARMACOLOGY AND NUTRITIONAL IMPACT OF ETHANOL

Ethanol blood levels are expressed as milligrams or grams of ethanol per deciliter (e.g., 100 mg/dL = 0.10 g/dL), with values of ~0.02 g/dL resulting from the ingestion of one typical drink. In round figures, a standard drink is 10–12 g of ethanol, as seen in 340 mL (12 oz) of beer, 115 mL (4 oz) of nonfortified wine, and 43 mL (1.5 oz) (a shot) of 80-proof (40% ethanol by volume) beverage (e.g., whisky); 0.5 L (1 pint) of 80-proof beverage contains ~160 g of ethanol (~16 standard drinks), and 750 mL of wine contains ~60 g of ethanol. These beverages also have additional components (*congeners*) that affect the drink's taste and might contribute to adverse effects on the body. Congeners include methanol, butanol, acetaldehyde, histamine, tannins, iron, and lead. As a depressant drug, alcohol acutely decreases neuronal activity and has similar behavioral effects and cross-tolerance with other depressants, including benzodiazepines, barbiturates, and some anticonvulsants.

Alcohol is absorbed from mucous membranes of the mouth and esophagus (in small amounts), from the stomach and large bowel (in modest amounts), and from the proximal portion of the small intestine (the major site). The rate of absorption is increased by rapid gastric emptying (as seen with carbonated beverages); by the absence of proteins, fats, or carbohydrates (which interfere with absorption); and by dilution to a modest percentage of ethanol (maximum at ~20% by volume).

Between 2% (at low blood alcohol concentrations) and 10% (at high blood alcohol concentrations) of ethanol is excreted directly through the lungs, urine, or sweat, but most is metabolized to acetaldehyde, primarily in the liver. The most important pathway occurs in the cell cytosol where alcohol dehydrogenase (ADH) produces acetaldehyde, which is then rapidly destroyed by aldehyde dehydrogenase (ALDH) in the cytosol and mitochondria (Fig. 464-1). A second pathway occurs in the microsomes of the smooth endoplasmic reticulum (the microsomal ethanol-oxidizing system [MEOS]) that is responsible for ≥10% of ethanol oxidation at high blood alcohol concentrations.

Although a standard drink contains ~300 kJ, or 70–100 kcal, these are devoid of minerals, proteins, and vitamins. In addition, alcohol

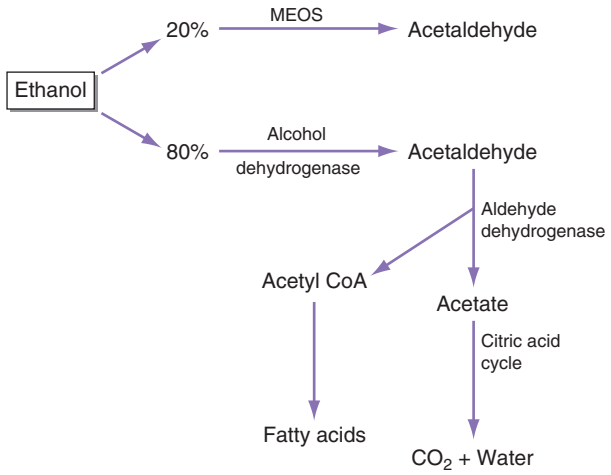

FIGURE 464-1 The metabolism of alcohol. CoA, coenzyme A; MEOS, microsomal ethanol oxidizing system.

interferes with absorption of vitamins in the small intestine and decreases their storage in the liver with modest effects on folate (folacin or folic acid), pyridoxine (B_6), thiamine (B_1), nicotinic acid (niacin, B_3), and vitamin A.

Heavy drinking in a fasting, healthy individual can produce transient hypoglycemia within 6–36 h, secondary to the acute actions of ethanol that decrease gluconeogenesis. This can result in temporary abnormal glucose tolerance tests (with a resulting erroneous diagnosis of diabetes mellitus) until the heavy drinker has abstained for 2–4 weeks. Alcohol ketoacidosis, probably reflecting a decrease in fatty acid oxidation coupled with poor diet or persistent vomiting, can be misdiagnosed as diabetic ketosis. With alcohol-related ketoacidosis, patients show an increase in serum ketones along with a mild increase in glucose but a large anion gap, a mild to moderate increase in serum lactate, and a β-hydroxybutyrate/lactate ratio of between 2:1 and 9:1 (with normal being 1:1).

In the brain, alcohol affects almost all neurotransmitter systems, with acute effects that are often the opposite of those seen following desistance after a period of heavy drinking. The most prominent acute actions relate to boosting γ-aminobutyric acid (GABA) activity, especially at $GABA_A$ receptors. Enhancement of this complex chloride channel system contributes to anticonvulsant, sleep-inducing, antianxiety, and muscle relaxation effects of all GABA-boosting drugs. Acutely administered alcohol produces a release of GABA, and continued use increases density of $GABA_A$ receptors, whereas alcohol withdrawal states are characterized by decreases in GABA-related activity. Equally important is the ability of acute alcohol to inhibit postsynaptic *N*-methyl-D-aspartate (NMDA) excitatory glutamate receptors, whereas chronic drinking and desistance are associated with an upregulation of these excitatory receptor subunits. The relationships between greater GABA and diminished NMDA receptor activity during acute intoxication and diminished GABA with enhanced NMDA actions during alcohol withdrawal explain much of intoxication and withdrawal phenomena.

As with all pleasurable activities, alcohol acutely increases dopamine levels in the ventral tegmentum and related brain regions, and this effect plays an important role in continued alcohol use, craving, and relapse. The changes in dopamine pathways are also linked to increases in "stress hormones," including cortisol and adrenocorticotropic hormone (ACTH), during intoxication and in the context of the stresses of withdrawal. Such alterations are likely to contribute to both feelings of reward during intoxication and depression during falling blood alcohol concentrations. Also closely linked to alterations in dopamine (especially in the nucleus accumbens) are alcohol-induced changes in opioid receptors, with acute alcohol causing release of β-endorphins.

Additional neurochemical changes include increases in synaptic levels of serotonin during acute intoxication and subsequent upregulation of serotonin receptors. Acute increases in nicotinic acetylcholine

TABLE 464-1 Effects of Blood Alcohol Levels in the Absence of Tolerance

BLOOD LEVEL, g/dL	USUAL EFFECT
0.02	Decreased inhibitions, a slight feeling of intoxication
0.08	Decrease in complex cognitive functions and motor performance
0.20	Obvious slurred speech, motor incoordination, irritability, and poor judgment
0.30	Light coma and depressed vital signs
0.40	Death

systems contribute to the impact of alcohol in the ventral tegmental region, which occurs in concert with enhanced dopamine activity. In the same regions, alcohol impacts on cannabinol receptors, with resulting release of dopamine, GABA, and glutamate as well as subsequent effects on brain reward circuits.

BEHAVIORAL EFFECTS, TOLERANCE, AND WITHDRAWAL

The acute effects of a drug depend on the dose, the rate of increase in plasma, the concomitant presence of other drugs, and past experience with the agent. "Legal intoxication" with alcohol in most states is based on a blood alcohol concentration of 0.08 g/dL, some states are considering lowering acceptable levels to <0.05 g/dL, and levels of 0.04 g/dL are cited for pilots in the United States and automobile drivers in some other countries. However, behavioral, psychomotor, and cognitive changes are seen at 0.02–0.04 g/dL (i.e., after one to two drinks) (Table 464-1). Deep but disturbed sleep can be seen at 0.15 g/dL in individuals who have not developed tolerance, and death can occur with levels between 0.30 and 0.40 g/dL. Beverage alcohol is probably responsible for more overdose deaths than any other drug.

Repeated use of alcohol contributes to the need for a greater number of standard drinks to produce effects originally observed with fewer drinks (acquired tolerance), a phenomenon involving at least three compensatory mechanisms. (1) After 1–2 weeks of daily drinking, *metabolic* or *pharmacokinetic tolerance* can be seen, with up to 30% increases in the rate of hepatic ethanol metabolism. This alteration disappears almost as rapidly as it develops. (2) *Cellular or pharmacodynamic tolerance* develops through neurochemical changes that maintain relatively normal physiologic functioning despite the presence of alcohol. Subsequent decreases in blood levels contribute to symptoms of withdrawal. (3) Individuals learn to adapt their behavior so that they can function better than expected under the influence of the drug (*learned* or *behavioral tolerance*).

The cellular changes caused by chronic ethanol exposure may not resolve for several weeks or longer following cessation of drinking. Rapid decreases in blood alcohol levels before that time can produce a withdrawal syndrome, which is most intense during the first 5 days, but with some symptoms (e.g., disturbed sleep and anxiety) lasting up to 4–6 months as part of a "protracted withdrawal" syndrome.

THE EFFECTS OF ETHANOL ON ORGAN SYSTEMS

Relatively low doses of alcohol (one or two drinks per day) may have mild potential beneficial effects by, for example, decreasing aggregation of platelets and potentially decreasing the risk for vascular dementia and Alzheimer's disease. However, any potential healthful effects disappear with the regular consumption of three or more drinks per day, and knowledge about the deleterious effects of alcohol can both help the physician to identify patients with alcohol use disorders and supply them with information that might help motivate changes in behavior.

NERVOUS SYSTEM

Approximately 35% of drinkers overall, including as many as 50% of drinking college students and a much higher proportion of individuals with alcohol use disorders, ever experience a *blackout*. This is an episode of temporary anterograde amnesia, in which the person was awake but forgot all (en bloc blackouts at blood alcohol levels >0.20 mg/dL) or part (fragmentary blackouts at >0.12 mg/dL) of what occurred during a drinking period.

Another common problem, one seen after as few as one or two drinks shortly before bedtime, is disturbed sleep. Although alcohol might initially help a person fall asleep, it disrupts sleep throughout the rest of the night. The stages of sleep are altered, and times spent in rapid eye movement (REM) and deep sleep early in the night are reduced. Alcohol relaxes muscles in the pharynx, which can cause snoring and exacerbate sleep apnea; symptoms of the latter occur in 75% of men with alcohol use disorders aged ≥60 years. Patients may also experience prominent and sometimes disturbing dreams later in the night. All these sleep impairments can contribute to relapses to drinking in persons with alcohol use disorders.

Other common consequences of alcohol use even at relatively low alcohol levels are impaired judgment and coordination, which increase the risk of injuries. In the United States, ~40% of drinkers have at some time driven while intoxicated. Heavy drinking can also be associated with headache, thirst, nausea, vomiting, and fatigue the following day, a hangover syndrome that is responsible for much missed work and school time and temporary cognitive deficits.

Chronic high alcohol doses cause *peripheral neuropathy* in ~10% of individuals with alcohol use disorders. Similar to diabetes, patients experience bilateral limb numbness, tingling, and paresthesias, all of which are more pronounced distally. Approximately 1% of those with alcohol use disorders develop *cerebellar degeneration* or *atrophy*, producing a syndrome of progressive unsteady stance and gait often accompanied by mild nystagmus. Perhaps 1 in 500 individuals with alcohol use disorders develop full *Wernicke's* (ophthalmoparesis, ataxia, and encephalopathy) and *Korsakoff's* (severe retrograde and anterograde amnesia) *syndromes*. These result from low levels of thiamine, especially in predisposed individuals with transketolase deficiencies. Repeated heavy drinking can contribute to *cognitive problems* and temporary memory impairment lasting for weeks to months after abstinence. Brain ventricular enlargement and widened cortical sulci on magnetic resonance imaging (MRI) and computed tomography (CT) scans occurs in ~50% of individuals with long-term alcohol use disorders; these changes are usually reversible if abstinence is maintained. Adolescents may be especially vulnerable to alcohol-related brain changes, as indicated by preclinical studies and prospective investigations in humans suggesting that alcohol exposure in the developing brain may adversely impact future cognitive processes related to cognition, reward recognition, and cue processing. There is no single "alcoholic dementia" syndrome; rather, this label describes patients who have irreversible cognitive changes (possibly from diverse causes) in the context of chronic alcohol use disorders.

Psychiatric Comorbidity Alcohol temporarily alters brain neurochemistry in a manner similar to ways observed in some psychiatric conditions, resulting in mood, anxiety, and psychotic disorders. However, those alcohol-induced psychiatric symptoms that are only observed during intense intoxication or withdrawal syndromes are likely to disappear within days to weeks of abstinence. For example, while about 40% of individuals with alcohol use disorder will at some point meet criteria for a major depressive episode, about half of those conditions are temporary substance-induced mood disorders that are likely to disappear within a month of abstinence without the use of antidepressant medications. In addition, several preexisting psychiatric disorders increase the risk for future alcohol use disorder including schizophrenia, manic-depressive disease, posttraumatic stress disorder, and anxiety syndromes such as panic disorder (Chap. 463). The comorbidities of alcohol use disorders with independent psychiatric disorders might represent an overlap in genetic vulnerabilities, impaired judgment regarding the use of alcohol as a consequence of the independent psychiatric condition, or an attempt to use alcohol to alleviate symptoms of the disorder or side effects of medications.

Treatment of all forms of alcohol-induced psychopathology includes helping patients achieve abstinence and offering supportive care, as well as reassurance and "talk therapy" such as cognitive-behavioral

approaches. However, with the exception of short-term antipsychotic medications for substance-induced psychoses, substance-induced psychiatric conditions only rarely require medications. Recovery is likely within several days to 4 weeks of abstinence. Conversely, because alcohol-induced conditions are temporary and do not indicate a need for long-term pharmacotherapy, a history of heavy alcohol intake is an important part of the workup for any patient who presents with any of these psychiatric syndromes.

THE GASTROINTESTINAL SYSTEM

Esophagus and Stomach Alcohol can cause inflammation of the esophagus and stomach causing epigastric distress and gastrointestinal bleeding, making alcohol one of the most common causes of hemorrhagic gastritis. Violent vomiting can produce severe bleeding through a Mallory-Weiss lesion, a longitudinal tear in the mucosa at the gastroesophageal junction.

Pancreas and Liver The incidence of acute pancreatitis (~25 per 1000 per year) is almost threefold higher in individuals with alcohol use disorders than in the general population, accounting for an estimated 10% or more of the total cases. Alcohol impairs gluconeogenesis in the liver, resulting in a fall in the amount of glucose produced from glycogen, increased lactate production, and decreased oxidation of fatty acids. These contribute to an increase in fat accumulation in liver cells. In healthy individuals, these changes are reversible, but with repeated exposure to ethanol, especially daily heavy drinking, more severe changes in the liver occur, including alcohol-induced hepatitis, perivenular sclerosis, and cirrhosis, with the latter observed in an estimated 15% of individuals with alcohol use disorders (Chap. 353). Perhaps through an enhanced vulnerability to infections, individuals with alcohol use disorders have an elevated rate of hepatitis C, and drinking in the context of that disease is associated with more severe liver deterioration.

CANCER

As few as 1.5 drinks per day increases a woman's risk of breast cancer 1.4-fold. For both sexes, four drinks per day increases the risk for oral and esophageal cancers approximately threefold and rectal cancers by a factor of 1.5; seven to eight or more drinks per day produces an approximately fivefold increased risk for many other cancers. These consequences may result directly from cancer-promoting effects of alcohol and acetaldehyde or indirectly by interfering with immune homeostasis.

HEMATOPOIETIC SYSTEM

Ethanol causes an increase in red blood cell size (mean corpuscular volume [MCV]), which reflects its effects on stem cells. If heavy drinking is accompanied by folic acid deficiency, there can also be hypersegmented neutrophils, reticulocytopenia, and a hyperplastic bone marrow; if malnutrition is present, sideroblastic changes can be observed. Chronic heavy drinking can decrease production of white blood cells, decrease granulocyte mobility and adherence, and impair delayed-hypersensitivity responses to novel antigens (with a possible false-negative tuberculin skin test). Associated immune deficiencies can contribute to vulnerability toward infections, including hepatitis and HIV, and interfere with their treatment. Finally, many individuals with alcohol use disorders have mild thrombocytopenia, which usually resolves within a week of abstinence unless there is hepatic cirrhosis or congestive splenomegaly.

CARDIOVASCULAR SYSTEM

Acutely, ethanol decreases myocardial contractility and causes peripheral vasodilation, with a resulting mild decrease in blood pressure and a compensatory increase in cardiac output. Exercise-induced increases in cardiac oxygen consumption are higher after alcohol intake. These acute effects have little clinical significance for the average healthy drinker but can be problematic when persisting cardiac disease is present.

The consumption of three or more drinks per day results in a dose-dependent increase in blood pressure, which returns to normal within weeks of abstinence. Thus, heavy drinking is an important factor in mild to moderate hypertension. Chronic heavy drinkers also have a sixfold increased risk for coronary artery disease, related, in part, to increased low-density lipoprotein cholesterol, and carry an increased risk for cardiomyopathy through direct effects of alcohol on heart muscle. Symptoms of the latter include unexplained arrhythmias in the presence of left ventricular impairment, heart failure, hypocontractility of heart muscle, and dilation of all four heart chambers with associated potential mural thrombi and mitral valve regurgitation. Atrial or ventricular arrhythmias, especially paroxysmal tachycardia, can also occur temporarily after heavy drinking in individuals showing no other evidence of heart disease—a syndrome known as the "holiday heart."

GENITOURINARY SYSTEM CHANGES, SEXUAL FUNCTIONING, AND FETAL DEVELOPMENT

Heavy drinking in adolescence can affect normal sexual development and reproductive onset. At any age, modest ethanol doses (e.g., blood alcohol concentrations of 0.06 g/dL) can increase sexual drive but also decrease erectile capacity in men. Even in the absence of liver impairment, a significant minority of chronic heavy-drinking men show irreversible testicular atrophy with shrinkage of the seminiferous tubules, decreases in ejaculate volume, and a lower sperm count (Chap. 403).

The repeated ingestion of high doses of ethanol by women can result in amenorrhea, a decrease in ovarian size, absence of corpora lutea with associated infertility, and an increased risk of spontaneous abortion. Drinking during pregnancy results in the rapid placental transfer of both ethanol and acetaldehyde, which may contribute to a range of consequences known as fetal alcohol spectrum disorder (FASD). One severe result is the *fetal alcohol syndrome* (FAS), seen in ~5% of children born to heavy-drinking mothers, which can include any of the following: facial changes with epicanthal eye folds; poorly formed ear concha; small teeth with faulty enamel; cardiac atrial or ventricular septal defects; an aberrant palmar crease and limitation in joint movement; and microcephaly with intellectual impairment. Less pervasive FASD conditions include combinations of low birth weight, a lower intelligence quotient (IQ), hyperactive behavior, and some modest cognitive deficits. The amount of ethanol required and the time of vulnerability during pregnancy have not been defined, making it advisable for pregnant women to abstain from alcohol completely.

OTHER EFFECTS

Between one-half and two-thirds of individuals with alcohol use disorders have skeletal muscle weakness caused by acute *alcoholic myopathy*, a condition that improves but that might not fully remit with abstinence. Effects of repeated heavy drinking on the *skeletal system* include changes in calcium metabolism, lower bone density, and decreased growth in the epiphyses, leading to an increased risk for fractures and osteonecrosis of the femoral head. *Hormonal changes* include an increase in cortisol levels, which can remain elevated during heavy drinking; inhibition of vasopressin secretion at rising blood alcohol concentrations and enhanced secretion at falling blood alcohol concentrations (with the final result that most individuals with alcohol use disorders are likely to be slightly overhydrated); a modest and reversible decrease in serum thyroxine (T_4); and a more marked decrease in serum triiodothyronine (T_3). Hormone irregularities may disappear after a month or more of abstinence.

ALCOHOL USE DISORDERS

Because many drinkers occasionally imbibe to excess, temporary alcohol-related problems are common, especially in the late teens to the late twenties. However, repeated problems in multiple life areas can indicate an alcohol use disorder as defined in the fifth edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-5).

DEFINITIONS AND EPIDEMIOLOGY

An *alcohol use disorder* (also called *alcoholism* or *alcohol dependence* in prior diagnostic manuals) is defined in DSM-5 of the American Psychiatric Association as repeated alcohol-related difficulties in at least 2 of 11 life areas that cluster together in the same 12-month period (Table 464-2). Ten of the 11 items in DSM-5 (published in 2013) were

TABLE 464-2 *Diagnostic and Statistical Manual of Mental Disorders*, Fifth Edition, Classification of Alcohol Use Disorder (AUD)

Criteria
Two or more of the following items occurring in the same 12-month period must be endorsed for the diagnosis of an alcohol use disorder[a]:
Drinking resulting in recurrent failure to fulfill role obligations
Recurrent drinking in hazardous situations
Continued drinking despite alcohol-related social or interpersonal problems
Tolerance
Withdrawal, or substance use for relief/avoidance of withdrawal
Drinking in larger amounts or for longer than intended
Persistent desire/unsuccessful attempts to stop or reduce drinking
Great deal of time spent obtaining, using, or recovering from alcohol
Important activities given up/reduced because of drinking
Continued drinking despite knowledge of physical or psychological problems caused by alcohol
Alcohol craving

[a] *Mild AUD:* 2–3 criteria required; *moderate AUD*: 4–5 items endorsed; *severe AUD:* 6 or more items endorsed.

taken directly from the dependence and abuse criteria in DSM-IV, after deleting legal problems and adding craving. Thus, diagnoses established across the two systems agree at >.84. Severity of DSM-5 alcohol use disorder is based on the number of items endorsed: mild is two or three items; moderate is four or five; and severe is six or more of the 11 criterion items.

The lifetime risk for an alcohol use disorder in most Western countries is ~10–20% for men and 5–10% for women; higher rates are seen in individuals who seek help from health care deliverers. Between 2001 and 2013, the proportion of the U.S. population with a current (i.e., past 12 months) alcohol use disorder increased by 49% with increases of almost 100% in women, African Americans, and individuals aged ≥45. Rates are similar in the United States, Canada, Germany, Australia, and the United Kingdom; tend to be lower in most Mediterranean countries, such as Italy, Greece, and Israel; and may be higher in Ireland, France, Eastern Europe (e.g., Russia), and Scandinavia. An even higher lifetime prevalence has been reported for most native cultures, including Native Americans, Eskimos, Maori groups, and aboriginal tribes of Australia. These differences in prevalence reflect both cultural and genetic influences, as described below. In Western countries, the typical individual with alcohol use disorder has a family and a career, and the lifetime risk among physicians is similar to that of the general population.

GENETICS

Some of the most exciting recent research developments into alcohol-related disorders have clarified the contribution of genetic influences to these conditions. These investigations include how variations in genes relate to environmental and attitudinal mediators of genetic effects. Understanding how specific gene variations contribute to the risk for a condition has the potential to help with early identification of individuals at high risk, development of effective prevention efforts, and, perhaps, identifying individuals most likely to respond to specific medications.

Approximately 60% of the risk for alcohol use disorder is attributed to genes, as indicated by the fourfold higher risk in children with an alcohol use disorder parent (even if adopted early in life and raised by nonalcoholics) and a higher risk in identical twins compared to fraternal twins of affected individuals. Like most medical and psychiatric conditions that are referred to as complex genetically influenced disorders, the risk for alcohol use disorders is related to hundreds of gene variations, many of which explain <1% of the risk. As a result, vulnerabilities toward the condition are often approached by considering multiple gene variations at the same time using polygenic risk scores. These genetic variations operate primarily through intermediate characteristics that subsequently combine with environmental influences to alter the risk for heavy drinking and alcohol problems. These include genes relating to a high risk for all substance use disorders that operate through impulsivity, schizophrenia, and bipolar disorder. Another characteristic, an intense skin flushing response when drinking, decreases risk for only alcohol use disorders, and not substance use conditions related to other drugs, through gene variations for several alcohol-metabolizing enzymes, especially ALDH (a mutation only seen in Japanese, Chinese, and Korean individuals), and to a lesser extent, variations in ADH.

An additional genetically influenced characteristic that increases the risk for heavy drinking, a low level of response or low sensitivity to alcohol, can be seen very early in the drinking career and before acquired tolerance or alcohol used disorders develop. The low response per drink operates, in part, through variations in genes relating to calcium and potassium channels, GABA, nicotinic, dopamine, and serotonin systems. Prospective studies have demonstrated that this need for higher doses of alcohol to achieve effects predicts future heavy drinking, alcohol problems, and alcohol use disorders, but not problems with drugs other than alcohol. The impact of a low response to alcohol on adverse drinking outcomes is partially mediated by a range of environmental and attitudinal influences, including the selection of heavier-drinking friends, more positive expectations of the effects of high doses of alcohol, and using alcohol to cope with stress. Several studies of college freshmen demonstrated that helping students who have a low sensitivity to alcohol modify these influences was associated with lower drinking quantities and fewer alcohol-related problems over the subsequent year.

NATURAL HISTORY

Although the average age of the first drink (~15 years) is similar in individuals who do and do not go on to develop alcohol use disorders, an earlier onset of regular drinking and drunkenness, especially in the context of conduct problems, is associated with a higher risk for later alcohol-related diagnoses. By the mid-twenties, most nonalcoholic men and women begin to moderate their drinking (perhaps learning from negative consequences), whereas those with alcohol use disorders are likely to escalate their drinking despite difficulties. The first major life problem from alcohol often appears in the late teens to early twenties, and a pattern of multiple alcohol difficulties by the mid-twenties. Once established, the course is likely to include exacerbations and remissions, with little difficulty in temporarily stopping or controlling alcohol use when problems develop, but without help desistance usually gives way to escalations in alcohol intake and subsequent problems. Following treatment, for at least a year, more than half of those with alcohol use disorder maintain a marked decrease in alcohol use and related problems or achieve full abstinence, including many who stop drinking permanently. Even without formal treatment or self-help groups, there is at least a 20% chance of spontaneous remission with long-term abstinence. However, should the individual continue to drink heavily, the life span is shortened by ~10 years on average, with the leading causes of early death being enhanced rates of heart disease, cancer, accidents, and suicide.

IDENTIFICATION AND TREATMENT

The approach to treating alcohol-related conditions is relatively straightforward: (1) recognize that at least 20% of patients have an alcohol use disorder; (2) learn how to identify and treat acute alcohol-related conditions (e.g., severe intoxication); (3) know how to help patients begin to address their alcohol problems; (4) know how to treat alcohol withdrawal symptoms; and (5) learn how to appropriately treat or refer patients for additional help.

IDENTIFICATION OF PATIENTS WITH ALCOHOL USE DISORDERS

Even in affluent locales, the ~20% of patients who have an alcohol use disorder can be identified by asking questions about *alcohol problems* and noting laboratory test results that can reflect regular consumption of six to eight or more drinks per day. The two blood tests with ≥60% sensitivity and specificity for heavy alcohol consumption are γ-glutamyl transferase (GGT) (>35 U) and carbohydrate-deficient

TABLE 464-3 The Alcohol Use Disorders Identification Test (AUDIT)[a]

ITEM	5-POINT SCALE (LEAST TO MOST)
1. How often do you have a drink containing alcohol?	Never (0) to 4+ per week (4)
2. How many drinks containing alcohol do you have on a typical day?	1 or 2 (0) to 10+ (4)
3. How often do you have six or more drinks on one occasion?	Never (0) to daily or almost daily (4)
4. How often during the last year have you found that you were not able to stop drinking once you had started?	Never (0) to daily or almost daily (4)
5. How often during the last year have you failed to do what was normally expected from you because of drinking?	Never (0) to daily or almost daily (4)
6. How often during the last year have you needed a first drink in the morning to get yourself going after a heavy drinking session?	Never (0) to daily or almost daily (4)
7. How often during the last year have you had a feeling of guilt or remorse after drinking?	Never (0) to daily or almost daily (4)
8. How often during the last year have you been unable to remember what happened the night before because you had been drinking?	Never (0) to daily or almost daily (4)
9. Have you or someone else been injured as a result of your drinking?	No (0) to yes, during the last year (4)
10. Has a relative, friend, doctor, or other health worker been concerned about your drinking or suggested that you should cut down?	No (0) to yes, during the last year (4)

[a]The AUDIT is scored by simply summing the values associated with the endorsed response. A score ≥8 may indicate harmful alcohol use.

transferrin (CDT) (>20 U/L or >2.6%); the combination of the two tests is likely to be more accurate than either alone. The values for these serologic markers are likely to return toward normal within several weeks of abstinence. Other useful blood tests include high-normal MCVs (≥91 μm^3) and serum uric acid (>416 mol/L, or 7 mg/dL).

The diagnosis of alcohol use disorder ultimately rests on the documentation of a pattern of repeated difficulties associated with alcohol (Table 464-2). The criteria can be paraphrased as reaching a point where alcohol means more to the person than the significant repetitive problems that it causes. Thus, in screening, it is important to probe for marital or job problems, legal difficulties, histories of accidents, medical problems, evidence of tolerance, and so on, and then attempt to relate these issues to use of alcohol. Some standardized questionnaires can be helpful, including the 10-item Alcohol Use Disorders Identification Test (AUDIT) **(Table 464-3)**, but these are only screening tools, and a face-to-face interview is still required for a meaningful diagnosis. The diagnostic criteria in the fourth and fifth versions of the American Psychiatric Association DSM (DSM-IV and DSM-5) are very similar, both are reliable across different clinicians, and both labels are very good at predicting future problems, especially for individuals with moderate or severe disorders.

TREATMENT

Alcohol-Related Conditions

ACUTE INTOXICATION

The first priority in treating severe intoxication is to assess vital signs and manage respiratory depression, cardiac arrhythmias, and blood pressure instability, if present. The possibility of intoxication with other drugs should be considered by obtaining, if needed, toxicology screens for other central nervous system (CNS) depressants such as benzodiazepines and for opioids. Aggressive behavior should be handled by offering reassurance but also by calling for help from an intervention team. If the aggressive behavior continues, relatively low doses of a short-acting benzodiazepine such as lorazepam (e.g., 1–2 mg PO or IV) may be used and can be repeated as needed, but care must be taken not to destabilize vital signs or worsen confusion. An alternative approach is to use an antipsychotic medication (e.g., olanzapine 2.5–10 mg IM repeated at 2 and 6 h, if needed).

INTERVENTION

The steps presented here follow the acronym of SBIRT, indicating *s*creening, *b*rief *i*nterventions, and treatment or *r*eferral to *t*reatment. There are two main elements to highlighting the need for compliance with treatment in a person with an alcohol use disorder: motivational interviewing and brief interventions. During motivational interviewing, the clinician helps the patient to think through the assets (e.g., comfort in social situations) and liabilities (e.g., health- and interpersonal-related problems) of the current pattern of drinking. The clinician should listen empathetically to the responses, help the patient weigh options, and encourage the taking of responsibility for needed changes. Patients should be reminded that only they can decide to avoid the consequences that will occur if heavy drinking continues. The process of brief intervention, a similar approach, has been summarized by the acronym FRAMES: *F*eedback to the patient; *R*esponsibility to be taken by the patient; *A*dvice, rather than orders, on what needs to be done; *M*enus of options that might be considered; *E*mpathy for understanding the patient's thoughts and feelings; and *S*elf-efficacy, i.e., offering support for the capacity of the patient to make changes.

Once the patient begins to consider change, the discussions can focus more on the consequences of high alcohol consumption, suggested approaches to stopping drinking, and help in recognizing and avoiding situations likely to lead to heavy drinking such as going to bars or associating with heavy-drinking friends. Both motivational interviewing and brief interventions can be carried out in 15-min sessions, but because patients often do not change behavior immediately, multiple meetings are often required to explore the problem and possible options, discuss optimal treatments, and explain the benefits of abstinence.

ALCOHOL WITHDRAWAL

If the patient agrees to stop drinking, sudden decreases in alcohol intake can produce withdrawal symptoms, most of which are the opposite of those produced by intoxication. Features include tremor of the hands (shakes); agitation and anxiety; autonomic nervous system overactivity including an increase in pulse, respiratory rate, sweating, and body temperature; and insomnia. These symptoms usually begin within 5–10 h of decreasing ethanol intake, peak on day 2 or 3, and improve by day 4 or 5, although mild levels of these problems may persist for 4–6 months as a protracted abstinence syndrome.

About 2% of individuals with alcohol use disorder experience a withdrawal seizure, with the risk increasing in the context of older age, concomitant medical problems, misuse of additional drugs, and higher alcohol quantities. The same risk factors also contribute to the ~1% rate of withdrawal delirium, also known as *delirium tremens* (DTs), where the withdrawal includes a severe agitated delirium (mental confusion, agitation, and fluctuating levels of consciousness) associated with a tremor and autonomic overactivity (e.g., marked increases in pulse, blood pressure, and respirations). The risks for seizures and DTs can be diminished by identifying and treating underlying medical conditions early in the course of withdrawal and by instituting adequate doses of depressant medications such as benzodiazepines.

Thus, the first step in dealing with possible withdrawal phenomena is a thorough physical examination in all heavy drinkers who are considering abstinence. This includes evaluation of possible liver impairment, gastrointestinal bleeding, cardiac arrhythmias, infection, and glucose or electrolyte imbalances. It is also important to offer adequate nutrition and oral multiple B vitamins, including 50–100 mg of oral thiamine daily for a week or more. Because most patients with alcohol use disorders who enter withdrawal are either normally hydrated or mildly overhydrated, IV fluids should be avoided unless there is a relevant medical problem or significant recent bleeding, vomiting, or diarrhea.

The next step is to recognize that because withdrawal symptoms reflect the acute decrease in the usual blood levels of a CNS depressant (i.e., alcohol), the symptoms can be controlled by administering any other depressant in doses that decrease symptoms (e.g., a rapid pulse and tremor) and then tapering the dose over 3–5 days. Although most depressants are effective, benzodiazepines **(Chap. 463)** have the most supportive data for use in this situation, combining a high level of safety and low cost. Short-half-life benzodiazepines can be considered for patients with serious liver impairment or evidence of significant brain damage, but they must be given every 4 h to avoid abrupt blood-level fluctuations that may increase the risk for seizures. Therefore, most clinicians use drugs with longer half-lives (e.g., chlordiazepoxide), adjusting the dose if signs of withdrawal escalate and withholding the drug if the patient is sleeping or has orthostatic hypotension. The average patient requires 25–50 mg of chlordiazepoxide or 10 mg of diazepam given PO every 4–6 h on the first day, with doses then decreased to zero over the next 5 days. Although alcohol withdrawal can be treated in a hospital, patients in good physical condition who demonstrate mild signs of withdrawal despite low blood alcohol concentrations and who have no prior history of DTs or withdrawal seizures can be considered for outpatient detoxification. For the next 4 or 5 days, these patients should receive only 1 or 2 days of medications at a time and return daily for evaluation of vital signs. They can be hospitalized if signs and symptoms of withdrawal markedly escalate.

Treatment of patients with DTs can be challenging, and the condition is likely to run a course of 3–5 days regardless of the therapy used. However, conditions that meet the criteria for DTs outlined above represent medical emergencies that carry an estimated mortality as high as 5%, and treatment is best carried out in an intensive care unit by well-trained clinicians who closely monitor vital signs. Medications can include high-dose benzodiazepines (e.g., as much as 800 mg/d of chlordiazepoxide has been reported) or, for those who do not respond to that regimen, closely monitored doses of propofol or dexmedetomidine. The focus of care is to identify and correct medical problems and to control behavior and prevent injuries. Antipsychotic medications are not recommended for treatment of alcohol withdrawal symptoms; although antipsychotics are less likely than benzodiazepines to exacerbate confusion, they may increase the risk of seizures.

Generalized withdrawal seizures rarely require more than the administration of an adequate dose of benzodiazepines. There is little evidence that anticonvulsants such as phenytoin or gabapentin are more effective than benzodiazepines for alcohol-withdrawal seizures, and the risk of seizures has usually passed by the time effective drug levels are reached. The rare patient with status epilepticus must be treated aggressively **(Chap. 436)**.

HELPING INDIVIDUALS WITH ALCOHOL USE DISORDERS TO STOP OR SIGNIFICANTLY DECREASE DRINKING: THE REHABILITATION PHASE

An Overview After completing alcoholic rehabilitation, ≥50% of individuals with alcohol use disorders, especially highly functioning patients, maintain abstinence or significant diminution of alcohol intake for at least a year; many also achieve long-term sobriety. The ideal outcome is abstinence, but treatment trials are increasing recognizing that outcomes shy of total abstinence can still improve levels of functioning and quality of life. The core components of the rehabilitation phase of treatment include cognitive-behavioral approaches to help patients recognize the need to change, while working with them to alter their behaviors to enhance compliance. A key step is to optimize motivation toward abstinence through education of patients and their significant others about alcohol use disorders and their likely course over time. It is important to recognize that contrary to what some physicians might think, the typical person with an alcohol use disorder is likely to have a job and a family and not fit the inaccurate "down and out" stereotype. However, after years of heavy drinking, some patients require vocational or avocational counseling to help to structure their days, and all patients should try self-help groups such as Alcoholics Anonymous (AA) to assist them in developing a sober peer group and to learn how to deal with life's stresses while remaining sober. *Relapse prevention education* helps patients identify situations in which a return to drinking is likely (e.g., stopping in a bar to meet friends but planning to only have a nonalcoholic beverage), formulate ways to avoid the risky situation, and when that is not possible, to mitigate the risks to which they are exposed. It is also important to develop coping strategies that increase the chances of a quick return to abstinence after an episode of drinking.

Although many individuals can be treated as outpatients, more intense interventions are more effective and some individuals with alcohol use disorders do not respond to just AA or outpatient groups. Whatever the setting, ongoing contact with outpatient treatment staff should be maintained for at least 6 months and preferably for a year after abstinence. Counseling focuses on areas of improved functioning in the absence of alcohol (i.e., why it is a good idea to continue abstinence), helping patients to manage free time without alcohol, encouraging them to develop a nondrinking peer group, and discussions of ways to handle stress without drinking.

The physician serves an important role in identifying the alcohol problem, diagnosing and treating associated medical and independent or substance-induced psychiatric syndromes, overseeing detoxification, referring the patient to outpatient or inpatient rehabilitation programs, providing counseling, and, if appropriate, selecting which (if any) medication might be needed. For insomnia, patients should be reassured that troubled sleep is likely to improve over subsequent weeks. They should be taught the elements of "sleep hygiene" including maintaining consistent schedules for bedtime and awakening, avoiding exercise or consumption of large meals before bedtime, and keeping the bedroom cool, dark, and quiet at night **(Chap. 33)**. Depressant sleep medications are not the optimal approach for this type of insomnia that often continues for several weeks or months. Patients are likely to develop rebound insomnia when the depressant dose is decreased or stopped. The rebound increases the chance they will increase the dose and potentially develop problems controlling the prescribed depressant drug. Sedating antidepressants (e.g., trazodone) should not be used because they interfere with cognitive functioning the next morning and disturb the normal sleep architecture, but occasional use of over-the-counter sleeping medications (sedating antihistamines) can be considered. An additional problem, anxiety symptoms, can be addressed by increasing patients' insights into the temporary nature of the symptoms and helping them develop strategies to achieve relaxation by using forms of cognitive therapy.

Medications for the Alcohol Rehabilitation Treatment Phase The core of the rehabilitation phase for any chronic relapsing condition, including alcohol use disorder, relates to cognitive and behavioral approaches that help people comply with treatment goals and improve health and quality of life. Any medication for this disorder is likely to operate optimally in the context of such cognitive-behavioral approaches. As a result, the efficacy of a medication is best measured as the gain in functioning over and above improvements associated with the motivational interviewing, brief interventions, and related behavioral approaches. Such additional treatments (e.g., medications) are likely to have modest effect sizes, which can be difficult to document. Adding to the challenge of establishing the efficacy of a medication for this condition are the fluctuations of the intensity of alcohol-related symptoms over time and the 20% or higher spontaneous remission for alcohol use disorder. Recognizing that all treatments might cause harm through side effects and financial costs, it is important to demonstrate that a medication has a beneficial asset-to-liability ratio using double-blind controlled treatment trials.

In that light, to date, well-structured controlled trials have revealed only a few medications that have even modest benefits when used in the first 6–12 months of recovery from an alcohol use disorder. The opioid antagonist naltrexone may shorten subsequent relapses, whether used in the oral form (50–150 mg/d) or

as a once-per-month 380-mg injection. By blocking opioid receptors, naltrexone decreases activity in the dopamine-rich ventral tegmental reward system and decreases the feeling of pleasure if alcohol is imbibed. A second medication, acamprosate (Campral) (~2 g/d divided into three oral doses), has similar modest effects. Acamprosate inhibits NMDA receptors, decreasing mild symptoms of protracted withdrawal. Several trials of combined naltrexone and acamprosate have reported that the combination is well tolerated, and the efficacy might be superior to either drug alone, although not all studies agree.

It is more difficult to establish the asset-to-liability ratio of a third drug, disulfiram, an ALDH inhibitor, used clinically at doses of 250 mg/d, a dose selected to avoid the side effects of the more effective 500 mg/d regimen. This drug produces vomiting and autonomic nervous system instability after drinking as a result of rapidly rising blood levels of acetaldehyde. This reaction to alcohol can be dangerous, especially for patients with heart disease, stroke, diabetes mellitus, or hypertension. The drug itself carries potential risks of temporary depressive or psychotic symptoms, peripheral neuropathy, and liver damage. Disulfiram is best given under supervision by someone (such as a spouse), especially during high-risk drinking situations (such as the Christmas holidays).

Regarding other medications, a 16-week, placebo-controlled trial in patients with histories of relatively severe acute withdrawal syndromes reported good outcomes during the rehabilitation phase with another depressant medication (gabapentin 1200 mg/d), but side effects were considerable; those results have not yet been replicated, and gabapentin can itself be misused. Additional drugs under investigation include another opioid antagonist, nalmefene; the nicotinic receptor agonist varenicline; the serotonin antagonist ondansetron; the α-adrenergic agonist prazosin, especially in combination with naltrexone; the $GABA_B$ receptor agonist baclofen; the anticonvulsant topiramate; ibudilast in individuals with low-intensity alcohol responses; and possible enhanced outcomes when talk therapies are combined with ketamine or psilocybin sessions. However, it is important to emphasize that currently there are insufficient data to determine the asset-to-liability ratio for these medications in treating alcohol use disorders, and therefore, there is insufficient support for the routine use of these medications in clinical settings.

GLOBAL CONSIDERATIONS

As described above, rates of alcohol use disorders differ across sex, age, ethnicity, and country. There are also differences across countries regarding the definition of a standard drink (e.g., 10–12 g of ethanol in the United States and 8 g in the United Kingdom) and the definition of being legally drunk. The preferred alcoholic beverage also varies across groups, even within countries. That said, regardless of sex, ethnicity, or country, the actual drug in the drink is still ethanol, and the risks for problems, course of alcohol use disorders, and approaches to treatment are similar across the world.

465 Nicotine Addiction

David M. Burns

Ingestion of nicotine in any form (combusted or heated tobacco leaf, oral use, nicotine pouches, or inhaled by vaping nicotine or nicotine salt) can create and sustain addiction if used with sufficient intensity for a sufficient duration. Addicted users of nicotine regulate their nicotine intake by adjusting the frequency and intensity of their tobacco use, both to obtain the desired psychoactive effects and avoid withdrawal. While nicotine does cause some disease processes including complications of pregnancy, the vast majority of the diseases produced by nicotine addiction result from repetitive exposure to the carcinogens and other toxicants in various nicotine containing products. These exposures produce incremental changes that accumulate to progress toward disease, but it is the addiction to nicotine that causes the long-term, multiple times per day exposures to these agents needed to create sufficient damage to manifest as cancer, heart, and lung disease.

Over the last decade, there have been major shifts in product use, with about 40% of the nicotine delivery products being noncombusted and non-tobacco-leaf formulations. This shift has made practitioner advice about nicotine addiction more complicated, in part because many of the noncombusted products offer the potential to deliver nicotine sufficient to satisfy addiction, but with dramatic reductions in most of the toxic constituents found in smoke. Substantial reduction in disease risk can be achieved with the use of nicotine "vaping" products to aid cessation success for combusted cigarette smokers, and their use is likely to provide meaningful disease reduction with long-term complete substitution for combusted cigarette smoking even without breaking nicotine addiction.

Nicotine offers little or no benefit for the nonaddicted individual, but regular use of inhaled nicotine can produce a powerful addiction that is difficult to break and expensive to sustain. Any use of nicotine earlier in life predicts a greater use of some nicotine product later in life. For the practitioner, despite the likelihood of much lower disease risks compared to combusted cigarette use, it is hard to justify, or ignore, high-frequency use of noncombusted inhaled nicotine products in recommendations to patients who have never used combusted tobacco products.

THE PROCESS OF NICOTINE ADDICTION

When nicotine reaches the brain, it reversibly attaches to nicotinic acetylcholine receptors, which are particularly active in brain networks involved in depression, joy, excitement, and happiness. With prolonged

high exposure to nicotine, nicotinic receptors are upregulated on brain cells. For most individuals, daily nicotine use is needed to produce changes in the brain that are the hallmark of addiction. The strength of addiction, and the speed with which it can develop, are influenced by the frequency of use and concentration of arterial levels of nicotine reaching the brain, which can vary widely with use of different products.

As the time since last cigarette becomes longer, nicotine levels in the blood drop, and nicotine detaches from the receptors, leaving them increasingly uncovered. Without high levels of nicotine attaching to these receptors, addicted smokers no longer feel "normal," creating a compulsive need for the next dose of nicotine. Addicted individuals perceive increasing withdrawal symptoms with increasing duration of abstinence, which can persist for 4–6 weeks.

For the practicing clinician, the diagnosis of nicotine addiction is straightforward and is manifest by the patient's loss of control over their next use of nicotine-containing products. The individual's need for the next dose of nicotine can be satisfied by the use of multiple products at different times. The loss of control is demonstrated by a history of daily nicotine use coupled with behaviors such as high numbers of uses per day, use shortly after waking in the morning, craving after periods of abstinence, and/or failure of past cessation efforts, among others.

Several genes have been associated with nicotine addiction. Some reduce the clearance of nicotine, and others have been associated with an increased likelihood of becoming dependent on tobacco and other drugs or a higher incidence of depression. It is likely that genetic susceptibility can influence the probability that adolescent experimentation with tobacco will lead to addiction as an adult. However, rates of smoking cessation have increased, and rates of nicotine addiction have decreased dramatically since the mid-1950s, suggesting that factors other than genetics are more important influences for tobacco use.

In tobacco smoke or vaping aerosol, the fraction of nicotine present in the unprotonated (freebase) form is greater at alkaline pH, and unprotonated nicotine is more easily absorbed into the bloodstream across the oral mucosa. However, high concentrations of unprotonated nicotine are irritating to the airway, reducing the tendency to inhale, limiting the amount of nicotine users will tolerate in the aerosol and slowing the rate of rise in nicotine blood levels. Products delivering nicotine that are highly addictive (cigarettes and aerosols of nicotine salts) are able to deliver high doses of nicotine and rapid rises in arterial blood concentration by producing aerosols that are mildly acidic in the mouth, reducing the irritation that inhibits inhalation. However, as the particles are inhaled into the lung, the pH of the smoke rapidly changes to the more alkaline pH of the blood (~7.4), increasing the fraction of readily absorbable unprotonated nicotine present in the alveoli. The high rate of blood flow through the alveoli rapidly removes the unprotonated nicotine, increasing conversion of the protonated nicotine or the nicotine salt to release the unprotonated form and allowing most of the nicotine in the aerosol to be absorbed into the bloodstream. The resulting rapid rise in arterial blood nicotine levels reaching the brain makes cigarettes and nicotine salt vaping devices more addictive, and more able to satisfy addiction, compared with other forms of nicotine delivery.

TRENDS IN NICOTINE PRODUCT USE

Manufactured cigarettes have been the dominant form of nicotine exposure over the last 100 years. **Figure 465-1** presents the rise and decline in U.S. per-capita consumption (total cigarettes sold divided by the U.S. population over age 18) since 1900, together with the rise and subsequent fall of the male and female lung cancer death rates resulting from that consumption. The figure demonstrates the enormous success of tobacco control efforts in changing a human risk behavior, with current adult cigarette smoking prevalence now approaching 10%.

Among high school seniors, any cigarette use in the last 30 days has declined from 31% in 2000 to 2.9% in 2023, with only 0.7% smoking daily. As these post-2000 high school students aged into their 20s, their smoking initiation rates did not increase substantially, and only 5% of 18- to 24-year-old adults currently smoke. Unfortunately, smoking prevalence rates among those over age 40, the population more likely to develop disease, have declined more slowly. In addition, the population continuing to smoke has shifted heavily toward socially disadvantaged groups, indicating that the need for health care–based smoking interventions remains a priority.

A vast array of devices to deliver nicotine without smoke have been introduced over the last decade. These include devices, many sold without U.S. Food and Drug Administration (FDA) approval, that aerosolize nicotine solution or nicotine salts, or deliver nicotine as strips or flavored nicotine pouches for oral use. With the exception of vaping, very limited data are available on patterns of use for most of these products in the United States.

For vaping among adolescents, any use in the last 30 days peaked at about 25% in high school seniors in 2019 and declined to about 17% in 2023 with daily use at about 5.8% in 2023. The dramatic fall in combusted cigarette use over the past 2 decades among adolescents resulted from changes in the regulation of cigarette advertising and

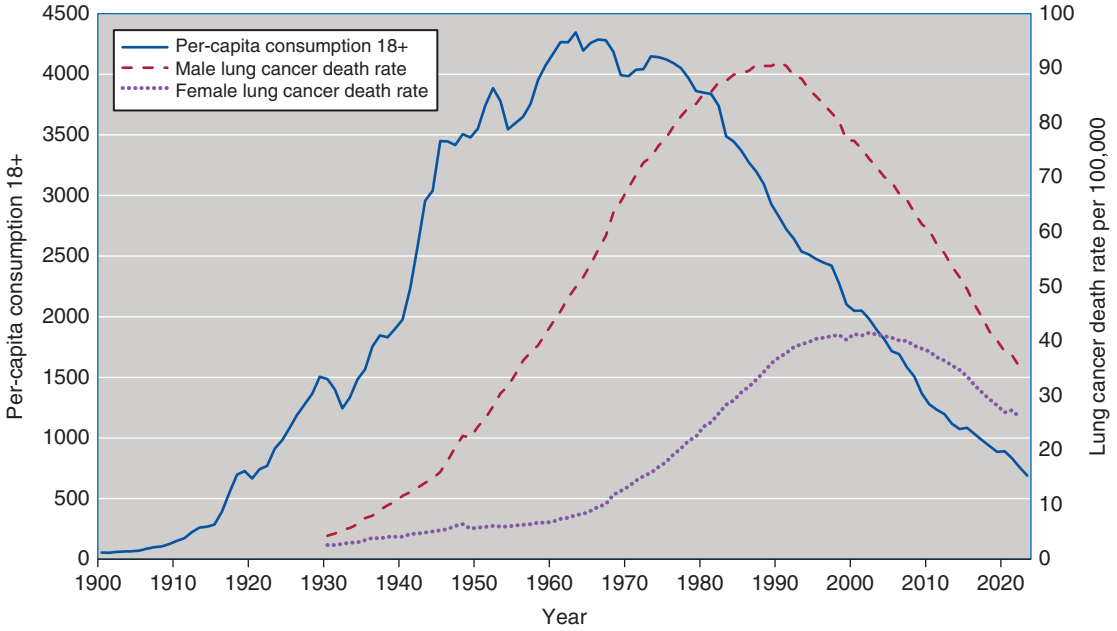

FIGURE 465-1 Changes in per-capita consumption and lung cancer death rates from 1900 to 2023.

the increasing social stigma associated with cigarette smoking. The introduction of vaping products as substitute sources of nicotine had little effect on the reduction in adolescent cigarette smoking, and the availability of vaping products has not increased adolescent smoking prevalence.

For adults, about 5% report using e-cigarettes some days or every day, with 11% of the 18–24 group reporting at least some days. Reasons for using e-cigarettes may include the following: for recreation, to sustain addiction, or to attempt to quit cigarette smoking. A substantial proportion of those using e-cigarettes for cessation report use of both e-cigarettes and combusted cigarettes interchangeably, called dual use.

In contrast to the United States, tobacco consumption in many other countries remains high, particularly among lesser developed countries. Worldwide tobacco consumption recently declined slightly for the first time after a persistent rise over the recent decades.

Changes in cost and relative rates of taxation for different tobacco products has resulted in an increase in smoking of cigars and "roll your own" cigarettes, but past recommendations about lower risk with use of cigars and pipe tobacco no longer apply. Most cigars are now manufactured in much the same way as cigarettes with small changes in weight to qualify for lower tax rates, and most pipe tobacco is now used for "roll your own" cigarettes also because of lower tax rates. As a result, smoking these products currently has risks similar to smoking manufactured cigarettes. Practitioners should ask about their use and should not recommend them as lower-risk forms of satisfying nicotine addiction.

DISEASE MANIFESTATIONS OF CIGARETTE SMOKING

Approximately 40% of cigarette smokers will die prematurely due to cigarette smoking unless they are able to quit. The major diseases caused by cigarette smoking are listed in **Table 465-1**. The ratio of smoking-related disease rates in smokers compared to never smokers (relative risk) increases with advancing age for most cancers and for chronic obstructive pulmonary disease (COPD). Relative risk declines with advancing age for cardiovascular diseases due to the increasing contribution of other risk factors to cardiovascular disease as age advances. Nevertheless, even for cardiovascular disease, the absolute difference in mortality rate between smokers and never smokers, called excess death rate, continues to increase with advancing age, as one would expect from a process of cumulative injury.

CARDIOVASCULAR DISEASES

Cigarette smokers are more likely than nonsmokers to develop both large-vessel atherosclerosis and small-vessel disease. Approximately 90% of peripheral vascular disease in the nondiabetic population can be attributed to cigarette smoking, as can ~50% of aortic aneurysms. In contrast, 24% of coronary artery disease and ~11% of ischemic and hemorrhagic strokes are attributed to cigarette smoking. There is a multiplicative interaction between cigarette smoking and other cardiac risk factors such that the increment in risk produced by smoking among individuals with hypertension or elevated serum lipids is substantially greater than the increment in risk produced by smoking for individuals without these risk factors.

In addition to its role in promoting atherosclerosis, cigarette smoking also increases the likelihood of myocardial infarction and sudden cardiac death by promoting platelet aggregation and vascular occlusion. Reversal of these effects on coagulation may explain the rapid benefit of smoking cessation for a new coronary event demonstrable among those who have survived a first myocardial infarction. This effect may also explain the substantially higher rates of graft occlusion among continuing smokers following vascular bypass surgery for cardiac or peripheral vascular disease.

Cessation of cigarette smoking reduces the risk of a second coronary event within 6–12 months. Rates of first myocardial infarction and death from coronary heart disease decline within 2–4 years following cessation among those with no prior cardiovascular history. After 15 years of abstinence, the risk of stroke, a new myocardial infarction, and death from coronary heart disease in former smokers is similar to that for those who have never smoked.

TABLE 465-1 Relative Risks for Current Smokers of Cigarettes

AGE	35–44	45–64	65–74	≥75
Males				
Lung cancer	14.33	19.03	28.29	22.51
Coronary heart disease	3.88	2.99	2.76	1.98
Cerebrovascular disease	2.17	1.48	1.23	1.12
Other vascular diseases			7.25	4.93
Chronic obstructive pulmonary disease (COPD)			29.69	23.01
All causes	2.55	2.97	3.02	2.40
Females				
Lung cancer	13.30	18.95	23.65	23.08
Other tobacco-related cancers	1.28	2.08	2.06	1.93
Coronary heart disease	4.98	3.25	3.29	2.25
Cerebrovascular disease	2.27	1.70	1.24	1.10
Other vascular diseases			6.81	5.77
COPD			38.89	20.96
All causes	1.79	2.63	2.87	2.47
Relative Risks for Selected Other Cancers				
Other cancers	Male		Female	
Larynx	14.6		13	
Lip, oral cavity, pharynx	10.9		5.1	
Esophagus	6.8		7.8	
Bladder	3.3		2.2	
Kidney	2.7		1.3	
Pancreas	2.3		2.3	
Stomach	2		1.4	
Liver	1.7		1.7	
Colorectal	1.2		1.2	
Cervix			1.6	
Acute myeloid leukemia	1.4		1.4	

CANCER

Tobacco smoking causes cancer of the lung; lip; oral cavity; naso-, oro-, and hypopharynx; nasal cavity and paranasal sinuses; larynx; esophagus; stomach; pancreas; liver (hepatocellular); colon and rectum; kidney (body and pelvis); ureter; urinary bladder; uterine cervix; and acute myeloid leukemia. There does not appear to be a causal link between cigarette smoking and cancer of the endometrium, and there is a lower risk of uterine cancer among postmenopausal women who smoke. The risks of cancer increase linearly with the increasing number of cigarettes smoked per day and logarithmically with increasing duration of smoking. Additionally, there are synergistic interactions between cigarette smoking and alcohol use for cancer of the oral cavity and esophagus. Several occupational exposures synergistically increase lung cancer risk among cigarette smokers, most notably occupational asbestos and radon exposure.

Cessation of cigarette smoking reduces the risk of developing cancer relative to continuing smoking after about 4 years of abstinence, but even 20 years after cessation, there is a persistent three- to fourfold increased risk of developing lung cancer compared to those who have never smoked.

RESPIRATORY DISEASE

Cigarette smoking is responsible for 80% of COPD. Within 1–2 years of beginning to smoke regularly, many young smokers will develop inflammatory changes in their small airways, although lung function measures of these changes do not predict subsequent development of chronic airflow obstruction. Chronic mucous hyperplasia of the larger airways results in a chronic productive cough in as many as 80% of smokers >60 years of age. Chronic inflammation and narrowing of the

small airways, and/or enzymatic digestion of alveolar walls resulting in pulmonary emphysema, reduce expiratory airflow sufficiently to produce clinical symptoms of respiratory limitation in ~15–25% of smokers.

Changes in the small airways of young smokers will reverse after 1–2 years of abstinence. There is also a small increase in measures of expiratory airflow following smoking cessation among many individuals who have already developed chronic airflow obstruction, but the major change following cessation is a slowing of the rate of decline in lung function with advancing age rather than a return of lung function toward normal.

PREGNANCY

Cigarette smoking is associated with several maternal complications of pregnancy: premature rupture of membranes, abruptio placentae, and placenta previa. There is also a small increase in the risk of spontaneous abortion among smokers. Infants of smoking mothers are more likely to experience preterm delivery, have a higher perinatal mortality rate, be small for their gestational age, and have higher rates of infant respiratory distress syndrome. They are more likely to die of sudden infant death syndrome and appear to have a developmental lag for at least the first several years of life. Since it is likely that some of these pregnancy-related risks are caused or enhanced by nicotine, vaping and oral use of nicotine remain a concern in pregnancy except as a strategy to abstain from cigarette smoking.

OTHER CONDITIONS

Smoking delays healing of peptic ulcers and increases the risk of developing periodontal disease, diabetes, active tuberculosis, rheumatoid arthritis, osteoporosis, senile cataracts, and neovascular and atrophic forms of macular degeneration. It results in premature menopause, wrinkling of the skin, gallstones, cholecystitis in women, and male impotence. Patients who continue to smoke during treatment for cancer with chemotherapy or radiation have poorer outcomes and reduced survival.

ENVIRONMENTAL TOBACCO SMOKE

Long-term exposure to environmental tobacco smoke increases the risk of lung cancer and coronary artery disease among nonsmokers. It also increases the incidence of respiratory infections, chronic otitis media, and asthma in children, and it causes exacerbation of asthma in children.

LOWER TAR AND NICOTINE CIGARETTES

Filtered cigarettes with lower machine-measured yields of tar and nicotine commonly use ventilation holes in the filters and other engineering designs to artificially lower the machine measurements. Smokers compensate for the lowered nicotine delivery resulting from these design changes by changing the manner in which they puff on the cigarette or the number of cigarettes smoked per day to restore their level of nicotine intake to that needed to satisfy their addiction. As a result, actual tar and nicotine deliveries to smokers are not reduced with use of these products, negating any reduction in disease risks from switching to these products.

The amount of carcinogenic tobacco-specific nitrosamines in the tobacco used in cigarettes has increased over time, and cigarette design changes that reduce machine-measured tar and nicotine also lead to deeper inhalation of the smoke in the lung, presenting increased amounts of the more carcinogenic smoke to the alveolar portions of the lung. These changes increase the risk of adenocarcinoma of the lung above that produced by smoking older nonfiltered cigarettes. The changes in cigarette design and composition of cigarettes over the past six decades are the cause of the increase in rates of adenocarcinoma of the lung observed over the past half century, and the increased adenocarcinoma rate has increased total lung cancer rates, as there has not been a decline in the risk of other cell types with the changes in cigarette design. An increased risk for COPD may also be present. There has been no increase in risk of all lung cancer or adenocarcinoma of the lung over the same period among never smokers.

PHARMACOLOGIC INTERACTIONS

Cigarette smoking may interact with a variety of other drugs. Cigarette smoking induces the cytochrome P450 system, which may alter the metabolic clearance of drugs such as warfarin. This may result in inadequate serum levels in smokers as outpatients when the dosage is established in the hospital under nonsmoking conditions. Correspondingly, serum levels may rise when smokers are hospitalized and not allowed to smoke. Smokers may also have higher first-pass clearance for drugs such as lidocaine, and the stimulant effects of nicotine may reduce the effect of benzodiazepines or beta blockers.

OTHER FORMS OF TOBACCO USE

Other major forms of tobacco use are loose moist snuff or packets deposited between the cheek and gum and chewing tobacco. Oral tobacco use leads to gum disease and can result in oral and pancreatic cancer. There are dramatically higher risks evident for products used in Africa or Asia as, including for heart disease, compared to those used in the United States and Europe.

NICOTINE AEROSOLS

A continually expanding array of devices and oral formulations that deliver nicotine in quantities capable of creating and sustaining addiction are available. Many of these devices deliver levels of nicotine comparable to a cigarette, and different concentrations of nicotine are often offered. Nicotine salt aerosols use mild acids to facilitate inhalation of the aerosol and can deliver very high amounts of nicotine even with novice users, potentially enhancing their addictiveness compared to devices that deliver solutions of nicotine. Nicotine intake is higher for users of devices delivering nicotine salts, and they report a greater frequency of symptoms of dependence with abstinence.

Biomarker evidence on exposure to smoke toxicants demonstrates markedly lower exposures among those using e-cigarettes exclusively compared to cigarette smokers, suggesting that they have less disease risk with use. However, both biomarker and behavioral evidence demonstrate the capacity for these devices to create and sustain addiction. The long-term rates with which adults addicted to nicotine vaping quit nicotine completely or migrate to or relapse back to combusted product use as they age remain to be determined.

There is convincing randomized controlled cessation trial evidence that the use of e-cigarettes that deliver sufficient nicotine are as effective as other nicotine-replacement or varenicline medications in achieving sustained abstinence from cigarettes, but a meaningful proportion of those who achieve abstinence still use e-cigarettes at 12-month follow-up, suggesting continued nicotine addiction. Rates of longer-term relapse back to smoking among individuals with persistent nicotine addiction remain to be examined.

An additional concern is that evidence on e-cigarette use in the United States shows that approximately one-half of adult e-cigarette users continue to also smoke conventional cigarettes, negating the benefits of reduced toxicant exposure and successful abstinence.

Refillable or reloadable e-cigarette devices can be used to aerosolize a variety of liquids other than those provided by the manufacturer. Disposable "pods" and liquids for these devices can be purchased from the manufacturer but are also available from other sources that may use poor-quality manufacturing practices and control of contaminants. They may also contain marijuana oils, other drugs, and flavors not evaluated for potential lung injury with inhalation.

CESSATION

The process of stopping smoking is commonly a cyclical one, with the smoker sometimes making multiple attempts to quit, and failing, before finally being successful. Approximately 70–80% of smokers would like to quit smoking. More than one-half of current cigarette smokers attempted to quit in the last year, but only 6% quit for 6 months, and only 3% remain abstinent for 2 years. Clinician-based smoking interventions should repeatedly encourage smokers to try to quit and to use different forms of cessation assistance with each new cessation attempt.

Advice from a clinician to quit smoking, particularly at the time of an acute illness, is a powerful trigger for cessation attempts, with up to half of patients who are advised to quit making a cessation effort.

CLINICIAN INTERVENTIONS (TABLE 465-2)

The shift in the nicotine market to products containing nicotine but not tobacco, and particularly to aerosolized nicotine salt products, has complicated provider diagnosis and treatment recommendations. Two considerations should guide this process. First, assessment of nicotine addiction should include the cumulative number of episodes of use for all nicotine products used regularly when considering the intensity of nicotine ingestion. This is important particularly when there is variation in the type of product used from day to day. Inquiries about cigar and roll your own use, as well as vaping and oral nicotine products, are necessary. It is the frequency of any nicotine dosing, not the product source, that creates and sustains addiction.

Second, it is the other toxicants carried along with the nicotine that cause the majority of the disease risk, so eliminating the smoke intake can have benefits even in the presence of continued addiction to nicotine.

All patients should be asked the total daily frequency with which they use any nicotine product, how long they have used at least one nicotine product regularly, their past experience with quitting, and whether they are currently interested in quitting.

The goal is to identify whether the individual has a pattern of use that demonstrates a compulsive need for the next dose of nicotine. The number of episodes of smoking or vaping per day, how they are spaced during the day, as well as use of nicotine smoking within 30 min of waking are helpful measures of the intensity of nicotine addiction.

Even those who are not interested in quitting should be encouraged and motivated to quit by providing a clear, strong, and personalized message by the clinician that smoking cigarettes is an important health concern and that vaping can be addicting. Those uninterested individuals should be told that assistance is available if they become interested in quitting in the future. Many of those not currently expressing an interest in quitting may nevertheless make an attempt to quit in the subsequent year.

TABLE 465-2 Clinical Practice Guidelines

Physician Actions
Ask: Systematically identify all tobacco and nicotine use at every visit
Advise: Strongly urge all smokers to quit
Identify smokers willing to quit
Assist the patient in quitting
Arrange follow-up contact
Effective Pharmacologic Interventions[a]
First-line therapies
Nicotine gum (1.5)
Nicotine patch (1.9)
Nicotine nasal inhaler (2.3)
Nicotine oral inhaler (2.1)
Nicotine lozenge (2 mg: 2.0, 4 mg: 2.8)
Bupropion (2.0)
Varenicline (3.1)
Other Effective Interventions[a]
Physician or other medical personnel counseling (10 min) (1.84)
Intensive group smoking cessation programs (at least 4–7 sessions of 20- to 30-min duration lasting at least 2 and preferably 8 weeks) (1.3)
Intensive individual counseling (1.7)
Systemwide cessation tracking and assistance (5)
Telephone counseling (1.6)
Exclusive E-cigarette use (3.0)

[a]Numerical value following the intervention is the multiple for cessation success compared to no intervention.

For those interested in quitting, a quit date should be negotiated, usually not the day of the visit but within the next few weeks. A follow-up contact by office staff around the time of the quit date should be provided. There is a relationship between the amount of assistance a patient is willing to accept and the success of the cessation attempt.

Building smoking cessation as a priority into health care delivery systems by including systemwide tracking of smoking status, prompting of practitioners to ask about smoking and interest in cessation, system-based outreach to smokers to offer cessation assistance and programs between visits, and tracking of cessation outcomes can dramatically enhance sustained abstinence, with 12-month abstinence rates as high as 25%.

There are a variety of cessation products listed in Table 465-2, including over-the-counter nicotine patches, gum, and lozenges, as well as nicotine nasal and oral inhalers available by prescription. These products can be used for up to 3–6 months, and some products are formulated to allow a gradual step-down in dosage with increasing duration of smoking abstinence. Antidepressants such as bupropion (300 mg in divided doses for up to 6 months) have also been shown to be effective, as has varenicline, a partial agonist for the nicotinic acetylcholine receptor (initial dose 0.5 mg daily increasing to 1 mg twice daily at day 8; treatment duration up to 6 months). Combined use of nicotine-replacement therapy (NRT) and antidepressants, as well as the use of gum or lozenges for acute cravings in patients using patches, can increase cessation outcomes.

Pretreatment with antidepressants or varenicline is recommended for 1–2 weeks prior to the quit date. Pretreatment with nicotine patches for 2 weeks prior to a cessation date is also useful. Longer duration of nicotine replacement as a maintenance therapy for those who are unsuccessful in quitting with a shorter duration of use is a useful strategy. NRT is provided in different dosages, with higher doses being recommended for more intense smokers. Antidepressants are more effective among smokers with a history of depression symptoms.

Current recommendations are to offer pharmacologic treatment, usually with nicotine patches or varenicline, to all who will accept it, and to provide counseling and other support as a part of the cessation attempt. Cessation advice alone by clinicians or their staff is likely to increase success compared with no intervention, but a more comprehensive approach with advice, pharmacologic assistance, and counseling can increase cessation success nearly threefold.

Data from multiple studies show that switching from cigarettes to exclusive use of e-cigarettes, particularly those with nicotine salts that deliver high doses of nicotine, is as or more effective in achieving smoking abstinence compared to FDA-approved medications, and it may be more acceptable for some patients. It should be recommended only with a strong caution to avoid dual use. Dual use with combusted cigarettes is unlikely to lead to smoking cessation or long-term risk reduction.

Current recommendations suggest that FDA-approved cessation methods be tried initially, with aerosolized nicotine salt products recommended to those who fail initial attempts to quit, are quitting on their own, or are reluctant to use FDA-approved medications.

PREVENTION

Prevention of smoking initiation must begin early, preferably in the elementary school years. Practitioners who treat adolescents should be sensitive to the prevalence of this problem even in the preteen population. Practitioners should ask all adolescents whether they have experimented with nicotine or currently use nicotine products, reinforce the fact that most adolescents and adults do not smoke or use nicotine, and explain that all forms of nicotine intake can be both addictive and potentially harmful.

466 Cannabis and Cannabis Use Disorder

Nora D. Volkow, Aidan Hampson, Ruben Baler

Cannabis/marijuana is used by more than >150 million people worldwide. The 2023 United States National Survey on Drug Use and Health, estimated that 42 million people used "marijuana" over the last month, while 62 million people used nicotine and 136 million drank alcohol (*https://www.samhsa.gov/data/release/2023-national-survey-drug-use-and-health-nsduh-releases*). Notably in 2023, 10 million younger people (12-25 year olds) consumed marijuana each month, while 12 million used tobacco products. For reference, nearly 19 million 12-25 year olds used alcohol on a monthly basis.

Since the Agriculture Improvement Act of 2018 (AIA; Public Law 115-334) amended the Controlled Substance Act, products made from *Cannabis sativa* species have been defined as marijuana when the plant or finished product contains >0.3% Δ-9-tetrahydrocannabinol (D9THC) by dry weight. Conversely, cannabis plant material, extracts, and derivatives that contain no more than 0.3% D9THC by dry weight are defined as "hemp." We will be using the terms marijuana and cannabis interchangeably in this report since marijuana is the term used in multiple surveys, and in state and Federal laws. Marijuana is primarily grown for its euphoric and medicinal properties, which are principally mediated by D9THC acting on neuronal type 1 cannabinoid receptors (CB1R). The contribution of minor cannabinoids (including cannabidiol [CBD]) or terpenes is limited and largely unproven to be clinically relevant at concentrations found in marijuana. Marijuana remains federally illegal as of May 2024, but 24 states, 3 U.S. territories, and Washington, DC, have passed measures to legalize nonmedicinal (adult) use, whereas 38 states, 4 U.S. territories, and Washington, DC, have legalized medicinal cannabis use. Hemp varietals are federally legal to grow and manufacture into seed/oil products, fiber, or CBD extracts. Some varietals can contain >12% (w/w) of the nonintoxicating CBD, while the D9THC level remains within the definition of "hemp" (0.3%). High CBD hemp was first envisaged as a source for the treatment of childhood seizure disorders (Federal bill H.R. 5226, 2014). However, after hemp legalization, processors began to derivatize hemp into Δ-8-tetrahydrocannabinol (D8THC) and other intoxicating hemp products (IHPs). According to one recent survey, people who use D8THC report it to be milder than D9THC and perceive it to be legal. Pharmacologic studies support lower potency of D8THC than D9THC, but other IHPs such as tetrahydrocannabiphorol can be considerably more potent (20–30×). It is worth noting that the 2023 Monitoring the Future national survey found that 11% of 12th-grade U.S. students reported past-year D8THC use.

Marijuana legalization has increased the demand for, and supply of, increasingly high D9THC-containing cannabis strains. Cannabis flower products now range from <0.3% in hemp to 20–30% in legal dispensary products. Further, extracts used as liquids in "vape pens" purportedly contain up to 75% D9THC, while advertisements of solid extracts (e.g., "shatter") containing up to 95% D9THC are not uncommon, although most of these claims appear to be exaggerated. Solid high-D9THC preparations are used for high-temperature vaporization ("dabbing"). Inhalation is a highly bioavailable (efficient) and rapid route of absorption for D9THC, so vaping products deliver high D9THC doses with rapid effect onset, conditions linked to increased risk of addiction. In contrast, edible D9THC-infused products (e.g., candies, cookies, and drinks) have slower rates of onset and are perceived to be associated with reduced harm. Edible products are less bioavailable than inhaled D9THC, but absorption can vary depending on the presence and nature of food in the stomach. Notably, "edibles" are favored by younger users and are associated with a higher probability of accidental dosing than inhaled products.

PHARMACOLOGIC EFFECTS

Cannabis is used recreationally because it enhances the subjective sense of well-being, provides rewarding sensations, and can dampen stress responses. However, consumption of high doses of D9THC can induce anxiety, paranoia, and panic. D9THC is primarily a partial agonist (activator) of G protein–coupled cannabinoid receptors (CB1R and CB2R), with the euphorigenic effects mediated through CB1Rs primarily located on excitatory glutamatergic and inhibitory γ-aminobutyric acid (GABA)-ergic interneurons and glial cells in brain regions that process stress, mood, and reward. These receptors are the effectors of the endocannabinoid system (ECS), which is physiologically activated by the endogenous ligands 2-arachidonoylglycerol (2-AG; a full agonist), and anandamide (a partial agonist). According to current understanding, 2-AG modulates synaptic signaling by inhibiting overstimulated synapses. Endocannabinoids are synthesized and eliminated *on demand* and thus provide a temporally and regionally specific modulatory signal. In contrast, the effect of intoxicating cannabinoids are defined by dose and their period of effect, not subtle "just in time" synaptic synthesis. Consequently exogenous cannabinoids disrupt important ECS neuroregulatory processes.

The rewarding effects of D9THC are thought to be mediated by modulating glutamatergic and GABAergic activity in the midbrain ventral tegmental area (VTA), from where dopaminergic neurons project into the nucleus accumbens (NAc). In the NAc, rewarding experiences are reinforced (learned) by glutamatergic and dopaminergic signal interactions. The anxiolytic effects of D9THC are mediated by its effects on the amygdala, a region critical for threat perception and emotional reactivity.

CANNABIS PHARMACOKINETICS

Smoking (e.g., joints and water pipes) remains the most common route of cannabis administration, but e-cigarette–type "vape pens" are increasingly being used. Vape pens use "e-liquid" concentrates, and the plasma concentrations achieved following their use depend on the e-liquid D9THC concentration and the "puffing profile." The ability to take a single puff from a vape pen offers easier dose control than smoking. Vaping is perceived to be less harmful than smoking, but the long-term toxicology of e-liquids in humans is not yet clear.

The subjective effects of cannabis are affected by dose, route of administration, (smoked, vaped, or ingested), and the subject's prior experience (which also modulates expectation). Smoked D9THC exhibits a bioavailability of 10–35%, with interindividual differences stemming from variations in the capacity to hold smoke in the lungs. The pharmacokinetics of heated (not burnt) cannabis flower and vaporized ethanolic extracts are similar to those of smoked flower, but no data are available to compare pharmacokinetics of smoked flower and commercial e-liquids or solid concentrates. When cannabis is smoked, plasma

D9THC concentrations become maximal within 5–10 min. After this time, plasma levels decrease with two phases governed by different elimination exponentials. There is an initial distribution phase with an (alpha) half-life ($t_{1/2}$) of ~6 min, governed by absorption into lipophilic tissues (e.g., brain). During this alpha phase, brain concentrations continue to increase even as plasma levels fall, resulting in a hysteresis (lag) between changes in plasma concentration and pharmacodynamic effects. Subjective effects tend to be maximal at 20–30 min after smoking. The plasma beta $t_{1/2}$ is approximately 1–2 h, and the total period of pharmacodynamic effect ranges from 4 to 8 h. Elimination of D9THC occurs by conversion to 11-hydroxy-THC (pharmacologically active) and subsequent conversion to a long-lasting, but pharmacologically inactive, 11-norcarboxy THC metabolite (11-COOH-THC). It is this analyte that is detected during marijuana urinalysis. Terminal elimination of 11-norcarboxy-THC exhibits a $t_{1/2}$ ranging from 20 to 35+ h, so THC use remains detectable for days in those who use occasionally and for weeks in those who use frequently and with saturated fat stores.

Regular D9THC use results in tolerance to its pharmacologic effects, so a given D9THC plasma concentration may not correlate to similar impairment levels in those using occasionally versus regularly. This challenge in correlating D9THC levels in biological matrices with behavioral effects has hampered efforts to regulate marijuana-impaired driving.

Orally consumed cannabis products (edibles and drinks) typically exhibit slower effect onset than smoked/vaped D9THC. This is partly due to stomach residence time but mainly because lipophilic cannabinoids are poorly absorbed through the water/mucus-rich layer of the intestine. The comparatively slower rate of oral cannabinoid absorption means that no hysteresis is observed, unlike after inhalation. Orally administered D9THC is extensively metabolized by intestinal and hepatic cytochromes (first-pass metabolism), so bioavailability ranges from 5 to 6% (compared to 30+% when smoked). However, when consumed with fatty foods, cannabinoids can exhibit 200–400% increased bioavailability because fatty foods (or pharmaceutical triglyceride vehicles) stimulate bile release. This emulsifies fat-associated cannabinoids, thus increasing the surface area for absorption into portal blood and stimulating absorption by enterocytes, which secrete into lymphatic lacteals. This allows a portion of fat-dissolved cannabinoids to bypass hepatic elimination, increasing bioavailability. However, lymphatic flow is slower than blood, so while lymphatically transported D9THC exhibits higher bioavailability, it also has a slower effect onset. In summary, depending on the edible product design or the consumer's feeding status, D9THC bioavailability and onset time can vary greatly. This unpredictability can complicate efforts to determine a precise dose and presents a potential overdose risk for the unwary.

HARMFUL EFFECTS

The frequency and severity of cannabis adverse effects are influenced by dose, frequency of use, route of administration, and the individual's health, age, and genetic background. Especially concerning are the potential negative effects of cannabis on the brain during early life stages. Perturbation of ECS signaling during early fetal development affects neuronal development, migration, and connectivity. A recent animal study found that deficiencies in vital fatty acids like docosahexaenoic acid could help explain the association between intrauterine exposure to D9THC and lifelong health disturbances in the offspring, including cognitive and memory impairments. The relevant human studies, which are few and confounded by the frequent use of other drugs, provide substantial evidence of lower birth weight and suggest an association between maternal marijuana use and fetal growth and preterm delivery. In addition, early results from the Adolescent Brain and Child Development (ABCD) study, a longitudinal neuroimaging, behavioral, and genetic study of close to 12,000 children in the United States, provide some evidence that exposure to cannabis during pregnancy can increase intracranial volumes and blunt development of visuospatial processing. Another analysis of the same cohort also found small but significant effects on white matter integrity during childhood, especially in the fornix, which has been implicated in the processing of emotions and memory. Not surprisingly, the American College of Obstetricians and Gynecologists recommends discouraging use of marijuana by women who are pregnant or planning a pregnancy.

Children and adolescents are also more vulnerable to the harmful effects of cannabis, the use of which increases markedly during adolescence and has been associated with lower grades, lower IQ, and higher risk of dropping out of school, although a causal relationship cannot yet be established. Brain imaging studies have revealed that use of cannabis at this stage is associated with structural and functional brain changes (not always replicated) often in the form of reduced brain connectivity and cortical thickness. Though it is not clear whether these are caused by early exposure to cannabis, research in 799 adolescents in Europe found a negative, dose-dependent correlation between self-reported cannabis use at age 14 and prefrontal cortex thickness at age 19, suggesting that cannabis use in middle to late adolescence may alter cortical development. Moreover, recent results from the ABCD study are consistent with the notion that preadolescence exposure to cannabis may contribute to lower scores on an episodic memory task and that more cannabis use may lead to poorer performances on verbal, inhibitory, working memory, and episodic memory tasks.

In 2019–2020, a syndrome known as e-cigarette or vaping product use-associated lung injury (EVALI) was observed. It became associated with vitamin E acetate, a thickening agent used to dilute black-market marijuana e-liquids. Once known, EVALI incidents diminished as this unapproved agent disappeared from use.

CANNABIS USE DISORDER

Repeated cannabis use, especially during adolescence, can result in cannabis use disorder (CUD), which the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition*, defines as "a problematic pattern of cannabis use leading to clinically significant impairment or distress." The diagnostic criteria for a use disorder include drug craving, tolerance to effects, a withdrawal syndrome, and failure to fulfill role obligations due to recurrent use and drug seeking. The risk of CUD increases with earlier age of initiation, frequency of use, and exposure to cannabis with high THC content. Several studies have found a broad reduction in cannabinoid receptors in the brains of people who use cannabis when compared to control participants who do not use cannabis, but receptor density recovers rapidly, returning to values similar to those of control participants within 28 days of abstinence. In people who use cannabis regularly, abstinence results in a withdrawal syndrome that peaks within 1–3 days of drug discontinuation and manifests as anxiety, restlessness, insomnia, depression, and reduced appetite. Many of these symptoms resolve within approximately 2 weeks of discontinuation. Insomnia often persists longer and may contribute to relapse, although the degree to which this represents withdrawal rather than cannabis use to self-medicate disordered sleep is unclear.

PREVENTION

Preventing cannabis use during adolescence reduces the risk for CUD and the risk of other substance use disorders. There are several evidence-based prevention strategies focused on children and adolescents that have shown benefits in decreasing cannabis use during adolescence or in delaying its age of initiation. Such prevention interventions can target the individual (e.g., Keepin' It Real, Life Skills, InShape), the family (e.g., Brief Strategic Family Therapy, Coping Power Program [CPP], Familia Adelante), or the community (e.g., The Abecedarian Project, Midwestern Prevention Project, Caring School Community). School-based prevention programs are the most widely implemented. Evidence from randomized controlled trials, prospective cohort trials, and longitudinal studies all demonstrate that comprehensive interventions that include antidrug information with refusal skills, self-management skills, and social skills training provide the most effective approaches for long-term reduction of cannabis (and alcohol) use in adolescents.

TREATMENT

The treatment of CUD involves tapering cannabis use and providing psychosocial support to alleviate withdrawal symptoms. There are currently no U.S. Food and Drug Administration (FDA)-approved medications for CUD. There is evidence of effectiveness of several behavioral interventions as CUD treatments. Contingency management is an effective therapeutic and combined motivational enhancement, and

cognitive behavioral techniques have also shown clinically significant improvements in abstinence and reduced cannabis use.

OTHER ADVERSE EFFECTS

MENTAL ILLNESS

The association between marijuana use and increased risk of mental illnesses is an area of major concern. The risk of psychosis increases with the frequent consumption of high-THC-content cannabis (>10% THC). Even upon first exposure, high-potency cannabis can trigger acute psychotic episodes, which constitute one of the main causes for emergency department (ED) visits associated with cannabis use. Most of these psychotic episodes are transient but can become chronic with regular cannabis use. In those vulnerable, cannabis may trigger or exacerbate the presentation of schizophrenia. Many earlier studies (though not all) have linked adolescent cannabis use with higher risk and earlier onset of chronic psychosis, particularly for those using cannabis at higher frequency or with higher D9THC content. A large recent study showed a stronger association between cannabis use during adolescence and risk of psychotic disorder than that documented in previous studies, consistent with the rise in cannabis potency. Concerns have also been raised regarding cannabis use during adolescence and a higher risk for depression and suicidality, though these associations have been much less studied.

ACCIDENTS

Cannabis use increases the risk of injuries when driving under its influence. D9THC impairs judgment, motor coordination, and reaction time, all necessary for safe driving. Studies have found a direct relationship between blood D9THC levels and impaired driving ability.

ACUTE AND CHRONIC TOXICITY

The increased availability of high-D9THC-content products over the past decade has been paralleled by increased marijuana-related ED visits and hospital admissions. Such emergencies can be caused by acute toxicity and chronic use syndromes. Cannabis edibles are involved in a significant portion of acute cannabis toxicity events. Patients include children accidentally consuming sweet edibles and infrequent users such as "cannabis tourists" with limited experience of the consumed products or the longer onset time of edible products. Actual D9THC dose is difficult to envisage, for both edible or inhaled products, so naïve or infrequent users are at increased risk of overdosing. Cannabis toxicity is frequently manifested by severe anxiety, tachycardia, and even acute psychoses. Chronic high-dose cannabis use can also induce a cannabis hyperemesis syndrome (presenting as severe cycles of nausea, vomiting, and abdominal pain), a growing cause for ED and hospital admissions.

THERAPEUTIC POTENTIAL

Currently, no FDA-approved medications contain cannabis-derived THC, although synthetic D9THC (or dronabinol) is approved for treatment of chemotherapy-induced nausea and appetite stimulation. Several countries have approved the cannabis-derived D9THC:CBD formulation Sativex for treating chronic pain and multiple sclerosis (MS)-induced spasticity. However, evidence of Sativex efficacy in MS is largely based on patient reports. Chronic pain is one of the most frequent indications for which medical marijuana is used. A recent analysis of data from the New York prescription drug monitoring database, from the years 2017-2019, revealed that chronic pain patients on long-term stable doses of opioid therapy (n >8000) who used medical marijuana for >8 months (compared to those who used medical marijuana for <30 days to 8 months) had a 30–50% reduction in opioid use.

467 Opioid-Related Disorders

Thomas R. Kosten, Colin N. Haile

Opioid analgesics have been used since at least 300 B.C. Nepenthe (Greek for "free from sorrow") helped the hero of the *Odyssey*, but widespread opium smoking in China and the Near East has caused harm for centuries. Since the first chemical isolation of opium and codeine 200 years ago, a wide range of synthetic opioids have been developed, and opioid receptors were cloned in the 1990s. Two of the most important adverse effects of all these agents are the development of opioid use disorder and overdose. Prescription opioids are primarily used for pain management, but due to ease of availability individuals procure and misuse these drugs with dire consequences. In 2022, for example, 8.9 million United States residents misused pain relievers and >76,000 overdose deaths involved opioids, nearly half combined with stimulants. These numbers continue to increase and have accelerated due to mixing of high-potency fentanyl derivatives with other opioids and stimulants. The accelerating death rates are partially because reversal of fentanyl overdoses can require severalfold larger doses of naloxone than the doses in the intranasal devices used for nonmedical street resuscitations. Fentanyl-associated deaths also increased during the COVID-19 pandemic. The World Drug Report attributes the greatest global burden of morbidity and mortality to opioid misuse, including disease transmission, increased health care, crime, law enforcement, family distress, and lost productivity.

The terms *dependence* and *addiction* have been replaced with opioid use disorder, opioid intoxication, and opioid withdrawal. Opioid use disorder is defined in the *Diagnostic and Statistical Manual of Mental Disorders,* Fifth Edition (DSM-5; 2022) as the repeated use of the opiate during a 12-month period while producing problems in two or more areas including tolerance, withdrawal, use of greater amounts of opioids than intended, craving, and use despite adverse consequences. This new definition reduces the diagnostic criteria from three problem areas to two, but this reduction has not changed the rates of these disorders because most opioid-using individuals meet more than three criteria.

A striking recent aspect of illicit opioid use has been its marked increase as the gateway to illicit drugs in the United States. Since 2007, prescription opiates have surpassed marijuana as the most common illicit drug that adolescents initially use, although overall rates of opioid use are far lower than marijuana. The most used opioids had been diverted prescriptions for oxycodone and hydrocodone until about 2015, when fentanyl misuse and lethal overdose rose exponentially. Two opioid maintenance treatment agents—methadone and buprenorphine—are also misused, but at substantially lower rates, and the partial opioid agonists such as butorphanol, tramadol, and pentazocine are misused even less frequently. Because the chemistry and general pharmacology of these agents are covered in major pharmacology texts, this chapter focuses on neurobiology and pharmacology relevant to opioid use disorder and its treatments. Although the neurobiology of misuse involves all four of the known opioid receptors—mu, kappa, delta, and nociceptin/orphanin—the mu receptor is the most clinically related to opioids.

TABLE 467-1 Actions of Opioid Receptors

RECEPTOR TYPE	ACTIONS
Mu (μ) (e.g., morphine, buprenorphine)	Analgesia, reinforcement euphoria, cough and appetite suppression, decreased respirations, decreased GI motility, sedation, hormone changes, dopamine and acetylcholine release
Kappa (κ) (e.g., butorphanol)	Dysphoria, decreased GI motility, decreased appetite, decreased respiration, psychotic symptoms, sedation, diuresis, analgesia
Delta (δ) (e.g., etorphine)	Analgesia, euphoria, physical dependence, hormone changes, appetite suppression, dopamine release
Nociceptin/orphanin (e.g., buprenorphine)	Analgesia, appetite, anxiety, tolerance to opioids, hypotension, decreased GI motility, 5-HT and NE release

Abbreviations: GI, gastrointestinal; 5-HT, serotonin; NE, norepinephrine.

NEUROBIOLOGY

After binding to mu opioid receptors, opioids downregulate intracellular messenger systems and activate potassium ion channels, as summarized in Table 467-1. All opioid receptors are G protein–linked and coupled to the cyclic adenosine monophosphate (cAMP) second messenger system and to G protein–coupled inwardly rectifying potassium channels (GIRKs). The GIRKs increase permeability to potassium ions, causing hyperpolarization and inhibiting action potential production. Thus, opioids inhibit the activity of all neurons with opioid receptors and induce analgesia, sedation, and drug reinforcement through various brain pathways.

Relevant pathways for the reinforcing euphoric effects of opioids include the mesolimbic dopaminergic pathway from the ventral tegmental area (VTA) to the nucleus accumbens (NAc), where opioids indirectly increase synaptic levels of dopamine through inhibition of GABAergic neurons that inhibit both the VTA and the NAc. The positive subjective effects of opioid drugs also include mu receptor desensitization and internalization, potentially related to stimulation of β-arrestin signaling pathways. However, the "high" only occurs when the *rate of change* in dopamine is fast. Large, rapidly administered doses of opioids block γ-aminobutyric acid (GABA) inhibition and produce a burst of VTA dopamine neuron activity that is associated with a "high" in commonly misused substances. Therefore, routes of administration that slowly increase opioid blood and brain levels, such as oral and transdermal routes, are effective for analgesia and sedation but do not produce an opioid "high" that follows smoking and intravenous routes. Other acute effects such as analgesia and respiratory depression involve opioid receptors located in other brain areas such as the periaqueductal grey for pain and medulla oblongata for respiration.

Opioid tolerance and withdrawal are related to genetic polymorphisms that impact several proteins and that after chronic opioid dosing affect the functioning of the cAMP–protein kinase A (PKA)–cAMP response-element binding protein (CREB) intracellular cascade within the locus coeruleus (LC) (Fig. 467-1). Up to 50% of the risk for withdrawal is related to specific functional polymorphisms including one in the mu opioid receptor gene producing a threefold increase in this receptor's affinity for opioids and the endogenous ligand β-endorphin. Epigenetic DNA methylation changes in the mu receptor gene also appear to act as compensation by inhibiting gene transcription and reducing the number of mu receptors.

After chronic opioid dosing and its sustained inhibition of the cAMP molecular cascade as shown in Fig. 467-1, a compensation occurs in this cascade within the LC neurons that mediate opioid tolerance and withdrawal. Noradrenergic (NE) neurons in the LC activate the cerebral cortex. When large opioid doses saturate and activate all of the LC's mu receptors, action potentials cease. When this direct inhibitory effect is sustained over weeks and months of opioid use, a secondary set of adaptive changes occur to upregulate cyclic AMP enzyme activity. When the inhibiting opioid is abruptly discontinued, overactivity occurs in NE neurons of the LC that contribute to withdrawal symptoms (Fig. 467-1). This molecular model of NE neuronal activation during withdrawal has had important treatment implications, such as the use of the presynaptic α_2-agonists clonidine and lofexidine to treat opioid withdrawal by again suppressing NE neuronal activation

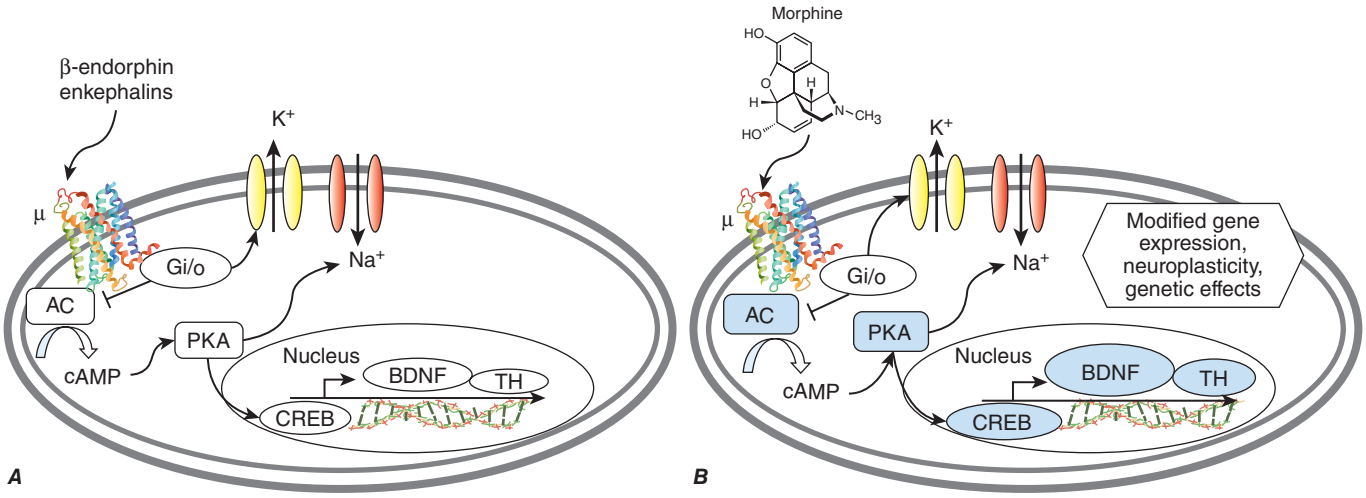

FIGURE 467-1 Normal mu-receptor activation by endogenous opioids inhibits the cyclic adenosine monophosphate (cAMP)-protein kinase A (PKA)-cAMP response-element binding protein (CREB) cascade in noradrenergic neurons within the locus coeruleus ***(A)*** through inhibitory Gi/o protein influence on adenylyl cyclase (AC). Similarly, acute exposure to opioids (e.g., morphine) inhibits this system, whereas chronic exposure to opiates ***(B)*** leads to upregulation of the cAMP pathway in an attempt to oppose opioid-induced inhibitory influence. Upregulation of this system is involved in opioid tolerance, and when the opioid is removed, unopposed noradrenergic neurotransmission is involved in opioid withdrawal. Upregulated PKA phosphorylates CREB, initiating the expression of various genes such as tyrosine hydroxylase (*TH*) and brain-derived neurotrophic factor (*BDNF*). *BDNF* is implicated in long-term neuroplastic changes in response to chronic opioids.

through feedback inhibition of this neuronal activity. Other contributors to withdrawal include deficits within the dopamine reward system and overactive neurotransmission within the glutamatergic system.

PHARMACOLOGY

Tolerance and withdrawal commonly occur with chronic daily use, developing as quickly as 6–8 weeks depending on dose concentration and dosing frequency. Tolerance is primarily pharmacodynamic with relatively limited induction of cytochrome P450 2D6 and 3A4 or other liver enzymes. Metabolism then includes conjugation to glucuronic acid and excretion of small amounts in feces. The plasma half-lives generally range from 2.5 to 3 h for morphine and >22 h for methadone. The shortest half-lives of several minutes are for fentanyl-related opioids, and the longest are for buprenorphine and its active metabolites, which can block opioid withdrawal for up to 3 days after a single dose. Tolerance to opioids leads to the need for increasing amounts of drugs to sustain the desired euphoric effects—as well as to avoid the discomfort of withdrawal. This combination has the expected consequence of strongly reinforcing misuse once it has started. Methadone taken chronically at maintenance doses is stored in the liver, which may reduce the occurrence of withdrawal between daily doses. The role of endogenous opioid peptides in tolerance and withdrawal is uncertain.

The clinical features of opioid misuse are tied to the route of administration and rapidity of the drug reaching the brain. Intravenous and smoked administration rapidly produces high drug concentrations in the brain. This produces a "rush," followed by euphoria, a feeling of tranquility, and sleepiness ("the nod"). Heroin produces effects that last 3–5 h, and several doses a day are required to forestall manifestations of withdrawal in chronic users. Symptoms of opioid withdrawal begin 8–10 h after the last dose; lacrimation, rhinorrhea, yawning, and sweating appear first. Restless sleep followed by weakness, chills, gooseflesh ("cold turkey"), nausea and vomiting, muscle aches, involuntary movements ("kicking the habit"), hyperpnea, hyperthermia, and hypertension occur in later stages of the withdrawal syndrome. The acute course of withdrawal may last 7–10 days. A secondary phase of protracted abstinence lasts for 26–30 weeks and is characterized by hypotension, bradycardia, hypothermia, mydriasis, and decreased responsiveness of the respiratory center to carbon dioxide.

Besides the brain effects of opioids on sedation and euphoria and the combined brain and peripheral nervous system effects on analgesia, a wide range of other organs can be affected. The release of several pituitary hormones is inhibited, including corticotropin-releasing factor (CRF) and luteinizing hormone, which reduces levels of cortisol and sex hormones and can lead to impaired stress responses and reduced libido. An increase in prolactin also contributes to the reduced sex drive in males. Two other hormones affected are thyrotropin, which is reduced, and growth hormone, which is increased. Respiratory depression results from opioid-induced insensitivity of brainstem neurons to increases in carbon dioxide, and in patients with pulmonary disease, this can result in clinically significant complications. In overdoses, aspiration pneumonia is common due to loss of the gag reflex. Opioids reduce gut motility, which is helpful for treating diarrhea but can lead to nausea, constipation, and anorexia with weight loss. Deaths occurred in early methadone maintenance programs due to severe constipation and toxic megacolon. Opioids such as methadone may prolong QT intervals and lead to sudden death in some patients. Orthostatic hypotension may occur due to histamine release and peripheral blood vessel dilation, which is an opioid effect usefully applied to managing acute myocardial infarction. During opioid maintenance, interactions with other medications are of concern; these include inducers of the cytochrome P450 system (usually CYP3A4) such as rifampin and carbamazepine.

Heroin users, in particular, tend to use opioids intravenously and are likely to be polydrug users, also using alcohol, sedatives, cannabinoids, and stimulants. None of these other drugs are substitutes for opioids, but they have desired additive effects. Therefore, one needs to be sure that the person undergoing a withdrawal reaction is not also withdrawing from alcohol or sedatives, which might be more dangerous and more difficult to manage.

Intravenous opioid use carries with it the risk of serious complications. The common sharing of hypodermic syringes can lead to infections with hepatitis B and HIV/AIDS, among others. Bacterial infections can lead to septic complications such as meningitis, osteomyelitis, and abscesses in various organs. Off-target effects or additions of other agents to opioids synthesized in illicit drug labs can lead to serious toxicity. For example, attempts to illicitly manufacture meperidine in the 1980s produced a parkinsonism-inducing neurotoxin, MPTP (Chap. 446). More recently, adding xylazine to illicit fentanyl markedly increased fentanyl's respiratory suppression, leading to overdose deaths. Individuals who inject fentanyl and xylazine also can develop necrosis and have an increased risk of limb amputation.

TREATMENT

Opioid Overdose

The acute treatment of opioid overdose with naloxone or nalmefene is a medical emergency, and after reversal of that life-threatening complication, clinicians have two general treatment options: opioid maintenance or detoxification. Opioid agonist and partial agonist medications are commonly used for both maintenance and detoxification purposes. α_2-Adrenergic agonists are primarily used for detoxification. Antagonists are used to accelerate detoxification and then continued after detoxification to prevent relapse. The residential medication-free programs have had some success but generally less than the medication-based programs. Success of the various treatment approaches is assessed as retention in treatment and reduced opioid and other drug use; secondary outcomes, such as reduced HIV risk behaviors, crime, psychiatric symptoms, medical comorbidity, and overdoses, also indicate successful treatment.

Potentially lethal overdoses require rapid recognition and treatment with naloxone or nalmefene, two highly specific reversal agents that are relatively free of complications. The diagnosis is based on recognition of characteristic signs and symptoms, including shallow and slow respirations, pupillary miosis (mydriasis does not occur until significant brain anoxia supervenes), bradycardia, hypothermia, and stupor or coma. Blood or urine toxicology studies can confirm a suspected diagnosis, but immediate management must be based on clinical criteria. If naloxone is not administered, progression to respiratory and cardiovascular collapse leading to death occurs. With fentanyl overdoses, the naloxone dose may be twice that needed for other opioids, and recent rescue preparations contain twice the traditional dosing. Additionally, nalmefene has recently become available for treatment of overdose and has higher potency and lasts longer than naloxone. Opioids generally do not produce seizures except for unusual cases of polydrug use with the opioid meperidine, with high doses of tramadol, or in the newborn.

In addition to naloxone, management of overdose requires support of vital functions, including intubation if needed (Table 467-2). If the overdose is due to buprenorphine or fentanyl, then naloxone might be required at total doses of 10 mg or greater, but primary buprenorphine overdose is nearly impossible because this agent is a partial opioid agonist, meaning that as the dose of buprenorphine is increased, it has greater opioid antagonist than agonist activity. Thus, a 0.2-mg buprenorphine dose leads to analgesia and sedation, while a hundred times greater 20-mg dose produces profound

TABLE 467-2 Management of Opioid Overdose

Establish airway. Intubation and mechanical ventilation may be necessary.
Naloxone 0.4–2.0 mg (IV, IM, or endotracheal tube). Onset of action with IV is ~1–2 min.
Repeat doses of naloxone if needed to restore adequate respiration or a continuous infusion of naloxone can be used.
One-half to two-thirds of the initial naloxone dose that reversed the respiratory depression is administered on an hourly basis (note: naloxone dosing is not necessary if the patient has been intubated).

opioid antagonism, precipitating opioid withdrawal in a person who had opioid use disorder from morphine or methadone. It is important to recognize that the goal is to reverse respiratory depression and not to administer so much naloxone that it precipitates opiate withdrawal. Because naloxone only lasts a few hours and most opioids last considerably longer, an IV naloxone drip with close monitoring is frequently employed to provide a continuous level of antagonism for 24–72 h depending on the opioid used in the overdose (e.g., morphine vs methadone). Whenever naloxone has only a limited effect, other sedative drugs that produce significant overdoses must be considered. The most common are benzodiazepines, which have produced overdoses and deaths in combination with buprenorphine. A specific antagonist for benzodiazepines, flumazenil at 0.2 mg/min can rapidly reverse overdoses, but it may precipitate seizures and increase intracranial pressure. Like naloxone, administration for a prolonged period is usually required because most benzodiazepines remain active for considerably longer than flumazenil. Support of vital functions may include oxygen and positive-pressure breathing, IV fluids, pressor agents for hypotension, and cardiac monitoring to detect QT prolongation, which might require specific treatment. Activated charcoal and gastric lavage may be helpful for oral ingestions, but intubation will be needed if the patient is stuporous.

OPIOID WITHDRAWAL

The principles of detoxification are the same for all drugs: to substitute a longer-acting, orally active, pharmacologically equivalent medication for the substance being used, stabilize the patient on that medication, and then gradually withdraw the substituted medication. Methadone and buprenorphine are the two principal medications used to treat opioid use disorder. Clonidine, a centrally acting sympatholytic agent, has also been used for detoxification in the United States. By reducing central sympathetic outflow, clonidine mitigates many of the signs of sympathetic overactivity but typically requires augmentation with other agents. Clonidine has no narcotic action and is not addictive. Lofexidine, a clonidine analogue with fewer hypotensive effects, was approved for use in the United States in 2018 for management of opioid withdrawal symptomology.

Methadone for Detoxification Dose-tapering regimens for detoxification using methadone range from 2–3 weeks to as long as 180 days, but this approach is controversial given the relative effectiveness of methadone maintenance and the low success rates of detoxification. Unfortunately, most patients tend to relapse to heroin or other opioids during or after the detoxification period, indicative of the chronic and relapsing nature of opioid use disorder.

Buprenorphine for Detoxification Buprenorphine does not appear to lead to better outcomes than methadone but is superior to clonidine in reducing symptoms of withdrawal, in retaining patients in a withdrawal protocol, and in completing treatment, although it can precipitate withdrawal in patients dependent on fentanyl or on maintenance doses of methadone (>80 mg daily).

α_2-Adrenergic Agonists for Detoxification Several α_2-adrenergic agonists have relieved opioid withdrawal by suppressing brain NE hyperactivity. Clonidine relieves some signs and symptoms of opioid withdrawal such as lacrimation, rhinorrhea, muscle pain, joint pain, restlessness, and gastrointestinal symptoms. Related agents are lofexidine, guanfacine, and guanabenz acetate. Lofexidine can be dosed up to ~2 mg/d and appears to be associated with fewer adverse effects. Clonidine or lofexidine is typically administered orally, in three or four doses per day, with dizziness, sedation, lethargy, and dry mouth as the primary adverse side effects. Outpatient-managed withdrawal regimens require close follow-up, often with naltrexone maintenance to prevent relapse.

Rapid and Ultrarapid Opioid Detoxification The opioid antagonist naltrexone, typically combined with an α_2-adrenergic agonist, has been purported to shorten the duration of withdrawal without significantly increasing patient discomfort. Completion rates using naltrexone and clonidine range from 75 to 81% compared to 40 to 65% for methadone or clonidine alone. Ultrarapid opioid detoxification is an extension of this approach using anesthetics but is highly controversial due to the medical risks and mortality associated with it.

Medications for Preventing Relapse to Illicit Opioids Stopping opioid use is much easier than preventing relapse. Long-term relapse prevention for individuals with opioid use disorder requires combined pharmacologic and psychosocial approaches. Chronic users tend to prefer pharmacologic approaches; those with shorter histories of drug use are more amenable to detoxification and psychosocial interventions.

Methadone maintenance substitutes a once-daily oral opioid dose for three to four times daily heroin. Methadone saturates the opioid receptors and, by inducing a high level of opioid tolerance, blocks the euphoria from additional opioids. Buprenorphine, a partial opioid agonist, also can be given once daily at sublingual doses of 4–32 mg daily, and in contrast to methadone, it can be given in an office-based primary care setting.

METHADONE MAINTENANCE Methadone's slow onset of action when taken orally, long elimination half-life (24–36 h), and production of cross-tolerance at doses from 80 to 150 mg are the basis for its efficacy in treatment retention and reductions in IV drug use, criminal activity, and HIV risk behaviors and mortality. Methadone can prolong the QT interval at rates as high as 16% above rates in non-methadone-maintained, drug-injecting patients, but it has been used safely in the treatment of opioid use disorder for >40 years.

BUPRENORPHINE MAINTENANCE Sublingual buprenorphine maintenance was first approved by the U.S. Food and Drug Administration (FDA) in 2002 as a Schedule III drug for managing opioid use disorder. Unlike the full agonist methadone, buprenorphine is a partial agonist of mu-opioid receptors with a slow onset and long duration of action. Its partial agonism reduces the risk of unintentional overdose but limits its efficacy to patients who need the equivalent of only 60–70 mg of methadone, and many patients in methadone maintenance require higher doses of up to 150 mg daily. Buprenorphine is combined with naloxone at a 4:1 ratio to reduce its abuse liability. Because of pediatric exposures and diversion of buprenorphine to illicit use, mucosal films are now used rather than sublingual pills that can be crushed and snorted. A long-acting buprenorphine injection that lasts a month is also available to prevent illicit diversion and to enhance compliance.

Primary care physicians often prescribe buprenorphine for opioid use disorder, which has reduced opioid-related deaths and drug-injection-related medical morbidity with treatment retention as high as 70% over a 6-month follow-up period.

Opioid Antagonist Medications Antagonist therapy blocks the action of self-administered opioids and should eventually extinguish the habit, but this therapy is poorly accepted by patients. Naltrexone, a long-acting pure opioid antagonist, can be given orally three times a week, or by monthly injection, which markedly improves adherence, retention, and drug use. Because it is an antagonist, the patient must first be detoxified from opioids before starting naltrexone. It is safe even when taken chronically for years, is associated with few side effects (headache, nausea, abdominal pain), and can be given to patients infected with hepatitis B or C without producing hepatotoxicity. However, most providers refrain from prescribing naltrexone if liver function tests are three times above normal levels. Naltrexone maintenance combined with psychosocial therapy is effective in reducing heroin use.

Medication-Free Treatment Most opioid users enter medication-free treatments in inpatient, residential, or outpatient settings, but 1- to 5-year outcomes are very poor compared to pharmacotherapy except for residential settings lasting 6–18 months. The residential programs require full immersion in a regimented system with progressively increasing levels of independence and responsibility within a controlled

community of fellow drug users. These medication-free programs, as well as the pharmacotherapy programs, also include counseling and behavioral treatments designed to teach interpersonal and cognitive skills for coping with stress and for avoiding situations leading to easy access to drugs or to craving. Relapse is prevented by having the individual very gradually reintroduced to greater responsibilities and to the working environment outside of the protected therapeutic community.

PREVENTION

Preventing the development of opioid use disorder represents a critically important challenge for physicians. Opioid prescriptions are a common source of drugs accessed by adolescents who begin a pattern of illicit drug use. The major sources of these drugs are family members, not drug dealers or the Internet. Pain management involves providing sufficient opioids to relieve the pain over as short a time as the pain warrants **(Chap. 14)**. The patient then needs to dispose of any remaining opioids, not save them in the medicine cabinet, because this behavior leads to diversion by adolescents. Finally, physicians should never prescribe opioids for themselves.

468 Cocaine, Other Psychostimulants, and Hallucinogens

Karran A. Phillips, Wilson M. Compton

The use of cocaine, methamphetamine, other psychostimulants, and hallucinogens reflects a complex interaction between the pharmacology of the drug, the personality and expectations of the individual using the drug, and the environmental context in which the drug is used. These substances cause significant harm, although they are less commonly used than other addictive substances such as alcohol **(Chap. 464)**, nicotine **(Chap. 465)**, cannabis **(Chap. 466)**, and opioids **(Chap. 467)**. It is also important to recognize that polydrug use, involving the concurrent use of several drugs with different pharmacologic effects, is common. Sometimes one drug is used to enhance the effects of another, as with the combined use of cocaine and nicotine, or cocaine and heroin in methadone-treated patients. Some forms of polydrug use, such as the combined use of intravenous (IV) heroin and cocaine, are especially dangerous and account for many hospital emergency department visits. Cocaine and psychostimulant use (especially chronic patterns of use) may cause adverse health consequences and exacerbate preexisting disorders such as hypertension and cardiac disease. In addition, the combined use of two or more drugs may accentuate medical complications associated with use of one drug. Chronic use is often associated with immune system dysfunction and increased vulnerability to infections, including risk for HIV infection. The concurrent use of cocaine and opiates ("speedball") is frequently associated with needle sharing by people using drugs intravenously (IV). People who use IV drugs represent the largest single group of individuals with HIV infection in several major metropolitan areas in the United States as well as in many parts of Europe and Asia. Furthermore, several outbreaks of HIV in the United States since 2015 in rural and suburban areas have been attributed to clusters of injection drug use.

Psychostimulants and hallucinogens have been used for centuries to induce euphoria and alter consciousness. Hallucinogens have become popular recently, and new drugs are continually being developed. This chapter describes the subjective and adverse medical effects of cocaine, other psychostimulants including methamphetamine, 3,4-methylenedioxymethamphetamine (MDMA), and cathinones; hallucinogens such as phencyclidine (PCP), D-lysergic acid diethylamide (LSD), and *Salvia divinorum*; and emerging drugs.

PSYCHOSTIMULANTS

Psychostimulants include cocaine and methamphetamine, as well as drugs with stimulant-like properties such as MDMA and cathinones. In addition, prescribed psychostimulants such as methylphenidate, dextroamphetamine, and amphetamine are considered here.

COCAINE

Cocaine is a powerful psychostimulant drug made from the cocoa plant. It has local anesthetic, vasoconstrictor, and stimulant properties. Cocaine is a Drug Enforcement Agency (DEA) Schedule II drug, which means that it has "high potential for abuse and the potential to create psychological and/or physical dependence" but can be administered by a physician for legitimate medical uses, such as local anesthesia for some eye, ear, and throat surgeries.

Pharmacology Cocaine comes in a variety of forms, the most commonly used being the hydrochloride salt, sulfate, and a base. The salt is an acidic, water-soluble powder with a high melting point, used by snorting or sniffing intranasally or by dissolving it in water and injecting it. When used intranasally, the bioavailability of cocaine is about 60%. Cocaine sulfate ("paste") has a melting point of almost 200°C, so it has limited use, but it is sometimes smoked with tobacco. The base form can be freebase or crystallized as crack. Cocaine freebase is made by adding a strong base to an aqueous solution of cocaine and extracting the alkaline freebase precipitate. It has a melting point of 98°C and can be vaporized and inhaled. Freebase cocaine can also be crystallized and sold as crack or rock, which is also smoked or inhaled. Street dealers often dilute (or "cut") cocaine with nonpsychoactive substances such as cornstarch, talcum powder, flour, or baking soda, or adulterate it with other substances with similar effects (like procaine or amphetamine) to increase their profits. A recent concern has been the adulteration of cocaine (and other psychostimulants) with fentanyl-related opioids, resulting in overdose deaths due to opioid effects or polydrug use. Xylazine, a nonopioid sedative, analgesic, and muscle relaxant only approved for veterinary use in the United States, has also been found cut into cocaine and other psychostimulants, as described below under "Psychostimulant Clinical Manifestations".

Given the extensive pulmonary vasculature, smoked or vaporized cocaine reaches the brain very quickly, similar in speed of onset to injected cocaine. The result is a rapid, intense, transient high, which enhances its addictive potential. Cocaine binds to the dopamine (DA) transporter and blocks DA reuptake, which increases synaptic levels of the monoamine neurotransmitters DA, norepinephrine (NE), and serotonin (5HT), in both the central nervous system (CNS) and the peripheral nervous system (PNS). Use of cocaine, like other harmful drugs abuse, induces long-term changes in the brain. Animal studies have shown adaptations in neurons that release the excitatory neurotransmitter glutamate after cocaine exposure.

Epidemiology According to the National Survey on Drug Use and Health (NSDUH), in 2023 an estimated 5 million people aged 12 years

or older (1.8% of the population) were past-year consumers of cocaine, including crack. Among those, 470,000 used cocaine for the first time (1287 cocaine initiates/day) including 23,000 adolescents aged 12–17 years. About 1.3 million people aged 12 years or older (0.4% of the population) in 2023 had a cocaine use disorder. According to the Centers for Disease Control and Prevention (CDC) National Center for Health Statistics, the age-adjusted rate of drug overdose deaths involving cocaine more than quintupled from 1.5 deaths per 100,000 standard population in 2011 to 8.2 in 2022. The rate of drug overdose deaths per 100,000 standard population involving both cocaine and opioids in 2021 (5.9) was 7.4 times the rate in 2011 (0.8) and was driven by the involvement of synthetic opioids including fentanyl and fentanyl analogues. The rate involving cocaine without opioid co-involvement in 2021 (1.5) was 2.1 times the rate in 2011 (0.7). The data are concerning because they describe increases over time in cocaine-related overdose both with and without the co-ingestion of opioids.

METHAMPHETAMINE

Methamphetamine is a psychostimulant drug usually used as a white, bitter-tasting powder or a pill. Crystal methamphetamine is a form of the drug that looks like glass fragments or shiny, bluish-white rocks. It can be inhaled/smoked, swallowed (pill), snorted, or injected (after being dissolved in water or alcohol).

Pharmacology When smoked, methamphetamine exhibits 90.3% bioavailability, compared to 67.2% for oral ingestion. Methamphetamine exists in two stereoisomers, the L- and D-forms. D-Methamphetamine, or the dextrorotatory enantiomer, is a more powerful psychostimulant, with 3–5 times the CNS activity as compared with L-methamphetamine. Methamphetamine is a cationic lipophilic molecule, which stimulates the release, and partially blocks the reuptake, of newly synthesized catecholamines in the CNS. Methamphetamine has a similar structure to the DA, NE, 5HT, and vesicular monoamine transporters and reverses their endogenous function, resulting in release of monoamines from storage vesicles into the synapse. Methamphetamine also attenuates the metabolism of monoamines by inhibiting monoamine oxidase.

Methamphetamine is more potent than amphetamine, resulting in much higher concentrations of synaptic DA and more toxic effects on nerve terminals. Outside the medical context, methamphetamine's pharmacokinetics and low cost often result in a chronic and continuous, high-dose self-administered use pattern.

Epidemiology According to the NSDUH, in 2023, 2.6 million people aged 12 years or older (0.9% of the population) used methamphetamine (not including use or misuse of prescription amphetamines or other stimulants) in the past year; of those, 78,000 used methamphetamine for the first time (213 people per day). In 2023, an estimated 1.8 million people aged 12 years or older (0.6% of the population and 69% of those with past-year use) had a methamphetamine use disorder. High rates of co-occurring substance use and mental illness exist in adults who use methamphetamine, and only about one-third of adults with past-year methamphetamine use disorder received addiction treatment. Methamphetamine availability and methamphetamine-related harms (e.g., overdose deaths, treatment admissions, infectious disease transmission) continue to increase in the United States. According to CDC data, psychostimulants (primarily methamphetamine) caused 36,251 overdose deaths in 2023. Stimulant-involved overdose deaths have risen markedly in recent years; with rates of psychostimulant overdose deaths increasing from 0.7 in 2011 to 10.4 in 2022. Further, while preliminary reports show overdose deaths involving opioids decreasing from an estimated 84,181 in 2022 to 81,083 in 2023, overdose deaths due to cocaine and psychostimulants (like methamphetamine) increased.

MDMA AND CATHINONES

MDMA also known as Molly, ecstasy, or X, is an illegal synthetic drug that has stimulant and psychedelic effects. Khât is a plant found in East Africa and the Middle East; it has been used for centuries for its mild stimulant-like effect. Synthetic cathinones or "bath salts" are manufactured psychostimulants that are chemically similar to the naturally occurring substance cathinone found in the khât plant and are discussed under "Emerging Drugs" below.

MDMA Molly, slang for "molecular," refers to the crystalline powder form of MDMA usually sold as powder or in capsules. The content of Molly varies and is often not MDMA at all but rather contains methylone or ethylone, which are synthetic substances commonly found in so-called bath salts and pose significant health risks. The clinician should always consider the possibility that the drug reported by the individual may be unwittingly contaminated with other substances.

With MDMA use, individuals experience increased physical and mental energy, distortions in time and perception, emotional warmth, empathy toward others, a general sense of well-being, decreased anxiety, and an enhanced enjoyment of tactile experiences. MDMA is usually taken orally in a tablet, capsule, or liquid form with first effect at 45 min on average, peak effect at 1–2 h, and duration ~3–6 h. MDMA binds to serotonin transporters and increases the release of serotonin, NE, and DA. Research in animals has shown that MDMA in moderate to high doses can cause loss of serotonin-containing nerve endings and permanent damage. MDMA is a Schedule I drug, along with other substances with no proven therapeutic value. MDMA has been given a breakthrough therapy designation by the U.S. Food and Drug Administration (FDA) as a possible treatment for posttraumatic stress disorder allowing for expedited clinical trials, but at present MDMA remains a Schedule I drug, along with other substances with no proven therapeutic value.

Adulteration of MDMA tablets with methamphetamine, ketamine, caffeine, the over-the-counter cough suppressant dextromethorphan (DXM), the diet drug ephedrine, and cocaine is common. MDMA is rarely used alone and is often mixed with other substances, such as alcohol and marijuana, making the specific impacts of its use difficult to ascertain. According to NSDUH 2023 data, among individuals aged 12 or older, 0.8% used MDMA in the past year and 507,000 people tried MDMA for the first time (>1300 per day). MDMA is predominantly used by men 18–25 years of age, with use typically beginning at age 21 years. There is evidence that gay or bisexual men and women are more likely than their heterosexual counterparts to have used MDMA in the last 30 days.

Cathinone This is an alkaloid psychostimulant structurally similar to amphetamine found in the khât (*Catha edulis*) plant, which grows at high altitudes in East Africa and the Middle East and whose leaves are chewed for their mild stimulant-like effect. The extraction of cathinone and other alkaloids from the leaves by chewing is very effective, leaving little as unabsorbed residue. The leaves and twigs can also be smoked, infused in tea, or sprinkled on food. Cathinone increases dopamine release and reduces dopamine reuptake.

Originally limited to its area of cultivation, with advances in rapid transportation and postal delivery, khât is now available in several continents including Europe and North America. Worldwide it is estimated that 10 million people chew khât, including up to 80% of all adults in some areas where the evergreen shrub is indigenous. In regions where the plant is indigenous, there have also been reports of khât use as a study aid among university students. Cathinone is a Schedule I drug in the United States, making its possession and use illegal.

PRESCRIBED PSYCHOSTIMULANTS

Methylphenidate, dextroamphetamine, and dextroamphetamine/amphetamine combination products are psychostimulants approved in the United States for treatment of attention-deficit hyperactivity disorder (ADHD), weight control, and narcolepsy. Prescription psychostimulants increase alertness, attention, and energy. Phenylpropanolamine, a psychostimulant used primarily for weight control, was found to be related to hemorrhagic stroke in women and removed from the market in 2005. Nonprescribed amphetamines and methylphenidate are used quite frequently by college students and as energy and productivity boosters by others. According to the 2023 NSDUH, past-year prescription stimulant misuse was reported by 3.9 million (1.4%) people aged 12 years or older. Of note, in 2023 among individuals aged

12 or older, 786,000 individuals misused prescription stimulants and cocaine; 190,000 misused prescription stimulants and methamphetamine; and 182,000 people misused or used all three. Past-year initiates of prescription stimulant misuse totaled 712,000, which averages to ~1950 people misusing prescription stimulants for the first time each day, including >1000 young adults aged 12–25 each day. Among people aged 12 years or older, 0.6% of the population in 2023 had a prescription stimulant use disorder in the past year.

PSYCHOSTIMULANT CLINICAL MANIFESTATIONS

Psychostimulants produce the same acute CNS effects: euphoria/elevated mood, increased energy/decreased fatigue, reduced need for sleep, decreased appetite, heightened sense of alertness, decreased distractibility, dose-dependent effects on focus, attention, and curiosity, increased self-confidence, increased libido, and prolonged orgasm, independent of the specific psychostimulant or route of administration. Peripheral effects may include tremor, diaphoresis, hypertonia, tachypnea, hyperreflexia, and hyperthermia. Many of the effects are biphasic; for example, low doses improve psychomotor performance, while higher doses may cause tremors or convulsions. α-Adrenergically mediated cardiovascular effects are also biphasic, with low doses resulting in increased vagal tone and decreased heart rate and high doses causing increased heart rate and blood pressure. Psychostimulant use can result in restlessness, irritability, and insomnia and, at higher doses, suspiciousness, repetitive stereotyped behaviors, and bruxism. Endocrine effects resulting from chronic use may include impotence, gynecomastia, menstrual function disruptions, and persistent hyperprolactinemia **(Table 468-1)**.

Overdose presents as sympathetic nervous system overactivity with psychomotor agitation, hypertension, tachycardia, headache, and mydriasis, and can lead to convulsions, cerebral hemorrhage or infarction, cardiac arrhythmias or ischemia, respiratory failure, or rhabdomyolysis. It is a medical emergency; treatment is largely symptomatic and should occur in an intensive care or telemetry unit. Inhalation of crack cocaine that is vaporized at high temperatures can cause airway burns, bronchospasm, and other symptoms of pulmonary disease. MDMA has also been shown to raise body temperature and can occasionally result in liver, kidney, or heart failure, or even death.

Psychostimulants are often used with other drugs, including opioids and alcohol, whose CNS-depressant effects tend to attenuate psychostimulant-induced CNS stimulation. These combinations often have additive deleterious effects, increasing the risk of morbidity and mortality. An example of this risk is the use of cocaine with alcohol, which results in the metabolite cocaethylene. Cocaethylene's effects on the cardiovascular system are additive to that of cocaine's effects, resulting in intensified pathophysiologic consequences.

Adulteration of psychostimulants, particularly cocaine, with other drugs is common and can have additional health consequences. In addition to contamination with fentanyl-related compounds, potentially resulting in fatal overdose, multiple other substances have been noted as contaminants of psychostimulants. Levamisole, an anthelminthic and immunomodulator used primarily in veterinary medicine, has been found in cocaine and can cause agranulocytosis, leukoencephalopathy, and cutaneous vasculitis, which has resulted in skin necrosis. Clenbuterol, a sympathomimetic amine used clinically as a bronchodilator, has also been found in cocaine and can result in tachycardia, hyperglycemia, palpitations, and hypokalemia. Xylazine, a nonopioid veterinary sedative, analgesic, and muscle relaxant, is most often described in the context of an opioid adulterant; however, it is also seen as an adulterant of cocaine, methamphetamine, and other stimulants. Effects associated with xylazine include dry mouth, drowsiness, hypertension, and tachycardia followed by hypotension and bradycardia, hyperglycemia, hypothermia, coma, respiratory depression, and dysrhythmia. Xylazine injection has been associated with necrotic soft tissue lesions both at the site of injection and elsewhere on the body. There is some evidence that xylazine itself can result in withdrawal symptoms such as sharp chest pains and seizures and cause physical dependence. Studies in Europe have found that, in addition to levamisole, some of the most common adulterants in cocaine include

TABLE 468-1 Complications of Psychostimulant Use

Cardiovascular	Acute • Arterial vasoconstriction • Thrombosis • Tachycardia • Hypertension • Increased myocardial oxygen demand • Increased vascular shearing forces • Coronary vasoconstriction • Cardiac ischemia • Left ventricular dysfunction/heart failure (high blood concentrations) • Supraventricular and ventricular dysrhythmias • Aortic dissection/rupture Chronic • Accelerated atherogenesis • Left ventricular hypertrophy • Dilated cardiomyopathy
Central and peripheral nervous systems	• Hyperthermia • Psychomotor agitation • Tremor • Hyperreflexia • Hypertonia • Headache • Seizures • Coma • Intracranial hemorrhage • Focal neurologic symptoms
Pulmonary	• Angioedema (inhaled) • Pharyngeal burns (inhaled) • Pneumothorax • Pneumomediastinum • Pneumopericardium • Reversible airway disease exacerbations • Bronchospasm • Shortness of breath ("crack lung") • Tachypnea • Pulmonary infarction
Gastrointestinal	• Perforated ulcers • Ischemic colitis • Bowel infarction • Impaction (body packing) • Hepatic enzyme elevation
Renal	• Metabolic acidosis • Renal infarction • Rhabdomyolysis
Endocrine	• Impotence • Gynecomastia • Menstrual function disruptions • Hyperprolactinemia
Other	• Diaphoresis • Irritability • Insomnia • Bruxism • Stereotypy • Splenic infarction • Acute angle-closure glaucoma • Vasospasm of the retinal vessels (unilateral or bilateral vision loss) • Mydriasis • Madarosis • Abruptio placentae

phenacetin, lidocaine, caffeine, diltiazem, hydroxyzine, procaine, tetracaine, paracetamol, creatine, and benzocaine.

Withdrawal from psychostimulants often includes hypersomnia, increased appetite, and depressed mood. Acute withdrawal typically lasts 7–10 days, but residual symptoms, possibly associated with neurotoxicity, may persist for several months. Debate remains whether psychostimulant withdrawal symptoms decline monotonically or occur in discrete phases, becoming worse before they improve. Psychostimulant withdrawal is not thought to be a major driver of ongoing use. Most current theories of psychostimulant addiction emphasize the primary role of conditioned craving, which can persist long after physiological withdrawal has abated. Conditioned craving includes the urge to use drugs in response to cues in the environment associated with drug use, such as associates who use drugs, drug paraphernalia, or drug-using locations.

Injection of psychostimulants places people at increased risk of contracting infectious diseases from exposure to HIV and hepatitis B or C in blood or other bodily fluids, as well as skin abscesses and endocarditis. Psychostimulant use can also increase risk for infection by causing altered judgment and decision-making, leading to risky behaviors such as unprotected sex. There is some evidence that psychostimulant use may worsen the progression of HIV/AIDS via increased injury to nerve cells exacerbating cognitive problems.

The actions and effects of khât are like those of other psychostimulants. Short-term effects include euphoria, increased alertness and arousal, loss of appetite, insomnia, headaches, and tremors. Long-term use may result in gastrointestinal disorders such as constipation, ulcers, and stomach inflammation, as well as increased risk for acute myocardial infarction and stroke due to inotropic and chronotropic effects on the heart, vasospasm of coronary arteries, and catecholamine-induced platelet aggregation. There is evidence that, rarely, heavy khât use may cause mild to moderate psychological dependence. Compulsive use has been described, with resulting grandiose delusions, paranoia, and hallucinations. A mild withdrawal syndrome from khât can include depression, nightmares, low blood pressure, and lack of energy.

DIAGNOSIS

The *Diagnostic and Statistical Manual of Psychiatric Disorders*, 5th edition (DSM-5) defines a stimulant use disorder (SUD) as a pattern of use of amphetamine-type substances, cocaine, or other stimulants leading to clinically significant impairment or distress, as manifested by at least 2 of the following 11 problems within a 12-month period: taking larger amounts, or over a longer period of time, than intended; persistent desire or unsuccessful efforts to reduce or control use; a great deal of time spent in activities necessary to obtain, use, or recover; craving; use resulting in failure to fulfill major role obligations; continued use, despite recurrent social or interpersonal problems; giving up social, occupational, or recreational activities; recurrent use in physically hazardous situations; continued use despite persistent or recurrent physical or psychological problems; tolerance; and withdrawal symptoms, or avoidance of withdrawal symptoms, by continued use.

The International Classification of Diseases (ICD) 10th Revision (ICD-10) recognizes "stimulant dependence syndrome" and "stimulant withdrawal state," and the ICD 11th Revision (ICD-11) further specifies the definition to "stimulant dependence including amphetamines, methamphetamines, or methcathinone."

TREATMENT

Acute Intoxication

As with all emergency situations, the first task is to check a patient's circulation, airway, and breathing. With cocaine use, succinylcholine is relatively contraindicated in rapid-sequence intubation; consider rocuronium (1 mg/kg IV) or another nondepolarizing agent as an alternative. If psychomotor agitation occurs, rule out hypoglycemia and hypoxemia first, and then administer benzodiazepines (e.g., diazepam 10 mg IV and then 5–10 mg IV every 3–5 hours until agitation controlled). Benzodiazepines are usually sufficient to address cardiovascular side effects. Severe or symptomatic hypertension can be treated with phentolamine, nitroglycerin, or nitroprusside. Hyperthermic patients should be cooled within ≤30 min with the goal to achieve a core body temperature of <39°C (102°F). Evaluation of chest pain in someone using cocaine should include an electrocardiogram, chest radiograph, and biomarkers to exclude myocardial infarction. The treatment approach is similar to nonstimulant-induced chest pain; however, it is recommended that whenever possible beta blockers not be used in people who use cocaine. The concern arises from the potential unopposed alpha-adrenergic stimulation that results from beta blockade possibly causing coronary arterial vasoconstriction, ischemia, and infarction and limited data supporting the benefit of beta blockers in cocaine-related cardiovascular complications. If beta blockers are to be given, it is suggested that mixed alpha/beta blockers, e.g., labetalol and carvedilol, be used rather than nonselective beta blockers, and only in situations where the benefits outweigh the risks. Because many instances of psychostimulant-related mortality have been associated with concurrent use of other illicit drugs (particularly opioids), the physician must be prepared to institute effective emergency treatment for multiple drug toxicities.

Psychostimulant Use Disorders

Treatment of psychostimulant use disorders requires the combined efforts of primary care physicians, addiction medicine physicians, psychiatrists, and psychosocial care providers. Early abstinence from psychostimulant use is often complicated by symptoms of depression and guilt, insomnia, and anorexia, which may be as severe as those observed in major affective disorders and can last for months and even years after use has stopped.

Behavioral therapies, including cognitive-behavioral therapy (CBT), the community reinforcement approach (CRA), contingency management (CM; providing structured and specific incentives to patients who remain substance free), motivational enhancement therapy (MET), combinations of these, and others, remain the mainstay of treatment for SUDs and show modest benefit. These behavioral therapies are designed to help modify the patient's thinking, expectancies, and behaviors, and to increase life-coping skills, with behavioral interventions to support long-term, drug-free recovery. There is robust evidence, including recent meta-analyses and systematic reviews, that contingency management, when implemented with fidelity to the principles of operant conditioning, is a highly effective treatment for psychostimulant use disorder, the benefit of which continues for up to 2 years beyond treatment discontinuation.

There are no FDA-approved medications for psychostimulant addiction. Current research includes several neurotransmitter-based strategies targeting DA, serotonin, γ-aminobutyric acid (GABA), and glutamate. Trials of agonist therapy with longer-acting psychostimulant medications such as dexamphetamine and methylphenidate have not been conclusive. Studies with the antidepressants mirtazapine, bupropion, sertraline, imipramine, and atomoxetine have been equivocal, as have studies with the atypical antipsychotic aripiprazole and the anticonvulsant topiramate. Other therapies being studied for the treatment of psychostimulant use disorder include acamprosate (possibly via a role in modulating the NMDA receptor), galantamine (reversible acetylcholine esterase inhibitor, which may strengthen impulse control, as well as cognitive and social abilities depleted by long-term psychostimulant use), naltrexone (opiate receptor antagonist), doxazosin (alpha-adrenergic antagonist), and varenicline (partial agonist of the α4β2 nicotinic acetylcholine receptor and DA neurotransmission enhancer). Overall, it is promising that some of the medications studied showed significant outcome improvements over placebo, but many were also underpowered due to issues of small sample size, sample bias, low participant retention, and low treatment adherence rates. Ongoing studies are investigating lisdexamfetamine (a dexamphetamine prodrug), a combination of extended-release naltrexone

with bupropion, pomaglumetad (a glutamate agonist), and several monoclonal antibodies. Special attention needs to be paid to the inclusion of underrepresented populations including women in future stimulant use disorder medication trials. Vaccines for cocaine and methamphetamine use disorders are also being developed. Finally, recent preliminary studies have brought attention to the potential use of brain stimulation techniques such as transcranial magnetic stimulation (TMS), theta-burst stimulation (TBS), and transcranial direct current stimulation (tDCS) to treat psychostimulant use disorders, although further studies will be required to determine their value, if any, in this situation.

HALLUCINOGENS

Hallucinogens are a diverse group of drugs causing alteration of thoughts, feelings, sensations, and perceptions. Some hallucinogens are found naturally in plants and mushrooms, while others are synthetic. They include ayahuasca (a tea made from Amazonian plants containing dimethyltryptamine [DMT], the primary mind-altering ingredient), DMT (aka Dimitri; can also be synthesized in a lab), LSD (clear or white odorless material made from lysergic acid found in rye and other grain fungus); peyote (mescaline, derived from a small, spineless cactus or made synthetically); and 4-phosphoryloxy-*N,N*-dimethyltryptamine (psilocybin, comes from certain South and North American mushrooms).

A subgroup of hallucinogens produces the added sensation of feeling out of control or disconnected from one's body or surroundings. These dissociative drugs include DXM (an over-the-counter cough suppressant, when used in high doses), ketamine (an FDA-approved human and veterinary anesthetic and a nasal spray [esketamine] for treatment-resistant depression); phencyclidine (PCP; a cyclohexylamine derivative and dissociative anesthetic); and *S. divinorum* (salvia, a Mexican, Central American, and South American plant). Dissociative drugs distort the way the user perceives time, motion, color, sound, and self, and their use can lead to bizarre and dangerous behavior and cause respiratory depression, heart rate abnormalities, and a withdrawal syndrome including drug craving, confusion, headache, and sweating.

Use of hallucinogens in religious and spiritual rituals goes back centuries, and they are ingested in a wide variety of ways, including orally, by smoking, intranasally, and transmucosally. Especially when taken orally, the onset of action of hallucinogens is within 20–90 min and the duration of action can be as long as 6–12 h, except for salvia, whose effects generally last about 30 min. Hallucinogens specifically disrupt the neurotransmitters serotonin and glutamate. Effects on the serotonin system can disturb mood, sensory perception, sleep, appetite, body temperature, sexual behavior, and muscle control. Glutamate system effects include perturbations in pain perception, responses to the environment, emotion, and learning and memory.

According to the NSDUH, in 2023, 2.6 million adults reported past-month use of hallucinogens and 8.8 million (3.1% of the population) reported past-year use of hallucinogens. Of these, 1.5 million used hallucinogens for the first time. Of note, these statistics include ecstasy (MDMA or "Molly") in the overall hallucinogen use category as well as LSD, PCP, peyote, mescaline, psilocybin mushrooms, ketamine, N,N-dimethyltryptamine (DMT)/Alpha-Methyltryptamine (AMT)/"Foxy," and *S. divinorum*. Past-year initiation numbers among people aged 12 years and older include 364,000 for LSD, 24,000 for PCP, and 507,000 for ecstasy. In 2023, 0.2% of people aged 12 or older had a hallucinogen use disorder.

Clinical manifestations of hallucinogen use include false sensory experiences (i.e., hallucinations), intensified feelings, heightened sensory experiences, and time perturbations. Additional physiologic responses include nausea; increases in heart rate, blood pressure, respiratory rate, or body temperature; loss of appetite; xerostomia; sleep problems; synesthesia; impaired coordination; and hyperhidrosis. Extremely negative experiences with hallucinogen use (the "bad trip") can include panic, paranoia, and psychosis, which may persist for up to 24 h. Such experiences are best treated with supportive reassurance, but benzodiazepines (e.g., diazepam 10 mg or lorazepam if liver damage is present) may be administered if agitation is severe. There is some evidence that chronic effects of hallucinogen use can occur, including persistent psychosis, memory loss, anxiety, depression, and flashbacks. Long-term effects of PCP and other dissociative drug use can include persistent speech difficulties, memory loss, depression, suicidal thoughts, anxiety, and social withdrawal that may persist for a year or more after chronic use stops.

The FDA issued breakthrough therapy designation for MDMA to expedite research into treatment of posttraumatic stress disorder and additional breakthrough therapy designations for two formulations of psilocybin for treatment of depression. In addition, some hallucinogens are being studied as potential treatment for certain SUDs, including psilocybin for alcohol and tobacco use disorders and ketamine for cocaine and methamphetamine use disorders. There is also some evidence that psilocybin and LSD may relieve pain in certain chronic pain conditions such as cluster headache, lower back pain, cancer-related pain, and phantom limb pain; studies are ongoing.

The DSM-5 defines hallucinogen use disorder as meeting 2 or more of the first 10 criteria (see above for SUD) in the past 12 months. The withdrawal criterion does not apply to hallucinogens, because hallucinogen use disorder is atypical in that use patterns are generally not chronic. There are currently no FDA-approved medications for the treatment of hallucinogen addiction. Research on behavioral treatments for hallucinogen addiction is underway.

EMERGING DRUGS

With the aid of the Internet and some basic over-the-counter (and other) ingredients, the rise of the "kitchen chemist" is upon us. The production of new psychoactive substances (NPS), such as recreationally manufactured synthetic cathinones (bath salts) and synthetic cannabinoids (K2, spice), is on the rise and has resulted in the use of unregulated psychoactive substances that are intended to copy the effects of more expensive illegal drugs such as methamphetamine and cocaine. NPS also include recreationally manufactured synthetic opioids containing brorphine and U-47700 and recreationally manufactured synthetic benzodiazepines such as bromazepams, desalkylgidazepam, and flubromazepam. In addition to NPS, nitazines (a synthetic opioid that can be more powerful than fentanyl) and tianeptine (a non-U.S.-approved antidepressant with opioid-like effects at high doses) are emerging and reemerging in the drug supply both alone and mixed into other drugs. These emerging drugs can be found online or sold in drug markets or convenience stores. Depending on the type of substance, whether a new type of opioid, depressant, synthetic cannabinoid, psychedelic, or stimulant, the effects will differ and may be unpredictable and unwanted, especially if unwittingly ingested as an adulterant in another drug. In addition, emerging substances are often not included in emergency department drug tests and are not routinely tested for when determining the cause of death after a fatal overdose.

Synthetic cathinones (bath salts) are human-made drugs chemically similar to cathinone found in khât and are often stronger and more dangerous than the natural product. They usually take the form of a white or brown crystal-like powder, packaged in small plastic or foil bundles labeled "not for human consumption," or as "plant food," "jewelry cleaner," or "phone screen cleaner," and sold online and in drug paraphernalia stores. The popular nickname Molly (slang for "molecular") often refers to the purported "pure" crystalline powder form of MDMA, usually sold in capsules. However, people who purchase powder or capsules sold as Molly often actually receive other drugs, such as synthetic cathinones. The uncertainty of what is actually in these synthetic products, whose components might change from batch to batch, makes them even more dangerous, as anyone using them is unaware of what the products actually contain and how they might respond.

The three most common synthetic cathinones are mephedrone, methylone, and MDPV (3,4-methylenedioxypyrovalerone). With oral ingestion, these drugs have an onset of action from 15–45 min, and a duration that varies from 2–7 h. Studies have found that MDPV affects the brain in a manner similar to cocaine but is at least 10 times more potent. MDPV is the most common synthetic cathinone found in the

blood and urine of patients admitted to emergency departments after taking "bath salts." High doses, or chronic use, of synthetic cathinones can lead to dangerous medical consequences, including psychosis, violent behaviors, tachycardia, hyperthermia, and even death.

The ability to synthesize addictive and dangerous drugs relatively simply and rapidly, changing just a few molecules, yet retaining the effects, has allowed many of these emerging drugs to outpace efforts to regulate them, resulting in a developing global public health concern.

SUBSTANCE USE AND MENTAL HEALTH

According to the NSDUH, in 2023, among adults aged 18 and older with no mental illness, 21% consumed illicit drugs, compared to 51.9% with severe mental illness and 42.4% with any mental illness. In 2023, among adults 18 years of age or older, 84.5 million people had either any mental illness or an SUD in the past year, 38.2 million had any mental illness in the absence of an SUD, 25.8 million had an SUD and no mental illness, and 20.4 million (7.2% of the population) had both. The percentage of adults aged 18 or older in 2023 who had both any mental illness and an SUD in the past year was highest among young adults aged 18 to 25 (14.1% or 4.8 million people). The percentage of adults aged 18 or older in 2023 who had both any mental illness and an SUD in the past year was higher among multiracial adults (13.3%) than among white (8.4%), black (7.8%), Hispanic (7.1%), or Asian adults (3.5%); the percentage could not be calculated with sufficient precision for Native Hawaiian or other Pacific Islander adults.

Among the 20.4 million adults aged 18 or older in 2023 with co-occurring any mental illness and an SUD in the past year, 62.4% (or 12.8 million people) received either substance use treatment or mental health treatment in the past year, and 37.6% (or 7.7 million people) received neither type of treatment. This equates to about two in five adults aged 18 or older with co-occurring any mental illness and an SUD in the past year who did not receive treatment for either condition. Taken together, these data point to the significant overlap of substance-related and other mental health problems and highlight the prodigious treatment gap that exists for both.

GLOBAL CONSIDERATIONS

After nicotine, alcohol, and cannabis, stimulants are the next most used drugs globally, worldwide in 2021, an estimated 22 million people used cocaine and 36 million people used amphetamines. The global cocaine supply reached a record high in 2022 with >2700 tons of cocaine produced, 20% more than the previous year, with main trafficking from the Andean region to other countries in the Americas and to Western and Central Europe. The two largest emerging methamphetamine markets in recent years have been the Near and Middle East/Southwest Asia and Southeastern Europe. The trafficking and use of synthetic stimulants, mainly cathinones, has risen notably in Central Asia and Eastern Europe. Globally, psychostimulant use has been associated with elevated mortality, increased incidence of HIV and hepatitis C infection, poor mental health (suicidality, psychosis, depression, and violence), and increased risk of cardiovascular events. The World Health Organization estimates that in 2019 global deaths attributed to cocaine and amphetamine use were 26,082 and 46,661, respectively.

Worldwide 7.4 million individuals have a stimulant use disorder, and the United Nations Office on Drugs and Crime (UNODC) estimates that only one in seven people with SUDs receives treatment. The number receiving treatment is much lower in individuals with stimulant use disorder despite the fact that cocaine treatment demand alone has risen almost 60% from 2011 to 2022 in subregions in Europe.

Globally, stigma and marginalization make treatment of drug use disorders difficult and hinder sustainable inclusive development incorporating gender and racial equity and the empowerment of women and underrepresented minorities. The existing treatment gap is further magnified when the intersectionality of gender, race, age, and ethnicity is considered, as is the treatment gap faced by populations with housing instability, low socioeconomic status, or low educational attainment, as well as LGBTQIA+, and veterans, among others.

FUTURE DIRECTIONS

Despite their prevalence and public health impact, psychostimulant and hallucinogen use disorders have no FDA-approved treatment medications. While behavioral therapies, such as contingency management and CBT, have been shown effective in psychostimulant use disorders, further research needs to be done regarding their utility for hallucinogen use disorders. Based on experience with opioid and alcohol use disorders, it is also likely that the most efficacious treatments will employ a combination of behavioral and pharmacologic therapy. Research on medications to treat psychostimulant use disorder is ongoing. Additionally, new approaches that utilize emerging technologies have considerable potential for future treatment of psychostimulant use disorders. These include neurostimulation/neuromodulation (TMS, TBS, tDCS), wearable biosensors, and mobile technology, including ecologic and geographic momentary assessment (EMA/GMA), as well as real-time interventions delivered via smartphone or other mobile devices.

469 Heavy Metal Poisoning

Howard Hu

Toxic metals (hereafter referred to simply as "metals") pose a significant threat to health through low-level as well as high level environmental and occupational exposures. One indication of their importance relative to other potential hazards is their ranking by the U.S. Agency for Toxic Substances and Disease Registry, which maintains an updated list of all hazards present in toxic waste sites according to their prevalence and the severity of their toxicity. The first, second, third, and seventh hazards on the list are heavy metals: arsenic, lead, mercury, and cadmium, respectively (*http://www.atsdr.cdc.gov/spl/*), positions they have held for many years. All four are also listed by the World Health Organization as among the 10 chemicals of highest concern in relation to health, globally. Specific information pertaining to each of these four metals, including sources and metabolism, toxic effects produced, diagnosis, and the appropriate treatment for poisoning, is summarized in **Table 469-1**.

Metals are inhaled primarily as dusts and fumes (the latter defined as tiny particles generated by combustion). Metal poisoning can also result from exposure to vapors (e.g., mercury vapor in creating dental amalgams). When metals are ingested in contaminated food or drink or by hand-to-mouth activity (implicated especially in children), their gastrointestinal absorption varies greatly with the specific chemical form of the metal and the nutritional status of the host. Once a metal is absorbed, blood is the main medium for its transport, with the precise kinetics dependent on diffusibility, protein binding, rates of biotransformation, availability of intracellular ligands, and other factors. Some organs (e.g., bone, liver, and kidney) sequester metals in relatively high concentrations for years. Most metals are excreted through renal clearance and gastrointestinal excretion; some proportion is also excreted through salivation, perspiration, exhalation, lactation, skin exfoliation, and loss of hair and nails. The intrinsic stability of metals facilitates tracing and measurement in biologic material, although the clinical significance of the levels measured is not always clear.

Some metals, such as copper and selenium, are essential to normal metabolic function as trace elements **(Chap. 344)** but are toxic at high levels of exposure. Others, such as lead and mercury, are xenobiotic and theoretically are capable of exerting toxic effects at any level of exposure. Indeed, much research is currently focused on the contribution of low-level xenobiotic metal exposure to subtle changes in health, chronic diseases, and/or increased risks of adverse events such as heart attacks, stroke, or cancer that may have significant public health consequences given the widespread nature of their exposures. Metals are well-known to be able to cause toxicity through the inhibition of enzymes, damage to subcellular organelles and DNA, covalent modification of proteins, formation of reactive oxygen species, and displacement of essential metals in metal dependent proteins. Recent research has also elucidated how metals may affect DNA methylation and other changes to the epigenome, thereby resulting in altered gene expression as well as the dysregulated expression of microRNAs. Genetic factors, such as polymorphisms that encode for variant enzymes with altered properties in terms of metal binding, transport, and effects, may modify the impact of metals on health. Nutritional status, comorbidities, and other factors can also contribute to variations in individual susceptibility to metal effects.

The most important component of treatment for metal toxicity is the recognition and termination of exposure. *Chelating agents* are used to bind metals into stable cyclic compounds with relatively low toxicity and to enhance their excretion. The principal chelating agents are dimercaprol (British anti-Lewisite [BAL]), ethylenediamine tetraacetic acid (EDTA), succimer (dimercaptosuccinic acid [DMSA]), and penicillamine; their specific use depends on the metal involved and the clinical circumstances. For the most part, they are reserved for treating acute, symptomatic metal toxicity. Activated charcoal does not bind metals and thus is of limited usefulness in cases of acute metal ingestion.

In addition to the information provided in Table 469-1, several other aspects of exposure, toxicity, or management are worthy of discussion with respect to the four most hazardous toxicants (arsenic, cadmium, lead, and mercury).

Arsenic, even at moderate levels of exposure, has been clearly linked with increased risks for cancer of the skin, bladder, renal pelvis, ureter, kidney, liver, and lung. These risks appear to be modified by smoking, folate and selenium status, genetic traits (such as ability to methylate arsenic), and other factors. Based on the accumulation of evidence, the American Heart Association concluded that low-level exposures to arsenic, lead, and cadmium are risk factors for hypertension, subclinical atherosclerosis, coronary artery stenosis, and calcification as well as ischemic heart disease and stroke, left ventricular hypertrophy and heart failure, and peripheral artery disease. Recent studies in community-based populations have also generated strong evidence that arsenic exposure is a risk factor for lung function impairment, acute respiratory tract infections, respiratory symptoms, and nonmalignant lung disease mortality. The association with cardiovascular disease may hold at levels of exposure in drinking water that are below the World Health Organization (WHO) provisional guideline value of 10 μg/L. Evidence has also continued to build indicating that low-level arsenic is a likely cause of neurodevelopmental delays in children and likely contributes to the development of type 2 diabetes and possibly nonalcoholic fatty liver disease and cirrhosis.

Serious *cadmium* poisoning from the contamination of food and water by mining effluents in Japan contributed to the 1946 outbreak of "itai-itai" ("ouch-ouch") disease, so named because of cadmium-induced bone toxicity that led to painful bone fractures. Modest exposures from environmental contamination have been associated in a growing number of studies with lower bone density, higher incidence of fractures, and faster decline in height in both men and women, effects that may be related to cadmium's calciuric and other toxic effects on the kidney. Cadmium burdens have also been associated with an increased risk of long-term kidney graft failure, and there is evidence for synergy between the adverse impacts of cadmium and lead on kidney function. Environmental exposures have also been linked to lower lung function (even after adjusting for smoking cigarettes, which contain cadmium) and, as noted earlier, the American Heart Association considers cadmium as a risk factor for cardiovascular disease and mortality, stroke, and heart failure. Cadmium triggers pulmonary inflammation, and recent population-based studies of U.S. adults found that higher cadmium burdens are associated with higher mortality from influenza, pneumonia, and COVID-19. The International Agency for Research on Cancer has classified cadmium as a known carcinogen, with evidence indicating it contributes to elevated risks of prostate, lung, breast, and endometrial cancer. Overall, this growing body of research indicates that cadmium exposure is contributing significantly to morbidity and mortality rates in the general population.

Advances in our understanding of *lead* toxicity have recently benefited by the development of x-ray fluorescence (KXRF) instruments for making safe in vivo measurements of lead levels in bone, which, in turn, reflect cumulative exposure over many years, as opposed to blood lead levels, which mostly reflect recent exposure. Higher levels of cumulative lead exposure in the general population are now well-established as a risk factor for chronic disease, even though blood lead levels have continued to decline in the general population over the past few decades following the removal of lead from gasoline, plumbing, solder in food cans, and other consumer products, with mean levels in the U.S. population now hovering in the 1–2 μg/dL range. For example, higher bone lead levels measured by KXRF have been linked to increased risk of hypertension and accelerated declines in

TABLE 469-1 Heavy Metals

MAIN SOURCES	METABOLISM	TOXICITY	DIAGNOSIS	TREATMENT
Arsenic				
Smelting and microelectronics industries; wood preservatives, pesticides, herbicides, fungicides; contaminant of deep-water wells; folk remedies; and coal; incineration of these products.	Organic arsenic (arsenobetaine, arsenocholine) is ingested in seafood and fish, but is nontoxic; inorganic arsenic is readily absorbed (lung and GI); sequesters in liver, spleen, kidneys, lungs, and GI tract; residues persist in skin, hair, and nails; biomethylation results in detoxification, but this process saturates.	Acute arsenic poisoning results in necrosis of intestinal mucosa with hemorrhagic gastroenteritis, fluid loss, hypotension, delayed cardiomyopathy, acute tubular necrosis, and hemolysis. Chronic arsenic exposure causes diabetes, vasospasm, ischemic heart disease, peripheral vascular insufficiency and gangrene, peripheral neuropathy, and cancer of skin, lung, liver (angiosarcoma), bladder, and kidney. Lethal dose: 120–200 mg (adults); 2 mg/kg (children).	Nausea, vomiting, diarrhea, abdominal pain, delirium, coma, seizures; garlicky odor on breath; hyperkeratosis, hyperpigmentation, exfoliative dermatitis, and Mees' lines (transverse white striae of the fingernails); sensory and motor polyneuritis, distal weakness. Radiopaque sign on abdominal x-ray; ECG–QRS broadening, QT prolongation, ST depression, T-wave flattening; 24-h urinary arsenic >67 μmol/d or 50 μg/d; (no seafood × 24 h); if recent exposure, serum arsenic >0.9 μmol/L (7 μg/dL). High arsenic in hair or nails.	If acute ingestion, ipecac to induce vomiting, gastric lavage, activated charcoal with a cathartic. Supportive care in ICU. Dimercaprol 3–5 mg/kg IM q4h × 2 days; q6h × 1 day, then q12h × 10 days; alternative: oral succimer.
Cadmium				
Metal plating, pigment, smelting, battery, and plastics industries; tobacco; incineration of these products; ingestion of food that concentrates cadmium (grains, cereals, organ meats).	Absorbed through ingestion or inhalation; bound by metallothionein, filtered at the glomerulus, but reabsorbed by proximal tubules (thus, poorly excreted). Biologic half-life: 10–30 y. Binds cellular sulfhydryl groups, competes with zinc, calcium for binding sites. Concentrates in liver and kidneys.	Acute cadmium inhalation causes pneumonitis after 4–24 h; acute ingestion causes gastroenteritis. Chronic exposure causes anosmia, yellowing of teeth, emphysema, minor LFT elevations, microcytic hypochromic anemia unresponsive to iron therapy, proteinuria, increased urinary β_2-microglobulin, calciuria, leading to chronic renal failure, osteomalacia, and fractures, ischemic heart disease and stroke. Cadmium exposure now known to cause lung, prostate, and kidney cancers.	With inhalation: pleuritic chest pain, dyspnea, cyanosis, fever, tachycardia, nausea, noncardiogenic pulmonary edema. With ingestion: nausea, vomiting, cramps, diarrhea. Bone pain, fractures with osteomalacia. If recent exposure, serum cadmium >500 nmol/L (5 μg/dL). Urinary cadmium >100 nmol/L (10 μg/g creatinine) and/or urinary β_2-microglobulin >750 μg/g creatinine (but urinary β_2-microglobulin also increased in other renal diseases such as pyelonephritis).	There is no effective treatment for cadmium poisoning (chelation not useful; dimercaprol can exacerbate nephrotoxicity). Avoidance of further exposure, supportive therapy, vitamin D for osteomalacia.
Lead				
Manufacturing of auto batteries, lead crystal, ceramics, fishing weights, etc.; demolition or sanding of lead-painted houses, bridges; stained glass making, plumbing, soldering; environmental exposure to paint chips, house dust (in homes built <1975), firing ranges (from bullet dust), food or water from improperly glazed ceramics or lead-contaminated cookware; lead pipes and plumbing; contaminated spices, herbal remedies, candies; exposure to environmental pollution from the combustion of leaded fuels, recycling of automobile batteries and electronic waste.	Absorbed through ingestion or inhalation; organic lead (e.g., tetraethyl lead) absorbed dermally. In blood, 95–99% sequestered in RBCs—thus, must measure lead in whole blood (not serum). Distributed widely in soft tissue, with half-life ~30 days; 15% of dose sequestered in bone with half-life of >20 years. Excreted mostly in urine, but also appears in other fluids including breast milk. Interferes with mitochondrial oxidative phosphorylation, ATPases, calcium-dependent messengers; enhances oxidation and cell apoptosis.	Acute exposure with blood lead levels (BPb) of >60–80 μg/dL can cause impaired neurotransmission and neuronal cell death (with central and peripheral nervous system effects); impaired hematopoiesis and renal tubular dysfunction. At higher levels of exposure (e.g., BPb >80–120 μg/dL), acute encephalopathy with convulsions, coma, and death may occur. Subclinical exposures in children (BPb 25–60 μg/dL) are associated with anemia; mental retardation; and deficits in language, motor function, balance, hearing, behavior, and school performance. Impairment of IQ appears to occur at even lower levels of exposure with no measurable threshold above the limit of detection in most assays of 1 μg/dL. In adults, chronic subclinical exposures (BPb >40 μg/dL) are associated with an increased risk of anemia, demyelinating peripheral neuropathy (mainly motor), impairments of reaction time and hearing, accelerated declines in cognition, hypertension, ECG conduction delays, hypertension, higher risk of cardiovascular disease and death, interstitial nephritis and chronic renal failure, diminished sperm counts, and spontaneous abortions.	Abdominal pain, irritability, lethargy, anorexia, anemia, Fanconi's syndrome, pyuria, azotemia in children with blood lead level (BPb) >80 μg/dL; may also see epiphyseal plate "lead lines" on long bone x-rays. Convulsions, coma at BPb >120 μg/dL. Clinically-apparent neurodevelopmental delays can be seen at BPb of 40–80 μg/dL with subclinical declines in IQ expected at lower levels of BPb down to 1 μg/dL. Screening of all U.S. children when they begin to crawl (~6 months) is recommended by the CDC; source identification and intervention is begun if the BPb >3.5 μg/dL. In adults, acute exposure causes similar symptoms as in children as well as headaches, arthralgias, myalgias, depression, impaired short-term memory, loss of libido. Physical examination may reveal a "lead line" at the gingiva-tooth border, pallor, wrist drop, and cognitive dysfunction (e.g., declines on the mini-mental state exam); lab tests may reveal a normocytic, normochromic anemia, basophilic stippling, an elevated blood protoporphyrin level (free erythrocyte or zinc), and motor delays on nerve conduction. U.S. OSHA requires regular testing of lead-exposed workers with removal if BPb >40 μg/dL. Newer guidelines have been proposed recommending that BPb be maintained at <10 μg/dL, removal of workers if BPb >20 μg/dL, and monitoring of cumulative exposure parameters.	Identification and correction of exposure sources are critical. In the United States, most states ask or require primary care physicians and/or laboratories to report all BPbs to the appropriate health agency. In the highly exposed individual with symptoms, chelation is recommended with oral DMSA (succimer); if acutely toxic, hospitalization and IV or IM chelation with ethylenediaminetetraacetic acid calcium disodium (CaEDTA) may be required, with the addition of dimercaprol to prevent worsening of encephalopathy. A large multicenter randomized trial of chelation showed no improvement in measures of intelligence among children with asymptomatic lead exposure (e.g., BPb 20–40 μg/dL). It is possible but remains unclear whether chelation among adults with chronic lead exposure may improve cardiovascular outcomes. Correction of dietary deficiencies in iron, calcium, magnesium, and zinc will lower lead absorption and may also improve toxicity. Vitamin C is a weak but natural chelating agent. Calcium supplements (1200 mg at bedtime) have been shown to lower blood lead levels in pregnant women.

(*Continued*)

TABLE 469-1 Heavy Metals (Continued)

MAIN SOURCES	METABOLISM	TOXICITY	DIAGNOSIS	TREATMENT
Mercury				
Metallic, mercurous, and mercuric mercury (Hg, Hg^{+}, Hg^{2+}) exposures occur in some chemical, metal-processing, electrical equipment, automotive industries; they are also in thermometers, dental amalgams, batteries. Mercury is dispersed by waste incineration. Environmental bacteria convert inorganic to organic mercury, which then bioconcentrates up the aquatic food chain to contaminate tuna, swordfish, and other pelagic fish.	Elemental mercury (Hg) is not well absorbed; however, it will volatilize into highly absorbable vapor. Inorganic mercury is absorbed through the gut and skin. Organic mercury is well absorbed through inhalation and ingestion. Elemental and organic mercury cross the blood-brain barrier and placenta. Mercury is excreted in urine and feces and has a half-life in blood of ~60 days; however, deposits will remain in the kidney and brain for years. Exposure to mercury stimulates the kidney to produce metallothionein, which provides some detoxification benefit. Mercury binds sulfhydryl groups and interferes with a wide variety of critical enzymatic processes.	Acute inhalation of Hg vapor causes pneumonitis and noncardiogenic pulmonary edema leading to death, CNS symptoms, and polyneuropathy. Chronic high exposure causes CNS toxicity (mercurial *erethism*; see Diagnosis); lower exposures impair renal function, motor speed, memory, coordination. Acute ingestion of inorganic mercury causes gastroenteritis, the nephritic syndrome, or acute renal failure, hypertension, tachycardia, and cardiovascular collapse, with death at a dose of 10–42 mg/kg. Ingestion of organic mercury causes gastroenteritis, arrhythmias, and lesions in the basal ganglia, gray matter, and cerebellum at doses >1.7 mg/kg. High exposure during pregnancy causes derangement of fetal neuronal migration resulting in severe mental retardation. Mild exposures during pregnancy (from fish consumption) are associated with declines in neurobehavioral performance in offspring. Dimethylmercury, a compound only found in research labs, is "supertoxic"—a few drops of exposure via skin absorption or inhaled vapor can cause severe cerebellar degeneration and death.	Chronic exposure to metallic mercury vapor produces a characteristic intention tremor and mercurial *erethism*: excitability, memory loss, insomnia, timidity, and delirium ("mad as a hatter"). On neurobehavioral tests: decreased motor speed, visual scanning, verbal and visual memory, visuomotor coordination. Children exposed to mercury in any form may develop *acrodynia* ("pink disease"): flushing, itching, swelling, tachycardia, hypertension, excessive salivation or perspiration, irritability, weakness, morbilliform rashes, desquamation of palms and soles. Toxicity from elemental or inorganic mercury exposure begins when blood levels >180 nmol/L (3.6 µg/dL) and urine levels >0.7 µmol/L (15 µg/dL). Exposures that ended years ago may result in a >20-µg increase in 24-h urine after a 2-g dose of succimer. Organic mercury exposure is best measured by levels in blood (if recent) or hair (if chronic); CNS toxicity in children may derive from fetal exposures associated with maternal hair Hg >30 nmol/g (6 µg/g).	Treat acute ingestion of mercuric salts with induced emesis or gastric lavage and polythiol resins (to bind mercury in the GI tract). Chelate with dimercaprol (up to 24 mg/kg per day IM in divided doses), DMSA (succimer), or penicillamine, with 5-day courses separated by several days of rest. If renal failure occurs, treat with peritoneal dialysis, hemodialysis, or extracorporeal regional complexing hemodialysis and succimer. Chronic inorganic mercury poisoning is best treated with *N*-acetyl penicillamine.

Abbreviations: ATPase, adenosine triphosphatase; BPb, blood lead; CDC, Centers for Disease Control and Prevention; CNS, central nervous system; DMSA, dimercaptosuccinic acid; ECG, electrocardiogram; GI, gastrointestinal; ICU, intensive care unit; IQ, intelligence quotient; LFT, liver function tests; OSHA, Occupational Safety and Health Administration; RBC, red blood cell.

cognition in both men and women living in urban communities. These relationships, in conjunction with other epidemiologic and toxicologic studies, persuaded multiple federal expert panels to conclude they were causal. Prospective studies have also demonstrated that higher bone lead levels, as well as blood lead levels as low as 1–7 µg/dL, are a major risk factor for resistant hypertension, coronary artery calcifications, and increased cardiovascular morbidity and mortality rates in both community-based and occupational-exposed populations. Lead exposure at community levels has also been associated with increased risks of hearing loss, Parkinson's disease, and amyotrophic lateral sclerosis. Occupational levels of lead exposures have been consistently linked with adverse indices of sperm health, such as reduction in semen volume, sperm concentration, total sperm count, sperm vitality, and total sperm motility. With respect to pregnancy-associated risks, high maternal bone lead levels were found to predict lower birth weight, head circumference, birth length, and neurodevelopmental performance in offspring by age 2 years. Offspring have also been shown to have higher blood pressures at age 7–14 years, an age range at which higher blood pressures are known to predict an elevated risk of developing hypertension. In a randomized trial, calcium supplementation (1200 mg daily) was found to significantly reduce the mobilization of lead from maternal bone into blood during pregnancy.

The toxicity of low-level organic *mercury* exposure (as manifested by neurobehavioral performance) is of increasing concern based on studies of the offspring of mothers who ingested mercury-contaminated fish. With respect to whether the consumption of fish by women during pregnancy is good or bad for offspring neurodevelopment, balancing the trade-offs of the beneficial effects of the omega-3-fatty acids (FAs) in fish versus the adverse effects of mercury contamination in fish has led to some confusion and inconsistency in public health recommendations. Overall, it would appear that it would be best for pregnant women to either limit fish consumption to those species known to be low in mercury contamination but high in omega-3-FAs (such as sardines or mackerel) or to avoid fish and obtain omega-3-FAs through supplements or other dietary sources. Well-conducted studies have convincingly debunked the contention that ethyl mercury, used as a preservative in multiuse vaccines administered in early childhood, has played a significant role in causing neurodevelopmental problems such as autism. With regard to adults, there is evidence that mercury exposure is associated with elevated markers of dyslipidemia and high-sensitivity C-reactive protein (a marker of chronic low-grade inflammation), but the direct evidence as to whether mercury exposure is associated with increased risk of hypertension and cardiovascular disease remains somewhat conflicting. There is also some evidence that mercury exposure in the general population is associated with the development of diabetes, perturbations in markers of autoimmunity, and depression. At this point, conclusions cannot be drawn and the clinical significance of these findings remains somewhat unclear.

Heavy metals pose risks to health that are especially burdensome in selected parts of the world. For example, *arsenic* exposure from natural contamination of shallow tube wells inserted for drinking water is a major environmental problem for millions of residents in parts of Bangladesh and Western India. Contamination was formerly considered only a problem with deep wells; however, the geology of this region allows most residents only a few alternatives for potable drinking water. Arsenic contamination of drinking water is also a major problem in China, Argentina, Chile, Mexico, and some regions of the United States (Maine, New Hampshire, Massachusetts). The global campaign to phase out *leaded* gasoline has successfully concluded. However, significant population exposures to lead remain,

particularly in the United States with respect to older housing that contains lead paint or that receives drinking water through lead pipes, and evidence indicates that exposures are beginning to increase again in many low- and middle-income countries due to industrial pollution, the recycling of automobile batteries, electronic waste, mining, and a variety of contaminated consumer products. Populations living in the Arctic have been shown to have particularly high exposures to *mercury* due to long-range transport patterns that concentrate mercury in the polar regions, as well as the traditional dependence of Arctic peoples on the consumption of fish and other wildlife that bioconcentrate methylmercury.

A few additional metals deserve brief mention but are not covered in Table 469-1 because of the relative rarity of their being clinically encountered or the uncertainty regarding their potential toxicities. *Aluminum* contributes to the encephalopathy in patients with severe renal disease, who are undergoing dialysis **(Chap. 422)**. High levels of aluminum are found in the neurofibrillary tangles in the cerebral cortex and hippocampus of patients with Alzheimer's disease, as well as in the drinking water and soil of areas with an unusually high incidence of Alzheimer's. The experimental and epidemiologic evidence for the aluminum–Alzheimer's disease link remains relatively weak, however, and it cannot be concluded that aluminum is a causal agent or a contributing factor in neurodegenerative disease. Hexavalent *chromium* is corrosive and sensitizing. Workers in the chromate and chrome pigment production industries have consistently had a greater risk of lung cancer. The introduction of *cobalt* chloride as a fortifier in beer led to outbreaks of fatal cardiomyopathy among heavy consumers, a condition that has also recently been reported in conjunction with the cobalt exposure associated with metal implants used in hip arthroplasty. Occupational exposure (e.g., of miners, dry-battery manufacturers, and arc welders) to *manganese* (Mn) can cause a parkinsonian syndrome within 1–2 years, including gait disorders; postural instability; a masked, expressionless face; tremor; and psychiatric symptoms. In contrast to typical cases of Parkinson's disease, manganese-induced parkinsonism is nonresponsive to treatment with L-dopa. With the introduction of methylcyclopentadienyl manganese tricarbonyl (MMT) as a gasoline additive, there is concern for the toxic potential of environmental manganese exposure. Some epidemiologic studies have found an association between the prevalence of parkinsonian disorders and estimated manganese exposures emitted by local ferroalloy industries; others have found evidence suggesting that manganese may interfere with early childhood neurodevelopment in ways similar to that of lead. Manganese toxicity is clearly associated with dopaminergic dysfunction, and its toxicity is likely influenced by age, gender, ethnicity, genetics, and preexisting medical conditions. *Nickel* exposure induces an allergic response, and inhalation of nickel compounds with low aqueous solubility (e.g., nickel subsulfide and nickel oxide) in occupational settings is associated with an increased risk of lung cancer. Overexposure to selenium may cause local irritation of the respiratory system and eyes, gastrointestinal irritation, liver inflammation, loss of hair, depigmentation, and peripheral nerve damage. Workers exposed to certain organic forms of *tin* (particularly trimethyl and triethyl derivatives) have developed psychomotor disturbances, including tremor, convulsions, hallucinations, and psychotic behavior.

Thallium, which is a component of some insecticides, metal alloys, and fireworks, is absorbed through the skin as well as by ingestion and inhalation. Severe poisoning follows a single ingested dose of >1 g or >8 mg/kg. Nausea and vomiting, abdominal pain, and hematemesis precede confusion, psychosis, organic brain syndrome, and coma. Thallium is radiopaque. Induced emesis or gastric lavage is indicated within 4–6 h of acute ingestion; Prussian blue prevents absorption and is given orally at 250 mg/kg in divided doses. Unlike other types of metal poisoning, thallium poisoning may be less severe when activated charcoal is used to interrupt its enterohepatic circulation. Other measures include forced diuresis, treatment with potassium chloride (which promotes renal excretion of thallium), and peritoneal dialysis.

Chelation therapy remains the treatment of choice for most toxic metals in the setting of severe acute clinical poisoning. However, the use of chelation for treating chronic diseases remains controversial, in part because of the lack of evidence from rigorous randomized clinical trials. One area for which there is moderate evidence is the use of chelation in patients with higher than average levels of accumulated lead burdens as a means of improving kidney function. The results from a series of randomized trials conducted in Taiwan suggest that among individuals with mildly elevated lead burdens (defined as between 150 and 600 μg of lead per 72-h urine upon an EDTA mobilization test [1 g EDTA]), weekly calcium disodium EDTA chelation treatments for between 2 and 27 months can improve renal function outcomes, both in individuals with and without type 2 diabetes.

The Trial to Assess Chelation Therapy (TACT-1), a multicenter, double-blind, placebo-controlled, prospective randomized trial funded by the National Institutes of Health of 1708 patients aged ≥50 years who had experienced a myocardial infarction (MI), found that a protocol of repeated intravenous chelation with disodium EDTA, compared with placebo, modestly but significantly reduced the risk of adverse cardiovascular outcomes, many of which were revascularization procedures. The effect was particularly pronounced among those with concurrent diabetes. However, the trial did not include rigorous measures of exposure to lead or other metals or any selection criteria based on metals exposure. By contrast, the recently released results of the TACT-2 trial, which reproduced the TACT-1 protocol with the addition of measures of metals, did not show benefit. However, the metals exposure levels among subjects was very low, likely reflecting the known decline in metals exposure over time in a study conducted more than 10 years after TACT-1, and it remains unclear whether chelation has a role in treating individuals with significant chronic metals exposure.

470 Poisoning and Drug Overdose

Mark B. Mycyk

Poisoning refers to the development of dose-related adverse effects following exposure to chemicals, drugs, or other xenobiotics. To paraphrase Paracelsus, the dose makes the poison. Although most poisons have predictable dose-related effects, individual responses to a given dose may vary because of genetic polymorphism, enzymatic induction or inhibition in the presence of other xenobiotics, or acquired tolerance. Poisoning may be local (e.g., skin, eyes, or lungs) or systemic depending on the route of exposure, the chemical and physical properties of the poison, and its mechanism of action. The severity and reversibility of poisoning also depend on the functional reserve of the individual or target organ, which is influenced by age and preexisting disease.

EPIDEMIOLOGY

More than 5 million poison exposures occur in the United States each year. Most are acute, are accidental (unintentional), involve a single agent, occur in the home (>90%), result in minor or no toxicity, and involve children <6 years of age. Pharmaceuticals are involved in 47% of poisoning exposures and in 84% of serious or fatal poisonings. Household cleaning substances and cosmetics/personal care products are the most common nonpharmaceutical exposures reported to the National Poison Data System (NPDS). Fatalities most commonly occur from intentional self-harm ingestions (suicide) of pharmaceuticals or from complications involving opioids and other psychoactive drugs of abuse. According to the Centers for Disease Control and Prevention (CDC), fatalities involving drugs have steadily increased since 1999. More than 106,600 deaths were attributed to drug overdose in the United States in 2021, with an age-adjusted overdose death rate of 32.4 per 100,000. Although prescription opioids have appropriately received attention as a major reason for the ongoing substance use disorder epidemic in the United States, the ever-expanding street availability of synthetic opioids (e.g., fentanyl) and the rapid proliferation of other psychoactive drugs of abuse (e.g., xylazine) are the main drivers of drug overdose deaths. State prescription monitoring programs, enhanced training in pain management for health care professionals, expanded harm reduction services, improved outreach education to the public, and improved partnerships with regional safety officials to monitor trends in the illicit drug supply continue to be the main prevention and response priorities for addressing this worsening epidemic. Unintentional exposures can result from the improper use of chemicals at work or play; label misreading; product mislabeling; mistaken identification of unlabeled chemicals; uninformed self-medication; and dosing errors by nurses, pharmacists, physicians, parents, and the elderly. Excluding the recreational use of ethanol, attempted suicide (deliberate self-harm) is the most common reported reason for intentional poisoning. Recreational use of prescribed and over-the-counter drugs for psychotropic or euphoric effects (*abuse*) or excessive self-dosing (*misuse*) is increasingly common and may also result in unintentional self-poisoning.

About 20–25% of exposures require bedside health-professional evaluation, and 5% of all exposures require hospitalization. Poisonings account for 5–10% of all ambulance transports, emergency department visits, and intensive care unit admissions. Hospital admissions related to poisoning are also associated with longer lengths of stay and increase the utilization of resources such as radiography and other laboratory services. Up to 35% of psychiatric admissions are prompted by attempted suicide via overdosage with cases involving adolescents steadily increasing during the last decade. Overall, the mortality rate is low: <1% of all poisoning exposures. It is significantly higher (1–2%) among hospitalized patients with intentional (suicidal) overdose or complications from drugs of abuse, who account for the majority of serious poisonings. Acetaminophen is the pharmaceutical agent most often implicated in fatal poisoning. Overall, carbon monoxide is the leading cause of death from poisoning, but this prominence is not reflected in hospital or poison center statistics because patients with such poisoning are typically dead when discovered and are referred directly to medical examiners.

DIAGNOSIS

Although poisoning can mimic other illnesses, the correct diagnosis can usually be established by the history, physical examination, routine and toxicologic laboratory evaluations, and characteristic clinical course.

HISTORY

The *history* should include the time, route, duration, and circumstances (location, surrounding events, and intent) of exposure; the name and amount of each drug, chemical, or ingredient involved; the time of onset, nature, and severity of symptoms; the time and type of first-aid measures provided; the medical and psychiatric history; and occupation.

In many cases, the patient is confused, comatose, unaware of an exposure, or unable or unwilling to admit to one. Suspicious circumstances include unexplained sudden illness in a previously healthy person or a group of healthy people; a history of psychiatric problems (particularly depression or bipolar disorder); recent changes in health, economic status, or social relationships; and onset of illness during work with chemicals or after ingestion of food, drink (especially ethanol), or medications. When patients become ill soon after arriving from a foreign country or being arrested for criminal activity, "body packing" or "body stuffing" (ingesting or concealing illicit drugs in a body cavity) should be suspected. Relevant information may be available from family, friends, paramedics, police, pharmacists, physicians, and employers, who should be questioned regarding the patient's habits, hobbies, behavioral changes, available medications, and antecedent events. Patients need to be asked explicitly about their prescribed medications, use of over-the-counter or herbal medications, and recreational drug use. Drugs previously considered "illicit" such as cannabinoids are now legal in many states and prescribed for therapeutic purposes. A search of clothes, belongings, and place of discovery may reveal a suicide note or a container of drugs or chemicals. If available, a review of a patient's recent social media posts may be helpful to the treating clinician because self-harm plans involving medications or drugs are often described there. Without a clear history in a patient clinically suspected to be poisoned, all medications available anywhere in the patient's home or belongings should be considered as possible agents, including medications for pets. Review of the patient's record in the state prescription monitoring program (PMP) may disclose relevant history of Schedule II, III, IV, and V controlled substance use. The imprint code on pills and the label on chemical products may be used to identify the ingredients and potential toxicity of a suspected poison by consulting a reference text, a computerized database, the manufacturer, or a regional poison information center (800-222-1222). Occupational exposures require review of any available safety data sheet (SDS) from the worksite. Because of increasing globalization from travel and internet consumerism, unfamiliar poisonings may result in local emergency department evaluation. Pharmaceuticals, industrial chemicals, or novel psychoactive drugs of abuse from foreign countries may be identified with the assistance of a local medical toxicologist, a regional poison center, or via the Internet.

PHYSICAL EXAMINATION AND CLINICAL COURSE

The *physical examination* should focus initially on vital signs, the cardiopulmonary system, and neurologic status. The neurologic examination should include documentation of neuromuscular abnormalities such as dyskinesia, dystonia, fasciculations, myoclonus, rigidity, and tremors. The patient should also be examined for evidence of trauma and underlying illnesses. Focal neurologic findings are uncommon in poisoning, and their presence should prompt evaluation for a structural central nervous system (CNS) lesion. Examination of the eyes (for nystagmus and pupil size and reactivity), abdomen (for bowel activity

and bladder size), and skin (for burns, bullae, color, warmth, moisture, pressure sores, and puncture marks) may reveal findings of diagnostic value. When the history is unclear, all orifices should be examined for the presence of chemical burns and drug packets. The odor of breath or vomitus and the color of nails, skin, or urine may provide important diagnostic clues.

The diagnosis of poisoning in cases of unknown etiology primarily relies on pattern recognition. The first step is to assess the pulse, blood pressure, respiratory rate, pulse oximetry, temperature, and neurologic status and to characterize the overall physiologic state as stimulated, depressed, discordant, or normal **(Table 470-1)**. Obtaining a complete set of vital signs and reassessing them frequently are critical. Measuring core temperature is especially important, even in difficult or combative patients, since temperature elevation is the most reliable prognosticator of poor outcome in poisoning from stimulants (e.g., cocaine) or drug withdrawal (e.g., alcohol or γ-hydroxybutyric acid [GHB]). The next step is to consider the underlying causes of the physiologic state and to attempt to identify a pathophysiologic pattern or toxic syndrome (*toxidrome*) based on the observed findings. Assessing the severity of physiologic derangements **(Table 470-2)** is useful in this regard and also for monitoring the clinical course and response to treatment. In cases of polydrug overdose involving different drug classes, identifying a clear toxidrome can be challenging if the different drugs counteract the physiologic effects of one another. The final step is to attempt to identify the particular agent involved by looking for unique or relatively poison-specific physical or ancillary test abnormalities. Distinguishing among toxidromes on the basis of the physiologic state is summarized next.

The Stimulated Physiologic State Increased pulse, blood pressure, respiratory rate, temperature, and neuromuscular activity characterize the *stimulated* physiologic state, which can reflect sympathetic,

TABLE 470-1 Differential Diagnosis of Poisoning Based on Physiologic State

STIMULATED	DEPRESSED	DISCORDANT	NORMAL
Sympathetics	Sympatholytics	Asphyxiants	Nontoxic exposure
Sympathomimetics	α_1-Adrenergic antagonists	Cytochrome oxidase inhibitors	Psychogenic illness
Ergot alkaloids	α_2-Adrenergic agonists	Inert gases	"Toxic time-bombs"
Methylxanthines	ACE inhibitors	Irritant gases	Slow absorption
Monoamine oxidase inhibitors	Angiotensin receptor blockers	Methemoglobin inducers	Anticholinergics
Thyroid hormones	Antipsychotics	Oxidative phosphorylation inhibitors	Carbamazepine
Anticholinergics	β-Adrenergic blockers	AGMA inducers	Concretion formers
Antihistamines	Calcium channel blockers	Alcohol (ketoacidosis)	Extended-release phenytoin sodium capsules (Dilantin Kapseals)
Antiparkinsonian agents	Cardiac glycosides	Ethylene glycol	Drug packets
Antipsychotics	Cyclic antidepressants	Iron	Enteric-coated pills
Antispasmodics	Cholinergics	Methanol	Diphenoxylate-atropine (Lomotil)
Belladonna alkaloids	Acetylcholinesterase inhibitors	Other alcohols	Opioids
Cyclic antidepressants	Muscarinic agonists	Salicylate	Salicylates
Mushrooms and plants	Nicotinic agonists	Toluene	Sustained-release pills
Hallucinogens	Opioids	CNS syndromes	Valproate
Cannabinoids (marijuana)	Analgesics	Extrapyramidal reactions	Slow distribution
LSD and analogues	GI antispasmodics	Hydrocarbon inhalation	Cardiac glycosides
Mescaline and analogues	Heroin	Isoniazid	Lithium
Mushrooms	Sedative-hypnotics	Lithium	Metals
Phencyclidine and analogues	Alcohols	Neuroleptic malignant syndrome	Salicylate
Withdrawal syndromes	Anticonvulsants	Serotonin syndrome	Valproate
Barbiturates	Barbiturates	Strychnine	Toxic metabolite
Benzodiazepines	Benzodiazepines	Membrane-active agents	Acetaminophen
Ethanol	GABA precursors	Amantadine	Carbon tetrachloride
GHB products	Muscle relaxants	Antiarrhythmics	Cyanogenic glycosides
Opioids	Other agents	Antihistamines	Ethylene glycol
Sedative-hypnotics	GHB products	Antipsychotics	Methanol
Sympatholytics	Xylazine	Carbamazepine	Methemoglobin inducers
		Cyclic antidepressants	Mushroom toxins
		Local anesthetics	Organophosphate insecticides
		Opioids (some)	Paraquat
		Quinoline antimalarials	Metabolism disruptors
			Antineoplastic agents
			Antiviral agents
			Colchicine
			Hypoglycemic agents
			Immunosuppressive agents
			MAO inhibitors
			Metals
			Other oral anticoagulants
			Salicylate
			Warfarin

Abbreviations: ACE, angiotensin-converting enzyme; AGMA, anion-gap metabolic acidosis; CNS, central nervous system; GABA, γ-aminobutyric acid; GHB, γ-hydroxybutyrate; GI, gastrointestinal; LSD, lysergic acid diethylamide; MAO, monoamine oxidase.

TABLE 470-2 Severity of Physiologic Stimulation and Depression in Poisoning and Drug Withdrawal

Physiologic Stimulation	
Grade 1	Anxious, irritable, tremulous; vital signs normal; diaphoresis, flushing or pallor, mydriasis, and hyperreflexia sometimes present
Grade 2	Agitated; may have confusion or hallucinations but can converse and follow commands; vital signs mildly to moderately increased
Grade 3	Delirious; unintelligible speech, uncontrollable motor hyperactivity; moderately to markedly increased vital signs; tachyarrhythmias possible
Grade 4	Coma, seizures, cardiovascular collapse
Physiologic Depression	
Grade 1	Awake, lethargic, or sleeping but arousable by voice or tactile stimulation; able to converse and follow commands; may be confused
Grade 2	Responds to pain but not voice; can vocalize but not converse; spontaneous motor activity present; brainstem reflexes intact
Grade 3	Unresponsive to pain; spontaneous motor activity absent; brainstem reflexes depressed; motor tone, respirations, and temperature decreased
Grade 4	Unresponsive to pain; flaccid paralysis; brainstem reflexes and respirations absent; cardiovascular vital signs decreased

anticholinergic, or hallucinogen poisoning or drug withdrawal (Table 470-1). Other features are noted in Table 470-2. Mydriasis, a characteristic feature of all stimulants, is most marked in anticholinergic poisoning since pupillary reactivity relies on muscarinic control. In sympathetic poisoning (e.g., due to cocaine), pupils are also enlarged, but some reactivity to light remains. The anticholinergic toxidrome is also distinguished by hot, dry, flushed skin; decreased bowel sounds; and urinary retention. Other stimulant syndromes increase sympathetic activity and cause diaphoresis, pallor, and increased bowel activity with varying degrees of nausea, vomiting, abnormal distress, and occasionally diarrhea. The absolute and relative degree of vital-sign changes and neuromuscular hyperactivity can help distinguish among stimulant toxidromes. Since sympathetics stimulate the peripheral nervous system more directly than do hallucinogens or drug withdrawal, markedly increased vital signs and organ ischemia suggest sympathetic poisoning. Findings helpful in suggesting the particular drug or class causing physiologic stimulation include reflex bradycardia from selective α-adrenergic stimulants (e.g., decongestants), hypotension from selective β-adrenergic stimulants (e.g., asthma therapeutics), limb ischemia from ergot alkaloids, rotatory nystagmus from phencyclidine and ketamine (the only physiologic stimulants that cause this finding), and delayed cardiac conduction from high doses of cocaine and some anticholinergic agents (e.g., antihistamines, cyclic antidepressants, and antipsychotics). Seizures suggest a sympathetic etiology, an anticholinergic agent with membrane-active properties (e.g., cyclic antidepressants, phenothiazines), or a withdrawal syndrome. Close attention to core temperature is critical in patients with grade 4 physiologic stimulation (Table 470-2).

The Depressed Physiologic State Decreased pulse, blood pressure, respiratory rate, temperature, and neuromuscular activity are indicative of the *depressed* physiologic state caused by "functional" sympatholytics (agents that decrease cardiac function and vascular tone as well as sympathetic activity), cholinergic (muscarinic and nicotinic) agents, opioids, and sedative-hypnotic γ-aminobutyric acid (GABA)-ergic agents (Tables 470-1 and 470-2). Miosis is also common and is most pronounced in opioid and cholinergic poisoning. Miosis is distinguished from other depressant syndromes by muscarinic and nicotinic signs and symptoms (Table 470-1). Pronounced cardiovascular depression in the absence of significant CNS depression suggests a direct or peripherally acting sympatholytic. In contrast, in opioid and sedative-hypnotic poisoning, vital-sign changes are secondary to depression of CNS cardiovascular and respiratory centers (or consequent hypoxemia), and significant abnormalities in these parameters do not occur until there is a marked decrease in the level of consciousness (grade 3 or 4 physiologic depression; Table 470-2). Other clues that suggest the cause of physiologic depression include cardiac arrhythmias and conduction disturbances (due to antiarrhythmics, β-adrenergic antagonists, calcium channel blockers, digitalis glycosides, propoxyphene, and cyclic antidepressants), mydriasis (due to tricyclic antidepressants, some antiarrhythmics, meperidine, and diphenoxylate-atropine [Lomotil]), nystagmus (due to sedative-hypnotics), and seizures (due to cholinergic agents, propoxyphene, and cyclic antidepressants).

The Discordant Physiologic State The *discordant* physiologic state is characterized by mixed vital-sign and neuromuscular abnormalities, as observed in poisoning by asphyxiants, CNS syndromes, membrane-active agents, and anion-gap metabolic acidosis (AGMA) inducers (Table 470-1). In these conditions, manifestations of physiologic stimulation and physiologic depression occur together or at different times during the clinical course. For example, membrane-active agents can cause simultaneous coma, seizures, hypotension, and tachyarrhythmias. Alternatively, vital signs may be normal while the patient has an altered mental status or is obviously sick or clearly symptomatic. Early, pronounced vital-sign and mental-status changes suggest asphyxiant or membrane-active agent poisoning; the lack of such abnormalities suggests an AGMA inducer; and marked neuromuscular dysfunction without significant vital-sign abnormalities suggests a CNS syndrome. The *discordant* physiologic state may also be evident in patients poisoned with multiple agents.

The Normal Physiologic State A *normal* physiologic status and physical examination may be due to a nontoxic exposure, psychogenic illness, or poisoning by "toxic time-bombs": agents that are slowly absorbed, are slowly distributed to their sites of action, require metabolic activation, or disrupt metabolic processes (Table 470-1). Because so many medications have now been reformulated into once-a-day preparations for the patient's convenience and adherence, toxic time-bombs are increasingly common. Diagnosing a nontoxic exposure requires that the identity of the exposure agent be known or that a toxic time-bomb exposure be excluded and the time since exposure exceed the longest known or predicted interval between exposure and peak toxicity. Psychogenic illness (fear of being poisoned, mass hysteria) may also follow a nontoxic exposure and should be considered when symptoms are inconsistent with exposure history. Anxiety reactions resulting from a nontoxic exposure can cause mild physiologic stimulation (Table 470-2) and be indistinguishable from toxicologic causes without ancillary testing or a suitable period of observation.

LABORATORY ASSESSMENT

Laboratory assessment may be helpful in the differential diagnosis. Increased AGMA is most common in advanced methanol, ethylene glycol, and salicylate intoxication but can occur with any poisoning that results in hepatic, renal, or respiratory failure; seizures; or shock. The serum lactate concentration is more commonly low (less than the anion gap) in the former and high (nearly equal to the anion gap) in the latter. An abnormally low anion gap can be due to elevated blood levels of bromide, calcium, iodine, lithium, or magnesium. An increased osmolal gap—a difference of >10 mmol/L between serum osmolality (measured by freezing-point depression) and osmolality calculated from serum sodium, glucose, and blood urea nitrogen levels—suggests the presence of a low-molecular-weight solute such as acetone; an alcohol (benzyl, ethanol, isopropanol, methanol); a glycol (diethylene, ethylene, propylene); ether (ethyl, glycol); or an "unmeasured" cation (calcium, magnesium) or sugar (glycerol, mannitol, sorbitol). Ketosis suggests acetone, isopropyl alcohol, salicylate poisoning, or alcoholic ketoacidosis. Hypoglycemia may be due to poisoning with β-adrenergic blockers, ethanol, insulin, oral hypoglycemic agents, quinine, and salicylates, whereas hyperglycemia can occur in poisoning with acetone, β-adrenergic agonists, caffeine, calcium channel blockers, iron, theophylline, or *N*-3-pyridylmethyl-*N*-*p*-nitrophenylurea (PNU [Vacor]). Hypokalemia can be caused by barium, β-adrenergic agonists, caffeine, diuretics, theophylline, or toluene; hyperkalemia

suggests poisoning with an α-adrenergic agonist, a β-adrenergic blocker, cardiac glycosides, or fluoride. Hypocalcemia may be seen in ethylene glycol, fluoride, and oxalate poisoning. Prothrombin time and international normalized ratio are useful for risk stratification in cases of warfarin or rodenticide poisoning but are not to be relied on when evaluating overdose or complications from direct oral anticoagulant pharmaceuticals (direct thrombin inhibitors and direct factor Xa inhibitors).

The *electrocardiogram* (ECG) can be useful for rapid diagnostic purposes. Bradycardia and atrioventricular block may occur in patients poisoned by α-adrenergic agonists, antiarrhythmic agents, beta blockers, calcium channel blockers, cholinergic agents (carbamate and organophosphate insecticides), cardiac glycosides, lithium, or tricyclic antidepressants. QRS- and QT-interval prolongation may be caused by hyperkalemia, various antidepressants, and other membrane-active drugs (Table 470-1). Ventricular tachyarrhythmias may be seen in poisoning with cardiac glycosides, fluorides, membrane-active drugs, methylxanthines, sympathomimetics, antidepressants, and agents that cause hyperkalemia or potentiate the effects of endogenous catecholamines (e.g., chloral hydrate, aliphatic and halogenated hydrocarbons).

Radiologic studies may occasionally be useful. Pulmonary edema (adult respiratory distress syndrome [ARDS]) can be caused by poisoning with carbon monoxide, cyanide, an opioid, paraquat, phencyclidine, a sedative-hypnotic, or salicylate; by inhalation of irritant gases, fumes, or vapors (acids and alkali, ammonia, aldehydes, chlorine, hydrogen sulfide, isocyanates, metal oxides, mercury, phosgene, polymers); or by prolonged anoxia, hyperthermia, or shock. Aspiration pneumonia is common in patients with coma, seizures, and petroleum distillate aspiration. Chest x-ray is useful for identifying complications from metal fume fever or elemental mercury. The presence of radiopaque densities on abdominal x-rays or abdominal computed tomography (CT) scan suggests the ingestion of chloral hydrate, chlorinated hydrocarbons, heavy metals, illicit drug packets, iodinated compounds, potassium salts, enteric-coated tablets, or salicylates.

Toxicologic analysis of urine and blood (and occasionally of gastric contents and chemical samples) can sometimes confirm or rule out suspected poisoning. Interpretation of laboratory data requires knowledge of the qualitative and quantitative tests used for screening and confirmation (enzyme-multiplied, fluorescence polarization, and radio-immunoassays; colorimetric and fluorometric assays; thin-layer, gas-liquid, or high-performance liquid chromatography; gas chromatography; mass spectrometry), their sensitivity (limit of detection) and specificity, the preferred biologic specimen for analysis, and the optimal time of specimen sampling. Personal communication with the hospital laboratory is essential to an understanding of institutional testing capabilities and limitations.

Rapid *qualitative* hospital-based urine tests for drugs of abuse are only screening tests that cannot confirm the exact identity of the detected substance and should not be considered diagnostic or used for forensic purposes. False-positive and false-negative results are common. A positive screen may result from other pharmaceuticals that interfere with laboratory analysis (e.g., fluoroquinolones commonly cause false-positive opiate screens). Confirmatory testing with gas chromatography/mass spectrometry can be requested, but it often takes weeks to obtain a reported result. A negative screening result may mean that the responsible substance is not detectable by the test used or that its concentration is too low for detection at the time of sampling. For instance, recent new drugs of abuse that often result in emergency department evaluation for unexpected complications, such as synthetic cannabinoids (spice), cathinones (bath salts), and opiate substitutes (kratom), are not detectable by hospital-based tests. In cases where a drug concentration is too low to be detected early during clinical evaluation, repeating the test at a later time may yield a positive result. Patients symptomatic from drugs of abuse often require immediate management based on the history, physical examination, and observed toxidrome without laboratory confirmation (e.g., apnea from opioid intoxication). When the patient is asymptomatic or when the clinical picture is consistent with the reported history, qualitative screening is neither clinically useful nor cost-effective. Thus, qualitative drug screens are of greatest value for the evaluation of patients with severe or unexplained toxicities, such as coma, seizures, cardiovascular instability, metabolic or respiratory acidosis, and nonsinus cardiac rhythms. In contrast to qualitative drug screens, *quantitative* serum tests are useful for evaluation of patients poisoned with acetaminophen **(Chap. 351)**, alcohols (including ethylene glycol and methanol), anticonvulsants, barbiturates, digoxin, heavy metals, iron, lithium, salicylate, and theophylline, as well as for the presence of carboxyhemoglobin and methemoglobin. The serum concentration in these cases guides clinical management, and results are often available within an hour.

The *response to antidotes* is sometimes useful for diagnostic purposes. Resolution of altered mental status and abnormal vital signs within minutes of IV administration of dextrose, naloxone, or flumazenil is virtually diagnostic of hypoglycemia, opioid poisoning, and benzodiazepine intoxication, respectively. The prompt reversal of dystonic (extrapyramidal) signs and symptoms following an IV dose of benztropine or diphenhydramine confirms a drug etiology. Although complete reversal of both central and peripheral manifestations of anticholinergic poisoning by physostigmine is diagnostic of this condition, physostigmine may cause some arousal in patients with CNS depression of any etiology.

TREATMENT

Poisoning and Drug Overdose

GENERAL PRINCIPLES

Treatment goals include support of vital signs, prevention of further poison absorption (decontamination), enhancement of poison elimination, administration of specific antidotes, and prevention of reexposure **(Table 470-3)**. Specific treatment depends on the identity of the poison, the route and amount of exposure, the time

TABLE 470-3 Fundamentals of Poisoning Management

Supportive Care	
Airway protection	Treatment of seizures
Oxygenation/ventilation	Correction of temperature abnormalities
Treatment of arrhythmias	Correction of metabolic derangements
Hemodynamic support	Prevention of secondary complications
Prevention of Further Poison Absorption	
Gastrointestinal decontamination	Decontamination of other sites
Gastric lavage	Eye decontamination
Activated charcoal	Skin decontamination
Whole-bowel irrigation	Body cavity evacuation
Dilution	
Endoscopic/surgical removal	
Enhancement of Poison Elimination	
Multiple-dose activated charcoal administration	Extracorporeal removal
Alteration of urinary pH	Hemodialysis
Chelation	Hemoperfusion
Hyperbaric oxygenation	Hemofiltration
	Plasmapheresis
	Exchange transfusion
	Continuous venovenous hemofiltration (CVVH)
Administration of Antidotes	
Neutralization by antibodies	Metabolic antagonism
Neutralization by chemical binding	Physiologic antagonism
Prevention of Reexposure	
Adult education	Notification of regulatory agencies
Child-proofing	Psychiatric referral
Naloxone distribution	Linkage to harm reduction services

of presentation relative to the time of exposure, and the severity of poisoning. Knowledge of the offending agents' pharmacokinetics and pharmacodynamics is essential.

During the *pretoxic phase*, prior to the onset of poisoning, decontamination is the highest priority, and treatment is based solely on the history. The maximal potential toxicity based on the greatest possible exposure should be assumed. Since decontamination is more effective when accomplished soon after exposure and when the patient is asymptomatic, the initial history and physical examination should be focused and brief. It is also advisable to establish IV access and initiate cardiac monitoring, particularly in patients with potentially serious ingestions or unclear histories.

When an accurate history is not obtainable and a poison causing delayed toxicity (i.e., a toxic time-bomb) or irreversible damage is suspected, blood and urine should be sent for appropriate toxicologic screening and quantitative analysis. During poison absorption and distribution, blood levels may be greater than those in tissue and may not correlate with toxicity. However, high blood levels of agents whose metabolites are more toxic than the parent compound (acetaminophen, ethylene glycol, or methanol) may indicate the need for additional interventions (antidotes, dialysis). Most patients who remain asymptomatic or who become asymptomatic 6 h after ingestion are unlikely to develop subsequent toxicity and can be discharged safely. Longer observation will be necessary for patients who have ingested toxic time-bombs.

During the *toxic phase*—the interval between the onset of poisoning and its peak effects—management is based primarily on clinical and laboratory findings. *Effects after an overdose usually begin sooner, peak later, and last longer than they do after a therapeutic dose*. A drug's published pharmacokinetic profile in standard references such as the *Physician's Desk Reference* (PDR) is usually different from its toxicokinetic profile in overdose. Resuscitation and stabilization are the first priority. Symptomatic patients should have an IV line placed and should undergo oxygen saturation determination, cardiac monitoring, and continuous observation. Baseline laboratory, ECG, and x-ray evaluation may also be appropriate. Intravenous glucose (unless the serum level is documented to be normal), naloxone, and thiamine should be considered in patients with altered mental status, particularly those with coma or seizures. Decontamination should also be considered, but it is less likely to be effective during this phase than during the pretoxic phase.

Measures that enhance poison elimination may shorten the duration and severity of the toxic phase. However, they are not without risk, which must be weighed against the potential benefit. Diagnostic certainty (usually via laboratory confirmation) is generally a prerequisite. Intestinal (gut) dialysis with repetitive doses of activated charcoal (see "Multiple-Dose Activated Charcoal," later) can enhance the elimination of selected poisons such as theophylline or carbamazepine. Urinary alkalinization may enhance the elimination of salicylates and a few other poisons. Chelation therapy can enhance the elimination of selected metals. Extracorporeal elimination methods are effective for many poisons, but their expense and risk make their use reasonable only in patients who would otherwise have an unfavorable outcome.

During the *resolution phase* of poisoning, supportive care and monitoring should continue until clinical, laboratory, and ECG abnormalities have resolved. Since chemicals are eliminated sooner from the blood than from tissues, blood levels are usually lower than tissue levels during this phase and again may not correlate with toxicity. This discrepancy applies particularly when extracorporeal elimination procedures are used. Redistribution from tissues may cause a rebound increase in the blood level after termination of these procedures (e.g., lithium). When a metabolite is responsible for toxic effects, continued treatment may be necessary in the absence of clinical toxicity or abnormal laboratory studies.

SUPPORTIVE CARE

The goal of supportive therapy is to maintain physiologic homeostasis until detoxification is accomplished and to prevent and treat secondary complications such as aspiration, bedsores, cerebral and pulmonary edema, pneumonia, rhabdomyolysis, renal failure, sepsis, thromboembolic disease, coagulopathy, and generalized organ dysfunction due to hypoxemia or shock.

Admission to an intensive care unit is indicated for the following: patients with severe poisoning (coma, respiratory depression, hypotension, cardiac conduction abnormalities, cardiac arrhythmias, hypothermia or hyperthermia, seizures); those needing close monitoring, antidotes, or enhanced elimination therapy; those showing progressive clinical deterioration; and those with significant underlying medical problems. Patients with mild to moderate toxicity can be managed on a general medical service, on an intermediate care unit, or in an emergency department observation area, depending on the anticipated duration and level of monitoring needed (intermittent clinical observation vs continuous clinical, cardiac, and respiratory monitoring). Patients who have attempted suicide require continuous observation and measures to prevent self-injury until they are no longer suicidal.

Respiratory Care Endotracheal intubation for protection against the aspiration of gastrointestinal contents is of paramount importance in patients with CNS depression or seizures as this complication can increase morbidity and mortality rates. Mechanical ventilation may be necessary for patients with respiratory depression or hypoxemia and for facilitation of therapeutic sedation or paralysis of patients in order to prevent or treat hyperthermia, acidosis, and rhabdomyolysis associated with neuromuscular hyperactivity. Since clinical assessment of respiratory function can be inaccurate, the need for oxygenation and ventilation is best determined by continuous pulse oximetry or arterial blood-gas analysis. The gag reflex is not a reliable indicator of the need for intubation. A patient with CNS depression may maintain airway patency while being stimulated but not if left alone. Drug-induced pulmonary edema is usually noncardiac rather than cardiac in origin, although profound CNS depression and cardiac conduction abnormalities suggest the latter. Measurement of pulmonary artery pressure may be necessary to establish the cause and direct appropriate therapy. Extracorporeal measures (membrane oxygenation, extracorporeal membrane oxygenation [ECMO], venoarterial perfusion, cardiopulmonary bypass) and partial liquid (perfluorocarbon) ventilation may be appropriate for severe but reversible respiratory failure. In the last decade, ECMO has been increasingly used for critically ill poisoned patients where standard resuscitative therapy or antidotes have not been helpful, but further research is still needed to determine the right toxicologic indications for this treatment strategy.

Cardiovascular Therapy Maintenance of normal tissue perfusion is critical for complete recovery to occur once the offending agent has been eliminated. Focused bedside echocardiography or measurement of central venous pressure may help prioritize therapeutic strategies. If hypotension is unresponsive to volume expansion and appropriate goal-directed antidotal therapy, treatment with norepinephrine, epinephrine, or high-dose dopamine may be necessary. Intraaortic balloon pump counterpulsation and venoarterial or cardiopulmonary perfusion techniques should be considered for severe but reversible cardiac failure. For patients with a return of spontaneous circulation after resuscitative treatment for cardiopulmonary arrest secondary to poisoning, therapeutic hypothermia should be used according to protocol. Bradyarrhythmias associated with hypotension generally should be treated as described in **Chaps. 251 and 252**. Glucagon, calcium, and high-dose insulin with dextrose may be effective in beta blocker and calcium channel blocker poisoning. Antibody therapy may be indicated for cardiac glycoside poisoning.

Supraventricular tachycardia associated with hypertension and CNS excitation is almost always due to agents that cause generalized physiologic excitation (Table 470–1). Most cases are mild or moderate in severity and require only observation or nonspecific sedation with a benzodiazepine. In severe cases or those associated with hemodynamic instability, chest pain,

or ECG evidence of ischemia, specific therapy is indicated. When the etiology is sympathetic hyperactivity, treatment with a benzodiazepine should be prioritized. Further treatment with a combined alpha and beta blocker (labetalol), a calcium channel blocker (verapamil or diltiazem), or a combination of a beta blocker and a vasodilator (esmolol and nitroprusside) may be considered for cases refractory to high doses of benzodiazepines only when adequate sedation has been achieved but cardiac conduction or blood pressure abnormalities persist. Treatment with an α-adrenergic antagonist (phentolamine) alone may sometimes be appropriate. If the cause is anticholinergic poisoning, physostigmine alone can be effective. Supraventricular tachycardia without hypertension is generally secondary to vasodilation or hypovolemia and responds to fluid administration.

For ventricular tachyarrhythmias due to tricyclic antidepressants and other membrane-active agents (Table 470-1), sodium bicarbonate is indicated, whereas class IA, IC, and III antiarrhythmic agents are contraindicated because of similar electrophysiologic effects. Although lidocaine and phenytoin are historically safe for ventricular tachyarrhythmias of any etiology, sodium bicarbonate should be considered first for any ventricular arrhythmia suspected to have a toxicologic etiology. Intravenous lipid emulsion therapy has shown benefit for treatment of arrhythmias and hemodynamic instability from various membrane-active agents. Beta blockers can be hazardous if the arrhythmia is due to sympathetic hyperactivity. Magnesium sulfate and overdrive pacing (by isoproterenol or a pacemaker) may be useful in patients with torsades des pointes and prolonged QT intervals. Magnesium and anti-digoxin antibodies should be considered in patients with severe cardiac glycoside poisoning. Invasive (esophageal or intracardiac) ECG recording may be necessary to determine the origin (ventricular or supraventricular) of wide-complex tachycardias **(Chap. 253)**. If the patient is hemodynamically stable, however, it is reasonable to simply observe the patient rather than to administer another potentially proarrhythmic agent. Arrhythmias may be resistant to drug therapy until underlying acid-base, electrolyte, oxygenation, and temperature derangements are corrected.

Central Nervous System Therapies Neuromuscular hyperactivity and seizures can lead to hyperthermia, lactic acidosis, and rhabdomyolysis and should be treated aggressively. Seizures caused by excessive stimulation of catecholamine receptors (sympathomimetic or hallucinogen poisoning and drug withdrawal) or decreased activity of GABA (isoniazid poisoning) or glycine (strychnine poisoning) receptors are best treated with agents that enhance GABA activity, such as benzodiazepine or barbiturates. Since benzodiazepines and barbiturates act by slightly different mechanisms (the former increases the frequency via allosteric modulation at the receptor and the latter directly increases the duration of chloride channel opening in response to GABA), therapy with both may be effective when neither is effective alone. Seizures caused by isoniazid, which inhibits the synthesis of GABA at several steps by interfering with the cofactor pyridoxine (vitamin B_6), may require high doses of supplemental pyridoxine. Seizures resulting from membrane destabilization (beta blocker or cyclic antidepressant poisoning) require GABA enhancers (benzodiazepines first, barbiturates second). Phenytoin is contraindicated in toxicologic seizures: Animal and human data demonstrate worse outcomes after phenytoin loading, especially in theophylline overdose. For poisons with central dopaminergic effects (methamphetamine, phencyclidine) manifested by psychotic behavior, a dopamine receptor antagonist, such as haloperidol or ziprasidone, may be useful. In anticholinergic and cyanide poisoning, specific antidotal therapy may be necessary. The treatment of seizures secondary to cerebral ischemia or edema or to metabolic abnormalities should include correction of the underlying cause. Neuromuscular paralysis is indicated in refractory cases. Electroencephalographic monitoring and continuing treatment of seizures are necessary to prevent permanent neurologic damage.

Other Measures Temperature extremes, metabolic abnormalities, hepatic and renal dysfunction, and secondary complications should be treated by standard therapies.

PREVENTION OF POISON ABSORPTION

Gastrointestinal Decontamination Whether or not to perform gastrointestinal decontamination and which procedure to use depends on the time since ingestion; the existing and predicted toxicity of the ingestant; the availability, efficacy, and contraindications of the procedure; and the nature, severity, and risk of complications. The efficacy of all decontamination procedures decreases with time, and data are insufficient to support or exclude a beneficial effect when they are used >1 h after ingestion. The average time from ingestion to presentation for treatment is >1 h for children and >3 h for adults. Most patients will recover from poisoning uneventfully with good supportive care alone, but complications of gastrointestinal decontamination, particularly aspiration, can prolong this process. Hence, gastrointestinal decontamination should be performed selectively, not routinely, in the management of overdose patients. It is clearly unnecessary when predicted toxicity is minimal or the time of expected maximal toxicity has passed without significant effect.

Activated charcoal has comparable or greater efficacy; has fewer contraindications and complications; and is less aversive and invasive than ipecac or gastric lavage. Thus, it is the preferred method of gastrointestinal decontamination in most situations. Activated charcoal suspension (in water) is given orally via a cup, straw, or small-bore nasogastric tube. The generally recommended dose is 1 g/kg body weight because of its dosing convenience, although in vitro and in vivo studies have demonstrated that charcoal adsorbs ≥90% of most substances when given in an amount equal to 10 times the weight of the substance. Palatability may be increased by adding a sweetener (sorbitol) or a flavoring agent (cherry, chocolate, or cola syrup) to the suspension. Charcoal adsorbs ingested poisons within the gut lumen, allowing the charcoal-toxin complex to be evacuated with stool. Charged (ionized) chemicals such as mineral acids, alkalis, and highly dissociated salts of cyanide, fluoride, iron, lithium, and other inorganic compounds are not well adsorbed by charcoal. In studies with animals and human volunteers, charcoal decreases the absorption of ingestants by an average of 73% when given within 5 min of ingestant administration, 51% when given at 30 min, and 36% when given at 60 min. For this reason, charcoal given before hospital arrival by prehospital emergency medical services (EMS) increases the potential clinical benefit. Side effects of charcoal include nausea, vomiting, and diarrhea or constipation. Charcoal may also prevent the absorption of orally administered therapeutic agents, so the timing and the dose administered need to be adjusted. Complications include mechanical obstruction of the airway, aspiration, vomiting, and bowel obstruction and infarction caused by inspissated charcoal. Charcoal is not recommended for patients who have ingested corrosives because it obscures endoscopy.

Gastric lavage should be considered for life-threatening poisons that cannot be treated effectively with other decontamination, elimination, or antidotal therapies (e.g., colchicine). Gastric lavage is performed by sequentially administering and aspirating ~5 mL of fluid per kilogram of body weight through a no. 40 French orogastric tube (no. 28 French tube for children). Except in infants, for whom normal saline is recommended, tap water is acceptable. The patient should be placed in Trendelenburg and left lateral decubitus positions to prevent aspiration (even if an endotracheal tube is in place). Lavage decreases ingestant absorption by an average of 52% if performed within 5 min of ingestion administration, 26% if performed at 30 min, and 16% if performed at 60 min. Significant amounts of ingested drug are recovered from <10% of patients. Aspiration is a common complication (occurring in up to 10% of patients), especially when lavage is performed improperly. Serious complications (esophageal and gastric perforation, tube misplacement in the trachea) occur in ~1% of patients. For this reason, the

physician should personally insert the lavage tube and confirm its placement, and the patient must be cooperative during the procedure. Gastric lavage is contraindicated in corrosive or petroleum distillate ingestions because of the respective risks of gastroesophageal perforation and aspiration pneumonitis. It is also contraindicated in patients with a compromised unprotected airway and those at risk for hemorrhage or perforation due to esophageal or gastric pathology or recent surgery. Finally, gastric lavage is absolutely contraindicated in combative patients or those who refuse, as most published complications involve patient resistance to the procedure.

Syrup of ipecac, an emetogenic agent that was once the substance most commonly used for decontamination, no longer has a role in poisoning management. Even the American Academy of Pediatrics—traditionally the strongest proponent of ipecac—issued a policy statement in 2003 recommending that ipecac should no longer be used in poisoning treatment. Chronic ipecac use (by patients with anorexia nervosa or bulimia) has been reported to cause electrolyte and fluid abnormalities, cardiac toxicity, and myopathy.

Whole-bowel irrigation is performed by administering a bowel-cleansing solution containing electrolytes and polyethylene glycol (Golytely, Colyte) orally or by gastric tube at a rate of 2 L/h (0.5 L/h in children) until rectal effluent is clear. The patient must be in a sitting position. Although data are limited, whole-bowel irrigation appears to be as effective as other decontamination procedures in volunteer studies. It is most appropriate for those who have ingested foreign bodies, packets of illicit drugs, and agents that are poorly adsorbed by charcoal (e.g., heavy metals). This procedure is contraindicated in patients with bowel obstruction, ileus, hemodynamic instability, and compromised unprotected airways.

Cathartics are salts (disodium phosphate, magnesium citrate and sulfate, sodium sulfate) or saccharides (mannitol, sorbitol) that historically have been given with activated charcoal to promote the rectal evacuation of gastrointestinal contents. However, no animal, volunteer, or clinical data have ever demonstrated any decontamination benefit from cathartics. Abdominal cramps, nausea, and occasional vomiting are side effects. Complications of repeated dosing include severe electrolyte disturbances and excessive diarrhea. Cathartics are contraindicated in patients who have ingested corrosives and in those with preexisting diarrhea. Magnesium-containing cathartics should not be used in patients with renal failure.

Dilution (i.e., drinking water, another clear liquid, or milk at a volume of 5 mL/kg of body weight) is recommended only after the ingestion of corrosives (acids, alkali). It may increase the dissolution rate (and hence absorption) of capsules, tablets, and other solid ingestants and should *not* be used in these circumstances.

Endoscopic or surgical removal of poisons may be useful in rare situations, such as ingestion of a potentially toxic foreign body that fails to transit the gastrointestinal tract, a potentially lethal amount of a heavy metal (arsenic, iron, mercury, thallium), or agents that have coalesced into gastric concretions or bezoars (heavy metals, lithium, salicylates, sustained-release preparations). Patients who become toxic from cocaine due to its leakage from ingested drug packets require immediate surgical intervention.

Decontamination of Other Sites Immediate, copious flushing with water, saline, or another available clear, drinkable liquid is the initial treatment for topical exposures (exceptions include alkali metals, calcium oxide, phosphorus). Saline is preferred for eye irrigation. A triple wash (water, soap, water) may be best for dermal decontamination. Inhalational exposures should be treated initially with fresh air or supplemental oxygen. The removal of liquids from body cavities such as the vagina or rectum is best accomplished by irrigation. Solids (drug packets, pills) should be removed manually, preferably under direct visualization.

ENHANCEMENT OF POISON ELIMINATION

Although the elimination of most poisons can be accelerated by therapeutic interventions, the pharmacokinetic efficacy (removal of drug at a rate greater than that accomplished by intrinsic elimination) and clinical benefit (shortened duration of toxicity or improved outcome) of such interventions are often more theoretical than proven. Accordingly, the decision to use such measures should be based on the actual or predicted toxicity and the potential efficacy, cost, and risks of therapy.

Multiple-Dose Activated Charcoal Repetitive oral dosing with charcoal can enhance the elimination of previously absorbed substances by binding them within the gut as they are excreted in the bile, are secreted by gastrointestinal cells, or passively diffuse into the gut lumen (*reverse absorption* or *enterocapillary exsorption*). Doses of 0.5–1 g/kg of body weight every 2–4 h, adjusted downward to avoid regurgitation in patients with decreased gastrointestinal motility, are generally recommended. Pharmacokinetic efficacy approaches that of hemodialysis for some agents (e.g., phenobarbital, theophylline). Multiple-dose therapy should be considered only for selected agents (theophylline, phenobarbital, carbamazepine, dapsone, quinine). Complications include intestinal obstruction, pseudo-obstruction, and nonocclusive intestinal infarction in patients with decreased gut motility. Because of electrolyte and fluid shifts, sorbitol and other cathartics are absolutely contraindicated when multiple doses of activated charcoal are administered.

Urinary Alkalinization Ion trapping via alteration of urine pH may prevent the renal reabsorption of poisons that undergo excretion by glomerular filtration and active tubular secretion. Since membranes are more permeable to nonionized molecules than to their ionized counterparts, acidic (low-pK_a) poisons are ionized and trapped in alkaline urine, whereas basic ones become ionized and trapped in acid urine. Urinary alkalinization (producing a urine pH ≥7.5 and a urine output of 3–6 mL/kg of body weight per hour by the addition of sodium bicarbonate to an IV solution) enhances the excretion of chlorophenoxyacetic acid herbicides, chlorpropamide, diflunisal, fluoride, methotrexate, phenobarbital, sulfonamides, and salicylates. Contraindications include congestive heart failure, renal failure, and cerebral edema. Acid-base, fluid, and electrolyte parameters should be monitored carefully. Although acid diuresis may make theoretical sense for some overdoses (amphetamines), it is *never* indicated and is potentially harmful.

Extracorporeal Removal Hemodialysis, charcoal or resin hemoperfusion, hemofiltration, plasmapheresis, and exchange transfusion are capable of removing any toxin from the bloodstream. Agents most amenable to enhanced elimination by dialysis have low molecular mass (<500 Da), high water solubility, low protein binding, small volumes of distribution (<1 L/kg of body weight), prolonged elimination (long half-life), and high dialysis clearance relative to total-body clearance. Molecular weight, water solubility, and protein binding do not limit the efficacy of the other forms of extracorporeal removal.

Dialysis should be considered in cases of severe poisoning due to carbamazepine, ethylene glycol, isopropyl alcohol, lithium, methanol, theophylline, salicylates, and valproate. Although hemoperfusion may be more effective in removing some of these poisons, it does not correct associated acid-base and electrolyte abnormalities, and most hospitals no longer have hemoperfusion cartridges readily available. Fortunately, recent advances in hemodialysis technology make it as effective as hemoperfusion for removing poisons such as caffeine, carbamazepine, and theophylline. Both techniques require central venous access and systemic anticoagulation and may result in transient hypotension. Hemoperfusion may also cause hemolysis, hypocalcemia, and thrombocytopenia. Peritoneal dialysis and exchange transfusion are less effective but may be used when other procedures are unavailable, contraindicated, or technically difficult (e.g., in infants). Continuous venovenous hemofiltration (CVVH) has also been used successfully when conventional intermittent hemodialysis is not well tolerated because of hemodynamic lability. Exchange transfusion may be indicated in the treatment of severe arsine- or sodium chlorate–induced hemolysis, methemoglobinemia, and sulfhemoglobinemia. Although hemofiltration can enhance elimination of aminoglycosides, vancomycin, and

metal-chelate complexes, the roles of hemofiltration and plasmapheresis in the treatment of poisoning are not yet defined.

Candidates for extracorporeal removal therapies include patients with severe toxicity whose condition deteriorates despite aggressive supportive therapy; those with potentially prolonged, irreversible, or fatal toxicity; those with dangerous blood levels of toxins; those who lack the capacity for self-detoxification because of liver or renal failure; and those with a serious underlying illness or complication that will adversely affect recovery.

Other Techniques The elimination of heavy metals can be enhanced by chelation, and the removal of carbon monoxide can be accelerated by hyperbaric oxygenation.

ADMINISTRATION OF ANTIDOTES

Antidotes counteract the effects of poisons by neutralizing them (e.g., antibody-antigen reactions, chelation, chemical binding) or by antagonizing their physiologic effects (e.g., activation of opposing nervous system activity, provision of a competitive metabolic or receptor substrate). Poisons or conditions with specific antidotes include acetaminophen, anticholinergic agents, anticoagulants, benzodiazepines, beta blockers, calcium channel blockers, carbon monoxide, cardiac glycosides, cholinergic agents, cyanide, drug-induced dystonic reactions, ethylene glycol, fluoride, heavy metals, hypoglycemic agents, isoniazid, membrane-active agents, methemoglobinemia, opioids, sympathomimetics, and a variety of envenomations. Intravenous lipid emulsion has been shown to be a successful antidote for poisoning from various anesthetics and membrane-active agents (e.g., cyclic antidepressants), but the exact mechanism of benefit is still under investigation. Antidotes can significantly reduce morbidity and mortality rates but are potentially toxic if used for inappropriate reasons. Since their safe use requires correct identification of a specific poisoning or syndrome, details of antidotal therapy are discussed with the conditions for which they are indicated **(Table 470-4)**.

TABLE 470-4 Pathophysiologic Features and Treatment of Specific Toxic Syndromes and Poisonings

PHYSIOLOGIC CONDITION, CAUSES	EXAMPLES	MECHANISM OF ACTION	CLINICAL FEATURES	SPECIFIC TREATMENTS
Stimulated				
Sympathetics[a]				
Sympathomimetics	α_1-Adrenergic agonists (decongestants): phenylephrine, phenylpropanolamine β_2-Adrenergic agonists (bronchodilators): albuterol, terbutaline Nonspecific adrenergic agonists: amphetamines, cocaine, ephedrine	Stimulation of central and peripheral sympathetic receptors directly or indirectly (by promoting release or inhibiting reuptake of norepinephrine and sometimes dopamine)	Physiologic stimulation (Table 470-2). Reflex bradycardia can occur with selective α_1 agonists; β agonists can cause hypotension and hypokalemia.	Phentolamine, a nonselective α_1-adrenergic receptor antagonist, for severe hypertension due to α_1-adrenergic agonists; propranolol, a nonselective β blocker, for hypotension and tachycardia due to β_2 agonists; *either* labetalol, a β blocker with α-blocking activity, *or* phentolamine with esmolol, metoprolol, or another cardioselective β blocker for hypertension with tachycardia due to nonselective agents (β blockers, if used alone, can exacerbate hypertension and vasospasm due to unopposed α stimulation); benzodiazepines; propofol
Ergot alkaloids	Ergotamine, methysergide, bromocriptine, pergolide	Stimulation and inhibition of serotonergic and α-adrenergic receptors; stimulation of dopamine receptors	Physiologic stimulation (Table 470-2); formication; vasospasm with limb (isolated or generalized), myocardial, and cerebral ischemia progressing to gangrene or infarction. Hypotension, bradycardia, and involuntary movements can also occur.	Nitroprusside or nitroglycerine for severe vasospasm; prazosin (an α_1 blocker), captopril, nifedipine, and cyproheptadine (a serotonin receptor antagonist) for mild-to-moderate limb ischemia; dopamine receptor antagonists (antipsychotics) for hallucinations and movement disorders
Methylxanthines	Caffeine, theophylline	Inhibition of adenosine synthesis and adenosine receptor antagonism; stimulation of epinephrine and norepinephrine release; inhibition of phosphodiesterase resulting in increased intracellular cyclic adenosine and guanosine monophosphate	Physiologic stimulation (Table 470-2); pronounced gastrointestinal symptoms and β agonist effects (see above). Toxicity occurs at lower drug levels in chronic poisoning than in acute poisoning.	Propranolol, a nonselective β blocker, or esmolol for tachycardia with hypotension; any β blocker for supraventricular or ventricular tachycardia without hypotension; elimination enhanced by multiple-dose charcoal, hemoperfusion, and hemodialysis. Indications for hemoperfusion or hemodialysis include unstable vital signs, seizures, and a theophylline level of 80–100 μg/mL after an acute overdose and 40–60 μg/mL with chronic exposure.
Monoamine oxidase inhibitors	Phenelzine, tranylcypromine, selegiline	Inhibition of monoamine oxidase resulting in impaired metabolism of endogenous catecholamines and exogenous sympathomimetic agents	Delayed or slowly progressive physiologic stimulation (Table 470-2); terminal hypotension and bradycardia in severe cases	Short-acting agents (e.g., nitroprusside, esmolol) for severe hypertension and tachycardia; direct-acting sympathomimetics (e.g., norepinephrine, epinephrine) for hypotension and bradycardia

TABLE 470-4 Pathophysiologic Features and Treatment of Specific Toxic Syndromes and Poisonings (Continued)

PHYSIOLOGIC CONDITION, CAUSES	EXAMPLES	MECHANISM OF ACTION	CLINICAL FEATURES	SPECIFIC TREATMENTS
Anticholinergics				
Antihistamines	Diphenhydramine, doxylamine, pyrilamine	Inhibition of central and postganglionic parasympathetic muscarinic cholinergic receptors. At high doses, amantadine, diphenhydramine, orphenadrine, phenothiazines, and tricyclic antidepressants have additional nonanticholinergic activity (see below).	Physiologic stimulation (Table 470-2); dry skin and mucous membranes, decreased bowel sounds, flushing, and urinary retention; myoclonus and picking activity. Central effects may occur without significant autonomic dysfunction.	Physostigmine, an acetylcholinesterase inhibitor (see below), for delirium, hallucinations, and neuromuscular hyperactivity. Contraindications include asthma and non-anticholinergic cardiovascular toxicity (e.g., cardiac conduction abnormalities, hypotension, and ventricular arrhythmias).
Antipsychotics	Chlorpromazine, olanzapine, quetiapine, thioridazine	Inhibition of α-adrenergic, dopaminergic, histaminergic, muscarinic, and serotonergic receptors. Some agents also inhibit sodium, potassium, and calcium channels.	Physiologic depression (Table 470-2), miosis, anticholinergic effects (see above), extrapyramidal reactions (see below), tachycardia	Sodium bicarbonate for ventricular tachydysrhythmias associated with QRS prolongation; magnesium, isoproterenol, and overdrive pacing for torsades des pointes. Avoid class IA, IC, and III antiarrhythmics.
Belladonna alkaloids	Atropine, hyoscyamine, scopolamine	Inhibition of central and postganglionic parasympathetic muscarinic cholinergic receptors	Physiologic stimulation (Table 470-2); dry skin and mucous membranes, decreased bowel sounds, flushing, and urinary retention; myoclonus and picking activity. Central effects may occur without significant autonomic dysfunction.	Physostigmine, an acetylcholinesterase inhibitor (see below), for delirium, hallucinations, and neuromuscular hyperactivity. Contraindications include asthma and non-anticholinergic cardiovascular toxicity (e.g., cardiac conduction abnormalities, hypotension, and ventricular arrhythmias).
Cyclic antidepressants	Amitriptyline, doxepin, imipramine	Inhibition of α-adrenergic, dopaminergic, GABA-ergic, histaminergic, muscarinic, and serotonergic receptors; inhibition of sodium channels (see membrane-active agents); inhibition of norepinephrine and serotonin reuptake	Physiologic depression (Table 470-2), seizures, tachycardia, cardiac conduction delays (increased PR, QRS, JT, and QT intervals; terminal QRS right-axis deviation) with aberrancy and ventricular tachydysrhythmias; anticholinergic toxidrome (see above)	Hypertonic sodium bicarbonate (or hypertonic saline) for ventricular tachydysrhythmias associated with QRS prolongation. Use of phenytoin is controversial. Avoid class IA, IC, and III antiarrhythmics. IV emulsion therapy may be beneficial in some cases.
Mushrooms and plants	*Amanita muscaria* and *A. pantherina*, henbane, jimson weed, nightshade	Inhibition of central and postganglionic parasympathetic muscarinic cholinergic receptors	Physiologic stimulation (Table 470-2); dry skin and mucous membranes, decreased bowel sounds, flushing, and urinary retention; myoclonus and picking activity. Central effects may occur without significant autonomic dysfunction.	Physostigmine, an acetylcholinesterase inhibitor (see below), for delirium, hallucinations, and neuromuscular hyperactivity. Contraindications include asthma and nonanticholinergic cardiovascular toxicity (e.g., cardiac conduction abnormalities, hypotension, and ventricular arrhythmias).
Depressed				
Sympatholytics				
α_2-Adrenergic agonists	Clonidine, guanabenz, tetrahydrozoline and other imidazoline decongestants, tizanidine and other imidazoline muscle relaxants	Stimulation of α_2-adrenergic receptors leading to inhibition of CNS sympathetic outflow. Activity at nonadrenergic imidazoline binding sites also contributes to CNS effects.	Physiologic depression (Table 470-2), miosis. Transient initial hypertension may be seen.	Dopamine and norepinephrine for hypotension; atropine for symptomatic bradycardia; naloxone for CNS depression (inconsistently effective)
Antipsychotics	Chlorpromazine, clozapine, haloperidol, risperidone, thioridazine	Inhibition of α-adrenergic, dopaminergic, histaminergic, muscarinic, and serotonergic receptors. Some agents also inhibit sodium, potassium, and calcium channels.	Physiologic depression (Table 470-2), miosis, anticholinergic effects (see above), extrapyramidal reactions (see below), tachycardia. Cardiac conduction delays (increased PR, QRS, JT, and QT intervals) with ventricular tachydysrhythmias, including torsades des pointes, can sometimes develop.	Sodium bicarbonate for ventricular tachydysrhythmias associated with QRS prolongation; magnesium, isoproterenol, and overdrive pacing for torsades des pointes. Avoid class IA, IC, and III antiarrhythmics.

TABLE 470-4 Pathophysiologic Features and Treatment of Specific Toxic Syndromes and Poisonings (Continued)

PHYSIOLOGIC CONDITION, CAUSES	EXAMPLES	MECHANISM OF ACTION	CLINICAL FEATURES	SPECIFIC TREATMENTS
β-Adrenergic blockers	Cardioselective (β_1) blockers: atenolol, esmolol, metoprolol Nonselective (β_1 and β_2) blockers: nadolol, propranolol, timolol Partial β agonists: acebutolol, pindolol α_1 Antagonists: carvedilol, labetalol Membrane-active agents: acebutolol, propranolol, sotalol	Inhibition of β-adrenergic receptors (class II antiarrhythmic effect). Some agents have activity at additional receptors or have membrane effects (see below).	Physiologic depression (Table 470-2), atrioventricular block, hypoglycemia, hyperkalemia, seizures. Partial agonists can cause hypertension and tachycardia. Sotalol can cause increased QT interval and ventricular tachydysrhythmias. Onset may be delayed after sotalol and sustained-release formulation overdose.	Glucagon for hypotension and symptomatic bradycardia. Atropine, isoproterenol, dopamine, dobutamine, epinephrine, and norepinephrine may sometimes be effective. High-dose insulin (with glucose and potassium to maintain euglycemia and normokalemia), electrical pacing, and mechanical cardiovascular support for refractory cases.
Calcium channel blockers	Diltiazem, nifedipine and other dihydropyridine derivatives, verapamil	Inhibition of slow (type L) cardiovascular calcium channels (class IV antiarrhythmic effect)	Physiologic depression (Table 470-2), atrioventricular block, organ ischemia and infarction, hyperglycemia, seizures. Hypotension is usually due to decreased vascular resistance rather than to decreased cardiac output. Onset may be delayed for ≥12 h after overdose of sustained-release formulations.	Calcium and glucagon for hypotension and symptomatic bradycardia. Dopamine, epinephrine, norepinephrine, atropine, and isoproterenol are less often effective but can be used adjunctively. High-dose insulin (with glucose and potassium to maintain euglycemia and normokalemia), IV lipid emulsion therapy, electrical pacing, and mechanical cardiovascular support for refractory cases.
Cardiac glycosides	Digoxin, endogenous cardioactive steroids, foxglove and other plants, toad skin secretions (Bufonidae spp.)	Inhibition of cardiac Na^+, K^+-ATPase membrane pump	Physiologic depression (Table 470-2); gastrointestinal, psychiatric, and visual symptoms; atrioventricular block with or without concomitant supraventricular tachyarrhythmia; ventricular tachyarrhythmias; hyperkalemia in acute poisoning. Toxicity occurs at lower drug levels in chronic poisoning than in acute poisoning.	Digoxin-specific antibody fragments for hemodynamically compromising dysrhythmias, Mobitz II or third-degree atrioventricular block, hyperkalemia (>5.5 meq/L; in acute poisoning only). Temporizing measures include atropine, dopamine, epinephrine, and external cardiac pacing for bradydysrhythmias and magnesium, lidocaine, or phenytoin, for ventricular tachydysrhythmias. Internal cardiac pacing and cardioversion can increase ventricular irritability and should be reserved for refractory cases.
Cyclic antidepressants	Amitriptyline, doxepin, imipramine	Inhibition of α-adrenergic, dopaminergic, GABA-ergic, histaminergic, muscarinic, and serotonergic receptors; inhibition of sodium channels (see membrane-active agents); inhibition of norepinephrine and serotonin reuptake	Physiologic depression (Table 470-2), seizures, tachycardia, cardiac conduction delays (increased PR, QRS, JT, and QT intervals; terminal QRS right-axis deviation) with aberrancy and ventricular tachydysrhythmias; anticholinergic toxidrome (see above)	Hypertonic sodium bicarbonate (or hypertonic saline) for ventricular tachydysrhythmias associated with QRS prolongation. Use of phenytoin is controversial. Avoid class IA, IC, and III antiarrhythmics. IV emulsion therapy may be beneficial in some cases.
Cholinergics				
Acetylcholinesterase inhibitors Muscarinic agonists Nicotinic agonists	Carbamate insecticides (aldicarb, carbaryl, propoxur) and medicinals (neostigmine, physostigmine, tacrine); nerve gases (sarin, soman, tabun, VX); organophosphate insecticides (diazinon, chlorpyrifos-ethyl, malathion) Bethanechol, mushrooms (*Boletus, Clitocybe, Inocybe* spp.), pilocarpine Lobeline, nicotine (tobacco)	Inhibition of acetylcholinesterase leading to increased synaptic acetylcholine at muscarinic and nicotinic cholinergic receptor sites Stimulation of CNS and postganglionic parasympathetic cholinergic (muscarinic) receptors Stimulation of preganglionic sympathetic and parasympathetic and striated muscle (neuromuscular junction) cholinergic (nicotine) receptors	Physiologic depression (Table 470-2). Muscarinic signs and symptoms: seizures, excessive secretions (lacrimation, salivation, bronchorrhea and wheezing, diaphoresis), and increased bowel and bladder activity with nausea, vomiting, diarrhea, abdominal cramps, and incontinence of feces and urine. Nicotinic signs and symptoms: hypertension, tachycardia, muscle cramps, fasciculations, weakness, and paralysis. Death is usually due to respiratory failure. Cholinesterase activity in plasma and red cells is <50% of normal in acetylcholinesterase inhibitor poisoning.	Atropine for muscarinic signs and symptoms; 2-PAM, a cholinesterase reactivator, for nicotinic signs and symptoms due to organophosphates, nerve gases, or an unknown anticholinesterase

TABLE 470-4 Pathophysiologic Features and Treatment of Specific Toxic Syndromes and Poisonings (Continued)

PHYSIOLOGIC CONDITION, CAUSES	EXAMPLES	MECHANISM OF ACTION	CLINICAL FEATURES	SPECIFIC TREATMENTS
Sedative-hypnotics[b]				
Anticonvulsants Barbiturates Benzodiazepines	Carbamazepine, ethosuximide, felbamate, gabapentin, lamotrigine, levetiracetam, oxcarbazepine, phenytoin, tiagabine, topiramate, valproate, zonisamide Short-acting: butabarbital, pentobarbital, secobarbital Long-acting: phenobarbital, primidone Ultrashort-acting: estazolam, midazolam, temazepam, triazolam Short-acting: alprazolam, flunitrazepam, lorazepam, oxazepam Long-acting: chlordiazepoxide, clonazepam, diazepam, flurazepam Pharmacologically related agents: zaleplon, zolpidem	Potentiation of the inhibitory effects of GABA by binding to the neuronal GABA–A chloride channel receptor complex and increasing the frequency or duration of chloride channel opening in response to GABA stimulation. Baclofen and, to some extent, GHB act at the GABA–B receptor complex. Meprobamate, its metabolite carisoprodol, felbamate, and orphenadrine antagonize NDMA excitatory receptors. Ethosuximide, valproate, and zonisamide decrease conduction through T-type calcium channels. Valproate decreases GABA degradation, and tiagabine blocks GABA reuptake. Carbamazepine, lamotrigine, oxcarbazepine, phenytoin, topiramate, valproate, and zonisamide slow the rate of recovery of inactivated sodium channels. Some agents also have α_2 agonist, anticholinergic, and sodium channel–blocking activity (see above and below).	Physiologic depression (Table 470-2), nystagmus. Delayed absorption can occur with carbamazepine, phenytoin, and valproate. Myoclonus, seizures, hypertension, and tachyarrhythmias can occur with baclofen, carbamazepine, and orphenadrine. Tachyarrhythmias can also occur with chloral hydrate. AGMA, hypernatremia, hyperosmolality, hyperammonemia, chemical hepatitis, and hypoglycemia can be seen in valproate poisoning. Carbamazepine and oxcarbazepine may produce hyponatremia from SIADH.	Benzodiazepines, barbiturates, or propofol for seizures. Hemodialysis and hemoperfusion may be indicated for severe poisoning by some agents (see "Extracorporeal Removal," in text). See above and below for treatment of anticholinergic and sodium channel (membrane)–blocking effects.
GABA precursors	γ-Hydroxybutyrate (sodium oxybate; GHB), γ-butyrolactone (GBL), 1,4-butanediol	Stimulation at GABA receptor complex increases chloride channel opening	Physiologic depression (Table 470-2)	Goal-directed supportive care
Muscle relaxants	Baclofen, carisoprodol, cyclobenzaprine, etomidate, metaxalone, methocarbamol, orphenadrine, propofol, tizanidine and other imidazoline muscle relaxants	Baclofen acts at GABA–B receptor complex; stimulation of α_2-adrenergic receptors inhibits CNS sympathetic outflow. Activity at nonadrenergic imidazoline binding sites also contributes to CNS effects. The others have centrally acting and various other unknown mechanisms of action.	Physiologic depression (Table 470-2)	Goal-directed supportive care; benzodiazepines and barbiturates for seizures
Discordant				
Asphyxiants				
Cytochrome oxidase inhibitors	Cyanide, hydrogen sulfide	Inhibition of mitochondrial cytochrome oxidase, with consequent blockage of electron transport and oxidative metabolism. Carbon monoxide also binds to hemoglobin and myoglobin and prevents oxygen binding, transport, and tissue uptake. (Binding to hemoglobin shifts the oxygen dissociation curve to the left.)	Signs and symptoms of hypoxemia with initial physiologic stimulation and subsequent depression (Table 470-2); lactic acidosis; normal PO_2 and calculated oxygen saturation but decreased oxygen saturation by co-oximetry. (That measured by pulse oximetry is falsely elevated but is less than normal and less than the calculated value.) Headache and nausea are common with carbon monoxide. Sudden collapse may occur with cyanide and hydrogen sulfide exposure. A bitter almond breath odor may be noted with cyanide ingestion, and hydrogen sulfide smells like rotten eggs.	High-dose oxygen; IV hydroxocobalamin or IV sodium nitrite and sodium thiosulfate (Lilly cyanide antidote kit) for coma, metabolic acidosis, and cardiovascular dysfunction in cyanide poisoning or victims from a fire; ECMO

(*Continued*)

TABLE 470-4 Pathophysiologic Features and Treatment of Specific Toxic Syndromes and Poisonings (Continued)

PHYSIOLOGIC CONDITION, CAUSES	EXAMPLES	MECHANISM OF ACTION	CLINICAL FEATURES	SPECIFIC TREATMENTS
Methemoglobin inducers	Aniline derivatives, dapsone, local anesthetics, nitrates, nitrites, nitrogen oxides, nitro- and nitrosohydrocarbons, phenazopyridine, primaquine-type antimalarials, sulfonamides	Oxidation of hemoglobin iron from ferrous (Fe^{2+}) to ferric (Fe^{3+}) state prevents oxygen binding, transport, and tissue uptake. (Methemoglobinemia shifts oxygen dissociation curve to the left.) Oxidation of hemoglobin protein causes hemoglobin precipitation and hemolytic anemia (manifesting as Heinz bodies and "bite cells" on peripheral-blood smear).	Signs and symptoms of hypoxemia with initial physiologic stimulation and subsequent depression (Table 470-2), gray-brown cyanosis unresponsive to oxygen at methemoglobin fractions >15–20%, headache, lactic acidosis (at methemoglobin fractions >45%), normal PO_2 and calculated oxygen saturation but decreased oxygen saturation and increased methemoglobin fraction by co-oximetry. (Oxygen saturation by pulse oximetry may be falsely increased or decreased but is less than normal and less than the calculated value.)	High-dose oxygen; IV methylene blue for methemoglobin fraction >30%, symptomatic hypoxemia, or ischemia (contraindicated in G6PD deficiency); exchange transfusion and hyperbaric oxygen for severe or refractory cases
AGMA inducers	Ethylene glycol	Ethylene glycol causes CNS depression and increased serum osmolality. Metabolites (primarily glycolic acid) cause AGMA, CNS depression, and renal failure. Precipitation of oxalic acid metabolite as calcium salt in tissues and urine results in hypocalcemia, tissue edema, and crystalluria.	Initial ethanol-like intoxication, nausea, vomiting, increased osmolar gap, calcium oxalate crystalluria; delayed AGMA, back pain, renal failure; coma, seizures, hypotension, ARDS in severe cases	Sodium bicarbonate to correct acidemia; thiamine, folinic acid, magnesium, and high-dose pyridoxine to facilitate metabolism; ethanol or fomepizole for AGMA, crystalluria or renal dysfunction, ethylene glycol level >3 mmol/L (20 mg/dL), and ethanol-like intoxication or increased osmolal gap if level not readily obtainable; hemodialysis for persistent AGMA, lack of clinical improvement, and renal dysfunction; hemodialysis also useful for enhancing ethylene glycol elimination and shortening duration of treatment when ethylene glycol level is >8 mmol/L (50 mg/dL).
	Iron	Hydration of ferric (Fe^{3+}) ion generates H^+. Non-transferrin-bound iron catalyzes formation of free radicals that cause mitochondrial injury, lipid peroxidation, increased capillary permeability, vasodilation, and organ toxicity.	Initial nausea, vomiting, abdominal pain, diarrhea; AGMA, cardiovascular and CNS depression, hepatitis, coagulopathy, and seizures in severe cases. Radiopaque iron tablets may be seen on abdominal x-ray.	Whole-bowel irrigation for large ingestions; endoscopy and gastrostomy if clinical toxicity and large number of tablets are still visible on x-ray; IV hydration; sodium bicarbonate for acidemia; IV deferoxamine for systemic toxicity, iron level >90 µmol/L (500 µg/dL)
	Methanol	Methanol causes ethanol-like CNS depression and increased serum osmolality. Formic acid metabolite causes AGMA and retinal toxicity.	Initial ethanol-like intoxication, nausea, vomiting, increased osmolar gap; delayed AGMA, visual (clouding, spots, blindness) and retinal (edema, hyperemia) abnormalities; coma, seizures, cardiovascular depression in severe cases; possible pancreatitis	Gastric aspiration for recent ingestion; sodium bicarbonate to correct acidemia; high-dose folinic acid or folate to facilitate metabolism; ethanol or fomepizole for AGMA, visual symptoms, methanol level >6 mmol/L (20 mg/dL), and ethanol-like intoxication or increased osmolal gap if level not readily obtainable; hemodialysis for persistent AGMA, lack of clinical improvement, and renal dysfunction; hemodialysis also useful for enhancing methanol elimination and shortening duration of treatment when methanol level is >15 mmol/L (50 mg/dL)
	Salicylate	Increased sensitivity of CNS respiratory center to changes in and stimulates respiration. Uncoupling of oxidative phosphorylation, inhibition of Krebs cycle enzymes, and stimulation of carbohydrate and lipid metabolism generate unmeasured endogenous anions and cause AGMA.	Initial nausea, vomiting, hyperventilation, alkalemia, alkaluria; subsequent alkalemia with both respiratory alkalosis and AGMA and paradoxical aciduria; late acidemia with CNS and respiratory depression; cerebral and pulmonary edema in severe cases. Hypoglycemia, hypocalcemia, hypokalemia, and seizures can occur.	IV hydration and supplemental glucose; sodium bicarbonate to correct acidemia; urinary alkalinization for systemic toxicity; hemodialysis for coma, cerebral edema, seizures, pulmonary edema, renal failure, progressive acid-base disturbances or clinical toxicity, salicylate level >7 mmol/L (100 mg/dL) following acute overdose

(*Continued*)

TABLE 470-4 Pathophysiologic Features and Treatment of Specific Toxic Syndromes and Poisonings (Continued)

PHYSIOLOGIC CONDITION, CAUSES	EXAMPLES	MECHANISM OF ACTION	CLINICAL FEATURES	SPECIFIC TREATMENTS
CNS syndromes				
Extrapyramidal reactions	Antipsychotics (see above), some cyclic antidepressants and antihistamines	Decreased CNS dopaminergic activity with relative excess of cholinergic activity	Akathisia, dystonia, parkinsonism	Oral or parenteral anticholinergic agent such as benztropine or diphenhydramine
Isoniazid		Interference with activation and supply of pyridoxal-5-phosphate, a cofactor for glutamic acid decarboxylase, which converts glutamic acid to GABA, results in decreased levels of this inhibitory CNS neurotransmitter; complexation with and depletion of pyridoxine itself; inhibition of nicotine adenine dinucleotide–dependent lactate and hydroxybutyrate dehydrogenases, resulting in substrate accumulation	Nausea, vomiting, agitation, confusion; coma, respiratory depression, seizures, lactic and ketoacidosis in severe cases	High-dose IV pyridoxine (vitamin B_6) for agitation, confusion, coma, and seizures; diazepam or barbiturates for seizures
Lithium		Interference with cell membrane ion transport, adenylate cyclase and Na^+, K^+-ATPase activity, and neurotransmitter release	Nausea, vomiting, diarrhea, ataxia, choreoathetosis, encephalopathy, hyperreflexia, myoclonus, nystagmus, nephrogenic diabetes insipidus, falsely elevated serum chloride with low anion gap, tachycardia; coma, seizures, arrhythmias, hyperthermia, and prolonged or permanent encephalopathy and movement disorders in severe cases; delayed onset after acute overdose, particularly with delayed-release formulations. Toxicity occurs at lower drug levels in chronic poisoning than in acute poisoning.	Whole-bowel irrigation for large ingestions; IV hydration; hemodialysis for coma, seizures, encephalopathy or neuromuscular dysfunction (severe, progressive, or persistent), peak lithium level >4 meq/L following acute overdose
Serotonin syndrome	Amphetamines, cocaine, dextromethorphan, meperidine, MAO inhibitors, selective serotonin (5-HT) reuptake inhibitors, tricyclic antidepressants, tramadol, triptans, tryptophan	Promotion of serotonin release, inhibition of serotonin reuptake, or direct stimulation of CNS and peripheral serotonin receptors (primarily 5-HT-1a and 5-HT-2), alone or in combination	Altered mental status (agitation, confusion, mutism, coma, seizures), neuromuscular hyperactivity (hyperreflexia, myoclonus, rigidity, tremors), and autonomic dysfunction (abdominal pain, diarrhea, diaphoresis, fever, flushing, labile hypertension, mydriasis, tearing, salivation, tachycardia). Complications include hyperthermia, lactic acidosis, rhabdomyolysis, and multisystem organ failure.	Discontinue the offending agent(s); benzodiazepines for agitation or signs of stimulation; the serotonin receptor antagonist cyproheptadine may be helpful in severe cases.
Membrane-active agent	Amantadine, antiarrhythmics (class I and III agents; some β blockers), antipsychotics (see above), antihistamines (particularly diphenhydramine), carbamazepine, local anesthetics (including cocaine), opioids (meperidine, propoxyphene), orphenadrine, quinoline antimalarials (chloroquine, hydroxychloroquine, quinine), cyclic antidepressants (see above)	Blockade of fast sodium membrane channels prolongs phase 0 (depolarization) of the cardiac action potential, which prolongs QRS duration and promotes reentrant (monomorphic) ventricular tachycardia. Class Ia, Ic, and III antiarrhythmics also block potassium channels during phases 2 and 3 (repolarization) of the action potential, prolonging the JT interval and promoting early after-depolarizations and polymorphic (torsades des pointes) ventricular tachycardia. Similar effects on neuronal membrane channels cause CNS dysfunction. Some agents also block α-adrenergic and cholinergic receptors or have opioid effects (see above and **Chap. 467**).	QRS and JT prolongation (or both) with hypotension, ventricular tachyarrhythmias, CNS depression, seizures; anticholinergic effects with amantadine, antihistamines, carbamazepine, disopyramide, antipsychotics, and cyclic antidepressants (see above); opioid effects with meperidine and propoxyphene **(see Chap. 467)**; cinchonism (hearing loss, tinnitus, nausea, vomiting, vertigo, ataxia, headache, flushing, diaphoresis), and blindness with quinoline antimalarials	Hypertonic sodium bicarbonate (or hypertonic saline) for cardiac conduction delays and monomorphic ventricular tachycardia; lidocaine for monomorphic ventricular tachycardia (except when due to class Ib antiarrhythmics); magnesium, isoproterenol, and overdrive pacing for polymorphic ventricular tachycardia; physostigmine for anticholinergic effects (see above); naloxone for opioid effects **(see Chap. 467)**; extracorporeal removal for some agents (see text).

[a]See above and **Chap. 468**. [b]See above and **Chap. 467**.

Abbreviations: AGMA, anion-gap metabolic acidosis; ARDS, adult respiratory distress syndrome; CNS, central nervous system; ECMO, extracorporeal membrane oxygenation; GABA, γ-aminobutyric acid; GBL, γ-butyrolactone; GHB, γ-hydroxybutyrate; G6PD, glucose-6-phosphate dehydrogenase; MAO, monoamine oxidase; NDMA, *N*-methyl-D-aspartate; 2-PAM, pralidoxime; SIADH, syndrome of inappropriate antidiuretic hormone secretion.

PREVENTION OF REEXPOSURE

Poisoning is a preventable illness. Unfortunately, some adults and children are poison-prone, and recurrences are common. Unintentional polypharmacy poisoning has become especially common among adults with developmental delays, among the growing population of geriatric patients who are prescribed a large number of medications, and among adolescents and young adults also being prescribed a larger number of medications or experimenting with pharmaceuticals for recreational euphoria. Adults with unintentional exposures should be instructed regarding the safe use of medications and chemicals (according to labeling instructions). Confused patients may need assistance with the administration of their medications. Errors in dosing by health care providers may require educational efforts. Patients should be advised to avoid circumstances that result in chemical exposure or poisoning. Appropriate agencies and health departments (e.g., Occupational Health and Safety Administration [OSHA]) should be notified in cases of environmental or workplace exposure. The best approach to young children and patients with intentional overdose (deliberate self-harm or attempted suicide) is to limit their access to poisons. In households where children live or visit, alcoholic beverages, medications, household products (automotive, cleaning, fuel, pet-care, and toiletry products), inedible plants, and vitamins should be kept out of reach or in locked or child-proof cabinets. Depressed, bipolar, or psychotic patients should undergo psychiatric assessment, disposition, and follow-up. They should be given prescriptions for a limited supply of drugs with a limited number of refills and should be monitored for compliance and response to therapy. Expanding naloxone distribution, improving access to substance use disorder treatment, and linkage to other harm reduction services should be priorities in regions with a high incidence of opioid overdose.

SPECIFIC TOXIC SYNDROMES AND POISONINGS

Table 470-4 summarizes the pathophysiology, clinical features, and treatment of toxidromes and poisonings that are common, produce life-threatening toxicity, or require unique therapeutic interventions. In all cases, treatment should include attention to the general principles discussed above and, in particular, supportive care. Poisonings not covered in this chapter are discussed in specialized texts.

Alcohol, cocaine, hallucinogen, and opioid poisoning and alcohol and opioid withdrawal are discussed in Chaps. 464, 467, and 468; nicotine addiction is discussed in Chap. 465; acetaminophen poisoning is discussed in Chap. 351; the neuroleptic malignant syndrome is discussed in Chap. 446; and heavy metal poisoning is discussed in Chap. 469.

GLOBAL CONSIDERATIONS

Risks of poisoning in the United States and throughout the world are in transition. Patterns of travel, immigration, and internet consumerism should always be considered in patients suspected of poisoning or overdose without a clear etiology. Immigrants into various countries may have underlying poisoning from various metals from work or the environment where they previously lived; herbal remedies, food products, and cosmetics imported from overseas or ordered from the internet may be contaminated with metals, toxic plants, or other pharmaceutical contaminants; and new drugs of abuse that originate in one part of the world quickly circulate due to the ease afforded by the internet. Climate change has recently been identified as a key reason for evolving differences in the geographic pattern of poisoning injuries from snakebites and environmental toxic metal exposures. Expanding the history at the time of evaluation, recruiting the assistance of global health specialists, and ordering expanded laboratory panels may be indicated. For instance, during the COVID-19 pandemic, poisoning from household cleaning substances and novel untested therapies increased worldwide.

471 Disorders Caused by Venomous Snakebites and Marine Animal Exposures

Nathaniel Mann, Michael D. Simpson, Erik Fisher

This chapter outlines general principles for the evaluation and management of victims of envenomation and poisoning by venomous snakes and marine animals. Because the incidence of serious bites and stings is relatively low in developed nations, true incidence and robust clinical data are often limited. As a result, therapeutic decision-making is frequently based on anecdotal information.

VENOMOUS SNAKEBITE

EPIDEMIOLOGY

The venomous snakes of the world belong to the families Viperidae (subfamily Viperinae: Old World vipers; subfamily Crotalinae: New World and Asian pit vipers), Elapidae (including cobras, coral snakes, sea snakes, kraits, and all Australian venomous snakes), Lamprophiidae (subfamily Atractaspidinae: burrowing asps), and Colubridae (a large family in which most species are nonvenomous). Death from snake envenomation represents the deadliest neglected tropical disease in the world. Most snakebites occur in developing countries with temperate and tropical climates in which populations subsist on agriculture and fishing **(Fig. 471-1)**. While estimates vary, worldwide data from 2019 suggest 63,415 (95% uncertainty interval (UI), 38,930–78,633) deaths globally from snake envenomation with a projected increase to 68,799 (95% UI, 41,372–97,613) by 2030, despite a World Health Organization (WHO) goal to half snake envenomation deaths over the same time period. There are an estimated 1.2 million to 5.5 million snakebites worldwide each year, with 421,000–1,200,000 envenomations. Such wide-ranging estimates reflect the challenges of collecting accurate data in the regions most affected by venomous snakes. Many victims in these areas either do not seek medical attention or have insufficient access to antivenom, and reporting and record-keeping are generally poor.

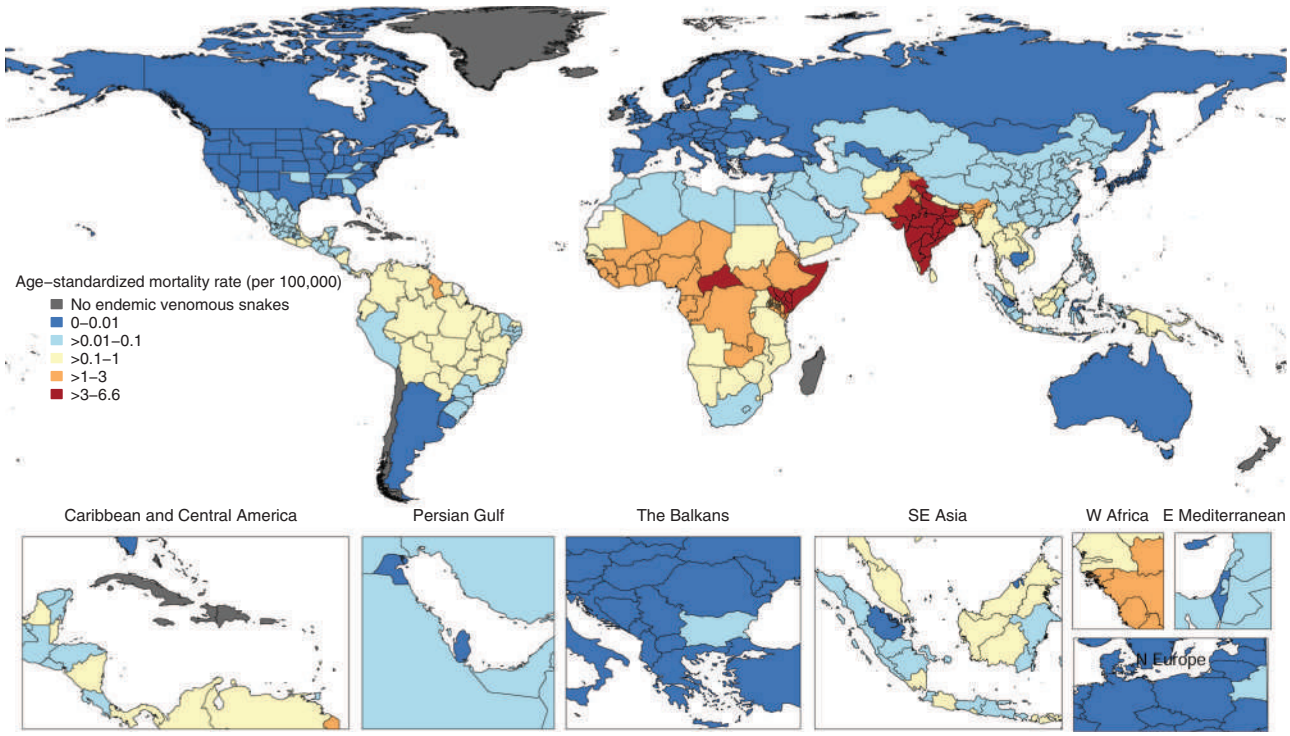

FIGURE 471-1 Age-standardized mortality rate of snakebite envenoming in 2019. GBD 2019 did not publish state-level estimates for China, so each state is colored based on China's national estimate. *(Reproduced from GBD 2019 Snakebite Envenomation Collaborators: Global Mortality of Snakebite Envenoming Between 1990 and 2019. Nat Commun 13:1, 2022.)*

SNAKE ANATOMY/IDENTIFICATION

The typical snake venom delivery apparatus consists of bilateral venom glands situated behind the eyes and hollow anterior maxillary fangs. In viperids, these fangs are long and highly mobile; they are retracted against the roof of the mouth when the snake is at rest, then brought to an upright position when about to strike. In elapids, the fangs are fixed in an erect position and smaller in size, which can lead to fewer distinct wounds after an envenomation. Venomous colubrids do not possess venom glands but instead have homologous structures known as Duvernoy's glands. Approximately 20–25% of pit viper bites and higher percentages of other snakebites (up to 75% for sea snakes) are "dry" bites, in which no venom is released.

Differentiating between venomous and nonvenomous snake species can be challenging. Identifying venomous snakes by color pattern can be misleading, as many nonvenomous snakes have color patterns that closely mimic those of venomous snakes found in the same region. Viperids are characterized by triangular heads (a feature shared with, or mimicked by, many harmless snakes), elliptical pupils (also seen in some nonvenomous snakes, such as boas and pythons), and enlarged maxillary fangs; pit vipers also possess heat-sensing organs (loreal pits) on each side of the head that assist with locating prey and aiming strikes. Rattlesnakes possess a series of interlocking hollow keratin plates (the rattle) on the tip of the tail that emit a buzzing sound when vibrated rapidly; this sound serves as a warning signal to perceived threats.

VENOMS AND CLINICAL MANIFESTATIONS

Snake venoms consist of highly complex mixtures of enzymes, polypeptides, glycoproteins, and other constituents. Venom components may vary greatly depending on the species, age, diet, and geographic location of the snake. Venom variability even exists within members of the same species. Snake venoms can cause local tissue necrosis, affect the coagulation pathway at various steps, impair organ function, or act at the neuromuscular junction to cause paralysis.

After an envenomation, the time to symptom onset and clinical presentation can be quite variable depending on the species involved, the anatomic location of the bite, and the amount of venom injected. Envenomations by most viperids and some elapids cause progressive local pain, soft tissue swelling, and ecchymosis **(Fig. 471-2)**. Hemorrhagic or serum-filled vesicles and bullae may develop at the bite site over a period of hours to days. In serious bites, tissue loss can be significant **(Fig. 471-3)**. Systemic findings are variable and can include generalized fatigue, nausea or vomiting, changes in taste, mouth numbness, tachycardia or bradycardia, hypotension, muscle fasciculations, pulmonary edema, renal dysfunction, or spontaneous hemorrhage. Envenomations by neurotoxic elapids, such as kraits (*Bungarus* species), many Australian elapids (e.g., death adders [*Acanthophis* species] and tiger snakes [*Notechis* species]), and some cobras (*Naja* species), as well as some viperids (e.g., the South American rattlesnake [*Crotalus durissus*], Mojave rattlesnake [*Crotalus scutulatus*], some Timber rattlesnakes [*Crotalus horridus*], and certain Indian Russell's vipers [*Daboia russelii*]), cause neurologic dysfunction. Early findings may consist of nausea and vomiting, headache, paresthesias or numbness, or altered mental status. Victims may develop cranial nerve abnormalities (e.g., ptosis, difficulty swallowing), followed by peripheral motor weakness. Severe envenomation may result in diaphragmatic paralysis and lead to death from respiratory failure and aspiration. Sea snake envenomation results in local pain (variable), generalized myalgias, trismus, rhabdomyolysis, and progressive flaccid paralysis; these manifestations can be delayed for several hours.

TREATMENT

Venomous Snakebite

FIELD MANAGEMENT

The most important aspect of prehospital care of a person bitten by a venomous snake is rapid transport to a medical facility equipped to provide supportive management (airway, breathing, and circulation) and antivenom therapy. Any jewelry or tight-fitting clothing near the bite should be removed to avoid constriction from anticipated soft tissue swelling. Although wound care should not delay transport, the wound should be cleaned with soap and running water and then covered with a sterile dressing. It is reasonable to apply a splint to the bitten extremity to limit movement and assist with positioning. If possible, the extremity should be maintained in

a neutral position of comfort at approximately heart level. Attempting to capture and transport the offending snake is not advised; instead, digital photographs taken from a safe distance may assist with snake identification and treatment decisions.

Most of the first-aid measures recommended in the past are of little benefit and may worsen outcomes. Incising and/or applying suction to the bite site should be avoided, as these measures exacerbate local tissue damage, increase the risk of infection, and have not been shown to be effective. Venom sequestration devices (e.g., lympho-occlusive bandages or tourniquets) are not advised, as they may intensify local tissue damage by restricting the spread of potentially necrotizing venom and may contribute to loss of function or ischemia. In developing countries, victims should be encouraged to seek immediate treatment at a medical facility equipped with antivenom instead of consulting traditional healers and thus incurring significant delays in reaching appropriate care.

Elapid envenomations that are primarily neurotoxic and have no significant effects on local tissue may be managed with pressure-immobilization, in which the entire bitten limb is immediately wrapped with a bandage and then immobilized. This technique is meant to restrict lymphatic drainage and has been shown to delay the systemic absorption of venom from predominantly neurotoxic species but is not recommend for viperid envenomation. For pressure-immobilization to be effective, the wrap pressure should not exceed 40–70 mmHg in upper-extremity application and 55–70 mmHg in lower-extremity application. As an estimate, the bandage should be snug enough to apply pressure but loose enough for a finger to slip underneath. Additionally, the victim must be carried out of the field because walking generates muscle-pumping activity that, regardless of the anatomic site of the bite, will disperse venom into the systemic circulation. Pressure-immobilization should be used only in cases in which the offending snake is reliably identified and known to be primarily neurotoxic, the rescuer is skilled in pressure-wrap application, the necessary supplies are readily available, and the victim can be fully immobilized and carried to medical care—a rare combination of conditions, particularly in the regions of the world where such bites are most common.

HOSPITAL MANAGEMENT

Initial hospital management should focus on the victim's airway, breathing, and circulation. Patients with bites to the face or neck may require early endotracheal intubation to prevent loss of airway patency caused by rapid soft-tissue swelling. Vital signs, cardiac rhythm, oxygen saturation, and urine output should be closely monitored. Two large-bore IV lines should be established in unaffected extremities. Because of the potential for coagulopathy, venipuncture attempts should be minimized and noncompressible sites (e.g., subclavian vein) avoided. Early hypotension may be caused by bradykinin-potentiating factors, which lead to vasodilation and pooling of blood in the pulmonary and splanchnic vascular beds. Additionally, systemic bleeding, hemolysis, and loss of intravascular volume into the soft tissues may play important roles in hypotension. Fluid resuscitation with isotonic crystalloid such as saline or lactated Ringer's (20–40 mL/kg IV) should be initiated if there is any evidence of hemodynamic instability. Vasopressors (e.g., norepinephrine, epinephrine) should be considered if venom-induced shock persists after aggressive volume resuscitation and antivenom administration (see below), as the victim may be experiencing anaphylaxis to the venom components or the antivenom itself.

A thorough history (including the time of the bite and any symptoms of envenomation) should be obtained and a complete physical examination performed, with a focus on the neurovascular status of the site of envenomation. For envenomation of a limb, palpation of axillary or inguinal lymph nodes can provide information about lymphatic spread. Bandages or wraps applied in the field should be removed as soon as possible, with cognizance that the release of such ligatures may result in hypotension or dysrhythmias when stagnant acidotic blood containing venom is released into the systemic circulation. To objectively evaluate the progression of

local envenomation, the leading edge of swelling, ecchymosis, and tenderness should be marked, and limb circumference should be measured at three points (e.g., at the bite site, the joint proximal, and the joint distal) every 15 min until the local tissue effects have stabilized. Once stabilized, measurements can be taken every 1–2 h. During this period of observation, the bitten extremity should be positioned above the level of the heart. Victims of neurotoxic envenomation should be monitored closely for evidence of cranial nerve dysfunction (e.g., ptosis) that may precede more overt signs of impending airway compromise (e.g., difficulty swallowing, respiratory insufficiency) necessitating endotracheal intubation and mechanical ventilation.

Blood should be drawn for laboratory evaluation as soon as possible. Important studies include a complete blood count to determine the degree of hemorrhage or hemolysis and to detect thrombocytopenia; blood type and cross-matching; assessment of renal and hepatic function; coagulation studies such as prothrombin time and fibrinogen level; measurement of fibrin degradation products such as a D-dimer; measurement of creatine kinase for suspected rhabdomyolysis; and testing of urine for blood or myoglobin. In developing regions, the 20-min whole-blood clotting test can be used to diagnose coagulopathy when access to laboratory tests is limited. To perform this test, 1–2 mL of venous blood is placed in a clean, dry glass receptacle (e.g., a test tube) and left undisturbed for 20 min. The sample is then inverted. If the blood is still liquid and a clot has not formed, coagulopathy is present. There have been some recent studies examining the utility of thromboelastography (TEG) in detecting venom-induced consumptive coagulopathy. In vitro studies have shown that TEG may be more sensitive than conventional coagulation studies in detecting coagulopathy at lower venom concentrations; however, it remains to be seen if this bears any clinical significance. Currently, there is insufficient evidence to suggest routine use of TEG. Electrocardiography and chest radiography may be helpful in severe envenomations or when there is significant comorbidity. After antivenom therapy (see below), laboratory values should be rechecked every 6 h until clinical stability is achieved.

The mainstay of treatment of a venomous snakebite resulting in significant envenomation is prompt administration of specific antivenom. Antivenoms are produced by injecting animals (generally horses or sheep) with venoms from medically important snakes. Once the stock animals develop antibodies to the venoms, their serum is harvested, and the antibodies are isolated for antivenom preparation. The goal of antivenom administration is to allow antibodies (or antibody fragments) to bind and deactivate circulating venom components before they can attach to target tissues and cause deleterious effects. Antivenoms may be monospecific (directed against a particular snake species) or polyspecific (covering several species in a geographic region). Unless the species are known to have homologous venoms, antivenoms rarely offer cross-protection against snake species other than those used in their production. Thus, antivenom selection must be specific for the offending snake; if the antivenom chosen does not contain antibodies to that snake's venom components, it will provide no benefit and may lead to unnecessary complications (see below). In the United States, assistance in finding appropriate antivenom can be obtained from a regional poison control center, which can be reached by telephone 24 h a day at (800) 222-1222.

For victims of bites by viperids or cytotoxic elapids, indications for antivenom administration include significant progressive local findings (e.g., rapidly spreading soft-tissue swelling, swelling that involves more than half the bitten limb, extensive blistering or bruising, severe pain) and any evidence of systemic envenomation (e.g., systemic symptoms or laboratory abnormalities). Caution must be used when determining the significance of isolated pain or soft-tissue swelling after the bite of an unidentified snake because the saliva of some relatively harmless species can cause mild discomfort or edema at the bite site; in such bites, antivenoms are useless and potentially harmful. Antivenoms have limited efficacy in preventing local tissue damage caused by necrotizing venoms, as venom components bind to local tissues very quickly. Nevertheless, antivenom should be administered as soon as the need for it is identified to limit further tissue damage and systemic effects. Antivenom administration after bites by neurotoxic elapids is indicated at the first sign of neurotoxicity (e.g., cranial nerve dysfunction, peripheral neuropathy). In general, antivenom is effective only in reversing active venom toxicity; it is of little benefit in reversing effects that have already been established (e.g., renal failure, established paralysis); these improve only with time and other supportive therapies.

Specific comments related to the management of venomous snakebites in the United States and Canada appear in **Table 471-1**. The package insert for the selected antivenom should be consulted regarding species covered, method of administration, starting dose, and need (if any) for redosing. Whenever possible, it is advisable for health care providers to seek advice from experts in snakebite management regarding indications for and dosing of antivenom.

Antivenom should only be administered intravenously, and the infusion should be started slowly, with the treating clinician at the bedside ready to immediately intervene at the first signs of an acute adverse reaction. In the absence of an adverse reaction, the rate of infusion can be increased gradually until the full starting dose has been administered (over a total period of ~1 h). Further antivenom may be necessary if the patient's acute clinical condition worsens or fails to stabilize, or if venom effects recur. The decision to administer further antivenom to a stabilized patient should be based on clinical evidence of the persistent circulation of unbound venom components. For viperid bites, antivenom administration should generally be continued until the victim shows definite improvement (e.g., reduced pain, stabilized vital signs, restored coagulation). Neurotoxicity from elapid bites may be more difficult to reverse with antivenom. Once neurotoxicity is established and endotracheal intubation is required, further doses of antivenom are unlikely to be beneficial. In such cases, the victim must be maintained on mechanical ventilation until recovery, which may take days to weeks.

Adverse reactions to antivenom administration include early (anaphylaxis) and late (serum sickness) hypersensitivity reactions. Clinical manifestations of early hypersensitivity may include tachycardia, rigors, vomiting, urticaria, dyspnea, laryngeal edema, bronchospasm, and hypotension. Although recommended by some antivenom manufacturers, skin testing for potential early hypersensitivity is neither sensitive nor specific and is of no benefit. The quality of antivenoms is highly variable worldwide; rates of acute anaphylactic reactions to some of these products exceed 50%. More recent data on North American snakebites suggest that the incidence of anaphylaxis to Crotalidae polyvalent immune fab (ovine) (CroFab®) (BTG International Inc., West Conshohocken, PA) antivenom may be closer to 1.1%. Incidence data on anaphylaxis to Crotalidae immune f(ab′) 2 (equine) (Anavip®) (Instituto Bioclon S.A de C.V., Tlalpan CDMX, Mexico for Rare Disease Therapeutics, Inc., Franklin, TN) are not currently available. Limited evidence from Sri Lanka supports routine pretreatment with low-dose SC epinephrine (0.25 mg of 1:1000 aqueous solution) to prevent acute anaphylactic reactions after antivenom infusion in that population. Although widely practiced, prophylactic use of antihistamines and glucocorticoids has not proved beneficial. Modest expansion of the patient's intravascular volume with crystalloids may blunt episodes of acute hypotension during antivenom infusion. Epinephrine and airway equipment should always be immediately available. If the patient develops an anaphylactic reaction to antivenom, the infusion should be stopped temporarily and the reaction treated immediately with IM epinephrine (0.01 mg/kg up to 0.5 mg), an IV antihistamine (e.g., diphenhydramine, 1 mg/kg up to 50 mg), and a glucocorticoid (e.g., hydrocortisone, 2 mg/kg up to 100 mg). Once the reaction has been controlled, if the severity of the envenomation warrants additional antivenom, the dose should be restarted as soon as possible at a slower rate (5–10 mL/h) and

TABLE 471-1 Management of Venomous Snakebites in the United States and Canada[a]

Pit Viper Bites: Rattlesnakes (*Crotalus* and *Sistrurus* spp.), Cottonmouth Water Moccasins (*Agkistrodon piscivorus*), and Copperheads (*Agkistrodon contortrix*)

- Stabilize airway, breathing, and circulation.
- Institute monitoring (vital signs, cardiac rhythm, and oxygen saturation).
- Establish two large-bore IV lines.
  - If patient is hypotensive, administer isotonic crystalloid bolus (20–40 mL/kg IV).
- Take thorough history and perform complete physical examination.
- Identify offending snake (if possible).
- Measure and record circumference of bitten extremity every 15 min until swelling has stabilized. Can take measurements every 1 h once stabilized.
- Order laboratory studies (CBC, blood type and cross-matching, metabolic panel, PT/INR/PTT, fibrinogen level, FDP, CK, urinalysis).
  - If normal, repeat CBC and coagulation studies every 4 h until it is clear that no systemic envenomation has occurred.
  - If abnormal, repeat every 6 h after antivenom administration until swelling has stabilized (see below).
- Determine severity of envenomation.
  - None: fang marks only ("dry" bite)
  - Mild: local findings only (e.g., pain, ecchymosis, nonprogressive swelling)
  - Moderate: swelling that is clearly progressing, systemic symptoms or signs, and/or laboratory abnormalities
  - Severe: neurologic dysfunction, respiratory distress, and/or cardiovascular instability/shock
- Contact regional poison control center.
- Locate and administer antivenom as indicated: Crotalidae polyvalent immune Fab (Ovine) (CroFab®) (BTG International Inc., West Conshohocken, PA) or Crotalidae immune $F(ab')_2$ (Equine) (Anavip®) (Instituto Bioclon S.A de C.V., Tlalpan CDMX, Mexico).
  - Starting dose:
    - Based on severity of envenomation
      - None or mild: none
      - Moderate: CroFab® (4–6 vials), Anavip® (10 vials)
      - Severe: CroFab® (6 vials), Anavip® (10 vials)
    - Dilute reconstituted vials in 250 mL of normal saline.
    - Infuse IV over 1 h (with medical provider in close attendance).
      - Start at rate of 25–50 mL/h for first 10 min.
      - If there is no allergic reaction, increase rate to 250 mL/h.
  - If there is an acute reaction to antivenom:
    - Stop infusion.
    - Treat with standard doses of epinephrine (IM or IV; latter route only in setting of severe hypotension), antihistamines (IV), and glucocorticoids (IV).
    - When reaction is controlled, restart antivenom as soon as possible (at rate of 5–10 mL/h; titrate up as tolerated).
  - Monitor clinical status over 1 h.
    - Stabilized or improved: Admit to hospital.
    - Progressing or unimproved: Repeat starting dose. Continue this pattern until patient's condition is stabilized or improved. Admit to ICU if possible.
- Blood products are rarely needed; if required, they should be given only after antivenom administration.
- Provide tetanus immunization as needed.
- Prophylactic antibiotics are unnecessary unless prehospital care included incision or mouth suction.
- Pain management: Administer acetaminophen and/or opioids as needed; avoid salicylates and nonsteroidal anti-inflammatory agents.
- Admit patient to hospital. (If there is no evidence of envenomation, monitor for 8–12 h before discharge.)
  - Give additional antivenom: CroFab® (2 vials every 6 h for 3 additional doses), Anavip® (4 vials for recurrent coagulopathy).
  - Monitor for evidence of rising intracompartmental pressures (see text).
  - Provide wound care (see text).
  - Start physical therapy (see text).
- At discharge, warn patient of possible recurrent coagulopathy and symptoms/signs of serum sickness. Schedule repeat laboratory testing to monitor for recurrent coagulopathy.

Coral Snake Bites: Eastern coral snake (*Micrurus fulvius*), Texas coral snake (*Micrurus tener*), and Sonoran coral snake (*Micruroides euryxanthus*)

- Stabilize airway, breathing, and circulation.
- Institute monitoring (vital signs, cardiac rhythm, and oxygen saturation).
- Establish two large-bore IV lines and initiate normal saline infusion.
- Take thorough history and perform complete physical examination.
- Identify offending snake (if possible).
- Laboratory studies are unlikely to be helpful.
- Contact regional poison control center.
- Locate and administer antivenom as indicated: Antivenin (*Micrurus fulvius*) (Equine) (commonly referred to as North American Coral Snake Antivenin; Pfizer Inc., Philadelphia, PA).[b]
  - Refer to antivenom package insert.
  - Dilute 3–5 reconstituted vials in 250–500 mL of normal saline.
  - Infuse IV over 1 h (with medical provider in close attendance).
  - If signs of envenomation progress despite initial dosing, repeat starting dose; up to 10 vials total may be required.

(*Continued*)

TABLE 471-1 Management of Venomous Snakebites in the United States and Canada[a] (Continued)

- If there is an acute adverse reaction to antivenom:
  - Stop infusion.
  - Treat with standard doses of epinephrine (IM or IV; latter route only in setting of severe hypotension), antihistamines (IV), and glucocorticoids (IV).
  - When reaction is controlled, restart antivenom as soon as possible (at rate of 5–10 mL/h; titrate up as tolerated).
- If there is evidence of neurologic dysfunction (e.g., any cranial nerve abnormalities):
  - Administer trial of acetylcholinesterase inhibitors (see Table 471-2).
  - If there is evidence of difficulty swallowing or breathing, proceed with endotracheal intubation and ventilatory support (may be required for days to weeks).
- Provide tetanus immunization as needed.
- Prophylactic antibiotics are unnecessary unless prehospital care included incision or mouth suction.
- Admit patient to hospital (ICU) even if there is no evidence of envenomation; monitor for at least 24 h.

[a]These recommendations are specific to the care of victims of venomous snakebites in the United States and Canada and should not be applied to bites in other regions of the world. [b]At the time of this writing, lot CL6814 of Antivenin has an extended expiration date of June 30, 2024.

Abbreviations: CBC, complete blood count; CK, creatine kinase; FDP, fibrin degradation products; ICU, intensive care unit; PT/INR/PTT, prothrombin time/international normalized ratio/partial thromboplastin time.

titrated upward as tolerated. In rare cases of refractory hypotension, a concomitant IV infusion of epinephrine may be initiated and titrated to clinical effect while antivenom is administered. The patient must be monitored very closely during such therapy, preferably in an emergency department or intensive care setting. Serum sickness typically develops 1–2 weeks after antivenom administration and may present as myalgias, arthralgias, fever, chills, urticaria, lymphadenopathy, or renal or neurologic dysfunction. Treatment for serum sickness consists of systemic glucocorticoids (e.g., oral prednisone, 1–2 mg/kg daily) until all symptoms have resolved, with a subsequent taper over 1–2 weeks. Oral antihistamines and analgesics may provide additional relief of symptoms.

Blood products are rarely necessary in the management of an envenomated patient. The venoms of many snake species can deplete coagulation factors and cause a decrease in platelet count or hematocrit. Nevertheless, these components usually rebound within hours after administration of adequate antivenom. If the need for blood products is thought to be great (e.g., a dangerously low platelet count in a hemorrhaging patient), these products should be given only after adequate antivenom administration to avoid fueling ongoing consumptive coagulopathy.

Rhabdomyolysis should be managed in standard fashion with IV fluids and close monitoring of urine output. Victims who develop acute renal failure should be evaluated by a nephrologist and referred for hemodialysis or peritoneal dialysis as needed. Such renal failure is usually due to acute tubular necrosis and is frequently reversible. If bilateral cortical necrosis occurs, however, the prognosis for renal recovery is less favorable, and long-term dialysis with possible renal transplantation may be necessary.

Most snake envenomations involve subcutaneous deposition of venom. On occasion, venom can be injected more deeply into muscle compartments, particularly if the offending snake was large and the bite occurred on the hand, forearm, or anterior compartment of the lower leg. Intramuscular swelling of the affected extremity may be accompanied by severe pain, decreased strength, altered sensation, cyanosis, and apparent pulselessness—signs suggesting a muscle compartment syndrome. If compartment syndrome is suspected, intracompartmental pressures may be measured, preferably with a minimally invasive technique (e.g., with a wick catheter or digital readout device). Elevation of compartment pressures above 30–40 mmHg is an indication for additional antivenom administration. The extremity should be elevated while antivenom is delivered.

Traditionally, acute compartment syndrome is treated with fasciotomy. However, in North American crotalid envenomations, there is no evidence to support fasciotomy and it should not be recommended, as modern antivenoms are effective in reducing compartment pressure. Current data suggest notable risk of increased morbidity with fasciotomy and no evidence of benefit for these patients. However, there are scant data from studies on Asian snake species that support fasciotomy in very limited circumstances. In these patients, if the intracompartmental pressure remains elevated after 1 h of such therapy, a surgical consultation may be obtained for possible fasciotomy, though published data support allowing compartment pressures up to 55 mmHg for up to 6 h before considering fasciotomy. This procedure should always be one of last resort. Fortunately, the incidence of compartment syndrome is very low after a snakebite, with fasciotomies required in <1% of cases. Nevertheless, vigilance is essential.

Acetylcholinesterase inhibitors (e.g., edrophonium and neostigmine) may promote neurologic improvement in patients bitten by snakes with postsynaptic neurotoxins. Snakebite victims with objective evidence of neurologic dysfunction may receive a test dose of acetylcholinesterase inhibitors, as outlined in **Table 471-2**. If they exhibit improvement, additional doses of long-acting neostigmine can be administered as needed. Acetylcholinesterase inhibitors are not a substitute for endotracheal intubation or the administration of appropriate antivenom when available.

Care of the bite wound includes simple cleansing with soap and water; application of a dry, sterile dressing; and splinting of the affected extremity with padding between the digits. Once antivenom therapy has been initiated, the extremity should be elevated to heart level to reduce swelling. Patients should receive tetanus immunization as appropriate. Prophylactic antibiotics are generally unnecessary after bites by North American snakes because the incidence of secondary infection is low. In some regions, secondary bacterial infection is more common, and the consequences are serious; as such, prophylactic treatment with broad-spectrum antibiotics may be appropriate. Antibiotics may also be considered if misguided first-aid efforts included incision or mouth suction of the bite site. Pain control may be achieved with acetaminophen or opioid analgesics. Salicylates and nonsteroidal anti-inflammatory agents should generally be avoided because of their potential effects on blood clotting.

TABLE 471-2 Use of Acetylcholinesterase Inhibitors in Envenomations by Neurotoxic Snakes and Cone Snails

1. Patients with clear, objective evidence of neurotoxicity (e.g., ptosis or inability to maintain upward gaze) should receive a test dose of edrophonium (if available) or neostigmine.
   a. Pretreat with atropine: 0.6 mg IV (children, 0.02 mg/kg with a minimum of 0.1 mg)
   b. Treat with:
      Edrophonium: 10 mg IV (children, 0.25 mg/kg)
      or
      Neostigmine: 0.02 mg/kg IV or IM (children, 0.04 mg/kg)
2. If objective improvement is evident after 30 min, treat with:
   a. Neostigmine: 0.5 mg IV, IM, or SC (children, 0.01 mg/kg) every 1 h as needed
   b. Atropine: 0.6 mg as IV continuous infusion over 8 h (children, 0.02 mg/kg over 8 h)
3. Closely monitor airway and perform endotracheal intubation if needed.

Wound care in the days after the bite should include careful aseptic debridement of clearly necrotic tissue once coagulopathy has been fully reversed. Intact serum-filled vesicles or hemorrhagic blebs should be left undisturbed. If ruptured, they should be debrided with sterile technique. Any debridement of damaged muscle should be conservative because there is evidence that such muscle may recover to a significant degree after antivenom therapy.

Physical therapy should be started as soon as possible to assist the patient in returning to a functional state. The incidence of long-term loss of function (e.g., reduced range of motion, impaired sensory function) is unclear.

Any patient with signs of envenomation should be observed in the hospital for at least 24 h. In North America, a patient with an apparently "dry" viperid bite should be closely monitored for at least 8–12 h before discharge, as significant toxicity occasionally develops after a delay of several hours. The onset of systemic symptoms commonly is delayed for several hours after bites by certain elapids (including coral snakes, *Micrurus* species), some non–North American viperids (e.g., the hump-nosed pit viper [*Hypnale hypnale*]), and sea snakes. Patients bitten by these snakes should be observed in the hospital for at least 24 h. Admission to an intensive care setting is advised for patients with progressive clinical findings despite initial antivenom administration; those bitten in the head, neck, or other high-risk sites; and those who develop an acute hypersensitivity reaction to antivenom.

At hospital discharge, victims of venomous snakebites should be warned about symptoms and signs of wound infection, antivenom-related serum sickness, and potential long-term sequelae, such as pituitary insufficiency from Russell's viper (*D. russelii*) bites. If coagulopathy developed in the acute stages of envenomation, it can recur during the first 2–3 weeks after the bite as venom antigens may have longer half-lives than their corresponding antivenoms. In such cases, victims should be warned to avoid elective surgery or activities posing a high risk of trauma during this period. Repeat laboratory tests (e.g., complete blood count, prothrombin time, fibrinogen level) should be scheduled to monitor for recurrent coagulopathy. Outpatient analgesic treatment, wound management, and physical therapy should be provided. For patients who present with delayed episodes of bleeding, severe isolated thrombocytopenia, or moderate thrombocytopenia with severe coagulopathy, repeat antivenom administration should be considered at typical maintenance dosing.

MORBIDITY AND MORTALITY

The overall mortality rates for victims of venomous snakebites are low in regions with rapid access to medical care and appropriate antivenoms. In the United States, for example, the mortality rate is <1% for victims who receive antivenom. Eastern and western diamondback rattlesnakes (*Crotalus adamanteus* and *Crotalus atrox*, respectively) are responsible for the majority of snakebite deaths in the United States. Snakes responsible for a large number of deaths in other countries include cobras (*Naja* species), carpet and saw-scaled vipers (*Echis* species), Russell's vipers (*D. russelii*), large African vipers (*Bitis* species), lancehead pit vipers (*Bothrops* species), and tropical rattlesnakes (*C. durissus*).

The incidence of morbidity, defined as permanent functional loss in a bitten extremity, is difficult to estimate but is substantial. Morbidity may be due to muscle, nerve, or vascular injury, or to scar contracture. Such morbidity can have devastating consequences for victims in the developing world when they lose the ability to work and provide for their families. In the United States, functional loss tends to be more common and severe after rattlesnake bites than after bites by copperheads (*Agkistrodon contortrix*) or water moccasins (*Agkistrodon piscivorus*).

GLOBAL CONSIDERATIONS

In May 2019, the WHO announced a comprehensive strategy to control and prevent snake envenomations worldwide, with the goal to reduce the number of deaths and cases of disability from snakebites by 50% by 2030. This strategy has been developed around four central tenets: empowering and engaging communities, ensuring safe and effective treatments, strengthening health systems, and improving partnerships, coordination, and resources. In many developing countries where snakebites are common, limited access to medical care and antivenoms contributes to high rates of morbidity and mortality. Recent data show that 6.85 billion people live within the regions inhabited by snakes, with >10% of people living >1 h from an urban center. Often, the available antivenoms are inappropriate and ineffective against the venoms of medically important indigenous snakes. In those regions, further research is necessary to determine the actual impact of venomous snakebites and the specific antivenoms needed in terms of both quantity and spectrum of coverage. Appropriate antivenoms must be available at the most likely first point of medical contact for patients (e.g., primary health centers) in order to minimize the common practice of referring victims to more distant, higher levels of care for the initiation of antivenom therapy. Just as important as getting the correct antivenoms into underserved regions is the need to educate populations about snakebite prevention and train medical care providers in proper management approaches. Local protocols written with significant input from experienced providers in the region of concern should be developed and distributed. Those who care for snakebite victims in these often-remote clinics must have the skills and confidence required to begin antivenom treatment (and to treat possible reactions) as soon as possible when indicated.

MARINE ENVENOMATIONS

The global incidence of marine envenomation is likely underestimated, as the majority of cases are mild. Much of the management of envenomation by marine animals is supportive, but a few specific antivenoms are available. This section provides general guidance, and patient management should be tailored to the practice patterns and known prevalence of specific venomous species in the region **(Fig. 471-4)**.

INVERTEBRATES

Cnidarians Cnidarians, such as hydroids, fire coral, jellyfish, and sea anemones, possess thousands of specialized stinging organelles called *cnidocysts* (a term that encompasses nematocysts, ptychocysts, and spirocysts) distributed along their tentacles. Nematocysts contain a barbed, coiled hollow thread bathed in venom that is discharged when provoked by mechanical stimuli, osmotic changes, or other chemical stimuli **(Fig. 471-5)**. The venom contains enzymes (phospholipases, metalloproteases), pore-forming toxins, neurotoxins, and nonprotein bioactive substances, such as tetramine, histamine, and serotonin. Venom flows through the hollow thread into the victim's skin. Because envenomation depends on intradermal delivery, only the subset of cnidarians whose barbs can pierce human skin are of toxicologic relevance.

After envenomation, immediate burning pain, pruritus, and paresthesias are common. The skin becomes reddened, darkened, edematous, and blistered, and may show signs of superficial necrosis. Rarely, systemic toxicity develops, affecting the cardiovascular, respiratory, gastrointestinal, and nervous systems, especially following stings from anemones, *Physalia* species, and scyphozoans. Anaphylaxis and secondary infection with marine bacteria can also occur.

Hundreds of deaths have been reported, many of them caused by *Chironex fleckeri, Stomolophus nomurai, Physalia physalis*, and *Chiropsalmus quadrumanus*. Irukandji syndrome is a potentially fatal condition associated with envenomation by the Australian jellyfish *Carukia barnesi* and *Malo* species. Symptoms generally manifest within 30 min and include hypertension; tachycardia; severe chest, abdominal, and back pain; nausea and vomiting; and headache. In the most serious cases, victims may develop cerebral hemorrhage, cerebral edema, cardiomyopathy, and pulmonary edema. Massive release of endogenous catecholamines induced by venom components appears to be the underlying cause of this syndrome, with catecholamine depletion occasionally resulting in delayed hypotension.

Initial management of *Cnidarian* envenomation should focus on removing the victim from the water and decontaminating the skin.

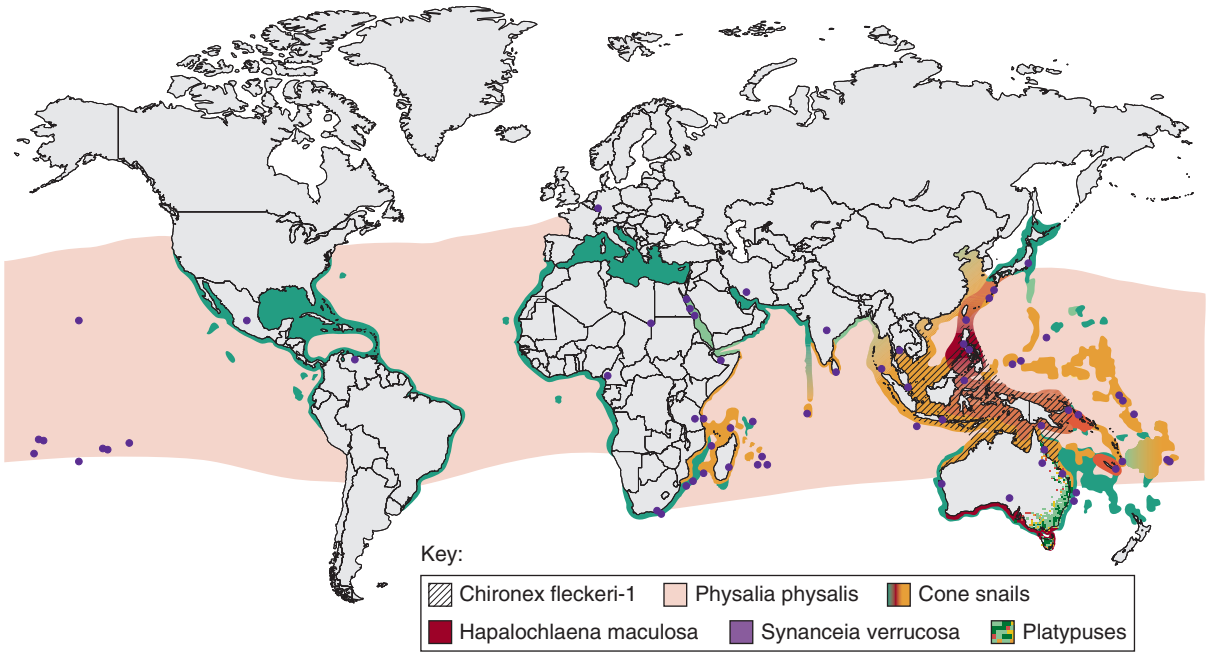

FIGURE 471-4 Geographic distribution of venomous marine animals.

Drowning is a common cause of death after significant *Cnidarian* envenomation. Once the victim is on land or a boat, the skin should be decontaminated with saline or seawater. Providers wearing protective equipment should carefully remove any adherent nematocysts. Vinegar (5% acetic acid) appears to be useful for relieving pain caused by several species, especially in the Indo-Pacific region where *C. fleckeri* and *C. barnesi* are common. In that region, decontamination with vinegar should be followed by hot water immersion up to 45°C (113°F). Vinegar may increase nematocyst discharge in *P. physalis* and *C. quinquecirrha*, species common in the United States. Victims in the United States should be decontaminated with seawater and then have affected areas immersed in hot water. Alternatively, vinegar may be tested on a small area of affected skin to assess effects before performing complete decontamination. If hot water is unavailable, commercial (chemical) cold packs or ice packs applied over a thin dry cloth or plastic membrane can be effective in alleviating pain, but do not denature venom components. Stingose, a commercial mixture of aluminum sulfate and surfactant sold in Australia, may denature venom components and provide rapid pain relief. In general, rubbing leads to further stinging by adherent cnidocysts and should be avoided.

After decontamination, topical application of a local anesthetic, antihistamine, or glucocorticoid may be helpful for symptom control. Persistent severe pain may be treated with opioid analgesics. Muscle spasms may respond to IV diazepam (2–5 mg, titrated upward as necessary). An antivenom is available from Seqirus (an affiliate of Commonwealth Serum Laboratories) for stings from *C. fleckeri* ("box jellyfish") found in Australian and Indo-Pacific waters. While initial in vitro studies demonstrated reversal of several *C. fleckeri* toxins, later animal studies were less promising, and there are no reports of human survival directly attributable to its administration. Use of the antivenom is recommended in the case of life-threatening toxicity when available, but this should not delay or replace aggressive supportive care (see "Sources of Antivenoms and Other Assistance," below). As expected, the antivenom appears less effective for envenomations from other *Cnidaria* species besides *C. fleckeri*. Adverse reactions to the antivenom include early (anaphylaxis) and late (serum sickness) hypersensitivity reactions. Acute allergic reactions should be treated with systemic antihistamines, glucocorticoids, and epinephrine when appropriate. Delayed serum sickness is relatively common, typically occurs 5–10 days after antivenom administration, and generally responds well to 5 days of oral glucocorticoids.

Treatment of Irukandji syndrome may require administration of opioid analgesics and aggressive treatment of hypertension. Appropriate antihypertensive agents include phentolamine, nicardipine, nitroprusside, nitroglycerin, and IV magnesium sulfate. Beta-adrenergic antagonists should be avoided due to the risk of worsening hypertension from unopposed alpha-adrenergic effects. All victims with systemic reactions should be observed for at least 6–8 h for rebound from any therapy and should be monitored for cardiac arrhythmias.

Safe Sea (Nidaria Technology Ltd.), a "jellyfish-safe" sunblock applied to the skin before an individual enters the water, inactivates the recognition and discharge mechanisms of nematocysts; it may prevent or diminish the effects of coelenterate stings. Whenever possible, a dive skin or wetsuit should be worn when entering ocean waters.

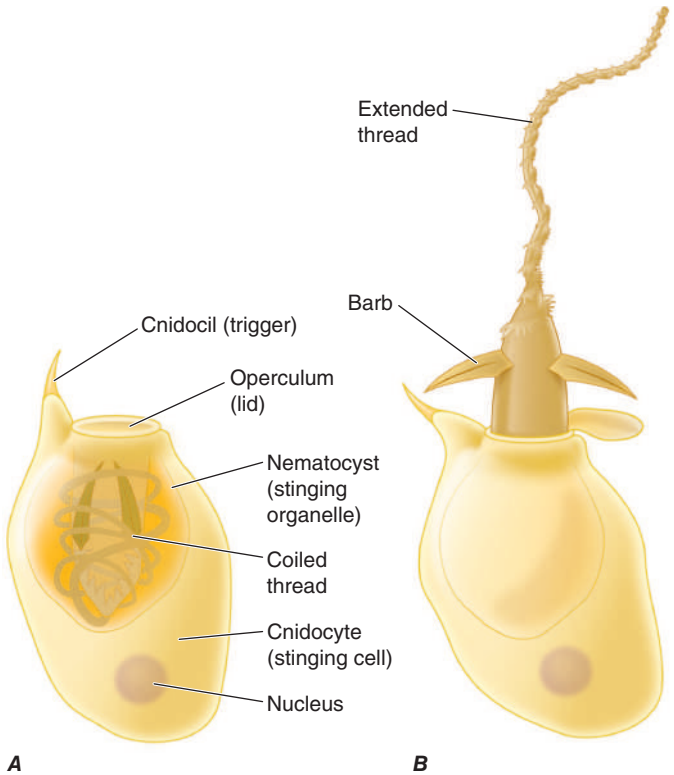

FIGURE 471-5 Schematic of a nematocyst. *A.* Undischarged. Note coiled hollow thread bathed in venom. ***B.*** Discharged.

FIGURE 471-7 Spines on the crown-of-thorns sea star (*Acanthaster planci*). *(Courtesy of Paul Auerbach, with permission.)*

Sea Sponges Several species of sea sponges (Phylum *Porifera*) produce irritants known as crinitoxins. Touching a sea sponge may result in allergic contact dermatitis. Irritant dermatitis may result if the sponge's spicules of silica or calcium carbonate penetrate the skin. Affected skin should be dried and adhesive tape, a commercial facial peel, or a thin layer of rubber cement used to remove embedded spicules. Vinegar should then be applied immediately, with repeated application for 10–30 min three or four times a day thereafter. Systemic corticosteroids should be reserved for severe allergic reactions (such as severe vesiculation) or erythema multiforme. Mild reactions generally subside within 7 days. Severe envenomation can lead to fevers, chills, and muscle spasms. Desquamation of affected skin has also been described and can occur up to 2 months after exposure. Outpatient wound care is essential to monitor for secondary infection.

Annelid Worms Annelid worms (bristle worms) are covered with chitinous spines capable of penetrating human skin and producing dermal symptoms similar to those of *Cnidarian* envenomation, including pain, prickling, urticaria, and discoloration. Pain usually subsides within hours, but urticaria can persist for days and discoloration for weeks **(Fig. 471-6)**. Victims should be instructed not to scratch as it may fracture the spines, complicating their removal and increasing the risk of secondary infection. Visible bristles should be removed with forceps, adhesive tape, rubber cement, or a commercial facial peel. Soaking the affected skin in vinegar may provide additional relief. Severe inflammation can be treated with systemic antihistamines or corticosteroids.

Sea Urchins Venomous sea urchins possess hollow, venom-filled, calcified spines and pincer-like, flexible pedicellariae with venom glands. The venom contains bradykinin-like substances, steroid glycosides, hemolysins, proteases, serotonin, and cholinergic substances. Envenomation causes immediate onset of severe pain, edema, and erythema. If multiple spines penetrate the skin, the patient may develop systemic symptoms, including nausea, vomiting, numbness, muscular paralysis, and respiratory distress. Synovitis and arthritis have been reported after joint-space penetration. Retained spines can cause the formation of painful granulomas.

The affected part should be immersed in hot water (see "Cnidarians," above). Embedded spines should be removed with care as they may fracture and leave remnants lodged in the victim. Soft-tissue radiography, ultrasonography, or magnetic resonance imaging (MRI) can be used to evaluate for the presence of retained fragments. Surgical removal may be necessary, especially if the spines are in close proximity to vital structures (e.g., joints, neurovascular bundles). Granulomas from retained spines are amenable to excision or intralesional injection with triamcinolone hexacetonide. Arthritis from joint penetration has been treated with synovectomy.

Starfish The crown-of-thorns starfish (*Acanthaster planci*) produces viscous venom that coats the surface of its spines **(Fig. 471-7)**. The venom contains saponins with hemolytic, myotoxic, hepatotoxic, and anticoagulant properties. Skin puncture causes immediate pain, bleeding, and local edema. Multiple punctures may result in reactions such as local muscle paralysis. The spines fracture easily, and retained fragments may cause granulomatous lesions and synovitis. Envenomated persons benefit from immediate immersion in hot water, local anesthesia, wound cleansing, imaging, and possible exploration to remove spines and foreign material. The hemolytic and hepatotoxic components are less heat labile than other venom constituents; hot water immersion may not prevent systemic toxicity.

Sea Cucumbers Sea cucumbers excrete holothurin (a cantharidin-like liquid toxin) from their anus. This toxin is then concentrated in the tentacular organs that are projected when the animal is threatened. Underwater, holothurin induces minimal contact dermatitis but can cause significant corneal and conjunctival irritation should ocular contact occur. A severe reaction can lead to blindness. Skin should be decontaminated with vinegar. The eyes should be anesthetized with 1–2 drops of 0.5% proparacaine and irrigated copiously with normal saline, with subsequent slit-lamp examination to identify corneal defects.

Cone Snails Cone snails possess a detachable dartlike tooth bathed in venom for hunting prey and self-defense. Numerous conotoxins have been identified, with two major common mechanisms: neuromuscular acetylcholine receptor antagonism and blockade of sodium, potassium, and calcium channels. Punctures result in small, painful wounds followed by local ischemia, cyanosis, and numbness. Syncope, dysphagia, dysarthria, ptosis, blurred vision, and pruritus also have been documented. Cardiac dysrhythmias and paralysis with resultant respiratory failure have also been reported. Pressure-immobilization (see "Octopuses," below), hot-water soaks, and local anesthetics have been successful for localized symptoms. Respiratory failure may necessitate mechanical ventilation. Cardiac dysrhythmias should be treated with electrical cardioversion as ion channel-blocking antidysrhythmic medications may worsen the dysrhythmia. No antivenom is available. Edrophonium has been recommended as therapy for paralysis if an edrophonium test is positive (see Table 471-2).

Octopuses Serious envenomations and deaths have followed bites of Australian blue-ringed octopuses (*Hapalochlaena maculosa* and *Hapalochlaena lunulata*). The classic blue rings appear only when the animal is threatened. These species are not aggressive, and human envenomations have typically occurred when handling the octopus. Their salivary glands contain symbiotic bacteria that produce tetrodotoxin, a potent sodium channel blocker that inhibits transmissions in the peripheral nervous system. The bite is minimally painful, but oral and facial numbness develop within minutes of a serious envenomation. Mild weakness can rapidly progress to total flaccid paralysis. Mentation is typically unaffected. The venom can also cause peripheral vasodilation leading to profound hypotension. Deaths from these

envenomations are due to respiratory failure or vasodilatory shock and hypoperfusion.

Immediately after envenomation, a wide circumferential pressure-immobilization bandage should be applied over a gauze pad placed directly over the sting. The dressing should be applied at venous-lymphatic pressure with the preservation of distal arterial pulses, and the limb should be splinted. The bandage can be released when the victim has been transported to a medical facility. There is no antidote, and treatment is supportive. Respiratory failure may necessitate mechanical ventilation. Appropriate analgesia and sedation are critical as mental status is generally unaffected even in cases of complete paralysis. Hypotension should be treated with crystalloid and vasopressors if needed. In animal studies, phenylephrine and norepinephrine were more effective than dopamine or epinephrine for treatment of vasodilatory shock. Recovery usually occurs within 24–48 h, and long-term sequelae are uncommon unless related to hypoxia or hypoperfusion. Tetrodotoxin is also found in the flesh of fish in the order Tetraodontiformes, which contains a number of "pufferfish" including blowfish, globefish, and balloonfish. The toxin can be absorbed orally when these fish are consumed. Fugu, a traditional Japanese delicacy, is a reported source of poisoning. When properly prepared by a licensed chef, fugu is meant to contain a sufficient dose of tetrodotoxin to cause mild perioral paresthesia without systemic toxicity. When larger doses of the toxin are consumed due to improper preparation, symptoms are similar to envenomation by the blue-ringed octopus.

VERTEBRATES

Stingrays A stingray injury is both an envenomation and a traumatic wound. Stingrays possess serrated spines with venom glands that can easily penetrate human skin. The venom contains serotonin, 5′-nucleotidase, and phosphodiesterase. Victims experience severe pain, bleeding, and edema at the site of injury that peak within 30–60 min and may persist for up to 2 days. Penetrating injuries to the thorax and heart as well as lacerations to major vessels (especially of the lower extremity) have been reported. The wound often becomes ischemic in appearance and heals poorly, with adjacent soft-tissue swelling and prolonged disability. Systemic effects of the venom include weakness, diaphoresis, nausea, vomiting, diarrhea, hypotension, dysrhythmias, syncope, seizures, muscle cramps, fasciculations, and paralysis. While the venom effects can be fatal in rare cases, most deaths are attributable to traumatic injury.

Stonefish Stonefish (*Synanceia* species) are members of the *Scorpaenidae* family and generally considered the most venomous bony fish in the world. Their venom contains pore-forming toxins, proteases, hyaluronidase, 5′-nucleotidase, acetylcholinesterase, and cardiac calcium channel blockers. The venom is delivered through 12 or 13 dorsal, 2 pelvic, and 3 anal spines when provoked by mechanical stimuli. Victims experience immediate, intense pain that peaks within 90 min, local edema, and wound cyanosis. Local symptoms most often resolve within 12 h but can persist for days. Signs of systemic toxicity include abdominal pain, vomiting, delirium, seizures, paralysis, respiratory distress, dysrhythmias, and congestive heart failure. An antivenom from Seqirus (see "Sources of Antivenoms and Other Assistance," below) can be used in cases of severe envenomation but should not replace supportive care.

Lionfish Also members of the family Scorpaenidae, lionfish (*Pterois* species) are much less toxic to humans than stonefish. The venom is delivered by curved dorsal spines and contains heat-labile, high-molecular-weight proteins. Reported symptoms include localized pain, blistering, edema, sensory changes (paresthesia, anesthesia, or hyperesthesia), and necrosis (rare).

Platypuses The platypus is a venomous mammal. The male has a keratinous spur on each hind limb that is connected to a venom gland within the upper thigh. Skin puncture causes soft-tissue edema and pain that may last for days to weeks. Care is supportive and should focus on appropriate analgesia and wound care. Hot water immersion does not appear to be beneficial.

TREATMENT

Marine Vertebrate Stings

The stings of all marine vertebrates are treated in a similar fashion. Antivenom is currently available for stonefish envenomation. The affected part should be immersed immediately in hot water up to 45°C (113°F) for 30–90 min or until there is significant pain relief. Recurrent pain may respond to repeated hot water immersion. Systemic opioids as well as wound infiltration or regional nerve block with local anesthetics can help alleviate pain and facilitate wound exploration and debridement. Advanced imaging (in particular, ultrasound or MRI) may be helpful in identification of retained foreign bodies, which may be missed on plain radiographs. After exploration and debridement, the wound should be irrigated vigorously with warm, sterile saline. Bleeding is generally controlled with local pressure. Most wounds should be left open to heal by secondary intention or treated by delayed primary closure. Early primary repair is occasionally preferred for cosmetic reasons but increases the risk of wound infection. Tetanus immunization should be provided as appropriate. Antibiotic treatment should be considered for serious wounds, immunocompromised hosts, and those undergoing hot water immersion, as the elevated temperature can increase bacterial growth. The initial antibiotics should cover *Staphylococcus* and *Streptococcus* species. If the victim is immunocompromised, if a wound is primarily repaired, or if an infection develops, antibiotic coverage should be broadened to include *Vibrio* species for wounds sustained in salt water or *Aeromonas* species for wounds sustained in freshwater.

APPROACH TO THE PATIENT

Marine Envenomations

It is useful to be familiar with the local marine fauna and to recognize patterns of injury.

Coelenterate (marine invertebrate) stings sometimes create diagnostic skin patterns. A diffuse urticarial rash on exposed skin is often indicative of exposure to fragmented hydroids or larval anemones. A linear, whiplike print pattern appears where a jellyfish tentacle has contacted the skin. In the case of the box jellyfish, a crosshatched appearance, followed by development of dark purple coloration within a few hours of the sting, heralds skin necrosis. An encounter with fire coral causes immediate pain, erythema, and swelling in the pattern of contact, similar to but more severe than the imprint left by exposure to an intact feather hydroid. Seabather's eruption, caused by thimble jellyfish and larval anemones, is a diffuse, intensely pruritic rash consisting of clusters of erythematous macules or papules that follow the pattern of bathing attire (Fig. 471-8). Toxic sponges create a burning and painful red rash on exposed skin, which may blister and later desquamate. Virtually all marine stingers cause cutaneous inflammation; thus, local erythema, swelling, and adenopathy are fairly nonspecific.

A large puncture wound or jagged laceration (particularly on the lower extremity) that is more painful than one would expect from the size and configuration of the wound is likely to be a stingray envenomation. Smaller puncture wounds, sometimes associated with purple or dark discoloration, represent the activity of a sea urchin or starfish. Stony corals cause rough abrasions and, in rare instances, lacerations or puncture wounds.

SOURCES OF ANTIVENOMS AND OTHER ASSISTANCE

In the United States, assistance in locating a specific antivenom can be obtained from a regional poison control center (800-222-1222). Divers Alert Network, a nonprofit organization designed to assist in the care of injured divers, also may help with the treatment of marine injuries. The network can be reached at *www.diversalertnetwork.org* or by telephone 24 h a day at 919-684-9111. The antivenoms for box jellyfish

FIGURE 471-8 Erythematous, papular rash typical of seabather's eruption caused by thimble jellyfish and larval anemones. *(Courtesy of Paul Auerbach, with permission.)*

(*C. fleckeri*) and stonefish or severe scorpionfish envenomations are made in Australia by Seqirus (63 Poplar Road, Parkville, Victoria, Australia 3052; *www.seqirus.com.au*; 61-3-9389-2000). When administering the box jellyfish antivenom, time is of the essence. For cardiac or respiratory decompensation, a minimum of 1 ampule and up to 6 ampules consecutively should be given IV, preferably in a 1:10 dilution with normal saline. For stonefish or severe scorpionfish envenomation, 1 ampule of specific antivenom should be administered IM for every one or two punctures, to a maximum of 3 ampules.

MARINE POISONINGS

HISTAMINE (SCOMBROID) FISH POISONING

Histamine fish poisoning, most often referred to as scombroid or pseudoallergenic fish poisoning, may be the most common type of seafood poisoning worldwide. It was originally described after consumption of scombroid (mackerel-like) fish (including albacore, bluefin, and yellowfin tuna; mackerel; saury; needlefish; wahoo; skipjack; and bonito) but is now more commonly reported with consumption of nonscombroid fish (including dolphinfish, kahawai, sardine, black marlin, pilchard, anchovy, herring, amberjack, Australian ocean salmon, and bluefish).

Under conditions of inadequate preservation or refrigeration, the amino acid L-histidine in fish muscle undergoes decarboxylation to histamine, histamine phosphate, and histamine hydrochloride by *Morganella morganii*, *Escherichia coli*, *Proteus* species, and *Klebsiella* species. Histamine levels of 50–100 mg/100 g are noted in toxic fish, with levels >400 mg/100 g on occasion. Toxic levels can be reached within 12 h of inadequate refrigeration. The pathophysiology of this intoxication remains unclear, as large doses of oral histamine do not reproduce the condition. It has been proposed that other biogenic amines such as cadaverine and putrescine may inhibit the metabolism of histamine. Another potential mechanism is the induction of mast cell degranulation by an unidentified toxin. However, affected individuals may have normal levels of mast cell–derived prostaglandins, which argues against this mechanism.

Once formed, the toxin or toxins involved are heat stable and are not destroyed by cooking or freezing. Affected fish may have a sharply metallic or peppery taste, although more often they are normal in appearance, color, and flavor. Not all persons who eat a contaminated fish necessarily become ill, perhaps because of uneven distribution of decay within the fish.

Symptoms develop within 15–90 min of ingestion. Most cases are mild, with tingling of the lips and mouth, mild abdominal discomfort, and nausea. The more severe and commonly described presentation includes intense, sharply demarcated flushing of the face, neck, and upper trunk, pruritus, urticaria, and angioedema. This syndrome may progress to bronchospasm, nausea, vomiting, diarrhea, epigastric pain, abdominal cramps, dysphagia, headache, palpitations, tachycardia, dizziness, hypotension, and cardiogenic shock. Without treatment, the symptoms generally resolve within 8–12 h. Because of blockade of gastrointestinal tract histaminase, the reaction may be more severe in individuals taking isoniazid.

TREATMENT

Scombroid Poisoning

Therapy is directed at reversing the histamine effect with systemic antihistamines. In case literature, H2 receptor antagonists (e.g., cimetidine, ranitidine) appear to further decrease the severity and duration of illness when added to H1 receptor antagonists (e.g., diphenhydramine, hydroxyzine). If bronchospasm is severe, an inhaled bronchodilator (e.g., albuterol) can be used. In rare cases, parenteral epinephrine may be needed. The use of activated charcoal is not recommended. Protracted nausea and vomiting may be controlled with antiemetics (e.g., ondansetron, prochlorperazine). Hypotension should be treated with IV fluids. If multiple patients present from the same meal with similar symptoms, or if the fish itself can be tested for histamine content, the diagnosis can be essentially confirmed, and the patient can be informed this was not an allergic reaction.

CIGUATERA

Epidemiology and Pathogenesis Ciguatera poisoning is the most common nonbacterial food poisoning associated with fish in the United States and accounts for approximately half of all cases. Florida and Hawaii account for 90% of reported U.S. cases, although with transportation of imported fish worldwide, all clinicians need to be aware of ciguatera. The poisoning almost exclusively involves carnivorous, bottom-dwelling reef fish native to the Indian Ocean, the South Pacific, and the Caribbean Sea. More than 500 different fish species have been implicated in ciguatera poisoning, but the most common are barracuda, snapper, moray eel, grouper, sea bass, and Spanish mackerel. Global estimates of incidence vary widely from 20,000–500,000 cases per year; it is suspected that a large majority of cases go unreported. Ciguatoxins are produced primarily by the bottom-dwelling, photosynthetic marine dinoflagellate *Gambierdiscus toxicus*. These lipophilic toxins bioaccumulate in the marine food chain when large carnivorous fish consume the grazing fish that feed on these dinoflagellates. Ciguatoxins are heat stable and unaffected by freezing, drying, cooking, or gastric acid. The toxins do not affect the odor, taste, or appearance of the fish, making identification and prevention difficult. Ciguatoxins are potent activators of neuronal sodium channels but may also have other effects such as antagonism of voltage-gated potassium channels. Toxins are found in the highest concentrations in the fish's skin, head, and viscera; therefore, consumption of these portions should be avoided.

Clinical Manifestations Symptoms can develop within 15–30 min of ingestion but more commonly in 2–6 h. Most victims develop symptoms within 12 h of ingestion, and virtually all are afflicted within 24 h. Numerous ciguatoxins have been identified, and their relative abundance in different species of fish and geographic regions likely explains the wide array of reported symptoms **(Table 471-3)**. Early symptoms include nausea, vomiting, diarrhea, abdominal cramps, headache, and diaphoresis. Neurologic manifestations include vertigo, dysesthesia, paresthesia, visual disturbance, dysgeusia, and reversal of hot and cold temperature discrimination. Some victims describe a sensation of loose teeth. Bradycardia, hypotension, and orthostasis have also been reported. Gastrointestinal symptoms generally resolve after 24–48 h, but neurologic manifestations may persist for days to weeks. More severe reactions tend to occur on repeat exposure. Persons who have ingested parrotfish (scaritoxin) may develop classic ciguatera poisoning as well as a "second-phase" syndrome (after a delay of 5–10 days)

TABLE 471-3 Representative Symptoms and Signs of Ciguatera Poisoning

SYSTEM	SYMPTOMS/SIGNS
Gastrointestinal	Abdominal pain, nausea, vomiting, diarrhea
Neurologic	Paresthesias, pruritus, tongue and throat numbness or burning, sensation of "carbonation" during swallowing, odontalgia or dental dysesthesias, dysphagia, tremor, fasciculations, athetosis, meningismus, aphonia, ataxia, vertigo, pain and weakness in the lower extremities, visual blurring, transient blindness, hyporeflexia, seizures, coma
Dermatologic	Conjunctivitis, maculopapular rash, skin vesiculations, dermographism
Cardiovascular	Bradycardia, heart block, hypotension, central respiratory failure[a]
Other	Chills, dysuria, dyspnea, dyspareunia, fatigue, nasal congestion and dryness, insomnia, hypersalivation, diaphoresis, headache, arthralgias, myalgias

[a]Tachycardia and hypertension may occur after potentially severe transient bradycardia and hypotension. Death is rare.

of disequilibrium with ataxia, dysmetria, and resting or kinetic tremor. This syndrome may persist for 2–6 weeks.

Diagnosis Ciguatera poisoning is a clinical diagnosis. The toxin can be detected by liquid chromatography and tandem mass spectrometry, and fish suspected of contamination can be tested using a ciguatoxin-specific enzyme immunoassay, but these techniques are generally not available in most health care institutions. The differential diagnosis of ciguatera includes paralytic shellfish poisoning, eosinophilic meningitis, type E botulism, organophosphate insecticide poisoning, tetrodotoxin poisoning, and psychogenic hyperventilation.

TREATMENT

Ciguatera Poisoning

Therapy is supportive and based on symptoms. Volume losses from vomiting and diarrhea should be treated with crystalloids and electrolyte repletion. Hypotension may rarely be unresponsive to fluids and require vasopressors. Symptomatic bradyarrhythmias generally respond well to atropine (0.5 mg IV, up to 2 mg). Problematic orthostasis can be treated with direct alpha-adrenergic agonists (e.g., phenylephrine). IV infusion of mannitol may be beneficial in moderate or severe cases in fluid-replete patients; however, the efficacy of this therapy has not been definitively proven. An initial IV dose of mannitol at 1 g/kg may be given over 45–60 min. If symptoms are alleviated, a second dose may be given within 3–4 h and a third dose the next day. Care must be taken to avoid dehydration. The mechanism of the drug's benefit against ciguatera poisoning is unclear but may be due to decreased sodium conductance across neuronal cell membranes. Hyperosmotic water-drawing action is another proposed mechanism but no changes in neuronal cell edema have been observed in vitro. Amitriptyline (25 mg orally twice a day) reportedly alleviates pruritus and dysesthesias and may decrease rates of subsequent development of chronic nerve symptoms. Gabapentin and pregabalin have shown some efficacy in the treatment of long-term nerve pain in case reports, but evidence from controlled trials is lacking.

During recovery from ciguatera poisoning, the victim should exclude the following from the diet for 6 months: fish (fresh or preserved), fish sauces, shellfish, shellfish sauces, alcoholic beverages, nuts, and nut oils. Consumption of fish in ciguatera-endemic regions should be avoided.

PARALYTIC SHELLFISH POISONING

Paralytic shellfish poisoning is induced by ingestion of filter-feeding organisms, including clams, oysters, scallops, mussels, chitons, limpets, starfish, and sand crabs. The most common toxin is saxitoxin, produced by dinoflagellates in the genera *Alexandrium*, *Gonyaulax*, and *Pyrodinium*. These unicellular phytoplankton form the foundation of the food chain for many filter-feeding organisms and the toxin accumulates in their tissues. In the United States, paralytic shellfish poisoning is acquired primarily from seafood harvested in the Northeast, the Pacific Northwest, and Alaska. During algal blooms ("red tides") in the summer months, these planktonic species can release massive amounts of toxic metabolites into the water and cause mortality in bird and marine populations. The paralytic shellfish toxins are water soluble as well as heat and acid stable; ordinary cooking or freezing does not destroy them. Contaminated seafood looks, smells, and tastes normal. Saxitoxin appears to block sodium conductance, inhibiting neuromuscular transmission at the axonal and muscle membrane levels. A toxin concentration of >75 μg/100 g of foodstuff is considered hazardous to humans. During an algal bloom, the concentration of saxitoxin in shellfish can exceed 9000 μg/100 g. A mouse bioassay that identifies saxitoxin in suspected shellfish is currently in use. Saxitoxin can be detected in body fluids by high-performance liquid chromatography, but this method is generally not available in the clinical setting.

Intraoral and perioral paresthesia can occur within minutes to a few hours after ingestion of contaminated shellfish and can progress rapidly to involve the neck and distal extremities. Other neurologic symptoms can include headache, vertigo, ataxia, diffuse muscle weakness, hyperreflexia, and cranial neuropathies such as dysarthria, dysphagia, dysphonia, and transient vision loss. Gastrointestinal symptoms can include nausea, vomiting, diarrhea, and abdominal pain. Flaccid paralysis and respiratory insufficiency may follow 2–12 h after ingestion. In the absence of hypoxia, the victim often remains alert but paralyzed. Mortality rates in paralytic shellfish poisoning approach 12%.

TREATMENT

Paralytic Shellfish Poisoning

Treatment is supportive and based on symptoms. If the victim seeks medical attention within the first few hours after ingestion, activated charcoal (50–100 g) can be administered in the absence of vomiting. Gastric lavage and cathartics have been attempted but there is no evidence of benefit, and most authors recommend against their use.

The most serious concern is respiratory paralysis. The victim should be closely observed for respiratory distress for at least 24 h in a hospital. With prompt recognition of respiratory failure and establishment of ventilatory support, anoxic myocardial and brain injury may be prevented. If the patient survives for 18 h, the prognosis is good for a complete recovery.

AMNESIC SHELLFISH POISONING

Amnesic shellfish poisoning occurs when humans consume shellfish containing domoic acid. Marine diatoms of the genera *Nitzschia* and *Pseudonitzchia* produce the toxin, which can bioaccumulate in filter feeders during algal blooms. Clams, mussels, oysters, anchovies, and Dungeness crabs have all been found to cause amnesic shellfish poisoning. Domoic acid is an excitotoxic amino acid capable of binding to kainate and AMPA-type glutamate receptors in the central nervous system. Uncontrolled calcium influx into neurons stimulated by domoic acid binding causes neurodegeneration and apoptosis. The toxin is heat stable and is not affected by cooking or freezing. Shellfish can be tested for domoic acid by mouse bioassay and high-performance liquid chromatography (HPLC). The regulatory limit for domoic acid in shellfish is 20 parts per million. An enzyme-linked immunoassay has been developed to detect domoic acid in human body fluids but is generally not available in clinical laboratories.

Most victims will report symptoms within 5 h of ingesting contaminated shellfish, but delayed onset of up to 40 h has been reported. Symptoms include nausea, vomiting, diarrhea, abdominal cramps, and a variety of neurologic manifestations, such as severe headache, memory loss, seizures, hemiparesis, ophthalmoplegia, grimacing, purposeless chewing, agitation, emotional lability, and coma. Cardiac

dysrhythmias, hypotension, and pulmonary edema have also been reported. Postmortem examination of brain tissue has shown neuronal necrosis or cell loss and astrocytosis, most prominently in the hippocampus and amygdala. Several months after the primary intoxication, victims may still display chronic residual memory deficits and motor or sensory neuropathy.

TREATMENT

Amnesic Shellfish Poisoning

Therapy is supportive and based on symptoms. IV fluids and antiemetics may be used for severe nausea, vomiting, and diarrhea. Domoic acid neurotoxicity is primarily seizure mediated; anticonvulsive therapy using GABA agonists (e.g., benzodiazepines, propofol, or barbiturates) should be instituted early. However, some patients without clinically evident seizure activity have developed neurologic sequelae.

DIARRHETIC SHELLFISH POISONING

Diarrhetic shellfish poisoning occurs with consumption of shellfish containing the lipophilic compound okadaic acid. This toxin inhibits serine and threonine protein phosphatases, with consequent protein accumulation and continued secretion of fluid by intestinal cells leading to diarrhea. Shellfish acquire these toxins by feeding on dinoflagellates, particularly of the genera *Dinophysis* and *Prorocentrum*.

Symptoms include diarrhea, nausea, vomiting, abdominal pain, and chills. Onset typically occurs between 30 min and 12 h after ingestion of contaminated shellfish. The illness is usually self-limited; most patients recover in 3–4 days and only a few require hospitalization. Treatment is supportive and focused on hydration. Toxins can be detected in food samples by a mouse bioassay, an immunoassay, and fluorometric HPLC.

Acknowledgment

Kirsten B. Hornbeak, Robert L. Norris, Alex Chen, and Charles Lei contributed to this chapter in the prior edition and material from that chapter has been retained here. We would like to dedicate this chapter to the late Dr. Paul S. Auerbach, who was a contributing author for the previous seven editions of Harrison's Principles of Internal Medicine. Dr. Auerbach had a tremendous impact on the field of emergency medicine and founded the subspecialty of wilderness medicine. Dr. Auerbach was a wonderful teacher, mentor, and friend, and will be deeply missed.

472 Ectoparasite Infestations and Arthropod Injuries

Silas A. Davidson, Scott A. Norton

Ectoparasites include arthropods and creatures from other phyla that infest the skin or hair of animals; the host animals provide them with sustenance and shelter. The ectoparasites may remain on the superficial surfaces of the skin or hair, attached by mouthparts or with specialized claws. Other ectoparasites may penetrate the skin's surface and reside in the epidermis, dermis, or subcutaneous tissues. Ectoparasites may inflict direct mechanical injury, consume blood or nutrients, induce hypersensitivity reactions, inoculate toxins, transmit pathogens, create openings in the skin for secondary bacterial infection, and incite fear or disgust. Human beings are obligate hosts for few ectoparasites but can serve as facultative, dead-end, or paratenic (accidental) hosts for many others. Of the organisms discussed in this chapter, only scabies mites (the *hominis* variety) and human-infesting lice are obligate parasites of humans.

Arthropods that are capable of ectoparasitism or that can otherwise cause injury include insects (such as lice, fleas, bed bugs, wasps, ants, bees, and diverse kinds of flies), arachnids (spiders, scorpions, mites, and ticks), and myriapods (millipedes and centipedes). Several arthropods can cause uncomfortable reactions when they, their setae (hair-like growths), or their exudates come into contact with skin, mucous membranes, or ocular tissues.

Certain nematodes (helminths), such as the hookworms **(Chap. 239)**, are ectoparasitic in that they must enter the skin in some manner, then traverse the skin to reach deeper tissues, or migrate within the skin. Infrequently encountered ectoparasites in other animal phyla include pentastomes (armillifers or tongue worms) and leeches.

Arthropods may cause injury when they attempt to take a blood meal or as they defend themselves by biting, stinging, or exuding venoms. Papular urticaria and other lesions caused by arthropod bites and stings are so diverse and variable (depending on the host's health status and prior exposure to the arthropod's saliva, venom, or other exudates) that it is difficult to identify the precise causative organism with visual examination alone without a bona fide specimen and taxonomic expertise. Specimens of the presumably offending arthropod should, whenever possible, be sampled directly (taken from the patient, ideally by medical personnel) or indirectly by using traps or other monitoring devices in the patient's home or workplace. Samples sent to laboratories for identification should be properly fixed, preserved, and packaged. The patient's history of travel and precautionary behaviors; occupational, recreational, and environmental exposures; and proximity to animals often helps the clinician and parasitologist resolve the cause.

SCABIES

The human itch mite, *Sarcoptes scabiei* var. *hominis*, is an obligate human ectoparasite and a common cause of itchy dermatosis, affecting ~250 million persons worldwide. Both the mites and the skin condition are called scabies. Gravid female mites (~0.3 mm in length) burrow superficially within the stratum corneum, depositing several eggs per day. Gravid adult females emerge to the skin's surface about 8 days later, then (re)invade the skin of the same person or another host. Newly fertilized female mites are transferred between people mainly by direct skin-to-skin contact. Transmission is facilitated by crowding, poor hygiene, and close physical contact with other people. Generally, scabies mites die within a day or so if not on a suitable host. Transmission by sharing contaminated bedding or clothing occurs less frequently than commonly thought. Outbreaks are known to occur in preschools, hospitals, nursing homes, prisons, other institutional residences, and other congregate settings.

The rash and pruritus associated with scabies arise from a sensitization reaction to mites and their secretions/excretions. A person's initial infestation typically remains asymptomatic for up to 6 weeks before intense pruritus starts. Reinfestation, however, promptly induces a hypersensitivity reaction. Burrows become surrounded by inflammatory infiltrates composed of eosinophils, lymphocytes, and histiocytes. Infested individuals often feel generalized pruritus, not just in the most heavily involved areas.

Pruritus typically intensifies at night and after hot showers. Burrows appear as dark wavy lines in the upper epidermis and are 3–15 mm long **(Fig. 472-1)**. Classic burrows are often difficult to find because most patients have perhaps only 10–15 burrows. However, most burrows are obscured by excoriations or secondary bacterial infections. Scabietic lesions are most common on the volar wrists and along the digital web spaces. In males, the genitalia (penile glans and shaft and the scrotum) are nearly always involved. Small papules and vesicles, often accompanied by eczematous plaques, pustules, or nodules, appear symmetrically at those sites. The axillae and other intertriginous areas; around the navel and belt line; and the buttocks and upper thighs are also common sites. Except in infants, the face, scalp, neck, palms, and soles are usually spared.

Hyperinfestation with thousands of mites, a condition known as *crusted* scabies (formerly *Norwegian* scabies), may result from glucocorticoid use, immunodeficiency (including that due to HIV/AIDS), and neurologic or psychiatric disorders that dampen the itch or impair the scratch response. Crusted scabies often resembles psoriasis: both are characterized by widespread thick yellowish-white keratotic crusts, scaly plaques, and dystrophic nails. Characteristic burrows are not seen in crusted scabies, and patients are often not itchy, even though their infestations are highly contagious and have been responsible for outbreaks of common scabies in hospitals.

FIGURE 472-1 Scabies burrows. Scabies mites create short, delicate, linear burrows within the superficial epidermis. Although burrows are pathognomonic for scabies, most have been altered by scratching or secondary bacterial infection.

Scabies should be in the differential diagnosis for patients with pruritus and symmetric superficial, excoriated, papulovesicular skin lesions in characteristic locations, particularly if they have had direct and prolonged contact with an infested person. The diagnosis can be confirmed by microscopic examination of material scraped from burrows. Burrows should be sought and unroofed with a sterile needle or scalpel blade, and the scrapings should be examined microscopically for mites, eggs, and fecal pellets. Examination of skin scrapings; biopsy specimens; material obtained by clear cellophane tape or cyanoacrylate adhesive lifted from lesions; dermatoscopic imaging of papulovesicular lesions; and microscopic inspection of clear cellophane tape lifted from lesions also may be diagnostic. In the absence of identifiable mites or eggs, a clinical diagnosis is based on a triad of pruritus, findings on physical examination, and an epidemiologic link. Unrelated skin diseases are frequently misdiagnosed as scabies, particularly in presumed "outbreak" situations. *Sarcoptes* mites of other mammals may cause transient irritation, but they do not reside or reproduce in human hosts. In some Australian Aboriginal communities, household dogs may serve as reservoirs for human scabies mites.

TREATMENT

Scabies

The U.S. Food and Drug Administration (FDA) has approved four scabicides: permethrin, crotamiton, spinosad, and lindane. They are topical products and available by prescription only. Permethrin cream (5%) is less toxic than 1% lindane preparations and is effective against lindane-resistant infestations. In adults, scabicides are applied thinly but thoroughly from the jawline to toes after bathing, with careful application to interdigital spaces, the navel, and under the nails. and washed off 6–14 h later with soap and water. These products are relatively ineffective against scabies eggs, so a second round of treatment 1 week later is advisable.

Treating crusted scabies is difficult and requires repeated courses of both topical (permethrin) and oral (ivermectin) agents. Preapplication of a keratolytic agent, such as 6% salicylic acid, will help debulk the crusts. Permethrin should be applied to the skin's entire surface, including the scalp, face, and ears. Oral ivermectin is not FDA-approved for treating scabies but is approved to treat the nematodal diseases hookworm and strongyloidiasis. A single oral dose of ivermectin (200 μg/kg) is effective in healthy patients with common (noncrusted) scabies. Patients with crusted scabies require three to seven doses of ivermectin over 8–30 days, along with repeated applications of topical permethrin and possibly a keratolytic compound.

Within 1 day of properly administered treatment, a scabies infestation is considered noncommunicable, thereby permitting a patient to return to work, school, and other public activities. Nevertheless, remind patients that dead mites and their detritus may continue to produce the pruritic hypersensitivity dermatitis for several weeks. Unnecessary retreatment with topical agents, especially permethrin cream, may cause an irritant contact dermatitis. Topical emollients and antipruritic agents, menthol and methyl salicylate products, calamine lotion, and oral antihistamines relieve itching during treatment. Topical glucocorticoids may calm pruritus that lingers after effective treatment. To prevent reinfestations, bedding and clothing should be washed and dried on high heat or heat-pressed, and other environmental surfaces or potential sources of fomites should be cleaned. Household members and other close contacts of confirmed cases, even if asymptomatic, should be treated simultaneously to help prevent back-and-forth reinfestations.

Scabies infestations often lead to secondary bacterial infections, usually with *Staphylococcus aureus*, *Streptococcus pyogenes*, or both. Consequences of superinfections include impetigo, cellulitis, invasive bacterial infections, poststreptococcal glomerulonephritis (and subsequent kidney disease), and possibly acute rheumatic fever (and subsequent cardiac valvular disease).

CHIGGERS AND OTHER BITING MITES

Chiggers are the larvae of trombiculid (harvest) mites that feed mostly on mice and other small vertebrates in grassy or brush-covered sites in tropical, subtropical, and (less frequently) temperate areas during warm months. They reside on low vegetation and attach themselves to passing vertebrate hosts. While feeding, larvae secrete proteolytic saliva that penetrates the epidermis, creating a tube-like invagination, called a stylostome, in the host's skin. The stylostome allows the mite to imbibe tissue fluids. The saliva is highly antigenic and causes small (usually <1 cm in diameter) but exceptionally itchy papular, urticarial, or pustulovesicular lesions. In people already sensitized to salivary antigens, the papules develop within hours of attachment. While attached, chiggers appear as minute (~0.5 mm diameter) red dots on the skin. Generally, lesions have a hemorrhagic base and are slightly elevated, resembling purpuric papules seen in cutaneous small-vessel vasculitis.

Chiggers remain on their host animals for several days before falling to the ground to complete the nonparasitic stages of their life cycle. However, in humans, the intense pruritus leads to scratching that invariably destroys the chigger before it completes feeding, although the itching and burning often persist for weeks. The rash is common on the ankles and along the belt line and in areas where circumferentially tight clothing obstructs the further wanderings of the mites. Topical repellents on one's skin and insecticide-treated clothing are useful for preventing chigger bites.

Chiggers (primarily *Leptotrombidium* species) serve as vectors for intracellular rickettsial organisms in the genus *Orientia* that cause scrub typhus. Scrub typhus caused by *Orientia tsutsugamushi* was traditionally confined to the eastern half of Asia and the Indomalayan and Australasian regions. Their bites may be asymptomatic. Endemic foci of closely related *Orientia* species have recently been identified in southern Chile, East Africa, and the Arabian peninsula, where they cause scrub typhus-like illnesses. Additional areas of transmission will likely be found outside the usual endemic regions. Only larval trombiculids are predatory on mammals, and the larvae acquire their *Orientia* load from transovarial transmission from their mother mites.

Many kinds of mites feed on peridomestic birds or rodents and become particularly bothersome when they invade homes and bite people. In North America, the northern fowl mite, chicken mite, tropical rat mite, and house mouse mite normally feed on poultry, other birds, and small mammals. After their natural hosts leave the nest or die, the mites disperse and may invade homes. Although the mites are rarely seen because of their small size, their bites can be painful and pruritic. House mouse mites (*Liponyssoides sanguineus*) serve as vectors for the agent of rickettsialpox, *Rickettsia akari*, an uncommon disease characterized by mild fevers, an eschar at the bite site, and a papulovesicular eruption. Rickettsialpox **(Chap. 192)** has been recognized mainly in large northern temperate urban areas. Once these environmental mites are confirmed as causing pruritic eruptions, they are best eliminated by excluding their animal hosts, removing their nests, and cleaning and treatment of the nesting area with appropriate acaricides.

Pyemotes mites are external parasites of insect larvae and commonly occur in insect-infested products such as grain, straw, cheese, hay, and oak leaf galls. Their saliva contains a potent neurotoxin they use to immobilize their prey. The straw itch mite (*Pyemotes tritici*) occurs worldwide and is an occupational hazard for agriculture workers and others who work with dry plant material. Bites in humans are associated with pruritic rashes and may produce a unique dermatologic "comet sign" lesion—a paisley-shaped urticarial plaque **(Fig. 472-2)**. The oak leaf gall mite (*Pyemotes herfsi*) has been associated with several outbreaks of dermatosis in the central and eastern United States. These mites feed on oak gall midges and periodic cicada eggs in oak trees, and their populations fluctuate widely each year based on host availability. In the late summer and fall, mites drop or are wind-blown from oak trees and may land on a person. Bites in people are usually reported on exposed surfaces, such as neck, face, arms, and upper torso. Intense itching is reported 10–16 h after the initial bite, which most people do not recall.

Diagnosis of mite-induced dermatitis (including those caused by chiggers) relies on confirmation of the mite's identity or elicitation of a history of exposure to the mite's source. Unlike scabies mites that burrow and live in one's skin, environmental mites do not reside on humans. Therefore, treatment of the patient with acaricides (e.g., permethrin) is discouraged. Oral antihistamines or topical steroids may reduce mite-induced pruritus temporarily.

The mites that cause house dust–related allergic conditions neither bite nor infest humans.

TICK BITES AND TICK PARALYSIS

Ticks attach superficially to skin and usually feed painlessly; blood is their only food. Their salivary secretions are biologically active, preventing the host's blood from coagulating while the tick feeds. Tick saliva can transmit various pathogens and can induce several "sterile reactions" in the host, such as a local inflammatory response, fevers, and tick-bite paralysis. The two main families of ticks are the hard ticks (Ixodidae) and soft ticks (Argasidae). Because no ticks are obligate parasites on humans, all tick-borne diseases (bacterial, viral, and protozoal) are zoonotic.

Generally, soft (argasid) ticks feed quickly, attaching to a host, completing a meal in <1 h, and then dropping off the host. Because of their rapid feeding habits, soft ticks are not carried widely by their vertebrate hosts. Soft tick–associated infections usually have fairly focal distributions. On humans, red macules may develop at the bite site. Some species in Africa, the western United States, and Mexico produce painful hemorrhagic lesions.

Hard (ixodid) ticks are much more common than soft ticks, and they transmit most tick-borne infections that are familiar to physicians, patients, and the public. Hard ticks attach to the host and feed for several days to >1 week, with the exact duration depending upon the tick's species and stage of development. At the site of hard-tick bites, small areas of induration, often purpuric, develop and may be surrounded by an erythematous rim. A necrotic eschar, called a *tâche noire* ("black spot"), occasionally develops. Long-lasting dermal nodules, called persistent tick-bite granulomas, occasionally appear where the host is bitten. The nodules are roughly 1–3 cm in diameter and may linger for months after the feeding tick has fallen off or been removed. The granulomas can be treated with injected intralesional glucocorticoids, by simple local excision, or simply left to resolve on their own over perhaps a year or more. Tick-induced fever, unassociated with any pathogen, is often accompanied by headache, nausea, and malaise but usually resolves ≤36 h after the tick is removed.

Tick bites are also associated with a recently recognized allergic condition known as alpha-gal syndrome (AGS) or red meat allergy. This syndrome occurs in humans when exposure to tick saliva induces production of IgE antibodies that cross-react with a carbohydrate molecule, galactose-α-1,3-galactose (alpha-gal), found in muscle tissues of all mammals except humans, other apes, and Old World monkeys. In the United States, AGS is attributed to bites from the lone star tick (*Amblyomma americanum*). The geographic distribution of human cases closely aligns with that tick's geographic range. In Australia and Europe, AGS is associated with *Ixodes* spp., and in Asia, it is associated with *Haemaphysalis longicornis*. It is important for individuals with AGS to avoid additional tick bites as this may prolong or worsen their allergic reactions.

Tick paralysis, an acute ascending flaccid paralysis, is believed to be caused by one or more unidentified toxins in tick saliva that block neuromuscular transmission and decrease nerve conduction. This rare complication has been associated with >70 species of ticks. Although it has been reported worldwide, most cases occur in the Rocky Mountain region, in northwestern United States and southwestern Canada, and along Australia's eastern seaboard. In North America, dog and wood ticks (*Dermacentor* species) are most commonly implicated. Weakness begins several days after the tick attaches to the host. The Guillain-Barré-like paralysis starts in the lower legs and ascends symmetrically over several days. The paralysis may culminate in complete paralysis of the extremities and cranial nerves. Deep tendon reflexes are diminished or absent, but sensory examination and findings on lumbar puncture are typically normal. Diagnosis and treatment depend on finding the tick, which is often hidden beneath scalp hair. Removal

FIGURE 472-2 Comet signs in individuals with known or suspected mite-bite reactions, likely due to *Pyemotes* species. Note central punctum at bite site, surrounded by edematous erythema. Linear or serpiginous "comet tails" emanate from the central site. *Pyemotes*-induced comet tails generally do not follow typical patterns of ascending lymphatic drainage.

of the tick generally leads to improvement within a few hours and complete recovery after several days, although the patient's condition may continue to deteriorate for a full day. Failure to remove the tick may lead to dysarthria, dysphagia, and ultimately death from aspiration or respiratory paralysis.

Removal of hard ticks during the first 24 h of attachment generally prevents transmission of the agents of Lyme disease, babesiosis, anaplasmosis, and ehrlichiosis, although tick-borne viruses may be transmitted more quickly. Ticks should be removed by traction with fine-tipped forceps placed firmly around the tick's mouthparts where they enter the skin. Careful handling (to avoid rupture of ticks) and use of gloves may avert accidental contamination with pathogens contained in the tick's body fluids. Attempting to induce the tick to detach by applying heat or occlusive compounds or dressings merely delays tick removal. After removal, the site of attachment should be disinfected. Tick mouthparts sometimes remain in the skin but generally are shed spontaneously within days without the need for surgical removal. Current guidelines from the Centers for Disease Control and Prevention suggest that, rather than awaiting the onset of erythema migrans, the results of tick testing, or seroconversion to antigens diagnostic for Lyme disease, physicians may appropriately administer prophylaxis—a one-time oral dose of doxycycline (200 mg) within 72 h of tick removal—to adult patients with bites thought to be from *Ixodes scapularis* (black-legged or deer ticks) in Lyme disease–endemic areas. Whereas antibiotic prophylaxis may help prevent Lyme disease, it is not recommended as a way to prevent other tick-borne infections.

The Asian longhorned tick (*Haemaphysalis longicornis*) is a newly invasive species in the United States, first detected in the northeastern states in 2017. Although it carries several pathogens to domestic animals, wildlife, and humans in its natural range (northeastern Asia), it has not yet been implicated in disease transmission in the United States.

LOUSE INFESTATION (PEDICULOSIS AND PTHIRIASIS)

Three kinds of biting lice are obligate blood-feeding ectoparasites of human beings. These include the human head louse and the human body louse that represent distinct genetic clades of *Pediculus humanus*, and the pubic ("crab") louse (*Pthirus pubis*). Nymphs and adults of these lice feed at least once a day, ingesting human blood exclusively, and they partition ecologically on the host. Head lice infest mainly the scalp and scalp hair; body lice infest clothing; and pubic lice infest mainly pubic hair. The saliva of lice produces a pruritic morbilliform or urticarial rash in some sensitized persons. Female head lice and pubic lice cement their eggs (nits) firmly to human hair, whereas female body lice cement their eggs to clothing, particularly to threads along clothing seams. After ~10 days of development within the egg, a nymph emerges. Empty eggs may remain affixed to hair for months thereafter.

Body lice are acquired by direct contact with an infested person or their recently used clothing or bedding. These lice venture for just minutes to the skin to feed, but otherwise sequester on clothing. They generally succumb in ≤2 days if separated from their host. In developed

countries, body lice are generally uncommon, found only on indigent persons who have relevant exposure and lack the wherewithal or desire to change or appropriately launder their clothing and bedding.

Body lice are vectors for the agents of louse-borne (epidemic) typhus (Chap. 192), louse-borne relapsing fever (Chap. 190), and trench fever (Chap. 177). Body lice and their associated diseases may proliferate whenever societal upheaval and disasters limit access to clean clothes or laundry facilities. This scenario was exacerbated during the trench warfare of World War I, when troops often wore one uniform for weeks or months at a time. During damp, cold months, entrenched soldiers huddled together to stay warm, enabling body lice and their pathogens to spread easily from person to person.

Infestations result in a postinflammatory hyperpigmentation and thickening of the skin known as *vagabond's disease*. When inspecting a patient for signs of a body lice infestation, one must examine their clothing seams for nits and live lice.

Head lice are acquired mainly by direct head-to-head contact rather than via fomites such as shared hats, caps, headgear, bed linens, and grooming implements. Worldwide, the prevalence of head lice varies widely as a function of age, geography, and cultural habits. In North America, the overall prevalence of head lice infestation is generally low, but most communities, irrespective of socioeconomic circumstances, experience episodic high-prevalence focal outbreaks among younger school-aged children. Although these events generally spare adults, they can create considerable distress among families in those communities.

An infested person generally hosts 10 or fewer head lice, but the nits, even when empty or nonviable, remain cemented to one's scalp hairs as they grow. Thus, accumulated nits make it seem that a person has hundreds of head lice, even after successful treatment. Consequently, many schools retain unnecessarily onerous "no nit" policies for school attendance, even though a child has been treated successfully. Bite reactions appear as small, <1 cm diameter edematous pink wheals and are most evident along the posterior hairline. Pruritus, attributed to hypersensitivity to the louse's saliva, leads to scratching, which may lead to secondary impetigo with *S. aureus* or *S. pyogenes*.

Body lice are well known to transmit diseases, but can head lice (besides superficial secondary bacterial infections)? Several studies using polymerase chain reaction on freshly caught head lice have detected pathogenic bacteria, but clinical and epidemiologic data are generally interpreted to show that head lice are *not* natural vectors of any disease. On the other hand, experimental models suggest that head lice may have some competence as vectors for *Rickettsia prowazekii* (louse-borne typhus) and *Bartonella quintana* (trench fever). Indeed, sporadic reports indicate that cycles of trench fever are maintained in Ethiopia and elsewhere in Africa by head lice in the absence of body lice.

Crab or pubic lice are found mostly on pubic hair and are transmitted mainly by direct sexual contact. They also occur uncommonly on axillary or facial hair, including the eyelashes, as the result of either sexual or close nonsexual contact. Intensely pruritic, bluish macules <5 mm in diameter (*maculae ceruleae*) may develop at bite sites. Blepharitis commonly accompanies infestations of the eyelashes. Eyelash infestations in children should not be construed as incontrovertible evidence of inappropriate sexual contact.

Pediculosis is often suspected upon the detection of presumed nits to hairs or simply on the basis of an itchy scalp. Objects presumed to be louse eggs are often pseudo-nits composed of debris, flakes of dry skin, and hair-associated fungi. Hatched and dead eggs remain firmly affixed to scalp hair for months. Such relics are frequently misconstrued to be signs of an active louse infestation. Confirmation of a louse infestation, therefore, should rely on the discovery of a live louse.

TREATMENT

Louse Infestation

Body lice usually are eliminated by bathing and by changing to new or properly laundered clothes. Fabric is effectively deloused by heat, such as in a clothes dryer at ≥55°C (≥131°F) for 30 min or by heat-pressing. Emergency mass delousing may be warranted in congregate settings during periods of civil strife and after natural disasters to reduce the high risk of disease transmission by body lice.

Head lice and nits may be removed with a fine-toothed louse or nit comb, but this effort is time-consuming and often fails to eradicate the lice. Treatment of newly identified, active infestations traditionally relies on a 10-min topical application of a FDA-approved 1% permethrin lotion or pyrethrin-based shampoo, which are available over the counter. Also FDA-approved, but requiring a prescription, are 0.5% malathion lotion, 0.5% ivermectin lotion, and 0.9% spinosad suspension. These products do not kill viable nits, so a second application roughly 10 days later is required to clear newly hatched lice. Lice persisting after this treatment may be due to back-and-forth reinfestations within a family, or the lice may be resistant to chemical treatment. Resistance to permethrin, malathion, and lindane is well documented, with less resistance associated with ivermectin and spinosad products. Although children infested by head lice—or those who simply have remnant nits from a previous infestation—are frequently isolated or excluded from school, this practice increasingly is considered to be unjustified, ineffective, and counterproductive.

Pubic louse infestations are treated with topical pediculicides, except for eyelid infestations (*pthiriasis palpebrum*), which generally respond to a coating of petrolatum applied for 3–4 days.

MYIASIS (FLY INFESTATION)

Myiasis refers to infestations by fly larvae (maggots) that invade living or necrotic tissues or body cavities and produce different clinical syndromes, depending on the species of fly.

In forested parts of Central and South America, larvae of the human botfly (*Dermatobia hominis*) produce furuncular (boil-like) dermal and subcutaneous nodules ≤3 cm in diameter. A gravid adult female botfly captures a mosquito or another bloodsucking insect and deposits her eggs on its abdomen. When the carrier insect attacks a human or another mammalian host (often cattle) several days later, the warmth and moisture of the host's skin stimulate the eggs to hatch. The emerging larvae, ~1 mm long, promptly penetrate the skin. After 6–12 weeks of development, mature larvae emerge from the skin, drop to the ground, pupate, and finally metamorphose into adults.

The African tumbu fly (*Cordylobia anthropophaga*, also called mango fly or mputsi fly) deposits its eggs on damp sand, leaf litter, drying laundry, or damp clothing contaminated by urine or sweat. Larvae hatch from eggs upon contact with a host's body and penetrate the skin, producing boil-like lesions from which mature larvae emerge ~9–10 days later. Furuncular myiasis is suggested by uncomfortable lesions with a central breathing pore that emit bubbles when submerged in water. The sensation of movement within the patient's skin may cause severe (and understandable) emotional distress (Fig. 472-3).

Larvae that cause furuncular myiasis may be induced to emerge if the breathing pore is coated with petrolatum or another occlusive substance. Removal may be facilitated by injection of a local anesthetic (or sterile injectable saline) into the subjacent tissue to uplift the larva through the breathing pore. Surgical excision is sometimes necessary because upward-pointing spines of some species hold larvae firmly in place.

Other fly larvae cause several forms of nonfuruncular myiasis. Larvae of the horse botfly (*Gasterophilus intestinalis*) emerge from eggs that typically are laid on the hairs of a horse's front legs. Direct contact with a person's skin may cause the eggs to hatch and the new larvae to invade human skin. After penetrating human skin, these larvae rarely mature but instead may migrate for weeks in the dermis. The resulting pruritic and serpiginous eruption resembles cutaneous larva migrans caused by canine or feline hookworms (Chap. 238). Larvae of rabbit and rodent botflies (*Cuterebra* species) occasionally cause cutaneous or tracheopulmonary myiasis. Larvae of the sheep botfly, *Oestrus ovis*, and other flies responsible for furuncular and wound myiasis also may cause ophthalmomyiasis. Sequelae include nodules in the eyelid, retinal detachment, and destruction of the globe.

FIGURE 472-3 Furuncular myiasis with larva of *Cordylobia anthropophaga* in the thigh of a teenage girl who recently returned from visiting relatives in East Africa ***(left)***. The central pore shows the respiratory elements of the embedded fly larva ***(right)***.

Certain flies are attracted to blood and pus, laying their eggs on open or draining sores. Newly hatched larvae enter wounds or diseased skin. Larvae of several species of green bottle flies (*Lucilia* spp.) usually consume only necrotic tissues. Specially raised, sterile "surgical maggots" are available as FDA-approved medical devices for debridement of chronic wounds, such as deeply infected diabetic ulcers. On the other hand, larvae of screwworm flies (*Cochliomyia* spp.) and flesh flies (*Wohlfahrtia* spp.) can invade viable tissues more deeply and cause large suppurating lesions. These can be extraordinarily harmful to domesticated herd animals. Larvae of the sheep botfly, *Oestrus ovis*, may cause nasal or external ophthalmomyiasis, involving tear ducts, eyelids, and conjunctivae.

Larvae that infest decaying tissues may enter body cavities such as the mouth, nose, ears, sinuses, anus, vagina, and lower urinary tract, particularly in unconscious or otherwise debilitated patients. The consequences range from harmless colonization to destruction of the nose, meningitis, and deafness. Treatment involves removal of maggots, surgical debridement of tissue, and treatment of secondary infections.

Maggots are occasionally found in human feces, usually the result of a fly laying eggs on recently passed stools, and not as evidence of an intestinal maggot infestation.

PENTASTOMIASIS

Pentastomids (tongue worms), an obscure type of crustacean, inhabit respiratory passages of reptiles and carnivorous mammals. Human infestation by *Linguatula serrata* is common in the Middle East and results from eating encysted larval stages in raw liver or lymph nodes of sheep and goats, which are true intermediate hosts for the tongue worms. In areas where raw sheep and goat liver are served, pentastomid larvae migrate to the person's nasopharynx and produce an acute self-limiting syndrome—known as *halzoun* in Lebanon and *marrara* in Sudan—characterized by rapid onset (within <12 h) of pain and itching of the throat and ears, coughing, hoarseness, dysphagia, and dyspnea. Severe edema may cause obstruction that requires tracheostomy. In addition, ocular invasion has been described. Diagnostic larvae measuring ≤10 mm in length appear in copious nasal discharge or vomitus.

Another type of tongue worm, *Armillifer armillatus*, infects people who consume its eggs in contaminated food or drink or after handling the definitive host, the African python. Larvae encyst in various organs, usually the liver or peritoneum, but rarely cause symptoms. Cysts may require surgical removal as they enlarge during worm molting, but they usually are encountered as an incidental finding at autopsy. Parasite-induced lesions may be misinterpreted as a malignancy, with the correct diagnosis only confirmed histopathologically. Larva migrans–type syndromes caused by other pentastomes have been reported from Southeast Asia and Central America.

LEECH INFESTATIONS

Medically important leeches are annelid worms that attach to their hosts with chitinous cutting jaws and draw blood through muscular suckers. Medicinal leeches (Europe: *Hirudo medicinalis* and other *Hirudo* species; Asia: *Hirudinaria manillensis*; North America: *Macrobdella decora*) are still used occasionally for medical purposes to reduce venous congestion in surgical flaps or replanted body parts. This practice has been complicated by intractable bleeding, wound infections, myonecrosis, and sepsis due to *Aeromonas hydrophila*, which colonizes the gullets of commercially available leeches.

Ubiquitous aquatic leeches that parasitize fish, frogs, and turtles readily attach to human skin—most often the nasal mucosa—and avidly suck blood. Attachment is usually painless, and the leeches will detach themselves when satiated with a blood meal. Hirudin, a powerful anticoagulant secreted by the leech, causes continued bleeding after the leech has detached. Healing of a leech-bite wound is slow, and secondary bacterial infections are not uncommon. Several kinds of aquatic leeches in Africa, Asia, and southern Europe can enter the mouth, nose, and genitourinary tract and attach to mucosal surfaces at sites as deep as the esophagus and trachea. Leeches may detach on exposure to gargled saline or may be removed by forceps or medical suction.

Arboreal land leeches, which live amid rain forest vegetation, are attracted by heat and can drop from a leaf onto one's skin. Externally attached leeches generally drop off after they have engorged, but removal is hastened by gentle scraping aside of the anterior and posterior suckers the leech uses for attachment and feeding. Some authorities dispute the wisdom of removing leeches with alcohol, salt, vinegar, insect repellent, a flame or heated instrument, or applications of other noxious substances.

SPIDER BITES

All spiders are carnivores and most have venomous bites intended to immobilize and digest their prey. However, very few spiders are capable of biting humans, and the vast majority of putative spider bites have nothing to do with spiders. Of >45,000 recognized species of spiders, only about 60 are medically important to humans. In the United States,

only recluse spiders (*Loxosceles* spp.) and widow spiders (*Latrodectus* spp.) are considered medically important.

Most spider bites are painful but do not require medical attention. Identification of the offending spider is important because specific treatments exist. Except when the patient actually observes a spider biting them or fleeing from a site of sudden sharp pain, most acute tender noduloulcerative lesions reported as spider-bite reactions are due to an unrelated minor injury or caused by an acute bacterial infection, particularly by methicillin-resistant *S. aureus* (MRSA).

Recluse Spider Bites and Necrotic Arachnidism Brown recluse spiders (*Loxosceles reclusa*) live mainly in the southcentral United States and have close relatives in Central and South America, Africa, the Mediterranean basin, and the Middle East. Recluse spiders are not aggressive toward humans and bite only if threatened or pressed against the skin. They generally live beneath rocks and logs or in caves and animal burrows. They invade homes and seek dark and undisturbed hiding spots in closets, garages, crawl spaces, and attics; under furniture and rubbish in storage rooms; and in folds of clothing. Despite their impressive abundance in some homes, these spiders rarely bite humans. Bites tend to occur while the victim is donning clothing in which the spider has hidden itself and are sustained primarily on the hands, arms, neck, and lower abdomen.

A brown recluse spider's bite may cause minor injury with edema and erythema, and envenomation can cause severe necrosis of skin and subcutaneous tissue and, more rarely, systemic hemolysis. Initially, the bite is painless or may produce a stinging sensation. Within a few hours, the site becomes painful and sensitive to touch, with central induration surrounded by a pale ischemic zone that itself is encircled by a zone of erythema. In most cases, the lesion resolves without treatment in just a few days. In severe cases, systemics signs, such as fever, chills, weakness, headache, nausea, vomiting, myalgia, arthralgia, and leukocytosis, may soon develop. As the bite site evolves, the erythematous zone expands, and the center becomes hemorrhagic or necrotic with an overlying bulla. A black eschar forms and sloughs several weeks later, leaving an ulcer that eventually may create a depressed scar. Healing usually takes place in ≤3 months. Local complications include injury to nerves and secondary bacterial infection. Reports of deaths attributed to bites of North American brown recluse spiders have not been verified.

The Mediterranean recluse spider (*Loxosceles rufescens*) is a widely invasive species in urban areas of both the Old and New Worlds. The dorsal surfaces of *L. rufescens* and *L. reclusa* are adorned with a fiddle-shaped pattern. *L. rufescens* is warier than *L. reclusa*, is less likely to bite, and rarely causes necrosis. Misidentification of this spider may create spurious reports of *L. reclusa* activity outside the known range of that species.

TREATMENT

Recluse Spider Bites

Initial management includes rest, ice, compression, and elevation (RICE). Analgesics, antihistamines, antibiotics, and tetanus prophylaxis should be administered if indicated. Early debridement or surgical excision of the wound without closure delays healing. Routine use of antibiotics or dapsone lacks utility. Patients should be monitored closely for signs of hemolysis, renal failure, and other systemic complications.

Widow Spider Bites The southern black widow spider (*Latrodectus mactans*) is common in the southeastern United States. Female bodies are ~1 cm in length, but the leg span may be ~5 cm across. Their bodies are shiny black with a red hourglass marking on the ventral abdomen. Other dangerous *Latrodectus* species occur elsewhere in temperate and subtropical parts of the world. The bites of the female widow spiders are notorious for their potent neurotoxins.

Widow spiders spin their webs under stones, logs, plants, or rock piles and in dark spaces in barns, garages, and outhouses. Bites are most common in the summer and early autumn and occur when a web is disturbed or a spider is trapped or provoked. The initial bite is perceived as a sharp pinprick or may go unnoticed. Fang-puncture marks are uncommon. Envenomation does not cause local tissue damage, and some persons experience no further symptoms.

α-Latrotoxin, the most active component of the venom, is a neurotoxin. It binds irreversibly to presynaptic nerve terminals and causes release and eventual depletion of acetylcholine, norepinephrine, and other neurotransmitters from those terminals. Painful cramps may spread within 60 min from the bite site to large muscles of the extremities and trunk. Extreme abdominal pain and rigidity may resemble peritonitis, but the abdomen is not tender on palpation and surgery is not warranted. The pain begins to subside during the first 12 h but may recur over the next few days or weeks before resolving spontaneously. A wide range of other sequelae, largely neurologic, may include salivation, diaphoresis, vomiting, hypertension, tachycardia, labored breathing, anxiety, headache, weakness, fasciculations, paresthesia, hyperreflexia, urinary retention, uterine contractions, and premature labor. Rhabdomyolysis and renal failure have been reported, and respiratory arrest, cerebral hemorrhage, or cardiac failure may end fatally, especially in very young, elderly, or debilitated persons.

TREATMENT

Widow Spider Bites

Treatment consists of RICE and tetanus prophylaxis. Hypertension that does not respond to analgesics and antispasmodics (e.g., benzodiazepines or methocarbamol) requires specific antihypertensive medication. The efficacy and safety of antivenin made from equine immunoglobulins are controversial for black widow bites because of potential anaphylaxis or serum sickness. Antivenins made from monoclonal antibodies are in development.

Tarantulas and Other Spiders Tarantulas are large hairy spiders of which 30 species are found in the United States, mainly in the Southwest. Several species of tarantulas have become popular household pets and are usually imported from Central or South America. Tarantulas bite people only when threatened and usually cause no more harm than a bee sting, but on occasion, the venom causes deep pain and swelling. Several species of tarantulas are covered with urticating hairs that are brushed off in the thousands when a threatened spider rubs its hind legs across its dorsal abdomen. These hairs can penetrate human skin and produce pruritic papules that may persist for weeks. Failure to wear gloves or to wash the hands after handling the Chilean Rose tarantula, a popular pet spider, has resulted in transfer of hairs to the eye with subsequent devastating ocular inflammation. Treatment of bites includes local washing and elevation of the bitten area, tetanus prophylaxis, and analgesic administration. Antihistamines and topical or systemic glucocorticoids are given for exposure to urticating hairs.

Atrax robustus, a funnel-web spider of Australia, and *Phoneutria* species, the South American banana spiders, are among the world's most dangerous spiders because of their aggressive behavior and potent neurotoxins. Envenomation by *A. robustus* causes a rapidly progressive neuromotor syndrome that can be fatal within 2 h. The bite of a banana spider causes severe local pain followed by profound systemic symptoms and respiratory paralysis that can lead to death within 2–6 h. Specific antivenins for use after bites by each of these spiders are available. Yellow sac spiders (*Cheiracanthium* species) are common in homes worldwide. Their bites, though painful, generally lead to only minor erythema, edema, and pruritus.

SCORPION STINGS

Scorpions are arachnids that feed on arthropods and other small animals. They paralyze their prey and defend themselves by injecting venom from a stinger on the tip of the tail. Painful but relatively harmless scorpion stings need to be distinguished from the potentially lethal envenomations from about 30 of roughly 1000 known species, which cause several thousand deaths worldwide each year. Scorpions are nocturnal and remain hidden during the day in crevices or burrows

or under wood, loose bark, or rocks. They occasionally enter houses and tents and may hide in shoes, clothing, or bedding. Scorpions sting humans only when threatened.

Of approximately 40 scorpion species in the United States, only bark scorpions (*Centruroides sculpturatus*/*C. exilicauda*) in the Southwest produce venom that is potentially lethal to humans. This venom contains neurotoxins that cause sodium channels to remain open. Such envenomations usually are associated with little swelling, but prominent pain, paresthesia, and hyperesthesia can be accentuated by tapping on the affected area (the *tap test*). These symptoms soon spread to other locations; dysfunction of cranial nerves and hyperexcitability of skeletal muscles develop within hours. Patients present with restlessness, blurred vision, abnormal eye movements, profuse salivation, lacrimation, rhinorrhea, slurred speech, difficulty in handling secretions, diaphoresis, nausea, and vomiting. Muscle twitching, jerking, and shaking may be mistaken for a seizure. Complications include tachycardia, arrhythmias, hypertension, hyperthermia, rhabdomyolysis, and acidosis. Symptoms progress to maximal severity in ~5 h and subside within a day or two, although pain and paresthesia can last for weeks. Fatal respiratory arrest is most common among young children and the elderly.

Envenomations by *Leiurus quinquestriatus* in the Middle East and North Africa, by *Mesobuthus tamulus* in India, by *Androctonus* species along the Mediterranean littoral and in North Africa and the Middle East, and by *Tityus serrulatus* in Brazil cause massive release of endogenous catecholamines with hypertensive crises, arrhythmias, pulmonary edema, and myocardial damage. Acute pancreatitis occurs with stings of *Tityus trinitatis* in Trinidad, and central nervous toxicity complicates stings of *Parabuthus* and *Buthotus* scorpions of South Africa.

In Iran and adjacent countries, *Hemiscorpius lepturus* causes the most scorpion envenomations. Its stings are relatively asymptomatic at first, but its cytotoxic venom causes pain, hemolysis, and tissue necrosis after the first day. Systemic complications include hemoglobinuria and subsequent acute kidney injury.

Stings of most other species cause immediate sharp local pain followed by edema, ecchymosis, and a burning sensation. Symptoms typically resolve within a few hours, and skin does not slough. Allergic reactions to the venom may occur.

TREATMENT

Scorpion Stings

Identification of the offending scorpion helps to determine the course of treatment. Stings of nonlethal species require at most ice packs, analgesics, or antihistamines. Because most victims experience only local discomfort, they can be managed at home with instructions to return to the emergency department if signs of cranial-nerve or neuromuscular dysfunction develop. Aggressive supportive care and judicious use of antivenom can reduce or eliminate deaths from more severe envenomations. Keeping the patient calm and applying pressure dressings and cold packs to the sting site are measures that decrease the absorption of venom. A continuous IV infusion of midazolam reduces the agitation and involuntary movements produced by scorpion stings. Treating people with neuromuscular symptoms with sedatives or opiates requires close monitoring due to potential respiratory compromise. Hypertension and pulmonary edema respond to nifedipine, nitroprusside, hydralazine, or prazosin. Dangerous bradydysrhythmia can be controlled with atropine.

Commercially prepared antivenins are available in several countries for some of the most dangerous scorpion species. The FDA has approved equine-derived *C. sculpturatus* IgG $F(ab')_2$ antivenin. IV administration of antivenin rapidly reverses cranial-nerve dysfunction and muscular symptoms.

HYMENOPTERA STINGS

Bees, wasps, hornets, yellow jackets, and ants (all of the insect order Hymenoptera) sting in defense or to subdue their prey. Their venoms contain a wide array of amines, peptides, and enzymes that cause local and systemic reactions. Although the toxic effect of multiple stings can be fatal to a human, nearly all of the ≥100 deaths due to hymenopteran stings in the United States each year result from type 1, immediate-type allergic reactions.

Bee and Wasp Stings The stinger of the honeybee (*Apis mellifera*) is unique in being barbed. The stinging apparatus and attached venom sac tear loose from the honeybee's body, and muscular contractions of the venom sac continue to infuse venom into the skin. Other kinds of bees, ants, and wasps have smooth stinging mechanisms and can sting numerous times in succession. Generally, a person sustains just one sting from a bee or social wasp unless a nest was disturbed. Africanized honeybees (now present in South and Central America and the southern and western United States) respond to minimal intrusions more aggressively. The sting of an Africanized bee contains less venom than that of its non-Africanized relatives, but victims tend to sustain far more stings and thus receive a far greater overall volume of venom. Most patients who report having sustained a "bee sting" are more likely to have encountered stinging wasps instead.

The venoms of different kinds of hymenopterans are biochemically and immunologically distinct. Direct toxic effects are mediated by mixtures of low-molecular-weight compounds such as serotonin, histamine, acetylcholine, and several kinins. Polypeptide toxins in honeybee venom include mellitin, which damages cell membranes; mast cell–degranulating protein, which causes histamine release; the neurotoxin apamin; and the anti-inflammatory compound adolapin. Enzymes in venom include hyaluronidase and phospholipases. There appears to be little cross-sensitization between the venoms of honeybees and wasps.

Uncomplicated hymenopteran stings cause immediate pain, a wheal-and-flare reaction, and local edema, all of which usually subside in a few hours. Multiple stings can lead to vomiting, diarrhea, generalized edema, dyspnea, hypotension, and nonanaphylactic circulatory collapse. Rhabdomyolysis and intravascular hemolysis may cause renal failure. Death from the direct (nonallergic) effects of venom has followed stings of several hundred honeybees. Stings to the tongue or mouth may induce life-threatening edema of the upper airways.

Large local reactions accompanied by erythema, edema, warmth, and tenderness that spread ≥10 cm around the sting site over 1–2 days are not uncommon. These reactions may resemble bacterial cellulitis but are caused by hypersensitivity rather than by secondary infection. Such reactions tend to recur on subsequent exposure but are seldom accompanied by anaphylaxis and are not prevented by venom immunotherapy.

An estimated 0.4–4.0% of the U.S. population exhibits clinical immediate-type hypersensitivity to hymenopteran stings, and 15% may have asymptomatic sensitization manifested by positive skin tests. Persons who experience severe allergic reactions are likely to have similar or more severe reactions after subsequent stings by the same or closely related species. Mild anaphylactic reactions to insect stings, as to other causes, consist of nausea, abdominal cramping, generalized urticaria or angioedema, and flushing. Serious reactions, including upper airway edema, bronchospasm, hypotension, and shock, may be rapidly fatal. Severe reactions usually begin within 10 min of the sting and only rarely develop after 5 h.

TREATMENT

Bee and Wasp Stings

Honeybee stingers embedded in the skin should be removed as soon as possible to limit the quantity of venom delivered. The stinger and venom sac may be scraped off with a blade, a fingernail, or the edge of a credit card or may be removed with forceps. The site should be cleansed and disinfected and ice packs applied to slow the spread of venom. Elevation of the affected site and administration of oral analgesics, oral antihistamines, and topical calamine lotion help relieve symptoms.

Anaphylactic reactions to bee or wasp venom can be a life-threatening emergency that requires prompt life-saving actions.

If the individual carries a bee-sting kit, then a subcutaneous injection of epinephrine hydrochloride (0.3 mL of a 1:1000 dilution) should be considered, with treatment repeated every 20–30 min as necessary. A tourniquet may slow the spread of venom. The patient should be transferred to a hospital emergency room where treatment for profound shock, if required, can be administered safely. Such treatment may entail the use of IV epinephrine and other vasopressors, intubation or provision of supplemental oxygen, fluid resuscitation, use of bronchodilators, and parenteral administration of antihistamines. Patients should be observed for 24 h for recurrent anaphylaxis, renal failure, or coagulopathy.

Persons with a history of allergy to insect stings should carry an anaphylaxis kit with a preloaded syringe containing epinephrine for self-administration. These patients should seek medical attention immediately after using the kit.

Prophylactic immunotherapy may greatly reduce the risk of life-threatening reactions to bee and wasp stings. Repeated injections of purified venom produce a blocking IgG antibody response to venom and reduce the incidence of recurrent anaphylaxis. Honeybee, wasp, and yellow jacket venoms are commercially available for desensitization and for skin testing. Results of skin tests and venom-specific radioallergosorbent tests (RASTs) aid in the selection of patients for immunotherapy and guide the design of such treatment.

STINGING ANTS

Stinging ants are an important medical problem in the United States. Imported fire ants (*Solenopsis* species) infest southern states from Texas to North Carolina, with colonies now established in California, New Mexico, Arizona, and Virginia. Slight disturbances of their mound nests have provoked massive outpourings of ants and as many as 10,000 stings on a single person. Elderly and immobile persons are at high risk for attacks when fire ants invade dwellings.

Fire ants attach to skin with powerful mandibles and rotate their bodies while repeatedly injecting venom with posteriorly situated stingers. The alkaloid venom consists of cytotoxic and hemolytic piperidines and several proteins with enzymatic activity. The initial wheal-and-flare reaction, burning, and itching resolve in ~30 min, and a sterile pustule develops within 24 h. The pustule ulcerates over the next 48 h and then heals in ≥1 week. Large areas of erythema and edema lasting several days are not uncommon and, in extreme cases, may compress nerves and blood vessels. Anaphylaxis occurs in <2% of victims; seizures and mononeuritis have been reported. Stings are treated with ice packs, topical glucocorticoids, and oral antihistamines. Pustules should be cleansed and then covered with bandages and antibiotic ointment to prevent bacterial infection. Epinephrine administration and supportive measures are indicated for anaphylactic reactions. Fire ant whole-body extracts are available for skin testing and immunotherapy, which appear to lower the rate of anaphylactic reactions.

European fire (red) ants (*Myrmica rubra*) have recently become public health pests in the northeastern United States and southern Canada. The western United States is home to harvester ants (*Pogonomyrmex* species). The painful local reaction that follows harvester ant stings often extends to lymph nodes and may be accompanied by anaphylaxis. The bullet or conga ant (*Paraponera clavata*) of South America is known locally as *hormiga veinticuatro* ("24-hour ant"), a designation that refers to the 24 h of throbbing, excruciating pain following a sting that delivers the potent paralyzing neurotoxin poneratoxin.

DIPTERAN (FLY AND MOSQUITO) BITES

In the process of feeding on vertebrate blood and tissue fluids, adults of certain fly species inflict painful bites, inject saliva that may cause vasodilation and produce local allergic reactions, and may transmit diverse pathogenic agents. Bites of mosquitoes (culicids), tiny "no-see-um" midges (ceratopogonids), and sand flies (phlebotomines) typically produce a wheal and a pruritic papule. Small humpbacked black flies (simuliids) lacerate skin, resulting in a lesion with serosanguineous discharge that is often painful and pruritic. Regional lymphadenopathy, fever, or anaphylaxis occasionally ensues. The widely distributed deerflies and horseflies as well as the tsetse flies of Africa are stout flies that attack during the day and produce large and painful bleeding punctures. House flies (*Musca domestica*) do not consume blood but use rasping mouthparts to scarify skin and feed upon tissue fluids and salt. Beyond direct injury from bites of any kind of fly, risks include transmission of diverse pathogens and secondary bacterial infection of the lesion.

TREATMENT

Fly and Mosquito Bites

Treatment of fly bites is symptom based. Topical application of antipruritic agents, glucocorticoids, or antiseptic lotions may relieve itching and pain. Allergic reactions may require oral antihistamines. Antibiotics may be necessary for the treatment of large bite wounds that become secondarily infected.

FLEA BITES

Common human-biting fleas include the dog and cat fleas (*Ctenocephalides* species) and the rat flea (*Xenopsylla cheopis*), which infest their respective hosts and their nests and resting sites. Sensitized persons develop erythematous pruritic papules (*papular urticaria*) and occasionally vesicles and bacterial superinfection at the site of the bite. Symptom-based treatment consists of antihistamines, topical glucocorticoids, and topical antipruritic agents.

Flea infestations are eliminated by removal and treatment of animal nests, frequent cleaning of pet bedding, and application of contact and systemic insecticides to pets and the dwelling. Flea infestations in the home may be abated or prevented if pets are regularly treated with veterinary antiparasitic agents, insect growth regulators, or chitin inhibitors.

Tunga penetrans, like other fleas, is a wingless, laterally flattened insect that feeds on blood. Also known as the chigoe flea, sand flea, or jigger (not to be confused with the chigger), it occurs in tropical regions of Africa and the Americas. Adult female chigoes live in sandy soil and burrow under the skin, usually between toes, under nails, or on the soles of bare feet. Gravid chigoes engorge on the host's blood and grow from pinpoint to pea size during a 2-week interval. They produce lesions that resemble a white pustule with a central black depression and that may be pruritic or painful. Occasional complications include tetanus, bacterial infections, and autoamputation of toes (*ainhum*). Tungiasis is treated by removal of the intact flea with a sterile needle or scalpel, tetanus vaccination, and topical application of antibiotics.

HEMIPTERAN/HETEROPTERAN (TRUE BUG) BITES

Most true bugs feed on plants, but some are predaceous or feed on blood. In order to feed or to defend themselves, they may inflict bites that produce allergic reactions and are sometimes painful. Bites of the cone-nose or "kissing bugs" (family Reduviidae) tend to occur at night and are painless. Reactions to such bites depend on prior sensitization and include tender and pruritic papules, vesicular or bullous lesions, extensive urticaria, fever, lymphadenopathy, and (rarely) anaphylaxis. Bug bites are treated with topical antipruritic agents or oral antihistamines. Persons with anaphylactic reactions to reduviid bites should keep an epinephrine kit available. Some reduviids transmit *Trypanosoma cruzi*, the agent of New World trypanosomiasis (Chagas disease) (Chap. 234).

The cosmopolitan and tropical bed bugs (*Cimex lectularius* and *C. hemipterus*) hide in crevices of mattresses, bed frames and other furniture, walls, and picture frames and under loose wallpaper, actively seeking blood meals at night. These bugs are now a common pest in homes, dormitories, and hotels; on cruise ships; and even in medical facilities. Their bite is painless. Bites on persons without prior exposure to bedbugs may not be noticeable. Persons sensitized to bed bug saliva develop erythema, itching, and wheals around a central hemorrhagic punctum. Reactions may manifest within minutes of the bites, or they

may be delayed for days or even a week or more. Bed bugs are not known to transmit pathogens.

CENTIPEDE BITES AND MILLIPEDE DERMATITIS

Two groups of myriapods ("many-footed" arthropods) can harm humans. Centipedes, with one pair of legs per body segment, are fast-moving, aggressive, and carnivorous. They stun and kill their prey—usually other arthropods, earthworms, and rarely small vertebrates—with a venomous bite. The fangs of centipedes of the genus *Scolopendra* can penetrate human skin and deliver a venom that produces intense burning pain, swelling, erythema, and sterile lymphangitis. Dizziness, nausea, and anxiety are described occasionally, and rhabdomyolysis and renal failure have been reported. Treatment includes washing of the site, application of cold dressings, oral analgesic administration or local lidocaine infiltration, and tetanus prophylaxis.

Millipedes, with two pairs of legs per segment, are slow-moving, docile, and feed mostly on decaying plant materials. They do not bite, but some secrete defensive fluids that may burn and discolor human skin. Affected skin turns brown overnight and may blister and exfoliate. Secretions in the eye cause intense pain and inflammation that can result in corneal ulcers and even blindness. Management includes irrigation with copious amounts of water or saline, use of analgesics, and local care of denuded skin.

CATERPILLAR STINGS AND DERMATITIS

Caterpillars of several moth species are covered with hairs or spines that produce mechanical irritation and may contain or be coated with venom. Contact with these caterpillars or their hairs may lead to erucism (a pruritic urticarial or papular rash) or caterpillar envenomation. The response typically consists of an immediate burning sensation followed by local swelling and erythema and occasionally by regional lymphadenopathy, nausea, vomiting, and headache. A rare reaction to a South American caterpillar, *Lonomia obliqua*, can cause disseminated coagulopathy and fatal hemorrhagic shock.

Dermatitis is most often associated with caterpillars of io, puss, saddleback, and browntail moths in North America and with the oak processionary moth in Europe. Even contact with detached hairs of other caterpillars, such as gypsy moth larvae, can later produce erucism. Spines may be deposited on tree trunks or drying laundry or may be airborne and cause irritation of the eyes and upper airways. Treatment of caterpillar stings consists of repeated application of adhesive or cellophane tape to remove the hairs, which can then be identified microscopically. Local ice packs, topical glucocorticoids, and oral antihistamines relieve symptoms.

Few adult moths cause human health problems. Adult yellowtail moths (*Hylesia* species), found mainly in coastal mangrove zones along the eastern coast of Central and South America, have bodies that are covered by fine hairs or setae. The hairs on the ventral surface can detach and, when in contact with human skin, cause an extremely pruritic reaction called "Carapito itch." This issue is especially problematic when the moths have population booms, creating swarms around coastal communities.

BEETLE VESICATION AND DERMATITIS

Several families of beetles have independently developed the ability to produce chemically unrelated vesicating toxins. When disturbed, blister beetles (family Meloidae) exude cantharidin, a low-molecular-weight toxin that produces thin-walled blisters (≤5 cm in diameter) 2–5 h after contact. The blisters are not painful or pruritic unless broken. They resolve without treatment in ≤10 days. Nephritis may follow unusually heavy cantharidin exposure.

The hemolymph of certain rove beetles (*Paederus* species, Staphylinidae family) contains pederin, a potent vesicant. When these beetles are crushed or brushed against the skin, the released fluid causes painful, red, flaccid bullae. These beetles occur worldwide but are most numerous and problematic in parts of Africa (where they are called "Nairobi fly") and southwestern Asia. Ocular lesions may develop after impact with flying beetles at night or unintentional transfer of the vesicant on the fingers. Treatment is rarely necessary, although ruptured blisters should be kept clean and bandaged.

Larvae of common carpet beetles are adorned with dense arrays of ornate hairs called *hastisetae*. Contact with these larvae or their setae results in delayed dermal reactions in sensitized individuals. The lesions are commonly mistaken for bites of bed bugs.

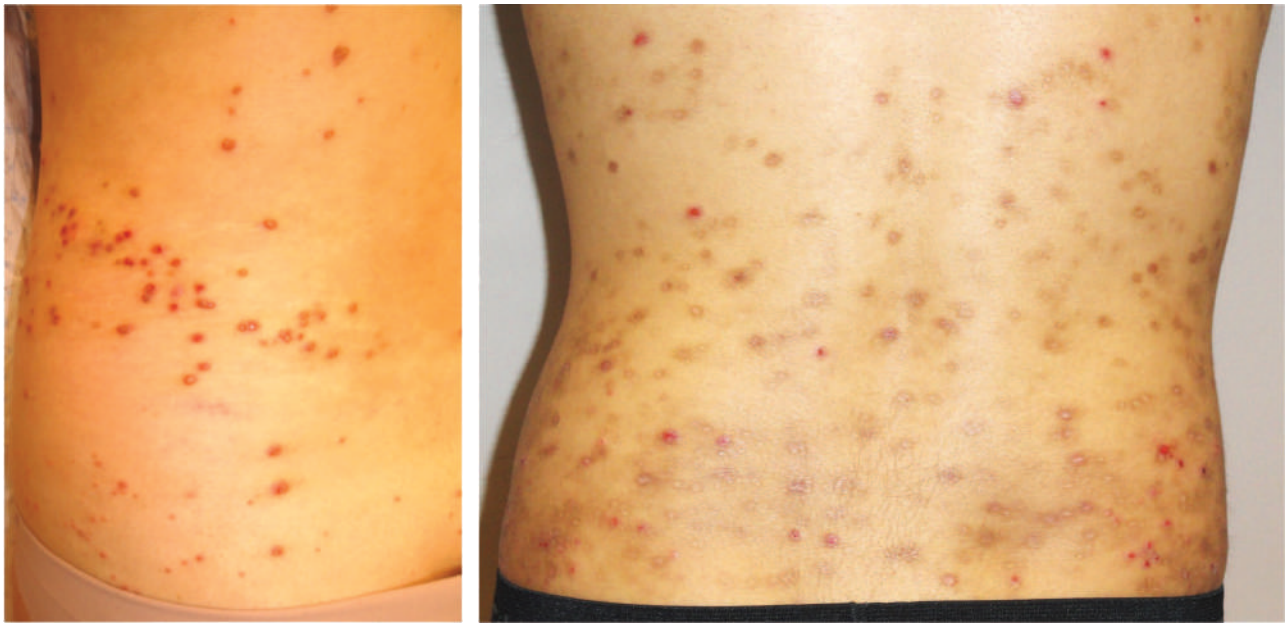

FIGURE 472-4 Real (*left*) versus delusional (*right*) infestation: comparable images of the lower backs of two young adults with multiple lesions. ***Left:*** A young woman developed innumerable widespread lesions during a camping ecotour near Manaus, Brazil. Note scattered clusters of irregularly spaced lesions, accompanied by dozens of single or isolated lesions, consistent with the semi-random feeding pattern of biting flies. Lesions appear to be in roughly the same stage of development, a feature indicating that they were acquired at roughly the same time. No lesions were present before her ecotour; none have arisen since. This patient scratches the intensely pruritic lesions and causes superficial erosions. Unexcoriated lesions are also present on her midback, where she cannot scratch. ***Right:*** A young man has innumerable widespread lesions that have accumulated for several years, with a few new lesions appearing several times a week. His lesions are in various stages of development (fresh, crusted, reepithelialized, pigmented, and scarred), a feature indicating a long-standing process. The lesions are distributed in a regular pattern consistent with periodic "excavations" to remove alleged parasites that he believes are crawling through his skin. Scarring is due to manipulations that create dermal ulcers rather than superficial excoriations and erosions. Parts of his upper midback, where he cannot scratch, are free of lesions.

DELUSIONAL INFESTATIONS

The groundless conviction that one is infested with arthropods or other parasites (Ekbom syndrome, delusory parasitosis, delusions of parasitosis, delusion of infestation, and perhaps Morgellons syndrome) is extremely difficult to treat and, unfortunately, is not uncommon **(Fig. 472-4)**. Patients describe uncomfortable sensations of something moving in or on their skin. Excoriations and self-induced ulcerations typically accompany the pruritus, dysesthesias, and imaginary insect bites. Patients often believe that some invisible or as-yet-undescribed creatures are infesting their skin, clothing, homes, or environment in general. Frequently, patients submit as evidence of infestation specimens that consist of plant-feeding and nonbiting peridomestic arthropods, pieces of skin, vegetable matter, lint, and other inanimate detritus. In the evaluation of a patient with possible delusional parasitosis, it is imperative to rule out true infestations and bites by arthropods, endocrinopathies, sensory disorders due to neuropathies, opiate and other drug use, environmental irritants (e.g., fiberglass threads), and other causes of tingling or prickling sensations. Frequently, such patients repeatedly seek medical consultations, resist alternative explanations for their symptoms, and exacerbate their discomfort by self-treatment. Recent evidence suggests that high levels of central nervous system dopamine, endogenous or pharmaceutical, may promote these delusions. Long-term pharmacotherapy with pimozide or other psychotropic agents has been more helpful than psychotherapy in treating this disorder. Patients with delusory parasitosis often develop the unshakeable conviction that they are infested by a previously unknown pathogen, while their personal lives, family support, and employment collapse around them.

473 Health Effects of Climate Change

Eugene Richardson, Maxine A. Burkett

Climate change refers to the effects of accumulated greenhouse gases (GHGs) in the atmosphere on long-term weather patterns. Anthropogenic emissions—in particular from the burning of fossil fuels and land conversion—have increased mean global temperatures by approximately 1.1° Celsius above preindustrial levels. Extreme weather events, including heatwaves and 'natural disasters' (e.g., wildfires, droughts, and floods) are becoming more frequent and lead to resource scarcity (including access to safe drinking water and food), increased environmental pollution and degradation, violent conflict, and precarious migration. The climate crisis thus has direct consequences for human health **(Fig. 473-1)**, the practice of medicine, and the stability of health care systems and as such represents a health emergency. **See Chap. 474 for an overview of climate science.**

EFFECTS OF CLIMATE CHANGE ON HEALTH

The World Health Organization predicts that between 2030 and 2050, there will be an additional 250,000 deaths from undernutrition, malaria, diarrhea, and heat stress alone **(Chap. 474)**. As with much of the global burden of disease, this increase in mortality will be disproportionately borne by low- and middle-income countries (LMICs) whose health infrastructures have been weakened by neocolonialism and structural adjustment. Within wealthier countries such as the United States, climate change will amplify existing health disparities between white people and black, Indigenous, and Latinx populations.

AIR POLLUTION AND SYNERGISTIC EFFECTS

Asthma and Other Respiratory Ailments Climate change exacerbates the negative health effects of harmful air pollutants (e.g., particulate matter, ozone, sulfur dioxide, and nitrogen dioxide). While increases in fine particulate matter (<2.5 microns—$PM_{2.5}$) are a function of wildfires and the burning of fossil fuels, the latter is the predominate driver of anthropogenic climate change. Exposure to ambient air pollution and/or indoor air pollution is estimated to cause 7 million premature deaths worldwide per year, making it the largest global environmental risk factor for reversible death and disability (see **Chap. 300** for an overview). Notably, air pollution from coal-burning power plants is associated with double the mortality risk when compared with other sources of $PM_{2.5}$.

By increasing ground-level ozone and/or particulate matter concentrations in some regions, the higher temperatures associated with climate change will directly increase the global burden and severity of asthma **(Chap. 298)**, the respiratory effects of allergies **(Chap. 363)**, rhinosinusitis, chronic obstructive pulmonary disease (COPD), respiratory tract infections, interstitial lung disease, and lung cancer, resulting in increased hospital admissions and premature death. **Figure 473-2** illustrates potential pathophysiologic mechanisms by which this may occur.

Cardiovascular Disease Cardiovascular (CV) complications of climate change share similar mechanisms with climate-sensitive respiratory disease. Concentrations of $PM_{2.5}$ are the most important environmental risk factor for myocardial infarction, cerebrovascular disease, heart failure, hypertension, diabetes mellitus, arrhythmias, and venous thromboembolism.

Studies have shown that the relative risk of acute CV events is increased 1–3% in the setting of short-term elevations of $PM_{2.5}$. Longer-term exposures convey an amplified risk (~10%), which is partially attributable to the exacerbation of chronic conditions (e.g., hypertension and diabetes). This holds true for areas with low mean

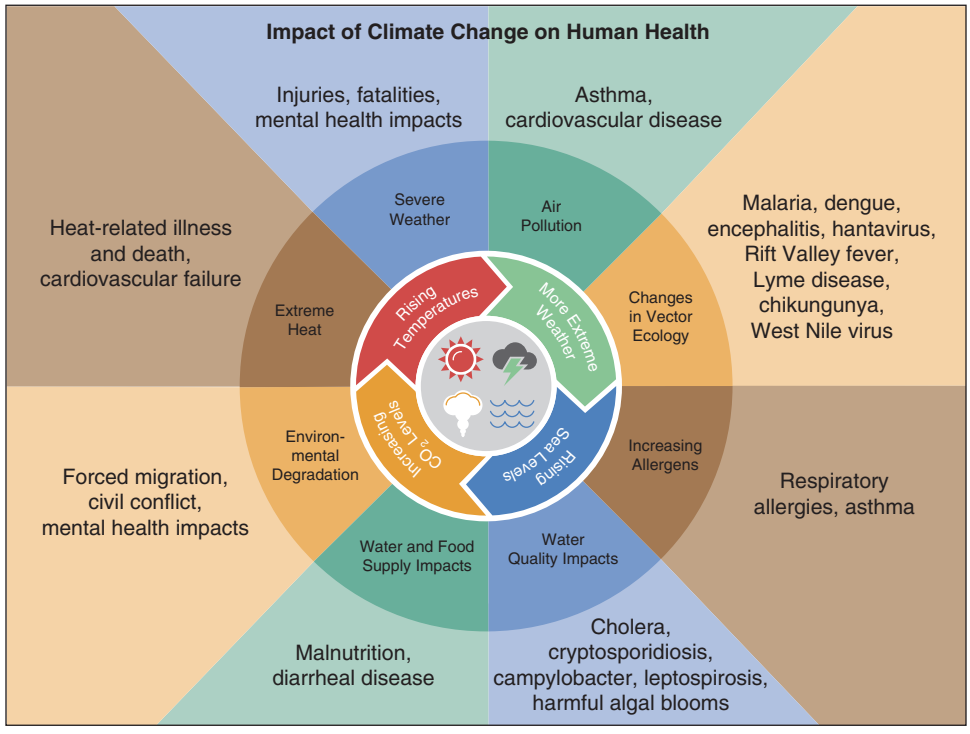

FIGURE 473-1 Climate change impacts a wide range of health outcomes. This figure illustrates the most significant climate change impacts (rising temperatures, more extreme weather, rising sea levels, and increasing carbon dioxide levels), their effect on exposures, and the subsequent health outcomes that can result from these changes in exposures. *(Source: https://www.cdc.gov/climateandhealth/effects/default.htm.)*

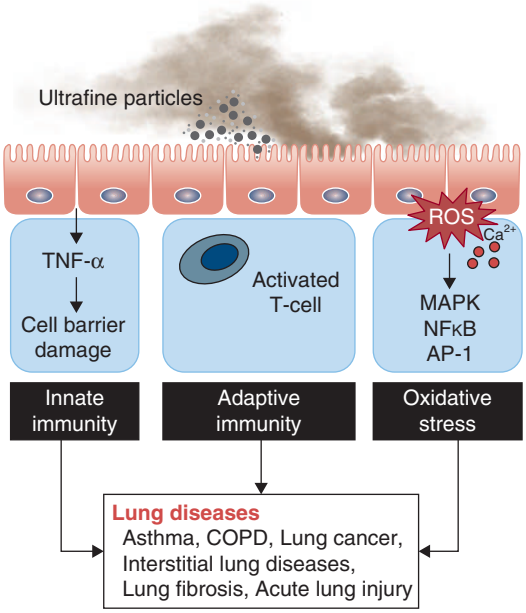

FIGURE 473-2 Mechanisms of ultrafine particle–induced respiratory health effects. *(Reproduced from GD Leikauf et al: Mechanisms of ultrafine particle-induced respiratory health effects. Exp Mol Med 52:329, 2020.)*

concentrations of $PM_{2.5}$ (i.e., where risk is determined by recurring short-term elevations). The biologic pathways whereby $PM_{2.5}$ promotes these complications are complex and multifactorial **(Fig. 473-3)**.

For clinicians, there are subtle management strategies to bear in mind for climate-sensitive CV disease. For example, in new heart failure patients, prescribers should be judicious about starting diuretics (especially diuretic-angiotensin–converting enzyme [ACE] inhibitor combinations) before the summer months or in areas with increased heatwaves in order to avoid exacerbating dehydration or heat-related illness. These patients may also benefit from increasing potassium uptake. **Figure 473-4** presents personal- and local-level interventions to reduce climate-sensitive disease associated with air pollution.

Pregnancy Women exposed to high temperatures and air pollution may be more likely to experience serious adverse pregnancy outcomes. A systematic review of studies across diverse U.S. populations found a statistically significant association of $PM_{2.5}$, ozone, and heat exposure with preterm birth, low birth weight at term, and stillbirth. As these environmental exposures become more common with climate change, an increased incidence of these complications is likely.

Potential pathophysiologic mechanisms for these outcomes are multifactorial: preterm birth may result from hematogenous transport of inhaled $PM_{2.5}$ and varied noxious chemicals and subsequent systemic inflammation or perturbation of the autonomic nervous system; low birth weight could be caused by the cumulative effect of alterations in maternal cardiac, pulmonary, and renal function, placental inflammation, and direct exposure to oxidative stress; and stillbirth may involve derangements in oxygen transport, DNA damage, and direct placental injury. Extreme heat events may lead to adverse pregnancy outcomes through dehydration and subsequent alterations in thermoregulation, blood viscosity, uterine blood flow, placental-fetal exchange, amniotic fluid volume, and hormone release (e.g., prostaglandin or oxytocin).

These risks are disproportionately borne by black mothers. Thus, failure to reduce air pollution to the World Health Organization guideline level of 10 $\mu g/m^3$ compounds structural racism.

HEAT-RELATED ILLNESSES

Renal Disease Various populations of agricultural workers who labor in hot climates around the world have been noted to suffer from chronic kidney disease (CKD), even those without common risk factors such as diabetes mellitus, hypertension, glomerular disease, or HIV. Although the cause has not been identified, potential mechanisms include genetic polymorphisms, nephrotoxicity secondary to agrochemicals or heavy metals, and heat-associated injury **(Fig. 473-5)**.

Heat Exhaustion and Heatstroke Please see **Chap. 478** for an overview of heat-related illnesses. These include heat cramps, heat exhaustion, and heatstroke and can be expected to increase in incidence as temperatures rise. Certain communities suffer from significant peaks in average temperature resulting from the urban heat island effect, which in the United States is related to policies such as redlining, racial covenants, and strategic underinvestment in neighborhoods segregated through such policies. Possible preventive measures include developing clear heatwave strategies and establishing early warning systems, mapping vulnerable populations, enhancing green space, and providing cool-down zones. It is important that clinicians provide guidance about heat-related illnesses prior to the start of summer because waiting for heat warnings will not obviate risk. Medication storage is an issue, especially for those that are carried by patients (e.g., epinephrine injections, naloxone, insulin). There are some data to suggest that exposure to extreme heat (e.g., leaving an albuterol inhaler in a vehicle on a hot day) can impair delivery mechanisms, degrade active ingredients of the medication, or cause inhalers to explode.

NATURAL DISASTERS, COASTAL FLOODING, AND DISPLACEMENT

Injury and Trauma While models predict fewer cyclones and hurricanes in a warmer late-twenty-first-century climate, they do forecast events of higher average intensity, precipitation, and the number and occurrence days of very intense category 4 and 5 storms **(Fig. 473-6)**. Such natural disasters would be expected to result in injuries and trauma seen in contemporary storms of high intensity (albeit with higher frequency), but there are other ways climate change will affect the incidence of physical trauma.

Studies have shown associations between anomalously warm temperatures and increased deaths from drownings (from people swimming longer and more frequently), transportation accidents (driving performance worsens at higher temperatures and traffic increases), and assaults (potentially from increased alcohol consumption and illicit drug use). These deaths were partly offset by decreased falls, especially among the elderly, in warmer years.

In addition, as more than half the world's population lives within 60 km of the ocean, rising sea levels will destroy homes, medical infrastructure, and other essential services, including sewage treatment systems and drinking water supplies. In concert with climate impacts such as extreme heat and lack of freshwater, subsequent displacement and migration will lead to increased mental illness, food insecurity, and communicable disease.

Finally, extreme sudden-onset events can affect the availability of medications through medical supply chain disruptions. Loss of electricity during intense storms can also compromise vaccination programs and the availability of needed medications. For example, in 2024, Hurricane Helene interrupted the production of essential parenteral drug products and intravenous (IV) fluids manufactured in North Carolina, resulting in nationwide shortages in the United States. Providers should ensure that patients with electricity-dependent medical devices have a reasonable contingency plan in case of power outages while noting that climate-related displacements can interrupt patients' access to medications for chronic diseases and limit access to clinical care in general.

Mental Illness As of 2022, an estimated 108.4 million people (i.e., 1.4% of humanity) were forcibly displaced from their homes, mainly on account of violent conflict. It is expected that millions more will be displaced in response to the effects of climate change. This has ramifications for mental health (as do natural disasters) where resultant psychosocial stress can lead to an increased incidence of anxiety, depression, and posttraumatic stress disorder (PTSD). Increased temperatures have also been found to be associated with higher rates of suicide and domestic violence. Lastly, regarding clinical practice, many psychoactive prescription drugs can interfere with thermoregulation; their use therefore confers added risk during extreme heat events.

FOOD SECURITY AND OCEAN RESOURCES

Malnutrition Climate change threatens food and nutritional security through decreased crop yields in the setting of changes in precipitation, desertification, severe weather events, temperature extremes, GHG emissions, ocean warming and acidification, coastal inundation affecting dryland agriculture and aquaculture, and increasing competition from weeds and pests (Fig. 473-7). Livestock and fish production are also projected to decline. For many, food will be less available, less nutritious, and more expensive.

As chronic noncommunicable diseases, both undernutrition (Chap. 345) and obesity (Chap. 413)—which affect nearly 3 billion people worldwide—share common drivers with climate change. Current dietary practices (through land conversion and overconsumption of ruminant meats) contribute to excess GHGs, decreases in biodiversity, and depletion of water supplies. Variable rainfall and increased flooding, which can contaminate freshwater supplies, will make water security a defining challenge of this century.

Plant-based diets have the potential to decrease GHG emissions; improve food security in LMICs; reduce mortality from stroke, type 2 diabetes mellitus, coronary heart disease, and cancer by 6–10%; and reduce diet-related GHGs by 29–70% by 2050 compared with a reference diet (Fig. 473-8).

SOCIETAL AND GOVERNMENTAL INTERVENTIONS	Shifting to clean fuels	• Switch coal-fired power plants to low-polluting renewable energy sources such as wind, tidal, geothermal, and solar.
	Transportation reform	• Promote use of low-emission and zero-emission vehicles. Reduce sulfur content of motor fuels. Restrict trucks from city centers, encourage active transport (walking and cycling).
	Reduce traffic emission(s)	• Diesel particle traps, catalytic converters, alternative fuels (natural gas, electric cars)
	Urban landscape reform	• Land-use assessment, minimum distances between sources and people, relocation of traffic sources (including major trafficked roads), avoidance of mixed-use areas (industrial-residential)
	Emission trading programs	• Revenues raised through taxes can be directed to pollution control. Emissions trading programs compensate companies who adhere to controls through credits that can be traded akin to carbon credits
	Redirection of science and funding	• Modifying priorities of climate change mitigation investments to a focus on near-term health co-benefits. Focus on the imminent near-term danger of health effects of air pollution.
	Empowering civil society	• Publicity and awareness campaigns through local data on air pollution within cities, counties
	Governmental and NGO-led publicity	• Hard-hitting media campaigns akin to smoking on media to mitigate lobbying by industries involved in power and automobiles
PERSONAL INTERVENTIONS	Face masks and air purifiers	• Wearing face masks and installing air purifiers in homes
	Reduce in-traffic exposures	• Avoid commutes during rush hour
	Reduce in-home penetration of outdoor air pollution	• Indoor air purifiers and closing windows; air conditioners
	Lifestyle changes and preventive medicine	• Exercise and healthy diet • Preventive medications and screening programs

INFECTIONS AND DIARRHEAL DISEASE

(See Chap. 474.)

POTENTIAL SOLUTIONS

Reductions in GHG emissions will require health professionals to voice their evidence-based understandings of climate-sensitive pathologies to lobby for political action. Other important systemic interventions in health care include achieving universal health coverage (including financial risk protection); equitable access to quality essential health care services as well as safe, effective, and affordable medicines and vaccines; making health care and health systems net-zero carbon; adding a climate-change lens to existing lines of research; improving data quality and enhancing, standardizing, and integrating data collection in LMICs; and anticipating and correcting disaster-related health care system failures, such as impacts to supply chains or loss of electric power resulting from extreme weather events.

Interventions related to environmental policy include advocating for a tighter particulate-matter air-quality standard, supporting institutional divestment from fossil fuels, and advocating for the rapid drawdown of emissions and negative emissions strategies. Ecosocial interventions, supported by national or global institutions, include the distribution of clean cookstoves globally, switching to plant-based diets, decreased air travel, reducing air conditioner use, and increased access to more public transportation. Finally, advocating for wealth-redistribution schemes (e.g., reparations, progressive taxation, debt cancellation, improved safety nets, underemployment insurance) to empower disadvantaged populations to cope with climate hazards will have positive ancillary effects on the social determinants of health, the administration of health services, and the outcomes of clinical interventions.

CONCLUSIONS

Without sweeping reductions in GHG emissions, over the next 50 to 100 years, models predict increases in average global temperature of 2–5°C (with localized highs), rising sea levels, and more frequent and severe extreme-weather events, with resultant complications for population health globally. The hostile consequences of climate change will disproportionately affect vulnerable and marginalized groups, particularly those whose ability to cope with climate hazards is curtailed by systemic racism, colonial legacies, illicit financial flows, and human rights failings.

Health care professionals find themselves on the front line of the climate crisis and remain, in many settings, sources of information and counsel. In order to mitigate the impact of climate-sensitive diseases and resulting health disparities, they must continue to extend their clinical purview to socioecological determinants and structural interventions.

474 Climate Change and Infectious Disease

Aaron S. Bernstein, Jonathan A. Patz

Since the late nineteenth century, humans have released greenhouse gases—mainly carbon dioxide and methane—into the atmosphere, creating a new climate unseen in human times. This new climate has already altered the epidemiology of infectious diseases, and the accumulation of more greenhouse gases in the atmosphere will further alter the incidence and severity of infections. In certain instances, climate

change may establish conditions promoting the emergence of infectious diseases, while in other instances, it may render areas that are presently suitable for certain diseases unsuitable. This chapter presents the current state of knowledge regarding the known and prospective infectious-disease consequences of climate change.

OVERVIEW

The term *climate change* refers to multidecadal alterations in temperature, precipitation, wind, humidity, and other components of weather outside of the natural climate variability seen in comparable time periods. Over the past 2.5 million years, the earth has warmed and cooled, cycling between glacial and interglacial periods during which average global temperatures moved up and down by 4–7°C. During the last glacial period, which ended roughly 12,000 years ago, global temperatures were, on average, 5°C cooler than in the mid-twentieth century **(Fig. 474-1)**.

The present climate period, known as the Holocene, is remarkable for its stability: temperatures have largely remained within a range of 2–3°C. This stability has enabled the successful population and cultivation of much of the earth's landmass by humanity. Current climate change differs from that in the past not only because its primary cause is human activities but also because its pace is faster. The current rate of warming on Earth is unprecedented in the last 50 million years. The 5°C of warming that occurred at the end of the last ice age about 12,000 years ago took roughly 5000 years, whereas such a temperature increment may occur within the next 150 years unless the release of greenhouse gases is substantially reduced in coming decades.

GREENHOUSE GASES

Greenhouse gases **(Table 474-1)** are a group of gases in Earth's atmosphere that absorb infrared radiation and thus warm the planet. Essentially, greenhouse gases act as a blanket on the earth to keep more of the sun's solar radiation in the atmosphere. Carbon dioxide, released into the atmosphere primarily from fossil fuel combustion and deforestation, has had the greatest effect on climate since the Industrial Revolution. Other greenhouse gases, such as methane, nitrous oxides, and fluorinated gases, are more potent than carbon dioxide, but make up a smaller proportion of greenhouse gases. Both carbon dioxide and methane have increased considerably from the nineteenth century until 2023, with methane concentrations more than doubling. Water vapor is the most abundant and a highly potent greenhouse gas but, given its short atmospheric life span and sensitivity to temperature, is not a major factor in recently observed warming.

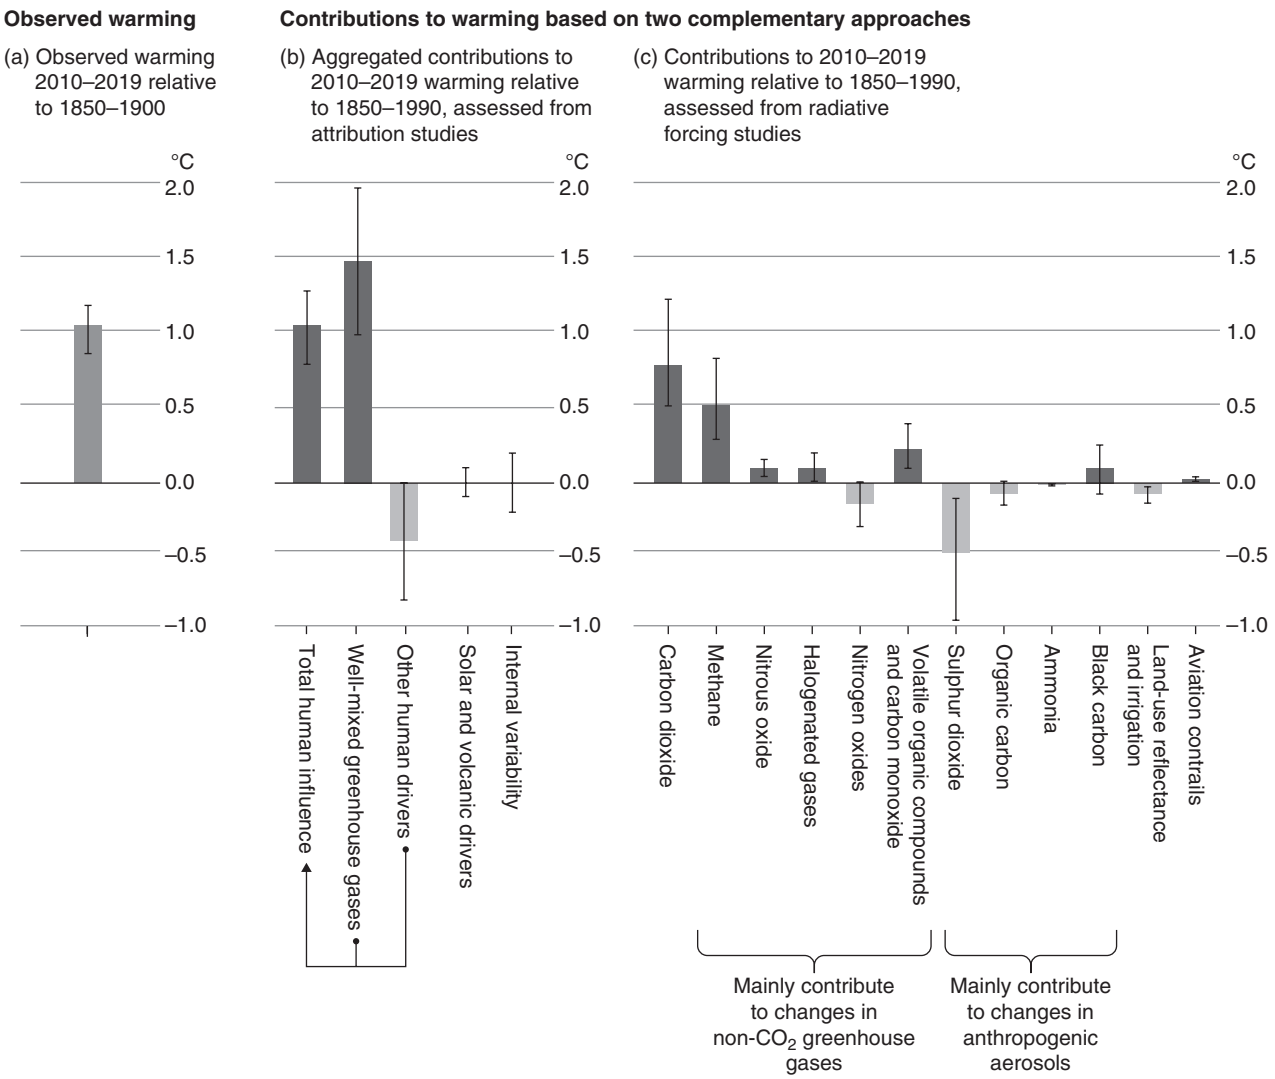

FIGURE 474-1 Assessed contributions to observed warming in 2010–2019 relative to 1850–1900. Assessed contributions to observed warming in 2010–2019 relative to 1850–1900. ***A.*** Observed global warming (increase in global surface temperature). Whiskers show the very likely range. ***B.*** Evidence from attribution studies, which synthesize information from climate models and observations. Temperature change attributed to total human influence; changes in well-mixed greenhouse gas (GHG) concentrations; other human drivers due to aerosols, ozone, and land-use change (land-use reflectance); solar and volcanic drivers; and internal climate variability. Whiskers show likely ranges. ***C.*** Evidence from the assessment of radiative forcing and climate sensitivity. Temperature changes from individual components of human influence: emissions of GHGs, aerosols, and their precursors; land-use changes (land-use reflectance and irrigation); and aviation contrails. Whiskers show very likely ranges. Estimates account for both direct emissions into the atmosphere and their effect, if any, on other climate drivers. For aerosols, both direct effects (through radiation) and indirect effects (through interactions with clouds) are considered. *(Used with permission from IPCC, 2021: Summary for Policymakers. TABLE 474-1 Greenhouse Gases: Sources, Sinks, and Forcings

GAS	HUMAN SOURCES	SINK[a]	RADIATIVE FORCING[b] (95% CONFIDENCE INTERVAL)
Carbon dioxide (CO_2)	Fossil fuel combustion, deforestation	Uptake by oceans (~30%), plants	1.68 (1.33–2.03)
Methane (CH_4)	Fossil fuel production, ruminant animals, decomposition in landfills	Hydroxyl radicals in the troposphere	0.97 (0.74–1.20)
Nitrous oxide (N_2O)	Fertilizer, fossil fuel combustion, biomass burning, livestock manure	Photolysis in the stratosphere	0.17 (0.14–0.23)
Halocarbons	Refrigerants, electrical insulation, aluminum production	Hydroxyl radicals in the troposphere, sunlight in the stratosphere	0.18 (0.01–0.35)

[a]In this table, a *sink* refers to the place where greenhouse gases are naturally stored or the mechanism through which they are destroyed. [b]*Radiative forcing*, measured in watts per meter squared, refers to how much an entity can alter the balance of incoming and outgoing radiation to and from Earth's atmosphere. It is measured relative to a preindustrial (i.e., 1750) baseline. Greenhouse gases have a positive "forcing"; that is, on balance, they increase the amount of radiation (and specifically infrared radiation) that is retained in Earth's atmosphere.

Source: Intergovernmental Panel on Climate Change Fifth Assessment Report, Working Group 1, Chapter 8; American Chemical Society "Greenhouse gas sources and sinks," available at *www.acs.org/content/acs/en/climatescience/greenhousegases/sourcesandsinks.html.*

The atmosphere, some of the aerosols suspended in it, and clouds reflect a portion of incoming solar radiation back toward space. The remainder reaches Earth's surface, where it is absorbed and some is emitted back into the atmosphere. The earth emits energy absorbed from the sun at longer wavelengths, primarily infrared, that greenhouse gases can absorb. The change in wavelength that occurs as solar radiation is absorbed and re-emitted from the earth's surface is fundamental to the greenhouse effect **(Fig. 474-2)**.

TEMPERATURE

Climate change has clearly caused global warming with the average surface temperature of Earth increasing 1.09°C from 1880 to 2020. Moreover, the rate of global warming is faster now than at any time in the last 1000 years. Yet, this mean warming fails to show that warming is occurring much faster in certain regions. The Arctic has warmed twice as fast overall, and winters are warming faster than summers. Nighttime minimum temperatures are also rising faster than daytime high temperatures. Each of these nuances bears upon the incidence of infectious diseases in general and vector-borne disease specifically.

Due to climate change, extreme heat waves are expected to be more common, longer, and more severe in the future. The hottest 5-year period ever recorded since records started in the mid-nineteenth century was 2016–2020. Besides contributing directly to morbidity and mortality in human populations, heat waves wilt crops and are predicted to contribute substantially to agricultural losses. For example, the 2010 heat wave in Russia, which was unprecedented in its severity, contributed to hundreds of forest fires that generated enough air pollution to kill an estimated 56,000 people and that burned 300,000 acres of crops, including roughly 25% of the nation's wheat fields. Nutritional deficiencies underlie a substantial portion of the global burden of many infectious diseases.

PRECIPITATION

In addition to changing temperature, the emission of greenhouse gases and the consequent increase in energy in Earth's atmosphere have influenced the planet's water cycle. Since 1950, substantial increases in the heaviest precipitation events (i.e., those above the 95th percentile) have been observed in Europe and North America. Moreover, in 2022, floods harmed an estimated 58 million people globally. Other areas have seen greater drought, notably southern Australia and the southwestern United States.

A warmer atmosphere holds more water vapor. Specifically, air holds 6–7.5% more water vapor per degree (Celsius) of warming in the lower

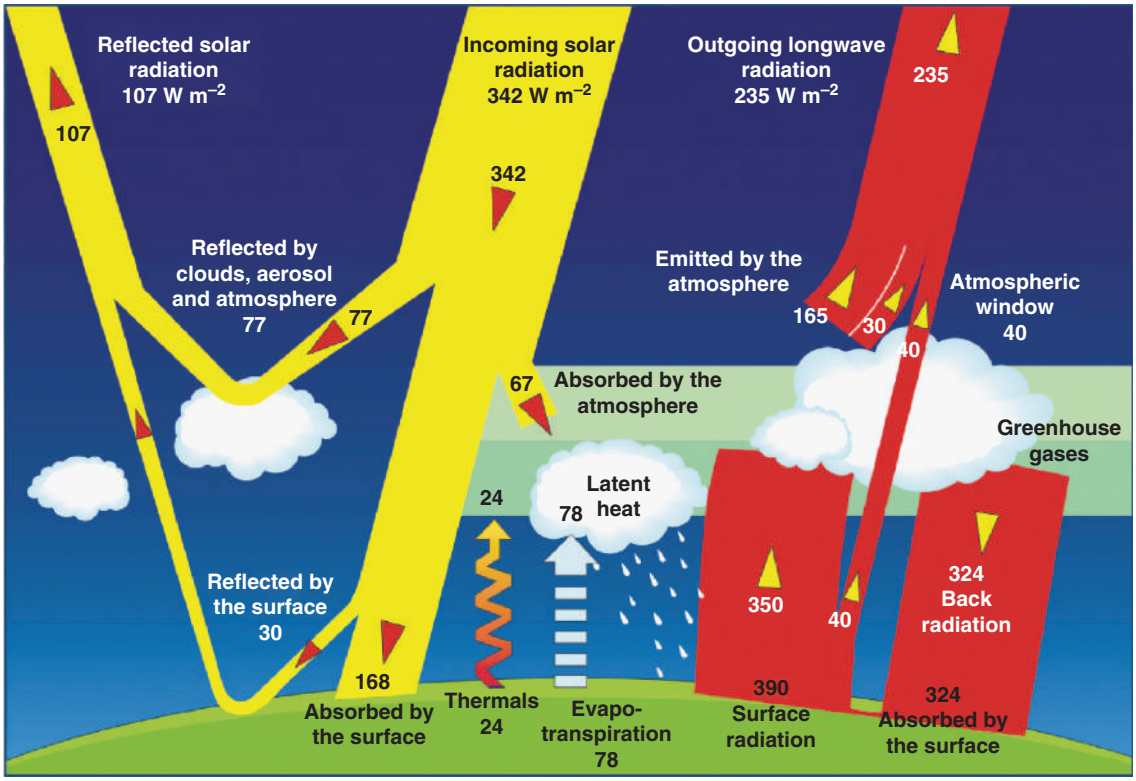

FIGURE 474-2 Earth's energy balance. *(Kiehl's Earth's Annual Global Mean Energy Budget, Bulletin of the American Meteorological Society, Vol. 78, No. 2, 1997 (Figure 7, page 206). © American Meteorological Society. Used with permission.)*

atmosphere. For areas that have traditionally had more precipitation on average, warming tends to promote heavier precipitation events. In contrast, in regions prone to drought, warming tends to result in greater periods between rainfalls and in the risk of drought. Floods and droughts have been associated with outbreaks of waterborne infectious diseases.

HURRICANES

The world's oceans have absorbed 90% of the excess heat that greenhouse gases have kept in Earth's atmosphere since the 1960s. Ocean heat provides energy for hurricanes, and warmer years tend to have greater hurricane activity. Stronger hurricanes (category 4 and 5) are expected with climate change, though climate change influence on hurricane frequency is uncertain. Modeling of future tropical cyclones suggests that their intensity may increase 2–11% by 2100 and that the average storm will bring 20% more rainfall.

SEA LEVEL RISE

Between 1901 and 2010, the global sea level rose ~200 mm, or ~1.7 mm per year on average. From 1993 to 2010, the rate of rise nearly doubled—i.e., to 3.2 mm annually. Most of this sea level rise has resulted from the thermal expansion of water. Glacial ice melt is the second greatest factor, and its contribution is accelerating. By 2100, global sea level may rise by 0.8–2 m, with an annual rate of rise of 8–16 mm at the century's end.

Sea level rise is not uniform. The rate of rise on the eastern seaboard of North America has been roughly double the global rate. Compounding sea level rise is the subsidence of coastal areas due to human settlement. In the absence of levee upgrades, an estimated 300 million people living near coasts worldwide will be at risk of flooding in 2050 because of the combined effects of subsidence, erosion, and sea level rise.

Along with extreme storms and overuse of coastal aquifers, rising seas also contribute to salinization of coastal groundwater. About 1 billion people rely on coastal aquifers for potable water.

EL NIÑO SOUTHERN OSCILLATION

The *El Niño Southern Oscillation* (ENSO) refers to periodic changes in water temperature in the eastern Pacific Ocean that occur roughly every 4–5 years. ENSO cycles have dramatic effects on weather around the globe. Warmer-than-average water temperatures in the eastern Pacific define *El Niño events* (see below), whereas cooler-than-average water temperatures define La Niña periods. Evidence is accruing that climate change may be increasing the frequency and severity of El Niño events.

El Niño events drive alterations in weather worldwide **(Fig. 474-3)** and are associated with extreme events and consequently higher rates of morbidity and mortality. Hurricane Mitch, one of the most powerful hurricanes ever observed, with winds reaching 290 km/h, dropped 1–1.8 m (3–6 feet) of rain over 72 h on parts of Honduras and Nicaragua. As a result of this storm, 11,000 people died and 2.7 million were displaced. Outbreaks of cholera, leptospirosis, and dengue occurred in the storm's aftermath.

POPULATION MIGRATION AND CONFLICT

The final common outcome of all climate-change effects is human displacement. Sea level rise, extreme heat and precipitation, droughts, and salinization of water supplies all conspire to make regions, including some inhabited by humans for millennia, uninhabitable. The 8 million inhabitants of low-lying South Pacific islands are vulnerable to sea level rise and could be a major source of climate migrants.

Climate change may also be contributing to humanitarian crises and conflicts. A severe 2011 drought in East Africa may have incited the Somali famine that resulted in 1 million refugees; mortality rates reached 7.4/10,000 in some refugee camps.

EFFECTS OF CLIMATE CHANGE ON INFECTIOUS DISEASE

The incidence of most, if not all, infectious diseases depends on climate. For any given infection, however, climate change is but one of many factors determining disease epidemiology. In instances in which climate change creates conditions favorable to the spread of infections,

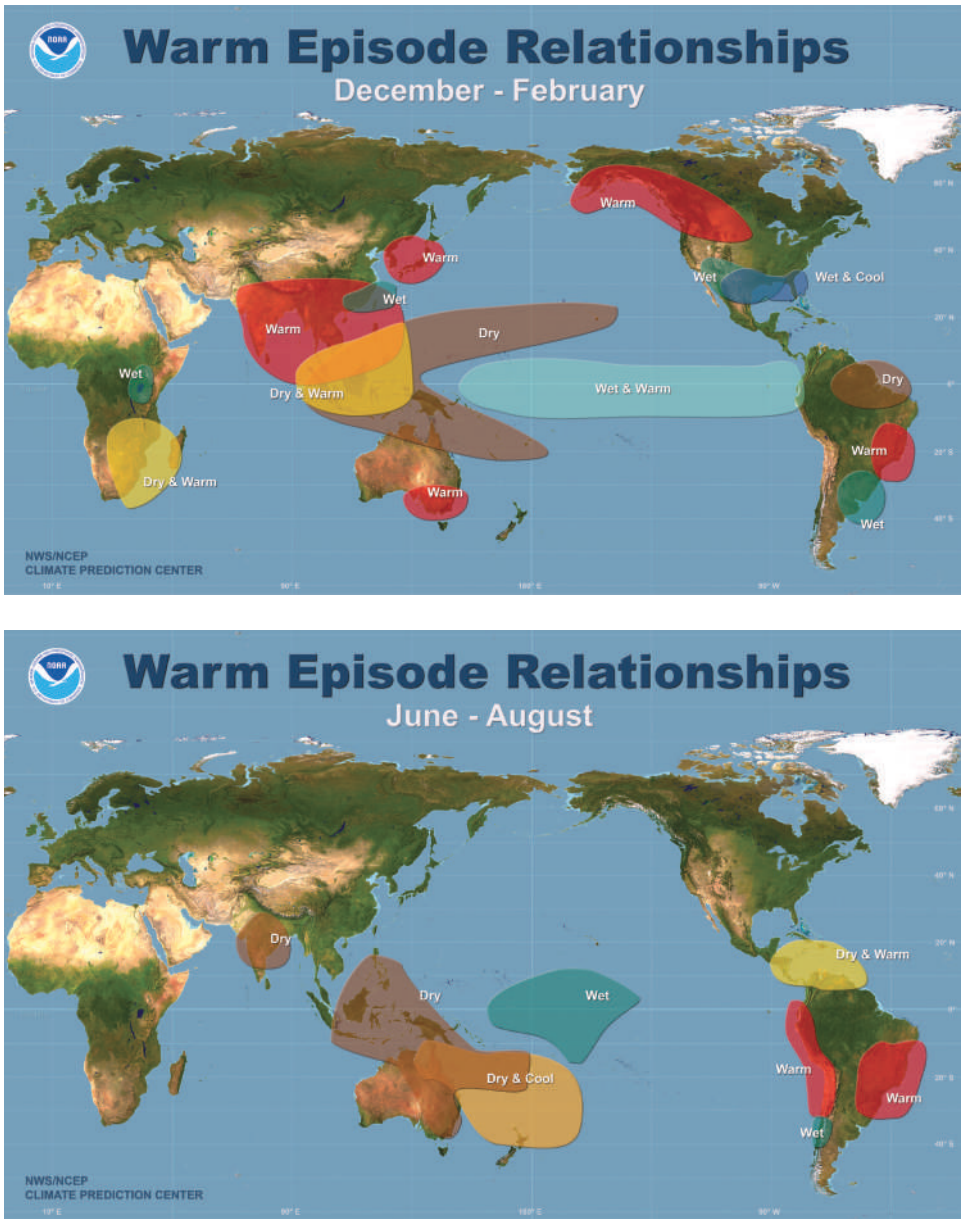

FIGURE 474-3 Characteristic weather anomalies, by season, during El Niño events. *(Source: Climate Prediction Center, https://www.cpc.ncep.noaa.gov/products/analysis_monitoring/impacts/warm_impacts.shtml.)*

diseases may be kept in check through interventions such as vector control or antibiotic treatment.

Detecting the influence of climate change amid the many competing forces that bear on infectious disease emergence and spread can be challenging. Research on animal pathogens, which in most instances are less intervened upon than that with their human counterparts, has suggested how climate change may independently influence disease spread. Avian malaria in Hawaii, for example, has clearly moved to higher elevations where warmer temperatures have enabled disease transmission. Many putative pathways have been identified that connect greenhouse gas emissions to infectious disease risk in people. Climate change influences extend beyond contagious diseases and include diseases from microbial toxins, such as those that result from harmful algal blooms. Warmer ocean temperatures cause *Pseudonitzschia* spp., blue–green cyanobacteria, and dinoflagellates to grow faster, resulting in concurrent disease outbreaks.

VECTOR-BORNE DISEASE

Because insects are cold-blooded, ambient temperature dictates their geographic distribution. With increases in temperatures (in particular, nighttime minimum temperatures), insects are freed to move poleward and up mountainsides. At the same time, as new areas become climatically suitable, current mosquito habitats may become unsuitable because of heat extremes.

In addition, insects tend to be sensitive to water availability. Mosquitoes that transmit malaria, dengue, and other infections may breed in pools of water created by heavy downpours. As has been observed in the Amazon, breeding pools can also appear during periods of drought when rivers recede and leave behind stagnant pools of water for *Anopheles* mosquitoes. These circumstances have raised interest in the potentially favorable impact of water-cycle intensification on the spread of mosquito-borne disease.

Malaria • **TEMPERATURE** Higher temperatures promote higher mosquito-biting rates, shorter parasite reproductive cycles, and the potential for the survival of mosquito vectors of *Plasmodium* infection in locations previously too cold to sustain them. Modeling experiments have identified highland areas of East Africa and South America as perhaps most vulnerable to increased malarial incidence as a result of rising temperatures. In addition, an analysis of interannual malaria in Ecuador and Colombia has documented a greater incidence of malaria at higher altitudes in warmer years. Highland populations may be more vulnerable to malaria epidemics because they lack immunity.

Although rising temperature has the potential to expand the viable range of disease, malaria incidence is not linearly associated with temperature. While mosquitoes and parasites may adapt to a warming climate, the present optimal temperature for malaria transmission is ~25°C, with a range of transmission temperatures between 16°C and 34°C. Rising temperatures can also have differential effects on parasite development during external incubation and on the mosquitoes' gonotrophic cycle. Asynchrony between these two temperature-sensitive processes has been shown to decrease the vectorial capacity of mosquitoes.[1]

PRECIPITATION The abundance of *Anopheles* mosquitoes is strongly correlated with the availability of surface-water pools for mosquito breeding, and biting rates have been linked to soil moisture (a surrogate for breeding pools). Research in the East African highlands has documented that increased variance in rainfall over time has strengthened the association between precipitation and disease incidence. These disease-promoting effects of precipitation may be countered by the potential for extreme rainfall to flush mosquito larvae from breeding sites.

PROJECTIONS Climate models have begun to deliver output on regional scales, permitting projections of climate-suitable regions to assist national and local health authorities. Climate models speak to the temperature and precipitation ranges necessary for malaria transmission but do not account for the capacity of malaria control programs to halt the spread of disease. The global reduction in malaria distribution over the past century makes it clear that, even with climate change, malaria occurs in far fewer places today because of public health interventions. Recent vaccine trials also show promise in further reducing malaria risk.

Despite intensive efforts, malaria remains the single greatest vector-borne disease cause of morbidity and death in the world. Particularly in regions that are most affected by malaria and where the public health infrastructure is inadequate to contain it, climate modeling may provide a useful tool in determining where the disease may spread. Modeling studies in sub-Saharan Africa have suggested that, although East African nations may encompass regions that will become more climatically suitable for malaria over this century, West African nations may not. By 2100, temperatures in West Africa may largely exceed those optimal for malaria transmission, and the climate may become drier; in contrast, higher temperatures and changes in precipitation may allow malaria to move up the mountainsides of East African countries. Climate change may create conditions favorable to malaria in subtropical and temperate regions of the Americas, Europe, and Asia as well.

Dengue Like malaria epidemics, dengue fever epidemics depend on temperature **(Fig. 474-4)**. Higher temperatures increase the rate of larval development and accelerate the emergence of adult *Aedes* mosquitoes. The daily temperature range may also influence dengue virus transmission, with a smaller range corresponding to a higher transmission potential. Temperatures <15°C or >36°C substantially reduce mosquito feeding. In a *Rhesus* model of dengue, viral replication can occur in as little as 7 days with temperatures of >32–35°C; at 30°C, replication takes ≥12 days; and replication does not reliably occur at 26°C. Research on dengue in New Caledonia has shown peak transmission at ~32°C, reflecting combined effects of a shorter extrinsic incubation period, a higher feeding frequency, and more rapid development of mosquitoes. Along with temperature, peak relative humidity is a strong predictor of dengue outbreaks.

The association between dengue epidemics and precipitation is less consistent in the peer-reviewed literature, possibly because of the mosquito vector's greater reliance on domestic breeding sites than on natural pools of water. For instance, in some studies, increased access to a piped water supply has been linked to dengue epidemics, presumably because of associated increased domestic water storage. Nonetheless, several studies have established rainfall as a predictor of the seasonal timing of dengue epidemics.

The current global distribution of dengue largely overlaps the geographic spread of *Aedes* mosquitoes **(Fig. 474-5)**. The presence of *Aedes* without dengue endemicity in large regions of North and South America and Africa illustrates the relevance of variables other than climate to disease incidence. Nevertheless, coupled climatic–epidemiologic modeling suggests dramatic shifts in the relative vectorial capacity for dengue by the end of this century should little or no mitigation of greenhouse gas emissions occur **(Fig. 474-6)**.

Other Arbovirus Infections Climate change may favor increased geographic spread of other arboviral diseases, including Zika virus disease, chikungunya virus disease, West Nile virus disease, and eastern equine encephalitis. Zika virus moved to the Western Hemisphere from French Polynesia around 2013 and rapidly spread in Brazil in 2016. Although air travel was essential for the delivery of the virus to the Americas, the available evidence suggests that the 2015 El Niño event provided an optimal climate for the infection to take root and spread (see "ENSO-Related Outbreaks," below). *Aedes aegypti* is the primary vector for Zika virus. Chikungunya virus disease emerged in Italy in 2007, having previously been mostly a disease of African nations. Climate models predict that, should competent vectors be present, conditions will be suitable for the chikungunya virus to gain a foothold in Western Europe, especially France, in the first half of

[1] rVc is the vectorial capacity relative to the vector-to-human population ratio and is defined by the equation $rVc = a^2 b_h b_m e^{-\mu m n}/\mu_m$ where a is the vector biting rate; bh is the probability of vector-to-human transmission per bite; b_m is the probability of human-to-vector infection per bite; n is the duration of the extrinsic incubation period; and μm is the vector mortality rate.

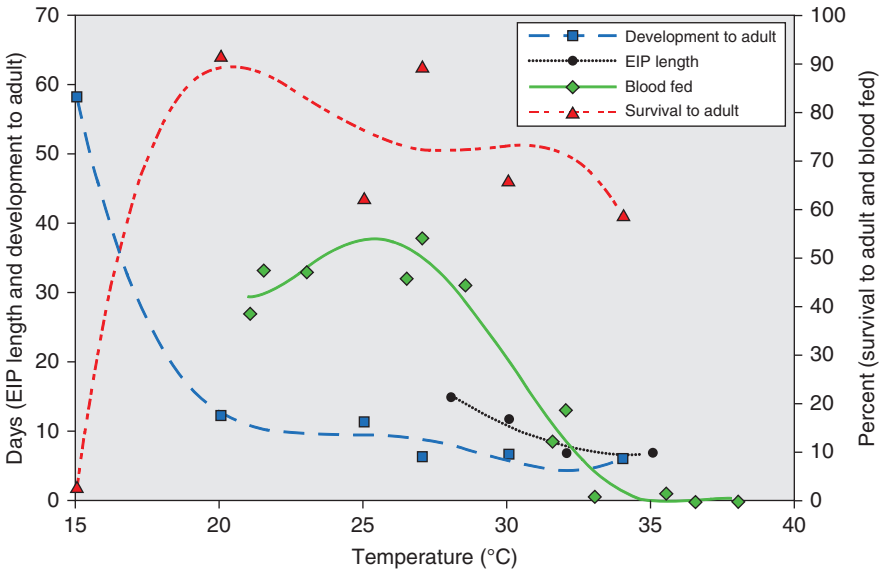

FIGURE 474-4 Effects of temperature on variables associated with dengue transmission. Shown are the number of days required for development of immature *Aedes aegypti* mosquitoes to adults, the length of the dengue virus type 2 extrinsic incubation period (EIP), the percentage of *Ae. aegypti* mosquitoes that complete a blood meal within 30 min after a blood source is made available, and the percentage of hatched *Ae. aegypti* larvae surviving to adulthood. *(Reproduced from CW Morin et al: Climate and dengue transmission: Evidence and implications. Environ Health Perspect 121:1264, 2013.)*

the twenty-first century. In North America, areas favorable to West Nile virus outbreaks are expected to shift northward in this century. Current hotspots in North America are the California Central Valley, southwestern Arizona, southern Texas, and Louisiana, which have both compatible climates and avian reservoirs for the disease. By mid-century, the upper Midwest and New England will be more climatically suited to West Nile virus; by the end of the century, the area of risk may shift even further north to southern Canada. Whether the disease will ultimately move northward will depend on reservoir availability and mosquito control programs, among other factors.

Lyme Disease In the past few decades, *Ixodes scapularis*, the primary tick vector for Lyme disease as well as for anaplasmosis and babesiosis in New England, has become established in Canada because of warming temperatures. With climate change, the range of the tick is expected to expand further **(Fig. 474-7)**.

Lyme disease, caused by the spirochete *Borrelia burgdorferi*, is the most commonly reported vector-borne disease in North America, with ~60,000 cases annually. In Europe, Lyme disease has also increased and expanded geographically. Furthermore, the timing and peaks of cases have been affected, with the annual peak case numbers in 2019 arriving 6 weeks earlier than 25 years prior.

WATERBORNE DISEASE

Many microorganisms, from bacteria to toxin-producing algae, cause waterborne disease **(Table 474-2)**. The outbreaks of waterborne disease are associated with heavy rainfall events. A review of 548 waterborne disease outbreaks in the United States found that 51% were preceded by precipitation levels above the 90th percentile. Since 1900, most regions of the United States except the Southwest and Hawaii have experienced an increase in heavy downpours with the greatest intensification of the water cycle in New England and Alaska.

Most disease outbreaks after heavy precipitation occur through contamination of drinking-water supplies. While outbreaks related to surface-water contamination generally occur within a month of the precipitation event, disease outbreaks from groundwater contamination tend to occur ≥2 months later. According to a review of published reports of waterborne disease outbreaks, *Vibrio* and *Leptospira* species are the pathogens most commonly involved in the wake of heavy precipitation.

Combined Sewer Systems Roughly 40 million people in the United States and millions more around the world rely on combined sewer systems in which storm water and sanitary wastewater are conveyed in the same pipe to treatment facilities. These systems were

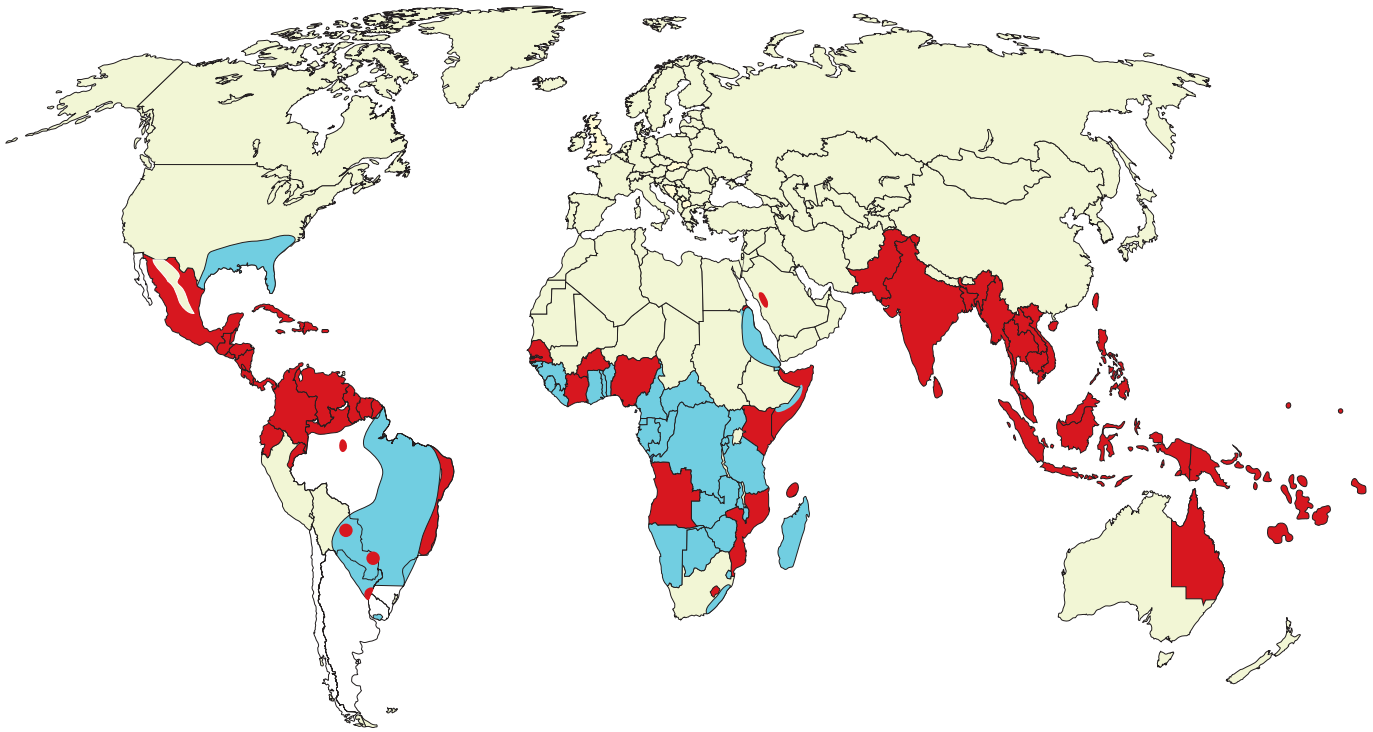

FIGURE 474-5 Distribution of *Aedes aegypti* mosquitoes (*turquoise*) and dengue fever epidemics (*red*). *(Map produced by the Agricultural Research Service of the U.S. Department of Agriculture.)*

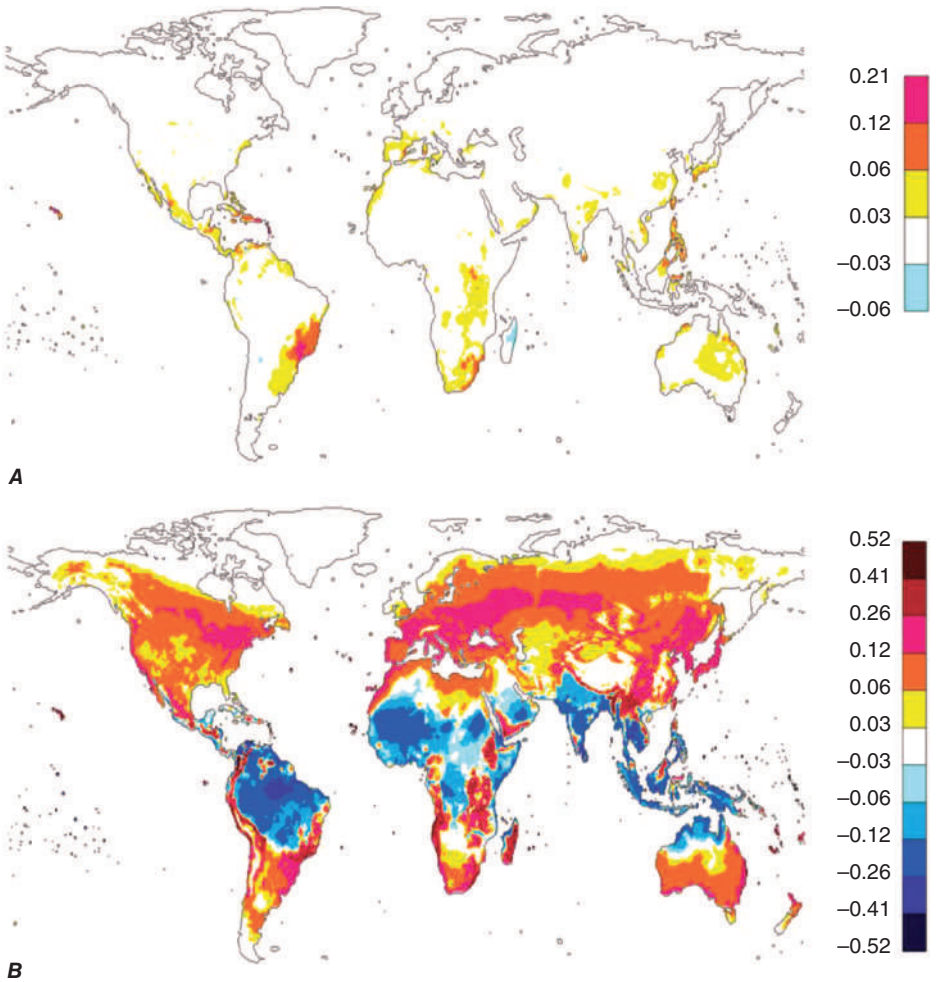

FIGURE 474-6 Trend of annually averaged global dengue epidemic potential (*rVc*). Differences in rVc are based on 30-year averages of temperature and daily temperature range. ***A.*** Differences between 1980–2009 and 1901–1930. ***B.*** Differences between 2070–2099 and 1980–2009. The mean value of rVc was averaged from five global climate models under RCP8.5, a scenario of high greenhouse-gas emission. The color bar describes the values of the rVc. *(From J Liu-Helmersson et al: Vectorial capacity of Aedes aegypti: Effects of temperature and implications for global dengue epidemic potential. PLoS One 9:e89783, 2014.)*

designed based on the nineteenth-century climate, in which heavy downpours were less frequent than they are today. The frequency of combined sewer overflows usually into freshwater bodies and resulting in untreated sewage and runoff potentially containing heavy metals and pesticides, has been increasing in cities worldwide. For instance, the channel leading into Lake Michigan from Milwaukee had its highest levels of *Escherichia coli*, up to 100 times the Environmental Protection Agency guidance for recreational waters, after combined sewer overflows **(Fig. 474-8)**.

Rising Temperatures and *Vibrio* Species Warmer temperatures favor proliferation of *Vibrio* species and disease outbreaks, as has been demonstrated in countries surrounding the Baltic Sea, Chile, Israel, northwestern Spain, and the U.S. Pacific Northwest. Around the Baltic Sea, outbreaks of *Vibrio* infection may be particularly likely because of faster warming near the poles and the sea's relatively low salt content. In the United States, levels of vibriosis roughly tripled from 1996–2010, with the highest number of cases occurring each summer.

ENSO-Related Outbreaks Weather extremes tied to El Niño events afford a window into a climate-changed future. Recent evidence indicates that climate change itself may be strengthening El Niño events. These events tend to promote epidemic infections in certain regions **(Fig. 474-9)**.

Associations of El Niño with outbreaks of Rift Valley fever in eastern and southern Africa have been known since the 1950s. El Niño favors wet conditions suitable for the insect vectors of the disease in these regions. Given the strong association between El Niño conditions and disease incidence, models have successfully predicted Rift Valley fever epidemics in humans and animals. In the 2006–2007 El Niño season, for example, outbreaks of Rift Valley fever were accurately predicted 2–6 weeks prior to epidemics in Somalia, Kenya, and Tanzania.

El Niño has had inconsistent associations with malaria incidence in African countries. Some of the strongest associations between El Niño and malaria have been identified in South Africa and Swaziland, where available data on incidence are relatively robust; however, even in these instances, the observed increased risk did not reach statistical significance. A stronger link to El Niño has been found in several studies done in South America. Research on malaria incidence in Colombia between 1960 and 2006 found that a 1°C temperature rise contributed to a 20% increase in incidence.

In the desert Southwest of the United States, hantavirus erupted following the strong El Niño of 1997. Unseasonal rainfall caused the desert to bloom, providing food resources and resulting in a boon to the mouse population. The following year saw the climate revert back to normal (arid) conditions, and as a result, increased human/mouse contact occurred as mice were forced to seek out food and nest in human dwellings.

In Bangladesh, a strong association has been observed between the El Niño Southern Oscillation Index and cholera epidemics. During El Niño, a combination of warmer sea-surface temperatures (SSTs) and rich nutrient runoff lead to phytoplankton blooms detectable by satellite. These blooms, in turn, feed zooplankton, which can harbor *V. cholerae* and, therefore, amplify their presence in the environment, causing cholera epidemics in the region **(Fig. 474-10)**.

El Niño years are often associated with an increased incidence of dengue. Research on dengue outbreaks in Thailand from 1996 to 2005 revealed that 15–22% of the variance in monthly dengue disease incidence was attributable to El Niño. In South America, data on dengue outbreaks between 1995 and 2010 showed an increased incidence during the El Niño events of 1997–1998 and 2006–2007.

El Niño may have contributed to the emergence of Zika virus in the wake of a very strong ENSO event during the winter of 2015–2016. Temperatures throughout South and Central America were exceptionally high and, just prior to the Zika epidemic, the vectorial capacity of *Ae. aegypti* was at its highest level compared with the previous 60 years. Not surprisingly (because carried by the same mosquito vector), large epidemics of dengue also occurred in Brazil and Colombia at that time. But laboratory studies show that the temperature optimum for Zika virus is 5°C warmer than for dengue. Thus, it is possible the extreme temperature played a role in the extent of the Zika epidemic.

CLIMATE CHANGE, POPULATION DISPLACEMENT, AND INFECTIOUS DISEASE EPIDEMICS

For many reasons, including freshwater shortages, flooding, food shortages, and climate change–driven conflicts, climate change has and will continue to put pressure on human populations to move. Human migrations have long been associated with epidemic disease in the

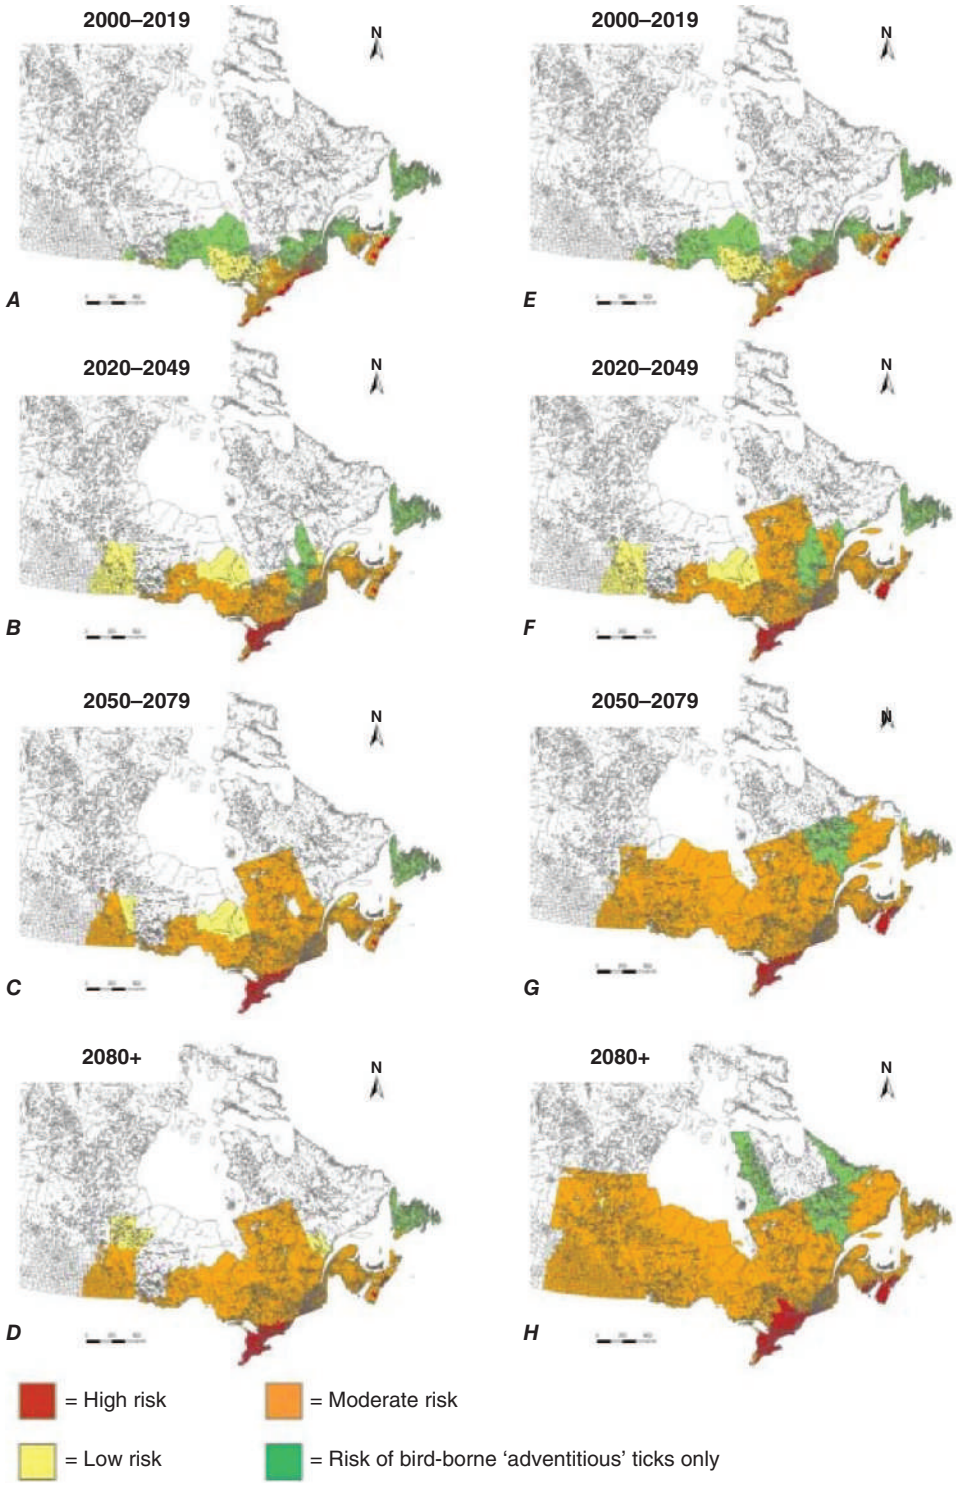

FIGURE 474-7 Risk maps for the occurrence of the Lyme disease vector *Ixodes scapularis*. Expansion of *I. scapularis*–affected census subdivisions (CSDs) in Canada from the present (using 1971–2000 temperature normals) to the 2080s (using temperature conditions predicted by the CGCM2 climate model under emissions scenario A2). In ***A–D*** ("slow" scenario), the model assumes that by the end of each time period, only risk CSDs with an algorithm value in the top 10% will contain an *I. scapularis* population. In ***E–H*** ("fast" scenario), the model assumes that by the end of each time period, all CSDs within the "moderate"-risk zone for *I. scapularis* establishment (risk CSDs) contain an *I. scapularis* population. For both scenarios, the time steps are 2000–2019, 2020–2049, 2050–2079, and 2080– 2109. "High"-risk regions for *I. scapularis* population establishment are indicated in *red*. "Moderate"-risk regions are in *orange*. "Low"-risk regions are in *yellow*. Regions with no risk of established populations but some risk from bird-borne "adventitious" ticks are in *green*. Regions with no predicted risk of either are colorless. *(Used from NH Ogden: Risk maps for range expansion of the Lyme disease vector, Ixodes scapularis, in Canada now and with climate change. Int J Health Geogr 7:1, 2008.)*

TABLE 474-2 Climate Sensitive Agents of Water-Related Illness

PATHOGEN OR TOXIN PRODUCER	EXPOSURE PATHWAY	SELECTED HEALTH OUTCOMES AND SYMPTOMS	MAJOR CLIMATE CORRELATION OR DRIVER (STRONGEST DRIVERS LISTED FIRST)
Algae: Toxigenic marine species of *Alexandrium, Pseudo-nitzschia, Dinophysis, Gambierdiscus; Karenia brevis*	Shellfish, fish Recreational waters (aerosolized toxins)	Gastrointestinal and neurologic illness caused by shellfish poisoning (paralytic, amnesic, diarrhetic, neurotoxic) or fish poisoning (ciguatera). Asthma exacerbations, eye irritations caused by contact with aerosolized toxins (*K. brevis*).	Temperature (increased water temperature), ocean surface currents, ocean acidification, hurricanes (*Gambierdiscus* spp. and *K. brevis*)
Cyanobacteria (multiple freshwater species producing toxins including microcystin)	Drinking water Recreational waters	Liver and kidney damage, gastroenteritis (diarrhea and vomiting), neurologic disorders, and respiratory arrest.	Temperature, precipitation patterns
Enteric bacteria and protozoan parasites: *Salmonella enterica; Campylobacter* species; toxigenic *Escherichia coli; Cryptosporidium*; *Giardia*	Drinking water Recreational waters Shellfish	Enteric pathogens generally cause gastroenteritis. Some cases may be severe and may be associated with long-term and recurring effects.	Temperature (air and water; both increase and decrease), heavy precipitation, and flooding
Enteric viruses: enteroviruses; rotaviruses; noroviruses; hepatitis A and E	Drinking water Recreational waters Shellfish	Most cases result in gastrointestinal illness. Severe outcomes may include paralysis and infection of the heart or other organs.	Heavy precipitation, flooding, and temperature (air and water; both increase and decrease)
Leptospira and *Leptonema* bacteria	Recreational waters	Mild to severe flu-like illness (with or without fever) to severe cases of meningitis, kidney, and liver failure.	Flooding, temperature (increased water temperature), heavy precipitation
Vibrio bacteria species	Recreational waters Shellfish	Varies by species but include gastroenteritis (*V. parahaemolyticus, V. cholerae*), septicemia (bloodstream infection) through ingestion or wounds (*V. vulnificus*), skin, eye, and ear infections (*V. alginolyticus*).	Temperature (increased water temperature), sea level rise, precipitation patterns (as it affects coastal salinity)

migrating populations themselves and in the communities in which they settle. The specific pathogens and patterns of disease that may appear after population migration relate to endemic diseases present in the migrant populations.

Large-scale migrations are common after extreme precipitation events. In August 2022, Pakistan experienced over three times the average rainfall, resulting in extensive flooding. Roughly 33 million people were affected, over 1400 people died, and 1.7 million homes were destroyed, all resulting in large-scale displacement. Additionally, standing water provided ideal breeding sites for vectors, and contaminated flood waters in two southern provinces led to outbreaks of diarrhea, cholera, and malaria. Accelerated computing power now allows for improved attribution of single weather events to climate change. For Pakistan, climate attribution analysis suggests that intense rainfall over short periods (5 days) has become more extreme with warming temperatures.

In low- and middle-income countries, infectious disease outbreaks associated with population displacement may be harder to detect and respond to. People forced to leave their homes en masse are at risk for contracting infections with any pathogen that may be present within the displaced population, including sexually transmitted diseases such as HIV, or airborne or droplet transmitted diseases such as tuberculosis and measles. Reducing disease risk requires overlaying of climate-related migration risk with foci of disease epidemics.

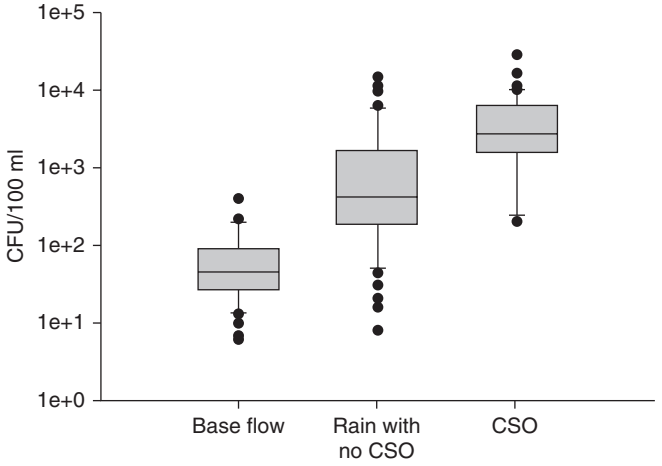

FIGURE 474-8 Levels of *Escherichia coli* in the Milwaukee estuary, which discharges to Lake Michigan, 2001–2007. Levels of *E. coli* in the Milwaukee estuary, which discharges to Lake Michigan, 2001–2007, during base flow (n = 46); following rain events with no CSO (n = 70); and following CSO events (n = 54). Boxes indicate 75% of values, with median values drawn in each. Whiskers are 95% of values, and outliers are shown as closed circles. There were significant differences in *E. coli* levels following rainfall and CSOs compared to base flow ($p \leq 0.05$). CFU, colony forming units; CSO, combined sewer overflow. *(Reproduced with permission from JA Patz et al: Climate change and waterborne disease risk in the Great Lakes region of the U.S. Am J Prev Med 35:451, 2008.)*

A BROADER VIEW OF CLIMATE CHANGE AND HEALTH

While climate change has far-reaching implications for the distribution and severity of infectious diseases worldwide, the greatest disease burdens related to climate change may not be due to infections, at least primarily. Climate change erodes the foundations of health, such as safe drinking water and food security, due to climatic extremes such as flooding or droughts. In addition, resource scarcity and climate instability are increasingly associated with conflicts. For example, severe droughts made more likely by climate change may have been a factor in the revolutions of the Arab Spring and the Syrian civil war. Of course, without adequate nutrition, water, or shelter, infectious disease risks rise.

The public health response to climate change entails both mitigation and adaptation measures. *Mitigation* represents primary prevention and involves the reduction of greenhouse gas emissions into the atmosphere. Although no clear safety threshold of greenhouse gas emissions has been agreed upon, in 2015 at the 21st Conference of the Parties (COP21) of the United Nations Framework Convention on Climate Change (UNFCCC) held in Paris, national governments from the major industrialized countries agreed to set a warming target of <2°C above preindustrial levels by 2050; the attainment of this goal will require reducing greenhouse gas emissions by 40–70% below 2010 levels. At COP21, a framework was established for a global carbon market and nationally determined contributions (NDCs) for countries to commit to greenhouse gas reductions to meet the Paris Climate Agreement. At the 2023 Conference of the Parties (COP28) held in Dubai,

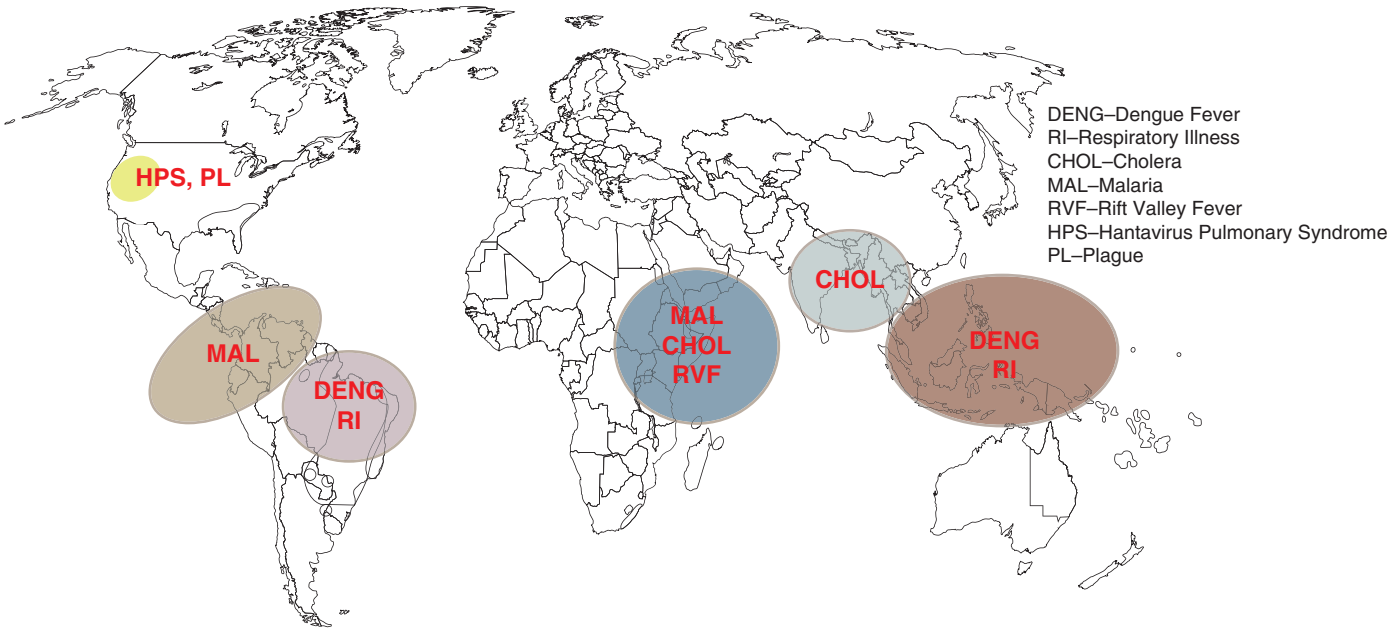

FIGURE 474-9 Characteristic patterns of disease outbreaks associated with El Niño events, determined on the basis of 2006–2007 conditions. *(From A Anyamba et al: Developing global climate anomalies suggest potential disease risks for 2006–2007. Int J Health Geogr 5:60, 2006.)*

for the first time the "need to transition from fossil fuels" was explicitly included in the final text of the agreement.

Mitigation also confers health co-benefits, including better air quality and lower incidence and severity of respiratory infections, associated with less bio- or fossil fuel combustion. One study estimated that by eliminating air quality pollutants (PM 2.5, sulfur dioxide, nitrous oxides) from energy generation across the United States, >53,000 premature deaths would be avoided. Of note, evidence has shown that long-term air pollution exposure may contribute to mortality risk from COVID-19 and influenza. Dietary and agricultural changes can also afford climate change mitigation and improve human health. Resource-intensive foods, like red meat and dairy, can lead to higher cases of diabetes and cardiovascular disease, so switching to plant-based diets can improve human health and reduce greenhouse gas emissions.

Climate *adaptation* is secondary prevention and seeks to reduce harms associated with sea level rise, heat waves, floods, droughts, wildfires, and other greenhouse gas–driven events. The efficacy of adaptation is constrained by the challenges inherent in predicting the precise location, duration, and severity of extreme weather events and flooding related to sea level rise, among other considerations **(Fig. 474-11)**.

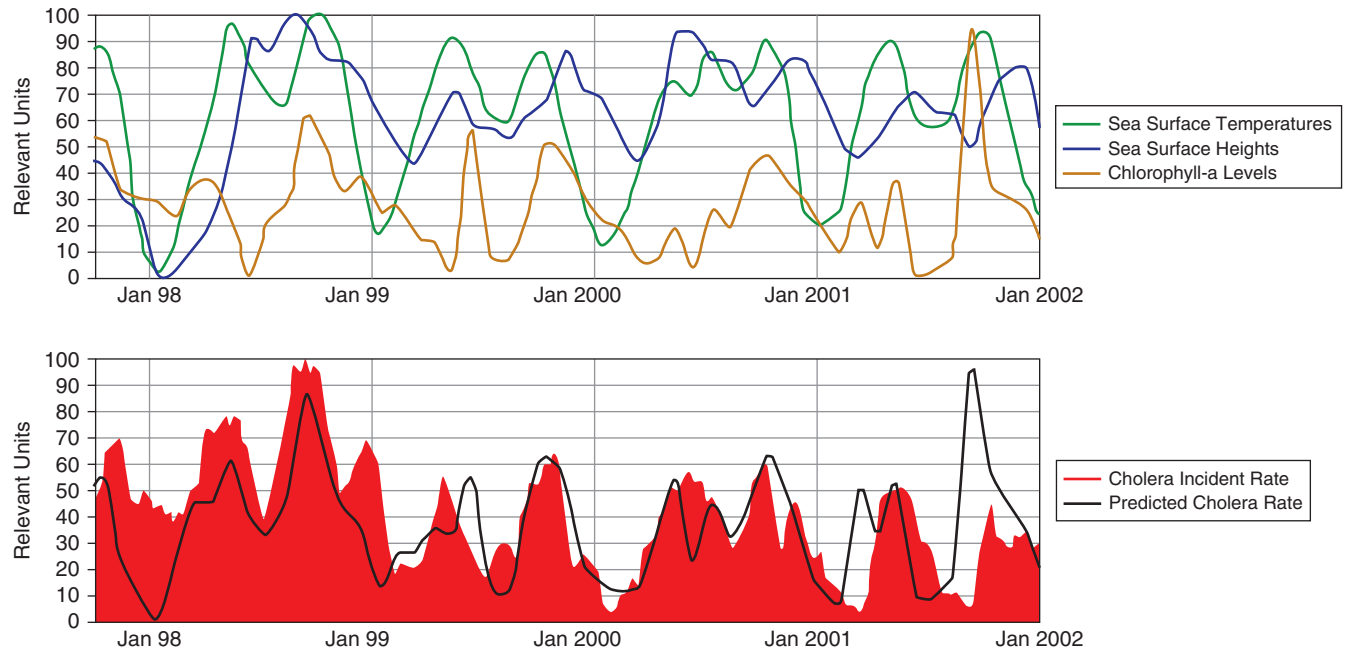

FIGURE 474-10 Predicting cholera rates. Sea surface temperature, sea surface height, and chlorophyll-a predicting cholera in Bangladesh. Top graph illustrates environmental data detected by satellite measurements from the Bay of Bengal from January 1998–January 2002 and includes sea surface temperature (*green line*), sea surface height (*blue line*), and chlorophyll-a levels (*yellow line*), an indicator for the abundance of phytoplankton. Bottom graph illustrates the incidence rate of cholera (*red*) in Bangladesh over that time period. The *black line* combines the three environmental parameters and, superimposed over cholera incidence rate, shows a strong correlation. *(Reproduced with permission from D Grimes et al: Viewing marine bacteria, their activity and response to environmental drivers from orbit: Satellite remote sensing of bacteria. Microb Ecol 67:489, 2014.)*

475 Altitude Illness

Buddha Basnyat, Geoffrey Tabin, Steven Roy

EPIDEMIOLOGY

Mountains cover one-fifth of the earth's surface; 140 million people live permanently at altitudes ≥2500 m, and 100 million people travel to high-altitude locations each year. Skiers in the Alps or Aspen; tourists to La Paz, Ladakh, or Lahsa; religious pilgrims to Kailash-Manasarovar or Gosainkunda; trekkers and climbers to Kilimanjaro, Aconcagua, or Everest; miners working in high-altitude sites in South America; and military personnel deployed to high-altitude locations are all at risk of developing acute mountain sickness (AMS), high-altitude cerebral edema (HACE), high-altitude pulmonary edema (HAPE), and other altitude-related problems. AMS is the benign form of altitude illness, whereas HACE and HAPE are life-threatening. Altitude illness is likely to occur above 2500 m but has been documented even at 1500–2500 m. In the Mount Everest region of Nepal, ~50% of trekkers who walk to altitudes >4000 m over ≥5 days develop AMS, as do 84% of people who fly directly to 3860 m. The incidences of HACE and HAPE are much lower than that of AMS, with estimates in the range of 0.1–4%. Finally, reentry HAPE, which in the past was generally limited to highlanders (long-term residents of altitudes >2500 m) in the Americas, is now being seen in Himalayan and Tibetan highlanders—and often misdiagnosed as a viral illness—as a result of recent rapid air, train, and motorable-road access to high-altitude settlements.

PHYSIOLOGY

Ascent to a high altitude subjects the body to a decrease in barometric pressure that results in a decreased partial pressure of oxygen in the inspired gas in the lungs. This change leads in turn to less pressure, driving oxygen diffusion from the alveoli and throughout the oxygen cascade. A normal initial "struggle response" to such an ascent includes increased ventilation—the cornerstone of acclimatization—mediated

by the carotid bodies. Hyperventilation may cause respiratory alkalosis and dehydration. Respiratory alkalosis may be extreme, with an arterial blood pH of >7.7 (e.g., at the summit of Everest). Alkalosis may depress the ventilatory drive during sleep, with consequent periodic breathing and hypoxemia. During early acclimatization, renal suppression of carbonic anhydrase and excretion of dilute alkaline urine combat alkalosis and tend to bring the pH of the blood to normal. Other physiologic changes during normal acclimatization include increased sympathetic tone; increased erythropoietin levels, leading to increased hemoglobin levels and red blood cell mass; increased tissue capillary density and mitochondrial numbers; and higher levels of 2,3-bisphosphoglycerate, enhancing oxygen utilization. Even with normal acclimatization, however, ascent to a high altitude decreases maximal exercise capacity (by ~1% for every 100 m gained above 1500 m) and increases susceptibility to cold injury due to peripheral vasoconstriction. If the ascent is made faster than the body can adapt to the stress of hypobaric hypoxemia, altitude-related disease states can result.

GENETICS

Hypoxia-inducible factor, which acts as a master switch in high-altitude adaptation, controls transcriptional responses to hypoxia throughout the body and is involved in the release of vascular endothelial growth factor (VEGF) in the brain, erythropoiesis, and other pulmonary and cardiac functions at high altitudes. In particular, the gene *EPAS1*, which codes for transcriptional regulator hypoxia-inducible factor 2α, appears to play an important role in the adaptation of Tibetans living at high altitude, resulting in lower hemoglobin concentrations than are found in Han Chinese or South American highlanders. Other genes implicated include *EGLN1* and *PPARA*, which are also associated with hemoglobin concentration. Some evidence indicates that these genetic changes occurred within the past 3000 years, which is very fast in evolutionary terms. An intriguing question is whether the Sherpas' well-known mountain-climbing ability is partially attributable to their Tibetan ancestry, with overrepresentation of variants of *EPAS*. A striking recent finding is that some of these genetic characteristics may stem from those of Denisovan hominids who were contemporaries of the Neanderthals.

For acute altitude illness, a single gene variant is unlikely to be found, but differences in the susceptibility of individuals and populations, familial clustering of cases, and a positive association of some genetic variants all clearly support a role for genetics.

ACUTE MOUNTAIN SICKNESS AND HIGH-ALTITUDE CEREBRAL EDEMA

AMS is a neurologic syndrome characterized by nonspecific symptoms (headache, nausea, fatigue, and dizziness), with a paucity of physical findings, developing 6–12 h after ascent to a high altitude. AMS is a clinical diagnosis. For uniformity in research studies, the Lake Louise Scoring System, created at the 1991 International Hypoxia Symposium, is generally used without the sleep disturbance score. AMS must be distinguished from exhaustion, dehydration, hypothermia, alcoholic hangover, and hyponatremia. AMS and HACE are thought to represent opposite ends of a continuum of altitude-related neurologic disorders. HACE (but not AMS) is an encephalopathy whose hallmarks are ataxia and altered consciousness with diffuse cerebral involvement but generally without focal neurologic deficits. Progression to these signal manifestations can be rapid. Papilledema and, more commonly, retinal hemorrhages may develop. In fact, retinal hemorrhages occur frequently at ≥5000 m, even in individuals without clinical symptoms of AMS or HACE.

Risk Factors The most important risk factors for the development of altitude illness are the rate of ascent and a prior history of high-altitude illness. Exertion is a risk factor, but lack of physical fitness is not. An attractive but still speculative hypothesis proposes that AMS develops in people who have inadequate cerebrospinal capacity to buffer the brain swelling that occurs at high altitude. Children and adults seem to be equally affected, but people >50 years of age may be less likely to develop AMS than younger people. In general, there is no gender difference in AMS incidence. Sleep desaturation—a common phenomenon at high altitude—is associated with AMS. Debilitating fatigue consistent with severe AMS on descent from a summit is an important risk factor for death in mountaineers. A prospective study involving trekkers and climbers who ascended to altitudes between 4000 and 8848 m showed that high oxygen desaturation and low ventilatory response to hypoxia during exercise are independent predictors of severe altitude illness. However, because there may be a large overlap between groups of susceptible and nonsusceptible individuals, accurate cutoff values are hard to define. Prediction is made more difficult because the pretest probabilities of HAPE and HACE are low. Neck irradiation or surgery damaging the carotid bodies, respiratory tract infections, and dehydration appear to be other potential risk factors for altitude illness. Unless guided by clinical signs and symptoms, pulse oximeter readings alone on a trek should not be used to predict AMS.

Pathophysiology Hypobaric hypoxia is the main trigger for altitude illness. In established AMS, raised intracranial pressure, increased sympathetic activity, relative hypoventilation, fluid retention and redistribution, and impaired gas exchange have all been well noted; these factors may play an important role in the pathophysiology of AMS. Severe hypoxemia can lead to a greater than normal increase in cerebral blood flow. However, the exact mechanisms underlying AMS and HACE are unknown. Evidence points to a central nervous system process. Magnetic resonance imaging (MRI) studies have suggested that vasogenic (interstitial) cerebral edema is a component of the pathophysiology of HACE. In the setting of high-altitude illness, the MRI findings shown in **Fig. 475-1** are confirmatory of HACE, with increased signal in the white matter and particularly in the splenium of the corpus callosum. In addition, hemosiderin deposits in the corpus callosum have been characterized as long-lasting footprints of HACE. Quantitative analysis in an MRI study revealed that hypoxia is associated with mild vasogenic cerebral edema irrespective of AMS. This finding is in keeping with case reports of suddenly symptomatic brain tumors and of cranial nerve palsies without AMS at high altitudes. Vasogenic edema may become cytotoxic (intracellular) in severe HACE.

Impaired cerebral autoregulation in the presence of hypoxic cerebral vasodilation and altered permeability of the blood-brain barrier due to hypoxia-induced chemical mediators like histamine, arachidonic acid, and VEGF may all contribute to brain edema. In 1995, VEGF was first proposed as a potent promoter of capillary leakage in the brain at

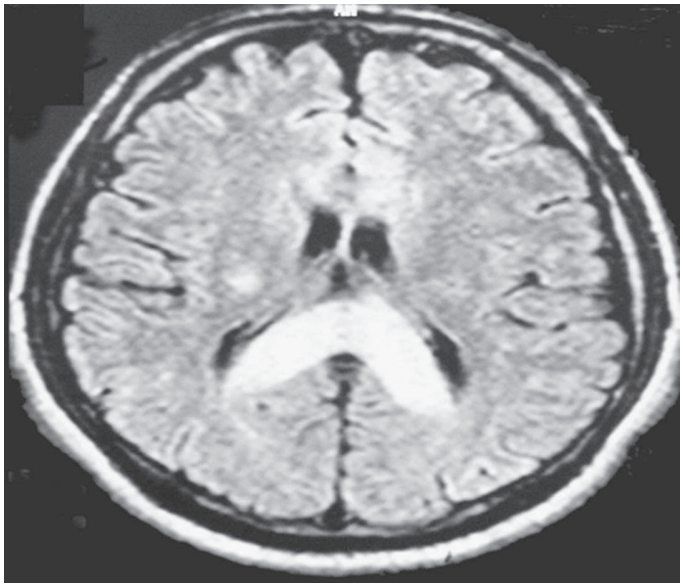

FIGURE 475-1 T2 magnetic resonance image of the brain of a patient with high-altitude cerebral edema (HACE) shows marked swelling and a hyperintense posterior body and splenium of the corpus callosum (area with dense opacity). The patient, a climber, went on to climb Mount Everest about 9 months after this episode of HACE. *(From B Basnyat et al: Clinical images. A mystery. Wilderness Environ Med 15: 53, 2004. Reused with permission from the Wilderness Medical Society. ©2004 Wilderness Medical Society.)*

high altitude, and studies in mice have borne out this role. Although studies of VEGF in climbers have yielded inconsistent results regarding its association with altitude illness, indirect evidence of a role for this growth factor in AMS and HACE comes from the observation that dexamethasone, when used in the prevention and treatment of these conditions, blocks hypoxic upregulation of VEGF. Other factors in the development of cerebral edema may be the release of calcium-mediated nitric oxide and neuronally mediated adenosine, which may promote cerebral vasodilation. Venous outflow obstruction resulting in increased brain capillary pressure is also thought to play an important role in the development of HACE. Lesions in the globus pallidum (which is sensitive to hypoxia) leading to Parkinson's disease have been reported to be complications of HACE.

The pathophysiology of the most common and prominent symptom of AMS—headache—remains unclear because the brain itself is an insensate organ; only the meninges contain trigeminal sensory nerve fibers. The cause of high-altitude headache is multifactorial. Various chemicals and mechanical factors activate a final common pathway, the trigeminovascular system. In the genesis of high-altitude headache, the response to nonsteroidal anti-inflammatory drugs and glucocorticoids provides indirect evidence for involvement of the arachidonic acid pathway and inflammation.

Prevention and Treatment **(Table 475-1)** Gradual ascent, with adequate time for acclimatization, is the best method for the prevention of altitude illness. Even though there may be individual variation in the rate of acclimatization, a conservative approach would be a graded ascent of ≤300 m from the previous day's sleeping altitude above 3000 m, and taking every third day of gain in sleeping altitude as an extra day for acclimatization is helpful. Spending one night at an intermediate altitude before proceeding to a higher altitude may enhance acclimatization and attenuate the risk of AMS. Another protective factor in AMS is recent high-altitude exposure; for example, the incidence and severity of AMS at 4300 m are reduced by 50% with an ascent after 1 week at an altitude ≥2000 m rather than with an ascent from sea level. However, regarding the benefits of acclimatization, clear-cut randomized studies are lacking. Repeated exposure at low altitudes to hypobaric or normobaric hypoxia is termed *preacclimatization*. Preacclimatization is gaining popularity with commercially available normobaric hypoxia "tents" used for weeks to months in preparation for the climb. However, current evidence has not shown significant effects of such technology.

Clearly, a flexible itinerary that permits additional rest days will be helpful. Sojourners to high-altitude locations must be aware of the symptoms of altitude illness and should be encouraged not to ascend further if these symptoms develop. Any hint of HAPE (see below) or HACE mandates descent. Proper hydration (but not overhydration) in high-altitude trekking and climbing, aimed at countering fluid loss due to hyperventilation and sweating, may play a role in avoiding AMS. Pharmacologic prophylaxis at the time of travel to high altitudes is warranted for people with a history of AMS or when a graded ascent and acclimatization are not possible—e.g., when rapid ascent is necessary for rescue purposes or when flight to a high-altitude location is required. Acetazolamide is the drug of choice for AMS prevention. It inhibits renal carbonic anhydrase, causing prompt bicarbonate diuresis that leads to metabolic acidosis and hyperventilation. Acetazolamide (125 mg twice daily), administered for 1 day before ascent and continued for about 3 days at the same altitude, is effective. Treatment can be restarted if symptoms return after discontinuation of the drug. Higher doses are not required. A meta-analysis limited to randomized controlled trials revealed that 125 mg of acetazolamide twice daily was effective in the prevention of AMS, with a relative-risk reduction of ~48% from values obtained with placebo. Paresthesia and a tingling sensation are common side effects of acetazolamide. Some other uncommon side effects are myopia and drowsiness. This drug is a nonantibiotic sulfonamide that has low-level cross-reactivity with sulfa antibiotics; as a result, severe reactions are rare. Dexamethasone (8 mg/d in divided doses) is also effective. A large-scale, randomized, double-blind, placebo-controlled trial in partially acclimatized trekkers clearly showed that *Ginkgo biloba* is ineffective in the prevention of AMS. In randomized studies, ibuprofen (600 mg three times daily) has been shown to be beneficial in the prevention of AMS. Recently, acetaminophen (1 g three times daily) was as effective as ibuprofen at the above dosage in a randomized, double-blind study, which did not have a placebo arm. However, more definitive studies are needed to clarify whether these medications mask the symptoms of altitude illness or whether they prevent the pathophysiology of AMS and assess the risk profile of side effects before these drugs can be routinely recommended for AMS prevention. Many drugs, including spironolactone, medroxyprogesterone, magnesium, calcium channel blockers, and antacids, confer no benefit in the prevention of AMS. Starkly conflicting results from a number of trials of inhaled budesonide for the prevention of AMS have recently been published, but, in all likelihood, the drug is ineffective. Similarly, no efficacy studies are available for coca leaves (a weak form of cocaine), which are offered to high-altitude travelers in the Andes, or for *soroche* pills, which contain aspirin, caffeine, and acetaminophen and are sold over the counter in Bolivia and Peru. Finally, a word of caution applies in the pharmacologic prevention of altitude illness. A fast-growing population of climbers in pursuit of a summit are injudiciously using prophylactic drugs such as glucocorticoids in an attempt to improve their performance; the outcome can be tragic because of potentially severe side effects of these drugs, especially if taken for a long duration.

For the treatment of mild AMS, rest alone with analgesic use may be adequate. Descent and the use of acetazolamide and (if available) oxygen are sufficient to treat most cases of moderate AMS. Even a minor descent (400–500 m) may be adequate for symptom relief. For moderate AMS or early HACE, dexamethasone (4 mg orally or parenterally) is highly effective. For HACE, immediate descent is mandatory. When descent is not possible because of poor weather conditions or darkness, a simulation of descent in a portable hyperbaric chamber **(Fig. 475-2)** can be very effective. Pressurization in the bag for 1–2 h often leads

TABLE 475-1 Management of Altitude Illness

CONDITION	MANAGEMENT
Acute mountain sickness (AMS), mild[a]	Discontinuation of ascent Treatment with acetazolamide (250 mg q12h) Descent[b]
AMS, moderate[a]	Immediate descent for worsening symptoms Use of low-flow oxygen if available Treatment with acetazolamide (250 mg q12h) and/or dexamethasone (4 mg q6h)[c] Hyperbaric therapy[d]
High-altitude cerebral edema (HACE)	Immediate descent or evacuation Administration of oxygen (2–4 L/min) Treatment with dexamethasone (8 mg PO/IM/IV; then 4 mg q6h) Hyperbaric therapy if descent is not possible
High-altitude pulmonary edema (HAPE)	Immediate descent or evacuation Minimization of exertion while patient is kept warm Administration of oxygen (4–6 L/min) to bring O_2 saturation to >90% Adjunctive therapy with nifedipine[e] (30 mg, extended-release, q12h) Hyperbaric therapy if descent is not possible

[a]Categorization of cases as mild or moderate is a subjective judgment based on the severity of headache and the presence and severity of other manifestations (nausea, fatigue, dizziness). [b]No fixed altitude is specified; the patient should descend to a point below that at which symptoms developed. [c]Acetazolamide treats and dexamethasone masks symptoms. For prevention (as opposed to treatment) of AMS, 125 mg of acetazolamide q12h or (when acetazolamide is contraindicated—e.g., in people with a history of sulfa anaphylaxis) 4 mg of dexamethasone q12h may be used. [d]In hyperbaric therapy (Fig. 475-2), the patient is placed in a portable altitude chamber or bag to simulate descent. [e]Nifedipine at this dose is also effective for the prevention of HAPE, as are tadalafil (10 mg twice daily), sildenafil (50 mg three times per day), and dexamethasone (8 mg twice daily). Preventative therapy should be continued for about 3 days after arriving at the target altitude. If prompt descent follows arrival at target altitude, continuation of preventative therapy is unnecessary.

FIGURE 475-2 A hyperbaric bag. The cylindrical, portable (<7 kg) nylon bag has a one-way valve to prevent carbon dioxide buildup. A patient with severe acute mountain sickness (AMS), high-altitude cerebral edema (HACE), or high-altitude pulmonary edema (HAPE) is zipped inside the bag, which is continuously inflated with a foot pedal. The increased barometric pressure (2 psi) inside the bag simulates descent; for example, at 4250 m, the equivalent "elevation" inside the bag is ~2100 m. No supplemental oxygen is required.

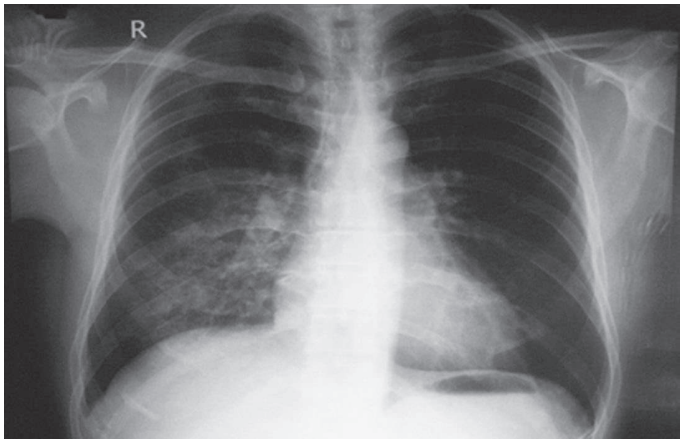

FIGURE 475-3 Chest radiograph of a patient with high-altitude pulmonary edema shows opacity in the right middle and lower zones simulating pneumonic consolidation. The opacity cleared almost completely in 2 days with descent and supplemental oxygen.

to spectacular improvement and, like dexamethasone administration, "buys time." Thus, in certain high-altitude locations (e.g., remote pilgrimage sites), the decision to bring along the lightweight hyperbaric chamber may prove lifesaving. Like nifedipine, phosphodiesterase-5 inhibitors have no role in the treatment of AMS or HACE. Finally, short-term oxygen inhalation using small cannisters of oxygen or by visiting oxygen bars is unhelpful in the prevention of AMS.

HIGH-ALTITUDE PULMONARY EDEMA

Risk Factors and Manifestations Unlike HACE (a neurologic disorder), HAPE is primarily a pulmonary problem and therefore is not necessarily preceded by AMS. HAPE develops within 2–4 days after arrival at high altitude; it rarely occurs after >4 or 5 days at the same altitude, probably because of remodeling and adaptation that render the pulmonary vasculature less susceptible to the effects of hypoxia. A rapid rate of ascent, a history of HAPE, respiratory tract infections, and cold environmental temperatures are risk factors. Men are more susceptible than women. People with abnormalities of the cardiopulmonary circulation leading to pulmonary hypertension—e.g., mitral stenosis, primary pulmonary hypertension, and unilateral absence of the pulmonary artery—may be at increased risk of HAPE, even at moderate altitudes. Although patent foramen ovale, a common condition, is four times more common among HAPE-susceptible individuals than in the general population, there is no compelling evidence to suggest causal effect. Echocardiography is recommended when HAPE develops at relatively low altitudes (<3000 m) and whenever cardiopulmonary abnormalities predisposing to HAPE are suspected. The differential diagnosis of HAPE includes anxiety attack, pneumonia, pneumothorax, and pulmonary embolism.

The initial manifestation of HAPE may be a reduction in exercise tolerance greater than that expected at the given altitude. Although a dry, persistent cough may presage HAPE and may be followed by the production of blood-tinged sputum, cough in the mountains is almost universal and the mechanism is poorly understood. Tachypnea and tachycardia, even at rest, are important markers as illness progresses. Crackles may be heard on auscultation but are not diagnostic. HAPE may be accompanied by signs of HACE. Patchy or localized opacities **(Fig. 475-3)** or streaky interstitial edema may be noted on chest radiography. In the past, HAPE was mistaken for pneumonia due to the cold or for heart failure due to hypoxia and exertion. Kerley B lines or a bat-wing appearance are not seen on radiography. Electrocardiography may reveal right ventricular strain or even hypertrophy. Hypoxemia and respiratory alkalosis are consistently present in patients with HAPE. Alkalemia is often present, unless the patient is taking acetazolamide, in which case metabolic acidosis may supervene. Assessment of arterial blood gases is not necessary in the evaluation of HAPE; an oxygen saturation reading with a pulse oximeter is generally adequate. The existence of a subclinical form of HAPE has been suggested by an increased alveolar-arterial oxygen gradient in Everest climbers near the summit, but hard evidence correlating this abnormality with the development of clinically relevant HAPE is lacking. Comet-tail scoring—an ultrasound technique initially validated in cardiogenic pulmonary edema—has been used for evaluation of extravascular lung water at high altitude. However, B-lines are not just seen in patients with HAPE and are frequently detected in individuals who never go on to develop clinical HAPE. For this reason, comet-tail scoring is sensitive but not specific for HAPE, and clinical correlation is important.

Pathophysiology HAPE is a noncardiogenic pulmonary edema with normal pulmonary artery wedge pressure. It is characterized by patchy pulmonary hypoxic vasoconstriction that leads to overperfusion in some areas. This abnormality leads in turn to increased pulmonary capillary pressure (>18 mmHg) and capillary "stress" failure. The exact mechanism for this hypoxic vasoconstriction is unknown. Endothelial dysfunction due to hypoxia may play a role by impairing the release of nitric oxide, an endothelium-derived vasodilator. At high altitude, HAPE-prone persons have reduced levels of exhaled nitric oxide. The effectiveness of phosphodiesterase-5 inhibitors in alleviating altitude-induced pulmonary hypertension, decreased exercise tolerance, and hypoxemia supports the role of nitric oxide in the pathogenesis of HAPE. One study demonstrated that prophylactic use of tadalafil, a phosphodiesterase-5 inhibitor, decreases the risk of HAPE by 65%. In contrast, the endothelium also synthesizes endothelin-1, a potent vasoconstrictor whose concentrations are higher than average in HAPE-prone mountaineers.

Exercise and cold lead to increased pulmonary intravascular pressure and may predispose to HAPE. In addition, hypoxia-triggered increases in sympathetic drive may lead to pulmonary venoconstriction and extravasation into the alveoli from the pulmonary capillaries. Consistent with this concept, phentolamine, which elicits α-adrenergic blockade, improves hemodynamics and oxygenation in HAPE more than do other vasodilators. The study of tadalafil cited above also investigated dexamethasone in the prevention of HAPE. Surprisingly, dexamethasone reduced the incidence of HAPE by 78%—a greater decrease than with tadalafil. Besides possibly increasing the availability of endothelial nitric oxide, dexamethasone may have altered the excessive sympathetic activity associated with HAPE: the heart rate of participants in the dexamethasone arm of the study was significantly lowered. Finally, people susceptible to HAPE also display enhanced sympathetic activity during short-term hypoxic breathing at low altitudes.

Because many patients with HAPE have fever, peripheral leukocytosis, and an increased erythrocyte sedimentation rate, inflammation

has been considered an etiologic factor in HAPE. However, strong evidence suggests that inflammation in HAPE is an epiphenomenon rather than the primary cause. Nevertheless, inflammatory processes (e.g., those elicited by viral respiratory tract infections) do predispose persons to HAPE—even those who are constitutionally resistant to its development.

Another proposed mechanism for HAPE is impaired transepithelial clearance of sodium and water from the alveoli. β-Adrenergic agonists upregulate the clearance of alveolar fluid in animal models. In a single double-blind, randomized, placebo-controlled study of HAPE-susceptible mountaineers, prophylactic inhalation of the β-adrenergic agonist salmeterol reduced the incidence of HAPE by 50%. However, the dosage of salmeterol (125 μg twice daily) used was very high, which could result in excessive tachycardia and tremors. Other effects of β agonists may also contribute to the prevention of HAPE, and these findings are in keeping with the concept that alveolar fluid clearance may play a pathogenic role in this illness.

Prevention and Treatment (Table 475-1) Allowing sufficient time for acclimatization by ascending gradually (as discussed above for AMS and HACE) is the best way to prevent HAPE. Sustained-release nifedipine (30 mg), given twice daily, prevents HAPE in people who must ascend rapidly or who have a history of HAPE. Other drugs for the prevention of HAPE are listed in Table 475-1 (footnote e). Although dexamethasone is listed for prevention, its adverse effect profile requires close monitoring. Acetazolamide has been shown to blunt hypoxic pulmonary vasoconstriction in animal models, and this observation warrants further study in HAPE prevention. However, one large study failed to show a decrease in pulmonary vasoconstriction in partially acclimatized individuals given acetazolamide. Inhaled salmeterol is not recommended as clinical experience with this drug is limited at high altitude. Finally, potent diuretics like furosemide should be avoided in the treatment of HAPE. Early recognition is paramount in the treatment of HAPE, especially when it is not preceded by the AMS symptoms of headache and nausea. Fatigue and dyspnea at rest may be the only initial manifestations. Descent and the use of supplementary oxygen (aimed at bringing oxygen saturation to >90%) are the most effective therapeutic interventions. Exertion should be kept to a minimum, and the patient should be kept warm. Hyperbaric therapy (Fig. 475-2) in a portable altitude chamber may be lifesaving, especially if descent is not possible and oxygen is not available. Oral sustained-release nifedipine (30 mg twice daily) can be used as adjunctive therapy. No studies have investigated phosphodiesterase-5 inhibitors in the treatment of HAPE, but reports have described their use in clinical practice. The mainstays of treatment remain descent and (if available) oxygen.

In AMS, if symptoms abate (with or without acetazolamide), the patient may reascend gradually to a higher altitude. Unlike that in acute respiratory distress syndrome (another noncardiogenic pulmonary edema), the architecture of the lung in HAPE is usually well preserved, with rapid reversibility of abnormalities (Fig. 475-3). This fact has allowed some people with HAPE to reascend slowly after a few days of descent and rest. In HACE, reascent after a few days may not be advisable during the same trip.

OTHER HIGH-ALTITUDE PROBLEMS

Sleep Impairment The mechanisms underlying sleep problems, which are among the most common adverse reactions to high altitude, include increased periodic breathing; changes in sleep architecture, with increased time in lighter sleep stages; and changes in rapid eye movement sleep. Sojourners should be reassured that sleep quality improves with acclimatization. In cases where drugs do need to be used, acetazolamide (125 mg before bedtime) is especially useful because this agent decreases hypoxemic episodes and alleviates sleeping disruptions caused by excessive periodic breathing. Whether combining acetazolamide with temazepam or zolpidem is more effective than administering acetazolamide alone is unknown. In combinations, the doses of temazepam and zolpidem should not be increased by >10 mg at high altitudes. Limited evidence suggests that diazepam causes hypoventilation at high altitudes and therefore is contraindicated. For trekkers with obstructive sleep apnea who are using a continuous positive airway pressure (CPAP) machine, the addition of acetazolamide, which will decrease centrally mediated sleep apnea, may be helpful. There is evidence to show that obstructive sleep apnea at high altitude may decrease and "convert" to central sleep apnea.

Gastrointestinal Issues High-altitude exposure may be associated with increased gastric and duodenal bleeding, but further studies are required to determine whether there is a causal effect. Because of decreased atmospheric pressure and consequent intestinal gas expansion at high altitudes, many sojourners experience abdominal bloating and distension as well as excessive flatus expulsion. In the absence of diarrhea, these phenomena are normal, if sometimes uncomfortable. Accompanying diarrhea, however, may indicate the involvement of bacteria or *Giardia* parasites, which are common at many high-altitude locations in the developing world. Prompt treatment with fluids and empirical antibiotics may be required to combat dehydration in the mountains. Hemorrhoids are common on high-altitude treks; treatment includes hot soaks, application of hydrocortisone ointment, and measures to avoid constipation.

High-Altitude Cough High-altitude cough can be debilitating and is sometimes severe enough to cause rib fracture, especially at >5000 m. The etiology of this common problem is probably multifactorial. Although high-altitude cough has been attributed to inspiration of cold dry air, this explanation appears not to be sufficient by itself; in long-duration studies in hypobaric chambers, cough has occurred despite controlled temperature and humidity. The implication is that hypoxia also plays a role. Exercise can precipitate cough at high altitudes, possibly because of water loss from the respiratory tract. In general, infection does not seem to be a common etiology. Many trekkers find it useful to wear a balaclava to trap some moisture and heat. In most situations, cough resolves upon descent.

High-Altitude Neurologic Events Unrelated to "Altitude Illness" Transient ischemic attacks (TIAs) and strokes have been well described in high-altitude sojourners outside the setting of altitude sickness. However, these descriptions are not based on cause (hypoxia) and effect. In general, symptoms of AMS present gradually, whereas many of these neurologic events happen suddenly. The population that suffers strokes and TIAs at sea level is generally an older age group with other risk factors, whereas those so afflicted at high altitudes are generally younger and probably have fewer risk factors for atherosclerotic vascular disease. Other mechanisms (e.g., migraine, vasospasm, focal edema, hypocapneic vasoconstriction, hypoxia in the watershed zones of minimal cerebral blood flow, or cardiac right-to-left shunt) may be operative in TIAs and strokes at high altitude.

Subarachnoid hemorrhage, transient global amnesia, delirium, and cranial nerve palsies (e.g., lateral rectus palsy) occurring at high altitudes but outside the setting of altitude sickness have been well described. Syncope is common at moderately high altitudes, generally occurs shortly after ascent, usually resolves without descent, and appears to be a vasovagal event related to hypoxemia. Seizures occur rarely with HACE, but hypoxemia and hypocapnia, which are prevalent at high altitudes, are well-known triggers that may contribute to new or breakthrough seizures in predisposed individuals. Nevertheless, the consensus among experts is that sojourners with well-controlled seizure disorders can ascend to high altitudes.

Finally, persons with hypercoagulable conditions (e.g., antiphospholipid syndrome, protein C deficiency) who are asymptomatic at sea level may experience cerebral venous thrombosis (possibly due to enhanced blood viscosity triggered by polycythemia and dehydration) at high altitudes. Proper history taking, examination, and prompt investigations where possible will help define these conditions as entities separate from altitude sickness. Administration of oxygen (where available) and prompt descent are the cornerstones of treatment of most of these neurologic conditions.

Ocular Problems Ocular issues are common in sojourners to high altitudes. Hypoxemia induced by altitude leads to increased retinal

blood flow, which can be visible as engorged retinal veins on ophthalmoscopic examination. Both high flow and hypoxemic vascular damage causing permeability have been implicated in a breakdown of the blood-retina barrier and the formation of retinal hemorrhages. Blot, dot, flame, and white-centered hemorrhages can be observed. These hemorrhages usually resolve spontaneously with descent, with only mild symptoms and no lasting visual damage in most healthy eyes. The exception is hemorrhage in the macular area. Macular hemorrhages can cause devastating initial visual loss, particularly if bilateral, and have been reported to cause permanently decreased vision in a few cases.

Stroke syndromes such as retinal vein occlusion, retinal artery occlusion, ischemic optic neuropathy, and cortical visual loss have all been reported. With unilateral vision loss, it is always important to check for a relative afferent pupillary defect. Increased hematocrit combined with dehydration may contribute to these maladies. Glaucomatous optic nerve damage may progress with hypoxemia of altitude. Acetazolamide is helpful both in combating the respiratory alkalosis that comes with increased ventilation at high altitude and in lowering the interocular pressure; its use should be considered in patients with stable controlled glaucoma. Macular degeneration and diabetic eye disease are not directly exacerbated by ascent to high altitude. Dry eye and solar damage to the cornea, known as "snow blindness," are common. Wearing of high-quality UV-blocking sunglasses, even on cloudy days, and attention to protecting and supplementing the tear film with artificial tear drops can greatly improve comfort and vision. Although modern refractive surgeries, such as photorefractive keratectomy (PRK) and laser in situ keratomileusis (LASIK), are stable at high altitude, patients who have undergone radial keratotomy should be cautioned that hypoxemia to the cornea can lead to swelling that shifts the refraction during ascent.

Psychological/Psychiatric Problems Delirium characterized by a sudden change in mental status, a short attention span, disorganized thinking, and an agitated state during the period of confusion has been well described in mountain climbers and trekkers without a prior history. In addition, anxiety attacks, often triggered at night by excessive periodic breathing, are well documented. The contribution of hypoxia to these conditions is unknown. Expedition medical kits need to include antipsychotic injectable drugs to control psychosis in patients in remote high-altitude locations.

PREEXISTING MEDICAL ISSUES

Because travel to high altitudes is increasingly popular, common conditions such as hypertension, coronary artery disease, and diabetes are more frequently encountered among high-altitude sojourners. This situation is of particular concern for the millions of elderly pilgrims with medical problems who visit high-altitude sacred areas (e.g., in the Himalayas) each year. In recent years, high-altitude travel has attracted intrepid trekkers who are taking immunosuppressive medications (e.g., kidney transplant recipients or patients undergoing chemotherapy). Recommended vaccinations and other precautions (e.g., hand washing) may be especially important for this group. Although most of these medical conditions do not appear to influence susceptibility to altitude illness, they may be exacerbated by ascent to altitude, exertion in cold conditions, and hypoxemia. Advice regarding the advisability of high-altitude travel and the impact of high-altitude hypoxia on these preexisting conditions is becoming increasingly relevant, but there are no evidence-based guidelines. In addition, recommendations made for relatively low altitudes (~3000 m) may not hold true for higher altitudes (>4000 m), where hypoxic stress is greater. Personal risks and benefits must be clearly thought through before ascent.

Hypertension At high altitudes, enhanced sympathetic activity may lead to a transient rise in blood pressure. Occasionally, nonhypertensive, healthy, asymptomatic trekkers have pathologically high blood pressure at high altitude that rapidly normalizes without medicines on descent. Sojourners should continue to take their antihypertensive medications at high altitudes. Importantly, hypertensive patients are not more likely than others to develop altitude illness. Because the probable mechanism of high-altitude hypertension is α-adrenergic activity, anti-α-adrenergic drugs such as prazosin have been suggested for symptomatic patients and those with labile hypertension. It is best to start taking the drug several weeks before the trip and to carry a sphygmomanometer if a trekker has labile hypertension. Sustained-release nifedipine may also be useful. A recent observational cohort study of 672 hypertensive and nonhypertensive trekkers in the Himalayas showed that most travelers, including those with well-controlled hypertension, can be reassured that their blood pressure will remain relatively stable at high altitude. Although blood pressure may be extremely elevated at high altitude in normotensive and hypertensive people, it is unlikely to cause symptoms.

Coronary Artery Disease Myocardial oxygen demand and maximal heart rate are reduced at high altitudes because the VO_2 max (maximal oxygen consumption) decreases with increasing altitude. This effect may explain why signs of cardiac ischemia or dysfunction usually are not seen in healthy persons at high altitudes. Asymptomatic, fit individuals with no risk factors need not undergo any tests for coronary artery disease before ascent. For persons with ischemic heart disease, previous myocardial infarction, angioplasty, and/or bypass surgery, an exercise treadmill test is indicated. A strongly positive treadmill test is a contraindication for high-altitude trips. Patients with poorly controlled arrhythmias should avoid high-altitude travel, but patients with arrhythmias that are well controlled with antiarrhythmic medications do not seem to be at increased risk. Sudden cardiac deaths are not noted with a greater frequency in the Alps than at lower altitudes; although sudden cardiac deaths are encountered every trekking season in the higher Himalayan range, accurate documentation is lacking.

Cerebrovascular Disease Patients with TIAs should avoid travel to high altitude for at least 3 months. Patients with known cerebral aneurysm should also avoid high-altitude travel because of possible rupture of the aneurysm due to increased cerebral blood flow at high altitude.

Migraine Trekkers with a history of migraine may have an increased likelihood of suffering from AMS and may also be predisposed to headaches including altered character of their migraine presenting with focal neurologic deficits. Oxygen inhalation may reduce AMS-triggered headache, whereas a migraine headache usually persists even after 10–15 min of oxygen inhalation.

Asthma Although cold air and exercise may provoke acute bronchoconstriction, asthmatic patients usually have fewer problems at high than at low altitudes, possibly because of decreased allergen levels and increased circulating catecholamine levels. Nevertheless, asthmatic individuals should carry all their medications, including oral glucocorticoids, with proper instructions for use in case of an exacerbation. Severely asthmatic persons should be cautioned against ascending to high altitudes.

Pregnancy In general, low-risk pregnant women ascending to 3000 m are not at special risk except for the relative unavailability of medical care in many high-altitude locations, especially in developing countries. Despite the lack of firm data on this point, venturing higher than 3000 m to altitudes at which oxygen saturation drops steeply seems unadvisable for pregnant women.

Obesity Although living at a high altitude has been suggested as a means of controlling obesity, obesity has also been reported to be a risk factor for AMS, probably because nocturnal hypoxemia is more pronounced in obese individuals. Hypoxemia may also lead to greater pulmonary hypertension, thus possibly predisposing the trekker to HAPE.

Sickle Cell Disease High altitude is one of the rare environmental exposures that occasionally provokes a crisis in persons with sickle cell anemia. Even when traversing mountain passes as low as 2500 m, people with sickle cell anemia have been known to have a vaso-occlusive crisis. Patients with known sickle cell anemia who need to travel to high altitudes should use supplemental oxygen and travel with caution. Thalassemia has not been known to cause problems at high altitude.

Diabetes Mellitus Well-controlled diabetes is not a contraindication for travel to high altitude. Most of the high-altitude diabetes advice is based on patients with type 1 diabetes and not type 2 diabetic patients with comorbidities. Altitude is known to both increase and decrease insulin sensitivity. An eye examination before travel may be useful. Insulin pumps are increasingly used, but bubble formation in the system may need to be closely monitored. For most diabetic patients, a continuous glucose monitor (CGM) is likely the best choice for glucose monitoring in the high-altitude environment, but a reliable glucometer should be carried by all diabetic patients. Regardless of the glucose monitoring modality selected, patients should be comfortable with the plan and transition appropriately. It is important for companions of diabetic trekkers to be fully aware of potential problems like hypoglycemia and have ready access to sweets.
