Chronic Lung Disease Depending on disease severity and access to medical care, preexisting lung disease may not always preclude high-altitude travel. A proper pretravel evaluation must be conducted. Supplemental oxygen may be required if the predicted PaO_2 for the altitude is <50–55 mmHg. Preexisting pulmonary hypertension may also need to be assessed in these patients. If the result is positive, patients should be discouraged from ascending to high altitudes; if such travel is necessary, treatment with sustained-release nifedipine (30 mg twice a day) should be considered. Small-scale studies have revealed that when patients with bullous disease reach ~5000 m, bullous expansion and pneumothorax are not noted. Compared with information on chronic obstructive pulmonary disease, fewer data exist about the safety of travel to high altitude for people with pulmonary fibrosis, but acute exacerbation of pulmonary fibrosis has been seen at high altitude. A handheld pulse oximeter can be useful to check for oxygen saturation.

Chronic Kidney Disease Patients with chronic kidney disease can tolerate short-term stays at high altitudes, but theoretical concern persists about progression to end-stage renal disease. Acetazolamide, the drug most commonly used for altitude sickness, should be avoided by anyone with preexisting metabolic acidosis, which can be exacerbated by this drug. In addition, the acetazolamide dosage should be adjusted when the glomerular filtration rate falls to <50 mL/min, and the drug should not be used at all if this value falls to <10 mL/min.

Cirrhosis Of patients with cirrhosis, 16% may have portopulmonary arterial hypertension, and 32% may have hepatopulmonary syndrome; these conditions may be detrimental at high altitude as they may cause exaggerated hypoxemia. Thus, screening for these problems is important in cirrhotic patients planning a high-altitude trip. In addition, acetazolamide may be inadvisable in these patients as the drug may increase the risk of hepatic encephalopathy.

COVID-19 Evaluation is warranted before planned high-altitude travel in individuals who required care in an intensive care unit or suffered from myocarditis or arterial or venous thromboembolism. Preparticipation evaluation is also warranted in patients with persistent symptoms at least 2 weeks after a positive COVID-19 test or hospital discharge. Depending on the results of this evaluation, planned high-altitude travel may need to be modified or even deferred pending resolution of the identified abnormalities.

Dental Problems Air resulting from decay in the root system could expand on ascent and lead to increasing pain. A good dental checkup before a trekking or climbing trip may be prudent.

Malignancy Patients with current or previous malignancy may be affected in a variety of ways by altitude. Both radiation of the neck or paraganglioma/chemodectomas (which are seen at higher rates in residents of high-altitude areas) may result in carotid body dysfunction and reduced acclimatization. Pulmonary toxicities from chemotherapies (e.g., bleomycin) and radiation of the chest increase pulmonary artery pressures and impair lung function, theoretically increasing the risk of HAPE and decreasing exercise tolerance. Some chemotherapies such as bleomycin have traditionally been thought to increase susceptibility of lung tissue to oxygen toxicity and may complicate the use of supplemental oxygen, if needed. Cardiotoxic therapies for cancer decrease exercise tolerance and increase cardiovascular disease. Such patients will be at increased cardiovascular risk with strenuous activity or hypoxic stress that is expected at altitude. Patients with known metastasis to bone or those at high risk should be evaluated prior to expedition travel.

CHRONIC MOUNTAIN SICKNESS AND HIGH-ALTITUDE PULMONARY HYPERTENSION IN HIGHLANDERS

The largest populations of highlanders live in the South American Andes, the Tibetan Plateau, and parts of Ethiopia. Chronic mountain sickness (*Monge's disease*) is a disease in highlanders that is characterized by excessive erythrocytosis with moderate to severe pulmonary hypertension leading to cor pulmonale. This condition was originally described in South America and has also been documented in Colorado and in the Han Chinese population in Tibet; it is much less common in Tibetans or in Ethiopian highlanders. Migration to a low altitude results in the resolution of chronic mountain illness. Venesection and acetazolamide are helpful.

High-altitude pulmonary hypertension is also a subacute disease of long-term high-altitude residents. Unlike Monge's disease, this syndrome is characterized primarily by pulmonary hypertension (not erythrocytosis) leading to heart failure. Indian soldiers living at extreme altitudes for prolonged periods and Han Chinese infants born in Tibet have presented with the adult and infantile forms, respectively. High-altitude pulmonary hypertension bears a striking pathophysiologic resemblance to brisket disease in cattle. Descent to a lower altitude is curative.

476 Hyperbaric and Diving Medicine

Simon J. Mitchell, Richard E. Moon

Hyperbaric medicine is the treatment of certain health disorders using whole-body exposure to pressures >101.3 kPa (1 atmosphere or 760 mmHg). In practice, this invariably includes breathing oxygen during the exposure, thus the administration of hyperbaric oxygen therapy (HBO_2T). The Undersea and Hyperbaric Medical Society (UHMS) defines HBO_2T as "a medical procedure requiring a physician's prescription and oversight" in which "patients must have their entire body placed within a hard sided hyperbaric chamber that meets

FIGURE 476-1 A monoplace chamber. The chamber is compressed with 100% oxygen. Although direct patient access is not possible, intravenous administration of fluids and drugs, ventilation, and invasive monitoring can be performed. *(Prince of Wales Hospital, Sydney.)*

the American Society of Mechanical Engineers and Pressure Vessels for Human Occupancy (ASME-PVHO-1) code, and the National Fire Protection Agency (NFPA 99) code and standards for hyperbaric chambers, at a pressure of not less than 2.0 atmospheres absolute (ATA) (202.65 kPa) while breathing physician prescribed medical grade oxygen for an amount of time that is typically between 90-120 minutes per treatment."

Historically, compression chambers were first used for the treatment of divers and compressed air workers suffering decompression sickness (DCS; "the bends"). Now they are used for treating a variety of problems, and relevant chambers are variously called a hyperbaric chamber, recompression chamber, or decompression chamber, depending on the clinical and historical context. They may be capable of compressing a single patient (a monoplace chamber) or multiple patients and attendants as required (a multiplace chamber) **(Figs. 476-1 and 476-2)**. In multiplace chambers, the chamber atmosphere is pressurized with air and the patient breathes oxygen through a special delivery system. The same may be true of monoplace chambers, although in some, the chamber environment is pressurized with oxygen and the patient simply breathes from that environment.

MECHANISMS OF HYPERBARIC OXYGEN THERAPY

In the late 1800s, the earliest systematic use of pressure as a therapeutic modality was in treating decompression sickness, a disorder caused by bubbles in blood or tissues. The use of pressure (recompression) to instantly reduce bubble size made mechanistic sense and met with obvious clinical success when instituted. In the 1960s, oxygen breathing during hyperbaric exposure was incorporated into recompression protocols to increase the diffusion gradient for inert gas from bubble to tissue to blood and alveoli. This too appeared to improve outcomes. Recompression of divers is further discussed under "Diving Medicine."

FIGURE 476-2 A multiplace chamber. Multiplace chambers are compressed with air; 100% oxygen is administered via head tent, mask, or endotracheal tube. These chambers can treat several patients simultaneously and can easily accommodate critically ill and intubated patients. *(Karolinska University Hospital.)*

Use of HBO_2T in nondiving disease focused initially on indications such as carbon monoxide poisoning, nonhealing wounds, and radiation tissue injury, where it was believed that hypoxia was a fundamental contributory problem and that hyperbaric oxygen could ameliorate this. Indeed, breathing oxygen at hyperbaric pressures not only ensures complete saturation of hemoglobin in blood but also results in markedly elevated quantities of dissolved oxygen in arterial plasma at a very high Po_2. Most HBO_2T regimens involve oxygen breathing at between 203 and 284 kPa (2 and 2.8 ATA). Breathing oxygen at 284 kPa (2.8 ATA) can theoretically increase the arterial Po_2 to more than ~270 kPa (~2025 mmHg) and the volume of oxygen dissolved in plasma to ~60 mL/L, with the latter being sufficient to sustain life without hemoglobin as proven in animal studies. The very high arterial Po_2 markedly improves oxygen diffusion distances through tissues. As with pressure and oxygen breathing for bubble disorders in diving, the use of markedly elevated plasma oxygen levels in treating hypoxic wounds and irradiated tissue also met with apparent success, initially reinforcing the belief that intermittent support of oxygen-dependent healing processes such as fibroblast replication, collagen deposition and cross-linking, and angiogenesis was the principal mechanism by which HBO_2T could be helpful.

As important as this mechanism may be, more recent research has revealed that intermittent hyperbaric hyperoxia has physical and biochemical/cell signaling effects that extend well beyond simple support of oxygen-dependent healing processes and the duration of the hyperbaric exposure. Indeed, there are pharmacologic effects that are profound and relatively long-lasting. Some of these are summarized in **Fig. 476-3**.

Thus, although removal from the hyperbaric chamber results in a rapid return of poorly vascularized tissues to their hypoxic state, even a single dose of HBO_2T produces changes in fibroblast, leukocyte and angiogenic functions, and antioxidant defenses that persist many hours after oxygen tensions are returned to pretreatment levels. Explanations for this effect focus on production of reactive oxygen species (ROS) such as superoxide (O_2^-), hydrogen peroxide (H_2O_2), and reactive nitrogen species (RNS) such as nitric oxide (NO) during exposure to hyperbaric hyperoxia. It appears that these species, often considered harmful in biological tissues, participate in diverse cell signaling pathways involved in production of a range of cytokines, angiogenic growth factors, and other modulators of inflammation and tissue repair whose net effect is to accelerate healing. Such mechanisms are complex and at times apparently paradoxical. For example, it is well established by in vitro and in vivo studies that notionally proinflammatory pulses of oxidative stress induced by hyperbaric hyperoxia actually result in subsequent anti-inflammatory effects such as reduced leukocyte β2 integrin adhesion molecule expression, an effect that may be protective when flaps and grafts are threatened or if endothelium is damaged by circulating bubbles.

Most of the important indications for HBO_2T are now recognized as benefiting in some way from activity in these cell signaling pathways. For example, when used to treat chronic hypoxic wounds, HBO_2T has been shown to enhance bacterial killing and phagocytosis by providing the oxygen substrate for macrophage activity; stimulate the synthesis of multiple angiogenic growth factors; inhibit leukocyte activation and adherence to damaged endothelium; and mobilize pluripotent vasculogenic progenitor cells from the bone marrow. The interactions between these mechanisms remain a very active field of investigation.

Figure 476-3 also depicts several other mechanisms of action that may be relevant in certain situations. Hyperoxia tends to induce vasoconstriction and that, along with the exaggerated standing osmotic gradient between an ultra-high Po_2 in arteriolar blood and the much lower Po_2 in tissues, may reduce tissue edema. Hyperoxia is also directly toxic or bacteriostatic to anaerobic bacteria.

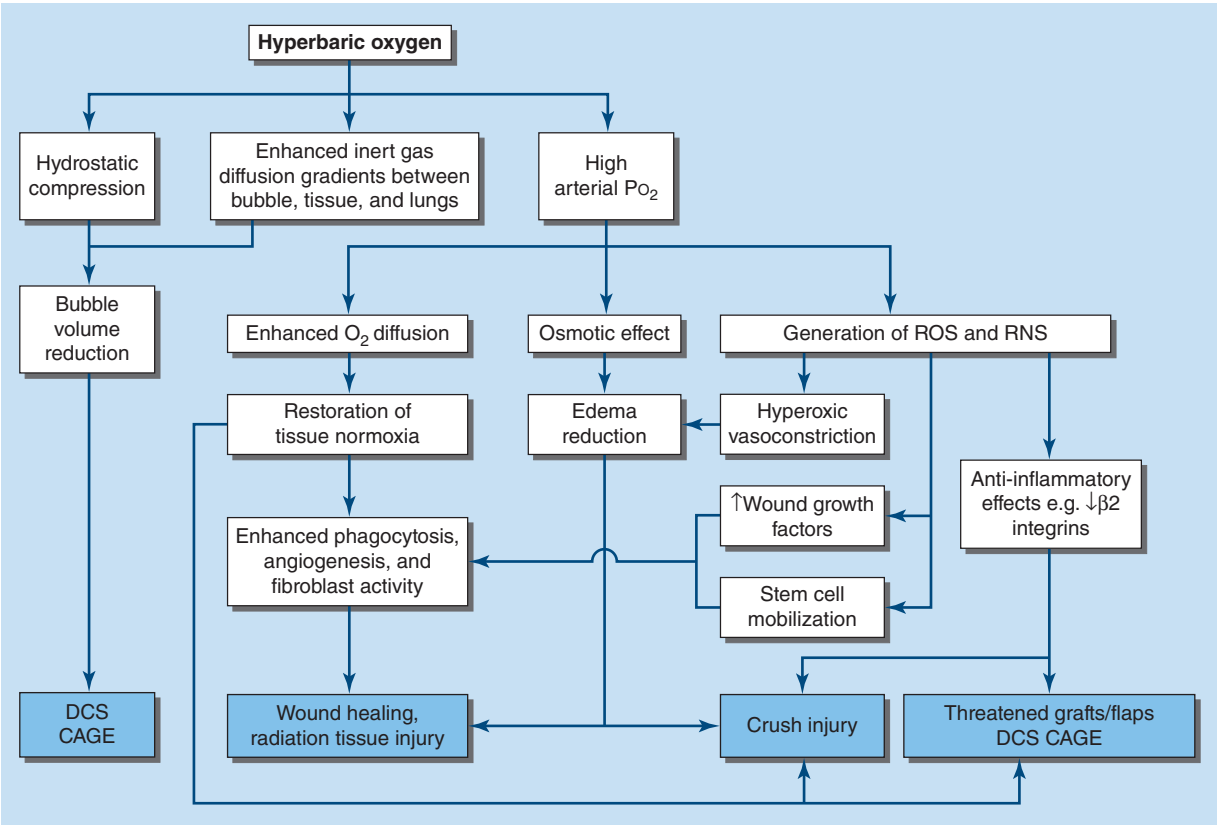

FIGURE 476-3 Mechanisms of action of hyperbaric oxygen. There are many consequences of compression and oxygen breathing. The cell-signaling effects are potentially most important. Examples of indications are shown in the shaded boxes. CAGE, cerebral arterial gas embolism; DCS, decompression sickness; RNS, reactive nitrogen species; ROS, reactive oxygen species.

INDICATIONS FOR HYPERBARIC OXYGEN THERAPY

The "accepted" indications for HBO_2T are evolving and sometimes controversial. In 1977, the UHMS systematically examined claims for the use of HBO_2T in >100 disorders and found sufficient evidence to support routine use in only 12. The Hyperbaric Oxygen Therapy Committee of that organization has continued to update this list periodically (to the current list of 15) **(Table 476-1)** with an increasingly formalized system of appraisal for new indications and emerging evidence. Around the world, other relevant medical organizations have generally taken a similar approach. However, accepted indications vary considerably—particularly those recommended by hyperbaric medical societies in Russia and China where HBO_2T has gained much wider support than in the United States, Europe, and Australasia. Nevertheless, there are now >30 Cochrane reviews summarizing the randomized trial evidence for 27 putative indications, and numerous other systematic reviews, including attempts to examine the cost-effectiveness of HBO_2T. Following are short reviews of three important indications currently accepted by the UHMS, and a brief summary of several exploratory indications.

Late Radiation Tissue Injury Radiotherapy is a well-established treatment for suitable malignancies. In the United States alone, ~300,000 individuals annually will become long-term survivors of cancer treated by irradiation. Developments in radiotherapy techniques such as intensity-modulated radiation therapy and hypofractionated stereotactic radiation therapy have improved the precision of radiation delivery. This has allowed the use of higher doses of radiation with better cure rates, but the incidence of radiation-related complications has not changed much. Serious radiation-related complications developing months or years after treatment (late radiation tissue injury [LRTI]) will significantly affect between 5 and 10% of long-term survivors, although incidence varies widely with dose, age, and site. LRTI may involve bone or soft tissue and is most common in the head and neck, chest wall, breast, and pelvis (where it may involve the bowel or bladder).

PATHOLOGY AND CLINICAL COURSE One explanation for long-term injury to irradiated tissue is that initial radiation exposure produces fibrosis and an obliterative endarteritis from which the tissue may be incapable of recovering because of its hypovascular hypoxic nature. Indeed, its microvascularity may continue to deteriorate slowly over months to years with breakdown occasionally occurring spontaneously or when accelerated by an event like trauma or surgery. An alternative model of pathogenesis suggests that rather than a primary hypoxic state, the principal trigger is an overexpression of inflammatory cytokines that promote fibrosis, probably through oxidative stress and mitochondrial dysfunction, with tissue hypoxia as a secondary provocation. Ultimately, and once again often triggered by a further physical insult such as surgery or infection, there may be insufficient

TABLE 476-1 Current List of Indications for Hyperbaric Oxygen Therapy

1. Air or gas embolism (includes diving-related, iatrogenic, and accidental causes)
2. Carbon monoxide poisoning (including poisoning complicated by cyanide poisoning)
3. Clostridial myositis and myonecrosis (gas gangrene)
4. Crush injury, compartment syndrome, and acute traumatic ischemias
5. Decompression sickness
6. Arterial insufficiency including central retinal arterial occlusion and problem wounds
7. Severe anemia
8. Intracranial abscess
9. Necrotizing soft tissue infections (e.g., Fournier's gangrene)
10. Osteomyelitis (refractory to other therapy)
11. Delayed radiation injury (soft tissue injury and bony necrosis)
12. Skin grafts and flaps (compromised)
13. Acute thermal burn injury
14. Sudden sensorineural hearing loss
15. Avascular necrosis (aseptic osteonecrosis)

Source: The Undersea and Hyperbaric Medical Society (2024).

oxygen to sustain normal function, and the tissue becomes necrotic (radiation necrosis).

LRTI may be life-threatening and significantly reduce quality of life. Historically, the management of these injuries has been unsatisfactory. Conservative treatment is usually restricted to symptom management, whereas definitive treatment traditionally entails surgery to remove the affected part and extensive repair. Surgical intervention in an irradiated field is often disfiguring and associated with an increased incidence of delayed healing, breakdown of a surgical wound, or infection. HBO_2T may act by several mechanisms, including edema reduction, vasculogenesis, and enhancement of macrophage activity (Fig. 476-3). However, the ability of HBO_2T to promote angiogenesis in irradiated tissue represents the most important effect. The intermittent application of HBO_2T is the only intervention shown in multiple studies to increase the microvascular density in irradiated tissue in both animals and humans.

CLINICAL EVIDENCE The typical course of HBO_2T consists of 30–60 once-daily compressions to 202.6–243.1 kPa (2–2.4 ATA) for 1.5–2 h each session, often bracketed around surgical intervention if required. Although HBO_2T has been used for LRTI since at least 1975, most clinical studies have been limited to small case series or individual case reports. A 2023 Cochrane systematic review included 18 randomized controlled trials (RCTs) published since 1985 and was able to draw the following conclusions based on meta-analysis. Pooled analysis of studies across all LRTI types suggested HBO_2T improves tissue healing (risk ratio [RR] of healing with HBO_2T, 1.39; 95% confidence interval [CI], 1.02–1.89). In patients with osteoradionecrosis of the jaw or at risk of osteoradionecrosis of the jaw following planned surgery, HBO_2T reduced the risk of wound dehiscence (RR, 0.24; 95% CI, 0.06–0.94). The report also detailed individual randomized studies with notable positive results, particularly in regard to radiation proctitis and radiation cystitis. There were also negative randomized studies in both these indications.

Current UHMS guidelines (see Huang in "Further Reading") support use of HBO_2T for most forms of LRTI, a problem that is notoriously difficult to treat by other means. The American Society of Colon and Rectal Surgeons designated HBO_2T as a class 1B intervention (strongly indicated based on moderate-quality evidence) for radiation proctitis. A previous strongly positive RCT in treating bleeding radiation cystitis (RR for complete or significant improvement after HBO_2T, 3.63; 95% CI, 1.69–7.79) was recently corroborated by the Dartmouth Multicenter International Registry Initiative. In 370 bleeding patients treated with HBO_2T, the Radiation Therapy Oncology Group hematuria score fell from a median of 2 (interquartile range [IQR], 2) to 0 (IQR, 2) (see Moses et al. in "Further Reading"). Despite occasional positive case reports, results for radiation-induced neurologic injuries (brain and spinal cord) are less encouraging.

Selected Problem Wounds A problem wound is any cutaneous ulceration that requires a prolonged time to heal, does not heal, or recurs. In general, wounds referred to hyperbaric facilities are those for which sustained attempts to heal by other means have failed. Problem wounds are common and constitute a significant health problem. It has been estimated that 1% of the population of industrialized countries will experience a leg ulcer at some time. The global cost of chronic wound care may be as high as U.S. $25 billion per year.

PATHOLOGY AND CLINICAL COURSE By definition, chronic wounds are indolent or deteriorating and resistant to the wide array of treatments applied. Although there are many contributing factors, these wounds most commonly arise in association with one or more comorbidities such as diabetes, peripheral venous or arterial disease, or prolonged pressure (decubitus ulcers). A common denominator among these various contributors is hypoxia. First-line treatments are aimed at correction of the underlying pathologies (e.g., vascular reconstruction, compression bandaging, normalization of nutritional deficiencies or normalization of blood glucose level). HBO_2T should be regarded as an adjunctive therapy to be applied simultaneously with amelioration of all modifiable risk factors for nonhealing wounds and good general wound care practice to maximize the chance of healing.

Not all problem wounds will respond to HBO_2T. A selection process based on responses to an oxygen challenge is often recommended. Wounds in hypoxic tissues often display poor or absent healing and have potential to benefit from HBO_2T depending on the cause, magnitude, and reversibility of hypoxia. Some causes of tissue hypoxia will be reversible with HBO_2T (e.g., microvascular disease and tissue edema), whereas some will respond better to surgical revascularization (e.g., critical arterial stenosis). When tissue hypoxia can be overcome by a high driving pressure of oxygen in the arterial blood, this can be demonstrated by measuring transcutaneous Po_2 using a modified transcutaneous Clarke electrode. It follows that many guidelines for patient selection for HBO_2T include the interpretation of transcutaneous oxygen tensions around the wound while breathing air and oxygen at pressure **(Fig. 476-4)**. Other methods include simple ankle-brachial index and skin perfusion pressure.

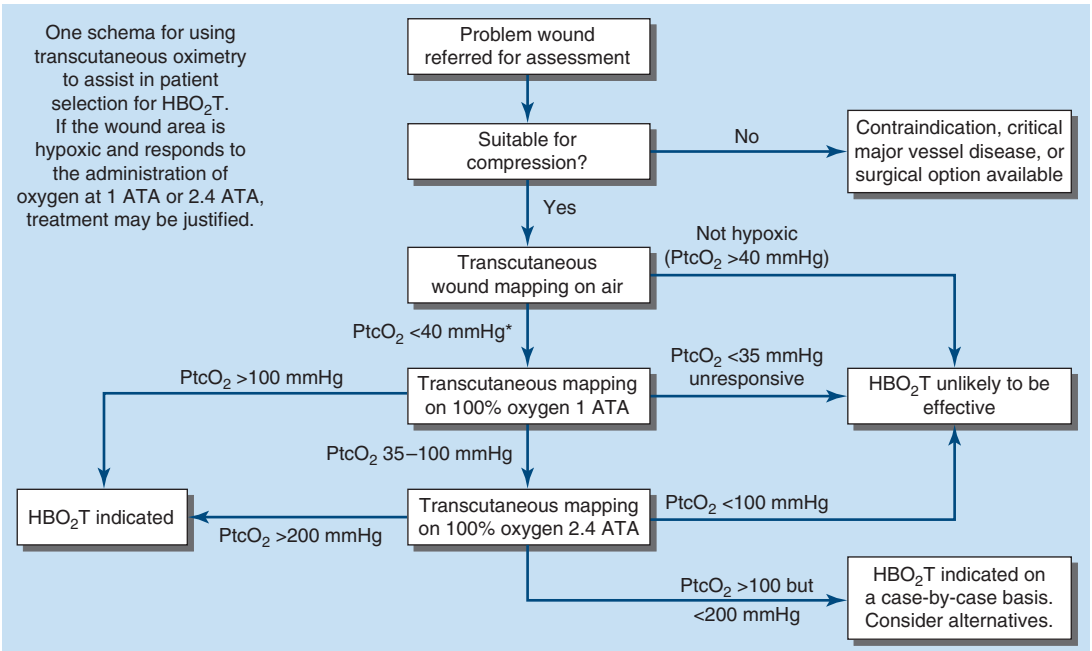

FIGURE 476-4 Determining suitability for hyperbaric oxygen therapy guided by transcutaneous oximetry around the wound bed. *In diabetic patients, <50 mmHg may be more appropriate. $PtcO_2$, transcutaneous oxygen pressure.

CLINICAL EVIDENCE The typical course of HBO_2T consists of 20–40 once-daily compressions to 2–2.4 ATA for 1.5–2 h each session but is highly dependent on the clinical response. Both retrospective and prospective cohort studies suggest that 6 months after a course of therapy, ~70% of indolent ulcers will be substantially improved or healed. Often these ulcers have been present for many months or years, suggesting the application of HBO_2T significantly improves the healing trajectory, either primarily or in conjunction with other strategies. A 2015 Cochrane review included 12 RCTs and concluded that the chance of a diabetic ulcer healing improved with HBO_2T (10 trials; RR, 2.35; 95% CI, 1.19–4.62). Although there was a trend toward reduced risk of major amputations with HBO_2T, it did not reach statistical significance (RR, 0.36; 95% CI, 0.11–1.18). A 2024 meta-analysis of 29 RCTs (see Chen et al. in "Further Reading") reported that in patients with diabetic foot ulcers treated with HBO_2T there was increased complete healing (odds ratio [OR], 2.8; 95% CI, 2.3–3.5) and reduced amputations (OR, 0.41; 95% CI, 0.18–0.95). Using data from a recent randomized trial, the cost per limb saved in treating severe (Wagner stage III/IV) diabetic foot ulcers with HBO_2T in the Netherlands was €19,005 (95% CI, –€18,487 to €264,334) (see Brouwer et al. in "Further Reading").

Carbon Monoxide Poisoning Carbon monoxide (CO) is a colorless, odorless gas formed during incomplete hydrocarbon combustion. Although CO is an essential endogenous neurotransmitter linked to NO metabolism and activity, it is also a leading cause of poisoning deaths and, in the United States alone, results in >50,000 emergency department visits per year and ~2000 deaths. Although there are large variations from country to country, about half of nonlethal exposures are due to self-harm. Accidental poisoning is commonly associated with defective or improperly installed heaters, house fires, and industrial exposures. The motor vehicle is by far the most common source of intentional poisoning.

PATHOLOGY AND CLINICAL COURSE The pathophysiology of CO exposure is incompletely understood. CO binds to hemoglobin with an affinity >200 times that of oxygen, directly reducing the oxygen-carrying capacity of blood and further promoting tissue hypoxia by shifting the oxyhemoglobin dissociation curve to the left. CO is also an anesthetic agent that inhibits evoked responses and narcotizes experimental animals in a dose-dependent manner. The associated loss of airway patency together with reduced oxygen carriage in blood may cause death from acute arterial hypoxia. CO also causes harm by other mechanisms including direct disruption of cellular oxidative processes, binding to heme proteins including cytochrome a/a3, and peroxidation of brain lipids.

The brain and heart are the most sensitive target organs, in part due to their high blood flow, poor tolerance of hypoxia, and high oxygen requirements. Minor exposures may be asymptomatic or present with vague constitutional symptoms such as headache, lethargy, and nausea, whereas higher doses may present with poor concentration and cognition, short-term memory loss, confusion, seizures, and loss of consciousness. Carboxyhemoglobin (COHb) levels on admission may confirm exposure but do not reliably reflect the severity or the prognosis of CO poisoning. Over the longer term, surviving patients commonly have neuropsychological sequelae that, for uncertain reasons, are sometimes delayed after an interval of days, weeks, or even months of apparent recovery. Motor disturbances, peripheral neuropathy, hearing loss, vestibular abnormalities, dementia, and psychosis have all been reported. Risk factors for poor outcome are age >35 years, exposure for >24 h, acidosis, and loss of consciousness.

CO poisoning is one of the longest-standing indications for HBO_2T, based traditionally on the obvious connection between exposure and tissue hypoxia and the ability of HBO_2T to rapidly overcome this hypoxia. Moreover, CO is eliminated rapidly via the lungs on application of HBO_2T, with a half-life of ~21 min breathing oxygen at 2.0 ATA versus 5.5 h or 71 min breathing air or oxygen (respectively) at sea level. In practice, it seems unlikely that HBO_2T could be delivered in time to prevent either acute hypoxic death or irreversible global cerebral hypoxic injury in severe cases. Thus, if HBO_2T is beneficial in CO poisoning, it must be by reducing the likelihood of persisting and/or delayed neurocognitive deficits through a mechanism(s) other than the simple reversal of arterial hypoxia due to high levels of COHb. There is evidence that relevant mechanisms include reversal of CO binding to cytochromes, upregulation of oxidative stress defenses, reduction in leukocyte adherence, impairment of lipid peroxidation, and others.

CLINICAL EVIDENCE The typical course of HBO_2T consists of two to three compressions to 2–2.8 ATA for 1.5–2 h each session. It is common for the first two compressions to be delivered within 24 h of the exposure. To date, there have been six RCTs of HBO_2T for CO poisoning, although only four have been reported in full. While a Cochrane review suggested there is insufficient evidence to confirm a beneficial effect of HBO_2T on the chance of persisting neurocognitive deficit following poisoning (34% of patients treated with oxygen at 1 atmosphere vs 29% of those treated with HBO_2T; OR, 0.78; 95% CI, 0.54–1.1), this may have more to do with poor reporting and inadequate follow-up than with evidence that HBO_2T is not effective. In the most methodologically rigorous of the analyzed studies (see Weaver et al. in "Further Reading"), at 6 weeks after poisoning, 46% of patients treated with normobaric oxygen alone had cognitive sequelae compared to 25% of those who received HBO_2T (p = .007; number needed to treat [NNT] = 5; 95% CI, 3–16). At 12 months, the difference remained significant (32 vs 18%; p = .04; NNT = 7; 95% CI, 4–124) despite considerable loss to follow-up.

On this basis, HBO_2T remains widely advocated for the routine treatment of patients with moderate to severe CO poisoning, in particular in those older than 35 years, presenting with a metabolic acidosis on arterial blood-gas analysis, exposed for lengthy periods, or with a history of unconsciousness.

EXPLORATORY INDICATIONS

Inflammatory Bowel Disease There is mounting evidence that HBO_2T enhances healing in flairs of fistulizing Crohn's disease or severe ulcerative colitis. Indeed, there are already two small positive RCTs along with numerous observational studies and case reports of apparent benefit. A multicenter RCT is underway. Benefit in these disorders may arise from enhancement of healing processes described earlier and/or anti-inflammatory activity.

Mild Traumatic Brain Injury After anecdotal reports of success, HBO_2T became a focus of interest for the treatment of veterans returning from Afghanistan with postconcussive syndromes. This led to the execution of three sham-controlled RCTs by the different branches of the U.S. military, which demonstrated improvements in patients receiving both HBO_2T and the sham. These improvements were considered due to placebo effects. However, a fourth study appeared to show benefit for HBO_2T independent of any placebo effect, and collective re-evaluation of all studies suggests that placebo effects account for some but not all of the measured improvements. It follows that there is ongoing interest in HBO_2T for mild traumatic brain injury, but a large definitive study is needed.

SARS-CoV-2 (COVID-19) Infection Although currently of dwindling relevance, it is notable that during the COVID-19 pandemic there were two RCTs of relatively small size and low quality that evaluated the benefit from HBO_2T in hypoxic patients at risk of requiring intubation and ventilation. The studies were underpowered for outcomes such as death or need for mechanical ventilation but did show a faster trajectory of recovery in patients treated with HBO_2T. Those studies along with several observational studies and case reports were recently summarized (see Boet et al. in "Further Reading"). To date, cases of pulmonary barotrauma precipitated by gas trapping in COVID pneumonia have not emerged, but little can be concluded about safety based on reporting of relatively low numbers of cases.

ADVERSE EFFECTS

HBO_2T is generally well tolerated and safe in clinical practice. Patients often experience an adverse event at some time during their treatment

course, but most are mild and self-limiting. Adverse effects are associated with both alterations in pressure (barotrauma) and the administration of oxygen.

Barotrauma Barotrauma may occur when any noncompliant gas-filled space within the body does not equalize with environmental pressure during compression or decompression. Middle ear pain during compression (analogous to descent in an airplane) is the most common complication of HBO_2T, reported in ~30% of patients. Most result in either no or only trivial injury as a result, and prevention by slower compression and training in insufflation of the middle ear via the Eustachian tube is usually successful. Patients unable to insufflate the middle ear and unconscious patients typically require myringotomies or formal grommets across the tympanic membrane. Other less common sites for barotrauma of compression include the respiratory sinuses and dental caries. The lungs are potentially vulnerable to barotrauma of decompression (see "Diving Medicine" below), but the decompression following HBO_2T is so slow that pulmonary barotrauma is extremely rare and has only been seen when a patient has slowly communicating gas trapping lesions such as bullae.

Oxygen Toxicity The practical limit to the oxygen dose (whose components are inspired pressure and duration) in a single treatment session is cerebral oxygen toxicity. The most common acute manifestation is a tonic-clonic seizure, often preceded by facial twitching, anxiety, and agitation. The cause is thought to be an effect of ROSs on excitable neurons. Although clearly dose-dependent, onset is very variable both between individuals and within the same individual on different days. In large series reporting routine clinical hyperbaric practice (compressions to 2–2.4 ATA), the incidence of seizures is ~1–2/10,000 compressions.

Chronic oxygen poisoning most commonly manifests as myopic shift. This is due to alterations in the refractive index of the lens following oxidative damage that reduces the solubility of lenticular proteins, a process similar to that associated with senescent cataract formation. Up to 75% of patients show alteration in visual acuity after a course of 30 treatments at 202.6 kPa (2 ATA). Although most return to pretreatment values 6–12 weeks after cessation of treatment, a small proportion do not revert and may require a change in corrective lenses. A more rapid maturation of preexisting cataracts has occasionally been associated with HBO_2T. Although a theoretical problem, the development of pulmonary oxygen toxicity over time does not seem to be problematic in practice—probably due to the short and intermittent nature of the exposures.

CONTRAINDICATIONS

There are few absolute contraindications to HBO_2T. Untreated pneumothorax is considered a contraindication because intrapleural gas may expand on decompression and come under tension. Prior to any compression, patients with a pneumothorax should have a patent chest drain in place. The presence of other obvious risk factors for pulmonary gas trapping such as bullae should trigger a careful analysis of the risks of treatment versus benefit.

Recent systemic bleomycin or mitomycin C treatment deserves mention because of its association with a partially dose-dependent pneumonitis in ~20% of people. Patients treated with bleomycin, particularly those suffering pneumonitis, are often considered at risk of deterioration in ventilatory function following exposure to high oxygen tensions, even some years after treatment. Published experience suggests the relationship between distant bleomycin exposure and subsequent risk of pulmonary oxygen toxicity may have been overstated, and such patients have undergone uncomplicated HBO_2T. Nevertheless, any patient with a history of receiving these drugs (particularly recently and particularly if there was a consequent pneumonitis) should be carefully evaluated and counseled prior to exposure to HBO_2T.

CHALLENGES AND CONTROVERSIES IN HYPERBARIC MEDICINE

Despite an increased understanding of mechanisms and an improving evidence base, hyperbaric medicine has struggled to achieve widespread adoption in treating relevant disorders. There are several contributing factors, but high among them are a lack of relevant teaching at medical schools and a paucity of large well-conducted RCTs that clearly demonstrate efficacy in the targeted indications.

In turn, it should be appreciated that there are multiple factors that combine as an impediment to large RCTs in hyperbaric medicine. First, funding for clinical research has been difficult in an environment where the pharmacologic agent under study is abundant, cheap, and unpatentable. Second, some of the indications (such as necrotizing fasciitis and central retinal artery occlusion) are rare, sporadic, and acute. Conducting RCTs of treatment in such problems is notoriously difficult, especially where the putative treatment is available in only a small minority of hospitals. Not surprisingly, many of the accepted treatments applied in such problems are not supported by large RCTs. Third, the natural history of an evolving indication in HBO_2T is that treatment might first be tried sporadically in a small number of patients on the basis that its use makes biological sense. Unlike a new drug under development, there are no significant regulatory barriers to this. If apparently successful, then there is a risk that application of HBO_2T may become "accepted" before an RCT is proposed or organized, and clinicians then become reluctant to have patients randomized into a study. Fourth, a course of HBO_2T typically involves substantial commitment in time and logistical effort. This is a disincentive to recruitment of patients into a study with a high likelihood of being allocated to a placebo group. Finally, the potentially powerful placebo effect of HBO_2T is well recognized and highlights the importance of blinded sham controls.

Despite these impediments to RCTs, many have been successfully executed across the various indications for HBO_2T. Some have emerged long after the indication was accepted onto the UHMS list on the basis of lower-level evidence. A good example is crush injury and traumatic ischemia, for which the best supporting RCT has only recently emerged (see Miller et al. in "Further Reading"). Recognizing these challenges, however, an international clinical registry has also been created and is now beginning to produce useful outcome data that, at the very least, can be compared to the known natural history during standard management of the various monitored indications (see "Late Radiation Tissue Injury," above, and Moses et al. in "Further Reading").

Another challenge to the widespread acceptance of HBO_2T for established uses is the continuing misguided advocacy for hyperbaric therapy (sometimes using air breathing) as a panacea for treating numerous diseases, improving general well-being, and slowing aging. The prescription and delivery of HBO_2T requires no medical license in many jurisdictions. Some claims of efficacy refer to small supportive studies with a high risk of bias or placebo effect. Physicians should focus their practice on accepted or approved indications that are periodically updated (see Huang in "Further Reading").

DIVING MEDICINE

Underwater diving is both a popular recreational activity and a means of employment in a range of tasks from underwater construction to military operations. It is a complex activity with unique hazards and medical complications arising mainly as a consequence of the dramatic changes in pressure associated with both descent and ascent through the water column. For every 10.1-m increase in depth of seawater, the ambient pressure (P_{amb}) increases by 101.3 kPa (1 atmosphere) so that, for example, a diver at 20 m depth is exposed to a P_{amb} of 303.9 kPa (3 ATA), made up of 1 ATA due to atmospheric pressure and 2 ATA generated by the water column.

BREATHING EQUIPMENT

Most diving is undertaken using a self-contained underwater breathing apparatus (scuba) consisting of one or more cylinders of compressed gas connected to a pressure-reducing regulator and a demand valve activated by inspiratory effort. Some divers use rebreathers, which comprise a closed or semi-closed breathing circuit with a carbon dioxide scrubber and an oxygen addition system designed to maintain a safe inspired Po_2. Exhaled gas is recycled, and gas consumption is limited to little more than the oxygen metabolized by the diver.

Rebreathers are therefore popular for deep dives where expensive helium is included in the respired mix (see below). Occupational divers frequently use "surface supply" equipment where gas, along with other utilities such as communications and power, is supplied via an "umbilical" cable from the surface.

All these systems must supply gas to the diver at the P_{amb} of the surrounding water or inspiration would be impossible against the water pressure. For most recreational diving, the respired gas is air. Pure oxygen is rarely used because there is a dose-dependent risk (where "dose" is a function of exposure time and inspired Po_2) that oxygen may provoke seizures above an inspired Po_2 of 130 kPa (1.3 ATA). The maximum acceptable inspired Po_2 in diving is often considered to be 161 kPa (1.6 ATA), which would be achieved when breathing pure oxygen at 6 m or air at 66 m. This is a conspicuously lower Po_2 than routinely used for hyperbaric therapy (see earlier), reflecting a higher risk of oxygen toxic seizures during immersion and exercise. In order to maintain a safe Po_2 and avoid dangerous oxygen exposures, very deep diving requires the use of inspired oxygen fractions lower than in air (Fo_2 0.21), and divers tailor the oxygen content of their gases to remain within recommended exposure guidelines. Deep-diving gases include helium as a substitute for some or all of the nitrogen to reduce both the narcotic effect and high gas density that result from breathing nitrogen at high pressures.

SUITABILITY FOR DIVING

The most common reason for physician consultation in relation to diving is for the evaluation of suitability for diver training or continuation of diving after a health event. Occupational diver candidates are usually compelled to see doctors with specialist training in the field, both at entry to the industry and periodically thereafter, and their medical evaluations are usually conducted according to legally mandated standards. In contrast, in most jurisdictions, prospective recreational diver candidates simply complete a self-assessment medical questionnaire prior to diver training. If there are no positive responses, the candidate proceeds directly to training, but positive responses mandate the candidate see a clinician, often a primary care physician, for evaluation of the identified medical issue. In the modern era, such consultations have evolved from a simple proscriptive exercise of excluding those with potential contraindications to an approach in which each case is considered on its own merits and an individualized evaluation of risk is made. Such evaluations require integration of diving physiology, the impact of associated medical problems, and knowledge of the specific medical condition(s) of the candidate. A detailed discussion is beyond the scope of this chapter, but several important principles are outlined below.

There are three primary questions that should be answered in relation to any medical condition reported by a prospective diver: (1) Could the condition be exacerbated by diving? (2) Could the condition make a diving medical problem more likely? (3) Could the condition prevent the diver from meeting the functional requirements of diving? As examples of positive answers to these questions (respectively): epilepsy is usually considered to imply high risk because there are epileptogenic stimuli such as high inspired oxygen pressures encountered in diving that could make a seizure (and drowning) more likely; active asthma is considered to increase risk because it could predispose to air trapping and pulmonary barotrauma (see below); and ischemic heart disease increases risk because it could prevent a diver from exercising sufficiently to get out of a difficult situation such as being caught in a current. It can be a complex matter to recognize the relevant interactions between diving and medical conditions and to determine their impact on suitability for diving. There may follow an equally complex discussion about whether such interactions impart a disqualifying risk, and this may be influenced by the individual candidate's level of risk acceptance and the extent to which others involved (such as dive partners) might be affected. Guidelines are occasionally published on assessment of diving candidates with risk factors for important comorbidities like cardiovascular disease or who have suffered topical problems such as COVID-19 infection (see Sadler in "Further Reading"). Physicians interested in regularly conducting such evaluations should obtain relevant training, for which short courses are offered by specialist groups in most countries.

BAROTRAUMA

Barotrauma is essentially tissue injury arising as a result of ambient pressure changes. Middle-ear barotrauma (MEBT) in diving is similar to the problem that may occur during descent from altitude in an airplane, but difficulties with equalizing pressure in the middle ear are exaggerated underwater by both the rapidity and magnitude of pressure change as a diver descends or ascends. Failure to periodically insufflate the middle-ear spaces via the eustachian tubes during descent results in increasing pain. As the P_{amb} increases, the tympanic membrane may be bruised or even ruptured as it is pushed inward. Relative negative pressure in the middle ear results in engorgement of blood vessels in the surrounding mucous membranes and leads to effusion or bleeding, which can be associated with a *conductive* hearing loss **(Chap. 36)**. MEBT is much less common during ascent because expanding gas in the middle-ear space tends to open the eustachian tube automatically. Barotrauma may also affect the respiratory sinuses, although the sinus ostia are usually widely patent and allow automatic pressure equalization without the need for specific maneuvers. If equalization fails, pain usually results in termination of the dive. Difficulty with equalizing ears or sinuses may respond to oral or nasal decongestants.

Much less commonly, divers may suffer inner ear barotrauma (IEBT). Several explanations have been proposed, of which the most favored holds that forceful attempts to insufflate the middle-ear space by Valsalva maneuvers during descent result in transmission of pressure to the perilymph via the cochlear aqueduct and outward rupture of the round window, which is already under tension because of relative negative middle-ear pressure. The clinician should be alerted to possible IEBT after diving by a *sensorineural* hearing loss or true vertigo (which is often accompanied by nausea, vomiting, nystagmus, and ataxia). These manifestations can also occur in vestibulocochlear decompression sickness (DCS; see below) but should never be attributed to MEBT. Immediate review by an expert diving physician is recommended, and urgent referral to an otologist will often follow.

The lungs are also vulnerable to barotrauma but are at most risk during ascent. If expanding gas becomes trapped in the lungs as P_{amb} falls, this may rupture alveoli and associated vascular tissue. Gas trapping may occur if divers intentionally or involuntarily hold their breath during ascent or if there are bullae. The extent to which asthma predisposes to pulmonary barotrauma is debated, but the presence of active bronchoconstriction must increase risk. For this reason, asthmatics who regularly require bronchodilator medications or whose airways are sensitive to exercise or cold air are usually discouraged from diving. While possible consequences of pulmonary barotrauma include pneumothorax and mediastinal emphysema, the most feared is the introduction of gas into the pulmonary veins leading to cerebral arterial gas embolism (CAGE). Manifestations of CAGE include loss of consciousness, confusion, hemiplegia, visual disturbances, and speech difficulties appearing immediately or within minutes after surfacing. The management is the same as for DCS described below. The natural history of CAGE often includes substantial or complete resolution of symptoms early after the event. This is probably the clinical correlate of bubble involution and redistribution with consequent restoration of blood flow. Patients exhibiting such remissions should still be reviewed at specialist diving medical centers because secondary deterioration or re-embolization can occur. Unsurprisingly, these events can be misdiagnosed as typical strokes or transient ischemic attacks (TIAs) **(Chap. 438)** when patients are seen by clinicians unfamiliar with diving medicine. *All patients presenting with neurologic symptoms after diving should have their symptoms discussed with a specialist in diving medicine and be considered for recompression therapy.*

DECOMPRESSION SICKNESS

DCS is caused by the formation of bubbles from dissolved inert gas (usually nitrogen) during or after ascent (decompression) from a compressed gas dive. Bubble formation is also possible following decompression for extravehicular activity in space and with ascent to altitude

in unpressurized aircraft. DCS in the latter scenarios is probably rare in comparison with diving, where the incidence is ~1 in 5000–10,000 recreational dives.

Breathing at elevated P_{amb} results in increased uptake of inert gas into blood and then into tissues. The rate at which tissue inert gas equilibrates with the inspired inert gas pressure is proportional to tissue blood flow and the blood-tissue partition coefficient for the gas. Similar factors dictate the kinetics of inert gas washout during ascent. If the rate of gas washout from tissues does not match the rate of decline in P_{amb}, then the sum of dissolved gas pressures in the tissue will exceed P_{amb}, a condition referred to as supersaturation. This is the prerequisite for bubbles to form during decompression, although other less well-understood factors are also involved. Deeper and longer dives result in greater inert gas absorption and greater likelihood of tissue supersaturation during ascent. Divers control their ascent for a given depth and time exposure using algorithms that often include periods where ascent is halted for a prescribed period at different depths to allow time for gas washout (decompression stops). Although a breach of these protocols increases the risk of DCS, adherence does not guarantee that it will be prevented. DCS should be considered in any diver manifesting postdive symptoms not readily explained by an alternative mechanism.

Bubbles may form within tissues themselves, where they cause symptoms by mechanical distraction of pain-sensitive or functionally important structures. They also appear in the venous circulation, almost certainly after forming in capillary beds as blood passes through supersaturated tissues. Some venous bubbles are tolerated without symptoms and are filtered from the circulation in the pulmonary capillaries. However, in sufficiently large numbers, these bubbles are capable of inciting inflammatory and coagulation cascades, damaging endothelium, activating formed elements of blood such as platelets, and causing symptomatic pulmonary vascular obstruction. Circulating bubbles can induce endothelial leak, intravascular hypovolemia, and high hematocrit. Moreover, if there is a right-to-left shunt through an atrial septal defect, patent foramen ovale (PFO), or an intrapulmonary shunt, then venous bubbles may enter the arterial circulation (25% of adults have a PFO). The risk of cerebral, spinal cord, inner ear, and skin manifestations appears higher in the presence of significant shunts, suggesting that these "arterialized" venous bubbles can cause harm, perhaps by disrupting flow in the microcirculation of target organs. Circulating microparticles, which are elevated in number and size after diving, are currently under investigation as indicators of decompression stress and as injurious agents in their own right. How they arise and their exact role in DCS remain unclear.

Table 476-2 lists manifestations of DCS grouped according to organ system. The majority of cases present with mild symptoms, including musculoskeletal pain, fatigue, and minor neurologic manifestations such as patchy paresthesias. Serious presentations are much less common. Pulmonary and cardiovascular manifestations can be life-threatening, and spinal cord involvement frequently results in permanent disability. Latency is variable. Serious DCS usually manifests within 60 min of surfacing, but mild symptoms may not appear for several hours. Symptoms arising >24 h after diving are very unlikely to be DCS, unless the diver is exposed to reduced ambient pressure such as during commercial air travel or surface travel at higher altitude. The presentation may be confusing and nonspecific, and there are no useful diagnostic investigations. Diagnosis is based on integration of findings from examination of the dive profile, the nature and temporal relationship of symptoms to diving, and the clinical examination. Some DCS presentations may be difficult to separate from CAGE following pulmonary barotrauma, but from a clinical perspective, the distinction is unimportant because the first aid and definitive management of both conditions are the same.

TABLE 476-2 Manifestations of Decompression Sickness

ORGAN SYSTEM	MANIFESTATIONS
Musculoskeletal	Limb pain
Neurologic	
Cerebral	Confusion
	Visual disturbances
	Speech disturbances
Spinal	Muscular weakness
	Paralysis
	Upper motor neuron signs
	Bladder and sphincter dysfunction
	Dermatomal sensory disturbances
	Abdominal pain
	Girdle pain
Vestibulocochlear	Hearing loss
	Vertigo and ataxia
	Nausea and vomiting
Peripheral	Patchy nondermatomal sensory disturbance
Pulmonary	Cough
	Dyspnea
Cardiovascular	Hemoconcentration
	Coagulopathy
	Hypotension
Cutaneous	Rash, itch
Lymphatic	Soft tissue edema, often relatively localized
Constitutional	Fatigue and malaise

TREATMENT

Decompression Sickness

First aid for either DCS or CAGE includes horizontal positioning, in the lateral decubitus position if consciousness is impaired; intravenous fluids (preferably glucose-free, isotonic intravenous, but if unavailable and the patient is sufficiently conscious, oral fluids); and sustained 100% oxygen administration. The latter accelerates inert gas washout from tissues and promotes resolution of bubbles. Definitive treatment of DCS or CAGE with recompression and hyperbaric oxygen is justified in most instances, although some mild or marginal DCS cases may be managed with first aid measures alone—an option that may be invoked by experienced diving physicians under various circumstances, but especially if evacuation for recompression is hazardous or extremely difficult. Long-distance evacuations are preferably undertaken using a helicopter flying at low altitude or a fixed-wing air ambulance pressurized to 1 ATA, although for serious cases, evacuation should not be delayed only because normobaric evacuation is not possible. Breathing oxygen en route is recommended. If oxygen toxicity is a concern during prolonged evacuation, expert opinion can provide guidance as to a schedule (see below).

Recompression reduces bubble volume in accordance with Boyle's law and increases the inert gas partial pressure difference between a bubble and surrounding tissue. At the same time, oxygen administration markedly increases the inert gas partial pressure difference between alveoli and tissue. The net effect is to significantly increase the rate of inert gas diffusion from bubble to tissue and tissue to blood, thus accelerating bubble resolution. Hyperbaric oxygen also helps oxygenate compromised tissues and may ameliorate some of the proinflammatory effects of bubbles. Various recompression protocols have been advocated, but there are no data that define the optimum approach. Recompression typically begins with oxygen administered at 2.8 ATA, the maximum pressure at which the risk of oxygen toxicity remains acceptable in a hyperbaric chamber. There follows a stepwise decompression over variable periods adjusted to symptom response. The most widely used algorithm is the U.S. Navy Table 6, whose shortest format lasts 4 h and 45 min. Typically, shorter follow-up recompressions are repeated daily while symptoms persist and appear responsive to treatment. Adjuncts to recompression include intravenous fluids and other supportive care

as necessary. For cases of arterial gas embolism, evidence supports the use of intravenous lidocaine to achieve standard antiarrhythmic plasma levels. Occasionally, very sick divers require intubation, ventilation, and intensive care.

The presentation of sick divers to physicians or hospitals without diving medicine expertise creates a risk of misinterpretation of nonspecific manifestations and of consequent mistakes in diagnosis and management. Physicians finding themselves in this situation are strongly advised to expeditiously contact the 24-h worldwide diving emergency advisory service provided by the Divers Alert Network (DAN) at +1-919-684-9111.

Acknowledgment

The authors gratefully acknowledge the major contributions of Professor Michael Bennett (1956–2023) to previous editions of this chapter.

477 Hypothermia and Peripheral Cold Injuries

Daniel F. Danzl

HYPOTHERMIA

Accidental hypothermia occurs when there is an unintentional drop in the body's core temperature below 35°C (95°F). At this temperature, many of the compensatory physiologic mechanisms that conserve heat begin to fail. *Primary accidental hypothermia* is a result of the direct exposure of a previously healthy individual to the cold. The mortality rate is much higher for patients who develop *secondary hypothermia* as a complication of a serious systemic disorder or injury.

TABLE 477-1 Risk Factors for Hypothermia

Age extremes	Endocrine-related
Elderly	Diabetes mellitus
Neonates	Hypoglycemia
Environmental exposure	Hypothyroidism
Occupational	Adrenal insufficiency
Sports-related	Hypopituitarism
Inadequate clothing	Neurologic
Immersion	Cerebrovascular accident
Toxicologic and pharmacologic	Hypothalamic disorders
Ethanol	Parkinson's disease
Anesthetics	Spinal cord injury
Antipsychotics	Multisystemic
Antidepressants	Trauma
Anxiolytics	Sepsis
Benzodiazepines	Shock
Neuromuscular blockers	Hepatic or renal failure
Insufficient fuel	Carcinomatosis
Malnutrition	Burns and exfoliative dermatologic disorders
Marasmus	
Kwashiorkor	Immobility or debilitation

CAUSES

Primary accidental hypothermia is geographically and seasonally pervasive. Although most cases occur in the winter months and in colder climates, this condition is surprisingly common in warmer regions as well. Multiple variables render individuals at the extremes of age—both the elderly and neonates—particularly vulnerable to hypothermia (Table 477-1). The elderly have diminished thermal perception and are more susceptible to immobility, malnutrition, and systemic illnesses that interfere with heat generation or conservation. Dementia, psychiatric illness, and socioeconomic factors often compound these problems. Neonates have high rates of heat loss because of their increased surface-to-mass ratio and their lack of effective shivering and adaptive behavioral responses. At all ages, malnutrition can contribute to heat loss because of diminished subcutaneous fat and as a result of depleted energy stores used for thermogenesis.

Individuals whose occupations or hobbies entail extensive exposure to cold weather are at increased risk for hypothermia. Military history is replete with hypothermic tragedies. Hunters, sailors, skiers, and climbers also are at great risk of exposure, whether it involves injury, changes in weather, or lack of preparedness.

Ethanol causes vasodilation (which increases heat loss), reduces thermogenesis and gluconeogenesis, and may impair judgment or lead to obtundation. Some antipsychotics, antidepressants, anxiolytics, benzodiazepines, and other medications reduce centrally mediated vasoconstriction. Many hypothermic patients are admitted to intensive care because of drug overdose. Anesthetics can block shivering responses; these effects are compounded when patients are not insulated adequately in the operating or recovery units.

Several types of endocrine dysfunction cause hypothermia. Hypothyroidism—particularly when extreme, as in myxedema coma—reduces the metabolic rate and impairs thermogenesis and behavioral responses. Adrenal insufficiency and hypopituitarism also increase susceptibility to hypothermia. Hypoglycemia, most commonly caused by insulin or oral hypoglycemic agents, is associated with hypothermia, in part because of neuroglycopenic effects on hypothalamic function. Increased osmolality and metabolic derangements associated with uremia, diabetic ketoacidosis, and lactic acidosis can lead to altered hypothalamic thermoregulation.

Neurologic injury from trauma, cerebrovascular accident, subarachnoid hemorrhage, and a hypothalamic lesion increases susceptibility to hypothermia. Agenesis of the corpus callosum (*Shapiro's syndrome*) is one cause of episodic hypothermia. In this syndrome, profuse perspiration is followed by a rapid fall in temperature. Acute spinal cord injury

disrupts the autonomic pathways that lead to shivering and will prevent cold-induced reflex vasoconstrictive responses.

Hypothermia associated with sepsis is a poor prognostic sign. Hepatic failure causes decreased glycogen storage and gluconeogenesis as well as a diminished shivering response. In acute myocardial infarction associated with low cardiac output, hypothermia may be reversed after adequate resuscitation. With extensive burns, psoriasis, erythrodermas, and other skin diseases, increased peripheral-blood flow leads to excessive heat loss.

THERMOREGULATION

Heat loss occurs through five mechanisms: radiation (55–65% of heat loss), conduction (10–15% of heat loss, increased in cold water), convection (increased in the wind), respiration, and evaporation; both of the latter two mechanisms are affected by the ambient temperature and the relative humidity.

The preoptic anterior hypothalamus normally orchestrates thermoregulation **(Chap. 20)**. The immediate defense of thermoneutrality is via the autonomic nervous system, whereas delayed control is mediated by the endocrine system. Autonomic nervous system responses include the release of norepinephrine, increased muscle tone, and shivering, leading to thermogenesis and an increase in the basal metabolic rate. Cutaneous cold thermoreception causes direct reflex vasoconstriction to conserve heat. Prolonged exposure to cold also stimulates the thyroid axis, leading to an increased metabolic rate.

CLINICAL PRESENTATION

In most cases of hypothermia, the history of exposure to environmental factors (e.g., prolonged exposure to the outdoors without adequate clothing) makes the diagnosis straightforward. In urban settings, however, the presentation is often more subtle, and other disease processes, toxin exposures, or psychiatric diagnoses should be considered. Predicting the core temperature based on the clinical presentation is very difficult.

After initial stimulation by hypothermia, there is progressive depression of all organ systems. The timing of the appearance of these clinical manifestations varies widely **(Table 477-2)**. Without knowing the core temperature, it can be difficult to interpret other vital signs. For example, tachycardia disproportionate to the core temperature suggests secondary hypothermia resulting from hypoglycemia, hypovolemia, or a toxin overdose. Because carbon dioxide production declines progressively, the respiratory rate should be low; persistent hyperventilation suggests a central nervous system (CNS) lesion or an organic acidosis. A markedly depressed level of consciousness in a patient with mild hypothermia suggests an overdose or CNS dysfunction due to infection or trauma.

Physical examination findings will also be altered by hypothermia. For instance, the assumption that areflexia is solely attributable to hypothermia can obscure the diagnosis of a spinal cord lesion. Patients with hypothermia may be confused or combative; these symptoms abate more rapidly with rewarming than with chemical or physical restraint. A classic example of maladaptive behavior in patients with hypothermia is paradoxical undressing, which involves the inappropriate removal of clothing in response to a cold stress. The cold-induced ileus and abdominal rectus spasm can mimic or mask the presentation of an acute abdomen **(Chap. 16)**.

When a patient in hypothermic cardiac arrest is first discovered, cardiopulmonary resuscitation (CPR) is indicated unless (1) a do-not-resuscitate status is verified, (2) obviously lethal injuries are identified, or (3) the depression of a frozen chest wall is not possible. Continuous CPR is normally recommended, and interruptions should be avoided if possible. In the field, when the core temperature is <28°C (82.4°F), intermittent CPR may also be effective.

As the resuscitation proceeds, the prognosis is grave if there is evidence of widespread cell lysis, as reflected by potassium levels >12 mmol/L (12 meq/L). Other findings that may preclude continuing resuscitation include a core temperature <10–12°C (<50–54°F), a pH <6.5, and evidence of intravascular thrombosis with a fibrinogen value <0.5 g/L (<50 mg/dL). The decision to terminate resuscitation before rewarming the patient past 33°C (91°F) should be predicated on the type and severity of the precipitants of hypothermia. Survival has occurred with a cardiac arrest time over 7 h. A history of asphyxia, as in an avalanche, with secondary cooling is the most important negative predictor of survival.

DIAGNOSIS AND STABILIZATION

Hypothermia is confirmed by measurement of the core temperature. When feasible, placement of a temperature probe in the lower third of the esophagus is preferable, and continuous monitoring essential. Ancillary rectal or bladder monitoring often lags behind core temperature changes.

Pulses may be undetectable in perfusing patients, and the amplitude of the QRS complex is decreased. Maximal amplification on the monitor is often helpful. Chest compressions, when not indicated, may convert a perfusing rhythm to a nonperfusing one. Bedside

TABLE 477-2 Physiologic Changes Associated with Accidental Hypothermia

SEVERITY	BODY TEMPERATURE	CENTRAL NERVOUS SYSTEM	CARDIOVASCULAR	RESPIRATORY	RENAL AND ENDOCRINE	NEUROMUSCULAR
Mild	35°C (95°F)–32.2°C (90°F)	Linear depression of cerebral metabolism; amnesia; apathy; dysarthria; impaired judgment; maladaptive behavior	Tachycardia, then progressive bradycardia; cardiac cycle prolongation; vasoconstriction; increase in cardiac output and blood pressure	Tachypnea, then progressive decrease in respiratory minute volume; declining oxygen consumption; bronchorrhea; bronchospasm	Diuresis; increase in catecholamines, adrenal steroids, triiodothyronine, and thyroxine; increase in metabolism with shivering	Increased preshivering muscle tone, then fatiguing
Moderate	<32.2°C (90°F)–28°C (82.4°F)	EEG abnormalities; progressive depression of level of consciousness; pupillary dilation; paradoxical undressing; hallucinations	Progressive decrease in pulse and cardiac output; increased atrial and ventricular arrhythmias; suggestive (J-wave) ECG changes	Hypoventilation: 50% decrease in carbon dioxide production per 8°C (17.6°F) drop in temperature; absence of protective airway reflexes	50% increase in renal blood flow; renal autoregulation intact; impaired insulin action	Hyporeflexia; diminishing shivering-induced thermogenesis; rigidity
Severe	<28°C (<82.4°F)	Loss of cerebrovascular autoregulation; decline in cerebral blood flow; coma; loss of ocular reflexes; progressive decrease in EEG abnormalities	Progressive decrease in blood pressure, heart rate, and cardiac output; reentrant dysrhythmias; maximal risk of ventricular fibrillation; asystole	Pulmonic congestion and edema; 75% decrease in oxygen consumption; apnea	Decrease in renal blood flow that parallels decrease in cardiac output; extreme oliguria; poikilothermia; 80% decrease in basal metabolism	No motion; decreased nerve-conduction velocity; peripheral areflexia; no corneal or oculocephalic reflexes

Abbreviations: ECG, electrocardiogram; EEG, electroencephalogram.

echocardiography and end-tidal carbon dioxide ($ETCO_2$) monitoring may confirm the perfusion status. If the core temperature is below 30°C (86°F) and there is no perfusion, consider up to three attempts at maximal power. If unsuccessful, rewarm to at least 30°C (86°F) before further attempts. Although cardiac pacing for hypothermic bradydysrhythmias is rarely indicated, the transthoracic technique is preferable. The J or Osborn wave at the junction of the QRS complex and ST segment suggests the diagnosis. Obvious J waves are routinely misdiagnosed by automated readings as injury current.

Supplemental oxygenation is always warranted, since tissue oxygenation is affected adversely by the leftward shift of the oxyhemoglobin dissociation curve. Pulse oximetry is often unreliable in patients with vasoconstriction. If protective airway reflexes are absent, gentle endotracheal intubation should be performed. Adequate preoxygenation will prevent ventricular arrhythmias.

Insertion of a gastric tube prevents dilation secondary to decreased bowel motility. Indwelling bladder catheters facilitate monitoring of cold-induced diuresis and can provide an ancillary approach for temperature monitoring. Dehydration is encountered commonly with chronic hypothermia, and most patients benefit from an intravenous or intraosseous crystalloid bolus. Normal saline is preferable to lactated Ringer's solution, as the liver in hypothermic patients inefficiently metabolizes lactate. The placement of a pulmonary artery catheter can cause perforation of the less compliant pulmonary artery. Insertion of a central venous catheter deeply into the cold right atrium should be avoided since this procedure, similar to transvenous pacing, can precipitate refractory arrhythmias.

Arterial blood gases should *not* be corrected for temperature **(Chap. 58)**. An uncorrected pH of 7.42 and a PCO_2 of 40 mmHg reflect appropriate alveolar ventilation and acid-base balance at any core temperature. Acid-base imbalances should be corrected gradually, since the bicarbonate buffering system is inefficient. A common error is overzealous hyperventilation in the setting of depressed CO_2 production. When the PCO_2 decreases by 10 mmHg at 28°C (82°F), it doubles the pH increase of 0.08 that occurs at 37°C (99°F). Consider $ETCO_2$ monitoring to prevent hyperventilation.

The severity of anemia may be underestimated because the hematocrit increases 2% for each 1°C drop in temperature. White blood cell sequestration and bone marrow suppression are common, potentially masking an infection. Although hypokalemia is more common in chronic hypothermia, hyperkalemia also occurs; the expected electrocardiographic changes are often obscured by hypothermia. Patients with renal insufficiency, metabolic acidosis, or rhabdomyolysis are at greatest risk for electrolyte disturbances.

Coagulopathies are common because cold inhibits the enzymatic reactions required for activation of the intrinsic cascade. In addition, thromboxane B_2 production by platelets is temperature dependent, and platelet function is impaired. The administration of platelets and fresh-frozen plasma is therefore not effective. Coagulation studies can be deceptively normal and contrast with the observed in vivo coagulopathy. This contradiction occurs because all coagulation tests are routinely performed at 37°C (99°F), and the enzymes are thus rewarmed.

REWARMING STRATEGIES

The key initial decision is whether to rewarm the patient passively or actively. *Passive external rewarming* simply involves covering and insulating the patient in a warm environment. With the head also covered, the rate of rewarming is usually 0.5°–2°C (1.10°–4.4°F) per hour. This technique is ideal for previously healthy patients who develop acute, mild primary accidental hypothermia. The patient must have sufficient glycogen to support endogenous thermogenesis.

The application of heat directly to the extremities of patients with chronic severe hypothermia should be avoided because it can induce peripheral vasodilation and precipitate core temperature "afterdrop," a response characterized by a continual decline in the core temperature after removal of the patient from the cold. Truncal heat application reduces the risk of afterdrop.

Active rewarming is necessary under the following circumstances: core temperature <32°C (<90°F) (*poikilothermia*), cardiovascular instability, age extremes, CNS dysfunction, hormone insufficiency, and suspicion of secondary hypothermia. *Active external rewarming* is best accomplished with forced-air heating blankets. Other options include devices that circulate water through external heat exchange pads, radiant heat sources, and hot packs. Monitoring a patient with hypothermia in a heated tub is extremely difficult. Electric blankets should be avoided because vasoconstricted skin is easily burned.

There are numerous widely available options for *active core rewarming*. Airway rewarming with heated humidified oxygen (40°–45°C [104°–113°F]) via mask or endotracheal tube is a convenient option. Although airway rewarming provides less heat than do some other forms of active core rewarming, it eliminates respiratory heat loss and adds 1°–2°C (2.2°–4.4°F) to the overall rewarming rate. Crystalloids should be heated to 40°–42°C (104°–108°F), but the quantity of heat provided is significant only during massive volume resuscitation. The most efficient method for heating and delivering fluid or blood is with a countercurrent in-line heat exchanger. Heated irrigation of the gastrointestinal tract or bladder transfers minimal heat because of the limited available surface area. These methods should be reserved for patients in cardiac arrest and then used in combination with all available active rewarming techniques.

If extracorporeal life support (ECLS) is unavailable, closed thoracic lavage is far more efficient in severely hypothermic patients with cardiac arrest. The hemithoraxes are irrigated through two inserted large-bore thoracostomy tubes. Thoracostomy tubes should not be placed in the left chest of a spontaneously perfusing patient for purposes of rewarming. Peritoneal lavage with the dialysate at 40°–45°C (104°–113°F) efficiently transfers heat when delivered through two catheters with outflow suction. Another option involves the use of endovascular temperature control catheters.

The HOPE (Hypothermia Outcome Prediction after Extracorporeal Life Support) score is a tool based on six covariates to help predict which patients may benefit from ECLS. ECLS options **(Table 477-3)** should be considered in severely hypothermic patients, especially those with *primary accidental hypothermia*. ECLS, including bypass, should be considered in nonperfusing patients without documented contraindications to resuscitation. Circulatory support may be the only effective option in patients with completely frozen extremities or those

TABLE 477-3 Options for Extracorporeal Life Support

EXTRACORPOREAL REWARMING TECHNIQUE	CONSIDERATIONS
Continuous venovenous (CVV) rewarming	Circuit: CV catheter to CV, dual-lumen CV, or peripheral catheter No oxygenator/circulatory support Flow rates 150–400 mL/min ROR 2°–3°C (4.4°–6.6°F)/h
Hemodialysis	Circuit: single- or dual-vessel cannulation Stabilizes electrolyte or toxicologic abnormalities or rhabdomyolysis Exchange cycle volumes 200–500 mL/min ROR 2°–3°C (4.4°–6.6°F)/h
Continuous arteriovenous rewarming (CAVR)	Circuit: percutaneous 8.5-Fr femoral catheters Requires systolic blood pressure of 60 mmHg No perfusionist/pump/anticoagulation Flow rates 225–375 mL/min ROR 3°–4°C (6.6°–8.8°F)/h
Cardiopulmonary bypass (CPB)	Circuit: full circulatory support with pump and oxygenator Perfusate-temperature gradient 5°–10°C (11°–22° F) Flow rates 2–7 L/min (average 3–4 L/min) ROR up to 9.5°C (20.9°F)/h
Venoarterial extracorporeal membrane oxygenation (VA-ECMO)	Decreased risk of post-rewarming cardiorespiratory failure Improved neurologic outcome

Abbreviations: CV, central venous; ROR, rate of rewarming.

with significant tissue destruction coupled with rhabdomyolysis. There is no evidence that extremely rapid rewarming improves survival in perfusing patients.

TREATMENT

Hypothermia

When a patient is hypothermic, target organs and the cardiovascular system respond minimally to most medications. Generally, medications are withheld below 30°C (86°F). In contrast to antiarrhythmics, low-dose vasopressor medications may improve the intra-arrest rates of return of spontaneous circulation. Because of increased binding of drugs to proteins as well as impaired metabolism and excretion, either a lower dose or a longer interval between doses should be used to avoid toxicity. As an example, the administration of repeated doses of digoxin or insulin would be ineffective while the patient is hypothermic, but the residual drugs would be potentially toxic during rewarming.

Achieving a mean arterial pressure of at least 60 mmHg should be an early objective. If the hypotension is disproportionate for temperature and does not respond to crystalloid/colloid infusion and rewarming, low-dose dopamine support (2–5 μg/kg per min) should be considered. Perfusion of the vasoconstricted cardiovascular system also may improve with low-dose IV nitroglycerin.

Atrial arrhythmias should be monitored initially without intervention, as the ventricular response should be slow and, unless preexistent, most will convert spontaneously during rewarming. The role of prophylaxis and treatment of ventricular arrhythmias is complex. Preexisting ventricular ectopy may be suppressed by hypothermia and reappear during rewarming. There is limited evidence to recommend any specific antiarrhythmic treatment.

Initiating empirical therapy for adrenal insufficiency usually is not warranted unless the history suggests steroid dependence or hypoadrenalism or efforts to rewarm with standard therapy fail. The administration of parenteral levothyroxine to euthyroid patients with hypothermia, however, is potentially hazardous. Because laboratory results can be delayed and confounded by the presence of the sick euthyroid syndrome **(Chap. 394)**, historic clues or physical findings suggestive of hypothyroidism should be sought. When myxedema is the cause of hypothermia, the relaxation phase of the Achilles reflex is prolonged more than is the contraction phase.

Hypothermia obscures most of the symptoms and signs of infection, notably fever and leukocytosis. Shaking rigors from infection may be mistaken for shivering. Except in mild cases, extensive cultures and repeated physical examinations are essential. Unless an infectious source is identified, empirical antibiotic prophylaxis is most warranted in the elderly, neonates, and immunocompromised patients.

FROSTBITE

Peripheral cold injuries include both freezing and nonfreezing cold injuries to tissue. Tissue freezes quickly when in contact with thermal conductors such as metal and volatile solutions. Other predisposing factors include constrictive clothing or boots, immobility, and vasoconstrictive medications. Frostbite occurs when the tissue temperature drops below 0°C (32°F). Ice-crystal formation subsequently distorts and destroys the cellular architecture. Once the vascular endothelium is damaged, stasis progresses rapidly to microvascular thrombosis. After the tissue thaws, there is progressive dermal ischemia. The microvasculature begins to collapse, arteriovenous shunting increases tissue pressures, and edema forms. Finally, thrombosis, ischemia, and superficial necrosis appear. The development of mummification and demarcation may take weeks to months.

CLINICAL PRESENTATION

The initial presentation of frostbite can be deceptively benign. The symptoms always include a sensory deficiency affecting light touch, pain, or temperature perception. The acral areas and distal extremities are the most common insensate areas. Some patients describe a clumsy or "chunk of wood" sensation in the extremity.

Deep frostbitten tissue can appear waxy, mottled, yellow, or violaceous-white. Favorable presenting signs include some warmth or sensation with normal color. The injury is often superficial if the subcutaneous tissue is pliable or if the dermis can be rolled over bony prominences.

Clinically, frostbite is superficial or deep. Superficial frostbite does not entail tissue loss but rather causes only anesthesia and erythema. The appearance of vesiculation surrounded by edema and erythema implies deeper involvement **(Fig. 477-1)**. Hemorrhagic vesicles reflect a serious injury to the microvasculature and indicate severe frostbite. Damages in subcuticular, muscular, or osseous tissues may result in amputation. An alternative classification establishes grades based on the location of presenting cyanosis; that is grade 1, absence of cyanosis; grade 2, cyanosis on the distal phalanx; grade 3, cyanosis up to the metacarpophalangeal (MP) joint; and grade 4 cyanosis proximal to the MP joint.

The two most common nonfreezing peripheral cold injuries are *chilblain* (*pernio*) and *immersion* (*trench*) *foot*. Chilblain results from neuronal and endothelial damage induced by repetitive exposure to damp cold above the freezing point. Young females, particularly those with a history of Raynaud's phenomenon, are at greatest risk. Persistent vasospasticity and vasculitis can cause erythema, mild edema, and pruritus. Eventually plaques, blue nodules, and ulcerations develop. These lesions typically involve the dorsa of the hands and feet.

In contrast, nonfreezing cold injury includes trench foot and immersion foot that results from repetitive exposure to wet cold above the freezing point. The feet initially appear cyanotic, cold, and edematous. The subsequent development of bullae is often indistinguishable

FIGURE 477-1 Frostbite with vesiculation, surrounded by edema and erythema.

from frostbite. This vesiculation rapidly progresses to ulceration and liquefaction gangrene. Consider administering amitriptyline early for pain. Patients with milder cases report hyperhidrosis, cold sensitivity, and painful ambulation for many years.

TREATMENT

Peripheral Cold Injuries

When frostbite accompanies hypothermia, hydration may improve vascular stasis. Frozen tissue should be thawed rapidly and completely by immersion in circulating water at 37°–40°C (99°–104°F) for 30–60 min and not by using hot air. Rapid rewarming often produces an initial hyperemia. The early formation of large clear distal blebs is more favorable than that of smaller proximal dark hemorrhagic blebs. A common error is the premature termination of thawing, since the reestablishment of perfusion is intensely painful. Parenteral narcotics will be necessary with deep frostbite. If cyanosis persists after rewarming, the tissue compartment pressures should be monitored carefully.

Many antithrombotic and vasodilatory treatment regimens have been evaluated. The prostacyclin analogue iloprost given within 48 h after rewarming is an option. There is no conclusive evidence that sympathectomy, steroids, calcium channel blockers, pentoxifylline, or hyperbaric oxygen salvages tissue.

Patients who have deep frostbite injuries with the potential for significant morbidity should be considered for intravenous or intraarterial thrombolytic therapy. Angiography, fluorescence microangiography, or pyrophosphate scanning may help evaluate the injury and monitor the progress of tissue plasminogen activator therapy. Heparin is recommended as adjunctive therapy. Intraarterial thrombolysis may reduce the need for digital and more proximal amputations when administered within 24 h of severe injuries. A treatment protocol for frostbite is summarized in **Table 477-4**.

Unless infection develops, any decision regarding debridement or amputation should generally be deferred. Angiography or technetium-99 bone scan may assist in the determination of surgical margins. Magnetic resonance angiography may also demonstrate the line of demarcation earlier than does clinical demarcation.

TABLE 477-4 Treatment for Frostbite

BEFORE THAWING	DURING THAWING	AFTER THAWING
Remove from environment.	Consider parenteral analgesia and ketorolac.	Gently dry and protect part; elevate; place pledgets between toes, if macerated.
Prevent partial thawing and refreezing.	Administer ibuprofen (400 mg PO).	If clear vesicles are intact, aspirate sterilely; if broken, debride and dress with antibiotic or sterile aloe vera ointment.
Stabilize core temperature and treat hypothermia.	Immerse part in 37°–39°C (99°–102.2°F) (thermometer-monitored) circulating water containing an antiseptic soap until distal flush (10–45 min).	Leave hemorrhagic vesicles intact to prevent desiccation and infection.
Protect frozen part—no friction or massage.	Encourage patient to gently move part.	Continue ibuprofen (400–600 mg PO [12 mg/kg per day] q8 to 12h).
Address medical or surgical conditions.	If pain is refractory, reduce water temperature to 35°–37°C (95°–99°F) and administer parenteral narcotics.	Consider tetanus prophylaxis; elevate part. Administer hydrotherapy at 37°C (99°F). Consider dextran or phenoxybenzamine or, in severe cases, thrombolysis rt-PA (IV or intraarterial).

Abbreviation: rt-PA, recombinant tissue plasminogen activator.

The most common symptomatic sequelae reflect neuronal injury and persistently abnormal sympathetic tone, including paresthesia, thermal misperception, and hyperhidrosis. Delayed findings include nail deformities, cutaneous carcinomas, and epiphyseal damage in children.

Management of the chilblain syndrome is usually supportive. With refractory perniosis, alternatives include nifedipine, steroids, and limaprost, a prostaglandin E_1 analogue.

478 Heat-Related Illnesses

Daniel F. Danzl

Climate change is globally increasing heat-related morbidity and mortality. Extreme heat events are more frequent and are occurring in more widespread locations. Heat-related illnesses include a spectrum of disorders ranging from heat syncope, muscle cramps, and heat exhaustion to medical emergencies such as heatstroke. The core body temperature is normally maintained within a very narrow range. Although significant levels of hypothermia are tolerated **(Chap. 477)**, multiorgan dysfunction occurs rapidly at temperatures >40.5°C (104.9°C). In contrast to heatstroke, the far more common sign of fever reflects intact thermoregulation.

THERMOREGULATION

Humans are capable of significant heat generation. Strenuous exercise can increase heat generation twentyfold. The heat load from metabolic heat production and environmental heat absorption is balanced by a variety of heat dissipation mechanisms. These central integrative dissipation pathways are orchestrated by the central thermostat, which is located in the preoptic nucleus of the anterior hypothalamus. Efferent signals sent via the autonomic nervous system trigger cutaneous vasodilation and diaphoresis to facilitate heat loss.

Normally, the body dissipates heat into the environment via four mechanisms. The *evaporation* of skin moisture is the single most efficient mechanism of heat loss but becomes progressively ineffective as the relative humidity rises to >70%. The *radiation* of infrared electromagnetic energy directly into the surrounding environment occurs

continuously. (Conversely, radiation is a major source of heat gain in hot climates.) *Conduction*—the direct transfer of heat to a cooler object—and *convection*—the loss of heat to air currents—become ineffective when the environmental temperature exceeds the skin temperature.

Factors that interfere with the evaporation of diaphoresis significantly increase the risk of heat illness. Examples include dripping of sweat off the skin, constrictive or occlusive clothing, dehydration, and excessive humidity. While air is an effective insulator, the thermal conductivity of water is 25 times greater than that of air at the same temperature. The *wet-bulb globe temperature* (WBGT) is a commonly used index to assess the environmental heat load. The WBGT is superior to the "heat index," which is only based on air temperature and humidity. The WBGT also incorporates radiant heat and wind speed.

The regulation of this heat load is complex and involves the central nervous system (CNS), thermosensors, and thermoregulatory effectors. The central thermostat activates the effectors that produce peripheral vasodilation and sweating. The skin surface is in effect the radiator and the principal location of heat loss, since skin blood flow can increase 25–30 times over the basal rate. This dramatic increase in skin blood flow, coupled with the maintenance of peripheral vasodilation, efficiently radiates heat. At the same time, there is a compensatory vasoconstriction of the splanchnic and renal beds.

Acclimatization to heat reflects a constellation of physiologic adaptations that permit the body to lose heat more efficiently. This process often requires 1 to several weeks of exposure and work in a hot environment. During acclimatization, the thermoregulatory set point is altered, and this alteration affects the onset, volume, and content of diaphoresis. The threshold for the initiation of sweating is lowered, and the amount of sweat increases, with a lowered salt concentration. Sweating rates can be 1–2 L/h in acclimated individuals during heat stress. Plasma volume expansion also occurs and improves cutaneous vascular flow. The heart rate lowers, with a higher stroke volume. After the individual leaves the hot environment, improved tolerance to heat stress dissipates rapidly, the plasma volume decreases, and deacclimatization occurs within weeks.

PREDISPOSING FACTORS AND DIFFERENTIAL DIAGNOSIS

When there is an excessive heat load, unacclimated individuals can develop a variety of heat-related illnesses. Heat waves exacerbate the mortality rate, particularly among the elderly and among persons lacking adequate nutrition and access to air-conditioned environments. Secondary vascular events, including cerebrovascular accidents and myocardial infarctions, occur at least 10 times more often in conditions of extreme heat.

Exertional heat illness continues to occur when laborers, military personnel, or athletes exercise strenuously in the heat. In addition to the very young and very old, preadolescents and teenagers are at risk since they may use poor judgment when vigorously exercising in high humidity and heat. Other risk factors include obesity, poor conditioning with lack of acclimatization, and mild dehydration.

Cardiovascular inefficiency is a common feature of heat illness. Any physiologic or pharmacologic impediment to cutaneous perfusion impairs heat loss. Many patients are unaware of the heat risk associated with their medications. Anticholinergic agents impair sweating and blunt the normal cardiovascular response to heat. Phenothiazines and heterocyclic antidepressants also have anticholinergic properties that interfere with the function of the preoptic nucleus of the anterior hypothalamus due to central depletion of dopamine.

Calcium channel blockers, beta blockers, and various stimulants also inhibit sweating by reducing peripheral blood flow. To maintain the mean arterial blood pressure, increased cardiac output must be capable of compensating for progressive dehydration. A variety of stimulants and substances of abuse also increase muscle activity and heat production.

Careful consideration of the differential diagnosis is important in the evaluation of a patient for a potential heat-related illness. The clinical setting may suggest other etiologies, such as malignant hyperthermia after general anesthesia. Neuroleptic malignant syndrome can be triggered by certain antipsychotic medications, including selective serotonin reuptake inhibitors. A variety of infectious and endocrine disorders as well as toxicologic or CNS etiologies may mimic heatstroke **(Table 478-1)**.

MINOR HEAT-EMERGENCY SYNDROMES

Heat edema is characterized by mild swelling of the hands, feet, and ankles during the first few days of significant heat exposure. The principal mechanism involves cutaneous vasodilation and pooling of interstitial fluid in response to heat stress. Heat also increases the secretion of antidiuretic hormone and aldosterone. Systemic causes of edema, including cirrhosis, nephrotic syndrome, and congestive heart failure, can usually be excluded by the history and physical examination. Heat

TABLE 478-1 Heat-Related Illness: Predisposing Factors and Differential Diagnosis

ILLNESS	PREDISPOSING FACTORS
Cardiovascular inefficiency	Age extremes Beta/calcium channel blockade Congestive heart failure Dehydration Diuresis Obesity Poor physical fitness
Central nervous system illness	Cerebellar injury Cerebral hemorrhage Hypothalamic cerebrovascular accident Psychiatric disorders Status epilepticus
Impaired heat loss	Antihistamines Heterocyclic antidepressants Occlusive clothing Skin abnormalities
Endocrine and immune-related illness	Diabetic ketoacidosis Multiple-organ dysfunction syndrome Pheochromocytoma Systemic inflammatory response syndrome Thyroid storm
Excessive heat load	Environmental conditions Exertion Fever Hypermetabolic state Lack of acclimatization
Infectious illness	Cerebral abscess Encephalitis Malaria Meningitis Sepsis syndrome Tetanus Typhoid
Toxicologic illness	Amphetamines Anticholinergic toxidrome Cocaine Dietary supplements Hallucinogens Malignant hyperthermia Neuroleptic malignant syndrome Salicylates Serotonin syndrome Strychnine Sympathomimetics Withdrawal syndromes (ethanol, hypnotics)

edema generally resolves without treatment in several days. Simple leg elevation or compression stockings will usually suffice. Diuretics are *not* effective and, in fact, predispose to volume depletion and the development of more serious heat-related illnesses.

Prickly heat (*miliaria rubra*, *lichen tropicus*) is a maculopapular, pruritic, erythematous rash that commonly occurs in clothed areas. Blockage of the sweat pores by debris from macerated stratum corneum causes inflammation in the sweat ducts. As the ducts dilate, they rupture and produce superficial vesicles. The predominant symptom is pruritus. In addition to antihistamines, chlorhexidine in a light cream or lotion provides some relief. In adults, localized areas may benefit from 1% salicylic acid TID, with caution taken to avoid salicylate intoxication. Clothing with breathable fabric should be clean and loose fitting, and activities or environments that induce diaphoresis should be avoided.

Heat syncope (exercise-associated collapse) can follow endurance exercise or occur in the elderly. Other common clinical scenarios include prolonged standing while stationary in the heat and sudden standing after prolonged exposure to heat. Heat stress routinely causes relative volume depletion, decreased vasomotor tone, and peripheral vasodilation. The cumulative effect of this decrease in venous return is postural hypotension, especially in nonacclimated elderly individuals. Many of those affected also have comorbidities. Therefore, other cardiovascular, neurologic, and metabolic causes of syncope should be considered. After removal from the heat source, most patients will recover promptly with cooling and rehydration.

Hyperventilation tetany occurs in some individuals when exposure to heat stimulates hyperventilation, producing respiratory alkalosis, paresthesia, and carpopedal spasm. Unlike heat cramps, heat tetany causes very little muscle-compartment pain. Treatment includes providing reassurance, moving the patient out of the heat, and addressing the hyperventilation.

HEAT CRAMPS

Heat cramps (exercise-associated muscle cramps) are intermittent, painful, and involuntary spasmodic contractions of skeletal muscles. They typically occur in an unacclimated individual who is at rest after vigorous exertion in a humid, hot environment. In contrast, cramps that occur in athletes during exercise last longer, are relieved by stretching and massage, and resolve spontaneously.

Of note, not all muscle cramps are related to exercise, and the differential diagnosis includes many other disorders. A variety of medications, myopathies, endocrine disorders, and sickle cell trait are other possible causes.

The typical patient with heat cramps is usually profusely diaphoretic and has been replacing fluid losses with copious water or other hypotonic fluids. Roofers, firefighters, military personnel, athletes, steel workers, and field workers are commonly affected. Other predisposing factors include insufficient sodium intake before intense activity in the heat and lack of heat acclimatization, resulting in sweat with a high salt concentration.

The precise pathogenesis of heat cramps appears to involve a relative deficiency of sodium, potassium, and fluid at the intracellular level. Coupled with copious hypotonic fluid ingestion, large amounts of sodium in the diaphoresis cause hyponatremia and hypochloremia, resulting in muscle cramps due to calcium-dependent muscle relaxation. Total-body depletion of potassium may be observed during the period of heat acclimatization. Rhabdomyolysis is very rare with routine exercise-associated muscle cramps.

Heat cramps that are not accompanied by significant dehydration can be treated with commercially available electrolyte solutions. Although the flavored electrolyte solutions are far more palatable, two 650-mg salt tablets dissolved in 1 quart of water produce a 0.1% saline solution. Individuals should avoid the ingestion of undissolved salt tablets, which are a gastric irritant and may induce vomiting.

HEAT EXHAUSTION

The physiologic hallmarks of heat exhaustion—in contrast to heatstroke—are the maintenance of thermoregulatory control and CNS function. The core temperature is usually elevated but is generally <40.5°C (<105°F). The two physiologic precipitants are water depletion and sodium depletion, which often occur in combination. Laborers, athletes, and elderly individuals exerting themselves in hot environments, without adequate fluid intake, tend to develop *water-depletion heat exhaustion*. Persons working in the heat frequently consume only two-thirds of their net water loss and are voluntarily dehydrated. In contrast, *salt-depletion heat exhaustion* occurs more slowly in unacclimated persons who have been consuming large quantities of hypotonic solutions.

Heat exhaustion is usually a diagnosis of exclusion because of the multitude of nonspecific symptoms. If any signs of heatstroke are present, rapid cooling and crystalloid resuscitation should be initiated immediately during stabilization and evaluation. Mild neurologic and gastrointestinal influenza-like symptoms are common. These symptoms may include headache, vertigo, ataxia, impaired judgment, malaise, dizziness, nausea, and muscle cramps. Orthostatic hypotension and sinus tachycardia develop frequently. More significant CNS impairment suggests heatstroke or other infectious, neurologic, or toxicologic diagnoses.

Hemoconcentration does not always develop, and rapid infusion of isotonic IV fluids should be guided by frequent electrolyte determinations and perfusion requirements. Most cases of heat exhaustion reflect mixed sodium and water depletion. Sodium-depletion heat exhaustion is characterized by hyponatremia and hypochloremia. Hepatic aminotransferases are mildly elevated in both types of heat exhaustion. Urinary sodium and chloride concentrations are usually low.

Some patients with heat exhaustion develop heatstroke after removal from the heat-stress environment. Aggressive cooling of nonresponders is indicated until their core temperature is 39°C (102.2°F). Except in mild cases, free water deficits should be replaced slowly over 24–48 h to avoid a decrease of serum osmolality by >2 mOsm/h.

The disposition of younger, previously healthy heat-exhaustion patients who have no major laboratory abnormalities may include hospital observation and discharge after IV rehydration. Older patients with comorbidities (including cardiovascular disease) or predisposing factors often require inpatient fluid and electrolyte replacement, monitoring, and reassessment.

HEATSTROKE

The clinical manifestations of heatstroke reflect a total loss of thermoregulatory function. Typical vital-sign abnormalities include tachypnea, various tachycardias, hypotension, and a widened pulse pressure. Although there is no single specific diagnostic test, the historical and physical triad of exposure to a heat stress, CNS dysfunction, and a core temperature >40.5°C (104.9°C) helps establish the preliminary diagnosis. Some patients with impending heatstroke will initially appear lucid. The definitive diagnosis should be reserved until the other potential causes of hyperthermia are excluded. Many of the usual laboratory abnormalities seen with heatstroke overlap with other conditions. If the patient's mental status does not improve with cooling, toxicologic screening may be indicated, and cranial computed tomography (CT) and spinal fluid analysis can be considered.

The premonitory clinical characteristics may be nonspecific and include weakness, dizziness, disorientation, ataxia, and gastrointestinal or psychiatric symptoms. These prodromal symptoms often resemble heat exhaustion. The sudden onset of heatstroke occurs when the maintenance of adequate perfusion requires peripheral vasoconstriction to stabilize the mean arterial blood pressure. As a result, the cutaneous radiation of heat ceases. At this juncture, the core temperature rises dramatically. Since many patients with heatstroke also meet the criteria for systemic inflammatory response syndrome (SIRS) and have a broad differential diagnosis, rapid cooling is essential during the extensive diagnostic evaluation. Heat-induced SIRS reflects the responses of both the innate and the adaptive immune systems (Table 478-1).

There are two forms of heatstroke with significantly different manifestations **(Table 478-2)**. Classic (epidemic) heatstroke (CHS) usually occurs during long periods of high ambient temperature and humidity, as during summer heat waves. Patients with CHS commonly have

TABLE 478-2 Typical Manifestations of Heatstroke

CLASSIC	EXERTIONAL
Older patient	Younger patient
Predisposing health factors/ medications	Healthy condition
Epidemiology (heat waves)	Sporadic cases
Sedentary	Exercising
Anhidrosis (possible)	Diaphoresis (common)
Central nervous system dysfunction	Myocardial/hepatic injury
Oliguria	Acute renal failure
Coagulopathy (mild)	Disseminated intravascular coagulation
Mild lactic acidosis	Marked lactic acidosis
Mild creatine kinase elevation	Rhabdomyolysis
Normoglycemia/calcemia	Hypoglycemia/calcemia
Normokalemia	Hyperkalemia
Normonatremia	Hyponatremia

chronic diseases that predispose to heat-related illness, and they may have limited access to oral fluids. Heat dissipation mechanisms are overwhelmed by both endogenous heat production and exogenous heat stress. Patients with CHS are often compliant with prescribed medications that can impair tolerance to a heat stress. In many of these dehydrated CHS patients, sweating has ceased and the skin is hot and dry.

The duration of core temperature elevation directly impacts morbidity and mortality. If cooling is delayed, severe hepatic dysfunction, renal failure, disseminated intravascular coagulation, and fulminant multisystem organ failure may occur. Hepatocytes are very heat sensitive. On presentation, the serum level of aspartate aminotransferase (AST) is routinely elevated. Eventually, levels of both AST and alanine aminotransferase (ALT) often increase to >100 times the normal values. Coagulation studies commonly demonstrate decreased platelets, fibrinogen, and prothrombin. Most patients with CHS require cautious crystalloid resuscitation, electrolyte monitoring, and—in certain refractory cases—consideration of central venous pressure (CVP) measurements and point of care ultrasonography (Chap. 493). Hypernatremia is secondary to dehydration in CHS. Many patients exhibit significant stress leukocytosis, even in the absence of infection.

Patients with exertional heatstroke (EHS), in contrast to those with CHS, are often young and previously healthy, and their diagnosis is usually more obvious from the history. Athletes, laborers, and military recruits are common victims. Unlike those with CHS, many EHS patients present profusely diaphoretic despite significant dehydration. As a result of muscular exertion, rhabdomyolysis and acute renal failure are more common in EHS. Studies to detect rhabdomyolysis and its complications, including hypocalcemia and hyperphosphatemia, should be considered. Hyponatremia, hypoglycemia, and coagulopathies are frequent findings. Elevated creatine kinase and lactate dehydrogenase levels also suggest EHS. Oliguria is a common finding. Renal failure can result from direct thermal injury, untreated rhabdomyolysis, or volume depletion. Common urinalysis findings include microscopic hematuria, myoglobinuria, and granular or red cell casts.

With both CHS and EHS, heat-related increases in cardiac biomarker levels may be present and reversible. Heatstroke often causes thermal cardiomyopathy. As a result, the CVP may be elevated despite significant dehydration. In addition, the patient often presents with potentially deceptive noncardiogenic pulmonary edema and basilar rales despite being significantly hypovolemic. The electrocardiogram commonly displays a variety of tachyarrhythmias, nonspecific ST-T wave changes, and heat-related ischemia or infarction. Rapid cooling—not the *initial* administration of antiarrhythmic medications—is essential.

Above 42°C (107.6°F), heat can rapidly produce direct cellular injury. Thermosensitive enzymes become nonfunctional, and eventually, there is irreversible uncoupling of oxidative phosphorylation. The production of heat-shock proteins increases, and cytokines mediate a systemic inflammatory response. The vascular endothelium is also damaged, and this injury activates the coagulation cascade. Significant shunting away from the splanchnic circulation produces gastrointestinal ischemia. Endotoxins further impair normal thermoregulation. As a result, if cooling is delayed, severe hepatic dysfunction, permanent renal failure, disseminated intravascular coagulation, and fulminant multisystem organ failure may occur.

COOLING STRATEGIES

Endotracheal intubation and continuous core-temperature monitoring should be considered both at the scene and as cooling is initiated. Peripheral methods to measure temperature are *not* reliable. Hypoglycemia is a frequent finding. Since peripheral vasoconstriction delays heat dissipation, repeated administration of discrete boluses of isotonic crystalloid for hypotension is preferable to the administration of α-adrenergic agonists. Patients who require inotropic support after cooling and fluid resuscitation may require norepinephrine, followed by epinephrine and dobutamine.

Rapid cooling is essential in both CHS and EHS, and an immediate improvement in vital signs and mental status may prove valuable for diagnostic purposes. Cool water (15°C [60°F]) is sprayed on the exposed skin while fans direct continuous airflow over the moistened skin. Cold packs applied to the neck, axillae, and groin are useful cooling adjuncts. If cardiac electrodes will not adhere, they can be applied to the patient's back.

Immersion cooling in ice-cold water may be a preferable option with EHS if appropriate medical staff and materials for aggressive cooling are available on scene until emergency medical services arrival. The initial increase in temperature from peripheral vasoconstriction will rapidly be overcome by the large conductive thermal transfer into cold water. This technique presents significant monitoring and resuscitation challenges in many clinical settings. The safety of immersion cooling is best established for young, previously healthy patients with EHS (but not for those with CHS). To improve patient access and monitoring, an alternative is ice water therapy. Ice cold water is continuously poured over the supine patient lying on a porous stretcher. Muscular massage improves vasodilatation. Another option that allows patient access is ice cold immersion in a commercial "cooling body bag." To avoid hypothermic afterdrop (continued cooling), active cooling should be terminated at ~38°–39°C (100.4°F–102.2°F).

The rate of cooling with commercial cooling blankets is very slow. Other methods are less efficacious and rarely indicated, such as IV infusion of cold fluids and cold irrigation of the bladder or gastrointestinal tract. Cold thoracic and peritoneal lavage are invasive and rarely necessary. Endovascular cooling also provides effective cooling.

RESUSCITATION

Aspiration commonly occurs in heatstroke, and endotracheal intubation is usually necessary. Depolarizing agents should be avoided. The metabolic demands are high, and supplemental oxygenation is essential due to hypoxemia induced by thermal stress and pulmonary dysfunction. The oxyhemoglobin dissociation curve is shifted to the right. Pneumonitis, pulmonary infarction, hemorrhage, edema, and acute respiratory distress syndrome occur frequently in heatstroke patients. Seizures are common and can occur during therapeutic cooling. Cold-induced tonic-clonic muscular rigidity mimics seizure activity. Refractory seizures may require monitoring with an electroencephalogram.

The circulatory fluid requirements, particularly in CHS, may be deceptively modest. Aggressive cooling and modest volume repletion usually elevate the CVP to 12–14 mmHg. The reading, however, may be deceptive. Many patients present with a thermally induced hyperdynamic circulation accompanied by a high cardiac index, low peripheral vascular resistance, and an elevated CVP caused by right-sided heart failure. In contrast, most patients with EHS require far more zealous isotonic crystalloid resuscitation.

The hypotension that is initially common among patients with heatstroke results from both dehydration and high-output cardiac failure caused by peripheral vasodilation. Inotropes causing α-adrenergic

stimulation (e.g., norepinephrine) can impede cooling by causing significant vasoconstriction. Vasoactive catecholamines such as dopamine or dobutamine may be necessary if the cardiac output remains depressed despite an elevated CVP, particularly in patients with a hyperdynamic circulation.

A wide variety of tachyarrhythmias are routinely observed on presentation and usually resolve spontaneously during cooling. The administration of atrial or ventricular antiarrhythmic medications is rarely indicated during cooling. Anticholinergic medications (including atropine) inhibit sweating and should be avoided. With a cardiac rhythm that sustains perfusion, electrical cardioversion of the hyperthermic myocardium should be deferred until the myocardium is cooled. Significant shivering, discomfort, or extreme agitation is preferably mitigated with short-acting benzodiazepines or propofol. On the other hand, chlorpromazine may lower the seizure threshold, has anticholinergic properties, and can exacerbate the hypotension or cause neuroleptic malignant syndrome.

Coagulopathies more commonly occur after the first day of illness. After cooling, the patient should be monitored for disseminated intravascular coagulation, and replacement therapy with fresh-frozen plasma and platelets should be considered. Consider a dose of empiric antibiotics after culturing during cooling if the etiology of the hyperthermia remains unclear.

There is no therapeutic role for antipyretics in the control of environmentally induced hyperthermia; these drugs block the actions of pyrogens at hypothalamic receptor sites. Salicylates can further uncouple oxidative phosphorylation in heatstroke and exacerbate coagulopathies. Acetaminophen may further stress hepatic function. Dantrolene is ineffective when the temperature elevation is not caused by malignant hyperthermia. Although aminocaproic acid impedes fibrinolysis, it may cause rhabdomyolysis and is not recommended in heatstroke.

DISPOSITION

Most patients with minor heat-emergency syndromes (including heat edema, heat syncope, and heat cramps) require only stabilization and treatment with outpatient follow-up. Although there are no decision rules to guide disposition choices in heat exhaustion, many of these patients have multiple predisposing factors and comorbidities that will require prolonged observation or hospital admission.

Essentially all patients with actual heatstroke require admission to a monitored setting, and most require intensive care. There are reports of very high survival rates of patients following prehospital immersion cooling without intensive care. Most or all of these patients appear to have had heat exhaustion. Many actual heatstroke patients also require prolonged tracheal intubation, invasive hemodynamic monitoring, and support for various degrees of multiorgan dysfunction syndrome. The prognosis worsens if the initial core temperature exceeds 42°C (107.6°F) or if there was a prolonged period during which the core temperature exceeded this level. Other features of a negative prognosis include acute renal failure, massively elevated liver enzymes, and significant hyperkalemia. As expected, the number of dysfunctional organ systems also correlates directly with mortality risk.

479 Principles of Human Genetics

J. Larry Jameson, Peter Kopp

IMPACT OF GENETICS AND GENOMICS ON MEDICAL PRACTICE

Over the past four decades, novel insights into human genetics and genomics have fundamentally impacted the practice of medicine, ushering in a new area with a deeper understanding of the genetic basis of numerous health conditions, novel diagnostic technologies, disease prevention and management, personalized medicine, and targeted therapies. Human genetics refers to the study of individual genes, their role and function in disease, and their mode of inheritance. Genomics refers to an organism's entire genetic information, the *genome*, and the function and interaction of DNA within the genome, as well as with environmental or nongenetic factors, such as a person's lifestyle. With the characterization of the human genome, genomics not only complements traditional genetics in our efforts to elucidate the etiology and pathogenesis of disease, but it also plays a prominent and expanding role in diagnostics, prevention, and therapy **(Chap. 480)**. These transformative developments, originally emerging from the Human Genome Project, have been variably designated *genomic medicine*, *personalized medicine*, or *precision medicine*. Precision medicine aims at customizing medical decisions to an individual patient. For example, a patient's genetic characteristics (genotype) can be used to optimize drug therapy and predict efficacy, adverse events, and drug dosing of selected medications (*pharmacogenomics*) **(Chap. 72)**. The characterization of the mutational profile of a malignancy allows the identification of driver mutations or overexpressed signaling molecules, which then facilitates the selection of targeted therapies. Genome-wide polygenic risk scores (PRS) for common complex diseases are beginning to emerge and may impact disease prevention in the future.

Genetics has traditionally been viewed through the window of relatively rare single-gene diseases. These disorders account for ~10% of pediatric admissions and childhood mortality. Historically, genetics has focused predominantly on chromosomal and metabolic disorders, reflecting the long-standing availability of techniques to diagnose these conditions. For example, conditions such as trisomy 21 (Down's syndrome) or monosomy X (Turner's syndrome) can be diagnosed using cytogenetics. Likewise, many metabolic disorders (e.g., phenylketonuria, familial hypercholesterolemia) are diagnosed using biochemical analyses. The advances in DNA and RNA diagnostics have extended the field of genetics to include virtually all medical specialties and have led to the elucidation of the pathogenesis of most monogenic disorders. In addition, virtually every medical condition has a genetic component. As is often evident from a patient's family history, many common disorders such as hypertension, heart disease, asthma, diabetes mellitus, and mental illnesses are significantly influenced by the genetic background. These polygenic or multifactorial (complex) disorders involve the contributions of many different genes, as well as environmental factors that can modify disease risk. Genome-wide association studies (GWAS) have elucidated numerous disease-associated loci and are providing novel insights into the allelic architecture of complex traits. These studies have been facilitated by the availability of comprehensive catalogues of human single nucleotide polymorphism (SNP) haplotypes (HapMap, International Genome Sample Resource). Next-generation DNA sequencing (NGS) technologies have evolved rapidly, and the cost of sequencing whole exomes (the exons within the genome; whole exome sequencing [WES]) or genomes (whole genome sequencing [WGS]) has plummeted. Comprehensive unbiased sequence analyses are now routinely used to characterize individuals with complex undiagnosed conditions or to determine the mutational profile of advanced malignancies in order to select optimal and targeted therapies. The assembly of diploid genomes, i.e., the characterization of the complete genetic information from both sets of chromosomes in an individual's genome, will further enhance the complete resolution of genetic variation and should provide further insights into heritability and disease mechanisms.

Cancer has a genetic basis because it results from acquired somatic mutations in genes controlling growth, apoptosis, and cellular differentiation **(Chap. 76)**. In addition, the development of many cancers is associated with a hereditary predisposition. Characterization of the genome (and epigenome) in various malignancies has led to fundamental new insights into cancer biology and reveals that the genomic profile of mutations is in many cases more important in determining the appropriate therapy than the organ in which the tumor originates. The Cancer Genome Atlas (TCGA) initiative of the National Cancer Institute and the National Human Genome Research Institute has already characterized the genomic landscape across >30 malignancies. TCGA consists of comprehensive analyses of genomic and proteomic alterations and provided fundamental new insights into the molecular pathogenesis of cancer. These data, together with comprehensive catalogues of somatic mutations identified in human cancer, have direct clinical ramifications that impact cancer taxonomy, as well as the development and choice of targeted therapies.

Genetic and genomic approaches have proven invaluable for the detection of infectious pathogens and are used clinically to identify agents that are difficult to culture such as mycobacteria, viruses, and parasites, or to track infectious agents locally or globally. In many cases, molecular genetics has improved the feasibility and accuracy of diagnostic testing and has opened new avenues for therapy, including gene and cellular therapies **(Chap. 483)**. Molecular genetics has also provided the opportunity to characterize the *microbiome*, a field that characterizes the population dynamics of bacteria, viruses, and parasites that coexist with humans and other animals **(Chap. 483)**. The microbiome has significant effects on normal physiology as well as various disease states, and the field is now focusing on defining the mechanisms underlying these interactions.

Molecular biology has significantly changed the treatment of human disease. Peptide hormones, growth factors, cytokines, and vaccines can be produced in large amounts using recombinant DNA and RNA technology (e.g., mRNA vaccines against SARS-CoV-2; small interfering RNA [siRNA] to treat hypercholesterolemia). Targeted modifications of recombinant peptides provide improved therapeutic tools, as illustrated by genetically modified insulin analogues with more favorable kinetics or glucagon-like peptide 1 (GLP-1) agonists for treatment of type 2 diabetes and for weight management.

The rate at which new genetic and genomic information is being generated presents many challenges for health care providers and systems. Although many functional aspects of the genome remain unknown, there are many clinical situations where genetic and genomic information optimize patient care. Much genetic information resides in databases that provide easy access to the expanding information about the human genome, genetic disease, and genetic testing **(Table 479-1)**. For example, several thousand monogenic disorders are summarized in a large, continuously evolving compendium, the *Online Mendelian Inheritance in Man* (OMIM) catalogue (Table 479-1). The constant refinement of bioinformatics and big data analytics, together with the widespread adoption of electronic health records (EHRs), are simplifying the access, analysis, and integration of this daunting amount of new information. Importantly, genomic data can be integrated readily into EHRs and thus impact clinical practice.

THE HUMAN GENOME

Structure of the Human Genome The Human Genome Project was initiated in the mid-1980s as an ambitious effort to characterize

Mouse genome informatics	*http://www.informatics.jax.org*	Mouse genome informatics, potential mouse models of human disease, information on phenotypic similarity between mouse models and human patients

Note: Databases are evolving constantly. Pertinent information may be found by using links listed in the few selected databases.

the entire human genome and culminated in the completion of the DNA sequence for the last of the human chromosomes in 2006. The scope of a WGS analysis can be illustrated by the following analogy. Human DNA consists of ~3 billion base pairs (bp) of DNA per haploid genome, which is nearly 1000-fold greater than that of the *Escherichia coli* genome. If the human DNA sequence were printed out, it would correspond to about 120 volumes of *Harrison's Principles of Internal Medicine*.

In addition to the human genome, the genomes of thousands of organisms have been sequenced completely or partially (Genomes Online Database [GOLD]; Table 479-1). They include, among others, eukaryotes such as the mouse (*Mus musculus*), *Saccharomyces cerevisiae*, *Caenorhabditis elegans*, and *Drosophila melanogaster*; bacteria (e.g., *E. coli*); and archaea, viruses, organelles (mitochondria, chloroplasts), and plants (e.g., *Arabidopsis thaliana*). Genomic information of infectious agents has significant impact for the characterization of infectious outbreaks and epidemics. Other ramifications arising from the availability of genomic data include, among others, (1) the comparison of entire genomes (*comparative genomics*); (2) the study of large-scale expression of RNAs (*functional genomics*), proteins (*proteomics*), or protein families (e.g., the *kinome*, the complete set of protein kinases) to detect differences between various tissues in health and disease; (3) the characterization of the variation among individuals by establishing catalogues of sequence variations and SNPs; and (4) the identification of genes that play critical roles in the development of polygenic and multifactorial disorders.

CHROMOSOMES The human genome is divided into 23 different chromosomes, including 22 autosomes (numbered 1–22) and the X and Y sex chromosomes **(Fig. 479-1)**. Adult cells are *diploid*, meaning they contain two homologous sets of 22 autosomes and a pair of sex chromosomes. Females have two X chromosomes (XX), whereas males have one X and one Y chromosome (XY). As a consequence of meiosis, germ cells (sperm or oocytes) are haploid and contain one set of 22 autosomes and one of the sex chromosomes. At the time of fertilization, the diploid genome is reconstituted by pairing of the homologous chromosomes from the mother and father. With each cell division (mitosis), chromosomes are replicated, paired, segregated, and divided into two daughter cells.

STRUCTURE OF DNA DNA is a double-stranded helix composed of four different bases: adenine (A), thymidine (T), guanine (G), and cytosine (C). Adenine is paired to thymidine, and guanine is paired

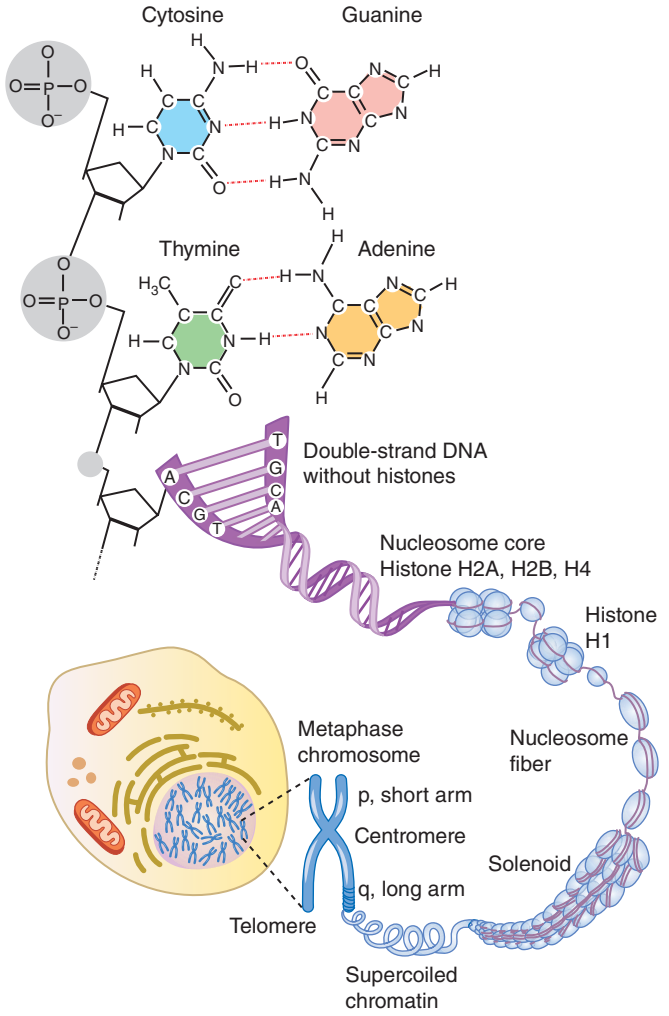

FIGURE 479-1 Structure of chromatin and chromosomes. Chromatin is composed of double-strand DNA that is wrapped around histone and nonhistone proteins forming nucleosomes. The nucleosomes are further organized into solenoid structures. Chromosomes assume their characteristic structure, with short (p) and long (q) arms at the metaphase stage of the cell cycle.

to cytosine, by hydrogen bond interactions that span the double helix (Fig. 479-1). DNA has several remarkable features that make it ideal for the transmission of genetic information. It is relatively stable, and the double-stranded nature of DNA and its feature of strict base-pair complementarity permit faithful replication during cell division. Complementarity also allows the transmission of genetic information from DNA → RNA → protein **(Fig. 479-2)**. mRNA is encoded by the so-called sense or coding strand of the DNA double helix and is translated into proteins by ribosomes.

The presence of four different bases provides surprising genetic diversity. In the protein-coding regions of genes, the DNA bases are arranged into codons, a triplet of bases that specifies a particular amino acid. It is possible to arrange the four bases into 64 different triplet codons (4^3). Each codon specifies 1 of the 20 different amino acids, or a regulatory signal such as initiation and stop of translation. Because there are more codons than amino acids, the genetic code is degenerate; that is, most amino acids can be specified by several different codons. By arranging the codons in different combinations and in various lengths, it is possible to generate the tremendous diversity of primary protein structure.

DNA length is normally measured in units of 1000 bp (kilobases, kb) or 1,000,000 bp (megabases, Mb). In the human genome, only ~1% of DNA accounts for protein-coding sequences. The noncoding DNA has multiple functional and structural roles including (1) sequences that form introns; (2) regulatory elements (promoters, enhancers, silencers, insulators); (3) sequences that generate RNAs that do not code for proteins; (4) centromeres and telomeres; (5) regions defining chromatin structure and histone modifications; (6) various forms of repetitive sequences of variable length; and (7) pseudogenes and regions without currently discernible functional or structural roles (Fig. 479-1).

GENES A *gene* is a functional unit that is regulated by transcription (see below) and encodes an RNA product, which is most commonly, but not always, translated into a protein that exerts activity within or outside the cell **(Fig. 479-3)**. Historically, genes were identified because they conferred specific traits that are transmitted from one generation to the next. Now, they are frequently characterized based on expression in various tissues (*transcriptome*). The size of genes is quite broad; some genes are only a few hundred base pairs, whereas others are extraordinarily large (2.3 Mb). The number of genes greatly underestimates the complexity of genetic expression, because single genes can generate multiple spliced messenger RNA (mRNA) products (*isoforms*), which are translated into proteins that are subject to complex posttranslational modification such as phosphorylation. *Exons* refer to the portion of genes that are eventually spliced together to form mRNA. *Introns* refer to the spacing regions between the exons that are spliced out of precursor RNAs during RNA processing. The gene locus also includes regions that are necessary to control its expression (Fig. 479-2). Current estimates predict roughly 20,000 protein-coding genes in the human genome with an average of about four different coding transcripts per gene. Remarkably, the exome only constitutes 1.14% of the genome. Of note, the number of transcripts is close to 200,000 and includes thousands of noncoding transcripts (RNAs of various length such as microRNAs [miRNA] and long noncoding RNAs [lncRNA]). These noncoding RNAs are involved in numerous cellular processes such as transcriptional and posttranscriptional regulation of gene expression, chromatin remodeling, and protein trafficking, among others. Not surprisingly, aberrant expression and/or mutations in these RNAs play a pathogenic role in numerous diseases.

SINGLE-NUCLEOTIDE POLYMORPHISMS On average, a typical genome differs from the reference human genome at 4 to 5 million sites. Some of these variants have no impact on health, whereas others may increase or lower the risk for developing a specific disease. Remarkably, however, the primary DNA sequence of humans has ~99.9% similarity compared to that of any other human. An SNP is a variation of a single base pair in the DNA. Across human populations from distinct ethnic backgrounds, there are more than 1 billion validated SNPs (Fig. 479-3). SNPs are the most common type of sequence variation and account for >90% of all sequence variation. They occur on average every 100–300 bases and are the major source of genetic heterogeneity. SNPs that are in proximity are inherited together (e.g., they are linked) and are referred to as *haplotypes* **(Fig. 479-4)**. Haplotype maps describe the nature and location of these SNP haplotypes and how they are distributed among individuals within and among populations, information that has been facilitating GWAS designed to elucidate the complex interactions among multiple genes and lifestyle factors in multifactorial disorders (see below). Moreover, haplotype analyses are useful to assess variations in responses to medications (*pharmacogenomics*) and environmental factors, as well as the prediction of disease predisposition.

COPY NUMBER VARIATIONS Copy number variations (CNVs) are relatively large genomic regions (1 kb to several Mb) that have been duplicated or deleted on certain chromosomes and hence alter the diploid status of the DNA **(Fig. 479-5)**. It has been estimated that 5–10% of the genome can display CNVs. When comparing the genomes of two individuals, ~0.4–0.8% of their genomes differ in terms of CNVs scattered throughout the genome. Some CNVs can increase or decrease gene dosage, potentially leading to detrimental effects if essential genes are impacted. Of note, de novo CNVs have been observed between monozygotic twins, who otherwise have identical genomes.

Replication of DNA and Mitosis

Genetic information in DNA is transmitted to daughter cells under two different circumstances: (1) somatic cells divide by *mitosis*, allowing the diploid ($2n$) genome to replicate itself completely in conjunction with cell division; and (2) germ cells (sperm and ova) undergo *meiosis*, a process that enables the reduction of the diploid ($2n$) set of chromosomes to the haploid state ($1n$).

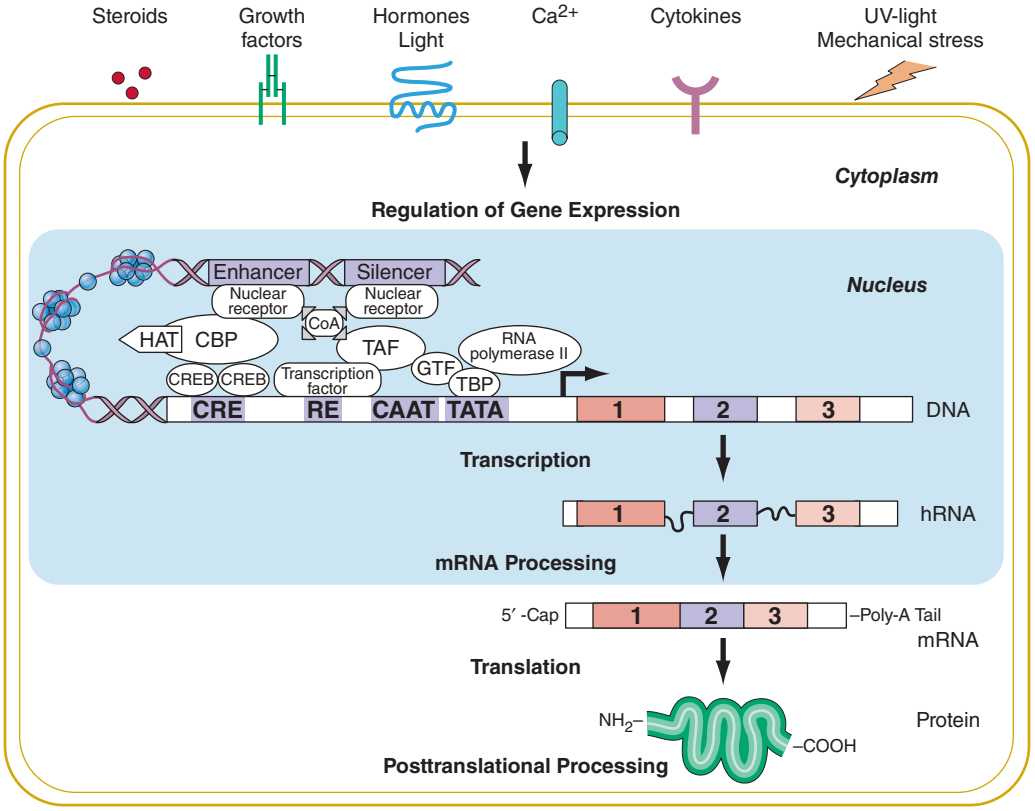

FIGURE 479-2 Flow of genetic information. Multiple extracellular signals activate intracellular signal cascades that result in altered regulation of gene expression through the interaction of transcription factors with regulatory regions of genes. RNA polymerase transcribes DNA into RNA that is processed to mRNA by excision of intronic sequences. The mRNA is translated into a polypeptide chain to form the mature protein after undergoing posttranslational processing. CBP, CREB-binding protein; CoA, co-activator; COOH, carboxyterminus; CRE, cyclic AMP responsive element; CREB, cyclic AMP response element–binding protein; GTF, general transcription factors; HAT, histone acetyl transferase; NH2, aminoterminus; RE, response element; TAF, TBP-associated factors; TATA, TATA box; TBP, TATA-binding protein.

Prior to mitosis, cells exit the resting, or G_0 state, and enter the cell cycle. After traversing a critical checkpoint in G_1, cells undergo DNA synthesis (S phase), during which the DNA in each chromosome is replicated, yielding two pairs of sister chromatids ($2n \rightarrow 4n$). The process of DNA synthesis requires stringent fidelity in order to avoid transmitting errors to subsequent generations of cells. Genetic abnormalities of DNA mismatch/repair include xeroderma pigmentosum, Bloom's syndrome, ataxia telangiectasia, and hereditary nonpolyposis colon cancer (HNPCC), among others. Many of these disorders strongly predispose to neoplasia because of the rapid acquisition of additional mutations **(Chap. 76)**. After completion of DNA synthesis, cells enter G_2 and progress through a second checkpoint before entering mitosis. At this stage, the chromosomes condense and are aligned along the equatorial plate at metaphase. The two identical sister chromatids, held together at the centromere, divide and migrate to opposite poles of the cell. After formation of a nuclear membrane around the two separated sets of chromatids, the cell divides and two daughter cells are formed, thus restoring the diploid ($2n$) state.

Assortment and Segregation of Genes During Meiosis Meiosis occurs only in germ cells of the gonads. It shares certain features with mitosis but involves two distinct steps of cell division that reduce the chromosome number to the haploid state. In addition, there is active recombination that generates genetic diversity. During the first cell division, two sister chromatids ($2n \rightarrow 4n$) are formed for each chromosome pair and there is an exchange of DNA between homologous paternal and maternal chromosomes. This process involves the formation of *chiasmata*, structures that correspond to the DNA segments that cross over between the maternal and paternal homologues **(Fig. 479-6)**. Usually there is at least one crossover on each chromosomal arm; recombination occurs more frequently in female meiosis than in male meiosis. Subsequently, the chromosomes segregate randomly. Because there are 23 chromosomes, there exist 2^{23} (>8 million) possible combinations of chromosomes. Together with the genetic exchanges that occur during recombination, chromosomal segregation generates tremendous diversity, and each gamete is genetically unique. The process of recombination and the independent segregation of chromosomes provide the foundation for performing linkage analyses, whereby one attempts to correlate the inheritance of certain chromosomal regions (or linked genes) with the presence of a disease or genetic trait (see below).

After the first meiotic division, which results in two daughter cells ($2n$), the two chromatids of each chromosome separate during a second meiotic division to yield four gametes with a haploid state ($1n$). When the egg is fertilized by sperm, the two haploid sets are combined, thereby restoring the diploid state ($2n$) in the zygote.

REGULATION OF GENE EXPRESSION

Regulation by Transcription Factors The expression of genes is regulated by DNA-binding proteins that activate or repress transcription. The number of DNA sequences and transcription factors that regulate transcription is much greater than originally anticipated. Most genes contain at least 15–20 discrete regulatory elements within 300 bp of the transcription start site. This densely packed promoter region often contains binding sites for ubiquitous transcription factors. However, factors involved in cell-specific expression may also bind to these sequences. Key regulatory elements may also reside at a large distance from the proximal promoter. The globin and the immunoglobulin genes, for example, contain *locus control regions* that are several kilobases away from the structural sequences of the gene. Specific groups of transcription factors that bind to these promoter and enhancer sequences provide a combinatorial code for regulating transcription. In this manner, relatively ubiquitous factors interact with more restricted factors to allow each gene to be expressed and regulated in a unique manner that is dependent on developmental state, cell type, and numerous extracellular stimuli. Regulatory factors also bind within the gene itself, particularly in the intronic regions. The

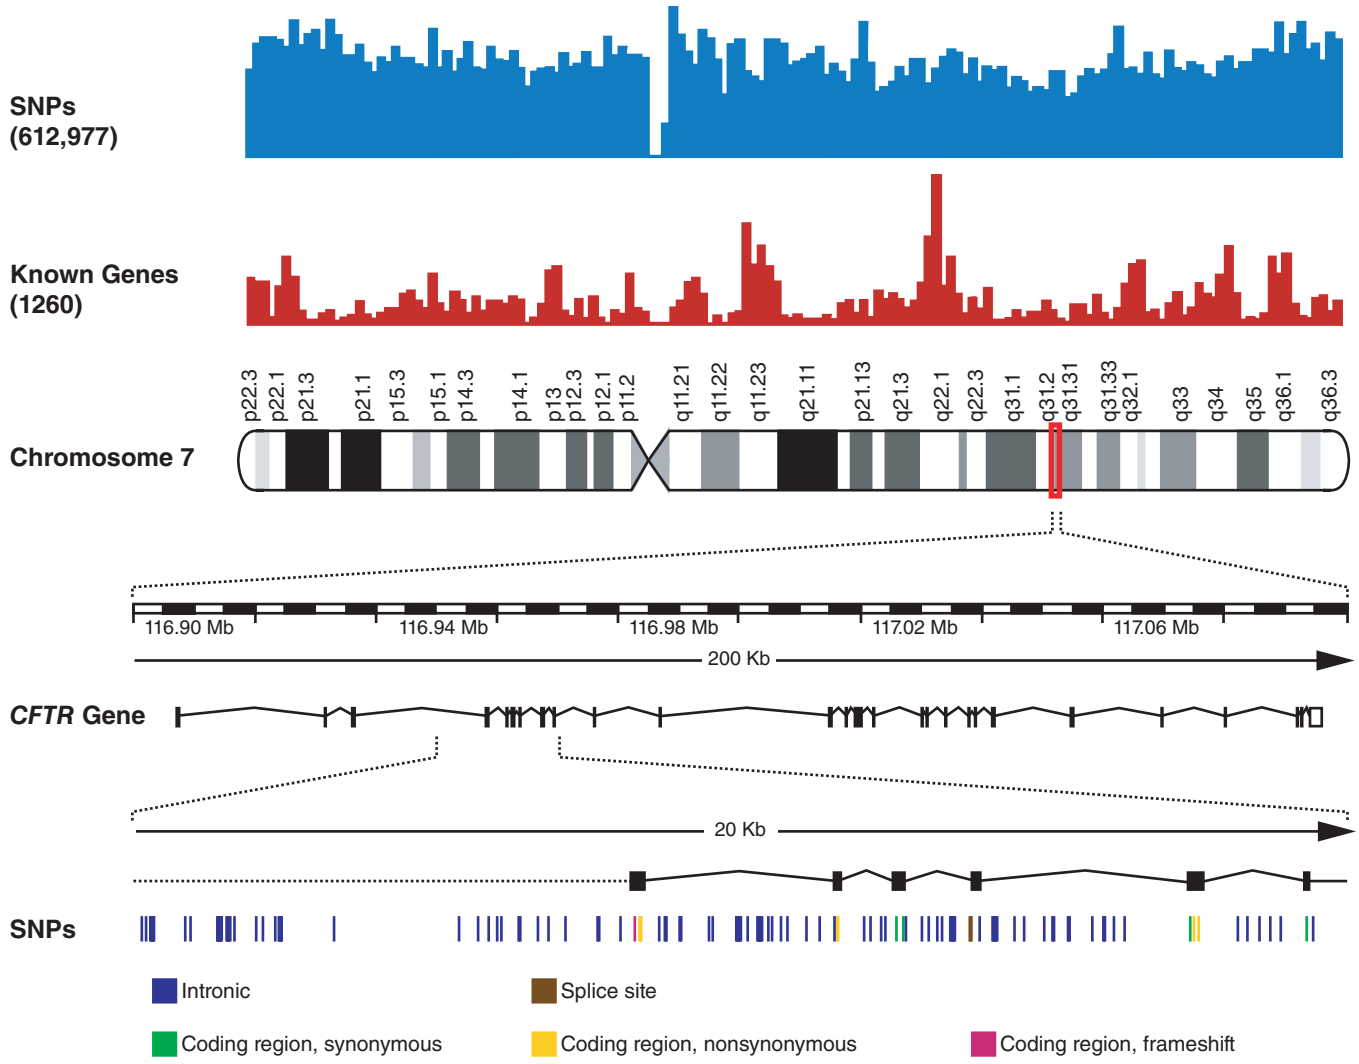

FIGURE 479-3 Chromosome 7 is shown with the density of single nucleotide polymorphisms (SNPs) and genes above. A 200-kb region in 7q31.2 containing the *CFTR* gene is shown below. The *CFTR* gene contains 27 exons. Close to 2000 mutations in this gene have been found in patients with cystic fibrosis. A 20-kb region encompassing exons 4–9 is shown further amplified to illustrate the SNPs in this region.

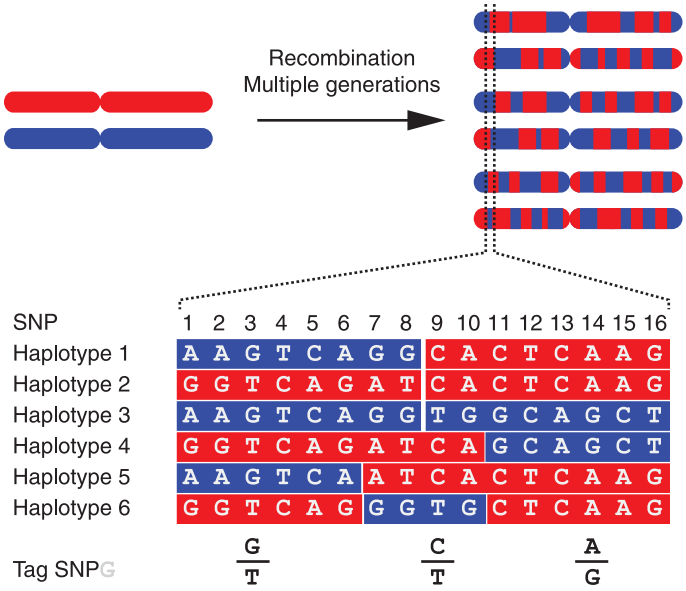

FIGURE 479-4 The origin of haplotypes is due to repeated recombination events occurring in multiple generations. Over time, this leads to distinct haplotypes. These haplotype blocks can often be characterized by genotyping selected Tag single nucleotide polymorphisms (SNPs), an approach that facilitates performing genome-wide association studies (GWAS).

transcription factors that bind to DNA represent only the first level of regulatory control. Other proteins—*co-activators* and *co-repressors*—interact with the DNA-binding transcription factors to generate large regulatory complexes. These complexes are subject to control by numerous cell-signaling pathways and enzymes, leading to phosphorylation, acetylation, sumoylation, and ubiquitination. Ultimately, the recruited transcription factors interact with, and stabilize, components of the basal transcription complex that assembles at the site of the TATA box and initiator region. This basal transcription factor complex consists of >30 different proteins. Gene transcription occurs when RNA polymerase begins to synthesize RNA from the DNA template. A large number of identified genetic diseases involve transcription factors (Table 479-2).

The field of *functional genomics* is based on the concept that understanding alterations of gene expression under various physiologic and pathologic conditions provides insight into the underlying functional role of the gene. The ENCODE (Encyclopedia of DNA Elements) project aims at identifying and annotating all functional sequences in the human genome. By revealing specific gene expression profiles, this knowledge can be of diagnostic and therapeutic relevance. The large-scale study of expression profiles is referred to as *transcriptomics* because the complement of mRNAs transcribed by the cellular genome is called the *transcriptome*.

Most studies of gene expression have focused on the regulatory DNA elements of genes that control transcription. However, it must be

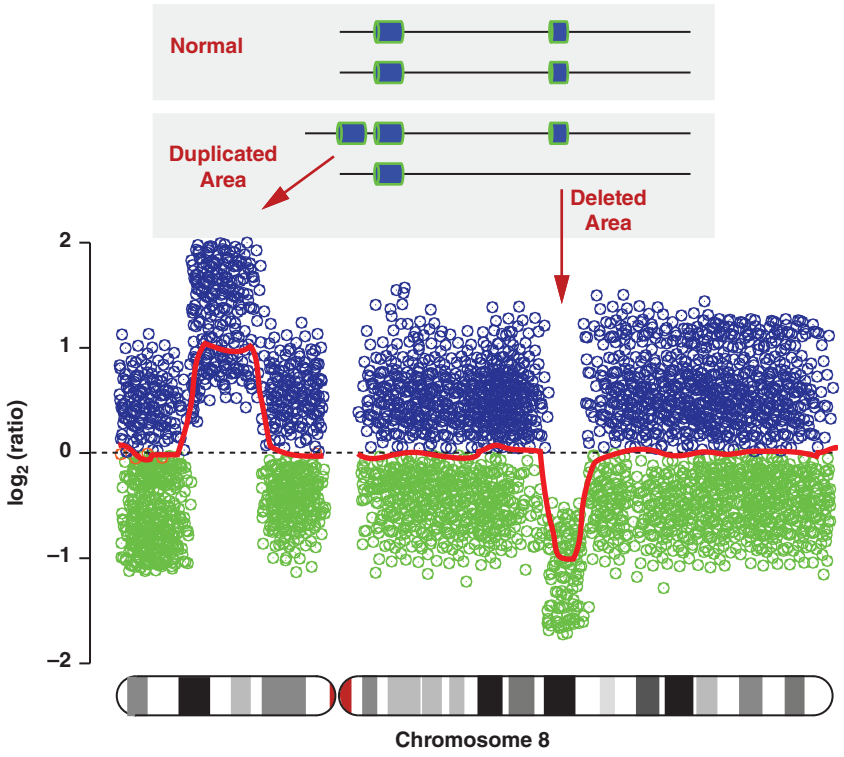

FIGURE 479-5 Copy number variations (CNV) encompass relatively large regions of the genome that have been duplicated or deleted. Chromosome 8 is shown with a CNV detected by genomic hybridization. An increase in the signal strength indicates a duplication, whereas a decrease reflects a deletion of the covered chromosomal regions.

emphasized that gene expression requires a series of steps, including mRNA processing, protein translation, and posttranslational modifications, all of which are actively regulated (Fig. 479-2).

Epigenetic Regulation of Gene Expression (see Chap. 497)

Epigenetics describes mechanisms and phenotypic changes that are not a result of variation in the primary DNA nucleotide sequence but are caused by secondary modifications of DNA or histones. These modifications include heritable changes such as X-inactivation and imprinting, but they can also result from dynamic posttranslational protein modifications in response to environmental influences such as diet, age, or drugs. The epigenetic modifications result in altered expression of individual genes or chromosomal loci encompassing multiple genes. The term *epigenome* describes the constellation of covalent modifications of DNA and histones that impact chromatin structure, as well as noncoding transcripts that modulate the transcriptional activity of DNA. Although the primary DNA sequence is usually identical in all cells of an organism, sex- and tissue-specific changes in the epigenome contribute to determining the transcriptional signature of a cell (transcriptome) and hence the protein expression profile (proteome).

Mechanistically, DNA and histone modifications can result in the activation or silencing of gene expression (Fig. 479-7). DNA methylation involves the addition of a methyl group to cytosine residues. This is usually restricted to cytosines of CpG dinucleotides, which are abundant throughout the genome. Methylation of these dinucleotides is thought to represent a defense mechanism that minimizes the expression of sequences that have been incorporated into the genome such as retroviral sequences. CpG dinucleotides also exist in so-called *CpG islands*, stretches of DNA characterized by a high CG content, which are found in the majority of human gene promoters. CpG islands in promoter regions are typically unmethylated, and the lack of methylation facilitates transcription.

Histone methylation involves the addition of a methyl group to lysine residues in histone proteins (Fig. 479-7). Depending on the specific lysine residue being methylated, this alters chromatin configuration, making it either more open or tightly packed. Acetylation of histone proteins is another well-characterized mechanism that results in an open chromatin configuration, which favors active transcription. Acetylation is generally more dynamic than methylation, and many transcriptional activation complexes have histone acetylase activity, whereas repressor complexes often contain deacetylases and remove acetyl groups from histones. Other histone modifications include, among others, phosphorylation and sumoylation.

Furthermore, noncoding RNAs and RNA regulatory networks that bind to DNA have a significant impact on transcriptional activity.

Physiologically, epigenetic mechanisms play an important role in several instances. For example, X-inactivation refers to the relative silencing of one of the two X chromosome copies present in females. The inactivation process is a form of dosage compensation such that females (XX) do not generally express twice as many X-chromosomal gene products as males (XY). In a given cell, the choice of which chromosome is inactivated occurs randomly in humans. But once the maternal or paternal X chromosome is inactivated, it will remain inactive, and this information is transmitted with each cell division. The *X-inactive specific transcript* (*Xist*) gene encodes a long non-coding RNA (lncRNA) that mediates gene silencing on one of the X chromosomes. The inactive X chromosome is highly methylated and has low levels of histone acetylation. While the majority of X-chromosomal genes are silenced by X-inactivation, ~15% escape inactivation and are expressed.

Epigenetic gene inactivation also occurs on selected chromosomal regions of autosomes, a phenomenon referred to as *genomic imprinting*. Through this mechanism, a small subset of genes is only expressed in a monoallelic fashion. Imprinting is

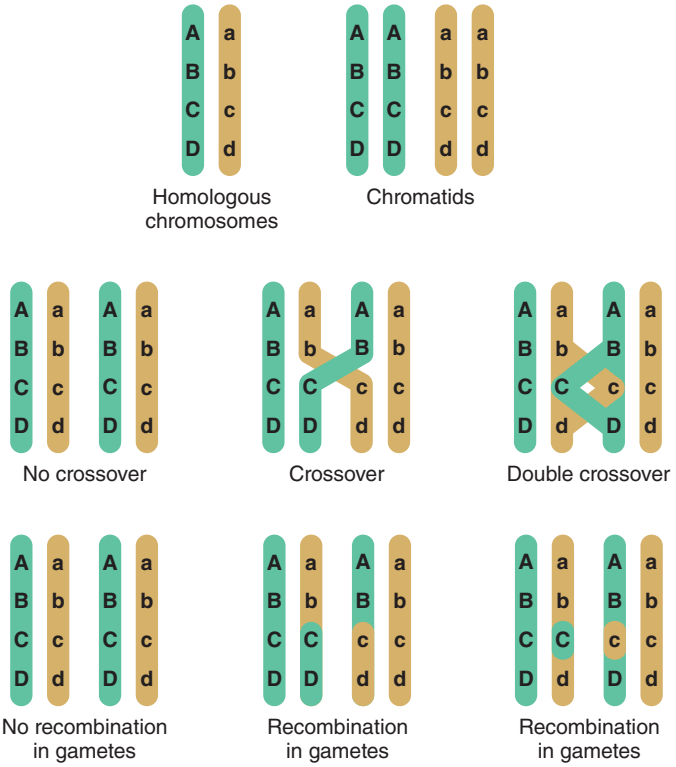

FIGURE 479-6 Crossing-over and genetic recombination. During chiasma formation, either of the two sister chromatids on one chromosome pairs with one of the chromatids of the homologous chromosome. Genetic recombination occurs through crossing-over and results in recombinant and nonrecombinant chromosome segments in the gametes. Together with the random segregation of the maternal and paternal chromosomes, recombination contributes to genetic diversity and forms the basis of the concept of linkage.

TABLE 479-2 Selected Examples of Diseases Caused by Mutations and Rearrangements in Transcription Factors

TRANSCRIPTION FACTOR CLASS	EXAMPLE	ASSOCIATED DISORDER
Nuclear receptors	Androgen receptor	Complete or partial androgen insensitivity (recessive missense mutations) Spinobulbar muscular atrophy (CAG repeat expansion)
Zinc finger proteins	WT1	WAGR syndrome: *W*ilms' tumor, *a*niridia, *g*enitourinary malformations, mental *r*etardation
Basic helix-loop-helix	MITF	Waardenburg's syndrome type 2A
Homeobox	IPF1	Maturity onset of diabetes mellitus type 4 (monoallelic mutation/haploinsufficiency) Pancreatic agenesis (biallelic mutations)
Leucine zipper	Retina leucine zipper (NRL)	Autosomal dominant retinitis pigmentosa
High mobility group (HMG) proteins	SRY	Sex reversal
Forkhead	HNF4α, HNF1α, HNF1β	Maturity onset of diabetes mellitus types 1, 3, 5
Paired box	PAX3	Waardenburg's syndrome types 1 and 3
T-box	TBX5	Holt-Oram syndrome (thumb anomalies, atrial or ventricular septum defects, phocomelia)
Cell cycle control proteins	P53	Li-Fraumeni syndrome, other cancers
Co-activators	CREB binding protein (CREBBP)	Rubinstein-Taybi syndrome
General transcription factors	TATA-binding protein (TBP)	Spinocerebellar ataxia 17 (CAG expansion)
Transcription elongation factor	VHL	von Hippel–Lindau syndrome (renal cell carcinoma, pheochromocytoma, pancreatic tumors, hemangioblastomas) Autosomal dominant inheritance, somatic inactivation of second allele (Knudson two-hit model)
Runt	RUNX1	Familial thrombocytopenia with propensity to acute myelogenous leukemia
Chimeric proteins due to translocations	PML-RAR	Acute promyelocytic leukemia t(15;17)(q22;q11.2-q12) translocation

Abbreviations: CREB, cAMP responsive element–binding protein; HNF, hepatocyte nuclear factor; PML, promyelocytic leukemia; RAR, retinoic acid receptor; SRY, sex-determining region Y; VHL, von Hippel–Lindau.

heritable and leads to the preferential expression of one of the parental alleles, which deviates from the usual biallelic expression seen for the majority of genes. Remarkably, imprinting can be limited to a subset of tissues. Imprinting is mediated through DNA methylation of one of the alleles. The epigenetic marks on imprinted genes are maintained throughout life, but during zygote formation, they are activated or inactivated in a sex-specific manner (imprint reset) **(Fig. 479-8)**, which allows a differential expression pattern in the fertilized egg and the subsequent mitotic divisions. Appropriate expression of imprinted genes is important for normal development and cellular functions. Imprinting defects and uniparental disomy, which is the inheritance of two chromosomes or chromosomal regions from the same parent, are the cause of several developmental disorders such as Beckwith-Wiedemann syndrome, Silver-Russell syndrome, Angelman's syndrome, and Prader-Willi syndrome (see below). Monoallelic loss-of-function mutations in the *GNAS1* gene lead to Albright's hereditary osteodystrophy (AHO). Paternal transmission of *GNAS1* mutations leads to an isolated AHO phenotype (pseudopseudohypoparathyroidism), whereas maternal transmission leads to AHO in combination with hormone resistance to parathyroid hormone, thyrotropin, and gonadotropins (pseudohypoparathyroidism type IA). These phenotypic differences are explained by tissue-specific imprinting of the *GNAS1* gene, which is expressed primarily from the maternal allele in the thyroid, gonadotropes, and the proximal renal tubule. In most other tissues, the *GNAS1* gene is expressed biallelically. In patients with isolated renal resistance to parathyroid hormone (pseudohypoparathyroidism type IB), defective imprinting of the *GNAS1* gene results in decreased $G_s\alpha$ expression in the proximal renal tubules. Rett syndrome is an X-linked dominant disorder resulting in developmental regression and stereotypic hand movements in affected girls. It is caused by mutations in the *MECP2* gene, which encodes a methyl-binding protein. The ensuing aberrant methylation results in abnormal gene expression in neurons, which are otherwise normally developed.

Remarkably, epigenetic differences also occur among monozygotic twins. Although twins are epigenetically indistinguishable during the early years of life, older monozygotic twins exhibit differences in the overall content and genomic distribution of DNA methylation and histone acetylation, which would be expected to alter gene expression in various tissues.

In cancer, the epigenome is characterized by simultaneous losses and gains of DNA methylation in different genomic regions, as well as repressive histone modifications. Hyper- and hypomethylation are associated with mutations in genes that control DNA methylation. Hypomethylation is thought to remove normal control mechanisms that prevent expression of repressed DNA regions. It is also associated with genomic instability. Hypermethylation, in contrast, results in the silencing of CpG islands in promoter regions of genes, including tumor-suppressor genes. Epigenetic alterations are more easily reversible compared to genetic changes; modification of the epigenome with demethylating agents and histone deacetylases is being used in the treatment of various malignancies.

TRANSMISSION OF GENETIC DISEASE

Origins and Types of Mutations The term *mutation* or *variant* is used to designate the process of generating genetic variations as well as the effect of these alterations. A *mutation* can be defined as any change in the primary nucleotide sequence of DNA regardless of its functional consequences, although it often has a negative connotation. There has been a shift towards using the more neutral term *variant* to describe sequence changes, and it is now recommended by several professional organizations and guidelines instead of *mutation*. Some variants may be lethal, others are less deleterious, and some may confer an evolutionary advantage. Variations can occur in the germline (sperm or oocytes); these can be transmitted to progeny. Alternatively, variants can occur during embryogenesis or in somatic tissues. Variations that occur during development lead to *mosaicism*, a situation in which tissues are composed of cells with different genetic constitutions. If the germline is mosaic, a mutation can be transmitted to some progeny but not others, which sometimes leads to confusion in assessing the pattern of inheritance. Somatic mutations that do not affect cell survival can sometimes be detected because of variable phenotypic effects in tissues (e.g., pigmented lesions in McCune-Albright syndrome). Other somatic mutations are associated with neoplasia because they confer a growth advantage to cells. Epigenetic events may also influence gene expression or facilitate genetic damage. With the exception of triplet nucleotide repeats, which can expand (see below), variations are usually stable.

Sequence variants are structurally diverse—they can involve the entire genome, as in triploidy (one extra set of chromosomes), or gross numerical or structural alterations in chromosomes or individual genes. Large deletions may affect a portion of a gene or an entire gene, or, if several genes are involved, they may lead to a *contiguous gene syndrome*. Unequal crossing-over between homologous genes can result in fusion gene mutations, as illustrated by color blindness. Variations involving single nucleotides are referred to as *point mutations*.

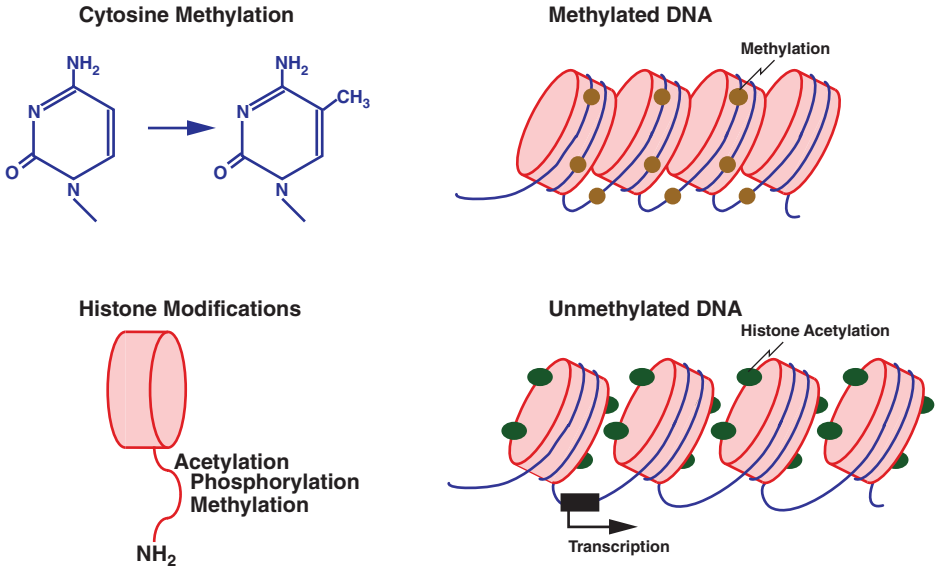

FIGURE 479-7 Epigenetic modifications of DNA and histones. Methylation of cytosine residues is associated with gene silencing. Methylation of certain genomic regions is inherited (imprinting), and it is involved in the silencing of one of the two X chromosomes in females (X-inactivation). Alterations in methylation can also be acquired, e.g., in cancer cells. Covalent posttranslational modifications of histones play an important role in altering DNA accessibility and chromatin structure and hence in regulating transcription. Histones can be reversibly modified in their amino-terminal tails, which protrude from the nucleosome core particle, by acetylation of lysine, phosphorylation of serine, methylation of lysine and arginine residues, and sumoylation. Acetylation of histones by histone acetylases (HATs), e.g., leads to unwinding of chromatin and accessibility to transcription factors. Conversely, deacetylation by histone deacetylases (HDACs) results in a compact chromatin structure and silencing of transcription.

Substitutions are called *transitions* if a purine is replaced by another purine base (A ↔ G) or if a pyrimidine is replaced by another pyrimidine (C ↔ T). Changes from a purine to a pyrimidine, or vice versa, are referred to as *transversions*. If the DNA sequence change occurs in a coding region and alters an amino acid, it is called a *missense mutation*. Depending on the functional consequences of such a missense mutation, amino acid substitutions in different regions of the protein can lead to distinct phenotypes.

Variants can occur in all domains of a gene **(Fig. 479-9)**. A point mutation occurring within the coding region leads to an amino acid substitution if the codon is altered **(Fig. 479-10)**. Point mutations that introduce a premature stop codon result in a truncated or missing protein. Large deletions may affect a portion of a gene or an entire gene, whereas small deletions and insertions alter the reading frame if they do not represent a multiple of three bases. These "frameshift" mutations, also designated as *amphigoric* amino acid changes, lead to an entirely altered carboxy terminus. Mutations in intronic sequences or in exon junctions may destroy or create splice donor or splice acceptor sites. Variants may also be found in the regulatory sequences of genes, resulting in reduced or enhanced gene transcription.

Certain DNA sequences are particularly susceptible to mutagenesis. Successive pyrimidine residues (e.g., T-T or C-C) are subject to the formation of ultraviolet light–induced photoadducts. If these pyrimidine dimers are not repaired by the nucleotide excision repair pathway, mutations will be introduced after DNA synthesis. The dinucleotide C-G, or CpG, is also a hot spot for a specific type of alteration. In this case, methylation of the cytosine is associated with an enhanced rate of deamination to uracil, which is then replaced with thymine. This C → T transition (or G → A on the opposite strand) accounts for at least one-third of point mutations associated with polymorphisms and mutations. In addition to the fact that certain types of mutations (C → T or G → A) are relatively common, the nature of the genetic code also results in overrepresentation of certain amino acid substitutions.

Polymorphisms are sequence variations that have a frequency of at least 1%. Usually, they do not result in a perceptible phenotype; the term *variant* is now preferred for the description of these sequence changes because allele frequency and functional consequences are often not known. Often, they consist of single base-pair substitutions that do not alter the protein coding sequence because of the degenerate nature of the genetic code (synonymous polymorphism), although it is possible that some might alter mRNA stability, translation, or the amino acid sequence (nonsynonymous polymorphism) (Fig. 479-10). The detection of sequence variants poses a practical problem because it is often unclear whether it creates a change with functional consequences or a benign variation. In this situation, the sequence alteration is also described as *variant of unknown significance (VUS)*.

MUTATION RATES Mutations represent an important cause of genetic diversity as well as disease. Mutation rates are difficult to determine in humans because many mutations are silent and because testing is often not adequate to detect the phenotypic consequences. Mutation rates vary in different genes but are estimated to occur at a rate of ~10^{-10}/bp per cell division. Germline mutation rates (as opposed to somatic mutations) are relevant in the transmission of genetic disease. Because the population of oocytes is established very early in development, only ~20 cell divisions are required for completed oogenesis, whereas spermatogenesis involves ~30 divisions by the time of puberty and 20 cell divisions each year thereafter. Consequently, the probability of acquiring new point mutations is much greater in the male germline than the female germline, in which rates of aneuploidy are increased. Thus, the incidence of new point mutations in spermatogonia increases with paternal age (e.g., achondrodysplasia, Marfan's syndrome, neurofibromatosis). It is estimated that about 1 in 10 sperm carries a new deleterious mutation. The rates for new mutations are calculated most readily for autosomal dominant and X-linked disorders and are ~10^{-5}–10^{-6}/locus per generation. Because most monogenic diseases are relatively rare, new mutations account for a significant fraction of cases. This is important in the context of genetic counseling because a new mutation can be transmitted to the affected individual, but this does not necessarily imply that the parents are at risk to transmit the disease to other children. An exception to this is when the new mutation occurs early in germline development, leading to *gonadal mosaicism*.

UNEQUAL CROSSING-OVER Normally, DNA recombination in germ cells occurs with remarkable fidelity to maintain the precise junction sites for the exchanged DNA sequences (Fig. 479-6). However, mispairing of homologous sequences leads to unequal crossover, with gene duplication on one of the chromosomes and gene deletion on the other chromosome. A significant fraction of growth hormone (*GH*) gene deletions, for example, involve unequal crossing-over **(Chap. 391)**. The *GH* gene is a member of a large gene cluster that includes a GH variant gene as well as several structurally related chorionic somatomammotropin genes and pseudogenes (highly homologous but functionally inactive relatives of a normal gene). Because such gene clusters contain multiple homologous DNA sequences arranged in tandem, they are particularly prone to undergo recombination and, consequently, gene duplication or deletion. Duplication of the *PMP22* gene because of unequal crossing-over results in increased gene dosage and type IA Charcot-Marie-Tooth disease. In contrast, unequal crossing-over resulting in deletion of *PMP22* causes a distinct neuropathy called *hereditary neuropathy with liability to pressure palsies* (HNPP) **(Chap. 457)**.

Glucocorticoid-remediable aldosteronism (GRA) is caused by a gene fusion or rearrangement involving the genes that encode aldosterone synthase (*CYP11B2*) and steroid 11β-hydroxylase (*CYP11B1*), normally arranged in tandem on chromosome 8q. These two genes are 95% identical, predisposing to gene duplication and deletion by

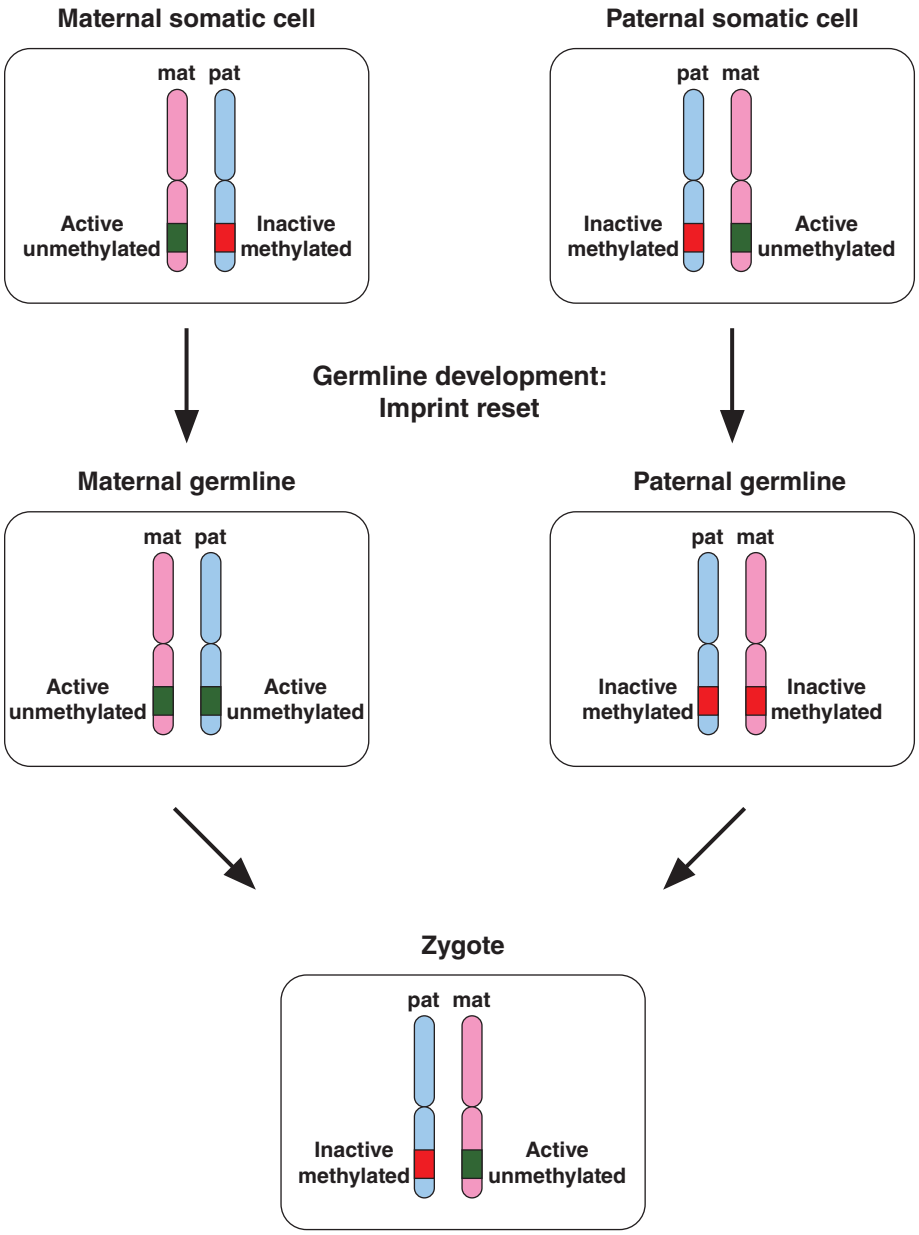

FIGURE 479-8 A few genomic regions are imprinted in a parent-specific fashion. The unmethylated chromosomal regions are actively expressed, whereas the methylated regions are silenced. In the germline, the imprint is reset in a parent-specific fashion: both chromosomes are unmethylated in the maternal (mat) germline and methylated in the paternal (pat) germline. In the zygote, the resulting imprinting pattern is identical with the pattern in the somatic cells of the parents.

unequal crossing-over. The rearranged gene product contains the regulatory regions of 11β-hydroxylase fused to the coding sequence of aldosterone synthetase. Consequently, the latter enzyme is expressed in the adrenocorticotropic hormone (ACTH)–dependent zona fasciculata of the adrenal gland, resulting in overproduction of mineralocorticoids and hypertension **(Chap. 398)**.

Gene conversion refers to a nonreciprocal exchange of homologous genetic information. It has been used to explain how an internal portion of a gene is replaced by a homologous segment copied from another allele or locus; these genetic alterations may range from a few nucleotides to a few thousand nucleotides. As a result of gene conversion, it is possible for short DNA segments of two chromosomes to be identical, even though these sequences are distinct in the parents. A practical consequence of this phenomenon is that nucleotide substitutions can occur during gene conversion between related genes, often altering the function of the gene. In disease states, gene conversion often involves intergenic exchange of DNA between a gene and a related pseudogene. For example, the 21-hydroxylase gene (*CYP21A2*) is adjacent to a nonfunctional pseudogene (*CYP21A1P*). Many of the nucleotide substitutions that are found in the *CYP21A2* gene in patients with congenital adrenal hyperplasia correspond to sequences that are present in the *CYP21A1P* pseudogene, suggesting gene conversion as one cause of mutagenesis. In addition, mitotic gene conversion has been suggested as a mechanism to explain revertant mosaicism in which an inherited mutation is "corrected" in certain cells. For example, patients with autosomal recessive generalized atrophic benign epidermolysis bullosa have acquired reverse mutations in one of the two mutated *COL17A1* alleles, leading to clinically unaffected patches of skin.

INSERTIONS AND DELETIONS Although many instances of insertions and deletions occur as a consequence of unequal crossing-over, there is also evidence for internal duplication, inversion, or deletion of DNA sequences. The fact that certain deletions or insertions appear to occur repeatedly as independent events indicates that specific regions within the DNA sequence predispose to these errors. For example, certain regions of the *DMD* gene, which encodes dystrophin, appear to be hot spots for deletions and result in muscular dystrophy **(Chap. 460)**. Some regions within the human genome are rearrangement hot spots and lead to CNVs.

ERRORS IN DNA REPAIR Because mutations caused by defects in DNA repair accumulate as somatic cells divide, these types of mutations are particularly important in the context of neoplastic disorders. Several genetic disorders involving DNA repair enzymes underscore their importance. Patients with xeroderma pigmentosum have defects in DNA damage recognition or in the nucleotide excision and repair pathway **(Chap. 81)**. Exposed skin is dry and pigmented and is extraordinarily sensitive to the mutagenic effects of ultraviolet irradiation. Variants in more than 10 different genes have been shown to cause the different forms of xeroderma pigmentosum.

Ataxia-telangiectasia is a multisystem disorder that includes progressive neurodegenerative cerebellar ataxia, immunologic defects, telangiectatic lesions, lymphomas and leukemias, and hypersensitivity to ionizing radiation **(Chap. 450)**. The discovery of the ataxia-telangiectasia mutated (*ATM*) gene revealed that it is homologous to genes involved in DNA repair and control of cell cycle checkpoints. Mutations in the *ATM* gene give rise to defects in meiosis as well as increasing susceptibility to damage from ionizing radiation. Fanconi's anemia is also associated with an increased risk of multiple acquired genetic abnormalities. It is characterized by diverse congenital anomalies and a strong predisposition to develop aplastic anemia and acute myelogenous leukemia **(Chap. 109)**. Cells from these patients are susceptible to chromosomal breaks caused by a defect in genetic recombination. It can be caused by mutations in the multiple genes forming the Fanconi's anemia pathway, which is involved in DNA repair and replication. HNPCC (Lynch syndrome) is characterized by autosomal dominant transmission of colon cancer, young age (<50 years) of presentation, predisposition to lesions in the proximal large bowel, and associated malignancies such as uterine cancer and ovarian cancer. HNPCC is predominantly caused by mutations in one of several different mismatch repair (MMR) genes including MutS

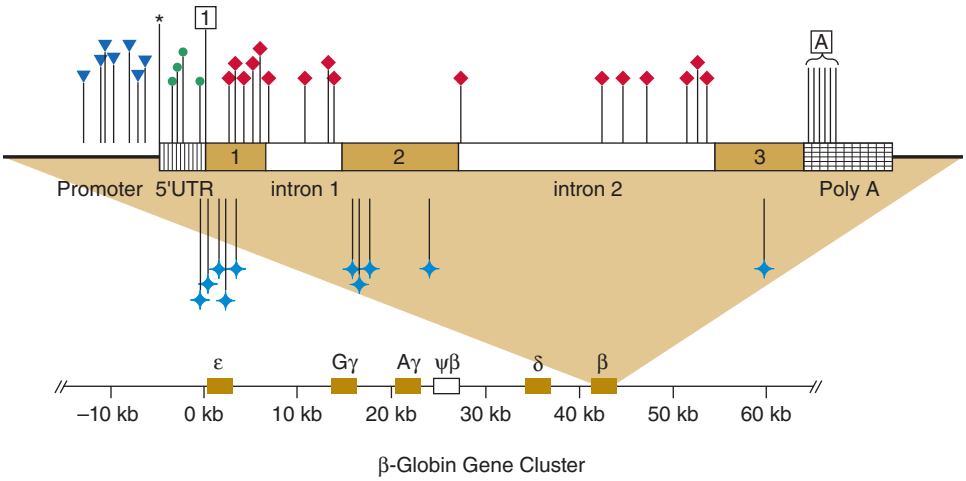

FIGURE 479-9 Point mutations causing β thalassemia as example of allelic heterogeneity. The *β-globin* gene is located in the globin gene cluster. Point mutations occur in the promoter, the CAP site, the 5′-untranslated region, the initiation codon, each of the three exons, the introns, or the polyadenylation signal. Many mutations introduce missense or nonsense mutations, whereas others cause defective RNA splicing. Not shown here are deletion mutations of the β-globin gene or larger deletions of the globin locus that can also result in thalassemia. ▼, promoter mutations; *, CAP site; ●, 5′UTR; 1, initiation codon; ◆, defective RNA processing; ✦, missense and nonsense mutations; A, Poly A signal.

homologue 2 (*MSH2*), MutL homologue 1 and 6 (*MLH1, MLH6*), *MSH6*, *PMS1*, and *PMS2* **(Chap. 86)**. These proteins are involved in the detection of nucleotide mismatches and in the recognition of slipped-strand trinucleotide repeats. Germline mutations in these genes lead to microsatellite instability and a high mutation rate in colon cancer. Genetic screening tests for this disorder are now being used for families considered to be at risk. Recognition of HNPCC allows early screening with colonoscopy and the implementation of prevention strategies using nonsteroidal anti-inflammatory drugs.

UNSTABLE DNA SEQUENCES *Trinucleotide repeats* may be unstable and expand beyond a critical number. Mechanistically, the expansion is thought to be caused by unequal recombination and slipped mispairing. A premutation represents a small increase in trinucleotide copy number. In subsequent generations, the expanded repeat may increase further in length and result in an increasingly severe phenotype, a process called *dynamic mutation* (see below for discussion of anticipation). Trinucleotide expansion was first recognized as a cause of the fragile X syndrome, one of the most common causes of intellectual disability. Other disorders arising from a similar mechanism include Huntington's disease, X-linked spinobulbar muscular atrophy, and myotonic dystrophy. Malignant cells are also characterized by genetic instability, indicating a breakdown in mechanisms that regulate DNA repair and the cell cycle.

Functional Consequences of Mutations Functionally, mutations can be broadly classified as gain-of-function and loss-of-function mutations. Gain-of-function mutations are typically dominant (e.g., they result in phenotypic alterations when a single allele is affected). Inactivating mutations are usually recessive, and an affected individual is homozygous or compound heterozygous (e.g., carrying two different mutant alleles of the same gene) for the disease-causing mutations. Alternatively, mutation in a single allele can result in *haploinsufficiency*, a situation in which one normal allele is not sufficient to maintain a normal phenotype. Haploinsufficiency is a commonly observed mechanism in diseases associated with mutations in transcription factors (Table 479-2). Remarkably, the clinical features among patients with an identical mutation often vary significantly. One mechanism underlying this variability consists in the influence of modifying genes. Haploinsufficiency can also affect the expression of rate-limiting enzymes. For example, haploinsufficiency in enzymes involved in heme synthesis can cause porphyrias **(Chap. 428)**.

An increase in dosage of a gene product may also result in disease, as illustrated by the duplication of the *DAX1 (NR0B1)* gene in dosage-sensitive sex reversal **(Chap. 402)**. Mutation in a single allele can also result in loss of function due to a dominant-negative effect. In this case, the mutated allele interferes with the function of the normal (wild type) gene product by one of several different mechanisms: (1) a mutant protein may interfere with the function of a multimeric protein complex, as illustrated by mutations in type 1 collagen (*COL1A1*, *COL1A2*) genes in osteogenesis imperfecta **(Chap. 425)**; (2) a mutant protein may occupy binding sites on proteins or promoter response elements, as illustrated by thyroid hormone resistance β, a disorder in which

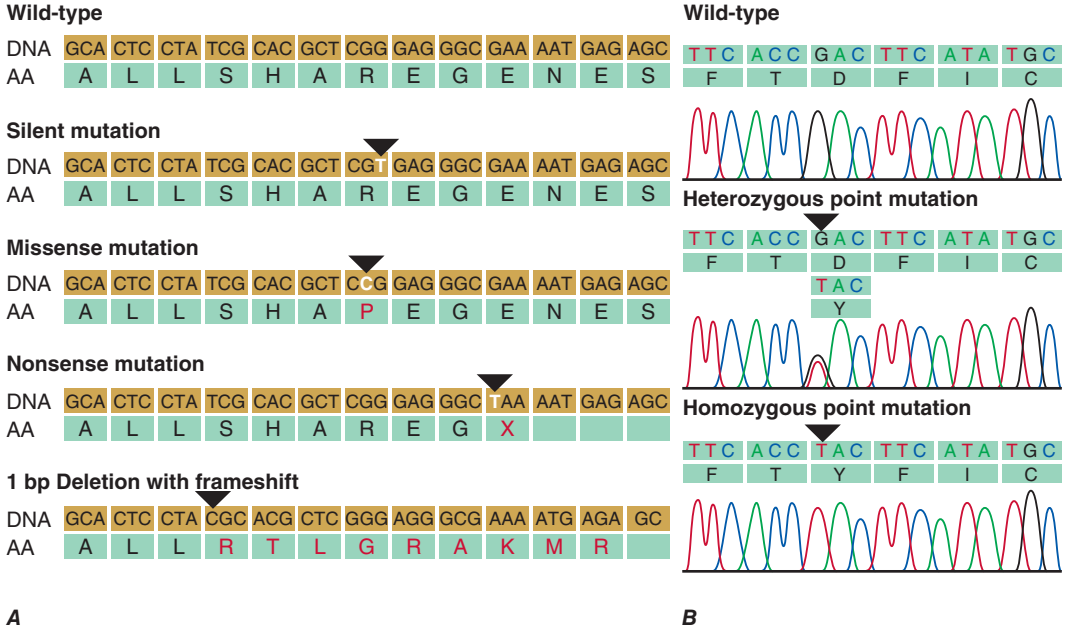

FIGURE 479-10 ***A.*** Examples of mutations (now commonly referred to as *variations*). The coding strand is shown with the encoded amino acid sequence. ***B.*** Chromatograms of sequence analyses after amplification of genomic DNA by polymerase chain reaction.

inactivated thyroid hormone receptor β binds to target genes and functions as an antagonist of normal receptors **(Chap. 394)**; or (3) a mutant protein can be cytotoxic as in α_1 antitrypsin deficiency **(Chap. 303)** or autosomal dominant neurohypophyseal diabetes insipidus **(Chap. 393)**, in which the abnormally folded proteins are trapped within the endoplasmic reticulum and ultimately cause cellular damage.

Genotype and Phenotype • **ALLELES, GENOTYPES, AND HAPLOTYPES** An observed trait is referred to as a *phenotype*; the genetic information defining the phenotype is called the *genotype*. Alternative forms of a gene or a genetic marker are referred to as *alleles*. Alleles may be polymorphic variants of nucleic acids that have no apparent effect on gene expression or function. In other instances, these variants may have subtle effects on gene expression, thereby conferring adaptive advantages associated with genetic diversity. On the other hand, allelic variants may reflect mutations that clearly alter the function of a gene product. The common Glu6Val (E6V) sickle cell mutation in the β-*globin* gene and the ΔF508 deletion of phenylalanine (F) in the *CFTR* gene are examples of allelic variants of these genes that result in disease. Because each individual has two copies of each chromosome (one inherited from the mother and one inherited from the father), an individual can have only two alleles at a given locus. However, there can be many different alleles in the population. The normal or common allele is usually referred to as *wild type*. When alleles at a given locus are identical, the individual is *homozygous*. Inheriting identical copies of a mutant allele occurs in many autosomal recessive disorders, particularly in circumstances of consanguinity or isolated populations. If the alleles are different on the maternal and the paternal copy of the gene, the individual is *heterozygous* at this locus (Fig. 479-10). If two different mutant alleles are inherited at a given locus, the individual is said to be a *compound heterozygote*. *Hemizygous* is used to describe males with a mutation in an X chromosomal gene or a female with a loss of one X chromosomal locus.

Genotypes describe the specific alleles at a particular locus. For example, there are three common alleles (E2, E3, E4) of the apolipoprotein E (*APOE*) gene. The genotype of an individual can therefore be described as *APOE3/4* or *APOE4/4* or any other variant. These designations indicate which alleles are present on the two chromosomes in the *APOE* gene at locus 19q13.2. In other cases, the genotype might be assigned arbitrary numbers (e.g., 1/2) or letters (e.g., B/b) to distinguish different alleles.

A *haplotype* refers to a group of alleles that are closely linked together at a genomic locus (Fig. 479-4). Haplotypes are useful for tracking the transmission of genomic segments within families and for detecting evidence of genetic recombination if the crossover event occurs between the alleles (Fig. 479-6). As an example, various alleles of the histocompatibility locus antigens (HLA) at the major histocompatibility complex (MHC) on chromosome 6 are used to establish haplotypes associated with certain disease states. For example, 21-hydroxylase deficiency, complement deficiency, and hemochromatosis are each associated with specific HLA haplotypes. It is now recognized that these genes lie in close proximity to the HLA locus, which explains why HLA associations were identified even before the disease genes were cloned and localized. In other cases, specific HLA associations with diseases such as ankylosing spondylitis (HLA-B27) or type 1 diabetes mellitus (HLA-DR4) reflect the role of specific HLA allelic variants in susceptibility to these autoimmune diseases. The characterization of common SNP haplotypes in numerous populations from different parts of the world has provided the necessary tools for association studies designed to detect genes involved in the pathogenesis of complex disorders (Table 479-1). The presence or absence of certain haplotypes can also be relevant for the customized choice of medical therapies (pharmacogenomics) or may have value for preventive strategies.

Genotype-phenotype correlation describes the association of a specific mutation and the resulting phenotype. The phenotype may differ depending on the location or type of the mutation in some genes. For example, in von Hippel–Lindau disease, an autosomal dominant multisystem disease that can include renal cell carcinoma, hemangioblastomas, and pheochromocytomas, among others, the phenotype varies greatly, and the identification of the specific mutation can be clinically useful in order to predict the spectrum of disease manifestations.

ALLELIC HETEROGENEITY *Allelic heterogeneity* refers to the fact that different mutations in the same genetic locus can cause an identical or similar phenotype. For example, many different mutations of the β-globin locus can cause β thalassemia **(Table 479-3)** (Fig. 479-9). In essence, allelic heterogeneity reflects the fact that many different mutations can alter protein structure and function. For this reason, maps of inactivating mutations in genes usually show a near-random distribution. Exceptions include (1) a founder effect, in which a particular mutation that does not affect reproductive capacity can be traced to a single individual; (2) "hot spots" for mutations, in which the nature of the DNA sequence predisposes to a recurring mutation; and (3) localization of mutations to certain domains that are particularly critical for protein function. Allelic heterogeneity creates a practical problem for genetic testing because one must often examine the entire genetic locus for mutations, because these can differ in each patient. For example, ~2000 variants have been identified in the *CFTR* gene to date, although some of them are very rare and some may not be disease-causing (Fig. 479-3). Mutational analysis may initially focus on a panel of mutations that are particularly frequent (often taking the ethnic background of the patient into account), but a negative result does not exclude the presence of a mutation elsewhere in the gene. Until recently, mutational analyses tended to focus on the coding region of a gene without considering regulatory and intronic regions. However, disease-causing mutations may be located outside the coding regions, so negative results need to be interpreted with caution. The increasingly widespread access to comprehensive sequencing technologies, WES and WGS, greatly facilitates unbiased mutational analyses. However, comprehensive sequencing can result in significant diagnostic challenges because the detection of a sequence alteration is not always sufficient to establish that it has a causal role (VUS).

PHENOTYPIC HETEROGENEITY *Phenotypic heterogeneity* occurs when more than one phenotype is caused by allelic mutations (e.g., by different mutations in the same gene) (Table 479-3). For example, laminopathies are monogenic multisystem disorders that result from mutations in the *LMNA* gene, which encodes the nuclear lamins A and C. Multiple autosomal dominant and recessive disorders are caused by mutations in the *LMNA* gene. They include several forms of lipodystrophies, Emery-Dreifuss muscular dystrophy, progeria syndromes, a form of neuronal Charcot-Marie-Tooth disease (type 2B1), and a group of overlapping syndromes. Remarkably, hierarchical cluster analysis has revealed that the phenotypes vary depending on the position of the mutation (*genotype-phenotype correlation*). Similarly, identical mutations in the *FGFR2* gene can result in very distinct phenotypes: Crouzon's syndrome (craniofacial synostosis) or Pfeiffer's syndrome (acrocephalopolysyndactyly).

LOCUS OR NONALLELIC HETEROGENEITY AND PHENOCOPIES *Nonallelic* or *locus heterogeneity* refers to the situation in which a similar disease phenotype results from mutations at different genetic loci (Table 479-3). This often occurs when more than one gene product produces different subunits of an interacting complex or when different genes are involved in the same genetic cascade or physiologic pathway. For example, osteogenesis imperfecta can arise from mutations in two different procollagen genes (*COL1A1* or *COL1A2*) that are located on different chromosomes and can involve multiple other genes **(Chap. 425)**. The effects of inactivating mutations in these two genes are similar because the protein products comprise different subunits of the helical collagen fiber. Similarly, muscular dystrophy syndromes can be caused by mutations in various genes, consistent with the fact that it can be transmitted in an X-linked (Duchenne or Becker), autosomal dominant (limb-girdle muscular dystrophy type 1), or autosomal recessive (limb-girdle muscular dystrophy type 2) manner **(Chap. 460)**. Mutations in the X-linked *DMD* gene, which encodes dystrophin, are the most common cause of muscular dystrophy. This feature reflects the large size of the gene (2.3 MB, 79 exons), as well as the fact that the phenotype is expressed in hemizygous males because they have only

TABLE 479-3 Selected Examples of Phenotypic Heterogeneity and Locus Heterogeneity

Phenotypic Heterogeneity

GENE, PROTEIN	PHENOTYPE	INHERITANCE	OMIM
LMNA, Lamin A/C	Emery-Dreifuss muscular dystrophy (AD)	AD	181350
	Familial partial lipodystrophy Dunnigan	AD	151660
	Hutchinson-Gilford progeria	AD	176670
	Atypical Werner's syndrome	AD	150330
	Dilated cardiomyopathy 1A	AD	115200
	Familial atrial fibrillation 3	AD	607554
	Charcot-Marie-Tooth type 2B1	AR	605588
KRAS	Noonan's syndrome	AD	163950
	Cardio-facio-cutaneous syndrome 1	AD	115150

Locus Heterogeneity

PHENOTYPE	GENE	CHROMOSOMAL LOCATION	PROTEIN
Familial hypertrophic cardiomyopathy	*MYH7*	14q11.2	Myosin heavy chain beta
Genes encoding sarcomeric proteins	*TNNT2*	1q32.1	Troponin-T2
	TPM1	15q22.2	Tropomyosin alpha
	MYBPC3	11p11q	Myosin-binding protein C

a single copy of the X chromosome. Dystrophin is associated with a large protein complex linked to the membrane-associated cytoskeleton in muscle. Mutations in several different components of this protein complex can also cause muscular dystrophy syndromes. Although the phenotypic features of some of these disorders are distinct, the phenotypic spectrum caused by mutations in different genes overlaps, thereby leading to nonallelic heterogeneity. It should be noted that mutations in dystrophin are also associated with allelic heterogeneity. For example, mutations in the *DMD* gene can cause either Duchenne's or the less severe Becker's muscular dystrophy, depending on the severity of the protein defect.

Recognition of nonallelic heterogeneity is important for several reasons: (1) the ability to identify disease loci in linkage studies is reduced by including patients with similar phenotypes but different genetic disorders; (2) genetic testing is more complex because several different genes need to be considered along with the possibility of different mutations in each of the candidate genes; and (3) novel information is gained about how genes or proteins interact, providing unique insights into molecular physiology.

Phenocopies refer to circumstances in which nongenetic conditions mimic a genetic disorder. For example, features of toxin- or drug-induced neurologic syndromes can resemble those seen in Huntington's disease, and vascular causes of dementia share phenotypic features with familial forms of Alzheimer's dementia **(Chap. 442)**. As in nonallelic heterogeneity, the presence of phenocopies has the potential to confound linkage studies and genetic testing. Patient history and subtle differences in phenotype can often provide clues that distinguish these disorders from related genetic conditions.

VARIABLE EXPRESSIVITY AND INCOMPLETE PENETRANCE The same genetic mutation may be associated with a phenotypic spectrum in different affected individuals, thereby illustrating the phenomenon of *variable expressivity*. This may include different manifestations of a disorder variably involving different organs (e.g., multiple endocrine neoplasia [MEN]), the severity of the disorder (e.g., cystic fibrosis), or the age of disease onset (e.g., Alzheimer's dementia). MEN 1 illustrates several of these features. In this autosomal dominant tumor syndrome, affected individuals carry an inactivating germline mutation that is inherited in an autosomal dominant fashion. After somatic inactivation of the alternate allele (loss of heterozygosity; Knudson two-hit model), patients can develop tumors of the parathyroid gland, endocrine pancreas, the pituitary gland, and dermatologic lesions **(Chap. 400)**. However, the pattern of tumors in the different glands, the age at which tumors develop, and the types of hormones produced vary among

affected individuals, even within a given family. In this example, the phenotypic variability arises, in part, because of the requirement for a second somatic mutation in the normal copy of the *MEN1* gene, as well as the large array of different cell types that are susceptible to the effects of *MEN1* gene mutations. In part, variable expression reflects the influence of modifier genes, or genetic background, on the effects of a particular mutation. Even in identical twins, in whom the genetic constitution is essentially the same, one can occasionally see variable expression of a genetic disease.

Interactions with the environment can also influence the course of a disease. For example, the manifestations and severity of hemochromatosis can be influenced by iron intake **(Chap. 426)**, and the course of phenylketonuria is affected by exposure to phenylalanine in the diet **(Chap. 431)**. Other metabolic disorders, such as hyperlipidemias and porphyria, also fall into this category. Many mechanisms, including genetic effects and environmental influences, can therefore lead to variable expressivity. In genetic counseling, it is particularly important to recognize this variability, because one cannot always predict the course of disease, even when the mutation is known.

Penetrance refers to the proportion of individuals with a mutant genotype that express the phenotype. If all carriers of a mutant express the phenotype, penetrance is complete, whereas it is said to be *incomplete* or *reduced* if some individuals do not exhibit features of the phenotype. Dominant conditions with incomplete penetrance are characterized by skipping of generations with unaffected carriers transmitting the mutant gene. For example, hypertrophic obstructive cardiomyopathy (HCM) caused by mutations in the *myosin-binding protein C* gene is a dominant disorder with clinical features in only a subset of patients who carry the mutation **(Chap. 267)**. Patients who have the mutation, but no evidence of the disease, can still transmit the disorder to subsequent generations. In many conditions with postnatal onset, the proportion of gene carriers who are affected varies with age. Thus, when describing penetrance, one must specify age. For example, for disorders such as Huntington's disease or familial amyotrophic lateral sclerosis, which present later in life, the rate of penetrance is influenced by the age at which the clinical assessment is performed. *Imprinting* can also modify the penetrance of a disease. For example, in patients with AHO, mutations in the $G_s\alpha$ subunit (*GNAS1* gene) are expressed clinically only in individuals who inherit the mutation from their mother **(Chap. 422)**.

SEX-INFLUENCED PHENOTYPES Certain mutations affect males and females quite differently. In some instances, this is because the gene resides on the X or Y sex chromosomes (X-linked disorders and Y-linked disorders). As a result, the phenotype of mutated X-linked genes will be expressed fully in males but variably in heterozygous females, depending on the degree of X-inactivation and the function of the gene. For example, most heterozygous female carriers of factor VIII deficiency (hemophilia A) are asymptomatic because sufficient factor VIII is produced to prevent a defect in coagulation **(Chap. 121)**. On the other hand, some females heterozygous for the X-linked lipid storage defect caused by α-galactosidase A deficiency (Fabry's disease) experience mild manifestations of painful neuropathy, as well as other features of the disease **(Chap. 429)**. Because only males have a Y chromosome, mutations in genes such as *SRY*, which causes male-to-female sex reversal, or *DAZ* (deleted in azoospermia), which causes abnormalities of spermatogenesis, are unique to males **(Chap. 402)**.

Other diseases are expressed in a sex-limited manner because of the differential function of the gene product in males and females. Activating mutations in the luteinizing hormone receptor cause dominant male-limited precocious puberty in boys **(Chap. 403)**. The phenotype is unique to males because activation of the receptor induces testosterone production in the testis, whereas it is functionally silent in the immature ovary. Biallelic inactivating mutations of the follicle-stimulating hormone (FSH) receptor cause primary ovarian failure in females because the follicles do not develop in the absence of FSH action. In contrast, affected males have a more subtle phenotype, because testosterone production is preserved (allowing sexual maturation) and spermatogenesis is only partially impaired **(Chap. 403)**. In congenital adrenal hyperplasia, most commonly caused by 21-hydroxylase deficiency, cortisol production is impaired and ACTH stimulation of the adrenal gland leads to increased production of androgenic precursors **(Chap. 398)**. In females, the increased androgen level causes ambiguous genitalia, which can be recognized at the time of birth. In males, the diagnosis may be made on the basis of adrenal insufficiency at birth, because the increased adrenal androgen level does not alter sexual differentiation, or later in childhood, because of the development of precocious puberty. Hemochromatosis is more common in males than in females, presumably because of differences in dietary iron intake and losses associated with menstruation and pregnancy in females **(Chap. 426)**.

Chromosomal Disorders *Chromosomal disorders* and the techniques used for their characterization have been discussed in detail in previous editions of this textbook. Chromosomal or cytogenetic disorders are caused by numerical (aneuploidy) or structural aberrations (deletions, duplications, translocations, inversions, dicentric and ring chromosomes, Robertsonian translocations) in chromosomes. They occur in ~1% of the general population, in 8% of stillbirths, and in close to 50% of spontaneously aborted fetuses. Indications for cytogenetic and cytogenomic chromosome analyses are summarized in **Table 479-4**. *Contiguous gene syndromes* (e.g., large deletions affecting several genes) have been useful for identifying the location of new disease-causing genes. Because of the variable size of gene deletions in different patients, a systematic comparison of phenotypes and locations of deletion breakpoints allows positions of particular genes to be mapped within the critical genomic region.

Monogenic Mendelian Disorders Monogenic human diseases are frequently referred to as *Mendelian disorders* because they obey the principles of genetic transmission originally set forth in Gregor Mendel's classic work. The continuously updated OMIM catalogue lists several thousand of these disorders and provides information about the clinical phenotype, molecular basis, allelic variants, and pertinent animal models (Table 479-1). The mode of inheritance for a given phenotypic trait or disease is determined by pedigree analysis. All affected and unaffected individuals in the family are recorded in a pedigree using standard symbols **(Fig. 479-11)**. The principles of allelic segregation, and the transmission of alleles from parents to children, are illustrated in **Fig. 479-12**. One dominant (A) allele and one recessive (a) allele can display three Mendelian modes of inheritance: autosomal dominant, autosomal recessive, and X-linked. About 65% of human monogenic disorders are autosomal dominant, 25% are autosomal recessive, and 5% are X-linked. Genetic testing is now readily available for the characterization of monogenic disorders and plays an important role in clinical medicine **(Chap. 480)**.

TABLE 479-4 Indications for Cytogenetic and Cytogenomic Analysis across the Life Span

TIMING OF TESTING	INDICATIONS FOR TESTING
Prenatal	Advanced maternal age Abnormalities on ultrasound Increased risk for genetic disorder on maternal serum screen
Neonatal and childhood	Multiple congenital anomalies Intellectual disability Autism spectrum disorders Developmental delay Failure to thrive Short stature Disorders of sexual development History of familial chromosomal alteration Cancer
Adult	Infertility Recurrent miscarriage Familial cancer

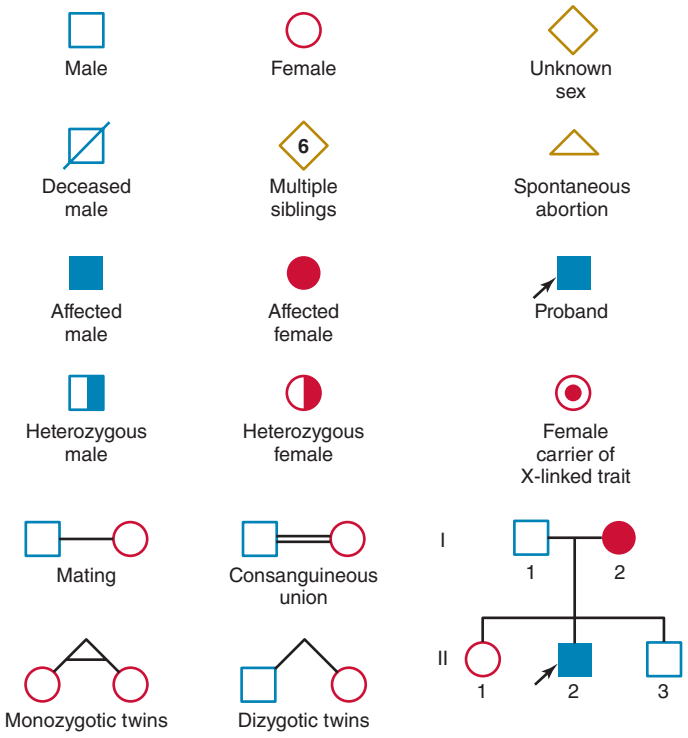

FIGURE 479-11 Standard pedigree symbols.

AUTOSOMAL DOMINANT DISORDERS In autosomal dominant disorders, mutations in a single allele are sufficient to cause the disease. In contrast to recessive disorders, in which disease pathogenesis is relatively straightforward because there is a biallelic loss of gene function, dominant disorders can be caused by various disease mechanisms, many of which are unique to the function of the genetic pathway involved. Mechanistically, the mutation may confer constitutive activation (gain of function), exert a dominant negative effect, or result in loss of function and haploinsufficiency.

In autosomal dominant disorders, individuals are affected in successive generations; the disease does not occur in the offspring of unaffected individuals. Males and females are affected with equal frequency because the defective gene resides on one of the 22 autosomes (**Fig. 479-13*A***). Autosomal dominant mutations alter one of the two alleles at a given locus. Because the alleles segregate randomly at meiosis, the probability that an offspring will be affected is 50%. Unless there is a new germline mutation, an affected individual has an affected parent. Children with a normal genotype do not transmit the disorder. Due to differences in penetrance or expressivity (see above), the clinical manifestations of autosomal dominant disorders may be variable. Because of these variations, it is sometimes challenging to determine the pattern of inheritance.

It should be recognized, however, that some individuals acquire a mutated gene from an unaffected parent due to de novo germline mutations. They occur more frequently during later cell divisions in gametogenesis, which explains why siblings are rarely affected. As noted, new germline mutations occur more frequently in fathers of advanced age. For example, the average age of fathers with new germline mutations that cause Marfan's syndrome is ~37 years, whereas fathers who transmit the disease by inheritance have an average age of ~30 years.

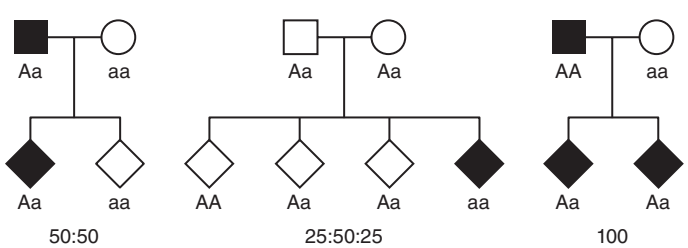

FIGURE 479-12 Segregation of alleles. Segregation of genotypes in the offspring of parents with one dominant (A) and one recessive (a) allele. The distribution of the parental alleles to their offspring depends on the combination present in the parents. Filled symbols = affected individuals.

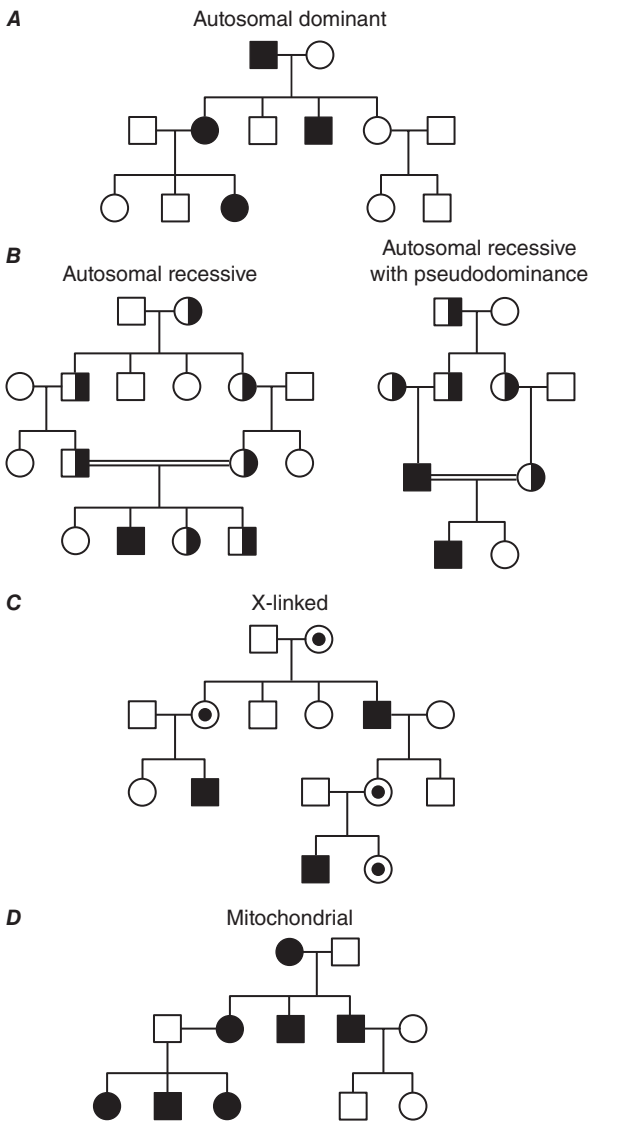

FIGURE 479-13 *A.* Dominant, ***B.*** recessive, ***C.*** X-linked, and ***D.*** mitochondrial (matrilinear) inheritance.

AUTOSOMAL RECESSIVE DISORDERS In recessive disorders, the mutated alleles result in a complete or partial loss of function. They frequently involve enzymes in metabolic pathways, receptors, or proteins in signaling cascades. In an autosomal recessive disease, the affected individual, who can be of either sex, is a homozygote or compound heterozygote for a single-gene defect. With a few important exceptions, autosomal recessive diseases are rare and occur more often in the context of parental consanguinity. The relatively high frequency of certain recessive disorders such as sickle cell anemia, cystic fibrosis, and thalassemia, is partially explained by a selective biologic advantage for the heterozygous state (see below). Although heterozygous carriers of a defective allele are usually clinically normal, they may display subtle differences in phenotype that only become apparent with more precise testing or in the context of certain environmental influences. In sickle cell anemia, for example, heterozygotes are normally asymptomatic. However, in situations of dehydration or diminished oxygen pressure, sickle cell crises can also occur in heterozygotes (**Chap. 103**).

In most instances, an affected individual is the offspring of heterozygous parents. In this situation, there is a 25% chance that the offspring will have a normal genotype, a 50% probability of a heterozygous state, and a 25% risk of homozygosity for the recessive alleles (**Figs.** 479-12 and **479-13*B***). In the case of one unaffected heterozygous and one affected homozygous parent, the probability of disease increases to 50% for

each child. In this instance, the pedigree analysis mimics an autosomal dominant mode of inheritance (*pseudodominance*). In contrast to autosomal dominant disorders, new mutations in recessive alleles are rarely manifest because they usually result in an asymptomatic carrier state.

X-LINKED DISORDERS Males have only one X chromosome; consequently, a daughter always inherits her father's X chromosome in addition to one of her mother's two X chromosomes. A son inherits the Y chromosome from his father and one maternal X chromosome. Thus, the characteristic features of X-linked inheritance are (1) the absence of father-to-son transmission and (2) the fact that all daughters of an affected male are obligate carriers of the mutant allele **(Fig. 479-13*C*)**. The risk of developing disease due to a mutant X-chromosomal gene differs in the two sexes. Because males have only one X chromosome, they are hemizygous for the mutant allele; thus, they are more likely to develop the mutant phenotype, regardless of whether the mutation is dominant or recessive. A female may be either heterozygous or homozygous for the mutant allele, which may be dominant or recessive. The terms *X-linked dominant* and *X-linked recessive* are therefore only applicable to expression of the mutant phenotype in women. In addition, the expression of X-chromosomal genes is influenced by X chromosome inactivation.

Y-LINKED DISORDERS The Y chromosome has a relatively small number of genes. One such gene, the sex-region determining Y factor (*SRY*), which encodes the testis-determining factor (*TDF*), is crucial for normal male development. Normally, there is infrequent exchange of sequences on the Y chromosome with the X chromosome. The *SRY* region is adjacent to the pseudoautosomal region, a chromosomal segment on the X and Y chromosomes with a high degree of homology. A crossing-over event occasionally involves the *SRY* region with the distal tip of the X chromosome during meiosis in the male. Translocations can result in XY females with the Y chromosome lacking the *SRY* gene or XX males harboring the *SRY* gene on one of the X chromosomes **(Chap. 402)**. Point mutations in the *SRY* gene may also result in individuals with an XY genotype and an incomplete female phenotype. Most of these mutations occur de novo. Men with oligospermia/azoospermia frequently have microdeletions on the long arm of the Y chromosome that involve one or more of the azoospermia factor (*AZF*) genes.

Exceptions to Simple Mendelian Inheritance Patterns

MITOCHONDRIAL DISORDERS Mendelian inheritance refers to the transmission of genes encoded by DNA contained in the nuclear chromosomes. In addition, each mitochondrion contains several copies of a small circular chromosome **(Chap. 481)**. The mitochondrial DNA (mtDNA) is ~16.5 kb and encodes transfer and ribosomal RNAs and 13 core proteins that are components of the respiratory chain involved in oxidative phosphorylation and ATP generation. The mitochondrial genome does not recombine and is inherited through the maternal line because sperm does not contribute significant cytoplasmic components to the zygote. A noncoding region of the mitochondrial chromosome, referred to as D-loop, is highly polymorphic. This property, together with the absence of mtDNA recombination, makes it a valuable tool for studies tracing human migration and evolution, and it is also used for specific forensic applications.

Inherited mitochondrial disorders are transmitted in a matrilineal fashion; all children from an affected mother will inherit the disease, but it will not be transmitted from an affected father to his children **(Fig. 479-13*D*)**. Alterations in the mtDNA that involves enzymes required for oxidative phosphorylation lead to reduction of ATP supply, generation of free radicals, and induction of apoptosis. Several syndromic disorders arising from mutations in the mitochondrial genome are known in humans, and they affect both protein-coding and tRNA genes. The broad clinical spectrum often involves (cardio) myopathies and encephalopathies because of the high dependence of these tissues on oxidative phosphorylation. The age of onset and the clinical course are highly variable because of the unusual mechanisms of mtDNA transmission, which replicates independently from nuclear DNA. During cell replication, the proportion of wild-type and mutant mitochondria can drift among different cells and tissues. The resulting heterogeneity in the proportion of mitochondria with and without a mutation is referred to as *heteroplasmia* and underlies the phenotypic variability that is characteristic of mitochondrial diseases.

Acquired somatic mutations in mitochondria are thought to be involved in several age-dependent degenerative disorders affecting predominantly muscle and the peripheral and central nervous system (e.g., Alzheimer's and Parkinson's diseases). Establishing that an mtDNA alteration is causal for a clinical phenotype is challenging because of the high degree of polymorphism in mtDNA and the phenotypic variability characteristic of these disorders. Certain pharmacologic treatments may have an impact on mitochondria and/or their function. For example, treatment with the antiretroviral compound azidothymidine (AZT) causes an acquired mitochondrial myopathy through depletion of muscular mtDNA.

MOSAICISM Mosaicism refers to the presence of two or more genetically distinct cell lines in the tissues of an individual. It results from a mutation that occurs during embryonic, fetal, or extrauterine development. The developmental stage at which the mutation arises will determine whether germ cells and/or somatic cells are involved. Chromosomal mosaicism results from nondisjunction at an early embryonic mitotic division, leading to the persistence of more than one cell line, as exemplified by some patients with Turner's syndrome **(Chap. 402)**. Somatic mosaicism is characterized by a patchy distribution of genetically altered somatic cells. The McCune-Albright syndrome, for example, is caused by activating mutations in the stimulatory G protein α ($G_s\alpha$) that occur postzygotically in early development **(Chap. 422)**. The clinical phenotype varies depending on the tissue distribution of the mutation; manifestations include ovarian cysts that secrete sex steroids and cause precocious puberty, polyostotic fibrous dysplasia, café-au-lait skin pigmentation, GH-secreting pituitary adenomas, and hypersecreting autonomous thyroid nodules.

X-INACTIVATION, IMPRINTING, AND UNIPARENTAL DISOMY According to traditional Mendelian principles, the parental origin of a mutant gene is irrelevant for the expression of the phenotype. There are, however, important exceptions to this rule. *X-inactivation* prevents the expression of most genes on one of the two X chromosomes in every cell of a female. Gene inactivation through genomic imprinting occurs on selected chromosomal regions of autosomes and leads to inheritable preferential expression of one of the parental alleles. It is of pathophysiologic importance in disorders where the transmission of disease is dependent on the sex of the transmitting parent and, thus, plays an important role in the expression of certain genetic disorders. Two classic examples are the Prader-Willi syndrome and Angelman's syndrome. Prader-Willi syndrome is characterized by diminished fetal activity, obesity, hypotonia, intellectual disability, short stature, and hypogonadotropic hypogonadism. Deletions of the paternal copy of the Prader-Willi locus located on the short arm of chromosome 15 result in a contiguous gene syndrome involving missing paternal copies of the *necdin* and *SNRPN* genes, among others. In contrast, patients with Angelman's syndrome, characterized by intellectual disability, seizures, ataxia, and hypotonia, have deletions involving the maternal copy of this region on chromosome 15. These two syndromes may also result from *uniparental disomy*. In this case, the syndromes are not caused by deletions on chromosome 15 but by the inheritance of either two maternal chromosomes (Prader-Willi syndrome) or two paternal chromosomes (Angelman's syndrome). Lastly, the two distinct phenotypes can also be caused by an imprinting defect that impairs the resetting of the imprint during zygote development (defect in the father leads to Prader-Willi syndrome; defect in the mother leads to Angelman's syndrome).

Imprinting and the related phenomenon of allelic exclusion may be more common than currently documented because it is difficult to examine levels of mRNA expression from the maternal and paternal alleles in specific tissues or in individual cells. Genomic imprinting, or uniparental disomy, is involved in the pathogenesis of several other disorders and malignancies. For example, hydatidiform moles contain a normal number of diploid chromosomes, but they are exclusively of

paternal origin. The opposite situation occurs in ovarian teratomata, with 46 chromosomes of maternal origin. Expression of the imprinted gene for insulin-like growth factor 2 (IGF-2) is involved in the pathogenesis of the cancer-predisposing Beckwith-Wiedemann syndrome (BWS). These children show somatic overgrowth with organomegalies and hemihypertrophy, and they have an increased risk of embryonal malignancies such as Wilms' tumor. Normally, only the paternally derived copy of the *IGF2* gene is active, and the maternal copy is inactive. BWS can be caused by several genetic defects that result in overactivity of IGF-2, or a missing active copy of *CDKN1C*, that result in inhibition of cell proliferation. They include paternal uniparental disomy (UPD) of chromosome 11, aberrant methylation of this region, maternal chromosomal rearrangements, or deletions within the locus.

Alterations of the epigenome through gain and loss of DNA methylation and altered histone modifications play an important role in the pathogenesis of malignancies.

SOMATIC MUTATIONS Cancer can be considered a genetic disease at the cellular level **(Chap. 76)**. Cancers are monoclonal in origin, indicating that they have arisen from a single precursor cell with one or several mutations in genes controlling growth (proliferation or apoptosis) and/or differentiation. These acquired somatic mutations are restricted to the tumor and its metastases and are not found in the surrounding normal tissue. The molecular alterations include dominant gain-of-function mutations in oncogenes, recessive loss-of-function mutations in tumor-suppressor genes and DNA repair genes, gene amplification, and chromosome rearrangements. Chromothripsis refers to a mutational process including multiple clustered chromosomal rearrangements in close vicinity, for example, after injury by ionizing radiation. Rarely, a single mutation in certain genes may be sufficient to transform a normal cell into a malignant cell. In most cancers, however, the development of a malignant phenotype requires several genetic alterations for the gradual progression from a normal cell to a cancerous cell, a phenomenon termed *multistep carcinogenesis*. Genome-wide analyses of cancers using deep sequencing often reveal somatic rearrangements resulting in fusion genes and mutations in multiple genes (Table 479-1 and **Fig. 479-14**). Comprehensive sequence analyses, now also possible through single-cell sequencing (SCS), provide insight into the evolution and genetic heterogeneity within malignancies; these include intratumoral heterogeneity among the cells of the primary tumor, intermetastatic and intrametastatic heterogeneity, and interpatient differences. These analyses further support the notion of cancer as an ongoing process of clonal evolution, in which successive rounds of clonal selection within the primary tumor and metastatic lesions result in diverse genetic and epigenetic alterations that require targeted (personalized) therapies (precision medicine). The heterogeneity of mutations within a tumor can also lead to resistance to targeted therapies because cells with mutations that are resistant to the therapy, even if they are a minor part of the tumor population, will be selected as the more sensitive cells are eliminated.

Telomeres, repeats of conserved sequences, protect the ends the chromosomes from DNA damage or fusion with neighboring chromosomes. Telomere length shortens with age. Most human tumors express telomerase, an enzyme formed of a protein and an RNA component, which adds telomere repeats at the ends of chromosomes during replication. This mechanism impedes shortening of the telomeres and is associated with enhanced replicative capacity in cancer cells. Telomerase inhibitors provide a strategy for treating advanced human cancers.

In many cancer syndromes, there is frequently an inherited *predisposition* to tumor formation. In these instances, a germline mutation is inherited in an autosomal dominant fashion inactivating one allele of an autosomal tumor-suppressor gene. If the second allele is inactivated by a somatic mutation or by epigenetic silencing in a given cell, this will lead to neoplastic growth (Knudson two-hit model). Thus, the defective allele in the germline is transmitted in a dominant mode, although tumorigenesis results from a biallelic loss of the tumor-suppressor gene in an affected tissue. The classic example to illustrate this phenomenon is retinoblastoma, which can occur as a sporadic or hereditary tumor. In sporadic retinoblastoma, both copies of the retinoblastoma (*RB*) gene are inactivated through two somatic events. In hereditary retinoblastoma, one mutated or deleted *RB* allele is inherited in an autosomal dominant manner and the second allele is inactivated by a subsequent somatic mutation. This two-hit model applies to other inherited cancer syndromes such as MEN 1 **(Chap. 400)** and neurofibromatosis types 1 and 2 **(Chap. 95)**. In contrast, in the autosomal dominant MEN 2 syndrome, the predisposition for tumor formation in various organs is caused by a gain-of-function mutation in a single allele of the *RET* gene **(Chap. 400)**.

NUCLEOTIDE REPEAT EXPANSION DISORDERS Several diseases are associated with an increase in the number of nucleotide repeats above a certain threshold **(Table 479-5)**. The repeats are sometimes located

TABLE 479-5 Selected Trinucleotide Repeat Disorders

DISEASE	LOCUS	REPEAT	TRIPLET LENGTH (NORMAL/DISEASE)	INHERITANCE	GENE PRODUCT
X-chromosomal spinobulbar muscular atrophy (SBMA)	Xq12	CAG	11–34/40–62	XR	Androgen receptor
Fragile X syndrome (FRAXA)	Xq27.3	CGG	6–50/200–300	XR	FMR-1 protein
Fragile X syndrome (FRAXE)	Xq28	GCC	6–25/>200	XR	FMR-2 protein
Dystrophia myotonica (DM)	19q13.32	CTG	5–30/200–1000	AD, variable penetrance	Myotonin protein kinase
Huntington's disease (HD)	4p16.3	CAG	6–34/37–180	AD	Huntingtin
Spinocerebellar ataxia type 1 (SCA1)	6p22.3	CAG	6–39/40–88	AD	Ataxin 1
Spinocerebellar ataxia type 2 (SCA2)	12q24.12	CAG	15–31/34–400	AD	Ataxin 2
Spinocerebellar ataxia type 3 (SCA3); Machado-Joseph disease (MD)	14q32.12	CAG	13–36/55–86	AD	Ataxin 3
Spinocerebellar ataxia type 6 (SCA6, CACNAIA)	19p13	CAG	4–16/20–33	AD	Alpha 1A voltage-dependent L-type calcium channel
Spinocerebellar ataxia type 7 (SCA7)	3p14.1	CAG	4–19/37 to >300	AD	Ataxin 7
Spinocerebellar ataxia type 12 (SCA12)	5q32	CAG	6–26/66–78	AD	Protein phosphatase 2A
Dentatorubral pallidoluysian atrophy (DRPLA)	12p13.31	CAG	7–23/49–75	AD	Atrophin 1
Friedreich's ataxia (FRDA1)	9q21.11	GAA	7–22/200–900	AR	Frataxin

Abbreviations: AD, autosomal dominant; AR, autosomal recessive; XR, X-linked recessive.

within the coding region of the genes, as in Huntington's disease or the X-linked form of spinal and bulbar muscular atrophy (SBMA; Kennedy's syndrome). In other instances, the repeats probably alter gene regulatory sequences. If an expansion is present, the DNA fragment is unstable and tends to expand further during cell division. The length of the nucleotide repeat often correlates with the severity of the disease. When repeat length increases from one generation to the next, disease manifestations may worsen or be observed at an earlier age; this phenomenon is referred to as *anticipation*. In Huntington's disease, for example, there is a correlation between age of onset and length of the triplet codon expansion **(Chap. 435)**. Anticipation has also been documented in other diseases caused by dynamic mutations in trinucleotide repeats (Table 479-5). The repeat number may also vary in a tissue-specific manner. In myotonic dystrophy, the CTG repeat may be 10-fold greater in muscle tissue than in lymphocytes **(Chap. 460)**.

Complex Genetic Disorders The expression of many common diseases such as cardiovascular disease, hypertension, diabetes, asthma, psychiatric disorders, and certain cancers is determined by a combination of genetic background, environmental factors, and lifestyle. A trait is called *polygenic* if multiple genes contribute to the phenotype or *multifactorial* if multiple genes are assumed to interact with environmental factors. Genetic models for these complex traits need to account for genetic heterogeneity and interactions with other genes and the environment. Complex genetic traits may be influenced by modifier genes that are not linked to the main gene involved in the pathogenesis of the trait. This type of gene-gene interaction, or *epistasis*, where the expression of a gene is altered by the expression of one or several independently inherited genes, plays an important role in polygenic traits. In aggregate, variants in multiple genes need to be present simultaneously to result in a pathologic phenotype.

Type 2 diabetes mellitus provides a paradigmatic example of a multifactorial disorder, because genetic, nutritional, and lifestyle factors are intimately interrelated in disease pathogenesis **(Table 479-6)** **(Chap. 415)**. The identification of genetic variations and environmental factors that either predispose to or protect against disease is essential for predicting disease risk, designing preventive strategies, and developing novel therapeutic approaches. The study of rare monogenic diseases may provide insight into some of the genetic and molecular mechanisms important in the pathogenesis of complex diseases. For example, the identification of the genes causing monogenic forms of permanent neonatal diabetes mellitus or maturity-onset diabetes defined them as *candidate genes* in the pathogenesis of diabetes mellitus type 2 (Tables 479-2 and 479-6) **(Fig. 479-15)**. Genome scans have identified numerous genes and loci that may be associated with susceptibility to development of diabetes mellitus in certain populations **(Fig. 479-16)**. Efforts to identify susceptibility genes require very large sample sizes, and positive results may depend on ethnicity, ascertainment criteria, and statistical analysis. Association studies analyzing the potential influence of (biologically functional) SNPs and SNP haplotypes on a particular phenotype have revealed new insights into the genes involved in the pathogenesis of these common disorders. Large variants ([micro]deletions, duplications, and inversions) present in the human population also contribute to the pathogenesis of complex disorders, but their contributions remain poorly understood.

Linkage and Association Studies There are two primary strategies for mapping genes that cause or increase susceptibility to human disease: (1) classic linkage can be performed based on a known genetic model or, when the model is unknown, by studying pairs of affected relatives; or (2) disease genes can be mapped using allelic association studies **(Table 479-7)**.

GENETIC LINKAGE *Genetic linkage* refers to the fact that genes are physically connected, or linked, to one another along the chromosomes. Two fundamental principles are essential for understanding the concept of linkage: (1) when two genes are close together on a chromosome, they are usually transmitted together, unless a recombination event separates them (Figs. 479-6); and (2) the odds of a crossover, or recombination event, between two linked genes is proportional to the distance that separates them. Thus, genes that are farther apart are more likely to undergo a recombination event than genes that are very close together. The detection of chromosomal loci that segregate with a disease by linkage can be used to identify the gene responsible for the disease and to predict the odds of disease gene transmission in genetic counseling.

Polymorphic variants are essential for linkage studies because they provide a means to distinguish the maternal and paternal chromosomes in an individual. On average, 1 out of every 1000 bp varies from one person to the next. Although this degree of variation seems low (99.9% identical), it means that >3 million sequence differences exist between any two unrelated individuals and the probability that the sequence at such loci will differ on the two homologous chromosomes is high (often >70–90%). These sequence variations include variable number of tandem repeats (VNTRs), short tandem repeats (STRs), and SNPs. Most STRs, also called *polymorphic microsatellite markers*, consist of di-, tri-, or tetranucleotide repeats that can be characterized readily using the polymerase chain reaction (PCR). Characterization of SNPs, using DNA chips or beads, permits comprehensive analyses of genetic variation, linkage, and association studies. Although these sequence variations often have no apparent functional consequences, they provide much of the basis for variation in genetic traits.

TABLE 479-6 Examples of Genes and Loci Involved in Mono- and Polygenic Forms of Diabetes

DISORDER	GENES OR SUSCEPTIBILITY LOCUS	CHROMOSOMAL LOCATION	OTHER FACTORS
Monogenic permanent neonatal diabetes mellitus	*KCNJ11* (inwardly rectifying potassium channel Kir6.2)	11p15.1	AD
	GCK (glucokinase)	7p13	AR
	INS (insulin)	11p15.5	AR, hyperproinsulinemia
	ABCC8 (ATP-binding cassette, subfamily c, member 8; sulfonylurea receptor)	11p15.1	AD or AR
	GLIS3 (GLIS family zinc finger protein 3)	9p24.2	AR, diabetes, congenital hypothyroidism
Maturity-onset diabetes of the young (MODY): monogenic forms of diabetes mellitus			
MODY 1	*HNF4α* (hepatocyte nuclear factor 4α)	20q13.12	AD inheritance
MODY 2	*GCK* (glucokinase)	7p13	
MODY 3	*HNF1α* (hepatocyte nuclear factor 1α)	12q24.31	
MODY 4	*IPF1* (insulin receptor substrate)	13q12.2	
MODY 5 (renal cysts, diabetes)	*HNF1β* (hepatocyte nuclear factor 1β)	17q12	
MODY 6	*NeuroD1* (neurogenic differentiation factor 1)	2q31.3	
MODY 7	*KLF1* (Kruppel-like factor 1)	19p13.13	
MODY 8	*CEL* (carboxyl ester lipase)	9q34.13	
MODY 9	*PAX4* (paired box transcription factor 4)	7q32.1	
MODY 10	*INS* (insulin)	11p15.5	
MODY 11	*BLK* (B-lymphocyte-specific tyrosine kinase)	8p23.1	
MODY 12	*ABCC8* (ATP-binding cassette, subfamily c, member 8; sulfonylurea receptor)	11p15.1	
MODY 13	*KCNJ11* (inwardly rectifying potassium channelKir6.2)	11p15.1	
Diabetes mellitus type 2; loci and genes linked and/or associated with susceptibility for diabetes mellitus type 2	Genes and loci identified by linkage/association studies *PPARG, KCNJ11/ABCC8, TCF7L2, HNF1B, WFS1, SLC30A8, FTO, HHEX, IGF2BP2, CDKN2A/B, CDKAL1, TSPAN8, ADAMTs9, CDC123/CAMK1D, JAZF1, NOTCH2, THADA, KCNQ1, DUSP8, MTNR1B, IRS1, SPRY2, SRR, ZFAND6, GCK, KLF14, TP53INP1, PROX1, PRC1, BCL11A, ZBED3, RBMS1, HNF1A, DGKB/TMEM195, CCND2, C2CD4A/C2CD4B, PTPRD, ARAP1/CENTD2, HMGA2, TLE4/CHCHD9, ADCY5, UBE2E2, DUSP9, GCKR, COBLL1/GRB14, HMG20A, VPS26A, ST6GAL1, AP3S2, HNF4A, BCL2, LAMA1, GIPR, MC4R, TLE1, KCNK16, ANK1, KLHDC5, ZMIZ1, PSMD6, FITM2/R3HDML/HNF4A, CILP2, ANKRD55, GLIS3, PEPD, GCC1/PAX4, ZFAND3, MAEA, BCAR1, RBM43/RND3, MACF1, RASGRP1, GRK5, TMEM163, SGCG, LPP, FAF1, TMEM154, MPHOSPH9, ARL15, POU5F1/TCF19, SSR1/RREB1, HLA-B, INS-IGF2, GPSM1, LEP, SLC16A13, PAM/PPIP5K2, SLC16A11, CCDC63, C12orf51, CCND2, HNF1A, TBC1D4, CCDC85A, INAFM2, ASB3, FAM60A, ATP8B2, MIR4686, MTMR3, DMRTA1, SLC35D3, GLP2R, GIP, MAP3K11, PLEKHA1, HSD17B12, NRXN3, CMIP, ZZEF1, MNX1, ABO, ACSL1, HLA-DQA1*		Heavily influenced by diet, energy expenditure, obesity

Abbreviations: AD, autosomal dominant; AR, autosomal recessive; MODY, maturity-onset diabetes of the young.

In order to identify a chromosomal locus that segregates with a disease, it is necessary to characterize polymorphic DNA markers from affected and unaffected individuals of one or several pedigrees. One can then assess whether certain marker alleles cosegregate with the disease. Markers that are closest to the disease gene are less likely to undergo recombination events and therefore receive a higher linkage score. Linkage is expressed as a lod (logarithm of odds) score—the ratio of the probability that the disease and marker loci are linked rather than unlinked. Lod scores of +3 (1000:1) are generally accepted as supporting linkage, whereas a score of −2 is consistent with the absence of linkage.

ALLELIC ASSOCIATION, LINKAGE DISEQUILIBRIUM, AND HAPLOTYPES *Allelic association* refers to a situation in which the frequency of an allele is significantly increased or decreased in individuals affected by a particular disease in comparison to controls. Linkage and association differ in several aspects. Genetic linkage is demonstrable in families or sibships. Association studies, on the other hand, compare a population of affected individuals with a control population. Association studies can be performed as case-control studies that include unrelated affected individuals and matched controls or as family-based studies that compare the frequencies of alleles transmitted or not transmitted to affected children.

Allelic association studies are particularly useful for identifying susceptibility genes in complex diseases. When alleles at two loci occur more frequently *in combination* than would be predicted (based on known allele frequencies and recombination fractions), they are said to be in *linkage disequilibrium*. Evidence for linkage disequilibrium can be helpful in mapping disease genes because it suggests that the two loci are tightly linked.

Detecting the genetic factors contributing to the pathogenesis of common complex disorders is challenging. In many instances, these are low-penetrance alleles (e.g., variations that individually have a subtle effect on disease development, and they can only be identified by unbiased GWAS) (Catalog of Published Genome-Wide Association Studies; Table 479-1) (Fig. 479-16). Most variants occur in noncoding or regulatory sequences but do not alter protein structure. The analysis of complex disorders is further complicated by ethnic differences in disease prevalence, differences in allele frequencies in known susceptibility genes among different populations, locus and allelic heterogeneity, gene-gene and gene-environment interactions, and the possibility of phenocopies. Catalogues of human variation and genotype data

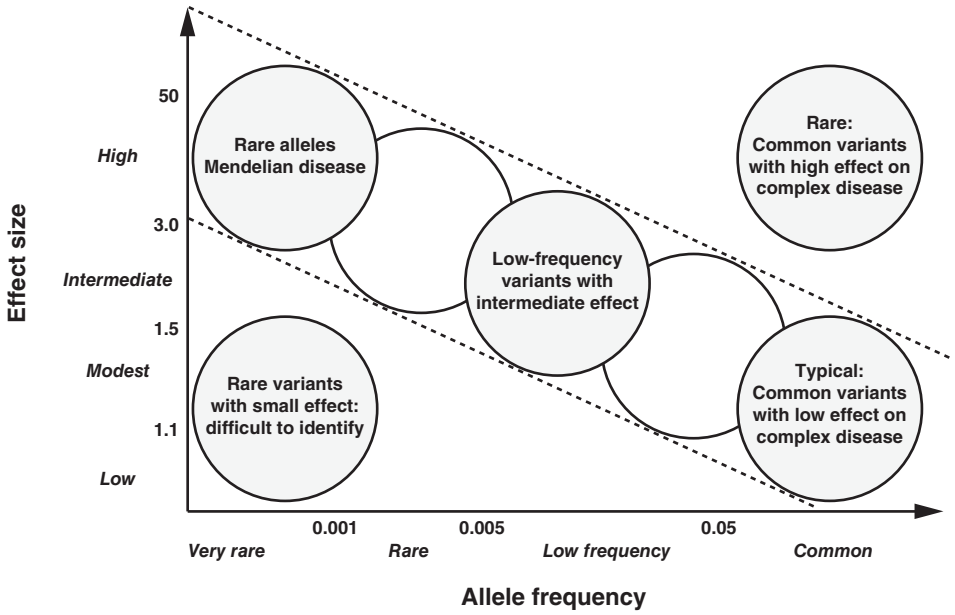

FIGURE 479-15 Relationship between allele frequency and effect size in monogenic and polygenic disorders. In classic Mendelian disorders, the allele frequency is typically low but has a high impact (single-gene disorder). This contrasts with polygenic disorders that require the combination of multiple low-impact alleles that are frequently quite common in the general population.

(HapMap, International Genome Sample Resource) have greatly facilitated GWAS for the characterization of complex disorders. Adjacent SNPs are inherited together as blocks, and these blocks can be identified by genotyping selected marker SNPs, so-called *Tag SNPs*, thereby reducing cost and workload (Fig. 479-4). The availability of this information permits the characterization of a limited number of SNPs to identify the set of haplotypes present in an individual (e.g., in cases and controls). This, in turn, permits performing GWAS by searching for associations of certain haplotypes with a disease phenotype of interest, an essential step for unraveling the genetic factors contributing to complex disorders.

POPULATION GENETICS In population genetics, the focus changes from alterations in an individual's genome to the distribution pattern of different genotypes in the population. In a case where there are only two alleles, A and a, the frequency of the genotypes will be $p^2 + 2pq + q^2 = 1$, with p^2 corresponding to the frequency of AA, $2pq$ to the frequency of Aa, and q^2 to aa. When the frequency of an allele is known, the frequency of the genotype can be calculated. Alternatively, one can determine an allele frequency if the genotype frequency has been determined.

Allele frequencies vary among ethnic groups and geographic regions. For example, heterozygous mutations in the *CFTR* gene are relatively common in populations of European origin but are rare in the African population. Allele frequencies may vary because certain allelic variants confer a selective advantage. For example, heterozygotes for the sickle cell mutation, which is particularly common in West Africa, are more resistant to malaria infection because the erythrocytes of heterozygotes provide a less favorable environment for *Plasmodium* parasites. Although homozygosity for the sickle cell mutation is associated with severe anemia and sickle 'crises, heterozygotes have a higher probability of survival because of the reduced morbidity and mortality from malaria; this phenomenon has led to an increased frequency of the mutant allele. Recessive conditions are more prevalent in geographically isolated populations because of the more restricted gene pool.

APPROACH TO THE PATIENT

Inherited Disorders

For the practicing clinician, the family history remains an essential step in recognizing the possibility of a hereditary predisposition to disease. When taking the history, it is useful to draw a detailed pedigree of the first-degree relatives (e.g., parents, siblings, and children), because they share 50% of genes with the patient. Standard symbols for pedigrees are depicted in Fig. 479-11. The family history should include information about ethnic background, age, health status, and deaths, including infants. Next, the physician should explore whether there is a family history of the same or related illnesses to the current problem. An inquiry focused on commonly occurring disorders such as cancers, heart disease, and diabetes mellitus should follow. Because of the possibility of age-dependent expressivity and penetrance, the family history will need intermittent updating. If the findings suggest a genetic disorder, the clinician should assess whether some of the patient's relatives may be at risk of carrying or transmitting the disease. In this circumstance, it is useful to confirm and extend the pedigree based on input from several family members. Emerging artificial intelligence tools analyzing facial features can aid the clinician in diagnosing patients with genetic conditions. In aggregate, this information may form the basis for genetic counseling, carrier detection, early intervention, and disease prevention in relatives of the index patient **(Chap. 480)**.

In instances where a diagnosis at the molecular level may be relevant, it is important to identify an appropriate laboratory that can perform the appropriate test. Genetic testing is available for a large number of monogenic disorders through commercial laboratories. For uncommon disorders, the test may only be performed in a specialized research laboratory. Approved laboratories offering testing for inherited disorders can be identified in continuously updated online resources (e.g., Genetic Testing Registry; Table 479-1). If genetic testing is considered, the patient and the family should be counseled about the potential implications of positive results, including psychological distress and the possibility of discrimination. The patient or caretakers should be informed about the meaning of a negative result, technical limitations, and the possibility of false-negative and inconclusive results. For these reasons, genetic testing should only be performed after obtaining *informed consent*. Published ethical guidelines address the specific aspects that should be considered when testing children and adolescents.

IDENTIFYING THE DISEASE-CAUSING GENE

Precision medicine aims to enhance the quality of medical care through the use of genotypic analysis (DNA testing) to identify genetic predisposition to disease, to select more specific

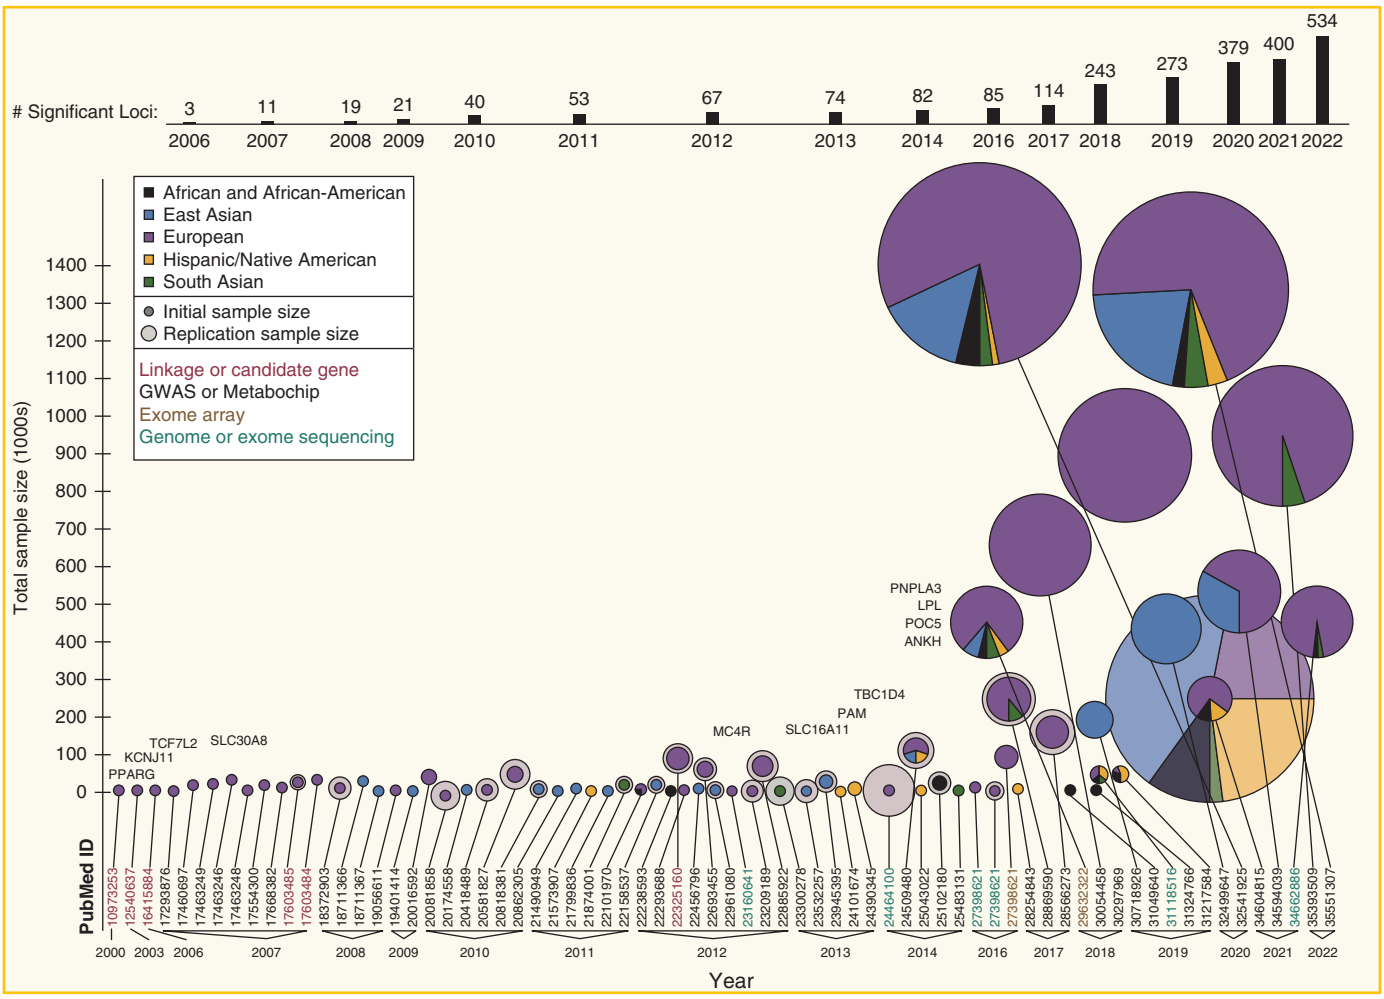

FIGURE 479-16 Genome-wide association studies (GWAS) across ancestries and discovery of loci over time. The pie charts represent type 2 diabetes GWAS, as well as candidate gene or sequencing studies. The *x* axis shows the year of publication, and the *y* axis shows discovery sample size. The inner circles are scaled in proportion to discovery sample size, and the outer circles are scaled in proportion to total (discovery + replication) sample size. Significant loci are defined as a *p* value of 5×10^{-8}. At the end of 2022, 534 type 2 diabetes distinct intervals (520 autosomal, 14 X chromosomal) were defined. *(Reproduced with permission from BF Voight.)*

pharmacotherapy, and to design individualized medical care based on genotype. Genotype can be deduced by analysis of protein (e.g., hemoglobin, apoprotein E), mRNA, or DNA. Many (pathogenic) variants can be readily identified by DNA analyses; technical advances in RNA sequencing now add increasing depth to genetic and genomic investigations (e.g., for the detection of gene fusions or aberrant gene expression patterns).

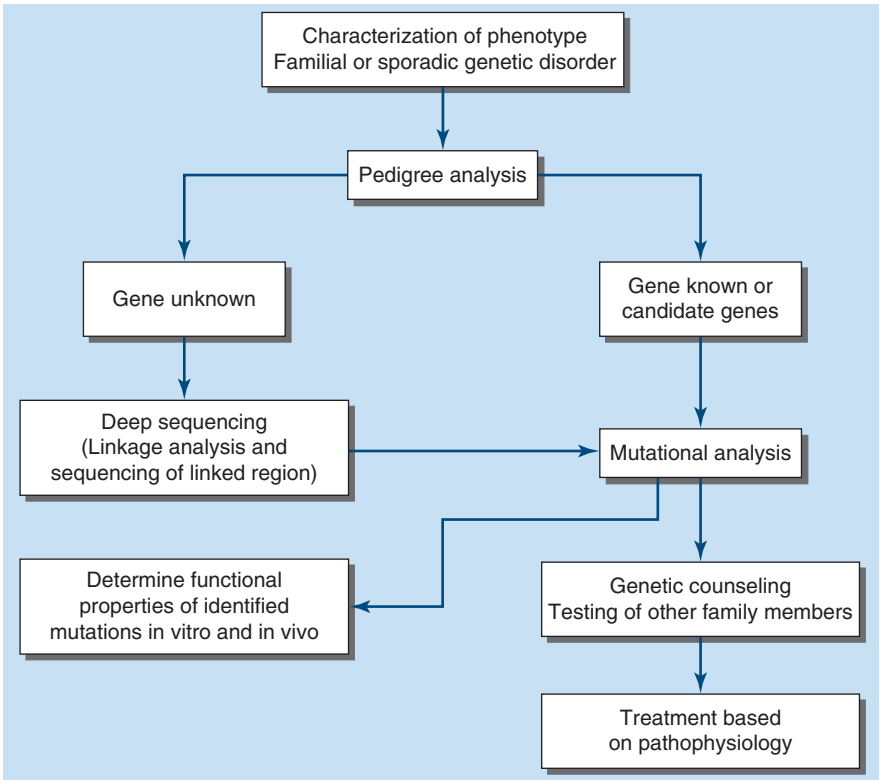
DNA testing is performed by mutational analysis or linkage studies in individuals at risk for a genetic disorder known to be present in a family. Mass screening programs require tests of high sensitivity and specificity to be cost-effective. The benefits and risks of screening newborns with genomic sequencing, and the potential impact on surveillance, preventative health care, and personalized treatment options are topics of current research (BabySeq Project). Prerequisites for the success of genetic screening programs include the following: that the disorder is potentially serious; that it can be influenced at a presymptomatic stage by changes in behavior, diet, and/or pharmaceutical manipulations; and that the screening does not result in any harm or discrimination. Screening in Jewish populations for the autosomal recessive neurodegenerative storage disease Tay-Sachs has reduced the number of affected individuals. In contrast, screening for sickle cell trait/disease in African Americans has led to unanticipated problems of discrimination by health insurers and employers. Mass screening programs harbor additional potential problems. For example, screening for the most common genetic alteration in cystic fibrosis, the ΔF508 mutation with a frequency of ~70% in northern Europe, is feasible and seems to be effective. One has to keep in mind, however, that there is pronounced allelic heterogeneity and that the *CFTR* gene can be affected by >2000 other mutations. While the search for less common mutations has been challenging in the past, next-generation genome sequencing now permits comprehensive and cost-effective mutational analyses. However, the bioinformatic analysis and the classification of the detected variants as pathogenic or benign alterations is still challenging. Occupational screening programs aim to detect individuals with increased risk for certain professional activities (e.g., α_1 antitrypsin deficiency and smoke or dust exposure). Integrating genomic data into electronic medical records is evolving and can provide significant decision support at the point of care, for example, by providing the clinician with genomic data and decision algorithms for the prescription of drugs that are subject to pharmacogenetic influences.

Mutational Analyses DNA sequence analysis is widely used as a diagnostic tool and has significantly enhanced diagnostic accuracy. It is used for determining carrier status and for prenatal testing in monogenic disorders. Numerous techniques, discussed in previous versions of this chapter, are available for the detection of mutations. Analyses of large alterations in the genome are possible using classic methods such as karyotype analysis, cytogenetics, fluorescent in situ hybridization (FISH), and array- or bead-based techniques that search for multiple single exon deletions or duplications.

TABLE 479-7 Genetic Approaches for Identifying Disease Genes

METHOD	INDICATIONS AND ADVANTAGES	LIMITATIONS
Linkage Studies		
Classical linkage analysis (parametric methods)	Analysis of monogenic traits Suitable for genome scan Control population not required Useful for multifactorial disorders in isolated populations	Difficult to collect large informative pedigrees Difficult to obtain sufficient statistical power for complex traits
Allele-sharing methods (nonparametric methods)	Suitable for identification of susceptibility genes in polygenic and multifactorial disorders	Difficult to collect sufficient number of subjects
Affected sib and relative pair analyses	Suitable for genome scan	Difficult to obtain sufficient statistical power for complex traits
Sib pair analysis	Control population not required if allele frequencies are known Statistical power can be increased by including parents and relatives	Reduced power compared to classical linkage, but not sensitive to specification of genetic mode
Association Studies		
Case-control studies	Suitable for identification of susceptibility genes in polygenic and multifactorial disorders	Requires large sample size and matched control population
Linkage disequilibrium	Suitable for testing specific allelic variants of known candidate loci	False-positive results in the absence of suitable control population
Transmission disequilibrium test (TDT)	Facilitated by comprehensive catalogs of genotypes and variants	Candidate gene approach does not permit detection of novel genes and pathways
Whole-genome association studies	Does not necessarily need relatives	Susceptibility genes can vary among different populations
Next-Generations Sequencing Technologies		
Whole exome or genome sequencing	Unbiased approach, analysis can be performed without reference sequences from parents or siblings	Requires appropriate bioinformatics, may have low sensitivity if CNV analysis is not included, detects numerous VUS, can lead to the detection of unrelated deleterious alleles
Targeted sequencing of gene panels	Captures multiple candidate genes and loci with hybridization techniques followed by deep sequencing	Permits analyses of multiple candidate genes in parallel; facilitates molecular characterization of disorders with locus heterogeneity

Abbreviations: CNV, copy number variation; VUS, variants of unknown significance.



The analysis of more discrete sequence alterations often rely on the use of PCR, which allows rapid gene amplification and analysis. Moreover, PCR makes it possible to perform genetic testing and mutational analysis with small amounts of DNA extracted from leukocytes or even from single cells, buccal cells, or hair roots. DNA sequencing can be performed directly on PCR products. The advent of comprehensive sequencing technologies analyzing the whole exome or genome, of selected chromosomes, or of numerous candidate genes in a single run with NGS platforms is now fundamentally transforming the characterization of patients with rare disorders and advanced malignancies. These techniques have the advantage of an unbiased comprehensive approach, and they are increasingly cost-effective. Analysis of cell-free DNA (cfDNA; also referred to as "liquid biopsy") present in body fluids is playing a growing role for minimally invasive diagnostics and disease monitoring. Genomic tests are also widely used for the detection of pathogens and for the identification of viral or bacterial sequence variations.

The integration of genomic tests into clinical medicine is associated with a number of ongoing challenges related to variable sensitivities of the tests, bioinformatics analyses, storage and sharing of data, and the difficulty of interpreting all genetic variants identified with comprehensive testing. The discovery of incidental (or secondary) findings that are unrelated to the indication for the sequencing analysis, but indicators of other disorders of potential relevance for patient care can pose a difficult ethical dilemma. It can lead to the detection of undiagnosed medically actionable genetic conditions but can also reveal deleterious mutations that cannot be influenced, as numerous sequence variants are of unknown significance.

A general algorithm for the approach to mutational analysis in patients with a suspected genetic disorder and (advanced) malignancies is outlined in **Fig. 479-17**. The importance of a detailed characterization of the clinical phenotype cannot be overemphasized. This is the step where one should also consider the possibility of genetic heterogeneity and phenocopies. If obvious candidate genes are suggested by the phenotype, they can be analyzed directly. After identification of a mutation, it is essential to demonstrate that it segregates with the phenotype. The functional characterization of novel mutations remains labor intensive and may require analyses in vitro or in transgenic models in order to document the relevance of the genetic alteration.

Prenatal diagnosis of numerous genetic diseases in instances with a high risk for certain disorders is possible by direct DNA analysis. *Amniocentesis* involves the removal of a small amount of amniotic fluid, usually at 16 weeks of gestation. Cells can be collected and submitted for karyotype analyses, FISH, and mutational analysis of selected genes (Table 479-4). The main indications for amniocentesis include advanced maternal age (>35 years), presence of an abnormality of the fetus on ultrasound examination, an abnormal serum "quad" test (α fetoprotein, β human chorionic gonadotropin, inhibin-A, and unconjugated estriol), a family history of chromosomal abnormalities, or a Mendelian disorder amenable to genetic testing. Prenatal diagnosis can also be performed by *chorionic villus sampling* (CVS), in which a small amount of the chorion is removed by a transcervical or transabdominal biopsy. Chromosomes and DNA obtained from these cells can be submitted for cytogenetic and mutational analyses. CVS can be performed earlier in gestation (weeks 9–12) than amniocentesis, an aspect that may be of relevance when termination of pregnancy is a consideration. Later in pregnancy, beginning at ~18 weeks of gestation, percutaneous umbilical blood sampling (PUBS; cordocentesis) permits collection of fetal blood for analysis. Prenatal cfDNA allows DNA analyses from the mother and fetus from a maternal blood sample to screen for certain chromosomal abnormalities and fetal sex. These approaches enable screening for clinically relevant and deleterious alleles inherited from the parents, as well as for de novo germline mutations, and they have the potential to identify genetic disorders in the prenatal setting.

In combination with in vitro fertilization (IVF) techniques, it is possible to perform genetic diagnoses in a single cell removed from the four- to eight-cell embryo or to analyze the first polar body from an oocyte. Preconceptual diagnosis thereby avoids therapeutic abortions but is costly and labor intensive. It should be emphasized that excluding a specific disorder by any of these approaches is never equivalent to the assurance of having a normal child.

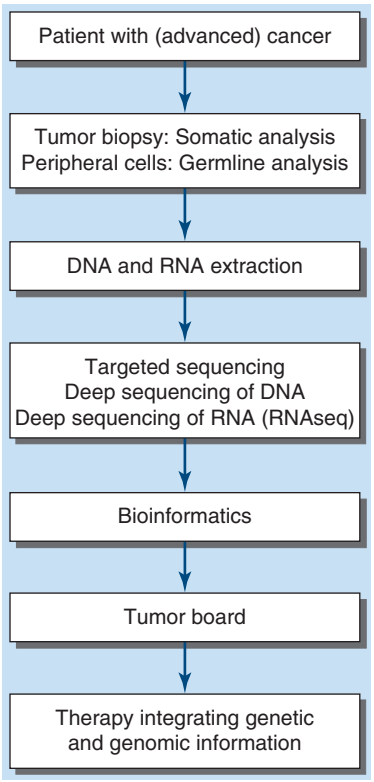


FIGURE 479-17 Approach to genetic disease.

Postnatal indications for cytogenetic analyses in infants or children include multiple congenital anomalies, suspicion of a known cytogenetic syndrome, developmental delay, dysmorphic features, autism, short stature, and disorders of sexual development, among others (Table 479-4).

Mutations in certain cancer susceptibility genes such as *BRCA1* and *BRCA2* may identify individuals with an increased risk for the development of malignancies and result in risk-reducing interventions. The detection of cytogenetic alterations and mutations is an important diagnostic and prognostic tool in leukemias, and it has also transformed the management of solid tumors. In addition to providing diagnostic information, mutational analysis can inform the choice of targeted therapies ("actionable mutations"), characterize the mutational load, identify gene signatures associated with effective immunotherapies, and be used for surveillance.

The demonstration of the presence or absence of mutations and polymorphisms is also relevant for the field of pharmacogenomics, including the identification of differences in drug treatment response or metabolism as a function of genetic background

Gene therapy through the introduction of a normal gene or the ability to make site-specific modifications to the human genome has, so far, limited clinical application. However, several gene transfer methods have now been approved for clinical use, for example, for the treatment of Leber congenital amaurosis, B-cell acute lymphoblastic leukemia, spinal muscular atrophy, and hereditary transthyretin-mediated amyloidosis. Genome editing (or gene editing) with CRISPR-Cas9 is a promising novel approach for the treatment of various diseases, for example cystic fibrosis, certain cancers, hemophilia, and sickle cell disease. The first therapies using this technology for the treatment of sickle cell disease were approved by the U.S. Food and Drug Administration in 2023 **(Chap. 483)**.

ETHICAL ISSUES

Determination of the association of genetic defects with disease, comprehensive data of an individual's genome, and studies of genetic variation raise many ethical and legal issues. Genetic information is generally regarded as sensitive information that should not be readily accessible without explicit consent (*genetic privacy*). The disclosure of genetic information may risk possible discrimination by insurers or employers. The scientific components of the Human Genome Project have been paralleled by efforts to examine ethical, social, and legal implications. An important milestone emerging from these endeavors is the Genetic Information Nondiscrimination Act (GINA), signed into law in 2008, which aims to protect asymptomatic individuals against the misuse of genetic information for health insurance and employment. It does not, however, protect the symptomatic individual. Provisions of the U.S. Patient Protection and Affordable Care Act, effective in 2014, have, in part, filled this gap and prohibit exclusion from, or termination of, health insurance based on personal health status. Potential threats to the maintenance of genetic privacy include the increasing integration of genomic data into electronic medical records, compelled disclosures of health records, and direct-to-consumer genetic testing.

It is widely accepted that identifying disease-causing genes can lead to improvements in diagnosis, treatment, and prevention. However, the information gleaned from genotypic results can have quite different impacts, depending on the availability of strategies to modify the course of disease. For example, the identification of mutations that cause MEN 2 or hemochromatosis allows specific interventions for affected family members. On the other hand, at present, the identification of an Alzheimer's or Huntington's disease gene does not currently alter therapy and outcomes. Most genetic disorders are likely to fall into an intermediate category where the opportunity for prevention or treatment is significant but limited. However, the progress in this area is unpredictable, as underscored by the finding that angiotensin II receptor blockers appear to slow disease progression in Marfan's syndrome. Genetic test results can generate anxiety in affected individuals and family members. Comprehensive sequence analyses are particularly challenging because most individuals can be expected to harbor several serious recessive gene mutations. Moreover, the sensitivity of comprehensive sequence analyses is not always greater, for example, if CNV analysis is not integrated. Genetic manipulation and patient selection for gene therapy approaches have raised ethical controversy and safety concerns that remain unresolved.

The impact of genetic testing on health care costs remains unclear. It does vary among disorders and depends on the availability of effective therapeutic modalities, and there are significant differences among health care systems. A significant problem has arisen from the marketing of genetic testing directly to consumers by commercial companies. The validity of these tests is, in part, not well defined, and there are persisting concerns about the lack of appropriate regulatory oversight, the accuracy and confidentiality of genetic information, the availability of counseling, and the handling of these results.

Many issues raised by the genome project are familiar, in principle, to medical practitioners. For example, an asymptomatic patient with increased low-density lipoprotein (LDL) cholesterol, high blood pressure, or a strong family history of early myocardial infarction is known to be at increased risk of coronary heart disease. In such cases, the identification of risk factors and an appropriate intervention are beneficial. Likewise, patients with phenylketonuria, cystic fibrosis, or sickle cell anemia are often identified as having a genetic disease early in life. These precedents can be helpful for adapting policies that relate to genetic information.

One confounding aspect of the rapid expansion of information is that our ability to make clinical decisions often lags behind initial insights into genetic mechanisms of disease. For example, when genes that predispose to breast cancer such as *BRCA1* are described, they generate tremendous public interest in the potential to predict disease, but many years of clinical research are still required to rigorously establish genotype and phenotype correlations.

Genomics may contribute to improvements in global health by providing a better understanding of pathogens and diagnostics and through contributions to drug development. There is, however, persisting concern about a widening "genomics divide" because of the costs associated with these developments and uncertainty as to whether these advances will be accessible to the populations of developing countries faced with pressing health needs associated with poverty, infectious diseases, and the relative lack of essential infrastructure. The World Health Organization's "Human Genomics in Global Health Initiative" aims at attenuating these inequities surrounding genomic medicine.

Whether related to informed consent, participation in research, or the management of a genetic disorder that affects an individual or their family, there is a great need for more information about fundamental principles of genetics. The pervasive nature of the role of genetics in medicine makes it important for physicians and other health care professionals to become more informed about genetics and to provide advice and counseling in conjunction with trained genetic counselors **(Chap. 480)**. Therefore, the application of screening and prevention strategies does require continuing patient and physician education, changes in health care financing, and legislation to protect patient's rights.

Acknowledgment

Selected sections and Table 479-4 have been integrated from the chapter on chromosome disorders by Dr. Nancy B. Spinner and Dr. Laura K. Conlin, published in the 19th edition of Harrison's Principles in Internal Medicine.

480 The Integration of Inherited Genetics into Clinical Practice

Susan M. Domchek, J. Larry Jameson

Genetic testing for inherited abnormalities associated with disease risk is increasingly used in the practice of clinical medicine. Germline alterations include chromosomal abnormalities, specific gene pathogenic variants (also called mutations) with autosomal dominant or recessive patterns of transmission **(Chap. 479)**, and single nucleotide polymorphisms (SNPs) with small relative risks associated with disease. Germline alterations are responsible for disorders beyond classic Mendelian conditions with genetic susceptibility to common adult-onset diseases such as asthma, hypertension, diabetes mellitus, macular degeneration, and a number of types of cancer. For many of these diseases, there is a complex interplay of genes (often multiple) and environmental factors that affect lifetime risk, age of onset, disease severity, and treatment options.

The expansion of human genetic knowledge is changing our understanding of pathophysiology and influencing our classification of diseases. Awareness of genetic etiology can have an impact on clinical management, including prevention and screening for or treatment of a range of diseases. Primary care physicians are relied upon to help patients navigate testing and treatment options. Consequently, they must understand the genetic basis for a large number of genetically

influenced diseases, incorporate personal and family history to determine the risk for a specific pathogenic variant, and be positioned to provide counseling. Even if patients are seen by genetic specialists who assess genetic risk and coordinate testing, primary care providers should be able to identify patients who meet guidelines for genetic testing, and offer information regarding the indications, limitations, risks, and benefits of genetic counseling and testing. They must also be prepared to offer risk-based management following genetic risk assessment. Given the pace of genetics, this is an increasingly difficult task. The field of clinical genetics has rapidly transitioned from single-gene testing to multigene panel testing, with techniques such as whole exome and genome sequencing available as well, increasing the complexity of test selection and interpretation, as well as patient education and medical decision-making.

COMMON ADULT-ONSET GENETIC DISORDERS

INHERITANCE PATTERNS

Adult-onset hereditary diseases follow multiple patterns of inheritance. Some are autosomal dominant conditions. These include many common cancer susceptibility syndromes such as hereditary breast and ovarian cancer (due to germline *BRCA1* and *BRCA2* pathogenic variants) and Lynch syndrome (caused by germline pathogenic variants in the mismatch repair genes *MLH1*, *MSH2*, *MSH6*, *PMS2* and *EPCAM*). In both of these examples, inherited pathogenic variants are associated with a high penetrance (lifetime risk) of cancer, although penetrance is incomplete (risk is not 100%). In other conditions, although there is autosomal dominant transmission, penetrance is lower, thereby making the disorders more difficult to recognize. For example, germline pathogenic variants in *CHEK2* increase the risk of breast cancer but with a moderate lifetime risk in the range of 20–30%, as opposed to 50–70% for pathogenic variants in *BRCA1* or *BRCA2*. Other adult-onset hereditary diseases are transmitted in an autosomal recessive fashion where two mutant alleles are necessary to cause full expression of disease. Examples include hemochromatosis and *MUTYH*-associated polyposis. There are more pediatric-onset autosomal recessive disorders, such as lysosomal storage diseases and cystic fibrosis.

The genetic risk for many adult-onset disorders is multifactorial. Risk can be conferred by genetic factors at a number of loci (polygenic), which individually have very small effects (usually with relative risks of <1.5). When such risk loci (generally SNPs) are combined together, a polygenic risk score (PRS) can be provided. How PRS combine with other genes and environmental factors to impact risk is an area of active study. Despite our incomplete understanding of gene-environment interactions, data suggest that a healthy lifestyle can mitigate risk associated with elevated polygenic risk diseases, such as cardiovascular disease. SNP panels, which provide a PRS, are available to assess risk of disease, but the optimal way of using this information in the clinical setting to improve patient outcomes remains uncertain.

Many diseases have multiple patterns of inheritance, adding to the complexity of evaluating patients and families for these conditions. For example, colon cancer can be associated with a single germline highly penetrant pathogenic variant in a mismatch repair gene (Lynch syndrome; autosomal dominant), biallelic pathogenic variants in *MUTYH* (autosomal recessive), or multiple SNPs (polygenic). Many more individuals will have SNP risk alleles than germline pathogenic variants in high-penetrance genes, but the cumulative lifetime risk of colon cancer related to the former is modest, whereas the risk related to the latter is significant. Personal and family histories provide important insights into the possible mode of inheritance.

FAMILY HISTORY

When two or more first-degree relatives are affected with asthma, cardiovascular disease, type 2 diabetes, breast cancer, colon cancer, or melanoma, the relative risk for disease among close relatives ranges from two- to fivefold, underscoring the importance of family history for these prevalent disorders. In most situations, the key to assessing the inherited risk for common adult-onset diseases is the collection and interpretation of a detailed personal and family medical history in conjunction with a directed physical examination.

Family history should be recorded in the form of a pedigree, conveying health-related data on first- and second-degree relatives. When such pedigrees suggest inherited disease, they should be expanded to include additional family members. The determination of risk for an asymptomatic individual will vary depending on the size of the family, the number of unaffected relatives, the types of diagnoses, and the ages of disease onset. For example, a woman with two first-degree relatives with breast cancer is at greater risk for a specific Mendelian disorder if she has a total of 3 female first-degree relatives (with only 1 unaffected) than if she has a total of 10 female first-degree relatives (with 8 unaffected). Factors such as adoption and limited family structure (few women in a family or multiple early deaths unrelated to the target disease) should be taken into consideration in the interpretation of a pedigree. Additional considerations include young age of disease onset (e.g., a 30-year-old nonsmoking woman with a myocardial infarction), unusual diseases (e.g., male breast cancer or medullary thyroid cancer), and the finding of multiple potentially related diseases in an individual (e.g., a woman with a history of both colon and endometrial cancer). Some adult-onset diseases are more prevalent in certain ethnic groups. For instance, 2.5% of individuals of Ashkenazi Jewish ancestry carry one of three founder pathogenic variants in *BRCA1* and *BRCA2*. Factor V Leiden pathogenic variants are much more common in Caucasians than in Africans or Asians.

Additional variables that should be documented are nonhereditary risk factors among those with disease (such as cigarette smoking and myocardial infarction; asbestos exposure and lung disease; and mantle radiation and breast cancer). Significant associated environmental exposures or lifestyle factors decrease the likelihood of a specific genetic disorder. In contrast, the absence of nonhereditary risk factors typically associated with a disease raises concern about a genetic association. A personal or family history of deep-vein thrombosis in the absence of known environmental or medical risk factors suggests a hereditary thrombotic disorder. The physical examination may also provide important clues about the risk for a specific inherited disorder. A patient presenting with xanthomas at a young age should prompt consideration of familial hypercholesterolemia. The presence of trichilemmomas in a woman with breast cancer raises concern for Cowden syndrome, associated with *PTEN* pathogenic variants.

Recall of family history is often inaccurate. This is especially so when the history is remote and families lose contact or separate geographically. It can be helpful to ask patients to fill out family history forms before or after their visits, because this provides them with an opportunity to contact relatives. Ideally, this information should be embedded in electronic health records and updated intermittently. Attempts should be made to confirm the illnesses reported in the family history before making important and, in certain circumstances, irreversible management decisions. This process is often labor intensive and ideally involves interviews of additional family members or review of medical records (including pathology reports) and death certificates.

Although many inherited disorders will be suggested by the clustering of relatives with the same or related conditions, it is important to note that disease penetrance is incomplete for most genetic disorders. As a result, the pedigree obtained in such families may not exhibit a clear Mendelian inheritance pattern because not all family members carrying the disease-associated alleles will manifest clinical evidence of the condition. Furthermore, genes associated with some of these disorders often exhibit variable disease expression. For example, pathogenic variants in the breast cancer–associated gene *BRCA2* can predispose to several different malignancies in the same family, including cancers of the breast, ovary, pancreas, and prostate. For common diseases such as breast cancer, some family members without the susceptibility allele (or genotype) may develop breast cancer (or phenotype) sporadically. Such *phenocopies* represent another confounding variable in the pedigree analysis.

Some of the aforementioned features of the family history are illustrated in **Fig. 480-1**. In this example, the proband (the individual serving as the starting point for genetic assessment in a family), a

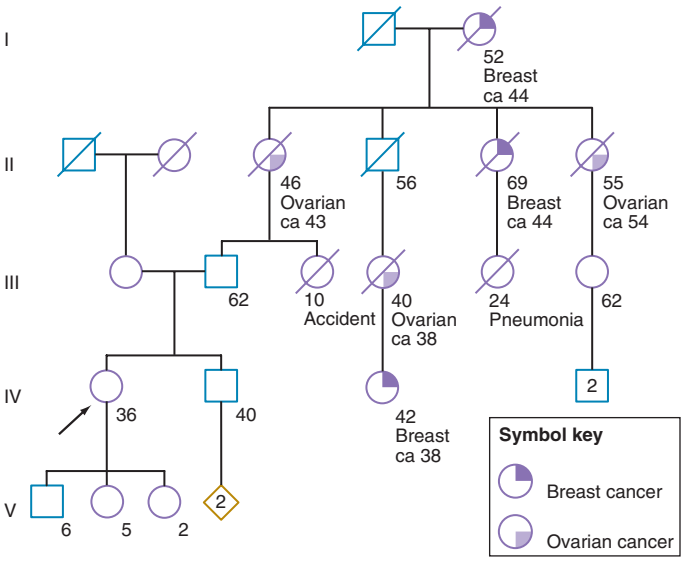

FIGURE 480-1 A 36-year-old woman (*arrow*) seeks consultation because of her family history of cancer. The patient expresses concern that the multiple cancers in her relatives imply an inherited predisposition to develop cancer. The family history is recorded, and records of the patient's relatives confirm the reported diagnoses.

36-year-old woman (IV-1), has a strong history of breast and ovarian cancer on the paternal side of her family. The early age of onset and the co-occurrence of breast and ovarian cancer in this family suggest the possibility of an inherited pathogenic variant in *BRCA1* or *BRCA2*. However, without genetic testing, it is unclear whether her father harbors such a pathogenic variant and transmitted it to her. After appropriate genetic counseling of the proband and her family, the most informative and cost-effective approach to DNA analysis in this family is to test the cancer-affected 42-year-old living cousin for the presence of a pathogenic variant in cancer susceptibility genes. If a pathogenic variant is found, then it is possible to test for this particular alteration in other family members, if they so desire. In the example shown, if the proband's cousin has a *BRCA1* pathogenic variant, testing for this alteration would be an option for the proband's father. If he tests positive, there is a 50:50 probability that the pathogenic variant was transmitted to her, and genetic testing can be used to establish the absence or presence of this alteration. In contrast, if he tests negative for the known familial *BRCA1* pathogenic variant (a true-negative result), the proband and her brother are not at risk for having inherited this variant from their father.

GENETIC TESTING FOR ADULT-ONSET DISORDERS

A critical first step before initiating genetic testing is to ensure that the correct clinical diagnosis has been made, whether it is based on family history, characteristic physical findings, pathology, or biochemical testing. Such careful clinical assessment can define the phenotype. In the traditional model of genetic testing, testing is directed initially toward the most probable genes (determined by the phenotype), which prevents unnecessary testing. Many disorders exhibit the feature of locus heterogeneity, which refers to the fact that pathogenic variants in different genes can cause phenotypically similar disorders. For example, osteogenesis imperfecta **(Chap. 425)**, long QT syndrome **(Chap. 259)**, muscular dystrophy **(Chap. 460)**, and hereditary predisposition to breast **(Chap. 84)** or colon **(Chap. 86)** cancer can each be caused by pathogenic variants in a number of distinct genes. The patterns of disease transmission, disease risk, clinical course, and treatment may differ significantly depending on the specific gene affected. Historically, the choice of which gene to test has been determined by unique clinical and family history features and the relative prevalence of candidate genetic disorders. However, rapid developments in genetic testing techniques, as discussed below, changed this paradigm. It is technically and financially feasible to sequence many genes (or even the whole exome) at one time. The incorporation of expanded testing for germline pathogenic variants has rapidly evolved both within the clinic as well as through direct-to-consumer marketing of genetic and genomic tests.

METHODOLOGIC APPROACHES TO GENETIC TESTING

Genetic testing is regulated and performed in much the same way as other specialized laboratory tests. In the United States, genetic testing laboratories are Clinical Laboratory Improvement Amendments (CLIA) approved to ensure that they meet quality and proficiency standards. A useful information source for various genetic tests is *www.genetests.org*. It should be noted that many tests need to be ordered through specialized laboratories.

Genetic testing is performed largely by DNA sequence analysis for pathogenic variants, although genotype can also be deduced through the study of RNA or protein (e.g., apolipoprotein E, hemoglobin S, and immunohistochemistry). For example, universal Lynch syndrome screening of colorectal and uterine cancers via immunohistochemical analysis for absence of expression of mismatch repair proteins is recommended by the National Comprehensive Cancer Network. The determination of DNA sequence alterations relies heavily on the use of polymerase chain reaction (PCR), which allows rapid amplification and analysis of the gene of interest. In addition, PCR enables genetic testing on minimal amounts of DNA extracted from a wide range of tissue sources including leukocytes (obtained from blood), leukocytes and mucosal epithelial cells (obtained via saliva or buccal swabs), and tumors (obtained from biopsies or archival tissues). Amplified DNA can be analyzed directly by DNA sequencing, or it can be hybridized to DNA chips or blots to detect the presence of normal and altered DNA sequences. Direct DNA sequencing is frequently used for determination of hereditary disease susceptibility and prenatal diagnosis. Analyses of large alterations (e.g., deletions, duplications, rearrangements, translocations) of the genome are possible using cytogenetics, fluorescent in situ hybridization (FISH), Southern blotting, multiplex ligation-dependent probe amplification (MLPA), and massively parallel sequencing.

Massively parallel sequencing has significantly altered the approach to genetic testing for adult-onset hereditary susceptibility disorder. This technology encompasses high-throughput approaches to DNA analysis that can reliably examine many genes at one time. Technically, this involves sequencing of millions of small fragments of DNA in parallel. Through bioinformatics, these fragments are pieced together by mapping the individual sequence reads to the human reference genome, a very different process than traditional Sanger sequencing, which is time-consuming and expensive.

Multiplex panels for inherited susceptibility are commercially available and include testing of a number of genes that have been associated with the condition of interest. For example, panels are available for Brugada syndrome, hypertrophic cardiomyopathy, and Charcot-Marie-Tooth neuropathy. For many syndromes, this type of panel testing makes sense as pathogenic variants in many different genes may lead to the same phenotype. A challenge is that the composition of commercially available gene panels often contains genes with no validated association with the disease of interest or a modest association for which clinical utility is uncertain. An additional problem of sequencing many genes, rather than focusing on a more limited panel of clearly associated gene, is the identification of one or more variants of uncertain significance (VUS), discussed below, or an unexpected yet clinically relevant result.

Whole exome sequencing (WES) is also now commercially available, although largely used in individuals with syndromes unexplained by traditional genetic testing. As cost declines, WES may be more widely used. Whole genome sequencing is also commercially available. Although it may be quite feasible to sequence the entire genome, there are many issues in doing so, including the daunting task of analyzing the vast amount of data generated. Other issues include (1) interpretation of frequent sequence variations of uncertain significance, (2) interpretation of alterations in genes with unclear relevance to specific

human pathology, and (3) management of unexpected but clinically significant genetic findings.

Testing strategies have evolved as a result of these newer genetic testing platforms. As the costs of multiplex gene panels and WES continue to fall and as interpretation and understanding of the clinical relevance of such test results improve, there has been a shift to more extensive panel-based genetic testing in the clinic. For example, in the past, a 30-year-old woman with breast cancer but no family history of cancer and no syndromic features would undergo *BRCA1/2* testing and would be offered *TP53* testing in light of her early-onset disease. Without features consistent with other high-risk, breast cancer–related conditions, the woman would not have been routinely offered, for example, *PTEN* analysis (associated with Cowden syndrome) or testing for other breast cancer–associated genes including *PALB2*, *CHEK2*, *BARD1,* and *ATM*. It is now possible to synchronously analyze all of the aforementioned genes, along with genes such as *BRIP, RAD51C,* and *RAD51D* (which are associated with moderate ovarian cancer risk) rather than testing for *BRCA1/2* alone. Concerns about such panels include strategies related to unclear findings, including one or more VUSs, unanticipated results, and the uncertain clinical utility of some of the genes included on the panel **(Fig. 480-2)**.

DIRECT-TO-CONSUMER GENETIC TESTING

Historically, genetic testing occurred entirely, or predominantly, in the context of clinical care. However, technologic advances combined with shifts in social norms have created an increasingly complex landscape for genetic information, and patients come to providers with a wide range of information.

Clinician-directed genetic testing is currently based on the individual's personal or family medical history. Results are disclosed by the clinician with a management plan formulated based on results, within the context of the individual's personal and family medical history. Consumer-directed genetic testing differs in that the individual electively requests the tests to be performed by a direct-to-consumer (DTC) company, submits the sample directly, and results are communicated directly to the consumer.

DTC testing can include assays for disease risk or disease carrier status; others examine ancestry, pharmacogenetics, and "recreational" genetics related to traits such as aversion to cilantro and earlobe type. From a clinical utility standpoint, such testing companies most often examine sets of SNPs, common "hot spots" in genes associated with specific diseases; however, SNP analysis does not provide a definitive risk/no risk answer. In contrast, clinical genetic testing thoroughly interrogates specific genes known be associated with an individual disease or disease risk. Quality standards between DTC and clinical laboratories vary greatly. In the United States, clinical genetic testing labs meet established strict quality standards discernible as CLIA certification and College of American Pathologists (CAP) accreditation. Some DTC labs are granted U.S. Food and Drug Administration (FDA) marketing authorization, yet such results often come with a disclaimer that they should not be used for medical management. Recommendations from the American College of Medical Genetics and Genomics are summarized in **Table 480-1**.

A third, hybrid model has been developed by commercial genetic testing laboratories, particularly focused on analysis for cancer and cardiovascular disease risk. Here, after an individual initiates the testing process, either their own physician or a physician provided by the company orders the test. Many of these tests are similar to those offered to a patient in the clinical setting; however, the order and results remain separate from the medical record unless integrated by the patient's primary or specialist physician or other health care provider.

LIMITATIONS OF GENETIC TESTING

Limitations to the accuracy and interpretation of genetic testing exist. In addition to technical errors, genetics tests are sometimes designed to detect only the most common pathogenic variants. In addition, genetic testing has evolved over time. For example, it was not possible to obtain commercially available, comprehensive, large genomic rearrangement testing for *BRCA1* and *BRCA2* until 2006. Therefore, a negative result must be qualified by the possibility that the individual may have a variant that was not detectable in the test. In addition, the individual may have a pathogenic variant in another untested cancer-associated gene or in a gene not yet reported to be associated with elevated disease risk. As such, unless there is a known pathogenic variant in the family, a negative result in an individual with a suggestive personal or family history is typically classified as an uninformative negative. In this circumstance, medical management decisions should be based on personal and family history. For example, a man with a strong family history of colon cancer who receives an uninformative negative panel-based genetic test result may still be eligible earlier and more frequent colonoscopy screening.

The finding of a VUS is another limitation to genetic testing. A VUS (also termed *unclassified variant*) is a sequence variation in a gene where the effect of the alteration on the function of the protein is not known. Many of these variants are single nucleotide substitutions (also called missense alterations) that result in a single amino acid change. Although most VUSs will ultimately be reclassified as benign variants, some will prove to be functionally important. As more genes are sequenced (e.g., in a multiplex panel or through WES), the percentage of individuals found to have one or more VUSs increases significantly. The finding of a VUS is difficult for patients and providers alike and complicates decisions regarding medical management. In this setting, until there is further reclassification of the variant, ongoing screening, surveillance, and care are typically determined based on personal and family history.

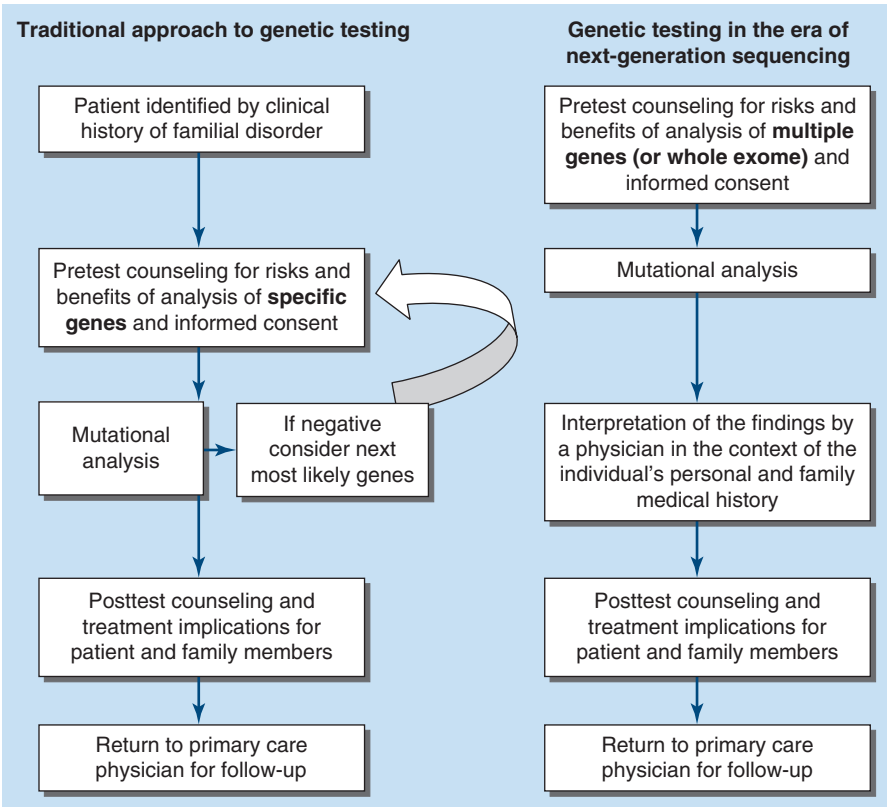

FIGURE 480-2 Approach to genetic testing.

TABLE 480-1 Summary of American College of Medical Genetics and Genomics Position Statement on Direct-to-Consumer Genetic Testing

The clinical laboratory must:	• Be accredited by the CLIA (Clinical Laboratory Improvement Amendments) program, the state, and/or other applicable accrediting agencies with this accreditation indicated on test result reports
Appropriately trained professionals should order, interpret, and disclose test result to avoid:	• Inadequate or lack of informed consent • Testing without appropriate indications • Selection of inadequate testing methods or incorrect test • Misinterpretation of results leading to improper clinical management
The individual undergoing testing should be adequately informed of:	• What the test can or cannot determine about their health or health risk • The potential for receiving results that neither confirm nor exclude the possibility of disease • Potential unexpected results, unrelated to the indication for testing • The potential impact of a given genetic test result on relatives
Professionals will review and provide information about:	• The validity and utility of a genetic test, including the limitations of a given test • Privacy issues to include review of who will have access to test results, the processes in place to protect results, and disposition of DNA samples once analysis is complete • Personal or family implications for life, long-term care, or disability insurance • Whether data generated will be shared with third parties

Clinical utility is an important consideration because genetic testing for susceptibility to chronic diseases is increasingly integrated into the practice of medicine. In some situations, there is proven clinical utility to genetic testing with significant evidence-based changes in medical management options and recommendations based on results. For example, there is clear evidence that risk-reducing bilateral salpingo-oophorectomy benefits women with a documented *BRCA1/2* pathogenic variant with improvement in mortality. In some cases, the discovery of disease-associated genes has outpaced studies that assess how such information should be used in the clinical management of the patient and family. Risks associated with genes often evolve with additional data. Therefore, predictive genetic testing should be done following appropriate pretest education.

TESTING STRATEGIES

Predictive genetic testing falls into two distinct categories. Presymptomatic testing applies to diseases where a specific genetic alteration is associated with a near 100% likelihood of developing disease. In contrast, predisposition testing predicts a risk for disease that is <100%. Presymptomatic testing is available for those at risk for Huntington's disease, whereas predisposition testing is considered for those at risk for hereditary colon cancer. It is important to note that for the majority of adult-onset disorders, testing is only predictive. Test results cannot reveal with confidence whether, when, or how the disease will manifest itself. For example, not everyone with the apolipoprotein ε4 allele will develop Alzheimer's disease, and individuals without this genetic marker can still develop the disorder.

The optimal testing strategy for a family is to initiate testing in a disease-affected family member first. Identification of a pathogenic variant can direct the testing of other at-risk family members (whether symptomatic or not). In the absence of additional familial or environmental risk factors, individuals who test negative for the pathogenic variant found in the affected family member are at general population risk for that particular disease. Furthermore, they can be reassured that they are not at risk for passing the pathogenic variant on to their children. On the other hand, asymptomatic family members who test positive for the known pathogenic variant must be informed that they are at increased risk for disease development and for transmitting the alteration to their children.

Pretest education is important, as is an assessment of the patient's ability to understand and cope with test results. Genetic testing has implications for entire families, and thus, individuals interested in pursuing genetic testing should consider how test results might impact their relationships with relatives, partners, spouses, and children. In families with a known genetic pathogenic variant, those who test positive must consider the impact of their carrier status on their present and future lifestyles; those who test negative may manifest survivor guilt. Parents who are found to have a disease-associated pathogenic variant often express considerable anxiety and despair as they address the issue of risk to their children. In addition, some individuals consider options such as preimplantation genetic testing (PGT) (which allows for selection of embryos without the familial pathogenic variant of concern) in their reproductive decision-making.

When a condition does not manifest until adulthood, clinicians and parents are faced with the question of whether at-risk children should be offered genetic testing and, if so, at what age. Although the matter is debated, several professional organizations have cautioned that genetic testing for adult-onset disorders should not be offered to children. Many of these conditions have no known interventions in childhood to prevent disease; consequently, such information can pose significant psychosocial risk to the child. In addition, there is concern that testing during childhood violates a child's right to make an informed decision regarding testing upon reaching adulthood. On the other hand, testing should be offered in childhood for disorders that may manifest early in life, especially when management options are available. For example, children with multiple endocrine neoplasia 2 (MEN 2) may develop medullary thyroid cancer early in life and should be considered for prophylactic thyroidectomy **(Chap. 400)**. Similarly, children with familial adenomatous polyposis (FAP) due to a pathogenic variant in *APC* may develop polyps in their teens with progression to invasive cancer in the twenties, and therefore, colonoscopy screening is started between the ages of 10 and 15 years **(Chap. 86)**.

INFORMED CONSENT

Individuals undergoing genetic testing should understand the risks, benefits, and limitations of genetic testing, as well as the potential implications of test results. Because molecular genetic testing of an asymptomatic individual often allows prediction of future risk, the patient should understand all potential long-term medical, psychological, and social implications of testing. There have long been concerns about the potential for genetic discrimination. The Genetic Information Nondiscrimination Act (GINA) was passed in 2008 and provides some protections related to job and health insurance discrimination, but does not address disability, long-term care, and life insurance coverage. Patients should understand that alternatives remain available if they decide not to pursue genetic testing, including the option of delaying testing to a later date. The option of DNA banking should be presented so that samples are readily available for future use by family members, if needed.

FOLLOW-UP CARE AFTER TESTING

Depending on the nature of the genetic disorder, posttest interventions may include (1) cautious surveillance and awareness; (2) specific medical interventions such as enhanced screening, chemoprevention, or risk-reducing surgery; (3) risk avoidance; and (4) referral to support services. For example, patients with known deleterious pathogenic variants in *BRCA1* or *BRCA2* are strongly encouraged to undergo risk-reducing salpingo-oophorectomy at an appropriate age and are offered intensive breast cancer screening with the addition of contrast-enhanced magnetic resonance imaging (MRI) as well as the option of risk-reducing mastectomy. In addition, such women may wish to take chemoprevention with tamoxifen, raloxifene, or exemestane. Those with more limited medical management and prevention options, such

as patients with Huntington's disease, should be offered continued follow-up and supportive services, including physical and occupational therapy and social services or support groups as indicated. Specific interventions will change as research continues to enhance our understanding of the medical management of these genetic conditions and more is learned about the functions of the gene products involved.

Individuals who test negative for a pathogenic variant in a disease-associated gene identified in an affected family member must be reminded that they may still be at risk for the disease. This is of particular importance for common diseases such as diabetes mellitus, cancer, and coronary artery disease. For example, a man who finds that he does not carry the disease-associated pathogenic variant in *MLH1* previously discovered in the family should be reminded that he still requires the same colon cancer screening recommended for the general population.

POPULATION SCREENING FOR GERMLINE DISEASE–ASSOCIATED VARIANTS

As costs of genetic testing have fallen, associated risks related to pathogenic variants have become more precise, and evidence for the clinical utility of interventions has increased, the conversation regarding the role of population screening has intensified. In an argument for population screening, several studies, including from large unselected biobanks, have demonstrated that many individuals with pathogenic variants in clearly established risk genes (e.g., *BRCA1*, *BRCA2*, *MLH1*, *MSH2*, *TTR*, *LDLR*) do not have a personal or family history that would have met current guidelines for genetic testing. In Israel, this had led to insurance coverage for all individuals of Ashkenazi Jewish descent for the three common *BRCA1* and *BRCA2* founder mutations (which are found in 2.5% of individuals of Ashkenazi Jewish descent). Challenges in the consideration of population screening include, but are not

TABLE 480-2 Examples of Genetic Testing and Possible Interventions

GENETIC DISORDER	INHERITANCE	GENES	INTERVENTIONS
Oncologic			
Lynch syndrome (HNPCC)	AD	*MLH1, MSH2, MSH6, PMS2*	Early endoscopic screening; risk-reducing surgery; aspirin
Familial adenomatous polyposis	AD	*APC*	Early and frequent endoscopy; prophylactic colectomy; chemoprevention
Hereditary breast and ovarian cancer	AD	*BRCA1, BRCA2*	Risk-reducing salpingo-oophorectomy; intensified breast surveillance including breast MRI; risk-reducing mastectomy; PARP inhibitors
Hereditary diffuse gastric cancer	AD	*CDH1*	Prophylactic gastrectomy; enhanced breast cancer surveillance
Hematologic			
Factor V Leiden	AD	*F5*	Avoidance of thrombogenic risk factors
Hemophilia A	XL	*F8*	Factor VIII replacement
Hemophilia B	XL	*F9*	Factor IX replacement
Glucose-6-phosphate dehydrogenase deficiency	XL	*G6PD*	Avoidance of oxidant drugs and certain foods
Sickle cell disease	AR	*HBB*	Bone marrow transplantation, hydroxyurea, gene therapy
Cardiovascular			
Hypertrophic cardiomyopathy	AD	>10 genes including *MYBPC3, MYH7, TNNT2, TPM1*	Echocardiographic screening; pharmacologic intervention; myomectomy
Long QT syndrome	AD, AR	>10 genes including *KCNQ1, SCN5A, KCNE1, KCNE2*	Electrocardiographic screening; pharmacologic intervention; implantable cardiac defibrillator devices
Marfan's syndrome	AD	*FBN1*	Echocardiographic screening; prophylactic beta blockers; aortic valve replacement as indicated
Gastrointestinal			
Familial Mediterranean fever	AR	*MEFV*	Colchicine
Hemochromatosis	AR	*HFE*	Phlebotomy
Pulmonary			
α_1 Antitrypsin deficiency	AR	*SERPINA1*	Avoidance of smoking and occupational and environmental toxins
Cystic fibrosis	AR	*CFTR*	Chest physiotherapy; agents to promote airway secretion clearance; *CFTR* modulators; lung transplantation
Endocrine			
Neurohypophyseal diabetes insipidus	AD	*AVP*	Replace vasopressin
Familial hypocalciuric hypercalcemia	AD	*CASR*	Avoidance of parathyroidectomy; calcimimetics
Multiple endocrine neoplasia type 2	AD	*RET*	Prophylactic thyroidectomy; screening for pheochromocytoma and hyperparathyroidism
Renal			
Polycystic kidney disease	AD, AR	*PKD1, PKD2, PKHD1*	Prevention of hypertension; prevention of urinary tract infections; kidney transplantation
Nephrogenic diabetes insipidus	XL, AR	*AVPR2, AQP2*	Fluid replacement; thiazides with or without amiloride
Neurologic			
Malignant hyperthermia	AD	*RYR1, CACNA1S*	Avoidance of precipitating anesthetics
Hyperkalemic periodic paralysis	AD	*SCN4A*	Diet rich in calcium and low in potassium; thiazides or acetazolamide
Duchenne's muscular dystrophy	XL	*DMD*	Corticosteroids; physical therapy; antisense oligonucleotide mediated exon skipping; abrogation of nonsense mediated decay by stop codon readthrough
Wilson's disease	AR	*ATP7B*	Zinc, trientine

Abbreviations: AD, autosomal dominant; AR, autosomal recessive; HNPCC, hereditary nonpolyposis colorectal cancer; MRI, magnetic resonance imaging; XL, X-linked.

limited to, variable penetrance, which may be significantly impacted by family history (thus, those individuals with germline pathogenic variants detected via population screening in the absence of a classic family history may have significantly lower risks of disease), consensus of which genes should be included, management of VUS, and practical issues of implementation including insurance coverage, counseling related to the limitations of GINA, the role of primary care providers in ordering, and concerns about the possibility of worsening socioeconomic and racial disparities that already exist in genetic testing.

THERAPEUTIC INTERVENTIONS BASED ON GENETIC RISK FOR DISEASE

Specific treatments are available for a number of genetic disorders. Strategies for the development of therapeutic interventions have a long history in childhood metabolic diseases; however, these principles have been applied in the diagnosis and management of adult-onset diseases as well **(Table 480-2)**. Hereditary hemochromatosis is usually caused by pathogenic variants in *HFE* (although other genes have been less commonly associated) and manifests as a syndrome of iron overload, which can lead to liver disease, skin pigmentation, diabetes mellitus, arthropathy, impotence in males, and cardiac issues **(Chap. 426)**. When identified early, the disorder can be managed effectively with therapeutic phlebotomy. Therefore, when the diagnosis of hemochromatosis has been made in a proband, it is important to counsel other family members in order to minimize the impact of the disorder.

Preventative measures and therapeutic interventions are not restricted to metabolic disorders. Identification of familial forms of long QT syndrome, associated with ventricular arrhythmias, allows early electrocardiographic testing and the use of prophylactic antiarrhythmic therapy, overdrive pacemakers, or defibrillators. Individuals with familial hypertrophic cardiomyopathy can be screened by ultrasound, treated with beta blockers or other drugs, and counseled about the importance of avoiding strenuous exercise and dehydration. Those with Marfan's syndrome can be treated with beta blockers or angiotensin II receptor blockers and monitored for the development of aortic aneurysms. The identification of germline abnormalities that increase the risk of specific types of cancer is rapidly changing clinical management. Identifying family members with pathogenic variants that predispose to FAP or Lynch syndrome leads to recommendations of early cancer screening and prophylactic surgery, as well as consideration of chemoprevention and attention to healthy lifestyle habits. Similar principles apply to familial forms of melanoma as well as cancers of the breast, ovary, and thyroid.

There has been a significant growth in the number of molecularly directed therapies for genetic diseases including transthyretin stabilizers for *TTR*-associated cardiac amyloid; poly (ADP-ribose) polymerase (PARP) inhibitors for treatment of *BRCA1/2* and *PALB2*-associated breast, ovarian, prostate, and pancreatic cancer; and medications for Duchenne's muscular dystrophy that can either promote exon skipping or allow bypass of nonsense mutations. Gene therapy either by replacement, such as in spinal muscular atrophy, or in sickle cell disease, increasing production of fetal hemoglobin or hemoglobin A, is an exciting area with tremendous opportunities **(Chap. 483)**.

The field of pharmacogenetics identifies genes that alter drug metabolism or confer susceptibility to toxic drug reactions. Pharmacogenetics seeks to individualize drug therapy in an attempt to improve treatment outcomes and reduce toxicity. Examples include thiopurine methyltransferase (TPMT) deficiency, dihydropyrimidine dehydrogenase deficiency, malignant hyperthermia, and glucose-6-phosphate deficiency. Despite successes in this area, it is not always clear how to incorporate pharmacogenetics into clinical care. For example, although there is an association with *CYP2C6* and *VKORC1* genotypes and warfarin dosing, there is no evidence that incorporating genotyping into clinical practice improves patient outcomes compared with clinical algorithms.

Although the role of genetic testing in the clinical setting continues to evolve, such testing holds the promise of allowing early and more targeted interventions that can reduce morbidity and mortality. Rapid technologic advances are changing the ways in which genetic testing is performed. As genetic testing has become less expensive and technically easier to perform, there has been significant expansion of its use. This has created both challenges and opportunities. It is critical that physicians and other health care professionals keep current with advances in genetic medicine in order to facilitate appropriate referral for genetic counseling and judicious use of genetic testing, as well as to provide state-of-the-art, evidence-based care for affected or at-risk patients and their relatives.

481 Mitochondrial DNA and Heritable Traits and Diseases

Karl L. Skorecki, Bruce H. Cohen

Mitochondria are cytoplasmic organelles whose major function is to generate ATP by the process of oxidative phosphorylation under aerobic conditions. This process is mediated by the respiratory electron transport chain (ETC) multiprotein enzyme complexes I–V and the two electron carriers, coenzyme Q_{10} (CoQ_{10}) and cytochrome c, located in the inner mitochondrial membrane. Other cellular processes to which mitochondria make a major contribution include apoptosis (programmed cell death) and additional cell type–specific functions **(Table 481-1)**. The efficiency of the mitochondrial ETC in ATP production is the major determinant of overall body energy balance and thermogenesis. In addition, mitochondria are the predominant source of reactive oxygen species (ROS), whose rate of production relates to the delicately balanced coupling of ATP production to oxygen consumption in health and disease. Given the centrality of oxidative phosphorylation to the normal activities of almost all cells, it is not surprising that mitochondrial dysfunction can affect almost any organ system **(Fig. 481-1)**. Until recently, it was thought that disruption of

energy production was the source of the pathophysiology in those with mitochondrial dysfunction, but recent evidence suggests that free radical production and the redox state of the mitochondria may play a role as well. Thus, physicians in many disciplines might encounter patients with mitochondrial diseases and should be aware of their existence and characteristics.

The integrated activity of an estimated 1500 gene products is required for normal mitochondrial biogenesis, function, maintenance, and integrity. Aside from the 37 genes that comprise the mitochondrial DNA (mtDNA) molecule, the remaining 1400+ gene products are encoded by nuclear genes (referred to as nDNA) and thus follow the rules and patterns of nuclear genomic inheritance **(Chap. 479)**. These nuclear-encoded proteins are synthesized in the cell cytoplasm and imported to their location of activity within the mitochondria through a complex biochemical process. This process includes unfolding of the nuclear-encoded protein, attachment to a chaperone protein that shuttles it through a specific channel to a specific mitochondrial location, and detachment from the chaperone followed by assembly with other mtDNA- and nDNA-encoded proteins. In addition, the mitochondria contain their own small genome consisting of numerous copies (polyploidy) per mitochondrion of a circular, double-strand mtDNA molecule comprising 16,569 nucleotides. This mtDNA sequence (also known as the "mitogenome") might represent the remnants of endosymbiotic prokaryotes from which mitochondria are thought to have originated. The mtDNA sequence contains a total of 37 genes, of which 13 encode mitochondrial protein components of the ETC **(Fig. 481-2)**. The remaining 22 tRNA- and 2 rRNA-encoding genes are mitochondria-specific and dedicated to the process of translating the 13 mtDNA-encoded proteins. The mtDNA itself replicates constantly, independent of cell division, and requires its own unique polymerase, referred to as polymerase gamma (polγ), which is encoded by the nuclear gene *POLG*, disorders of which are discussed in **Chaps. 460 and 480**. However, mutations in *POLG* can disrupt the endonuclease function of polγ, resulting in somatic mutations in the mtDNA that endure with future replication. Unless this mutation occurs and is propagated in the oocyte, it is not heritable. Mutations in *POLG* can also affect the polymerase function of polγ that results in decreased replication of the mtDNA and can lead to mtDNA depletion. This dual nuclear and mitochondrial genetic control of mitochondrial function results in unique and diagnostically challenging patterns of inheritance. The current chapter focuses on heritable traits and diseases related to the mtDNA component of the dual genetic control of mitochondrial function. The reader is referred to **Chaps. 460 and 479** for consideration of mitochondrial disease originating from mutations in the nuclear genome. The former include (1) disorders due to mutations in nuclear genes directly encoding structural components or assembly factors of the oxidative phosphorylation complexes, (2) disorders due to mutations in nuclear genes encoding proteins indirectly related to oxidative phosphorylation, (3) mtDNA depletion syndromes (MDSs) characterized by a reduction of mtDNA copy number in affected tissues without mutations or rearrangements in the mtDNA, and (4) disorders due to mutations in nuclear genes that disrupt normal mitochondrial dynamics (biosynthesis, mitophagy, fission, and fusion).

The classic physical structure of the mitochondria is that of a thread-like organelle, which under fixed conditions, such as observed with immunohistochemical stains or electron microscopy, has a submarine shape and measures about 1 μm in length. However, in the living state, mitochondria comprise a network, with the mitochondrial shape being highly

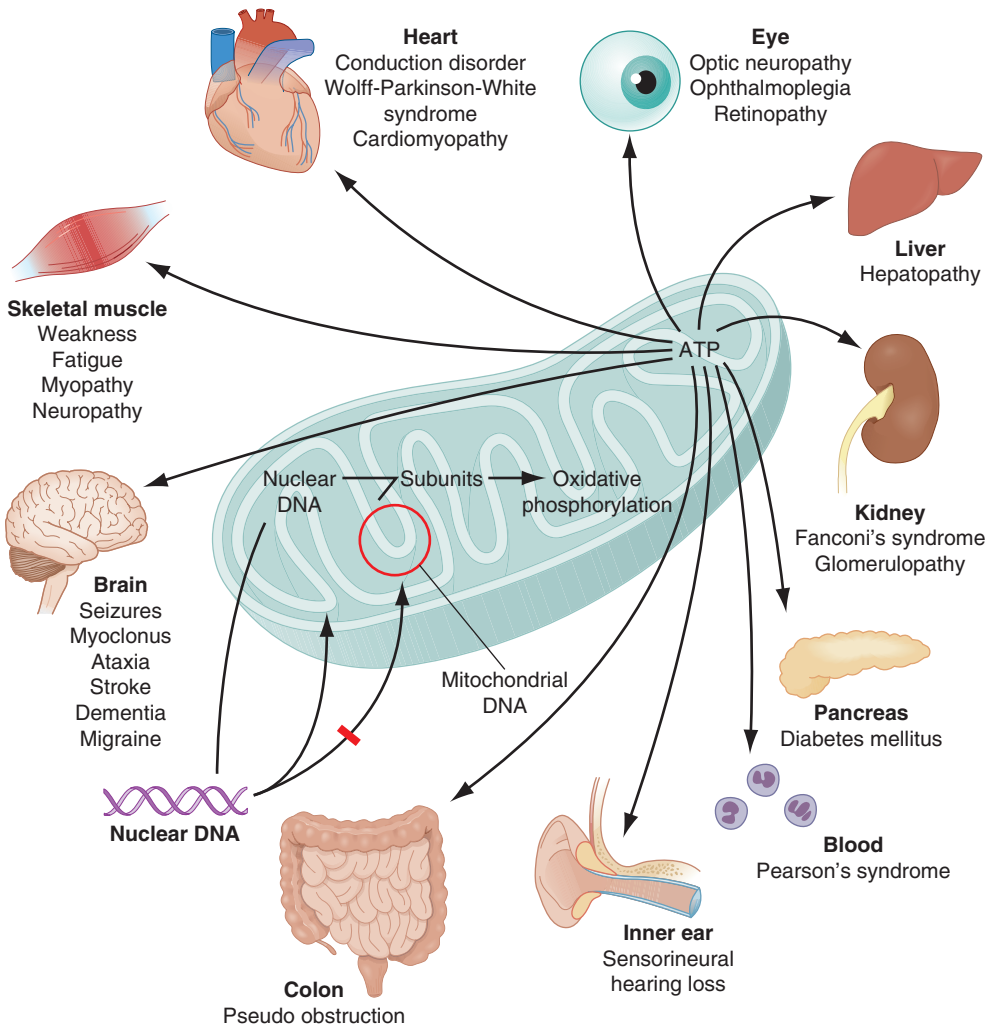

FIGURE 481-1 Dual genetic control and multiple organ system manifestations of mitochondrial disease. *(From DR Johns: Mitochondrial DNA and disease. N Engl J Med 333:638, 1995. Copyright © 1995, Massachusetts Medical Society. Reprinted with permission from Massachusetts Medical Society.)*

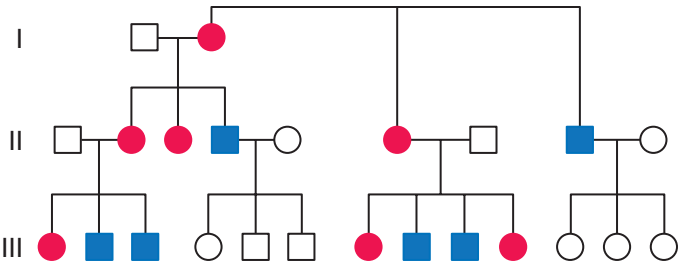

FIGURE 481-2 Maternal inheritance of mitochondrial DNA (mtDNA) disorders and heritable traits. Affected women (*filled circles*) transmit the trait to their children. Affected men (*filled squares*) do not transmit the trait to any of their offspring.

variable based on the cell type, and manifests a complex and ever-changing syncytial form, with continuous appearance and disappearance of budding structures (representing mitochondrial fission) and reorganization of separate mitochondria (representing mitochondrial fusion). Although mitochondrial number per cell type appears in the medical literature, this is no longer considered as a reliable expression of actual functional mitochondrial volume or mass.

Although the presence of mitochondria has been known for >150 years, and knowledge of their respiratory function was proposed ~100 years ago, the initial description of an illness linked to mitochondrial dysfunction was only made in 1962. The presence of mtDNA was also only reported in the 1960s, and it was not until 1988 that the first mutations in the mtDNA causing human illness were described. These included the demonstration of a large-scale mtDNA deletion causing Kearns-Sayre syndrome (KSS) and the discovery of a point mutation in *ND4*, an mtDNA-encoded complex I gene, causing Leber's hereditary optic neuropathy (LHON). Following these two discoveries, >400 pathogenic mtDNA mutations or deletions have been reported.

MITOCHONDRIAL DNA STRUCTURE AND FUNCTION

As a result of its circular structure and extranuclear location, the replication and transcription mechanisms of mtDNA differ from the corresponding mechanisms in the nuclear genome, whose nucleosomal packaging and structure are more complex. Specifically, mitochondria have their own transcription system, and the mtDNA itself replicates independently of cellular replication. Because each cell contains many copies of mtDNA and because the number of mitochondria can vary during the lifetime of each cell, mtDNA copy number is not directly coordinated with the cell cycle. Thus, vast differences in mtDNA copy number are observed between different cell types and tissues and during the lifetime of a cell. Another important feature of the mtDNA replication process is a reduced stringency of proofreading and replication error correction, leading to a greater degree of sequence variation compared to the nuclear genome. Some of these sequence variants are silent polymorphisms that do not have the potential for a phenotypic or pathogenic effect, whereas others may be considered pathogenic mutations. There are some mutations that may be considered ecogenetic, as they typically remain silent, meaning they do not cause disease, unless an external event occurs. One classic example is seen in a common (1:800) mutation in the mitochondrial 12S rRNA gene, m.A1555G, which is associated with hearing loss that is rapidly exacerbated by exposure to normal dosages of an aminoglycoside antibiotic. Because mtDNA replication is independent of cellular replication, the percentage of mutant mtDNA copies tend to increase with age, especially in cells that are terminally differentiated (nonreplicative) at birth such as neurons and myocytes, which may explain some features of mitochondrial dysfunction with aging.

With respect to transcription, initiation can occur on both strands and proceeds through the production of an intronless polycistronic precursor RNA, which is then processed to produce the 13 individual mRNA and 24 individual tRNA and rRNA products. The 37 mtDNA genes comprise fully 93% of the 16,569 nucleotides of the mtDNA in what is known as the *coding region*. The *control region*, which is contained in the D-loop, consists of ~1.1 kilobases (kb) of noncoding DNA and is thought to have an important role in replication and transcription initiation.

MATERNAL INHERITANCE AND LACK OF RECOMBINATION

In contrast to homologous pair recombination that takes place in the nucleus, mtDNA molecules do not undergo recombination, such that mutational events represent the only source of mtDNA genetic diversification. Moreover, it is only the maternal DNA that is transmitted to the offspring. The fertilized oocyte degrades the paternal mitochondria involving the ubiquitin proteasome system and autophagy that takes place on the inner membrane of the oocyte. However, additional studies suggest that human spermatozoa do not contain intact mtDNA and are missing TFAM, the mitochondrial transcription factor necessary for mtDNA transcription. Thus, although mothers transmit their mtDNA to both their sons and daughters, only the daughters can transmit the inherited mtDNA to future generations. Accordingly, mtDNA sequence variation and associated phenotypic traits and diseases are inherited exclusively along maternal lines, meaning both sons and daughters have equal chances of having symptomatic disease, with the only significant exception being LHON, as described below.

The phenotypic expression, including age of onset and the specific pattern and severity of organ dysfunction, of a pathogenic mtDNA mutation may vary greatly, even within families. Because of this complex relationship between mtDNA mutations and disease expression, sometimes it is difficult to recognize the maternal pattern of inheritance at the clinical or pedigree level. However, evidence of paternal transmission can almost certainly exclude an mtDNA genetic origin of phenotypic variation or disease; conversely, a disease affecting both sexes without evidence of paternal transmission strongly suggests a heritable mtDNA disorder (Fig. 481-2).

MULTIPLE COPY NUMBER (POLYPLOIDY), HIGH MUTATION RATE, HETEROPLASMY, AND MITOTIC SEGREGATION

Each aerobic cell in the body has multiple mitochondria, often numbering many hundreds or more in cells with extensive energy production requirements. Furthermore, the number of copies of mtDNA within each mitochondrion varies from several to hundreds; this is true of both somatic as well as germ cells, including oocytes in females. In the case of somatic cells, this means that the impact of most newly acquired somatic mtDNA mutations is likely to be very small in terms of total cellular or organ system function; however, because of the manyfold higher mutation rate during mtDNA replication, numerous different mutations may accumulate with aging of the organism. It has been proposed that the total cumulative burden of acquired somatic mtDNA mutations with age may result in an overall perturbation of mitochondrial function, contributing to age-related reduction in the efficiency of oxidative phosphorylation and increased production of damaging ROS. Because certain mtDNA (and nDNA) mutations may result in electron leak within the ETC, the ROS damage may rise to a level causing increased susceptibility to somatic mtDNA damage and disease expression. The accumulation of such acquired somatic mtDNA mutations with aging may contribute to age-related diseases, such as metabolic syndrome and diabetes, cancer, and neurodegenerative and cardiovascular disease in any given individual. However, somatic mutations are not carried forward to the next generation, and the hereditary impact of mtDNA mutagenesis requires separate consideration in the female germline.

The multiple mtDNA copy number within each cell, including the maternal germ cells, results in the phenomenon of heteroplasmy, in contrast to the much greater uniformity (homoplasy) of somatic nuclear DNA sequence. Heteroplasmy for a given mtDNA sequence variant or mutation arises as a result of the coexistence within a cell, tissue, or individual of mtDNA molecules bearing more than one version of the sequence variant **(Fig. 481-3)**. The importance of the heteroplasmy phenomena to the understanding of mtDNA-related

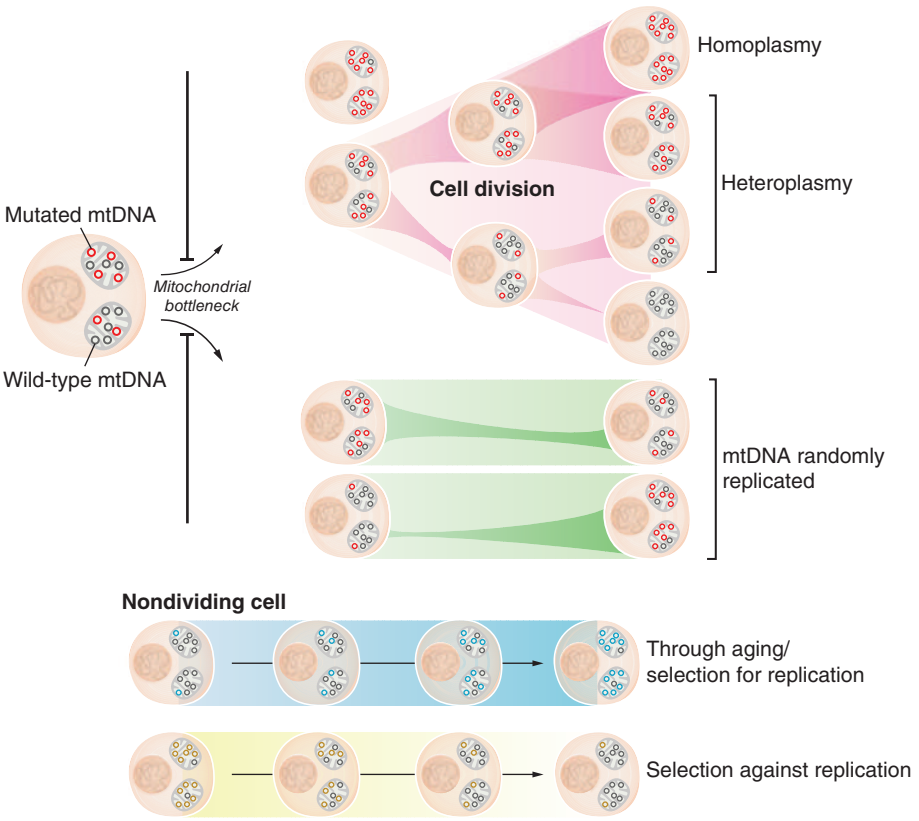

FIGURE 481-3 mtDNA genetic bottleneck and changes of heteroplasmy level throughout the lifetime. Each oocyte can inherit a different proportion of mutated mtDNA molecules from maternal mitochondria. When cells divide (shown in *pink*), heteroplasmy levels in each daughter cell can either increase, decrease, or stay approximately the same. Once inherited, mtDNA mutations can continuously "clonally expand" throughout life, even in nondividing cells (shown in *green, blue,* and *yellow*). If one genotype is copied more frequently than another, it will change the overall proportion of different genotypes within the cell over time. The direction of this change can be influenced by selection for or against a particular mtDNA variant (shown in *blue* and *yellow*). When a mutated mtDNA molecule has a replicative advantage, the level will increase during life and possibly exceed the biochemical threshold, and thus contribute to the age-related pathologies or the aging process (shown in the *blue box*). *(Reproduced from W Wei, PF Chinnery: Inheritance of mitochondrial DNA in humans: Implications for rare and common diseases. J Intern Med 2020; 287:634.)*

mitochondrial diseases is critical. The coexistence of mutant and nonmutant (wild-type) mtDNA and the variation of the mutant load, which can be thought of as the percentage of mutant mtDNA molecules within a specific cell, tissue, organ, or organism, contribute to the expression of a phenotype among individuals from the same maternal sibship. At the level of the oocyte, the percentage of mtDNA molecules bearing each version of the polymorphic sequence variant or mutation depends on stochastic events related to partitioning of mtDNA molecules during the process of oogenesis itself. Thus, oocytes differ from each other in the degree of heteroplasmy for that sequence variant or mutation. In turn, the heteroplasmic state is carried forward to the zygote and to the organism as a whole, to varying degrees, depending on mitotic segregation of mtDNA molecules during organ system development and maintenance. For this reason, in vitro fertilization, followed by preimplantation genetic diagnosis (PGD), is not as predictive of the genetic health of the offspring in the case of mtDNA mutations as in the case of mutations and subsequent diseases occurring in the nuclear genome. Similarly, the impact of somatic mtDNA mutations acquired during development and subsequently also shows a wide spectrum of variability. In general, a higher mutant load will result in a more severe and earlier phenotypic presentation. However, measuring heteroplasmy in one tissue (lymphocytes from blood or urine sediment containing kidney and bladder epithelial cells, for example) may not represent the percentage of mutant heteroplasmy in the tissue or organs most affected, such as the cardiac atrioventricular node or brain. Furthermore, the threshold of mutant heteroplasmy that results in clinical illness may vary depending on the specific mutation.

Mitotic segregation refers to the unequal distribution of wild-type and mutant versions of mtDNA molecules during all cell divisions that occur during prenatal development and subsequently throughout the lifetime of an individual. The phenotypic effect or disease impact will be a function not only of the inherent disruptive effect (pathogenicity) on the mtDNA-encoded gene (coding region mutations) or integrity of the mtDNA molecule (control region mutations) but also of its distribution among the multiple copies of mtDNA in the various mitochondria, cells, and tissues of the affected individual. Thus, one consequence can be the generation of a bottleneck due to the marked decline in given sets of mtDNA variants, pathogenic and nonpathogenic, consequent to such mitotic segregation. It is postulated that the main effects of this bottleneck occur between the primordial germ cell state and the primary oocyte stage of development. Heterogeneity arises from differences in the degree of heteroplasmy among oocytes of the transmitting female, together with subsequent, probably random, mitotic segregation of the pathogenic mutation during tissue and organ development and throughout the lifetime of the individual offspring. The actual expression of disease is believed to primarily depend on a threshold percentage of mitochondria whose function is disrupted by mtDNA mutations. This in turn confounds hereditary transmission patterns and hence genetic diagnosis of pathogenic heteroplasmic mutations. Generally, if the proportion of mutant mtDNA is <60%, the individual is unlikely to be affected, whereas proportions exceeding 90% likely result in clinical disease. One notable exception is LHON, in which these mutations are present either in 100% mutant homoplasmy, which causes the disease expression, or 100% wild-type homoplasmy. It is not understood why this specific phenotype and the several known mtDNA alleles that result in LHON behave in this manner.

HOMOPLASMIC VARIANTS AND HUMAN mtDNA PHYLOGENY

In contrast to classic mtDNA diseases, most of which have clinical onset during childhood and are the result of heteroplasmic mutations as noted above, during the course of human evolution, certain mtDNA sequence variants have drifted to a state of homoplasmy, wherein all of the mtDNA molecules in the organism contain the new sequence variant. This arises due to a "bottleneck" effect followed by genetic drift during the very process of oogenesis itself (Fig. 481-3). In other words, during certain stages of oogenesis, the mtDNA copy number becomes so substantially reduced that the particular mtDNA species bearing the novel or derived sequence variant may become the increasingly predominant, and eventually exclusive, version of the mtDNA for that particular nucleotide site. All of the offspring of a woman bearing an mtDNA sequence variant or mutation that has become homoplasmic will also be homoplasmic for that variant and will transmit the sequence variant forward in subsequent generations.

Considerations of reproductive fitness limit the evolutionary or population emergence of pathogenic homoplasmic mutations that are lethal or cause severe disease in infancy or childhood. Thus, with a number of notable exceptions (e.g., as noted mtDNA mutations causing LHON; and see below), most homoplasmic mutations are considered to be neutral markers of human evolution, which are useful and interesting in the population genetics analysis of shared maternal

ancestry but have little significance in human phenotypic variation or disease predisposition.

More important is the understanding that this accumulation of homoplasmic mutations occurs at a genetic locus that is transmitted only through the female germline and that lacks recombination. In turn, this enables reconstruction of the sequential topology and radiating phylogeny of mutations accumulated through the course of human evolution since the time of the most recent common mtDNA ancestor of all contemporary mtDNA sequences, some 200,000 years ago. The term *haplogroup* is usually used to define major branching points in the human mtDNA phylogeny, nested one within the other, which often demonstrate striking continental geographic ancestral partitioning. At the level of the complete mtDNA sequence, the term *haplotype* is usually used to describe the sum of mutations observed for a given mtDNA sequence and as compared to a reference sequence, such that all haplotypes falling within a given haplogroup share the total sum of mutations that have accumulated since the most recent common ancestor and the bifurcation point they mark. The remaining observed variants are private to each haplotype. Consequentially, the human mtDNA sequence serves with high fidelity as a molecular prototype for a nonrecombining locus, and its variation has been extensively used in phylogenetic studies. Moreover, the mtDNA mutation rate is considerably higher than the rate observed for the nuclear genome, especially in the control region, which contains the displacement loop, or D-loop, in turn comprising two adjacent hypervariable regions (HVR-I and HVR-II). Together with the absence of recombination, this amplifies drift to high frequencies of novel haplotypes that are highly partitioned across geographically defined populations. Despite extensive research, it has not been well established that such haplotype-based partitioning has a significant influence on human health conditions. However, mtDNA-based phylogenetic analysis can be used both as a quality assurance tool and as a filter in distinguishing neutral mtDNA variants comprising human mtDNA phylogeny from potentially deleterious mutations.

MITOCHONDRIAL DNA DISEASE

The true prevalence of mtDNA disease is difficult to estimate because of the phenotypic heterogeneity that occurs as a function of heteroplasmy, the challenge of detecting and assessing heteroplasmy in different affected tissues, and the other unique features of mtDNA function and inheritance described above. It is estimated that at least 1 in 200 healthy humans harbors a pathogenic mtDNA mutation with the potential to causes disease but that heteroplasmic germline pathogenic mtDNA mutations actually result in clinical disease in ~1 in 5000 individuals.

The true disease burden relating to mtDNA sequence variation will only be known when the following capabilities become available: (1) ability to distinguish a completely neutral sequence variant from a true phenotype-modifying or pathogenic mutation, (2) accurate assessment of heteroplasmy that can be determined with high fidelity, and (3) a systems biology approach **(Chap. 499)** to determine the network of epistatic interactions of mtDNA sequence variations with mutations in the nuclear genome.

OVERVIEW OF CLINICAL AND PATHOLOGIC FEATURES OF HUMAN mtDNA DISEASE

Given the vital roles of mitochondria in all nucleated cells, it is not surprising that mtDNA mutations can affect numerous tissues with pleiotropic effects. More than 200 different disease-causing, mostly heteroplasmic mtDNA mutations have been described affecting ETC function. **Figure 481-4** provides a partial mtDNA map of some of the better characterized of these disorders. A number of clinical clues can increase the index of suspicion for a heteroplasmic mtDNA mutation as an etiology of a heritable trait or disease, including (1) familial clustering with absence of paternal transmission; (2) adherence to one of the classic syndromes (see below) or paradigmatic combinations of disease phenotypes involving several organ systems that normally do not fit together within a single nuclear genomic mutation category; (3) a complex of laboratory and pathologic abnormalities that reflect disruption in cellular energetics (e.g., lactic acidosis and neurodegenerative and myodegenerative symptoms with the finding of ragged red fibers, reflecting the accumulation of abnormal mitochondria under the muscle sarcolemmal membrane); or (4) a mosaic pattern reflecting a heteroplasmic state. There are no truly sensitive and specific biomarkers of disease, and the presence of a historically quintessential finding of ragged red fibers can be seen in numerous muscle disorders, so laboratory tests must always be interpreted in the context of their limitations and should not be used to define the disease. Because of the improved availability and decreasing cost for mtDNA sequencing, the presence or absence of a pathogenic mtDNA mutation can be diagnostic when the clinical phenotype and family history are suggestive.

Heteroplasmy can sometimes be elegantly demonstrated at the tissue level using histochemical staining for enzymes in the oxidative phosphorylation pathway, with a mosaic pattern indicating heterogeneity of the genotype for the coding region for the mtDNA-encoded enzyme.

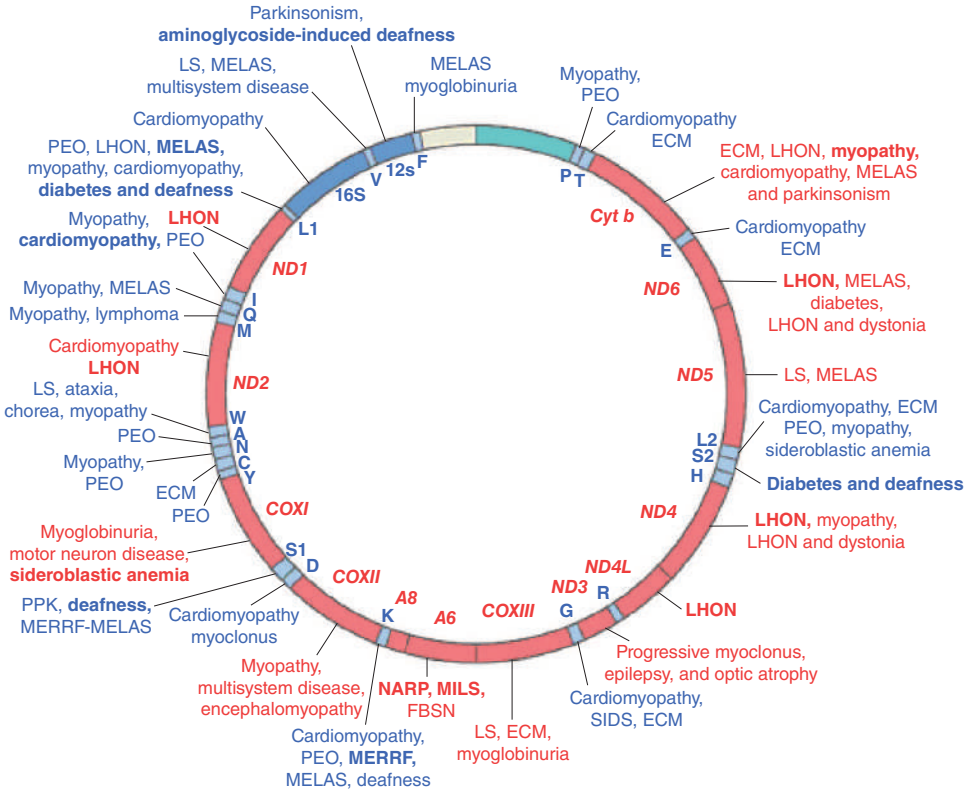

FIGURE 481-4 Mutations in the human mitochondrial genome known to cause disease. Disorders that are frequently or prominently associated with mutations in a particular gene are shown in *boldface*. Diseases due to mutations that impair mitochondrial protein synthesis are shown in *blue*. Diseases due to mutations in protein-coding genes are shown in *red*. ECM, encephalomyopathy; FBSN, familial bilateral striatal necrosis; LHON, Leber's hereditary optic neuropathy; LS, Leigh's syndrome; MELAS, mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes; MERRF, myoclonic epilepsy with ragged red fibers; MILS, maternally inherited Leigh's syndrome; NARP, neuropathy, ataxia, and retinitis pigmentosa; PEO, progressive external ophthalmoplegia; PPK, palmoplantar keratoderma; SIDS, sudden infant death syndrome. *(From S DiMauro, E Schon: Mitochondrial respiratory-chain diseases. N Engl J Med 348:2656, 2003. Copyright © 2003, Massachusetts Medical Society. Reprinted with permission from Massachusetts Medical Society.)*

Complex II, CoQ, and cytochrome c are exclusively encoded by nuclear DNA. In contrast, complexes I, III, IV, and V contain at least some subunits encoded by mtDNA. Just 3 of the 13 subunits of the ETC complex IV enzyme, cytochrome c oxidase (COX), are encoded by mtDNA, and therefore, this enzyme has the lowest threshold for dysfunction when a threshold level of mutated mtDNA is reached. Histochemical staining for COX activity in tissues of patients affected with heteroplasmic inherited mtDNA mutations (or with the somatic accumulation of mtDNA mutations, see below) can show a mosaic pattern of reduced histochemical staining in comparison with histochemical staining for the complex II enzyme succinate dehydrogenase (SDH) **(Fig. 481-5)**.

Next-generation sequencing (NGS) has dramatically improved the clinical genetic diagnostic evaluation of mitochondrial diseases at the level of both the nuclear genome and mtDNA. Low sequencing costs, high throughput, and short turnaround time expedite whole exome (WES) or whole genome sequencing (WGS) to identity genes and mutations with known pathogenicity or based on bioinformatics assessment of likely pathogenicity. In the context of the mtDNA, the deep coverage enabled by NGS compared to Sanger sequencing now provides rapid and reliable detection of heteroplasmy in different affected tissues. NGS yields accurate information about a patient's predominant mtDNA sequence as well as lower frequency heteroplasmic variants and can reliably reach detection of even single mutant nucleotide heteroplasmy down to levels of <10%. Lower levels are often only clinically relevant if in the setting of a striking difference in heteroplasmy in different tissues.

Clinically, the most striking overall characteristic of mitochondrial genetic disease is the phenotypic heterogeneity associated with mtDNA mutations. This extends to intrafamilial phenotypic heterogeneity for the same mtDNA pathogenic mutation and, conversely, to the overlap of phenotypic disease manifestations with distinct mutations. Thus, although fairly consistent and well-defined "classic" syndromes have been attributed to specific mutations, frequently "nonclassical" combinations of disease phenotypes ranging from isolated myopathy to extensive multisystem disease are often encountered, rendering genotype-phenotype correlation challenging. In both classical and nonclassical mtDNA disorders, there is often a clustering of some combination of abnormalities affecting the neurologic system (including optic nerve atrophy, pigment retinopathy, and sensorineural hearing loss), cardiac and skeletal muscle (including extraocular muscles), and endocrine and metabolic systems (including diabetes mellitus). Additional organ systems that may be affected include the hematopoietic, renal, hepatic, and gastrointestinal systems, although these are more frequently involved in infants and children. Disease-causing mtDNA coding region mutations can affect either one of the 13 protein-encoding genes or one of the 24 protein synthetic genes. Clinical manifestations do not readily distinguish these two categories, although lactic acidosis and specific muscle pathologic findings (e.g., ragged red and ragged blue fibers, immunohistochemical staining, paracrystalline inclusions on ultrastructure) tend to be more prominent in the latter. In all cases, either defective ATP production due to disturbances in the ETC or enhanced generation of ROS has been invoked as the mediating biochemical mechanism between mtDNA mutation and disease manifestation.

mtDNA DISEASE PRESENTATIONS

The clinical presentation of adult patients with mtDNA disease can be divided into three categories: (1) clinical features suggestive of mitochondrial disease **(Table 481-2)** but not a well-defined classic syndrome; (2) classic mtDNA syndromes; and (3) clinical presentation confined to one organ system (e.g., isolated sensorineural deafness, cardiomyopathy, or diabetes mellitus). It is important to note, especially when young adults come to medical attention, that symptoms of an mtDNA disorder may have begun during childhood.

Table 481-3 provides a summary of eight illustrative classic mtDNA syndromes or disorders that affect adult patients and highlights some of the most interesting features of mtDNA disease in terms of molecular pathogenesis, inheritance, and clinical presentation. The first five of these syndromes result from heritable point mutations in either protein-encoding or protein synthetic mtDNA genes; the other three result from rearrangements or deletions that usually do not involve the germline.

LHON is a common cause of maternally inherited visual failure. LHON typically presents during young adulthood with subacute painless loss of vision in one eye, with symptoms developing in the other eye 6–12 weeks later. In some instances, cerebellar ataxia, peripheral neuropathy, and cardiac conduction defects are observed. In >95% of cases, LHON is due to one of the three homoplasmic point mutations of mtDNA that affect genes encoding different subunits of complex I of the mitochondrial ETC; however, not all individuals who inherit a primary LHON mtDNA mutation develop optic neuropathy, and the male-to-female ratio is 8.2, indicating that additional environmental (e.g., tobacco exposure) or independent genetic factors are important in the etiology of the disorder. Estrogen may also play a role in the decreased clinical penetrance in women. Both the nuclear and mitochondrial genomic backgrounds modify disease penetrance. Indeed, a region of the X chromosome containing a high-risk haplotype for LHON has been identified, supporting the formulation that nuclear genes act as modifiers and affording an explanation for the male prevalence of LHON. This haplotype can be used in predictive genomic testing and prenatal screening for this disease. In contrast to the other classic mtDNA disorders, it is of interest that

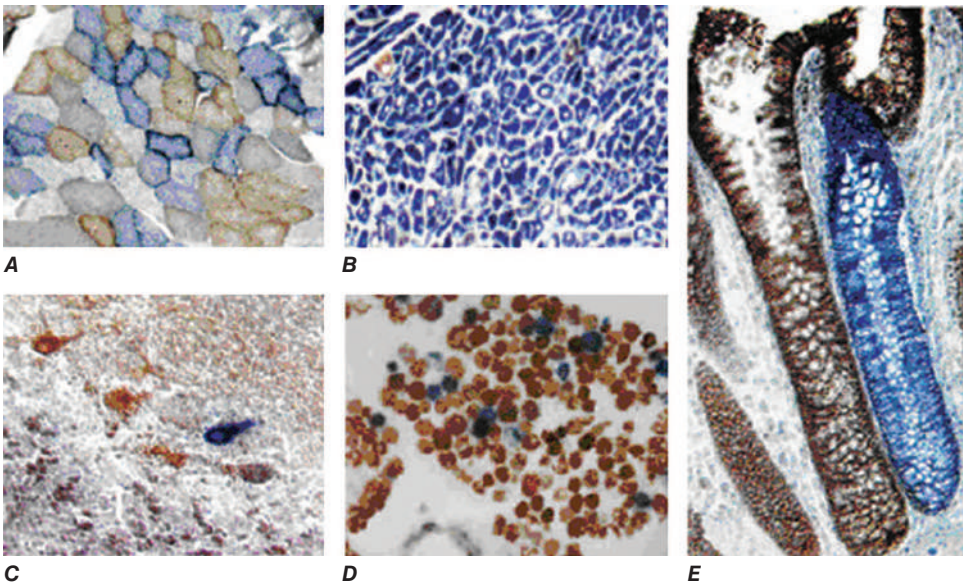

FIGURE 481-5 Cytochrome c oxidase (COX) deficiency in mitochondrial DNA (mtDNA)–associated disease. Transverse tissue sections that have been stained for COX and succinate dehydrogenase (SDH) activities sequentially, with COX-positive cells shown in *brown* and COX-deficient cells shown in *blue*. ***A.*** Skeletal muscle from a patient with a heteroplasmic mitochondrial tRNA point mutation. The section shows a typical "mosaic" pattern of COX activity, with many muscle fibers harboring levels of mutated mtDNA that are above the crucial threshold to produce a functional enzyme complex. ***B.*** Cardiac tissue (left ventricle) from a patient with a homoplasmic tRNA mutation that causes hypertrophic cardiomyopathy, which demonstrates an absence of COX in most cells. ***C.*** A section of cerebellum from a patient with mtDNA rearrangement that highlights the presence of COX-deficient neurons. ***D, E.*** Tissues that show COX deficiency due to clonal expansion of somatic mtDNA mutations within single cells—a phenomenon that is seen in both postmitotic cells (***D***; extraocular muscles) and rapidly dividing cells (***E***; colonic crypt) in aging humans. *(Reproduced with permission from R Taylor, D Turnbull: Mitochondrial DNA mutations in human disease. Nat Rev Genetics 6:389, 2005.)*

TABLE 481-2 Common Features of Mitochondrial DNA–Associated Diseases in Adults

Neurologic: stroke, epilepsy, migraine headache, peripheral neuropathy, ataxia, dystonia, myoclonus, cranial neuropathy (optic atrophy, sensorineural deafness, dysphagia, dysphasia)
Skeletal myopathy: ophthalmoplegia, exercise intolerance, myalgia, weakness
Cardiac: conduction block, cardiomyopathy
Respiratory: hypoventilation, aspiration pneumonitis
Endocrine: diabetes mellitus, premature ovarian failure, hypothyroidism, hypoparathyroidism
Ophthalmologic: cataracts, pigment retinopathy, neurologic and myopathic (optic atrophy, ophthalmoplegia)

patients with this syndrome are often homoplasmic for the disease-causing mutation. The somewhat later onset in young adulthood and modifying effect of protective background nuclear genomic haplotypes may have enabled homoplasmic pathogenic mutations to have escaped evolutionary censoring.

Mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes (MELAS) is a multisystem disorder with a typical onset between 2 and 10 years of age, although adult presentations also occur. Following normal early psychomotor development, the most common initial symptoms are seizures, recurrent headaches, anorexia, and recurrent vomiting. Exercise intolerance or proximal limb weakness can be the initial manifestation, followed by generalized tonic-clonic seizures. Short stature is common. Seizures are often associated with stroke-like episodes of transient hemiparesis or cortical blindness that may produce recurrent encephalopathy with impaired consciousness. It is often not possible to determine if the encephalopathy is due to refractory clinical or subclinical seizures or should be attributed to an independent effect. The cumulative residual effects of the stroke-like episodes gradually impair motor abilities, vision, and cognition, often by adolescence or young adulthood. Sensorineural hearing loss adds to the progressive decline of these individuals. A plethora of less common symptoms have been described including myoclonus, ataxia, episodic coma, optic atrophy, cardiomyopathy, pigmentary retinopathy, ophthalmoplegia, diabetes mellitus, hirsutism, gastrointestinal dysmotility, and nephropathy. The typical age of death ranges from 10 to 35 years, but some individuals live into their sixth decade. Intercurrent infections or intestinal obstructions are often the terminal events. It is proposed that the clinical diagnosis of MELAS can only be applied if the following three criteria are met: (1) stroke-like episode before age 40 years, (2) encephalopathy due to seizures and/or dementia, and (3) lactic acidosis and/or ragged red fibers. It is not atypical for some family members to have much less severe or later onset illness, presumably because of a lessor mutation load, and "MELAS" is not used as a diagnosis for these restricted phenotypes. This creates somewhat of a disconnect between the genotype for MELAS (most commonly the m.3243A>G mutation) and a diverse phenotype, which includes the syndrome MELAS, a syndrome of high-frequency hearing loss and diabetes with onset later in life, as well as many other phenotypes between these two extreme syndromes. Certain other mtDNA mutations can also cause such patterns of diverse phenotypic expression. Laboratory investigation commonly demonstrates elevated blood lactate concentrations at rest with excessive increase after moderate exercise. Magnetic resonance imaging (MRI) of the brain shows areas of involvement on T2- or fluid-attenuated inversion recovery (FLAIR) sequences, with decreased signal on perfusion-weighted sequences, which typically involve the posterior cerebrum and do not conform to the distribution of major arteries. These abnormalities may be temporary or evolve to subsequent atrophy **(Fig. 481-6)**. Electrocardiography (ECG) may show evidence of cardiomyopathy, preexcitation, or incomplete heart block. Electromyography and nerve conduction studies are consistent with a myopathic process, without or with coexisting axonal and sensory neuropathic findings. Muscle biopsy typically shows ragged red fibers with the modified Gomori trichrome stain or "ragged blue fibers" with the SDH histochemical stain, resulting from the hyperintense reaction. The diagnosis of MELAS is based on a combination of clinical findings and molecular genetic testing. Mutations in the mtDNA gene *MT-TL1* encoding $tRNA^{leu}$ are causative. The most common mutation, present in ~80% of individuals with typical clinical findings, is an A-to-G transition at nucleotide 3243 (m.3243A>G). Mutations can usually be detected in mtDNA from leukocytes in individuals with typical MELAS; however, the occurrence of heteroplasmy can result in varying tissue distribution of mutated mtDNA. In the absence of specific treatment, various manifestations of MELAS are treated according to standard modalities for prevention, surveillance, and treatment. Recent developments in therapy are described below.

Myoclonus epilepsy with ragged red fiber (MERRF) is a multisystem disorder characterized by myoclonus, seizures, ataxia, and myopathy with ragged red fibers. Hearing loss, exercise intolerance, neuropathy, ataxia, cervical lipomas, and short stature are often present. Ataxia and lipomas can be a feature in adults or adult-onset MERRF. Cerebrospinal fluid (CSF) analysis reveals an elevated protein content. Almost all MERRF patients have a mutation in the mtDNA $tRNA^{lys}$ gene, and the m.8344A>G mutation in the mtDNA gene encoding the lysine amino acid tRNA is responsible for 80–90% of MERRF cases.

Neuropathy, ataxia, and retinitis pigmentosa (NARP) is characterized by moderate diffuse cerebral and cerebellar atrophy and symmetric lesions of the basal ganglia on MRI **(Figs. 481-7 and 481-8)**. A heteroplasmic m.8993T>G mutation in the ATPase 6 subunit gene

TABLE 481-3 Mitochondrial Diseases Due to Mitochondrial DNA (mtDNA) Point Mutations and Large-Scale Rearrangements

DISEASE	PHENOTYPE	MOST FREQUENT mtDNA MUTATIONS	HETEROPLASMIC/ HOMOPLASMIC	MATERNAL
NARP, Leigh's syndrome	Loss of central vision leading to blindness in young adult life	m.1778G>A, m.14484T>C, m.3460G>A	Heteroplasmic	Maternal
MELAS	*M*itochondrial *e*ncephalomyopathy, *l*actic *a*cidosis, and *s*troke-like episodes; may manifest only as diabetes mellitus	Point mutation in $tRNA^{leu}$	Heteroplasmic	Maternal
MERRF	*M*yoclonic *e*pilepsy, *r*agged *r*ed *f*ibers in muscle, ataxia, increased CSF protein, sensorineural deafness, dementia	Point mutation in $tRNA^{lys}$	Heteroplasmic	Maternal
Deafness	Progressive sensorineural deafness, often induced by aminoglycoside antibiotics	m.1555A>G mutation in 12S rRNA	Homoplasmic	Maternal
	Nonsyndromic sensorineural deafness	m.7445A>G mutation in 12S rRNA	Homoplasmic	Maternal
Chronic progressive external ophthalmoplegia (PEO)	Late-onset bilateral ptosis and ophthalmoplegia, proximal muscle weakness, and exercise intolerance	Single deletions or duplications	Heteroplasmic	Mostly sporadic, somatic mutations
Pearson's syndrome	Pancreatic insufficiency, pancytopenia, lactic acidosis	Large deletion	Heteroplasmic	Sporadic, somatic mutations
Kearns-Sayre syndrome (KSS)	External ophthalmoplegia, heart block, retinal pigmentation, ataxia	The 5-kb "common deletion"	Heteroplasmic	Sporadic, somatic mutations

Abbreviations: CSF, cerebrospinal fluid; NARP, neuropathy, ataxia, and retinitis pigmentosa.

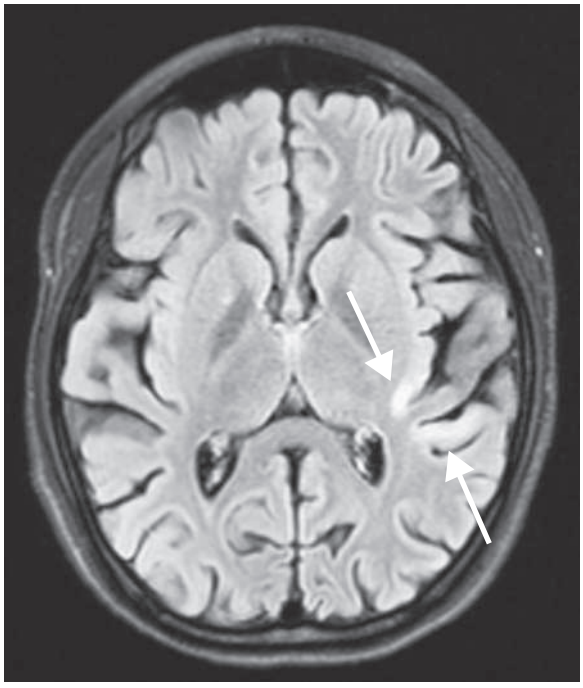

FIGURE 481-6 A 15-year-old girl with MELAS (mitochondrial encephalomyopathy, lactic acidosis, and stroke-like episodes) due to m.A3243G (tRNA$^{Leu(UUR)}$), 85% mutant heteroplasmy, presenting at age 5 with focal motor seizures, ataxia, and short stature, with episodes of acute language and motor dysfunction and progress cognitive impairment. The fluid-attenuated inversion recovery (FLAIR) magnetic resonance image (MRI) shows increased signal intensity (*white arrows*) in the left temporal-parietal region in addition to global mild volume loss (increased extra-axial cerebrospinal fluid spaces).

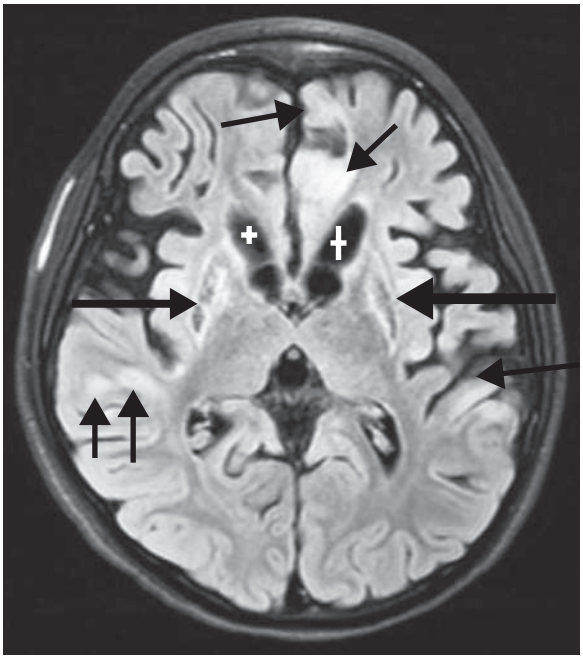

FIGURE 481-8 A 12-year-old boy with Leigh's syndrome due to m.T10191C (ND3 gene, complex I), heteroplasmy percentage not determined, presenting with infantile spasms at 8 months of life. He responded well to adrenocorticotropic hormone (ACTH), and his magnetic resonance imaging (MRI) and development were normal until 30 months when he developed dystonia and progressive medically intractable epilepsy. The fluid-attenuated inversion recover (FLAIR) MRI at 6 years of life shows global atrophy with large extra-axial cerebrospinal fluid spaces, increased signal intensity in the cortex (*thin arrows*), necrotic bilaterally symmetric lesions in the putamina, and enlarged lateral ventricles due to loss of bilateral caudate nuclei volume (*stars*).

has been identified as causative, which underscores the lack of definitive genotype-phenotype correlation in mtDNA diseases. Ragged red fibers are not observed in muscle biopsy. When >95% of mtDNA molecules are mutant, a more severe clinical, neuroradiologic, and neuropathologic picture (Leigh's syndrome) emerges. Not uncommonly, an infant is diagnosed with Leigh's syndrome due to the m.8993T>G mutation and not until several years later will the mother present with symptoms of NARP, a situation that highlights the concept of a higher threshold for lower levels of tissue heteroplasmy.

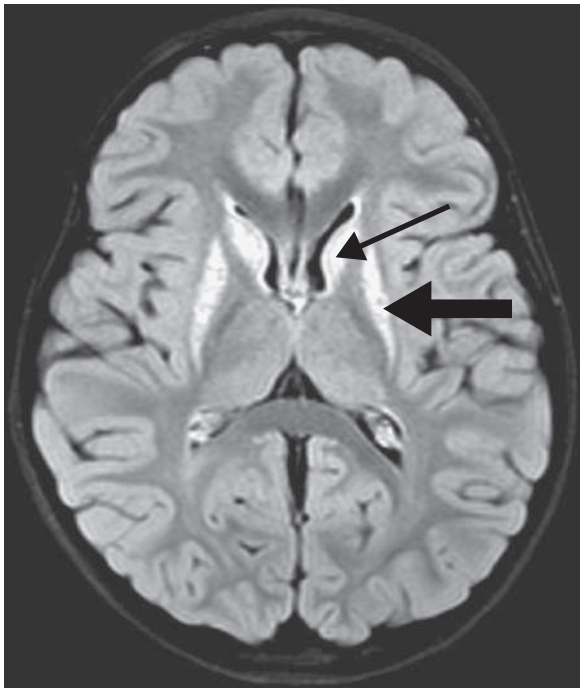

FIGURE 481-7 A 9-year-old girl with Leigh's syndrome due to m.T8993G (ATPase subunit 6), 99% heteroplasmy, presenting at age 14 months with a motor delay and who underwent magnetic resonance imaging (MRI) at 24 months, at which time she had just begun to walk. She has moderate cognitive impairment, arm chorea, and distal leg dystonia. The fluid-attenuated inversion recover (FLAIR) MRI shows symmetric bilateral increased signal in the caudate nuclei (*thin arrow*) and putamen (*thick arrow*); only left-sided lesions indicated with *arrows*.

Point mutations in the mtDNA gene encoding the 12S rRNA (m.A1555G) result in heritable nonsyndromic hearing loss. One such mutation causes heritable ototoxic susceptibility to standard dosing of aminoglycoside antibiotics, which opens a pathway for a simple pharmacogenetic test in the appropriate clinical settings. This is an example of an ecogenetic disorder in that most people with this mutation do not develop any symptoms until exposed to an external agent.

KSS, sporadic progressive external ophthalmoplegia (PEO), and Pearson's syndrome are three disease phenotypes caused by large-scale mtDNA rearrangements including partial deletions or partial duplication. The majority of single large-scale rearrangements of mtDNA are thought to result from clonal amplification of a single sporadic mutational event, occurring in the maternal oocyte during early embryonic development. The typical mtDNA deletion specifically involves 4977 nucleotides, lost at identical breakpoints, and accounting for most KSS and PEO of mtDNA deletion origin. Because germline involvement is rare, most cases are sporadic rather than inherited. KSS is characterized by the triad of onset before age 20, chronic PEO, and pigmentary retinopathy. Cerebellar syndrome, heart block, increased CSF protein content, diabetes mellitus, and short stature are also part of the syndrome. Single deletions/duplication can also result in milder phenotypes such as PEO, characterized by late-onset PEO, proximal myopathy, and exercise intolerance. In both KSS and PEO, diabetes mellitus and hearing loss are frequent accompaniments. Pearson's syndrome is characterized by infantile onset of a sideroblastic anemia accompanied by lactic acidosis and failure to thrive caused in part by exocrine pancreatic insufficiency. If the child survives, the manifestations appear phenotypically similar to those of severe KSS with myopathy, PEO, encephalopathy, and cardiomyopathy. Pearson's syndrome is generally caused by

large-scale sporadic deletion of several mtDNA genes that differ from the common deletion seen in KSS. Typically, the deletion size is larger in Pearson's syndrome, and located with different breakpoints, than in KSS or PEO, but this is not always the case.

Two important dilemmas in classic mtDNA disease have benefited from recent important research insights. The first relates to the greater involvement of neuronal, muscular, renal, hepatic, and pancreatic manifestations in mtDNA disease in these syndromes. This observation has appropriately been mostly attributed to the high energy utilization of the involved tissues and organ systems and, hence, greater dependency on mitochondrial ETC integrity and health. However, because mutations are stochastic events, mitochondrial mutations should occur in any organ during embryogenesis and development. Recently, additional explanations have been suggested based on studies of the common m.3243A>G transition. The proportion of this mutation in peripheral blood cells was shown to decrease exponentially with age. A selective process acting at the stem cell level with a strong bias against the mutated form would have its greatest effect to reduce the mutant mtDNA only in highly proliferating cells, such as those derived from the hematopoietic system. Tissues and organs carrying pathogenic mtDNA mutations and having a lower cell turnover, such as brain, nerve, or retina, would not benefit from this effect and, thus, would be expected to accumulate mutational load and be the most affected. However, age-related clonal hematopoiesis might mitigate some of this disparity.

The other dilemma arises from the observation that only a subset of mtDNA mutations accounts for the majority of the familial mtDNA diseases. The random occurrence of mutations in the mtDNA sequence should yield a more uniform distribution of disease-causing mutations. However, recent studies using the introduction of one severe and one mild point mutation into the female germline of experimental animals demonstrated selective elimination during oogenesis of the severe mutation and selective retention of the milder mutation, with the emergence of mitochondrial disease in offspring after multiple generations. Thus, oogenesis itself can act as an "evolutionary" filter for the most harmful mtDNA disease.

THE INVESTIGATION OF SUSPECTED mtDNA DISEASE

The clinical presentations of classic syndromes, groupings of disease manifestations in multiple organ systems, or unexplained isolated presentations of one of the disease features of a classic mtDNA syndrome should prompt a systematic clinical investigation as outlined in Fig. 481-9. However, some tests are not universally available or are costly, and WGS is not only more readily available but also less costly than the cost of obtaining tissue such as muscle for biochemical and pathologic evaluation. In many medical centers, a history and exam suggestive of an mtDNA disorder will result in a molecular genetic evaluation before tissue evaluation. Indeed, mitochondrial disease should be considered in the differential diagnosis of any progressive multisystem disorder. Despite the centrality of disruptive oxidative phosphorylation, an elevated blood lactate level is neither specific nor sensitive, because there are many causes of blood lactic acidosis and many patients with mtDNA defects presenting at any age may have normal blood lactate levels. An elevated CSF lactate is a more specific test for mitochondrial disease if there is central nervous system involvement but is still not diagnostic. The serum creatine kinase may be elevated but is often normal, even in the presence of a proximal myopathy. Recently, testing for elevated levels of growth differentiating factor 15 (GDF15) has shown a high degree of sensitivity and specificity in those with a mitochondrial myopathy, but the degree of elevation for an individual patient reflects the severity of the illness and does not seem to be a sensitive marker of disease activity. Urinary organic acids (specifically TCA cycle intermediates) and amino acids (alanine, proline) may also be abnormal, reflecting metabolic as well as kidney proximal tubule dysfunction. Every patient with seizures, episodes of confusion or atypical behavioral changes, or cognitive decline should have an electroencephalogram. A brain computed tomography

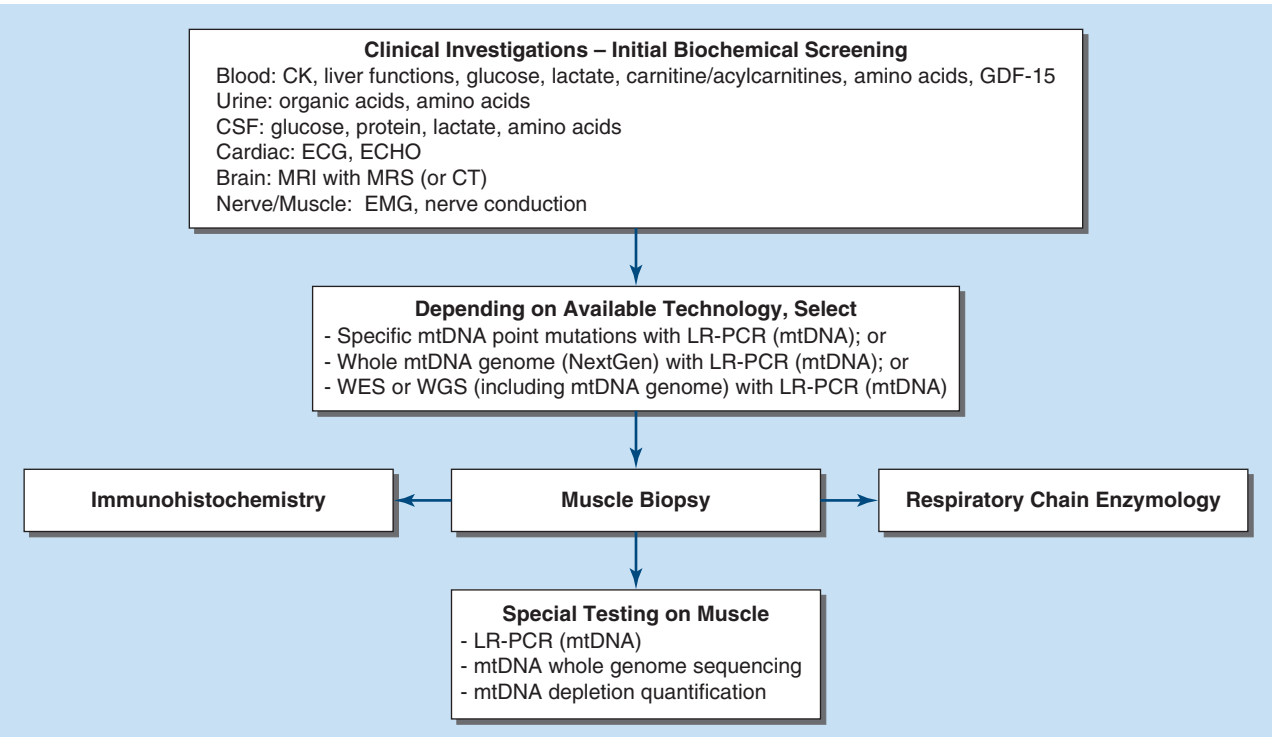

FIGURE 481-9 Clinical and laboratory investigation of a suspected mitochondrial DNA (mtDNA) disorder. Following history including the family history and examination, a screening biochemical evaluation and other testing is selectively warranted, and if the evaluation suggests a mitochondrial disease, further genetic evaluation is warranted. The specific molecular genetic testing depends on available technology and costs, with clinical acumen essential for determining the extent of testing. The use of muscle investigation can support the genetic testing. Of note, mtDNA deletion disorders at times require LR-PCR on skeletal muscle tissue to find the deletion. CSF, cerebrospinal fluid; CT, computed tomography; ECG, electrocardiogram; ECHO, echocardiography; EEG, electroencephalogram; EMG, electromyogram; LHON, Leber's hereditary optic neuropathy; LR-PCR, long-range polymerase chain reaction; MELAS, mitochondrial encephalomyopathy, lactic acidosis, and stoke-like episodes; MERRF, myoclonic epilepsy with ragged red fibers; MRI, magnetic resonance imaging; MRS, magnetic resonance spectroscopy, PCR, polymerase chain reaction; RFLP, restriction fragment length polymorphism; WES, whole exome sequencing; WGS, whole genome sequencing.

(CT) scan may show calcified basal ganglia or bilateral hypodense regions with cortical atrophy. MRI is indicated in patients with brainstem signs or stroke-like episodes.

For an increasing number of mitochondrial diseases, it is possible to obtain an accurate diagnosis with a simple molecular genetic screen. For examples, 95% of patients with LHON harbor one of the three mtDNA point mutations (m.11778A>G, m.A3460A>G, or m.14484T>C). These patients have very high levels of mutated mtDNA in peripheral blood cells, and therefore, it is appropriate to send a blood sample for molecular genetic analysis by polymerase chain reaction (PCR) or restriction fragment length polymorphism (RFLP). The same is true for most MERRF patients who harbor a point mutation in the lysine tRNA gene at position 8344. In contrast, patients with the m.3243A>G MELAS mutation often have low levels of mutated mtDNA in blood. If clinical suspicion is strong enough to warrant peripheral blood testing, then patients with a negative result should have testing repeated using a saliva sample or be investigated further by performing a skeletal muscle biopsy to obtain mtDNA from a relatively nonreplicative tissue.

Muscle biopsy histochemical analysis had been the historical cornerstone for investigation of patients with suspected mitochondrial disease. Histochemical analysis may show subsarcolemmal accumulation of mitochondria with the appearance of ragged red fibers, especially in those with mtDNA mutations affecting the tRNA and rRNA genes. Electron microscopy might show abnormal mitochondria with paracrystalline inclusions. Muscle histochemistry may show COX-deficient fibers, which indicate mitochondrial dysfunction (Fig. 481-5). Respiratory chain complex assays may also show reduced enzyme function. If enzymatic or polarographic data are used to aid in the confirmation of diagnosis, a standard method of analysis should be employed. Either of these two abnormalities, within the exact context of established peer-reviewed criteria, may confirm the presence of a mitochondrial disease, to be followed by an in-depth molecular genetic analysis. In most major centers, genetic testing has become the primary means of obtaining a definitive diagnosis, using muscle pathology and biochemistry to assist with interpretation of inconclusive genetic results. It is proposed to use of the term *primary mitochondrial disease* only when a pathogenic mutation is identified that matches the clinical phenotype.

Recent evidence has provided important insights into the importance of nuclear-mtDNA genomic cross-talk and has provided a descriptive framework for classifying and understanding disorders that emanate from perturbations in this cross-talk. Although not strictly considered as mtDNA genetic disorders, manifestations do overlap those highlighted above **(Fig. 481-10)**.

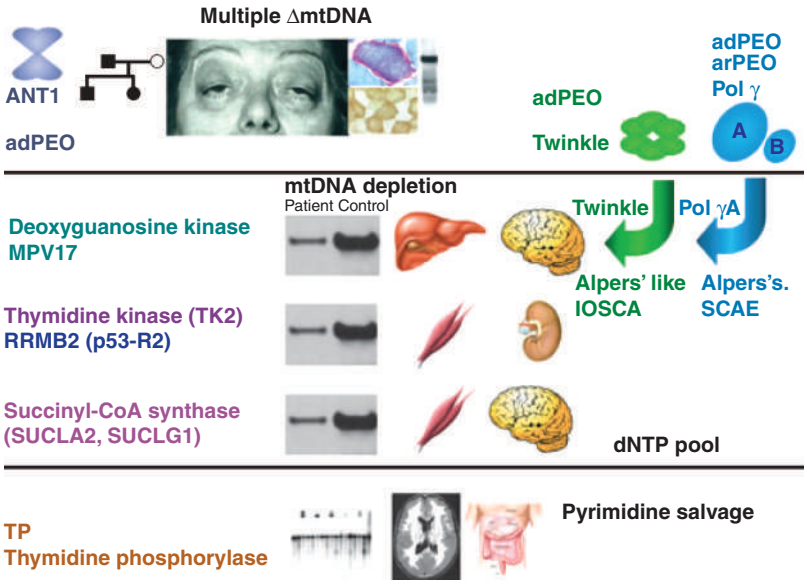

FIGURE 481-10 Disorders associated with perturbations in nuclear-mitochondrial genomic cross-talk. Clinical features and genes associated with multiple mitochondrial DNA (mtDNA) deletions, mtDNA depletion, and mitochondrial neurogastrointestinal encephalomyopathy syndromes. adPEO, autosomal dominant progressive external ophthalmoplegia; ANT, adenine nucleotide translocators; arPEO, autosomal recessive progressive external ophthalmoplegia; IOSCA, infantile-onset spinocerebellar ataxia; SCAE, spinocerebellar ataxia and epilepsy. *(Reproduced with permission from A Spinazzola, M Zeviani: Disorders from perturbations of nuclear-mitochondrial intergenomic cross-talk. J Intern Med 265:174, 2009.)*

IMPACT OF HOMOPLASMIC SEQUENCE VARIATION ON HERITABLE TRAITS AND DISEASE

The relationship among the degree of heteroplasmy, tissue distribution of the mutant mtDNA, and disease phenotype simplifies inference of a clear causative relationship between heteroplasmic mutation and disease. With the exception of certain mutations (e.g., those causing most cases of LHON), drift to homoplasmy of such mutations would be precluded normally by the severity of impaired oxidative phosphorylation and the consequent reduction in reproductive fitness. Therefore, sequence variants that have reached homoplasmy should be neutral in terms of human evolution and, hence, useful for tracing phylogeny, demography, and migration, as described above. Thus, novel homoplasmic variants are seldom pathogenic. One important exception is in the case of one or more of the homoplasmic population-level variants, which designate the mtDNA haplogroup J, and the interaction with the mtDNA mutations causing LHON. Reduced disease predilection suggests that one or more of the ancient sequence variants designating mtDNA haplogroup J appear to attenuate predisposition to degenerative disease, in the presence of other risk factors. Whether or not additional epistatic interactions between population-level mtDNA haplotypes and common health conditions will be found remains to be determined. If such influences do exist, then they are more likely to be relevant to health conditions in the postreproductive age groups, wherein evolutionary filters would not have had the opportunity to censor deleterious effects and interactions and wherein the effects of oxidative stress during aging or with poor diet or lack of exercise may play a role. Although much has been written about the possible associations between population-level common mtDNA variants and human health and disease phenotypes or adaptation to different environmental influences (e.g., climate), clinical implications have not been forthcoming.

Many studies that purport to show such associations with phenotypes such as longevity, athletic performance, and metabolic and neurodegenerative disease are limited by small sample sizes, possible genotyping inaccuracies, and the possibility of population stratification or ethnic ancestry bias. Because mtDNA haplogroups are so prominently partitioned along phylogeographic lines, it is difficult to exclude the possibility that a haplogroup for which an association has been reported is simply a marker for otherwise unappreciated population heterogeneity, wherein a nongenetic (societal or environmental) difference among the populations marked by the mtDNA haplogroup differences is actually causally related to the disease of interest. The experimental difficulty in generating cellular or animal models to test the functional influence of homoplasmic sequence variants (as a result of mtDNA polyploidy) further compounds the challenge. The most likely formulation is that the risk conferred by different mtDNA haplogroup-defining homoplasmic mutations for common diseases depends on the concomitant nuclear genomic background, together with environmental influences. Progress in minimizing potentially misleading associations in mtDNA heritable trait and disease studies should include ensuring adequate sample size taken from a large sample recruitment base, using carefully matched controls and population structure determination, and performing analysis that takes into account epistatic interactions with other genomic loci and environmental factors.

IMPACT OF ACQUIRED SOMATIC mtDNA MUTATION ON HUMAN HEALTH AND DISEASE

Studies on aging humans and animals have shown a potentially important correlation of age with the accumulation of heterogeneous mtDNA mutations, especially in organ systems that undergo the most prominent age-related degenerative tissue phenotype. Sequencing of PCR-amplified single mtDNA molecules has demonstrated an average of two-to-three-point mutations per molecule in elderly subjects when compared with younger ones. Point mutations observed include those responsible for known heritable heteroplasmic mtDNA disorders, such as the m.3344A>G and m.3243A>G mutations responsible for the MERRF and MELAS syndromes, respectively. However, the cumulative burden of these acquired somatic point mutations with age was observed to remain well below the threshold expected for phenotypic expression (<2%). Point mutations at other sites not normally involved in inherited mtDNA disorders have also been shown to accumulate to much higher levels in some tissues of elderly individuals, with the description of tissue-specific "hot spots" for acquired somatic mtDNA point mutations. Likewise, an age-associated and tissue-specific accumulation of mtDNA deletions has been observed, including deletions involved in known heritable mtDNA disorders, as well as others. The accumulation of functional mtDNA deletions in a given tissue is expected to be associated with mitochondrial dysfunction, as reflected in an age-associated patchy and reduced COX activity on histochemical staining, especially in skeletal and cardiac muscle and brain. A particularly well-studied and potentially important example is the accumulation of mtDNA deletions and COX deficiency observed in neurons of the substantia nigra in Parkinson's disease patients.

The progressive accumulation of ROS has been proposed as the key factor connecting mtDNA mutations with aging and age-related disease pathogenesis **(Fig. 481-11)**. As noted above, ROS are a by-product of normal oxidative phosphorylation and are removed by detoxifying antioxidants into less harmful moieties; however, environmental factors or mutations that result in exaggerated production of ROS or impaired removal result in ROS accumulation and subsequent cellular injury. One of the main targets for ROS-mediated injury is DNA, and mtDNA is particularly vulnerable because of its proximity to the origin of free radical production, the lack of protective histones, and less efficient injury repair systems compared with nuclear DNA. In turn, accumulation of mtDNA mutations results in inefficient oxidative phosphorylation, with the potential for excessive production of ROS, generating a "vicious cycle" of cumulative mtDNA damage. Indeed, measurement of the oxidative stress biomarker 8-hydroxy-2-deoxyguanosine has been used to measure age-dependent increases in mtDNA oxidative damage at a rate exceeding that of nuclear DNA. It should be noted that mtDNA mutations can potentially occur in postmitotic cells as well, because mtDNA replication is not synchronized with the cell cycle. Two other proposed links between mtDNA mutation and aging, besides ROS-mediated tissue injury, are the perturbations in efficiency of oxidative phosphorylation with disturbed cellular aerobic function and perturbations in apoptotic pathways, whose execution steps involve mitochondrial activity.

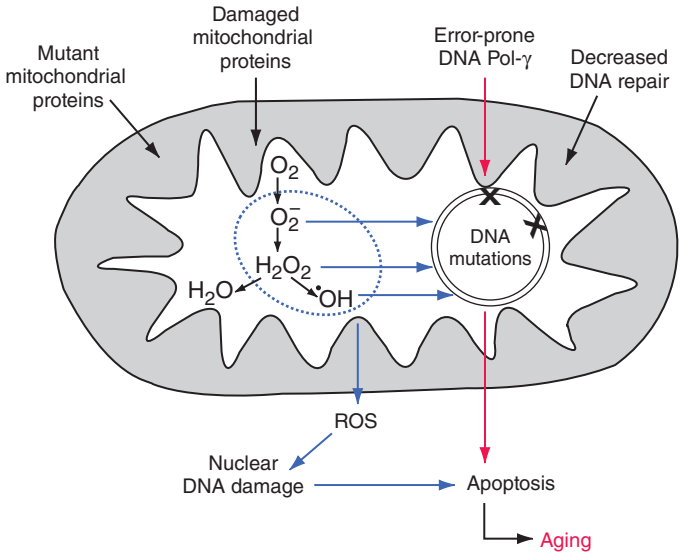

FIGURE 481-11 Multiple pathways of mitochondrial DNA (mtDNA) damage and aging. Multiple factors may impinge on the integrity of mitochondria that lead to loss of cell function, apoptosis, and aging. The classic pathway is indicated with *blue arrows*; the generation of reactive oxygen species (ROS; superoxide anion, hydrogen peroxide, and hydroxyl radicals), as a by-product of mitochondrial oxidative phosphorylation, results in damage to mitochondrial macromolecules, including the mtDNA, with the latter leading to deleterious mutations. When these factors damage the mitochondrial energy-generating apparatus beyond a functional threshold, proteins are released from the mitochondria that activate the caspase pathway, leading to apoptosis, cell death, and aging. *(Reproduced with permission from L Loeb et al: The mitochondrial theory of aging and its relationship to reactive oxygen species damage and somatic mt DNA mutations. Proc Natl Acad Sci USA 102 (52):18769-18770, 2005.)*

Genetic intervention studies in animal models have sought to clarify the potential causative relationship between acquired somatic mtDNA mutation and the aging phenotype and the role of ROS in particular. Replication of the mitochondrial genome is mediated by the activity of the nuclear-encoded *POLG*. A transgenic homozygous mouse knock-in mutation of this gene renders the polymerase enzyme deficient in proofreading and results in a threefold to fivefold increase in mtDNA mutation rate. Such mice develop a premature aging phenotype, which includes subcutaneous lipoatrophy, alopecia, kyphonia, and weight loss with premature death. Although the finding of increased mtDNA mutation and mitochondrial dysfunction with age has been solidly established, the causative role and specific contribution of mitochondrial ROS to aging and age-related disease in humans have yet to be proved. Similarly, although many tumors display higher levels of heterogeneous mtDNA mutations, a causal relationship to tumorigenesis has not been proved.

Besides the age-dependent acquired accumulation in somatic cells of heterogeneous point mutations and deletions, a quite different effect of nonheritable and acquired mtDNA mutations has been described affecting tissue stem cells. In particular, disease phenotypes attributed to acquired mtDNA mutation have been observed in sporadic and apparently nonfamilial cases involving a single individual or even tissue, usually skeletal muscle. The presentation consists of decreased exercise tolerance and myalgias, sometimes progressing to rhabdomyolysis. As in the case of the sporadic, heteroplasmic, large-scale deletion, classic syndromes of chronic PEO, Pearson's syndrome, and KSS, the absence of a maternal inheritance pattern and the finding of limited tissue distribution suggest a molecular pathogenic mechanism emanating from mutations arising de novo in muscle stem cells after germline differentiation (somatic mutations that are not sporadic and occur in tissue-specific stem cells during fetal development or in the postnatal maintenance or postinjury repair stage). Such mutations would be expected to be propagated only within the progeny of that stem cell and affect a singular tissue within a given individual, without evidence of heritability.

PROSPECTS FOR CLINICAL MANAGEMENT OF mtDNA DISEASE

TREATMENT OF mtDNA DISORDERS

No specific curative treatment for mtDNA disorders is currently available; therefore, the management of mitochondrial disease is largely supportive. Management issues may include early diagnosis and medical management of epilepsy, gastrointestinal dysfunction, weakness, diabetes mellitus, cardiac dysrhythmia, hearing loss, endocrinopathy, ptosis, and cataracts. Rapid identification of subclinical seizures, which may present with focal neurologic signs or even mild mental status changes, is critical in the management of MELAS and other mtDNA disorders associated with epilepsy. The value of aggressive symptom management cannot be understated. Less specific interventions in the case of other disorders involve combined treatment strategies including dietary intervention and removal of toxic

metabolites. Cofactors and vitamin supplements are widely used in the treatment of diseases of mitochondrial oxidative phosphorylation, although there is little evidence, apart from anecdotal reports, to support their use. This includes administration of artificial electron acceptors, including vitamin K_3, vitamin C, and ubiquinone (CoQ_{10}); administration of cofactors (coenzymes) including riboflavin, carnitine, and creatine; and use of oxygen radical scavengers, such as vitamin E, copper, selenium, ubiquinone, and idebenone. Drugs that could interfere with mitochondrial function, such as the anesthetic agent propofol, barbiturates, and high doses of valproate, can generally be avoided if possible. The use of valproate in patients with pathogenic mutations in *POLG* and possibly other mutations affecting mtDNA stability and replication is especially contraindicated. Supplementation with the nitric oxide synthase substrate L-arginine and, more recently, L-citrulline has been advocated as a vasodilator treatment during stroke-like episodes as well as for chronic management in patients with MELAS. Open-label studies demonstrate that levoarginine and levocitrulline may be helpful in reducing the stroke-like symptoms in MELAS but may have serious side effects. As CSF folate deficiency has been reported in some cases of mitochondrial disease, this can be treated with oral folinic acid.

The physician should also be familiar with environmental interactions, such as the strong and consistent association between visual loss in LHON and smoking or ethanol consumption. A clinical penetrance of 93% was found in men who smoked. Asymptomatic carriers of an LHON mtDNA mutation should, therefore, be strongly advised not to smoke and to moderate their alcohol intake. Although not a cure, these interventions might stave off the devastating clinical manifestations of the LHON mutation. Another example is strict avoidance of aminoglycosides in the familial syndrome of ototoxic susceptibility to aminoglycosides in the presence of the mtDNA m.1555A>G mutation of the 12SrRNA encoding gene.

Clinical trials using novel agents have been initiated and launched. These agents include elamipretide (Stealth Biotherapeutics) and KL-1333 (Abliva). In an open-label study of α-tocotrienol used to treat 10 children with Leigh's syndrome, there were improvements in the primary endpoints, including the Newcastle Pediatric Mitochondrial Diseases Scale, the Gross Motor Function Measure, and the PedsQL Neuromuscular Module.

GENETIC COUNSELING, PRENATAL DIAGNOSIS, AND PGD IN mtDNA DISORDERS

The provision of accurate genetic counseling and reproductive options to families with mtDNA mutations is challenging due to the unique genetic features of mtDNA inheritance that distinguish it from Mendelian genetics. mtDNA defects are transmitted by maternal inheritance. mtDNA de novo mutations are often large deletions, affect one family member, and usually represent no significant risk to other members of the family. In contrast, mtDNA point mutations or duplications can be transmitted maternally. Accordingly, the father of an affected individual has no risk of harboring the disease-causing mutation, and a male cannot transmit the mtDNA mutation to his offspring. In contrast, the mother of an affected individual usually harbors the same mutation but may be completely asymptomatic. This wide phenotypic variability is primarily related to the phenomena of heteroplasmy and the mutation load carried by different members of the same family. Consequently, a symptomatic or asymptomatic female harboring a disease-causing mutation in a heteroplasmic state will transmit to her offspring variable amounts of the mutant mtDNA molecules. The offspring will be symptomatic or asymptomatic primarily according to the mutant load transmitted via the oocyte and, to some extent, subsequent mitotic segregation during development. Interactions with the mtDNA haplotype background or nuclear human genome (as in the case of LHON) serve as an additional important determinant of disease penetrance. Because the severity of the disease phenotype associated with the heteroplasmic mutation load is a function of the stochastic differential segregation and copy number of mutant mtDNA during the oogenesis bottleneck and, subsequently, following tissue and organ development in the offspring, it is rarely predictable with any degree of accuracy. For this reason, prenatal diagnosis (PND) and PGD techniques that have evolved into integral and well-accepted standards of practice are severely hampered in the case of mtDNA-related diseases.

The value of PND and PGD is limited, partly due to the absence of data on the rules that govern the segregation of wild-type and mutant mtDNA species (heteroplasmy) among tissue in the developing embryo. Three factors are required to ensure the reliability of PND and PGD: (1) a close correlation between the mutant load and the disease severity, (2) a uniform distribution of mutant load among tissues, and (3) no major change in mutant load with time. These criteria are suggested to be fulfilled for the NARP m.8993T>G mutation but do not seem to apply to other mtDNA disorders. In fact, the level of mutant mtDNA in a chorionic villous or amniotic fluid sample may be very different from the level in the fetus, and it would be difficult to deduce whether the mutational load in the prenatal samples provides clinically useful information regarding the postnatal and adult state.

PREVENTION OF MITOCHONDRIAL DISEASE INHERITANCE BY ASSISTED REPRODUCTIVE TECHNOLOGIES

Because the treatment options for patients with mitochondrial disease are rather limited, with no current U.S. Food and Drug Administration (FDA)–approved therapies for established mitochondrial DNA disease, preventive interventions that eliminate the likelihood of transmission of affected mtDNA into offspring are desirable. The poor reliability of prenatal and preimplantation approaches in predicting mitochondrial DNA disease has resulted in the search for alternative preventive approaches. The common purpose underlying various emerging approaches is to reduce mutant heteroplasmy levels to a level below a pathogenic threshold. This is based on the observed relationship between heteroplasmy and disease inheritance patterns, which indicates that even a small increase in copy number of nonmutant mtDNA molecules in the fertilized egg can exceed the threshold required to ameliorate serious clinical disease. Use of gene editing, with clustered regularly interspaced short palindromic repeats (CRISPR) or mitochondrial-targeted TALEN (transcription activator-like effector nucleases) technology, and others, for example, to shift the heteroplasmy load in affected tissues will require future development of corrective gene delivery techniques. Likewise, induced pluripotent cell technology has not yet met with widespread success in the preclinical research setting. This has prompted the application of mitochondrial replacement therapy (MRT) approaches **(Fig. 481-12)**. These approaches substitute in vitro the entire oocyte or zygote complement of mitochondria, together with their mtDNA from the carrier mother, with the unaffected complement of mitochondria and their unaffected mtDNA from a donor woman. This can be accomplished either by removing and transferring the carrier mother's spindle with her nuclear DNA into the unfertilized oocyte of the donor or, alternatively, by transferring the pronucleus from the fertilized oocyte of the carrier mother to the unfertilized donor oocyte from which the pronucleus has been removed. These approaches provide a "bulk" substitution and hence do not target the specific mtDNA mutation, and they are potentially applicable to a wide variety of mtDNA disorders. This is a form of germline genetic therapy, and therefore, it projects onto future generations in the case of a female offspring. Accordingly, ethical and regulatory bodies have appropriately weighed in on the societal implications of such approaches and have been tentatively supportive of human clinical investigation for situations that would prevent great suffering and when the clinical need is clear and unambiguous, subject to specified conditions and principles and subject to ethical scrutiny. Several such studies have been initiated, and careful examination and follow-up are needed to determine developmental and longer-term health and fertility of children who have undergone genetic manipulation at the earliest stages of human development and whose genomes comprise

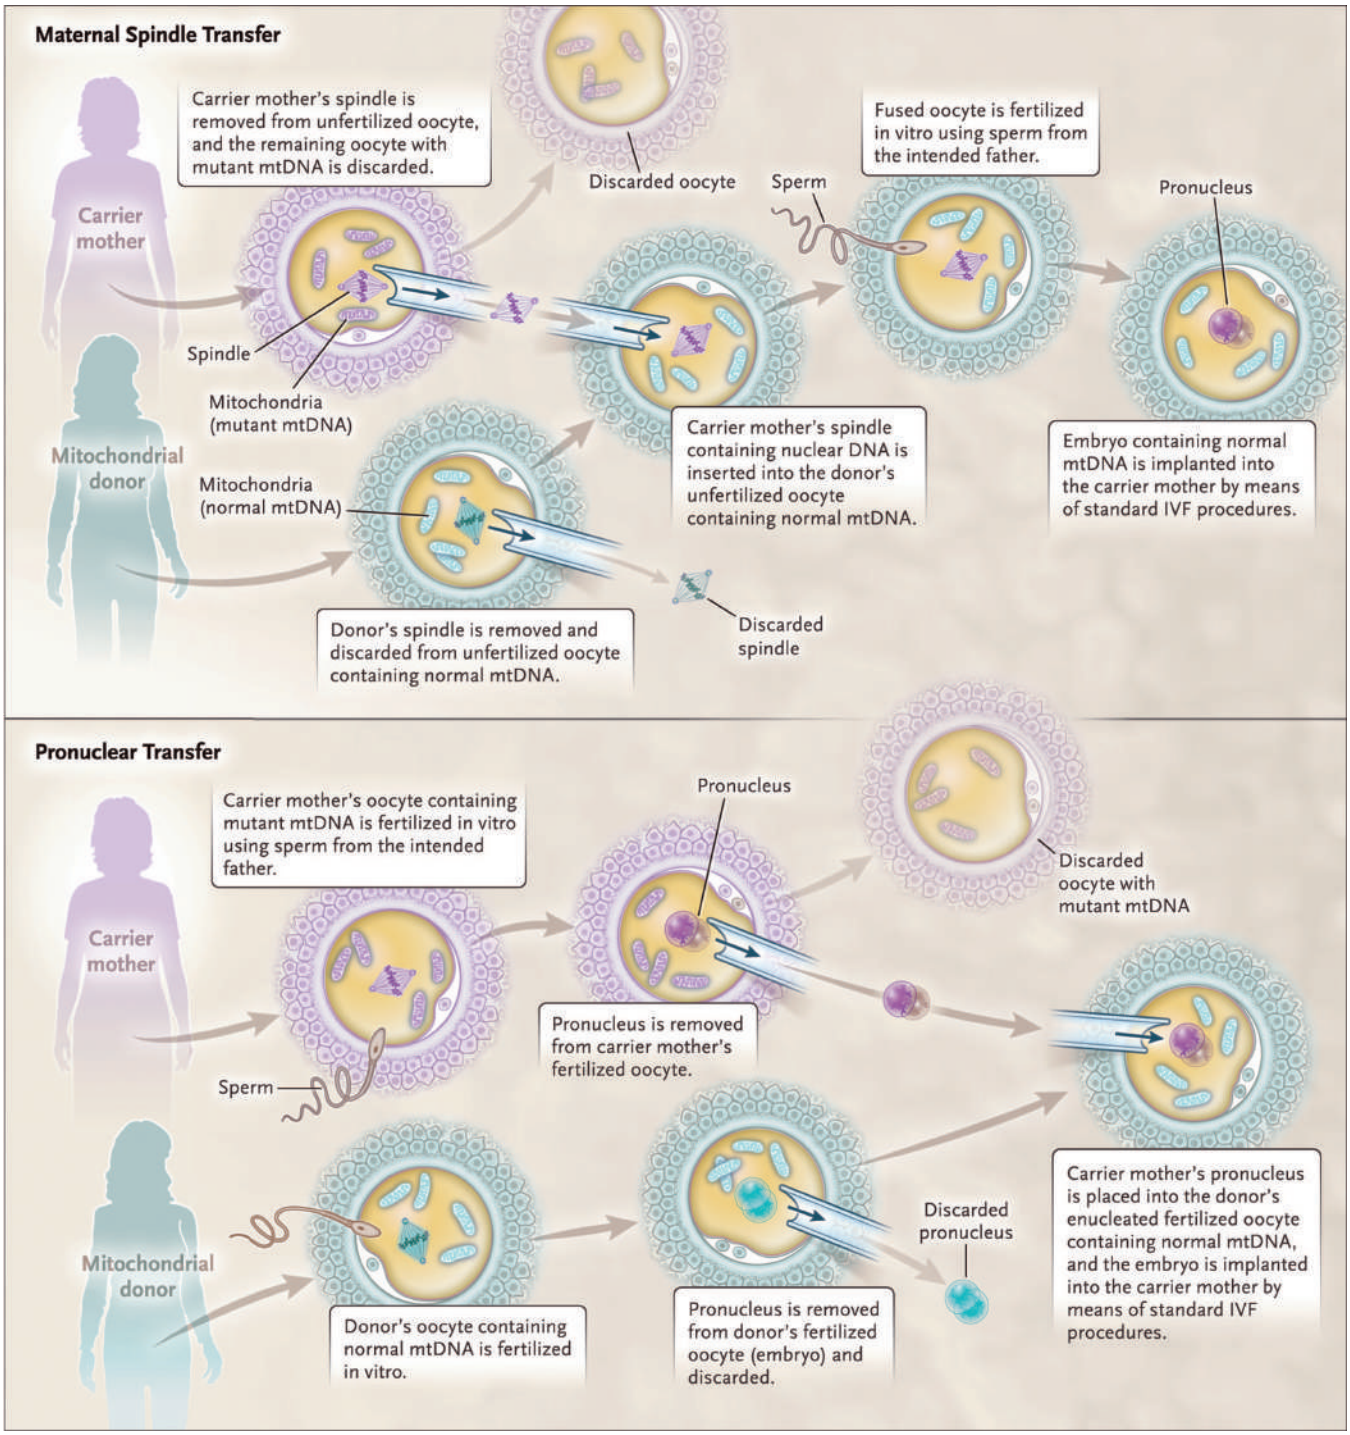

FIGURE 481-12 Mitochondrial replacement techniques—maternal spindle transfer and pronuclear transfer. In both procedures, some mutant mtDNA, estimated at 1–2%, might be carried over together with the spindle or pronucleus, but the levels are low enough to avoid disease risk. IVF, in vitro fertilization. *(From MJ Falk et al: Mitochondrial replacement techniques—Implications for the clinical community. N Engl J Med 374:1103, 2016. Copyright © 2016, Massachusetts Medical Society. Reprinted with permission from Massachusetts Medical Society.)*

separate maternal origins of nuclear and mtDNA genomes. It has been recommended that such studies be limited to male offspring, who cannot then transmit the donor mtDNA to future generations, until such time as the health, ethical, and societal issues are well understood and live up to the exciting promise of reducing the burden of clinical mtDNA disease in the future.

482 Telomere Disease

Rodrigo T. Calado, Neal S. Young

DEFINITION

In telomere diseases (*telomeropathies* or *telomere biology disorders*), organ dysfunction is caused by excessive loss of the ends of chromosomes, a process termed *accelerated telomere attrition*, which results from germline mutations in genes involved in telomere maintenance. Inadequate repair or insufficient protection of telomeres and their resulting accelerated erosion induces cell death, deficient cell proliferation, and chromosome instability; affected tissues show defective regeneration, fibrosis or replacement by fat, and a proclivity for cancer. Bone marrow, lungs, liver, and skin especially suffer accelerated telomere loss and dysfunction. Telomeres shorten in humans at an average of 50 base pairs/year as measured in peripheral blood leukocytes. However, normal aging is not associated with developing manifestations of a telomere disease. In normal aging, sufficient stem cell number and function are maintained to sustain vital processes. Telomere length associates with life span in the general population. While shorter leukocyte telomeres correlate with increased mortality risk, especially from nonmalignant causes, telomere loss is not established as the cause of physiologic aging. Long telomeres due to rare inherited mutations do associate with clonal hematopoiesis and predisposition to cancer.

DISEASE MECHANISM

Telomeres, the physical termini of linear chromosomes, are repeated hexanucleotide sequences physically associated with specific proteins. Telomeres protect the chromosome ends against recognition as damaged or infectious DNA by the DNA repair machinery **(Fig. 482-1)**. During mitosis, the DNA polymerase employs an RNA oligonucleotide with a 3′ hydroxyl group to prime replication. The primer dissociates as the DNA polymerase advances along the template strand, and a gap is left at the ends of linear DNA molecules: the newly synthesized DNA strand is necessarily shorter than the original template—the "end-replication problem." Chromosome erosion is thus inevitable with mitotic cell division, but the repetitive structure buffers the loss of genetic information. In human cells, telomeres consist of hundreds to thousands of TTAGGG tandem repeats in the leading and CCCTAA in the lagging DNA strand. At birth, telomeres are long, but they inexorably shorten with aging (Fig. 482-1). In an individual cell, critically short telomere length triggers the p53 pathway, leading to proliferative arrest and apoptosis. Telomere loss is the molecular basis for the "Hayflick phenomenon," the limit to cell division. If a cell overcomes proliferation arrest, extremely short telomeres engage the DNA damage repair machinery, and chromosome end-to-end fusions, chromosome breaks, aneuploidy, and chromosome instability may occur. In addition to the telomere repeated sequences, a group of specialized proteins, collectively termed *shelterins*, directly bind to or indirectly associate with telomeres, assisting in the organization of the telomere tertiary structure and inhibiting the activity of DNA damage response proteins (Fig. 482-1).

To escape telomere attrition, cells with high proliferative demand, including embryonic and adult stem cells, lymphocytes, and most cancer cells, preserve telomere length by the synthesis of telomeric repeats. Telomerase adds GTTAGG hexanucleotides to the 5′ end of the leading DNA strand using a reverse transcriptase enzyme (TERT), and TERC, its RNA template (Fig. 482-1). The telomerase holoenzyme complex comprises two copies of TERT, TERC, and dyskerin and associated proteins. TERC binds to TERT and serves as the RNA template for its function as a reverse transcriptase. Dyskerin, encoded by *DKC1*, stabilizes the complex, and TCAB1, encoded by the *WRAP53* gene, aids telomerase trafficking to the Cajal bodies, nuclear structures for ribonucleoprotein processing where telomerase associates with telomeres for elongation. Telomerase expression is tightly regulated: MYC, sex hormones, and many additional factors stimulate *TERT* transcription. In mature cells, the *TERT* gene is highly repressed. In addition, shelterin proteins (such as POT1) regulate telomerase function and processivity (the ability to consecutively synthesize telomeric repeats in a single interaction with the telomere), modulating its catalytic activity on telomeres. Other proteins also are necessary for telomere length maintenance. RTEL1, a DNA helicase, dismantles t-loops and resolves g-quadruplexes, ensuring adequate telomere elongation.

Pathologic accelerated telomere attrition has a genetic origin. Germline loss-of-function mutations in genes involved in telomere biology impair telomere length repair, increasing the rate of telomere erosion in highly proliferative cells, reaching critically short lengths fast. The consequences are limited cell proliferation and impaired tissue regeneration. Some organs appear to be particularly susceptible to telomere erosion. Billions of blood cells are produced daily **(Chap. 101)**, and telomere attrition curtails cell proliferation, producing a hypocellular marrow and low blood counts. Lymphocytes also have high proliferative capacity and activate telomerase, but when telomeres are very short, B and T cells have an aged, more exhausted, and proinflammatory profile, and immunodeficiency may occur. The liver is also an organ with high proliferative capacity, and telomere dysfunction impairs hepatic regeneration after injury, with a variety of pathologic consequences. The lung alveolar epithelium is in contact with exogenous toxins that stimulate regeneration, and telomere loss may cooperate with other events to hinder these physiologic responses. However, it remains unclear why other regenerative tissues, like the intestine, are less affected by telomere dysfunction, or the mechanism by which telomere loss provokes a fibrotic response in the lungs (pulmonary fibrosis), an adipose response in the marrow (aplastic anemia), and both in the liver (hepatic steatosis and cirrhosis). These phenotypes appear to result from a combination of genetic, epigenetic, and environmental determinants.

When telomeres are critically short, the DNA damage response machinery may be recruited, mistaking telomeres for damaged or infectious DNA and forcing inappropriate repair. Activation of this pathway may cause chromosome instability due to end-to-end fusion of chromosomes or translocations; these alterations generate genomic instability and potentially malignant clones of cells. That telomere dysfunction increases the risk of cancer development has been demonstrated in murine models of telomerase deficiency, and patients with telomere diseases are prone to develop malignant neoplasms, particularly acute myeloid leukemia and head and neck squamous cell carcinomas.

GENETICS

The pattern of inheritance may be X-linked, autosomal recessive, and autosomal dominant, and penetrance is highly variable, even within a pedigree. The genetic architecture may be complex, and affected patients may inherit pathogenic loss-of-function variants in more than one gene involved in the same telomere biology pathway. At least 17 genes have been implicated in the etiology of telomeropathies **(Table 482-1)**.

CLINICAL MANIFESTATIONS

Presentation of telomere disease in the clinic is highly variable—in the tissues affected, in the severity of organ dysfunction, and in patterns of

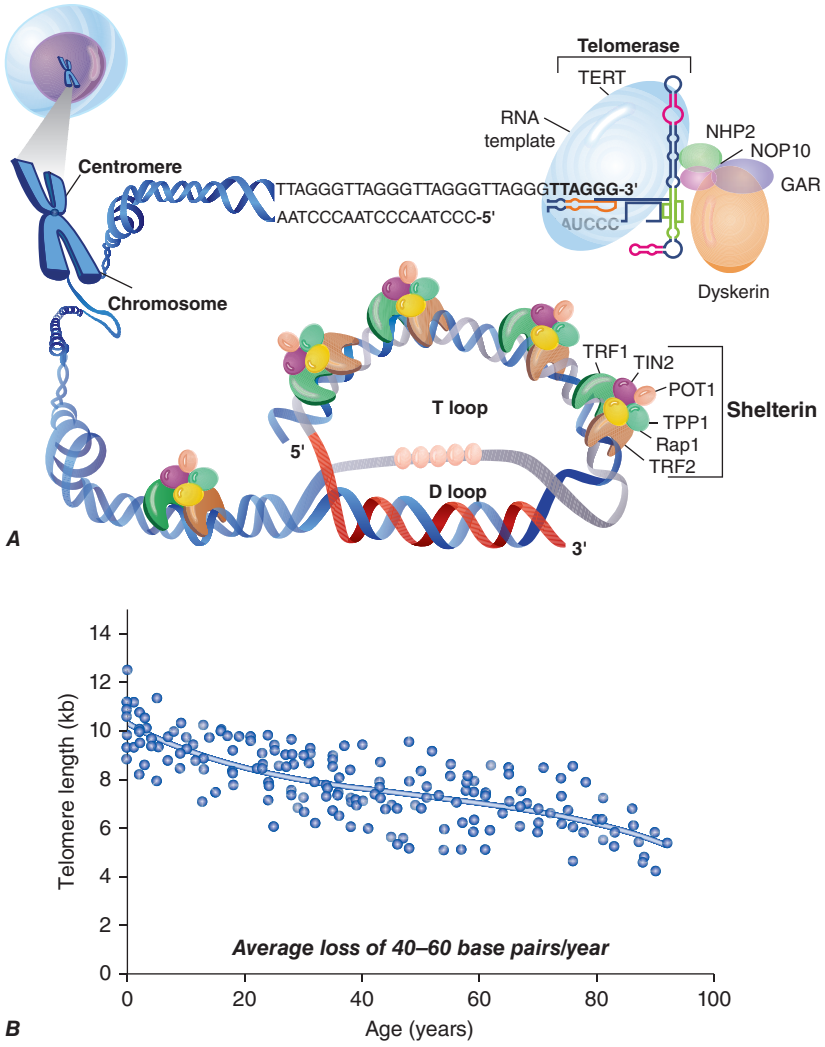

FIGURE 482-1 Telomeres and telomerase. ***A.*** Telomeres are ribonucleoprotein structures located at the termini of linear chromosomes inside the cell nucleus composed of hundreds of tandem hexameric DNA repeats. A group of proteins bind directly or indirectly to telomere sequences in order to provide protection to the structure and are collectively termed *shelterin* or *telosome* (TRF1, TRF2, TIN2, POT1, TPP1, and RAP1). As the 3′ end of the leading strand forms a single-stranded overhang, it folds back and invades the telomeric double helix, forming a lariat termed *T loop*. The telomerase complex is composed of the enzyme telomerase reverse transcriptase (TERT), its RNA component (TERC), the protein dyskerin, and associated proteins (NHP2, NOP10, and GAR). This enzymatic complex elongates telomeres by adding GTTAGG hexameric repeats to the 3′ end of the telomeric leading strand, using a sequence in TERC as the template. ***B.*** The average telomere length in human leukocytes varies: it is longer at birth (10–11 kilobases) and progressively shortens with aging (6–7 kilobases at age 90 years) at an average loss of 40–60 base pairs/year. However, there is significant variability in telomere length in each given age.

disease within a pedigree and between families with similar mutations. In a same family, one individual may be severely affected, but close relatives carrying the same mutation may be asymptomatic and with normal laboratory results. Asymptomatic carriers may have subclinical organ dysfunction, which may be detected by directed or specialized testing (reduced forced vital capacity on pulmonary function test, hypocellular bone marrow at biopsy, hepatic steatosis on ultrasound). Somatic genetic rescue is a rare spontaneous genetic event in a somatic cell, conferring a selective advantage and annulling the effect of the original pathogenic germline mutation and may occur in telomere diseases, mitigating the phenotype. Clonal hematopoiesis may be maladaptive, as acquired mutations in a specific set of genes (e.g., *TP53*) lead to myeloid neoplasms.

Environmental regenerative stresses, including factors such as smoking, alcohol consumption, and viral infection, may increase susceptibility to organ damage and contribute to disease heterogeneity.

Disease anticipation, in which clinical phenotype manifests at an earlier age in successive generations, is observed in some families with telomeropathies due to the direct inheritance of short telomeres in sperm and oocytes.

The diagnosis of a telomere disease is suggested by personal and family history, strengthened by simple measurement of leukocyte telomere length, and usually definitively established by next-generation sequencing for genes encoding telomere repair enzyme complex and shelterin components. In a machine-learning tool that differentiates acquired immune aplastic anemia from inherited bone marrow failure syndromes, telomere length is a top predictor.

Dyskeratosis Congenita Dyskeratosis congenita is the classic telomere disease of childhood and usually diagnosed in the first two decades of life. Affected children often have at least two features of the mucocutaneous triad of ungual dystrophy, reticular skin pigmentation, and oral leukoplakia **(Fig. 482-2)**. In more severe syndromes, affected newborns have cerebellar hypoplasia (Hoyeraal-Hreidarsson syndrome) or exudative retinopathy (Revesz syndrome) **(Fig. 482-3)**. Telomeres are usually extremely short, below the first percentile expected for age **(Fig. 482-4)**. Most patients with dyskeratosis congenita develop bone marrow failure, often requiring transfusions and, ultimately, bone marrow transplant. Pulmonary fibrosis appears in as many as 20% of cases and liver disease in 10%, often after bone marrow transplant for hematopoietic failure. Other tissues and organs also may be affected (Fig. 482-3). Mutations most common in dyskeratosis congenita patients are in *DKC1*, *TINF2*, *TERT*, *TERC*, and *RTEL1* genes, and triallelic inheritance (involving two genes in the same pathway) also may occur (Table 482-1).

Bone Marrow Failure Aplastic anemia **(Chap. 107)** is the most common major clinical manifestation of dyskeratosis congenita. However, young or older patients carrying a telomere defect, without typical physical stigmata, can also develop marrow failure. Genetic variants usually are monoallelic (one mutated allele and one wild-type allele), resulting in haploinsufficiency, and *TERT*, *TERC*, and *RTEL1* are the genes usually affected. Telomere loss in these cases is often less intense than in classic dyskeratosis congenita. As a result of inadequate telomerase function, the stem cell pool is limited in size and in its ability to regenerate, leading to marrow hypocellularity, and insufficient production of erythrocytes, platelets, and granulocytes **(Fig. 482-5)**. The most typical presentation is moderate aplastic anemia after a long history of macrocytic mild to moderate anemia and/or thrombocytopenia, with preservation of leukocyte numbers. A comprehensive personal and family history is important, querying especially for blood count abnormalities and cytopenia as well as lung and liver disease; early hair graying, while not specific to telomeropathies, strongly suggests telomere disease in the appropriate context.

Myeloid Neoplasms Some patients diagnosed with myelodysplastic syndrome **(Chap. 107)** or acute myeloid leukemia **(Chap. 109)** have a family history of bone marrow failure or other myeloid neoplasms. One of the genetic causes for myeloid neoplasia predisposition is a telomere defect, and these disorders are now classified together by the World Health Organization as "myeloid neoplasms associated with telomere biology disorders." Telomere length measurement may be confounded by circulating immature cells, which may have very short telomeres, precluding accurate test interpretation.

Pulmonary Fibrosis Pulmonary fibrosis appears in ~20% of children with dyskeratosis congenita. Conversely, ~10–15% of patients with idiopathic pulmonary fibrosis **(Chap. 304)** or familial pulmonary

fibrosis have an etiologic telomerase gene mutation. Regardless of mutation status, most pulmonary fibrosis patients have short telomeres for their age but not as short as in dyskeratosis congenita. How telomere erosion causes pulmonary fibrosis is unclear, but it might prevent adequate proliferation and regeneration of pneumocytes type II. Idiopathic pulmonary fibrosis due to a telomere disease usually appears after the fourth decade of life, with a restrictive pattern on pulmonary function testing associated with decreased diffusion capacity for carbon monoxide (DL_{CO}) and a diffuse "honeycomb" appearance on high-resolution computed tomography (CT) (Fig. 482-5). Histopathology of biopsied lung shows interstitial pneumonia. The pulmonary clinical presentation in telomere disease is indistinguishable from idiopathic pulmonary fibrosis, except that those with an underlying telomere defect may have cryptic hepatic cirrhosis, macrocytosis, cytopenias, and a family history of lung, liver, or bone marrow disease. Pulmonary arteriovenous malformation leading to right-to-left shunting is observed in patients with pulmonary fibrosis due to telomere disease. Patients with idiopathic pulmonary fibrosis or familial pulmonary fibrosis should have leukocyte telomere length assayed and, if telomeres are short, undergo screening for mutations in telomere-associated genes and telomeres; telomere length may be normal in some cases despite the presence of pathogenic mutations. *TERT*, *TERC*, *RTEL1*, and *PARN* are the most commonly mutated genes.

Liver Disease Genetic telomere defects may cause hepatic cirrhosis (Chap. 355), nodular regenerative hyperplasia of the liver, nonalcoholic fatty liver disease (Chap. 354), and hepatocellular carcinoma (Chap. 87). Hepatocytes of most patients with cirrhosis have very short telomeres. Eroded telomeres limit hepatocyte proliferation, especially upon chronic injury. Additionally, hepatocytes with short telomeres display abnormal metabolic patterns and defective mitochondrial function. Abnormal liver pathology may be uncovered incidentally during the evaluation of telomeropathy patients with aplastic anemia or pulmonary fibrosis, but cirrhosis also may be the sole or most prominent clinical presentation of a telomere defect. A minority of individuals with cirrhosis associated with virus B or C infection or alcohol-associated liver disease may carry a telomere-associated gene mutation. Liver histopathology is variable, but cirrhosis is usually associated with inflammation (Fig. 482-5), increased iron deposit, positivity for CD34 in sinusoid endothelial cells, and widening of hepatocyte plates. Defective telomere maintenance may increase the susceptibility of the liver to environmental challenges, such as alcohol and viruses, increasing the risk for developing severe hepatic disease in mutation carriers.

FIGURE 482-2 Skin manifestations of dyskeratosis congenita. The pediatric syndrome dyskeratosis congenita is characterized by the mucocutaneous triad of ***(A)*** reticular skin pigmentation, ***(B)*** oral leukoplakia, and ***(C, D)*** nail dystrophy.

LONG TELOMERE SYNDROME

POT1 is a shelterin component that modulates telomerase access to telomeres, thus regulating telomere elongation. Heterozygous germline loss-of-function mutations in the *POT1* gene cause excessively long telomeres that clinically translate into clonal hematopoiesis and a predisposition to benign and malignant tumors. Very long telomeres appear to augment the capacity for cell proliferation, facilitating the acquisition of harmful driver somatic mutations.

TELOMERE LENGTH MEASUREMENT

Length of telomeres can be accurately measured in peripheral blood leukocytes by commercial laboratories. Of several methods available, flow–fluorescence in situ hybridization (FISH) and quantitative real-time polymerase chain reaction (qPCR) are most widely

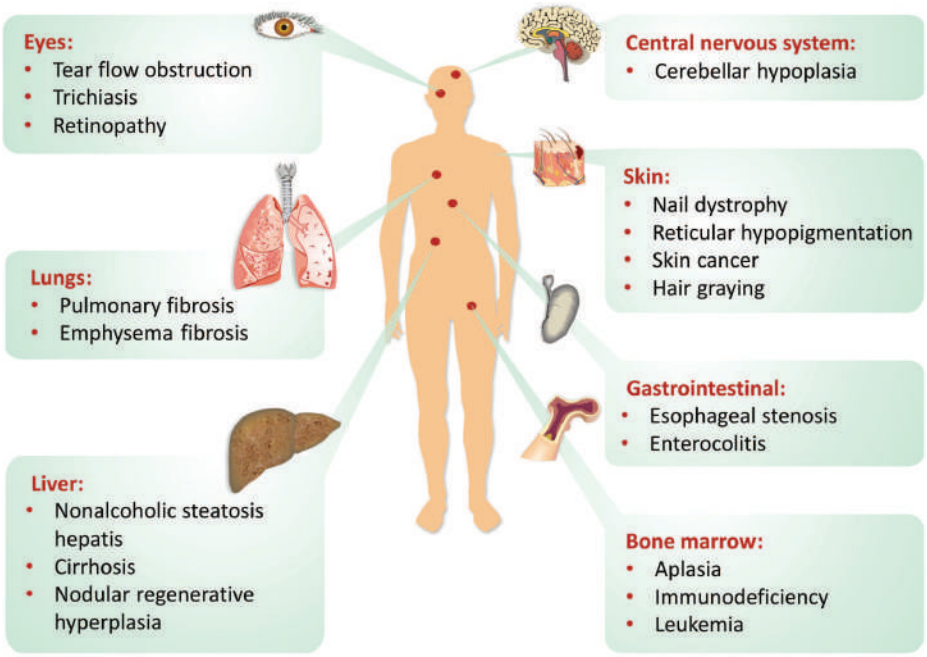

FIGURE 482-3 Clinical consequences of telomere diseases. Telomere dysfunction affects a variety of organs: cerebellum, eyes, lungs, liver, skin, gastrointestinal tract, and the bone marrow.

utilized. Both methods have advantages and limitations and require high-quality samples, usually fresh or freshly processed, as cell death and DNA degradation impact the accuracy of testing. Results are usually expressed as leukocyte telomere length in kilobases. However, the interpretation of length must account for patient age, due to physiologic telomere loss. A normal range for telomeres is available for each year of age, longest at birth and shortening at 40–60 base pairs per year (Fig. 482-1). For each age bracket, the percentile curves are calculated, and a given patient's test result is interpreted in the context of normal age variation: telomeres below the tenth percentile for age are defined as "short" and telomeres below the first percentile are considered "very short" (Fig. 482-4). Telomeres above the 99th percentile are considered "very long."

Short telomeres may also be present in some chronic conditions, such as cardiovascular disease or diabetes. In these settings, telomere erosion is not thought to be etiologic but rather a secondary consequence of chronic inflammation; telomere testing does not have clinical utility and is not recommended. Likewise, telomere length tests, despite commercial hyperbole, have not been shown to be useful in the assessment of aging and longevity or as a basis for therapeutic interventions, absent a diagnosis of genetic telomere disease.

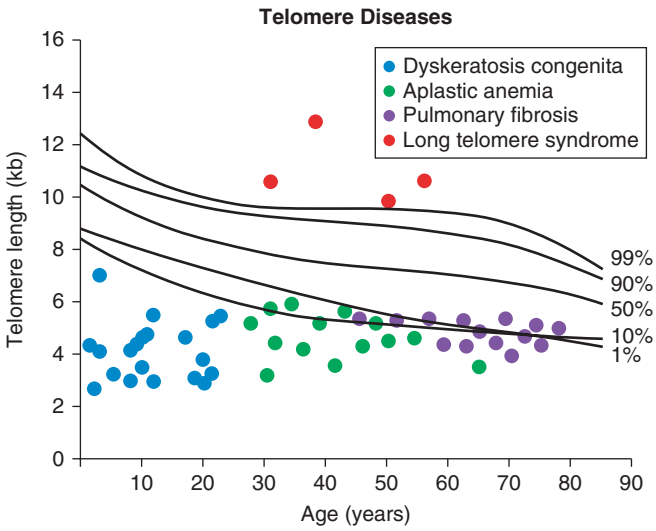

FIGURE 482-4 Telomere length measurement in telomere diseases. Telomeres shorten with aging, and solid curves represent the percentiles for age in healthy subjects. Telomeres are considered "short" when below the 10th percentile, very short when below the first percentile, and very long when above the 99th percentile. In patients with dyskeratosis congenita, telomeres are usually below the first percentile, regardless of the gene lesion, whereas in patients with aplastic anemia or pulmonary fibrosis, telomeres are usually below the 10th percentile. In patients with long telomere syndrome, telomeres are usually above the 99th percentile.

Flow-FISH uses a fluorescent-labeled nucleotide probe specific for telomere repeats to estimate telomere content in an individual cell. It has the advantage of determining telomere length in individual cells and in leukocyte subpopulations; lymphocyte telomere shortening is more specific for telomere diseases than in other cells. A limitation of flow-FISH is the requirement for intact cells for analysis, which are not always available, and neutrophils are susceptible to damage during processing, freezing, and thawing.

qPCR uses telomere-binding modified primers to measure telomere content in comparison to a housekeeping gene in the whole leukocyte population and thus does not require intact cells. qPCR provides an estimate of the average telomere length of a given sample without determining telomere length in individual cells. Good DNA quality is essential for adequate qPCR testing and automation or semi-automation is required for clinical purposes, as variability in conditions among batches may result in interassay variation.

The standard Southern blot is very accurate but requires larger amounts of DNA and is labor intensive. Other measures have been developed in research laboratories (single telomere length analysis [STELA], telomere shortest length assay [TESLA]) to assess critically short telomeres in particular.

GENETIC TESTING

When a patient with a suspected telomeropathy has short or very short telomeres, genetic screening for mutations in genes involved in telomere maintenance and biology is indicated (Table 482-1). Genetic testing has been restricted to patients with suspected telomere disorders but is increasingly incorporated into genomic screening in the bone marrow failure syndromes in general, and next-generation sequencing has been routinely used. Mutations may be biallelic or triallelic involving two genes (especially in dyskeratosis congenita), but usually only one allele is mutated. Interpretation of genetic screening results is challenging, as rare singleton polymorphisms of unknown significance have been identified in large cohorts of healthy individuals. In silico analysis, mutation location, and functional studies are helpful to interpret the mutation significance.

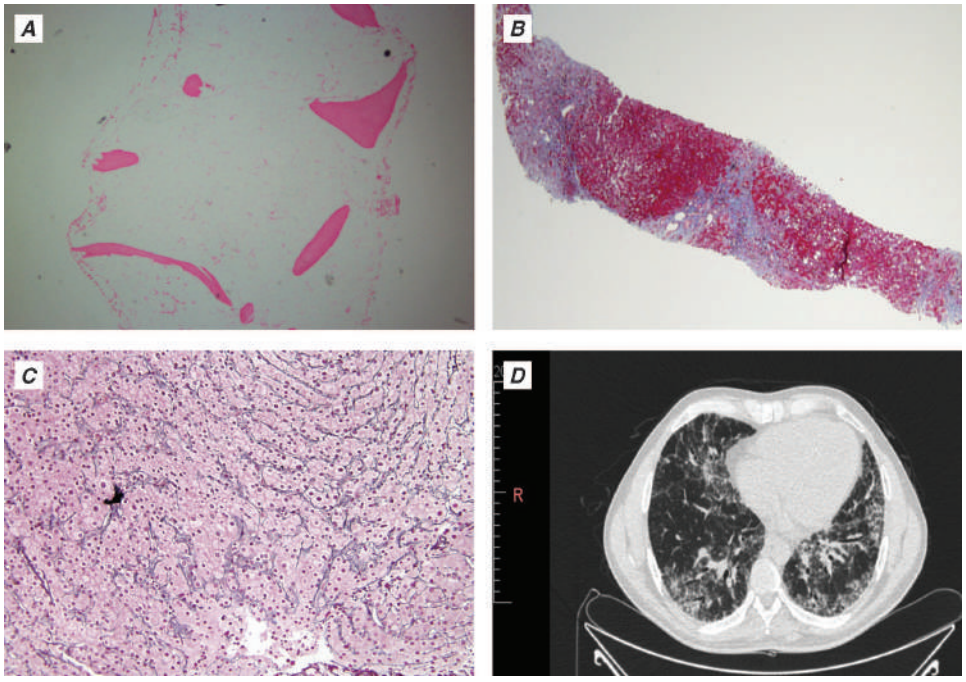

FIGURE 482-5 Pathologic manifestations of telomere diseases. ***A.*** In the bone marrow, telomere erosion predisposes to aplastic anemia, characterized by an empty hematopoietic marrow replaced by fat (hematoxylin and eosin). ***B.*** In the liver, telomere attrition predisposes to cirrhosis (hematoxylin and eosin). ***C.*** Telomere shortening may also result in nodular regenerative hyperplasia of the liver (reticulin stain). ***D.*** In the lungs, telomere dysfunction predisposes to pulmonary fibrosis mainly in the subpleural regions, which may be detected by high-resolution computed tomography scan.

Genetic counseling is necessary after screening, as the inheritance pattern may be autosomal dominant, mutation penetrance is highly variable, and phenotypes may be diverse even within a pedigree. Potential family stem cell donors must be screened before transplantation to ensure that they do not have mutations.

TREATMENT

Telomere Disease

Patients with severe aplastic anemia due to telomere disease may undergo allogeneic hematopoietic stem cell transplant when a suitable donor is available. Treatment-related mortality may be increased due to pulmonary and hepatic complications, for which reduced intensity conditioning regimens appear advantageous. Lung transplant for pulmonary fibrosis is feasible but often not performed due to coexisting cytopenias and other comorbidities. Patients with pulmonary fibrosis associated with telomere disease have a poorer outcome after lung transplant and with nontransplant therapies. Similarly, there is no specific treatment for the liver in telomere disease; liver transplant has been performed in several cases with good outcome and without excessive posttransplant mortality and improvement in the respiratory status. Telomeropathy patients should be advised to avoid toxins (metal dust, busulfan, amiodarone), ionizing radiation, cigarette smoke, and alcohol, as these can be possibly harmful.

Long-term therapy with androgens may mitigate telomere attrition and even elongate leukocyte telomere length in humans. In research trials, danazol and nandrolone improved blood counts in marrow failure patients and reduced transfusion requirements.

483 Gene and Cell-Based Therapy in Clinical Medicine

Katherine A. High, Marcela V. Maus

Gene therapy is a novel area of therapeutics in which the active agent is a nucleic acid sequence rather than a protein or small molecule. One of the most powerful concepts in modern molecular medicine, gene therapy has the potential to address a host of diseases for which there are currently no available treatments. Because delivery of naked DNA or RNA to a cell is an inefficient process, most gene therapy is carried out using a vector, or gene delivery vehicle, typically engineered from viruses by deleting some or all of the viral genome and replacing it

TABLE 483-1 Characteristics of Commonly Used Gene Delivery Vehicles

	VIRAL BASE		NONVIRAL	
FEATURES	RETROVIRAL/LENTIVIRAL	ADENOVIRAL	AAV	LIPID NANOPARTICLES
Genome	RNA	DNA	DNA	RNA
Cell division requirement	G_1 phase	No	No	No
Packaging limitation	8 kb	8–30 kb	5 kb	10 kb or more
Immune responses to vector		Extensive	Few	Few
Genome integration	Yes	Poor	Poor	May be used to package either RNA or DNA
Long-term expression	Yes	No	Yes	Transient for RNA
Main advantages	Persistent gene transfer in transduced tissues	Highly effective in transducing various tissues	Elicits few inflammatory responses, nonpathogenic	RNA expressed transiently
Main disadvantages	Might induce oncogenesis in some cases; only used ex vivo	Viral capsid elicits strong immune responses	Limited packaging capacity	Immunogenic; predominantly targets the liver; challenging manufacturing process

with the therapeutic gene of interest under the control of a suitable promoter. Nonviral delivery vehicles such as lipid nanoparticles are increasingly being used (Table 483-1). Gene therapy strategies can thus be described in terms of three essential elements: (1) a gene delivery vehicle; (2) a gene to be delivered, sometimes called the transgene; and (3) a physiologically relevant target cell to which the DNA or RNA is delivered. The series of steps in which the vector and donated DNA or RNA enter the target cell and express the transgene is referred to as *transduction*. Gene delivery can take place in vivo, in which the vector is directly injected into the patient, or, in the case of hematopoietic, liver, immune, and some other target cells, ex vivo, with removal of the target cells from the patient, followed by return of the gene-modified autologous cells to the patient after manipulation in the laboratory. The latter approach effectively combines gene transfer techniques with cellular therapies.

In the past few years, gene therapy for genetic disease has moved from addressing ultra-rare inherited diseases to more common ones including sickle cell disease and hemophilia. Similarly, chimeric antigen receptor (CAR) T cells have expanded beyond hematologic malignancies to address solid tumors and autoimmune diseases (currently investigational products). Therapeutic approaches have expanded from gene transfer to gene editing, and RNA-based therapies have gained ground rapidly, partly as a key component of CRISPR-based gene editing (guide RNAs and mRNAs encoding editing enzymes) and as the active agent in multiple SARS-CoV-2 vaccines. This chapter will focus primarily on approved therapies (Table 483-2), with some discussion of investigational therapies in late-phase development and earlier trials critical to the development of the field.

Clinical trials of gene therapy have been under way since 1990; the first gene therapy product to be licensed in the United States or Europe was approved in 2012 (see below). Given that vector-mediated gene therapy is arguably one of the most complex therapeutics yet developed, typically consisting of both a nucleic acid and a protein component, this time course from first clinical trial to licensed product is noteworthy for being similar to those seen with other novel classes of therapeutics, i.e., monoclonal antibodies or bone marrow transplantation. Thousands of people have now received approved products or participated in investigational studies of gene transfer. Potential adverse events, predicted based on first principles (Table 483-3), have occurred but have been rare. Some of the initial trials were characterized by an overabundance of optimism and a failure to be appropriately critical of preclinical studies in animals; in addition, it was sometimes not fully appreciated that animal studies are only a partial guide to safety profiles of products in humans (e.g., in the setting of insertional mutagenesis or human immune responses to the vector). Clinical experience and laboratory research led to a more nuanced understanding of the actual risks (Table 483-4) and dramatic benefits of these new therapies and to more sophisticated selection of disease targets. Currently, gene therapies are being developed for a variety of disease entities. Critical aspects of the history to be assessed when evaluating a patient who has received a gene therapy product (or investigational agent) are outlined in Table 483-5.

GENE TRANSFER AND GENE EDITING FOR GENETIC DISEASES

Most approved gene therapies for genetic diseases involve gene addition therapy. Recently the first gene editing products, for sickle cell disease and β-thalassemia, have been approved. Gene therapy strategies generally involve transfer of the missing gene to a physiologically relevant target cell. However, other strategies are possible, including supplying a truncated form of the gene with comparable biological activity (e.g., a gene encoding B domain-deleted FVIII for hemophilia A or microdystrophin for Duchenne muscular dystrophy); supplying a gene that achieves a similar biologic effect through an alternative pathway (e.g., utrophin in place of dystrophin for Duchenne muscular dystrophy); or downregulating a harmful effect through a small interfering or short hairpin RNA. From a therapeutic standpoint, gene therapies for genetic diseases fall into two distinct categories: (1) they may provide treatment for diseases that have hitherto lacked any pharmacologic therapies; or (2) they may provide an alternative to complex medical regimens that are frequently characterized by significant nonadherence due to the burden of treatment (e.g., monthly red blood cell transfusions and iron chelation in transfusion-dependent β-thalassemia).

Gene therapy for genetic disease requires long-term expression of the transgene. Two distinct strategies are available to achieve this goal: one is to transduce stem cells with an integrating vector, so that all progeny cells will carry the donated gene; and the other is to transduce long-lived, postmitotic cells, such as skeletal muscle or neurons. In the case of long-lived cells, integration into the target cell genome is unnecessary. Instead, because the cells are nondividing, the donated DNA, even if stabilized predominantly in an episomal form, will give rise to expression for the life of the cell. This latter approach mitigates risks related to integration and insertional mutagenesis.

CRISPR/Cas9-based gene editing differs from gene therapy in that the therapeutic moiety utilizes a bacterial Cas9 enzyme and a guide RNA to introduce a double strand break (DSB) at a specific site in the DNA. When co-delivered with an appropriately designed gene-targeting vector, gene insertion can take place at the site of the DSB, resulting in a corrected sequence at the endogenous locus of a gene. This permanent correction in the genome is thus under the control of endogenous regulatory signals and will be passed to every daughter cell. In practice, the Cas9 enzyme is complexed with the guide RNA to form a ribonucleoprotein (RNP), which is then delivered to the cell, where the guide RNA directs the RNP complex to the genome target, introducing the DSB at a precise locus. In the *absence* of a gene-targeting vector, the DSB will be repaired using nonhomologous end joining (NHEJ), which typically results in small deletions or insertions, disrupting the expression of the target gene. In the presence of a targeting vector, repair at the DSB may occur by homology-directed repair, resulting in gene replacement at the targeted locus. With currently available systems, the

TABLE 483-2 Currently Approved Gene and Cell Therapy Products in North America and/or Europe

PRODUCT	INDICATION	AGE GROUP	YEAR FIRST APPROVED	WHERE APPROVED	VECTOR	TRANSGENE	TARGET TISSUE
Strimvelis®[a]	ADA-SCID	Pediatric	2016	Europe	Retroviral	*ADA* (adenosine deaminase)	Autologous hematopoietic stem cells (HSCs)
Kymriah® (tisagenlecleucel)	Relapsed or refractory (R/R) B-cell acute lymphoblastic leukemia (pediatric); R/R large B-cell lymphoma (adult); third-line follicular lymphoma	Pediatric and adult, different disease indications	2017	United States, Europe, China, Japan	Lentiviral	CAR directed to CD19 with 4-1BB signaling domain	Autologous T cells
Yescarta® (axicabtagene ciloleucel)	R/R and second-line large B-cell lymphomas; third-line follicular lymphoma	Adult	2017	United States, Europe, Japan	Retroviral	CAR directed to CD19 with CD28 signaling domain	Autologous T cells
Luxturna® (voretigene neparvovec)	Confirmed biallelic *RPE65* mutation–associated retinal dystrophy	Pediatric and adult	2017	United States and Europe	AAV2	*RPE65* (retinal pigment epithelial 65 kD protein)	Retinal pigment epithelial cells by single subretinal injection
Zolgensma® (onasemnogene abeparvovec)	Spinal muscular atrophy type 1 due to biallelic mutations in the *SMN1* gene	Pediatric <2 years of age	2019	United States and Europe	AAV9	*SMN1* (survival motor neuron 1)	Spinal motor neurons by single IV infusion
Zynteglo® (betibeglogene autotemcel)	Transfusion-dependent β thalassemia; sickle cell disease	Adults and pediatric ≥12 years of age	2019	Europe and United States	Lentiviral	$\beta^{A\text{-}T87Q}$ globin gene	Autologous HSCs
Libmeldy®[b] (aditarsagene autotemcel)	Metachromatic leukodystrophy due to biallelic mutations in the arylsulfatase A gene	Pediatric	2020	Europe, United States	Lentiviral	*ARSA* (arylsulfatase A)	Autologous HSCs
Tecartus® (brexucabtagene autoleucel)	R/R mantle cell lymphoma; R/R B-cell acute lymphoblastic leukemia	Adults	2020	United States and Europe	Retroviral	Same molecular construct as axicabtagene	Autologous T cells
Breyanzi® (lisocabtagene maraleucel)	R/R and second-line large B-cell lymphoma	Adult	2021	United States, Europe, and Japan	Lentiviral	CAR directed at CD19 with 4-1BB signaling domain; CD4 and CD8 T-cell products manufactured and infused separately	Autologous T cells
Abecma® (idecabtagene vicleucel)	Fifth-line treatment for multiple myeloma	Adult	2021	United States and Europe	Lentiviral	CAR directed to B-cell maturation antigen (BCMA); 4-1BB signaling domain	Autologous T cells
Carvykti® (ciltacabtagene autoleucel)	Fifth-line treatment for multiple myeloma	Adult	2022	United States and Europe	Lentiviral	CAR directed to BCMA with two single-domain antibodies; 4-1BB signaling domain	Autologous T cells
Skysona® (elivaldogene autotemcel)	Early active cerebral adrenoleukodystrophy	Boys age 4–17	2022	Europe and United States	Lentiviral	Adenosine triphosphate–binding cassette, subfamily D, member 1 (*ABCD1*)	Autologous HSCs
Upstaza® (eladocagene exuparvovec)	Confirmed AADC deficiency with severe phenotype	Children 18 months and older	2022	Europe	AAV2	Human aromatic L-amino acid decarboxylase (*AADC*)	Cells in putamen via single neurosurgical procedure
Roctavian® (valoctocogene roxaparvovec)	Severe hemophilia A and no history of inhibitors	Adults	2022	Europe and United States	AAV5	cDNA encoding human factor VIII, B domain-deleted, SQ form	Hepatocytes via single IV infusion
Hemgenix® (etranacogene dezaparvovec)	Severe or moderately severe hemophilia B	Adults	2022	Europe and United States	AAV5	cDNA encoding factor IX Padua	Hepatocytes via single IV infusion
Vyjuvek® (beremagene geperpavec)	Dystrophic epidermolysis bullosa due to mutations in *COL7A1*	Age 6 months and older	2023	United States	Herpes simplex viral vector	Collagen type VII alpha 1 chain (*COL7A1*)	Keratinocytes and fibroblasts at sites of lesions
Elevidys® (delandistrogene moxeparvovec)	Duchenne muscular dystrophy	Ages 4–5	2023	United States	AAVrh74	cDNA encoding microdystrophin	Skeletal muscle via single IV infusion
Casgevy® (exagamglogene autotemcel)	Sickle cell anemia and β thalassemia	Ages 12 and up	2023	United States and Europe	Gene editing	Inactivates *BCL11a* in RBCs	Autologous HSCs
Beqvez® (fidanacogene elaparvovec)	Severe or moderately severe hemophilia B	Adults	2024	Canada, United States and Europe	AAVrh74variant	cDNA encoding factor IX Padua	Hepatocytes via single IV infusion

[a]Autologous CD34+-enriched cell fraction that contains CD34+ cells transduced with retroviral vector that encodes for the human ADA cDNA sequence. [b]Autologous CD34+ cells encoding arylsulfatase A.

Abbreviations: AAV, adeno-associated virus; ADA-SCID, adenosine deaminase severe combined immunodeficiency; CAR, chimeric antigen receptor; RBC, red blood cell.

TABLE 483-3 Potential Complications of Gene Therapy

Gene silencing—repression of promoter
Genotoxicity—complications arising from insertional mutagenesis, or acceleration of malignant transformation in a cell on the path to oncogenesis before transduction (i.e., CAR introduced into a premalignant T cell)
Phenotoxicity—complications arising from overexpression or ectopic expression of the transgene
Immunotoxicity—harmful immune response to either the vector or transgene, or a harmful immune response of the vector (e.g., CAR T cells)
Risks of horizontal transmission—shedding of infectious vector into environment
Risks of vertical transmission—germline transmission of donated DNA

Abbreviation: CAR, chimeric antigen receptor.

first (cleavage) step is much more efficient than the second (targeting) step. The only approved gene editing product requires only the cleavage step (*vide infra*), and the same is true for most investigational products that have been published as clinical studies.

EX VIVO GENE TRANSFER

Early attempts to effect gene replacement into hematopoietic stem cells (HSCs) were stymied by the relatively low transduction efficiency of retroviral vectors, which require dividing target cells for integration. Because HSCs are normally quiescent, they are a formidable transduction target. However, identification of cytokines that induce cell division without promoting differentiation of stem cells, along with technical improvements in the isolation and transduction of HSCs, led to modest but real gains in transduction efficiency.

Immunodeficiency Disorders: Proof of Principle The first convincing therapeutic effect from gene transfer occurred in children with X-linked severe combined immunodeficiency disease (SCID), which results from mutations in the gene (*IL2RG*) encoding the γc subunit of cytokine receptors required for normal development of T and natural killer (NK) cells **(Chap. 362)**. Affected infants present in the first few months of life with overwhelming infections and/or failure to thrive. In this disorder, it was recognized that successfully transduced cells, even if few in number, would have a proliferative advantage compared to nontransduced cells, which lack receptors for the cytokines required for lymphocyte development and maturation. Isolation of autologous CD34+ cells, followed by transduction with a retroviral vector encoding the γc subunit and transplantation of the gene-modified autologous cells, led to complete reconstitution of the immune system, including documented responses to standard childhood vaccinations, clearing of infections, and remarkable gains in growth in most treated

TABLE 483-4 Adverse Events in Gene Therapy and Gene Editing

VECTOR OR TREATMENT MODALITY	SYMPTOM OR LABORATORY FINDING	MECHANISM	DOSE DEPENDENCE	MITIGATION STRATEGIES
Retroviral or lentiviral vectors	Malignancy[a]	Insertional mutagenesis[a]	Yes for retroviral vectors	Less frequent with lentiviral vectors, likely because of differences in integration patterns
AAV	Vector sequences in semen, risk of germline transmission	Based on animal studies, present in prostatic fluid but not in gametes	Yes	Barrier birth control until three sequential semen samples are negative for vector DNA
	Immune responses directed to capsid, sometimes accompanied by loss of expression	Memory T cells directed to vector capsid in humans, who are natural hosts for wild-type AAV	Yes	Reduce doses Administer immunomodulatory agents (short-term) to reduce or ablate response
	Thrombotic microangiopathy with high-dose systemic infusion	Rapid rise in antibodies to AAV, formation of antigen-antibody complexes, triggering of complement activation	Yes	Has responded to therapy with complement inhibitors including eculizumab
Ex vivo and in vivo genome editing	Off-target cleavage resulting in unintended gene silencing	Guide RNA lacks requisite specificity	Likely	Preclinical assessment for off-target effects Long-term follow-up of trial participants and patients
In vivo genome editing	Liver-directed in vivo editing has shown mild and transient transaminase elevations but excellent efficacy at doses studied clinically	Possibly immune responses to bacterial proteins in editing machinery, potentially resulting in loss of edited cells	Yes	Careful dose-ranging studies in early-phase testing Consider short-term immunomodulatory agents if needed at higher doses
CAR-T therapy	Cytokine release syndrome: fever, hypotension, tachycardia, hypoxia, multiorgan failure	Systemic inflammatory response caused by cytokines released by CAR T cells	Possibly	Tocilizumab/corticosteroids
	Neurotoxicity-cerebral edema and encephalopathy	Peripheral immune overactivation, endothelial activation-induced blood-brain barrier dysfunction, CNS inflammation	Possibly	Avoid seizure-threshold-lowering medications in early phase of treatment Treat with dexamethasone as early as possible (use specific management guidelines)
	Immunodeficiency (hypogammaglobulinemia and susceptibility to viral injections)	On-target effect against B cells and/or plasma cells Preparatory lymphodepleting chemotherapy regimen also contributes	No	Prophylaxis for opportunistic infections (PJP, VZV) for at least 1 year; vaccination schedule (specific guidelines)
	New T-cell malignancy	Insertional mutagenesis or potentially chronic activation due to new transgene	No	Report to FDA and manufacturer Consider activation of suicide gene if present in the transgene expression cassette Treat per standard guidelines

[a]In target cells, either hematopoietic stem cells or T cells.

Abbreviations: AAV, adeno-associated virus; CAR, chimeric antigen receptor; CAR-T, chimeric antigen receptor T cell; CNS, central nervous system; FDA, U.S. Food and Drug Administration; PJP, *Pneumocystis jirovecii* pneumonia; VZV, varicella-zoster virus.

TABLE 483-5 Taking History from Patients Who Have Received Gene Therapies or Gene Editing

Elements of History for Patients Who Received Gene Therapy (or Have Participated in Trials)
1. What vector was administered? Is it predominantly integrating (retroviral, lentiviral, herpesvirus, or gene editing) or nonintegrating (plasmid, adenoviral, adeno-associated viral)?
2. What were the dose and the route of administration of the vector?
3. What was the target tissue?
4. What gene was transferred in? The gene that is defective in the patient's disease? A truncated version? A gene encoding a different protein with similar properties? A knockdown approach?
5. Were there any adverse events noted after gene transfer?
Screening Questions for Long-Term Follow-Up in Gene Transfer Subjects[a]
1. Has a new malignancy been diagnosed? If so, clinicians should contact the manufacturer to report the event and obtain instructions on the collection of patient samples for testing.
2. Has a new neurologic/ophthalmologic disorder, or exacerbation of a preexisting disorder, been diagnosed?
3. Has a new autoimmune or rheumatologic disorder been diagnosed?
4. Has a new hematologic disorder been diagnosed?

[a]Factors influencing long-term risk include integration of the vector into the genome, vector persistence without integration, and transgene-specific effects.

children. However, among 20 children treated in the initial trials, five eventually developed a syndrome similar to T-cell acute lymphocytic leukemia, with splenomegaly, rising white counts, and the emergence of a single clone of T cells. Molecular studies revealed that, in most of these children, the retroviral vector had integrated within a gene, *LMO-2* (LIM only-2), which encodes a component of a transcription factor complex involved in hematopoietic development. The retroviral long terminal repeat acted as a promoter to increase the expression of *LMO-2*, resulting in T-cell leukemia.

The X-linked SCID studies were a watershed event in the evolution of gene therapy. They demonstrated conclusively that gene therapy could cure disease, with dramatic and durable clinical results. However, they also demonstrated that insertional mutagenesis leading to cancer was more than a theoretical possibility (Table 483-3). As a result of the experience in these trials, all protocols using integrating vectors in hematopoietic cells must include a plan for monitoring sites of insertion and clonal proliferation for 15 years after treatment. Initial strategies to overcome the possible complication of insertional mutagenesis included using a "suicide" gene cassette in the vector, so that errant clones can be quickly ablated, or using "insulator" elements in the cassette, which can limit the activation of genes surrounding the insertion site. However, the occurrence of malignancy in the X-linked SCID trials led to a transition to lentiviral vectors. These vectors efficiently transduce nondividing target cells and are characterized by a different pattern of integration into the genome that appears to be safer than retroviral vectors. However, recent developments in the field of CAR-T therapy, notably reports of development of T-cell lymphoma, have underscored the need for caution (*vide infra*).

Transfusion-Dependent Thalassemia: Extension of Principle Therapeutic success for inherited immunodeficiencies, though a clear unmet medical need, affects only a very small population. The success of gene therapy in β thalassemia, one of the most common genetic diseases in Asian and Mediterranean populations, and one that provided the foundation for success in sickle cell disease, the most common genetic disease in Africans, demonstrated conclusively the therapeutic impact of gene therapy. The red cell disorders β thalassemia and sickle cell disease are more challenging targets for gene therapy than the immunodeficiencies for several reasons. First, in immunodeficiency disorders, the transduced stem cells have a survival advantage over nontransduced cells, which is not the case in red cell disorders (although the fully differentiated gene-modified red blood cells [RBCs] have a survival advantage compared to thalassemic or sickle RBCs). Second, in order to achieve transfusion independence or freedom from vaso-occlusive crises, one must achieve higher transduction efficiency as well as engraftment of higher numbers of stem cells. There are now two approved products, one a lentiviral-based gene therapy and the other a gene editing approach, for both of these conditions (Table 483-2). Standard of care for transfusion-dependent β thalassemia (TDT) consists of lifelong regular RBC transfusions, typically monthly, to support hemoglobin (Hgb) levels >9 g/dL, coupled with an intensive regimen of iron chelation to minimize iron overload to the liver, heart, and endocrine system **(Chap. 103)**. Allogeneic stem cell transplantation addresses the underlying cause of the disease but carries risks of myeloablation, graft-versus-host disease (GVHD), and graft rejection and thus is reserved primarily for those with an human leukocyte antigen (HLA)-matched sibling donor (<25% of patients). The first approved gene therapy for β thalassemia consists of a lentiviral vector driving expression of an antisickling variant of β-globin (β^{T87Q}, the same product used for sickle cell disease), introduced into autologous HSCs, which are then transplanted back into the patient after myeloablation. Results of clinical trials for both β^0/β^0 genotype (the most severe) and for non-β^0/β^0 showed durable transfusion independence, defined as Hgb ≥9 g/dL and no transfusion for ≥12 months, in 20 of 22 evaluable participants in one phase 3 study and 12 of 14 patients in a second study. The remaining subjects all demonstrated reduction in the transfusion requirement, enabling iron removal therapy by either phlebotomy or iron chelation and removing risks related to iron overload. Gene therapy with lentiviral transduction of autologous cells thus dramatically simplifies the medical regimen for these patients, since it eliminates the need for ongoing transfusion and iron chelation and carries no risk of GVHD or graft rejection because it is generated from the patient's own cells. Similarly, since the transduced cells are autologous, there is no requirement for an HLA-matched donor, expanding the numbers of patients who can be treated. Safety in the initial trials has been excellent, with most adverse events related to the known risks of the myeloablative conditioning regimen.

The same lentiviral vector is also now approved for sickle cell disease; a single-arm, 24-month, open-label study assessed 36 participants who underwent apheresis followed by myeloablative conditioning and transplantation of gene-modified autologous cells. Of the 32 evaluable patients, 30 achieved complete elimination of vaso-occlusive crises between 6 and 18 months after infusion, a key efficacy endpoint in the study, and 31 of 36 achieved a globin response defined as hemoglobin A^{T87Q} (the transgene product) of at least 30% of total Hgb and an increase in total Hgb of ≥3 g/dL. Using an earlier version of this product that was prepared using a different manufacturing process and a different transplant procedure, two patients died following development of acute myeloid leukemia. Interpretation of these data is not straightforward, since patients with sickle cell disease have an increased risk of hematologic malignancy compared to the general population. The product carries a boxed warning summarizing this risk; twice yearly monitoring of a complete blood count is recommended.

Neurodegenerative Disease: Broadening of Principle The SCID trials gave support to the hypothesis that gene transfer into HSCs could be used to treat any disease for which allogeneic bone marrow transplantation was therapeutic. Moreover, the use of genetically modified autologous cells carried the advantages noted above, i.e., no risk of GVHD, guaranteed availability of a "donor" (unless the disease itself damages the stem cell population of the patient), and low likelihood of failure of engraftment. Investigators in Paris capitalized on this realization to conduct the first trial of lentiviral vector transduction of HSCs for a neurodegenerative disorder, X-linked adrenoleukodystrophy (ALD). The key to the mechanism of action is that a subpopulation of the gene-modified cells gives rise to myeloid cells that cross the blood-brain barrier and engraft as central nervous system (CNS)-resident microglia and perivascular CNS macrophages. The transduced cells carry the gene encoding the missing protein, in this case an adenosine triphosphate–binding cassette transporter (Table 483-2). Following lentiviral transduction of autologous HSCs in young boys with the disease, dramatic stabilization of disease occurred, demonstrating that

stem cell transduction could work for neurodegenerative as well as immunologic disorders.

Investigators in Milan carried this observation one step further to develop a treatment for another pediatric neurodegenerative disorder that had previously responded poorly to bone marrow transplantation. Metachromatic leukodystrophy is a lysosomal storage disorder caused by mutations in the gene encoding arylsulfatase A (ARSA). The late infantile form of the disease is characterized by progressive motor and cognitive impairment and death within a few years of onset, due to accumulation of the ARSA substrate sulfatide in oligodendrocytes, microglia, and some neurons. Recognizing that endogenous levels of production of ARSA were too low to provide cross-correction by allogeneic transplant, a lentiviral vector was used to create supraphysiologic levels of ARSA expression in transduced cells. Transduction of autologous HSCs from children born with the disease, at a point when they were still presymptomatic, has led to preservation and continued acquisition of motor and cognitive milestones at time periods as long as 8 years after treatment, with observation ongoing. This product is approved in Europe and the United States for those with late infantile or early juvenile forms of the disease (Table 483-2). These results illustrate that the ability to engineer levels of expression can allow gene therapy approaches to succeed where allogeneic bone marrow transplantation cannot. A similar approach may be useful in other neurodegenerative conditions.

EX VIVO GENOME EDITING

The first approved genome editing product, and those furthest along in clinical development, all use strategies that require only a cleavage event, rather than both a cleavage and a targeting event. For sickle cell disease **(Chap. 103)**, the genome editing strategy is carried out ex vivo in HSCs. A Cas9/guide RNA ribonucleoprotein complex targeting the erythroid enhancer of the *BCL11A* gene, which normally represses γ-globin (the fetal β-like globin) during the fetal-to-adult β-globin switch, is introduced into autologous CD34+ cells of patients with TDT or sickle cell disease. Reduced *BCL11*A expression results in increased γ-globin expression and Hgb F production in erythroid cells, reducing the Hgb S levels and preventing sickling. The product was approved based on a study of 44 children and adults (age range 12–34 years) with sickle cell disease; of these, 31 had been followed for at least 16 months after gene editing, myeloablation, and engraftment. Of the 31 participants with adequate follow-up, 29 achieved the primary efficacy endpoint of at least 12 consecutive months without any protocol-defined vaso-occlusive crisis. The mean total Hgb at month 18 was 13.3 g/dL, compared to a baseline mean of 7.5 g/dL. This product is now approved for children (12 and older) and adults with sickle cell disease and recurrent vaso-occlusive crisis.

Other genome editing strategies, in earlier stages of clinical development, use Cas9/guide RNA to introduce a cleavage within the β-globin locus near the site of the sickle mutation and simultaneously supply a targeting vector (in this case, an AAV6 vector) encoding a short sequence of the wild-type β-globin gene. In a process dependent on the cellular homology-directed repair pathway, this sequence is used as a DNA repair template at the site of the break, resulting in replacement of the mutant β^s sequence with the wild-type sequence.

LONG-TERM EXPRESSION IN GENETIC DISEASE: IN VIVO GENE TRANSFER WITH RECOMBINANT ADENO-ASSOCIATED VIRAL VECTORS

Recombinant adeno-associated viral (AAV) vectors have emerged as attractive gene delivery vehicles for genetic disease. Engineered from a small replication-defective DNA virus, they are devoid of viral coding sequences and trigger very little immune response in experimental animals. They are capable of transducing nondividing target cells, and the donated DNA is stabilized primarily in an episomal form, thus minimizing risks arising from insertional mutagenesis. Because the vector has a tropism for certain long-lived cell types, such as skeletal muscle, neurons, and hepatocytes, long-term expression can be achieved even in the absence of integration. Of note, because the donated DNA is predominantly nonintegrated, long-term expression requires targeting of nondividing or slowly dividing cells; otherwise, expression is lost as cells divide. The other shortcoming of AAV as a gene delivery vehicle is that it cannot package inserts of more than ~5 kb, owing to the fact that the wild-type viral genome is only ~4.7 kb; fortunately, with some notable exceptions, most cDNAs fall below this limit.

First Approved Products for Ultra-Rare Diseases As was the case with ex vivo gene transfer, the first approved products for in vivo gene therapy were for ultra-rare disorders. In the Western world, the first approved gene therapy product for genetic disease was an AAV vector, conditionally approved in Europe in 2012, for treatment of the autosomal recessive disorder lipoprotein lipase deficiency. The sponsor allowed the approval to expire in 2017, without completing the postmarketing requirements, but the initial approval was a crucial catalyst for the current robust activity in gene therapy, and AAV vectors are now the largest category of approved products for genetic disease, including products for spinal muscular atrophy type 1, a rare form of genetic blindness, hemophilia A and B, and Duchenne muscular dystrophy (Table 483-2).

The first approved AAV therapy for genetic disease in the United States was also for an ultra-rare disease, an inherited retinal dystrophy due to mutations in the gene encoding retinal pigment epithelial-associated 65-kDa protein (*RPE65*). The retina is an attractive target for AAV-mediated gene transfer. It is a relatively immunoprivileged space, obviating problems related to immune responses, and the photoreceptors, retinal ganglion cells, and retinal pigment epithelial cells are all long-lived postmitotic cells. Routes of administration for these cell types—either intravitreal or by subretinal injection—involve standard procedures in ophthalmology. Given the small space, doses required are relatively low, lessening the manufacturing burden. Finally, canine models of a number of inherited retinal dystrophies have been well-characterized and faithfully model the human diseases. Work carried out in the 1990s had demonstrated that the canine disease could be reversed, with durable restoration of visual behavior, by subretinal injection of an AAV vector in dogs with a mutation in the gene encoding RPE65, an enzyme key to the visual cycle. Like the canine disease, the human disease is characterized by early-onset visual impairment, with most patients progressing to blindness over time. Phase 1 clinical trials by multiple groups established the safety of subretinal injections of an AAV vector expressing RPE65. A single phase 3 trial, the first randomized controlled trial in human gene therapy, demonstrated improvement in multiple measures of retinal and visual function. Of note, and likely to be a recurring theme as gene therapies address diseases for which there are no existing treatments, successful clinical development required the development and validation of a novel clinical endpoint that could measure improvements in functional vision. This product, the first licensed AAV gene therapy product in the United States, is now approved worldwide (Table 483-2). Trials for both inherited and complex acquired retinal disorders such as age-related macular degeneration, affecting millions worldwide, are now underway.

Hemophilia B: Addressing More Common Genetic Disorders and Unraveling the Human Immune Response to Systemically Administered AAV Hemophilia is the X-linked bleeding diathesis caused by mutations in the genes encoding factor VIII (hemophilia A) or factor IX (hemophilia B) **(Chap. 121)**. Current treatment relies on intravenous infusion of clotting factor concentrates or, as an alternative in hemophilia A, administration of a bispecific antibody that replaces the cofactor factor VIII by binding to the enzyme (factor IXa) and its substrate (factor X), resulting in a biologically active conformation. Gene therapy for hemophilia began with hemophilia B, a smaller patient population compared to hemophilia A, but the *F9* cDNA is smaller (2.8 kb) and is more easily accommodated in an AAV vector. The early vectors were successful at demonstrating long-term expression of factor IX at therapeutic levels in hemophilic mice and dogs when vector was delivered to the liver (hepatocytes are the normal site of synthesis of factor IX), but the initial clinical trials uncovered a plethora of problems not predicted by animal models that had to be addressed to allow successful development to proceed. Fortunately, the solutions to these problems were generalizable across multiple

therapeutic indications that rely on systemic delivery of AAV vector (*vide infra*) (Table 483-4). Most complex among these was working out the human immune responses, both innate and adaptive, to the AAV vector. With systemic administration, the presence of neutralizing antibodies, harbored in a substantial portion of children and even more prevalent in adults, can prevent transduction before the target cells are reached, and the cellular immune response, not predicted by animal models, which are not natural hosts for AAV and thus lack memory T cells directed to the capsid, can result in the loss of the transduced cells in a matter of weeks after successful initial transduction. The preexisting antibodies can be screened for in advance, assuring that only those likely to benefit receive the therapy. The cellular immune response typically presents as asymptomatic transaminase elevation and concomitant loss of factor IX (or the transgene product) in the circulation. This response is dose-dependent and can be mitigated by the use of immunomodulatory agents such as glucocorticoids or by strategies that reduce the vector dose. The use of appropriately timed steroid treatment to dampen the cellular immune response resulted in the first report of durable factor IX expression in men with severe hemophilia B. The eventual widely adopted solution for hemophilia B gene therapy came from human genetics, specifically the use of a high specific activity variant of factor IX, factor IX Padua, that allowed a substantial reduction in vector dose and/or higher levels of circulating factor IX; this strategy has shown durable expression. The two currently approved hemophilia B gene therapies show an increase in mean factor IX levels well into the mild hemophilia range; these levels result in annualized bleeding rates that are noninferior to clotting factor prophylaxis in men with the disease.

Successful extension to hemophilia A required the use of a truncated version of the factor VIII cDNA. The only approved product drives therapeutic levels of expression, but durability has been less than that seen in gene therapy for hemophilia B.

Spinal Muscular Atrophy Type 1 Spinal muscular atrophy type 1 is the most common genetic cause of death in infancy and affects about 1 in 11,000 births. The disease is caused by autosomal recessive mutations in the *SMN1* gene, encoding survival motor neuron 1; affected infants undergo degeneration and loss of lower motor neurons, presenting as hypotonia, severe weakness, and failure to sit without support. In a large natural history study of untreated infants with the disease, by age 20 months, only 8% of patients with the disease were alive and free of ventilator support. In a phase 1 gene therapy study, intravenous infusion of an AAV vector (one with tropism for the nervous system [AAV9]) expressing SMN1 showed survival without ventilator support in 100% of participants (n = 15) at 20 months of age. A phase 3 trial was initiated, but the treatment was approved in the United States based on the efficacy data from the first 21 participants enrolled in that study, coupled with the safety data from the ongoing phase 3 and the completed phase 1 study (Table 483-2). The major safety concern was the risk of acute serious liver injury; because the vector is infused intravenously, there is considerable biodistribution to the liver (and to the spinal motor neurons, the therapeutic target). The approved dose of 1.1×10^{14} vector genomes/kg is quite high, and results in marked elevation of liver transaminases if untreated. Leveraging the results in the early hemophilia trials, the phase 1 study showed that the liver toxicity could be controlled using a course of corticosteroids begun 1 day before the vector infusion and continued for 30 days, with tapering begun at that point and carried out with monitoring of liver transaminases. Postmarketing studies revealed an additional rare adverse reaction, thrombotic microangiopathy (TMA). Presenting as thrombocytopenia, microangiopathic hemolytic anemia, and acute kidney injury, this constellation of findings in the setting of AAV gene therapy was first described in the AAV gene therapy trials for Duchenne muscular dystrophy, which also use very high doses of vector. When it occurs, TMA appears early after vector infusion, is complement-mediated, and has responded to complement inhibitors, i.e., eculizumab. Patients receiving onasemnogene abeparvovec are currently followed in a registry designed to assess effectiveness, long-term safety, and overall survival of patients with Spinal muscular atrophy.

IN VIVO GENOME EDITING

Clinical trials using ex vivo genome editing of HSCs by CRISPR/Cas9 systems have been ongoing for several years and have now led to the first approved genome editing product (*vide supra*). More recently, investigators have begun to explore the feasibility of in vivo genome editing, with intriguing results. As has been the case with ex vivo editing, these initial trials all center on strategies that require a cleavage step only, i.e., not a cleavage event followed by a targeting event. For in vivo editing of hepatocytes, lipid nanoparticles containing an mRNA encoding the Cas9 protein and a single guide RNA directed to the gene of interest are infused intravenously. The major safety concern involves the risk of off-target editing; an additional concern prior to clinical trials was whether a robust immune response to the bacterial Cas9 enzyme would result in unacceptable toxicity or loss of efficacy. Published experience to date does show mild, transient, dose-dependent rises in liver transaminases, but also robust efficacy in reducing circulating levels of transgene products of interest, including transthyretin in transthyretin amyloidosis and plasma kallikrein B1 in hereditary angioedema. Additional in vivo genome editing trials are underway, notably for cardiovascular conditions, to reduce circulating levels of lipoprotein(a), proprotein convertase subtilisin/kexin type 9 (PCSK9), or angiopoietin-like protein 3, all associated with atherosclerotic cardiovascular disease. An advantage of genome editing approaches is that the edit will be passed to every daughter cell; thus, changes should persist over time, and this treatment can be used even in children, without fear that the edit will be lost as the liver grows in size.

GENE THERAPY FOR CANCER

The majority of clinical gene transfer experience has been in subjects with cancer. The intent has been to increase the precision of cancer therapies and thereby make them less toxic and more effective. Most approaches have either modified the tumor directly or altered the host's response to the malignancy to produce immune effector cells that are precisely targeted to the tumor phenotype.

MODIFYING THE CANCER

Since cancer is an (acquired) genetic disorder, initial efforts were directed at correcting the genetic deficits of the tumor or introducing lethal genes. Two major and persisting obstacles, however, are the poor biodistribution and transduction efficiency of all currently available vectors, and the heterogeneity and genetic instability of the tumor targets themselves, so that correction of single driver mutations does not preclude the evolution of a resistant population.

Tumor Correction One widely used direct intratumoral approach was adenoviral-mediated expression of the tumor suppressor p53, which is mutated in many different cancers. Initial studies showed some complete and partial responses in squamous cell carcinoma of the head and neck, esophageal cancer, and non-small cell lung cancer, but as yet, there have been no successful product licensing studies for this approach except in China.

Prodrug Metabolizing Genes Efforts to overcome the above limitations have included the introduction of a prodrug or a suicide gene that would increase sensitivity of tumor cells to cytotoxic drugs. A strategy used early on was intratumoral injection of an adenoviral vector expressing the thymidine kinase (*TK*) gene. Cells that take up and express the *TK* gene can be killed after the administration of ganciclovir, which is phosphorylated to a toxic nucleoside by *TK*. The advantage of this approach is that the effects of transducing even a limited number of tumor cells are amplified by the spread of active drug to adjacent tumor cells. Although the approach continues to be examined in aggressive brain tumors and locally recurrent prostate, breast, and colon tumors, progress remains slow, and systemic benefits against metastatic disease have not been established.

MODIFYING THE HOST

Recruiting the Immune System The successful use of monoclonal antibodies that produce antitumor activity by activating the

immune response has demonstrated the feasibility of manipulating the immune system to recognize the abnormal pattern of antigen expression on tumor cells. Immune cells are capable of almost unlimited expansion and persistence and can provide long-term tumor control. They can also traffic to tumor sites irrespective of location and, in principle, have the potential to evolve with the changing pattern of tumor cell phenotype and function. Antibodies targeting "checkpoint" molecules, particularly CTLA-4 and the PD-1/PD-L1 axis, which naturally limit T-cell responses and maintain tolerance, have been particularly successful.

Vaccination This strategy promotes more efficient recognition of tumor cells by the immune system, but the development of a therapeutic as opposed to the preventative vaccines required to combat infectious diseases has proved to be a considerable challenge. Approaches have included direct injection of tumor or tumor-antigen–derived RNA or DNA; transduction of tumor cells with immune-enhancing genes encoding cytokines, chemokines, or co-stimulatory molecules; and the ex vivo manipulation of dendritic cells to enhance the presentation of tumor antigens. A dendritic cell vaccine for treatment of recurrent prostate cancer has received approval in the United States, but its limited potency and high cost have constrained commercial success.

Adoptive Cell Transfer Host immune cells such as T cells, NK cells, and others can be modified to express new transgenic receptors intended to recognize tumor cells and their microenvironment (Fig. 483-1). Retargeting may use a modification of the cells' own receptor or a molecularly synthesized CAR that is usually composed of the antigen recognition portion of an antibody and the signaling components of the cell's native antigen receptor along with one or more additional signaling domains that boost T-cell activation. Both approaches have been successful, with significant responses reported with native receptors targeted to melanoma and synovial cell sarcoma and—most dramatically—with CARs targeted to CD19, an antigen expressed at high levels on normal and many malignant B cells, or B-cell maturation antigen (BCMA), an antigen expressed at high levels in normal and multiple myeloma plasma cells. Infused CAR T cells can expand many thousand-fold in vivo, persist long term, and have produced >80% complete response rates when targeting intractable B-cell acute lymphoblastic leukemia; approximately half of those patients have remained in remission for many years afterward without further cancer therapies (i.e., have been "cured"). This approach has also been successful in adult patients with relapsed or chemotherapy-refractory B-cell–derived large cell lymphoma, mantle cell lymphoma, and multiple myeloma. Many responses are sustained long term, and several of these CAR T-cell products have been approved by the U.S. Food and Drug Administration (FDA), as well as international regulatory agencies, and adopted as standard of care. In 2021, the first reports of T-cell lymphoma were reported with the use of piggyBac-modified (transposon) CAR-T therapy; 2 of 10 patients developed CAR-T lymphoma, but this may have been a result of widespread copy number variations and multiple insertions, and there was no apparent evidence of insertional mutagenesis. In November 2023, the FDA issued a warning for most approved CAR-T therapies, all of which use retroviral or lentiviral vectors for gene delivery of the CAR, suggesting that there was a higher-than-expected rate of T-cell lymphoma and that patients treated with CAR-T therapy should be monitored for secondary malignancies for life. Nevertheless, the overall benefits of these products continued to outweigh their potential risks for their approved uses. Although the FDA did not list the frequency, a flurry of subsequent reports noted that the rate of T-cell malignancies after CAR-T treatment for patients with relapsed or refractory hematologic malignances was ~20 in 34,000 patients (~0.06%); however, because reporting to the FDA on the incidence of T-cell malignancies is voluntary once products are approved, it is possibly an underestimated frequency. A boxed warning listing the possibility of secondary malignancies was added to the label of most CAR-T products in January 2024, and the FDA published instructions on reporting secondary malignancies to the community in order to gather more information. It is important to keep in mind that the vast majority of secondary malignancies in patients treated with approved CAR-T therapies are unrelated to the presence of the CAR transgene, including solid tumors and myeloid malignancies; such secondary malignancies may be related to age, the presence of clonal hematopoiesis, and exposure to prior chemotherapy or other antineoplastic treatments.

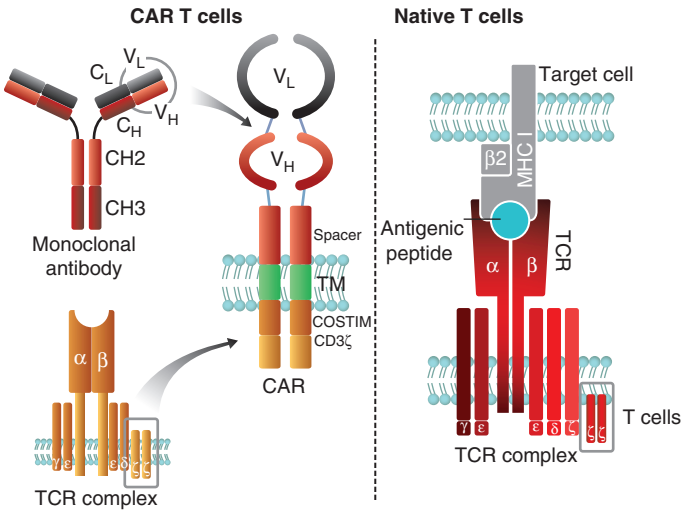

FIGURE 483-1 T-cell receptors. A native T-cell receptor (TCR) recognizes processed peptide antigens bound to major histocompatibility (MHC) molecules through its αβ chains. Signaling then occurs through a multichain intracellular CD3 complex. A chimeric antigen receptor (CAR) usually contains an extracellular receptor component derived from the antigen binding portion (V_H and V_L) of a monoclonal antibody. This produces a receptor that can recognize either protein or nonprotein antigens independent of the MHC. A transmembrane (TM) domain then connects this receptor to the ζ chain of the CD3 complex derived from the native TCR. A costimulation domain (COSTIM), such as CD28 or 4-1BB, is also present.

The general approach of CAR-T therapy is under rapid development, including trials with CAR T cells targeting different antigens for solid tumors and other hematologic malignancies and CAR T cells with different molecular structures and different gene transfer vectors. Remaining challenges in the field and application of adoptive T-cell approaches include the following: (1) the immune inhibitory microenvironment associated with most solid tumors, and recent studies further modify the T cells with countermeasures to tumor inhibitory signals; (2) acute and severe (though rarely fatal) systemic inflammatory and neurologic toxicities during the phase of T-cell expansion and tumor killing, which typically require access to intensive care for clinical management; (3) the off-target or on-target but off-tumor effects that may damage normal host tissues (e.g., normal B cells following CD19 CAR therapy); and (4) the cost, time, and complexity of manufacture, which are particular problems when antigens unique to each tumor's individual mutations are targeted (neoantigens), rather than widely shared tumor-associated antigens.

Nonimmunologic Modifications to Host Gene transfer can be used to protect normal cells from the toxicities of chemotherapy and thereby increase the therapeutic index of these drugs. The most extensively studied approach has been to transduce hematopoietic cells with genes encoding resistance to chemotherapeutic agents, including the multidrug resistance gene *MDRI* or the gene encoding O^6-methylguanine DNA methyltransferase (*MGMT*). Although such approaches reduce hematologic toxicity, cytotoxic dose escalation quickly reveals dose-limiting toxicities to other organ systems. Chemotherapy resistance can also be engineered into immune cells redirected to target cancer, to enable combination treatments with cells and chemotherapy.

Finally, gene transfer can be used to inhibit the host angiogenesis required for tumor support, for example by constitutive expression of inhibitors such as angiostatin and endostatin, or the transfer of T cells genetically modified to recognize antigens specific to newly forming vasculature. These studies are in early phases.

COMBINATION APPROACHES: MODIFICATION OF HOST AND TUMOR BY VIROTHERAPY—IMMUNO-ONCOLYTIC VIRUSES

These viruses are genetically modified to replicate in malignant but not normal cells. The replicating vectors thus proliferate and spread within the tumor, facilitating eventual tumor clearance. However, physical limitations to viral spread, including fibrosis, intermixed normal cells, basement membranes, and necrotic areas within the tumor, may reduce clinical efficacy, and their activity against metastatic disease has proved limited. Recently, the FDA granted licensing approval to talimogene laherparepvec, an oncolytic herpes virus containing the human granulocyte-macrophage colony-stimulating factor (GM-CSF) gene, for treatment of melanoma. This success has led to resurgent interest in combining the local tumor destruction and tumor antigen release mediated directly by oncolytic viruses with the recruitment of a systemic immune response mediated by immunostimulatory genes contained within the oncolytic virus. In principle, such immune-oncolytic viruses should produce responses in both local and metastatic disease. Numerous novel viral agents are now entering early-phase clinical testing.

SUMMARY AND FUTURE DIRECTIONS

Cell and gene therapies have progressed from halting beginnings to the current status as the fastest-growing sector of medicine and the health care industry. The speed of technical evolution results in a continuously changing landscape. Key advances likely to assume greater importance in the coming decade include bioengineered AAV capsids selected for tropism and increased expression, leading to lower doses, fewer adverse events, and lower manufacturing burden; extension of therapeutic trials from single-gene disorders to complex acquired disorders, including chronic heart failure, age-related macular degeneration, and Alzheimer's disease; continued expansion of in vivo genome editing; and application of CAR-T technology to solid tumors and autoimmune disorders (e.g., systemic lupus erythematosus). The power and versatility of gene therapy approaches are such that there are few serious disease entities for which gene therapies are *not* under development. Approved products and examples of clinical success are now abundant, and cell and gene therapies are likely to become increasingly important as therapeutic modalities in the twenty-first century. Realization of the therapeutic benefits of modern molecular medicine will depend on continued progress in cell and gene therapy technology.

484 The Human Microbiome in Health and Disease

Neeraj K. Surana, Dennis L. Kasper

"All disease begins in the gut."

—Hippocrates

Nearly two and a half millennia after Hippocrates made this statement, we are just coming to truly appreciate its profundity. Since the beginning of humankind, scholars have been investigating the underpinnings of disease with an almost singular focus on the human side of the equation. Microbes were not recognized as an important cause of disease until the inception of the "germ theory" in the late nineteenth century. During the first century of medical microbiology, research largely centered on the role of microbes as pathogens. Only recently has there been a resurgence of interest in understanding how commensal organisms—the bacteria, viruses, fungi, and Archaea that make up the *microbiota*—impact human physiology. The idea that these microorganisms are vital to the well-being of humans has challenged our traditional notions of "self." Indeed, a human being can most accurately be described as a *holobiont*: a complex assemblage of human cells and microorganisms interacting in an elaborate *pas de deux* that drives normal physiologic processes.

Aimed at a better understanding of this relationship, myriad studies during the past decade have begun to catalogue the microbiota at various body sites and in a multitude of disease conditions. Diseases in virtually every organ system have been associated with changes in the microbiota. Indeed, the microbiota has been linked to intestinal disorders, disturbances in metabolic function, autoimmune diseases, and psychiatric conditions and has been shown to influence susceptibility to infection and the efficacy of pharmaceutical therapies. Knowledge of the specific mechanism(s) underlying most of these microbe–disease associations is lacking; it remains unclear whether the disease-associated alterations in the microbiota represent mere biomarkers of disease, a causal relationship, or a combination of the two. Although cause-and-effect relationships are still being elucidated for many diseases, it is clear that humans coexist in an intricate relationship with commensal organisms. This chapter explores in detail the nature of these host–commensal interactions, focusing on how this information might be translated into clinically meaningful interventions.

HISTORICAL PERSPECTIVE

Massive undertakings, such as the Human Microbiome Project (HMP) sponsored by the National Institutes of Health and MetaHIT sponsored by the European Commission, have catalogued all the bacteria present at multiple body sites in people with and without disease. Coupled with the confluence of advances in sequencing technologies **(Chap. 126)**, gnotobiotic animal availability, and microbial culture, significant progress has been made toward an understanding of the interplay between the microbiota and human health. However, current findings were foreshadowed by work done centuries ago.

The human microbiota was first explored in 1683 when Antony van Leeuwenhoek described in a letter to the Royal Society of London the "very little living animalcules, very prettily a-moving" that he had observed in the plaque between his teeth. Leeuwenhoek went on to perform the first comparative "microbiota" studies by assessing how fecal and oral bacteria differ, how oral microbes change in the setting of disease (e.g., alcoholism and tobacco use), and how microbial composition changes across the age spectrum (e.g., in young children vs old men). He attempted—unsuccessfully—to eliminate these bacteria. Although Leeuwenhoek was not taken seriously when he first reported his findings, his studies laid the groundwork for what is now the field of microbiome research, and investigators are still trying to answer

many of the same overarching questions that he raised more than three centuries ago.

Although Leeuwenhoek first reported the existence of bacteria and their association with humans at the end of the seventeenth century, the significance of commensal bacteria was not realized until late in the nineteenth century. In 1885, Pasteur suggested that animals could not survive if they were "artificially and completely deprived of the common microbes." Although Pasteur's preconceived ideas were proven incorrect in 1912 by the advent of germ-free (GF) animals (animals raised without exposure to any microorganisms), the underlying concept that commensal organisms are critical to health has held up. Élie Metchnikoff made another conceptual advance in this field by suggesting at the beginning of the twentieth century that clinical outcomes could be altered by the administration of specific beneficial organisms (*probiotics*). In particular, Metchnikoff believed that aging was caused by toxic bacteria in the gut and that lactic acid–producing bacteria (e.g., *Lactobacillus* species) present in sour milk and yogurt could mitigate against this process. The data behind this specific claim are still lacking, but contemporary discoveries offer continued hope that the microbiome can be effectively harnessed to protect against and treat a variety of diseases. Thus, although the field of microbiome research is sometimes considered to have emerged over the last two decades, the basic tenets—that the microbiota varies according to body site and clinical characteristics, that microbes are critical for human health, and that specific modulation of the microbiota may lead to improved clinical outcomes—are far from new.

A PRIMER ON TAXONOMY

Given that microbiome-based studies have identified and compared microbes at different levels of taxonomic resolution **(Fig. 484-1)**, some understanding of taxonomy is essential for better comprehension of the implications of these studies. Of the ~100 bacterial phyla that exist in nature, only five (Actinobacteria, Bacteroidetes, Firmicutes, Fusobacteria, and Proteobacteria) are dominant members of the human microbiome. Each of these phyla can be further categorized into multiple classes, orders, families, genera, and species. Early studies on the microbiota focused on changes in the relative abundance at the phylum level between different groups (e.g., obese vs normal-weight patients); however, these comparisons are at such a broad taxonomic level that they often provide little or no biologic insight. As illustrated in Fig. 484-1, drawing comparisons between organisms in two different bacterial phyla is analogous to comparing humans to sea stars: the evolutionary distance between the two is tremendous. Examining microbial profiles at the phylum, family, or even genus level—as is often done at present—ignores the great heterogeneity within different strains of the same bacterial species. The analytical pipelines are beginning to enable strain-level comparisons, and these improvements will likely facilitate our ongoing investigation of host–commensal interactions.

THE MICROBIOTA AND HUMAN HEALTH

OVERVIEW OF THE HUMAN MICROBIOTA

The overwhelming majority of microbiota studies have focused on stool, given that this sample type represents the most ecologically rich anatomic site, is easy to obtain, and can readily be followed longitudinally in the same individual. A landmark study by the HMP sought to define the "normal" microbiota throughout the entire body in healthy Western adults. To this end, the microbial populations at 15–18 body sites were characterized in 242 people. One striking finding was that all samples from a given body region (e.g., skin) were more similar to each other than they were to samples from a different body region (e.g., stool), even in the same individual **(Fig. 484-2*A*)**. In essence, the effect of the anatomic site on microbial composition is far greater than the effect of heterogeneity between individuals. That said, there was a remarkable amount of interindividual variation at any given body site **(Fig. 484-2*B*)**. In stool, for example, the abundance of the phylum Bacteroidetes ranged from ~10% in some individuals to >90% in others. Remarkably, even with person-to-person variability and differences among body sites, the functional capacity of the microbiota—assessed using metagenomic data to identify gene pathways—was quite similar across different people and different body sites **(Fig. 484-2*C*)**. This discrepancy between the substantial differences in microbial composition and the little or no resulting change in the functional properties of the microbiota reflects an important ecologic property of the microbiota: the microbial communities at different body sites and in different people assemble in such a way that all the core metabolic functions are maintained. This finding also hints at the likely possibility of significant functional redundancy within the microbiota, with different species executing the same biologic functions in different people and/or at different anatomic sites.

While the HMP provided the first large-scale catalogue of the microbiome in multiple people and at many different body sites, the amount of data generated by what, at the time, was by far the largest microbiome study has been dwarfed by subsequent studies. These more recent studies have confirmed the HMP's major tenets: the composition of the microbiota differs by body site, there is tremendous interindividual variation, and the microbial gene content is relatively conserved irrespective of the body site or individual. No microbial species are ubiquitous in all individuals and at all body sites, but some species are highly prevalent at a given body site: in the HMP study, *Staphylococcus epidermidis* was present in 93% of nares samples and *Escherichia coli* in 61% of stool samples. These findings highlight the remarkable personalization of the human microbiome. While the human genome is typically >99.5% identical in different people, the microbiotas of two individuals may not overlap at all. Although the "precision medicine" approach currently focuses on teasing out how differences in the human genome relate to different clinical end

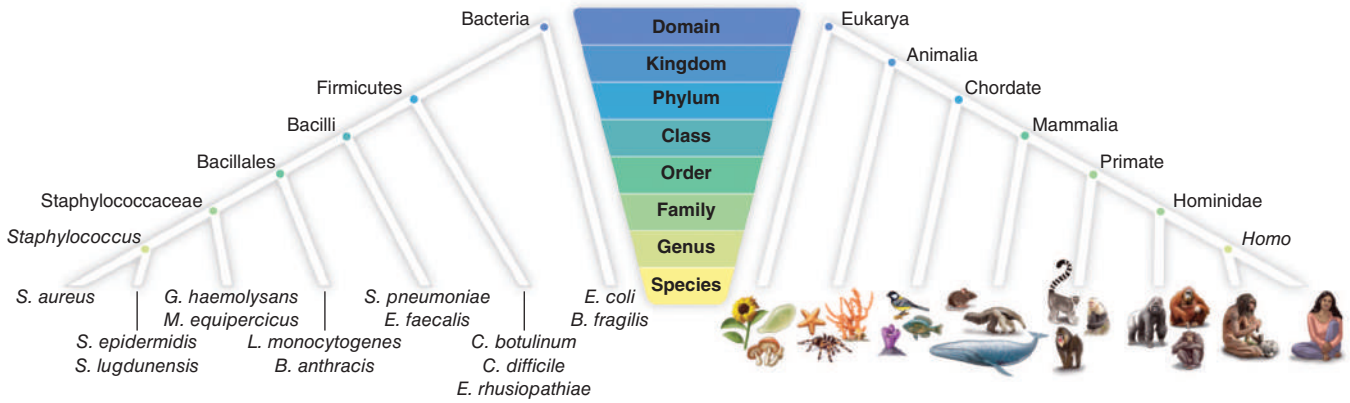

FIGURE 484-1 Juxtaposition of bacterial and human taxonomy highlights the evolutionary distance between different taxonomic levels. The listed species represent exemplars that are members of the taxon to which they are connected but that are not contained within the next-lower-level taxon listed. For example, *Clostridium botulinum, Clostridioides difficile,* and *Erysipelothrix rhusiopathiae* are members of the phylum Firmicutes, but are in classes other than Bacilli. Similarly, starfish and humans are both members of the kingdom Animalia, but they are in different phyla.

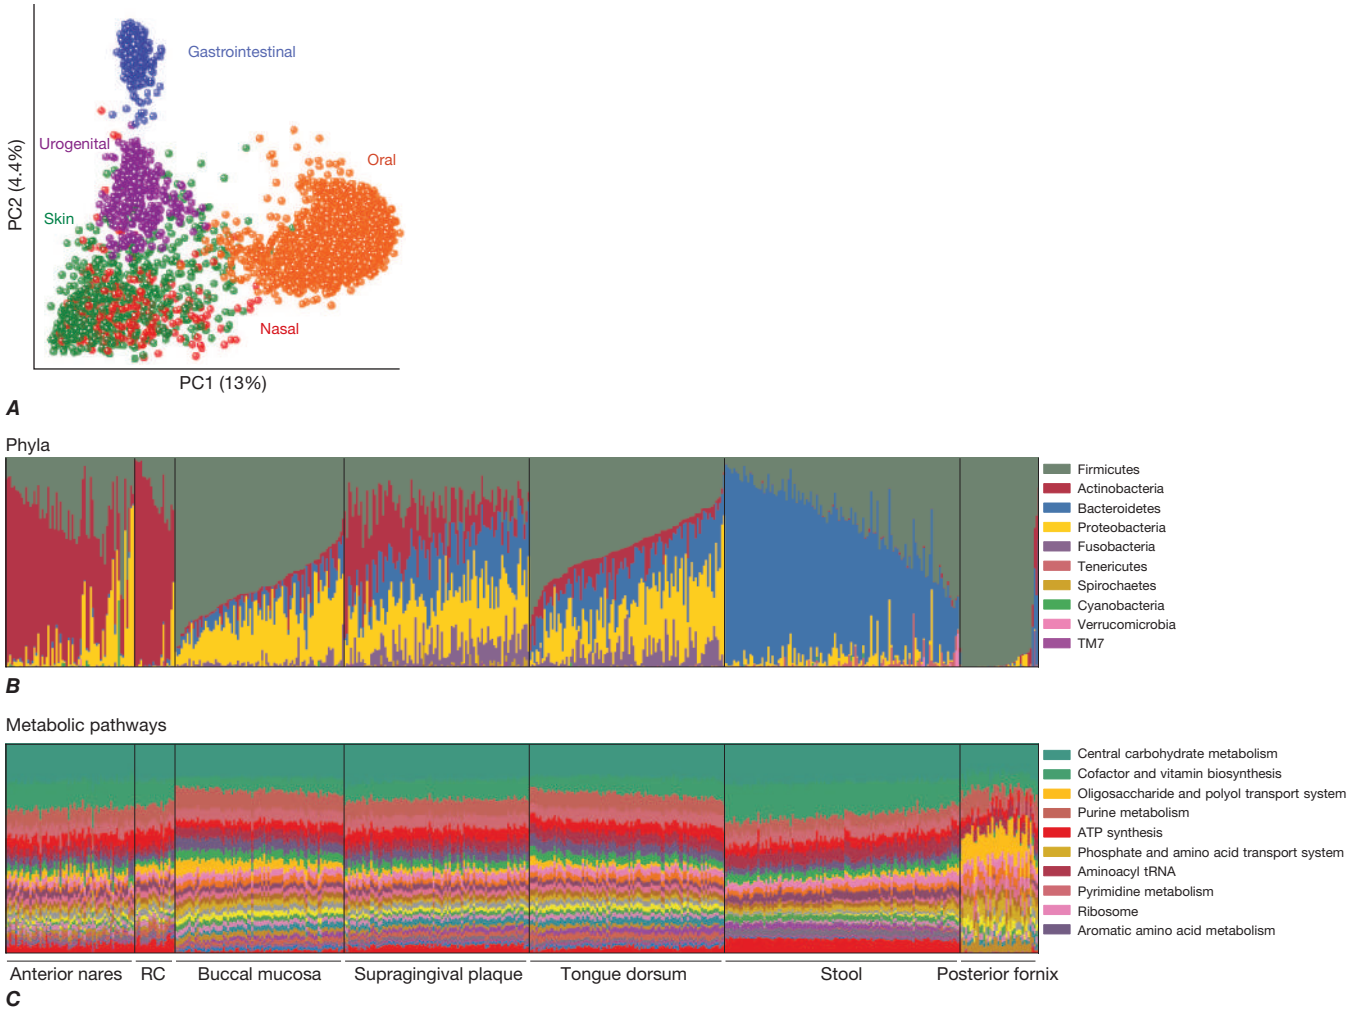

FIGURE 484-2 The human microbiome exhibits significant taxonomic variability among body sites and between individuals while maintaining core metabolic pathways. ***A.*** Principal coordinates (PC) plot showing variation among samples demonstrates that primary clustering is by body area, with the oral, gastrointestinal, skin, and urogenital habitats separate; the nares habitat bridges oral and skin habitats. Each circle represents an individual sample. ***B, C.*** Vertical bars represent microbiome samples by body habitat, with each bar within a given body site representing a different individual. Bars indicate relative abundances colored by microbial phyla (***B***) and metabolic pathways (***C***). The legend on the right indicates the most abundant phyla/pathways. RC, retroauricular crease. *(Reproduced with permission from Human Microbiome Project Consortium: Structure, function and diversity of the healthy human microbiome. Nature 486:207, 2012.)*

points, the human microbiome clearly represents a critical component for consideration.

THE MICROBIOTA BY THE NUMBERS

It has long been known that the human-associated microbiota is numerically dense. Leeuwenhoek estimated that there were more "animals living in the scrum on the teeth in man's mouth than there are men in a kingdom." Specific enumeration of the components of the microbiota has been challenging, in part because of its variability across time, space (body region), and clinical conditions. Moreover, the majority of human-associated microbes are not readily cultivable—a situation that raises questions about the best methodology for such quantitation. Initial back-of-the-envelope calculations performed in the 1970s suggested that there were roughly tenfold more bacteria in the body than there were human cells. This rather astounding estimate suggested that humans are really only ~10% "human" and that by far the greatest part of the holobiont is represented by microbes. This stark numerical discrepancy has prompted some to question "who parasitizes whom." However, it has been suggested that there are "only" ~1.3 times more bacteria in the body than there are human cells and thus that humans are ~56% "bacterial." Of note, this study does not include the numbers of viruses (known to generally be approximately tenfold more abundant than other microbes), fungi, or Archaea. Given these additional microorganisms, the notion that microbes constitute >90% of the cells present in a human body is likely correct. These ratios are even starker when one considers the genetic potential of human cells versus that of commensal organisms. In contrast to the ~20,000 genes in the human genome, the estimated total number of genes in the microbiota (which together constitute the *microbiome*)—i.e., >2,000,000—indicates that the human genome contributes <1% to the total genetic potential of the overall holobiont. Most microbiome studies have focused almost exclusively on the bacterial component; much remains to be learned about the functional interplay of bacteria, viruses, fungi, and Archaea and how these other classes of microorganisms impact human health.

In terms of overall diversity, >10,000 different bacterial species are present in the human microbiota; the intestines alone contain >1000 species. At any given time, the body of any given individual harbors 500–1000 bacterial species, with 100–200 bacterial species in the gut alone. If one considers different strains of the same bacterial species, which may be functionally different from one another, the diversity of the microbiota is probably at least an order of magnitude greater. Although marked diversity exists at the strain and species level, only limited bacterial phyla are generally found in the human microbiota at any given body site **(Fig. 484-3)**.

INFLUENCES ON THE MICROBIOTA

An individual's specific microbial configuration is dynamic and is quickly altered in response to subtle changes in the microenvironments in which the bacteria reside. On a day-to-day basis, these changes usually reflect alterations in the relative abundance of the various microbes. However, some exposures have a greater effect on

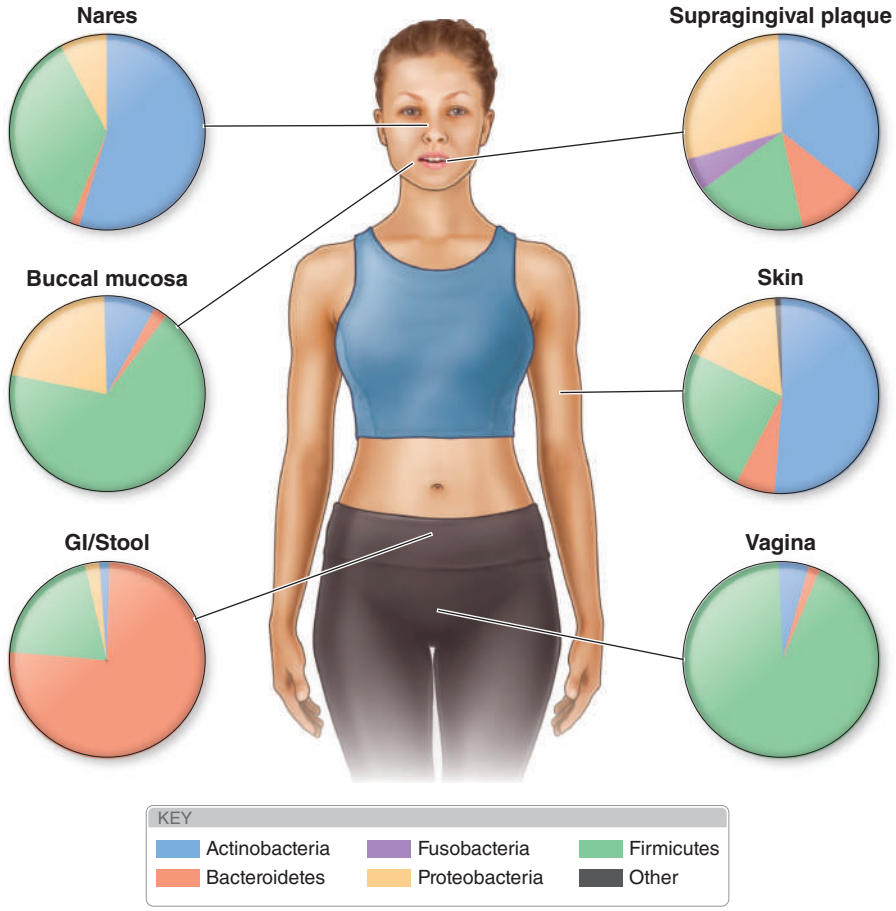

FIGURE 484-3 Different anatomic sites harbor very different microbiomes. The figure indicates the relative proportion of sequences determined at the taxonomic phylum level at six anatomic sites. *(Data for stool, vagina, nares, buccal mucosa, and supragingival plaque are from the Human Microbiome Project; data for the skin are from EA Grice et al: Topographical and temporal diversity of the human skin microbiome. Science 324:1190, 2009.)*

the microbiota and can shift the microbial population to a new equilibrium via the loss of specific species and/or the acquisition of others; this new microbial equilibrium can be associated with either health or a disease state **(Fig. 484-4)**. Identification of the factors that influence the microbiota's composition is critical to an understanding of what leads to and controls intra- and interindividual variation. Moreover, an understanding of the influences on the microbiota will facilitate the design and proper interpretation of microbiota studies. While it is clear that the microbiota can be altered through these various mechanisms, it is not yet clear whether these changes are biologically significant.

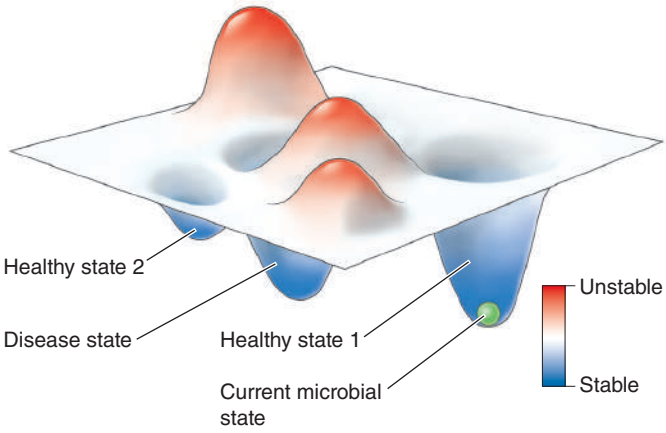

FIGURE 484-4 A stability landscape of the human microbial ecosystem. A stable state, illustrated as a depression in the landscape, can be associated with either a healthy state or a disease state. The topology of an individual's landscape reflects that person's genetics, age, diet, medications, medical history, and lifestyle. The position of the green ball represents the current microbial state. Clinical changes (e.g., administration of antibiotics, development of disease) can influence both the current state and the overall topology.

Genetics Studies of monozygotic and dizygotic twins have revealed that host genetics have a small but statistically significant effect on the microbiota's composition. Notably, some taxa, such as *Christensenella* species, are more heritable than others. A cross-sectional study of >1000 healthy individuals who have distinct ancestral origins and a relatively shared common environment confirmed a weak association between host genetics and the microbiome but highlighted that environmental factors are more prominent modulators of the microbiome. That said, the host's genetic contribution to the microbiota, albeit small, may be meaningful. Studies in mice have demonstrated that genetic variation in the major histocompatibility complex, a specific set of immune-related genes, leads to changes in the microbiota that alter susceptibility to an autoimmune disease. These studies offer a proof of concept for the notion that the genetic predisposition observed for certain diseases may actually be mediated by indirect alterations in the microbiota.

Age Burgeoning evidence now indicates that microbial exposure may begin in utero: bacterial DNA from bacteria typically associated with the oral microbiota has been identified in otherwise healthy placentas, in amniotic fluid obtained at early stages of gestation, and in meconium of term newborns. Although some controversy persists about whether these results reflect contamination and/or the presence of nonviable bacteria, they raise the possibility that human exposure to the microbial world begins before birth. The delivery mode (vaginal vs cesarean section) and the method of feeding (breast milk vs formula, timing of solid food introduction) are major determinants of an infant's early microbiota. After birth, the infant's microbiota goes through a stereotyped succession process; with increases in bacterial diversity and functional capacity, the child's microbiota resembles that of an adult by the age of 2–3 years. Cross-sectional studies that have examined the microbiota across the entire age spectrum have revealed a general stability of the fecal microbiota after 2–3 years of age; however, the microbiota of the elderly (persons >80 years of age) demonstrates notable differences from those of their younger counterparts, with increases in *Bacteroides* and *Eubacterium* species and decreases in the bacterial family Lachnospiraceae. Although there has been significant interest in defining microbial features that predispose towards longevity, there has been poor concordance of findings between studies, potentially due to very different populations being studied.

Diet Diet is a strong determinant of human health. The impact of diet is mediated, in part, by its effects on the composition of the gut microbiota. This makes intuitive sense, as the human diet provides nutrients needed not only by our own cells but also by the microbes living in the alimentary tract. In young children, this dietary influence is marked by major shifts (e.g., a decrease in *Bifidobacterium* species) in the intestinal microbiota that occur at weaning and with the introduction of solid food. In adults, long-term dietary patterns are associated with relatively stable microbial compositions. However, drastic changes in short-term macronutrient availability cause rapid (within 1 day) and reproducible fluctuations in the fecal microbiota that reflect the biologic processes needed to degrade and metabolize the nutrients in the new diet. For example, vegetarian diets are associated with a microbiota

that has an increased ability to metabolize plant polysaccharides (e.g., *Roseburia* species, *Eubacterium rectale*, *Ruminococcus bromii*), while animal-based diets result in an increased abundance of bile-tolerant organisms (e.g., *Alistipes*, *Bilophila*, and *Bacteroides* species). At the completion of dietary interventions and the resumption of the individual's normal dietary pattern, the microbial communities revert back to their previous states, probably because the individual resumes their typical diet. Taken together, dietary studies confirm that the microbiota is highly adaptable and varies in relation to changes in the diet. Of note, virtually all these studies have focused on how the diet influences the fecal microbiota, with emerging evidence showing that it may similarly influence the microbiota at some nonintestinal sites.

Drugs Virtually all drugs have the capacity to change the microbiota by altering the chemical landscape in which the microorganisms live (e.g., statins, bile acid sequestrants), modulating the host's ability to recognize and react to microbes (e.g., immunosuppressants) and/or directly interfering with the microbiota's constituents (e.g., antibiotics). These potential effects have made critical interpretation of microbiota studies much more difficult. A prominent study that claimed to identify a fecal microbiota signature associated with type 2 diabetes was later found actually to have identified a signature for patients taking metformin instead; the effects of this drug on the microbiota were far greater than the effects of the disease itself. These results highlight the importance of controlling for clinical variables in microbiota studies.

Antibiotics are the most obvious and best-studied class of drugs that modulate the microbiota. Multiple groups have demonstrated that antibiotics exert a considerable effect on the gut microbiota by depleting antibiotic-sensitive strains. What is more surprising is that many strains resistant to the antibiotic tested are also eliminated. For example, treatment with ciprofloxacin, which has little to no activity against clinically relevant anaerobes, leads to a loss of roughly one-third of the bacterial taxa in the gut. This broad effect is likely mediated by the depletion of certain "keystone" species that are required for the persistence of other, unrelated species and highlights the intricate microbe–microbe interactions that are fundamental to maintenance of the overall microbial community. While many of the observed antibiotic effects (e.g., loss of specific taxa) are shared across many different individuals, some effects vary greatly among people. For example, studies found that microbiota recovery following antibiotic treatment differed significantly in terms of timing and degree. The microbiota of most healthy people who received ciprofloxacin for 5 days had completely recovered within 4 weeks, whereas microbiologic changes lasted up to 6 months in other individuals. Moreover, the degree of variation was compounded by repeated antibiotic administration, with fewer individuals reverting to their baseline microbiota after a second course of ciprofloxacin given 6 months after the first. These findings are consistent with those of microbial ecology experiments, which also showed that this type of repeated disturbance leads to less predictable results.

Lifestyle Many seemingly innocuous lifestyle decisions can impact the human microbiota. For example, a person's skin and fecal microbiotas are more similar to those of their household members, regardless of genetic relatedness, than to those of residents of different households. The degree of similarity in skin microbiotas is even greater if a dog also lives in the home; in contrast, the presence of a cat or a young child does not accentuate this microbial relatedness. The presumption is that the dog serves as a more effective "vector" for transmitting microbes during its frequent direct contact with adults in the household. The type of setting in which a person lives also impacts the microbiota. Living in a rural or farm setting leads to a different fecal microbiota than living in an urban environment. Similarly, the individual's country of residence affects the microbiota. An analysis of daily fecal samples from an individual who temporarily (i.e., for a couple of months) moved from the United States to Thailand demonstrated a large shift in the fecal microbiota that coincided with arrival in Thailand and a reversion in most respects to the "American" microbial configuration upon return to the United States. Similarly, immigration to the United States "westernizes" the microbiome of individuals coming from non-Western countries. These geography-driven changes probably reflect a combination of environmental and dietary differences between locations.

Circadian Rhythms Many human biologic processes follow a circadian clock; aspects of physiology are tuned by external cues, including the degree and timing of ambient light, temperature, and availability of nutrients. This endogenous biologic clock enables animals to efficiently adapt to changing environmental conditions. Similarly, the microbiota maintains a circadian rhythm that is linked to—and helps entrain—the host's circadian clock. If circadian oscillations are disrupted in the host, they are similarly disrupted in the microbiota, and vice versa. These bacterial vacillations occur at the level of spatial localization within the intestine, relative species abundance, and bacterial metabolite secretion. Work in the 1960s showed that mice exhibited daily periodicity of susceptibility to infection with either *Streptococcus pneumoniae* or *E. coli* lipopolysaccharide (LPS). Although the fundamental basis for this difference was not known at the time, it is likely to be related, in part, to the microbial circadian clock. Derangements of these microbial oscillations have also been linked to the development of metabolic diseases and may underlie some of the health hazards associated with shift work and jet lag.

THE MICROBIOTA AND DISEASE

THE HYGIENE HYPOTHESIS

Over the past few decades, abundant epidemiologic data have revealed an inverse correlation between exposure to microbes and the incidence of autoimmune and/or atopic diseases **(Fig. 484-5)**. This type of epidemiologic correlation led to the proposal of the "hygiene hypothesis" in 1989. Initially, this hypothesis focused on the development of atopic diseases in young children, with the idea that these epidemiologic observations could "be explained if allergic diseases were prevented by infection in early childhood, transmitted by unhygienic contact with older siblings, or acquired prenatally from a mother infected by contact with her older children."[1] In fact, this notion that differences in living conditions and environmental exposures contribute to susceptibility to hay fever (*summer catarrh*) dates back to at least the early nineteenth century. The hygiene hypothesis has continued to evolve over the past three decades and now posits that inadequacies in microbial exposure—in combination with genetic susceptibilities—lead to a collapse of the normally highly coordinated, homeostatic immune response. At its core, the hygiene hypothesis holds that specific early-life microbial exposures are required to prevent subsequent disease and that the "westernization" of society has led to a decrease in such exposures. This concept is being applied beyond atopic diseases to other inflammatory and autoimmune diseases and is thought to reflect processes that occur in later life as well.

RELATIONSHIP BETWEEN THE MICROBIOTA AND SPECIFIC DISEASE STATES

The ideas inherent in the hygiene hypothesis—in sum, that microbial exposure can affect long-term health outcomes—laid the theoretical foundation for translational microbiome studies. While most of the studies described earlier sought to describe how the microbiota responds to specific and often transient influences (e.g., a course of antibiotics, dietary interventions, travel), a multitude of studies have characterized the microbiota in patients with various diseases in the hope that a better understanding of the nature of disease-specific microbial communities will provide insight into disease pathogenesis and potentially uncover novel treatment modalities. Remarkably, virtually all these studies have demonstrated differences between the microbiotas of healthy controls and patients, irrespective of the specific disease process examined. Although it is difficult to generalize across all studies, a couple of general themes have emerged. First, disease states are typically associated with microbiotas that are less diverse than those of healthy individuals. This loss of diversity can be measured

[1] D. Strachan: BMJ 299:1259, 1989.

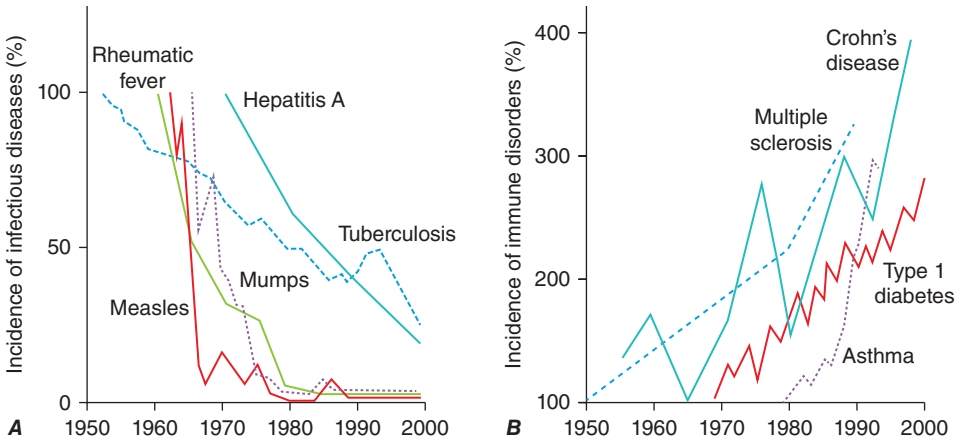

FIGURE 484-5 There was an inverse relationship between the incidence of select infectious diseases and the incidence of autoimmune disorders during the latter half of the twentieth century. *A.* Relative incidence of prototypical infectious diseases from 1950 to 2000. ***B.*** Relative incidence of select autoimmune disorders from 1950 to 2000. *(From JF Bach: The effect of infections on susceptibility to autoimmune and allergic diseases. N Engl J Med 347:911, 2002. Copyright © 2002, Massachusetts Medical Society. Reprinted with permission from Massachusetts Medical Society.)*

either as a decrease in the number of species (*alpha diversity*; often measured as the number of operational taxonomic units or amplicon sequence variants, which are the bioinformatic equivalent of species) or as a reduction in the microbial relatedness of the species present (*beta diversity*). Often, both alpha and beta diversity decrease in the setting of disease. Second, states of inflammation—regardless of site or underlying disease process—are often associated with an increase in the relative abundance of the bacterial family Enterobacteriaceae and a decrease in the relative abundance of Lachnospiraceae.

Dissecting Correlation and Causality Given that most of these investigations have been designed as case-control studies, it is difficult to determine whether microbiologic findings are the cause or the effect of the disease. Even studies that examine treatment-naïve patients at the time of initial diagnosis are still confounded by this "chicken or egg" issue. Moreover, prospective, longitudinal clinical studies—still rare in the microbiome field—may simply yield correlations between the microbiome and subclinical disease rather than necessarily proving causality. Experiments in animals—specifically, studies using gnotobiotic mice (GF mice that have been colonized with specified microbial communities)—have been critical in this regard as they allow investigation of specific differences in microbial components while controlling for the host's genetics, diet, and housing conditions. Moreover, human microbes can be transplanted into gnotobiotic mice to permit in-depth mechanistic studies of how these microbial communities affect disease pathogenesis. This marriage of human samples and animal experiments has facilitated the identification of causal roles played by some microbes in disease pathogenesis; these findings provide a critical proof of concept for the interplay of the microbiota with human health. However, the vast majority of microbiome studies are still at the level of correlation. The next several sections describe the clinical and animal data for many different disease processes. Given the voluminous and rapidly changing nature of this field, it is impossible to cover all of the disease associations known to date; rather, the following discussion represents a combination of the leading exemplars of microbiome data and nascent areas of significant clinical interest. In all cases, the hope is that further study of the role of the microbiota will provide novel diagnostics, new therapeutic modalities, and/or additional insight into disease pathogenesis.

Gastrointestinal Diseases Given that the intestines harbor the largest number and greatest diversity of organisms in the body, much work has focused on how the microbiota impacts gastrointestinal diseases. Even though the luminal surface area of the gastrointestinal tract is 30–40 square meters (~90% of which is contained within the small intestine) and features marked anatomic and functional differences that result in many discrete macro- and micro-ecosystems, stool is often used as a surrogate for the intestinal microbiota given the relative ease of collecting samples. A few studies that have compared the microbial profile in stool with the mucosa-adherent organisms present in biopsy samples have demonstrated that stool is, in fact, a reasonable proxy for biopsy samples; however, the relative microbial "noise" present in stool can sometimes overwhelm the "signal," making biopsy samples more informative for some scientific questions. The key issue is to ensure that the biopsy samples evaluated represent relatively similar intestinal regions, as there are significant differences between the organisms present in the crypt and the tip of the villus and between microbes found in the ascending versus the descending colon. Newer technologies (e.g., smart capsules) are being developed that will allow for noninvasive sampling of microbial communities along the length of the gastrointestinal tract, which will provide new insight into regional differences in host–microbiota interactions.

OBESITY Obesity is a worsening epidemic throughout the world, and multiple studies have linked the composition of the intestinal microbiota to the development of obesity in animal models and in humans. Indeed, many of the initial translational microbiome studies performed in mice at the beginning of the twenty-first century focused on obesity. Gnotobiotic mouse studies have demonstrated the gut microbiota impacts host metabolism—resulting in body weight and adiposity changes—through several different mechanisms: the microbiota impacts the amount of energy extracted from the diet, promotes small-intestinal absorption of dietary fatty acids, regulates expression of lipid metabolism genes in the intestines, and induces hepatic lipogenesis and synthesis of triglycerides. Consistent with these findings, GF mice are resistant to diet-induced obesity, which establishes the requirement of the microbiota in the development of obesity. Over the past ~15 years, numerous human studies examining the relationship between the microbiome and obesity have been completed, all with mixed results. Although initial studies suggested obesity was associated with a lower ratio of the relative abundance of Bacteroidetes to Firmicutes, this has not held up in subsequent studies. Beyond this ratio of major bacterial phyla, obesity was linked to a microbiome with a lower alpha diversity. A meta-analysis of 10 studies including nearly 3000 individuals revealed an apparent lack of relationship between the Bacteroidetes/Firmicutes ratio and obesity, though there is ~2% lower diversity associated with obesity that is statistically significant but of unclear biologic significance. This finding highlights a problem common to microbiome studies: i.e., there is no sense as to what magnitude of change is biologically meaningful. Ultimately, although murine studies have indicated a causal link between the microbiota and obesity, the human data are less convincing, and their significance may be limited because the studies primarily examined only high-level taxonomic information rather than also assessing differences in bacterial products or metabolites.

The rise in obesity has elicited a plethora of ideas about the type of diet that might be most successful in leading to sustained weight loss. However, it has become clear that the same dietary ingredient can have highly diverse effects on blood glucose measurements in different people and that this effect is mediated largely by the microbiome. These observations suggest that the "optimal" diet needs to be individualized in the context of the person's microbiome, which itself may continue to change over the course of the diet. Moreover, the microbiota may also influence dietary preferences, which suggests important feedback loops between the microbiome and diet.

MALNUTRITION Representing the other end of the metabolic spectrum from obesity, malnutrition is also linked to an altered microbiome. Analysis of Malawian twin pairs (≤3 years of age) who were

discordant for kwashiorkor—a severe form of malnutrition—revealed that kwashiorkor is associated with a microbiologically "immature" fecal microbiota that resembles that of a chronologically younger child. Transplantation of the fecal microbiota from these discordant twins into gnotobiotic mice that were fed a diet similar in composition to a typical Malawian diet established that the kwashiorkor-associated microbiome is causally related to poor weight gain. Subsequent studies demonstrated these same general trends in malnourished Bangladeshi children. Investigators were able to identify five bacterial species (*Faecalibacterium prausnitzii*, *Ruminococcus gnavus*, *Clostridium nexile*, *Clostridium symbiosum*, and *Dorea formicigenerans*) that—when administered together as a "cocktail" to mice colonized with a kwashiorkor-associated microbiome—were able to prevent growth impairments. Moreover, children with moderate acute malnutrition fed therapeutic food purposefully designed for its ability to alter the microbiota in defined manners have improved growth. These results demonstrate that rationally designed modulation of the microbiota may lead to improved health outcomes.

INFLAMMATORY BOWEL DISEASE Ulcerative colitis and Crohn's disease, the two predominant forms of inflammatory bowel disease (IBD), are chronic gastrointestinal inflammatory conditions that differ in their locations and patterns of inflammation **(Chap. 337)**. The following observations have led to the suggestion that IBD is the result of an immune response to a dysbiotic microbiota in a genetically susceptible individual: genes account for only ~20% of susceptibility to IBD (and many of the relevant genes are related to host–microbe interactions), antibiotic treatment reduces the clinical severity of disease, and relapses of Crohn's disease are prevented by diversion of the fecal stream. While the microbiota clearly is not the only driver of disease, it is considered to be an important element. Accordingly, numerous animal and clinical studies have been designed to tease out the nature of the relationship between the microbiota and IBD.

Most of these studies have focused on comparing the microbiome's composition in IBD patients with that in healthy controls, concentrating on microbial diversity and specific bacterial taxa that are associated with health or disease. Unfortunately, few, if any, results have been universally obtained, probably because of differences in study design, inclusion criteria, and methodology (e.g., the use of stool, rectal swabs, or biopsy samples; the choice of sequencing primers; the analysis pipeline). Even with these differences among studies, patients with IBD typically have reduced alpha and beta diversity in their fecal microbiotas. Moreover, *Clostridium* clusters IV and XIVa, which are polyphyletic and encompass several different bacterial families, are generally reduced in patients with IBD. *F. prausnitzii* is a notable example from *Clostridium* cluster IV that is often underrepresented in the stool of patients who have Crohn's disease, with more mixed results in biopsy samples. The bacterial family Lachnospiraceae, which is largely contained in *Clostridium* cluster XIVa, and other butyrate-producing organisms are also reduced in the stool of patients with IBD. Some of these species produce butyrate by using acetate generated by other members of the microbiome, and some of these acetate-producing species are similarly reduced (e.g., *Ruminococcus albus*). These complex interactions and dependencies among bacterial species pose unique challenges to definitive ascertainment of the cause–effect relationships between microbes and disease. Even before researchers were able to assess the entire microbiome at once, they often noted that patients with Crohn's disease had a higher representation of adherent invasive *E. coli* in the ileal mucosa, an observation consistent with the increased abundance of Enterobacteriaceae seen in sequencing-based microbiome studies. Beyond bacteria, burgeoning evidence supports a role for Caudovirales bacteriophages in IBD pathogenesis, though these findings may merely reflect the underlying dysbiosis related to the loss of bacterial diversity in IBD. Moreover, dysregulation of the fungal component of the microbiota (the *mycobiota*) alters the mucosal immune system and is linked to IBD disease severity. It is still unclear whether any of these microbial associations reflect the cause of IBD or merely serve as biomarkers of disease.

Studies of antibiotic-treated mice and gnotobiotic mice colonized with IBD-associated microbiotas have been useful in confirming that the microbiota affects colitis severity. Several bacterial species have been identified as either promoting colitis in mice (e.g., *Klebsiella pneumoniae*, *Prevotella copri*) or protecting against it (e.g., *Bacteroides fragilis*, *Clostridium* species); however, these organisms do not always correlate with the taxa identified as differentially abundant across multiple clinical studies. In contrast, IgA-coated commensal organisms isolated from patients with IBD promote more severe colitis in mice than either IgA-uncoated bacteria from patients with IBD or IgA-coated bacteria from healthy controls. These data suggest that functional categorization of the microbiota based on immune recognition (e.g., IgA coating) may be a useful approach for identifying pathogenic organisms.

Cardiovascular Disease Inflammation helps drive the pathogenesis of atherosclerosis, and it has long been postulated that microbes are involved in the atherosclerotic process. Early work demonstrated that patients with cardiovascular disease have higher titers of antibody to *Chlamydia pneumoniae* than control patients, that *C. pneumoniae* is present within atherosclerotic lesions, and that *C. pneumoniae* can both initiate and exacerbate atherosclerotic lesions in animal models. This type of analysis has been extended to other bacteria, such as *Porphyromonas gingivalis*, with the idea that multiple different bacteria may play some role in the pathogenesis of atherosclerosis.

Studies have demonstrated clinical correlations between serum levels of trimethylamine *N*-oxide (TMAO) and atherosclerotic heart disease. Animal studies have confirmed that transfer of the gut microbiota from atherosclerosis-susceptible strains of mice to atherosclerosis-resistant animals leads to increased serum levels of TMAO and a dietary choline-dependent increase in atherosclerotic plaques; this observation confirms the role of the gut microbiota in the generation of TMAO and atherosclerosis. Given that red meat, eggs, and dairy products are important sources of carnitine and choline (both precursors of TMAO), it is not surprising that levels of TMAO are higher in omnivores than in vegans. The gut microbiota converts carnitine into the intermediary metabolite γ-butyrobetaine, which it further metabolizes—in a diet-dependent fashion—into trimethylamine (TMA); hepatic flavin-containing monooxygenases then transform TMA into TMAO. Moreover, treatment of atherosclerosis-susceptible strains of mice with a structural analogue of choline that inhibits the first enzymatic step in TMAO formation leads to decreased circulating TMAO levels and, more importantly, restrains macrophage foam-cell formation and atherosclerotic lesion development. In a study of >4000 patients, plasma TMAO levels were also predictive of incident thrombosis risk (myocardial infarction, stroke). Gnotobiotic animals were used to demonstrate that this risk was dependent on the microbiota; although eight bacterial taxa were identified as being associated with both plasma TMAO levels and thrombotic risk, organisms with choline-utilization genes that represent the first step of TMAO production were not more abundant in animals at greater risk for thrombosis. This discrepancy highlights the complexity of the microbiota and suggests that other aspects of the overall dynamics of the microbial community may be in play.

Oncology Studies exploring the link between the microbiota and cancer have demonstrated that specific members of the microbiota can affect treatment efficacy in both a positive and a negative manner. For example, therapy with antibody to programmed cell death ligand 1 (anti-PD-L1) has proven highly effective for many different cancers **(Chap. 78)**; however, a significant proportion of patients do not respond even when their tumors have high PD-L1 expression levels. Three groups have independently performed clinical studies—sometimes coupled with gnotobiotic mouse experiments to verify causal relationships—to demonstrate that specific bacteria can potentiate checkpoint blockade inhibition in melanoma, non-small-cell lung cancer, and renal cell carcinoma. Intriguingly, these groups identified different bacteria (*Bifidobacterium*, *Faecalibacterium*, and *Akkermansia* species) as being associated with the anticancer effects, even when the same

oncologic process was being studied. The biologic factors driving these differences are not yet clear but may relate to differences in adjunctive therapies, geography, and/or other as-of-yet unidentified factors. Although these seemingly disparate findings raise concern about the generalizability of microbiome studies, it may be that identifying relevant bacterial species—as opposed to their bioactive molecules—does not offer sufficient granularity for comparison across studies. The clinical relevance of the microbiota in this process was highlighted by proof-of-concept clinical trials demonstrating that fecal microbiota transplantation (FMT)—the "transplantation" of stool from one individual into another—led to clinical benefit in a few patients who previously did not respond to anti-PD-1 therapy after they received stool from patients who had previously responded to anti-PD-1 therapy, findings which still require confirmation in larger clinical trials.

In a separate set of studies, the efficacy of therapy with antibody to cytotoxic T lymphocyte–associated antigen 4 (anti-CTLA-4) was associated with T-cell responses specific for either *Bacteroides thetaiotaomicron* or *B. fragilis*. In particular, administration of *B. fragilis* to GF or antibiotic-treated mice restored the normally absent anticancer response to anti-CTLA-4 therapy. While these examples demonstrate potentiation of anticancer therapies by the microbiota, other therapies can be antagonized. Some cancers, such as pancreatic ductal adenocarcinoma, contain intratumoral bacteria, particularly Gammaproteobacteria, that can metabolize the chemotherapeutic agent gemcitabine and thereby contribute to the drug resistance of these tumors. In addition, the gut microbiota can increase the half-life of irinotecan, a chemotherapeutic agent commonly used in treating rhabdomyosarcoma and colorectal cancer, by converting an inactive metabolite back to the active form, which leads to increased drug toxicities. Overall, these examples highlight the microbiota's critical impact—both direct and indirect—on the efficacy and safety profile of drugs. Many other notable examples have been described (e.g., involving cyclophosphamide, digoxin, levodopa, and sulfasalazine), and many more likely remain to be discovered.

Using advances in computational tools for sequence decontamination and batch effect correction, reanalysis of data repositories generated by The Cancer Genome Atlas (TCGA) Research Network has identified microbial signatures within tumor genome sequences that predicted clinical outcomes in cancer, although these findings have been questioned given potential errors in the computational pipeline. This ongoing controversy highlights the complexity within the bioinformatic pipelines, the requirement for detailed reference databases, and dealing with samples that have an overall low abundance of microbes. Additional work is required to validate these signatures in prospective cohorts and to understand the biology underlying microbe–cancer interactions within the tumor milieu.

The application of microbiome science to hematopoietic stem cell transplantation (HSCT) is an area of expanding interest, particularly given the significant morbidity and mortality related to graft-versus-host disease (GVHD). In light of studies in the 1970s showing that GF mice developed less frequent and less severe gut GVHD than wild-type mice, clinicians began to use antibiotics to decontaminate the gut of patients undergoing HSCT. This decontamination approach yielded mixed results, probably because of differences in the antibiotic regimens used. The natural history of patients undergoing allogeneic HSCT includes a substantial loss of diversity in the fecal microbiota and intestinal domination (≥30% abundance in the fecal microbiota) by *Enterococcus* species and other pathogens, with a higher bacterial diversity at time of neutrophil engraftment associated with lower mortality. Moreover, a retrospective analysis of ~850 patients undergoing allogeneic HSCT revealed that receipt of imipenem-cilastatin or piperacillin-tazobactam for neutropenic fever was associated with increased GVHD-related mortality at 5 years; this observation suggested that specific bacteria may help protect against GVHD-related mortality. More detailed analyses revealed an association between the abundance of *Blautia* species and protection against GVHD and mortality, though this correlation is still being examined with regard to its causal relationship. Despite significant interest in examining these microbial relationships with HSCT, little has yet been studied in the context of solid organ transplantation, which likely represents the next frontier of transplantation-related microbiome investigation.

Autoimmune Diseases The dramatic rise in the incidence of many autoimmune diseases over the past few decades has been far more rapid than can be explained simply by genetic factors (Fig. 484-5). It is increasingly thought that environmental triggers, including the microbiome, are partially responsible for the development of these autoimmune diseases.

TYPE 1 DIABETES Type 1 diabetes (T1D) is an autoimmune disorder characterized by T cell–mediated destruction of insulin-producing pancreatic islets **(Chap. 415)**. There is a clear genetic predisposition for the disease: ~70% of patients with T1D have human leukocyte antigen (HLA) risk alleles. However, only 3–7% of children with these risk alleles actually develop disease, an observation that suggests a role for other environmental factors. Studying a prospective, densely sampled, longitudinal cohort of at-risk, HLA-matched children from Finland and Estonia, investigators detailed changes in the microbiota prior to development of disease. Although only 4 of the 33 children studied developed T1D within the time frame of the study, a marked decrease of ~25% in alpha diversity occurred after seroconversion but before disease diagnosis. The low number of cases in this study unfortunately precluded identification of any specific disease-associated taxa. A follow-up study compared the microbiomes of a larger cohort of these high-risk northern European children with those of low-risk Russian children who lived in geographic proximity. *Bacteroides* species were more abundant in the high-risk group than in the low-risk group, particularly at early ages. This difference was postulated to be associated with an altered structure of the bacterial LPS to which children were exposed at a young age. It was further suggested that *Bacteroides*-derived LPS was not able to provide the immunogenic stimulus necessary to prevent T1D. These two studies offer attractive—though logistically complicated—options for future clinical investigations aimed at exploring the role of the microbiome. The first approach—longitudinally following individuals who are at high risk for a given disease—may provide insight into host–microbe relationships by mapping temporal changes in the microbiome with disease onset. An important caveat with this type of study, though, is that the associations identified may reflect preclinical disease rather than specifically indicating causality for any observed changes. The second approach illustrates how careful selection of study participants may offer an opportunity to uncover more meaningful associations that can subsequently be experimentally verified.

RHEUMATOID ARTHRITIS Similar to many other autoimmune diseases, rheumatoid arthritis (RA) is a multifactorial disease that comes to clinical attention after an environmental factor triggers symptoms in an individual with preexisting autoantibodies. Multiple lines of evidence support the notion that RA pathogenesis is reliant on the microbiota, including the findings that GF mice do not develop symptoms in several RA models and that antibiotic treatment of mice mitigates against RA development. Several taxa (e.g., *Bacteroides* species, *Lactobacillus bifidus*, and segmented filamentous bacteria) have been implicated in promoting RA in murine models, and analysis of the fecal microbiota of patients with newly diagnosed RA has indicated that *P. copri* is a biomarker of disease. That this association with *P. copri* does not exist for chronic, treated RA or for psoriatic arthritis suggests some specificity for new-onset RA. A major limitation of this approach is that the identified association is shown to be a biomarker of disease (and, in this case, potentially of response to treatment), but no added insight is gained into a possible causal relationship between *P. copri* and RA. In fact, many of the patients with new-onset RA had no *Prevotella* detected, and several of the healthy controls had significant levels of *Prevotella*. The lack of a strict concordance between the presence (or absence) of a specific taxon and a given disease state argues against a possible causal role.

MULTIPLE SCLEROSIS Epidemiologic studies of twin pairs and at-risk individuals moving between high- and low-risk geographic areas indicate that genetics plays a minor component in multiple sclerosis

(MS) susceptibility relative to environmental factors. For example, in monozygotic twin pairs in which one sibling has MS, the other sibling also develops MS in only ~30% of cases. Although MS is a disease of the central nervous system (CNS), there is growing evidence of a link between MS and the microbiota, specifically that of the gut. In murine models of MS, GF and antibiotic-treated animals displayed reduced disease incidence and severity, and gnotobiotic mice harboring the fecal microbiota of individuals with MS—but not that of healthy controls—had increased disease activity. Clinical studies have bioinformatically associated numerous microbial changes with the presence of MS, including prior infection with Epstein-Barr virus. Importantly, a causal role has not yet been established for any of these microbes in MS pathogenesis. Although work relating the microbiome to MS is ongoing, it has opened the door to exploring this link with other neurologic diseases. Animal studies have linked the microbiota with Parkinson's disease, Alzheimer's disease, and autism, and there are clinical data assessing fecal microbiomes in relation to a variety of neurologic conditions. It is not yet clear how the gut microbiota is communicating with the CNS—i.e., whether communication takes place via bacterial metabolites that travel in the bloodstream and cross the blood-brain barrier, via migration of whole organisms into the CNS, or via feedback through the vagus nerve. Emerging data suggest that a subset of enteroendocrine cells in the intestinal epithelium is synaptically connected to the CNS, which may provide another means for the gut microbiota to impact neurologic function. Although our understanding of this brain-gut axis is still in its infancy, research in this area has elicited tremendous excitement as a tractable approach to potential treatments for these challenging diseases.

Atopic Diseases The incidence and prevalence of allergic diseases continue to steadily increase, as do more severe clinical presentations. Life-threatening food allergies are now such a public health issue that nut-free classrooms are the norm in many cities. The development of allergic diseases often follows a stereotyped progression that begins with atopic dermatitis (AD) and continues, in order, with food allergy, asthma, and allergic rhinitis. The microbiome has been linked to all of these conditions and has the potential to modulate effects anywhere along this spectrum.

ATOPIC DERMATITIS The skin is the largest organ in the body, and its different anatomic sites (e.g., antecubital fossa, volar forearm, alar crease) represent distinct ecologic niches and harbor unique microbial communities. Moreover, given that the skin serves as a critical interface between the body and the external environment (e.g., microbes), it must be able to respond to unwanted microbes with an adequate immune response. AD is an inflammatory skin disorder involving immune dysfunction and a dysbiotic skin microbiota that is typically marked by greater abundances of *Staphylococcus aureus* and reduced bacterial diversity. Effective treatment of AD does not require complete elimination of *S. aureus* but is associated with restoration of the normal level of diversity. It is likely that this increase in bacterial diversity reestablishes normal immune homeostasis in the skin; specific members of the skin microbiota have been shown to induce protective skin-restricted immune responses. Coagulase-negative staphylococci (CoNS; primarily *S. epidermidis* and *S. hominis*) obtained from lesional and nonlesional skin of patients with AD were functionally screened and compared to CoNS from healthy controls; AD-lesional CoNS were much less often able to produce antimicrobial peptides (lantibiotics) directed against *S. aureus*. To demonstrate that these lantibiotic-producing CoNS were biologically relevant, they were incorporated into a lotion and applied to the arms of patients with AD. Surprisingly, a single application of the probiotic-laced lotion led to a decrease in the abundance of *S. aureus* recovered; no such decrease was observed when lantibiotic-negative strains were used. The authors of this study did not specifically comment on the clinical improvement of the AD lesions. Nevertheless, this is one of a limited number of studies that is beginning to extend microbiome-related findings into clinical trials.

ASTHMA Asthma is characterized by the clinical triad of airflow obstruction, bronchial hyperresponsiveness, and inflammation in the lower respiratory tract. Although the long-standing dogma was that the lungs are sterile, there is now convincing evidence for a constant ebb and flow of bacteria within the lower airways. In healthy states, the mucociliary escalator continually eliminates these bacteria soon after they land in the airways; in disease states (e.g., cystic fibrosis, chronic obstructive pulmonary disease), these bacteria establish long-term colonization of the airways and influence disease pathogenesis. In asthma specifically, both fecal and airway microbes have been linked to clinical outcomes.

Early studies of the microbiome's influence on asthma used culture-based methods to assess the hypopharyngeal microbiota of asymptomatic 1-month-old infants. Intriguingly, in one study, early-life colonization with *S. pneumoniae*, *Haemophilus influenzae*, *Moraxella catarrhalis*, or a combination of these organisms—but not *S. aureus*—was significantly associated with persistent wheeze and asthma at 5 years of age. Eosinophilia and total IgE levels at 4 years of age were also increased in children who were neonatally colonized with these organisms. Although this study examined a focused set of bacteria, it laid the experimental groundwork indicating that early-life microbial exposures influence subsequent development of asthma. A later longitudinal investigation of the fecal microbiota in a general-population birth cohort of >300 children demonstrated that lower abundances of the genera *Lachnospira*, *Veillonella*, *Faecalibacterium*, and *Rothia* at 3 months of age were associated with an increased risk for development of asthma. The fact that these bacterial changes were no longer apparent when the children were 1 year of age is consistent with the notion that microbial exposures early in life are important to disease pathogenesis later in life. Transplantation of stool samples from 3-month-old children at risk for asthma into gnotobiotic mice resulted in significant airway inflammation in a murine model of asthma; pre- and postnatal exposure of mice to a four-species cocktail (*F. prausnitzii*, *Veillonella parvula*, *Rothia mucilaginosa*, and *Lachnospira multipara*) inhibited airway inflammation, with a marked reduction in neutrophil numbers in bronchoalveolar lavage fluid. These data suggest that early-life modulation of the microbiome may be an effective strategy to help prevent asthma, though the specific logistics (e.g., strains, dose, timing of exposure, patient selection) remain to be clarified.

Infectious Diseases The increased susceptibility of antibiotic-treated mice to infection with a wide range of enteric pathogens was initially observed in the 1950s and led soon thereafter to the concept of *colonization resistance*, which holds that the normal intestinal microbiota plays a critical role in preventing colonization—and therefore disease production—by invading pathogens. Seminal work in the 1970s demonstrated that this protection is largely reliant on anaerobic gram-positive organisms, and the subsequent half-century has been spent trying to identify the specific microbes involved. Although much of the work relating the microbiota to infection has focused on enteric pathogens, the intestinal microbiota has also been clearly linked to bacterial pneumonia in mouse models, and changes in the microbial composition of the gut have been causally related to changes in the severity of disease. Although this gut-lung axis clearly exists in animals, its relevance in humans is still unclear. Several groups are beginning to study the human lung microbiome in the context of pneumonia and tuberculosis. Moreover, the relationships between the microbiota and both systemic infections (e.g., HIV infection, sepsis) and the response to vaccination are starting to be explored.

ENTERIC INFECTIONS *Clostridioides difficile* infection (CDI) represents a growing worldwide epidemic and is the leading cause of antibiotic-associated diarrhea (Chap. 139). Roughly 15–30% of patients who are successfully treated for CDI end up with recurrent disease. The strong association between antibiotic exposure and CDI initially raised the idea that the microbiota is inextricably linked to acquisition of disease, presumably because of the loss of colonization resistance. Consistent with the epidemiologic data, characterization of the fecal microbiota of patients with CDI revealed that it is a markedly less diverse, dysbiotic community. FMT using stool from a healthy individual was successfully used in the 1950s to treat four patients with severe CDI and has since been demonstrated in numerous studies to be an effective

therapy for recurrent CDI, with clinical cure in 85–90% of patients (as detailed below). Thus, FMT for recurrent CDI has become the "poster child" for the idea that microbiome-based therapies can transform the management of many diseases previously considered to be refractory to medical therapy. Although FMT is agnostic as to the underlying mechanism of protection, work is ongoing to identify specific microbes and host pathways that can protect against CDI. Studying mice with differential susceptibilities to CDI due to antibiotic-induced changes in their microbiota, investigators identified a cocktail of four bacteria (*Clostridium scindens*, *Barnesiella intestihominis*, *Pseudoflavonifractor capillosus*, and *Blautia hansenii*) that conferred protection against CDI in a mouse model. Intriguingly, treatment of mice with just *C. scindens* offered significant, though not complete, protection in a bile acid–dependent manner. Clinical data from patients who underwent HSCT also associated *C. scindens* with protection from CDI, an observation that suggests the possibility of translating these findings from mice to humans. This study provides another example of the identification of relevant bacterial factors through examination of microbial differences in populations that differ in disease risk.

Microbiome-related changes associated with *Vibrio cholerae* infection include a striking loss of diversity (largely due to *V. cholerae* becoming the dominant member of the microbiota) and an altered composition that rapidly follows the onset of disease. These changes, which occur in a reproducible and stereotypical manner, are reversible with treatment of the disease. This recovery phase involves a microbial succession that is similar to the assembly and maturation of the microbiota of healthy infants. In addition to *V. cholerae*, streptococcal and fusobacterial species bloom during the early phases of diarrhea, and the relative abundances of *Bacteroides*, *Prevotella*, *Ruminococcus/Blautia*, and *Faecalibacterium* species increase during the resolution phase and mark the return to a healthy adult microbiota. Analysis of these microbial changes occurring in patients with cholera and in healthy children led to the selection of 14 bacteria that were transplanted into gnotobiotic mice, which were then challenged with *V. cholerae*. Bioinformatic analysis of specific taxa changing during cholera determined that *Ruminococcus obeum* restrained *V. cholerae* growth. Subsequently, this relationship was experimentally confirmed, and the *R. obeum* quorum-sensing molecule AI-2 (autoinducer 2) was found to be responsible for restricting *V. cholerae* colonization via an unclear mechanism. These studies highlight the potential for use of microbiome-based therapies to prevent and/or treat infectious diseases. Moreover, they suggest that temporal analysis of longitudinal microbiome data may be an effective strategy for identifying microbes with causal relationships to disease.

VIRAL INFECTIONS One long-standing maxim for management of infectious diseases is that antibiotics are only to be used for treatment of bacterial infections. Studies using mouse models have demonstrated, however, that a variety of viruses require the bacterial component of the microbiota for pathogenesis. Moreover, antibiotic therapy, which has bacteria-independent effects on the host, leads to reduced disease severity in some animal models of viral infection, though the clinical relevance of this is not yet clear. In addition to being required for some viral infections to proceed, commensal bacteria have also been shown to play a critical role in inducing type I interferons, which represent a potent defense mechanism against many viruses, and for modulating cellular physiology in ways that inhibit viral replication.

HIV INFECTION The augmentation of HIV pathogenesis by some viral, bacterial, and parasitic co-infections suggests that a patient's underlying microbial environment can influence the severity of HIV disease. Moreover, it has been hypothesized that the intestinal immune system plays a significant role in regulating HIV-induced immune activation; this seems particularly likely since the intestines are an early site for viral replication and exhibit immune defects before peripheral CD4+ T-cell counts decrease. Several studies of HIV-infected individuals have identified substantial differences in the HIV-associated fecal microbiota that correlate with systemic markers of inflammation. Curiously, these microbial changes do not necessarily normalize with antiretroviral therapy; this finding suggests that the microbiota may have some "memory" of the previously high HIV loads and/or that HIV infection helps reset the "normal" microbiota. This memory-like capacity of the microbiota has been demonstrated in animal models in the context of other infections and in response to dieting.

Given that the majority of new HIV transmission events follow heterosexual intercourse, there has been significant interest in examining the relationship between the vaginal microbiota and HIV acquisition. A longitudinal study of South African adolescent girls who underwent high-frequency testing for incident HIV infection facilitated the identification of bacteria that were associated with reduced risk of HIV acquisition (*Lactobacillus* species other than *L. iners*) or with enhanced risk (*Prevotella melaninogenica*, *Prevotella bivia*, *Veillonella montpellierensis*, *Mycoplasma*, and *Sneathia sanguinegens*). In mice inoculated intravaginally with *Lactobacillus crispatus* or *P. bivia*, the latter organism induced a greater number of activated CD4+ T cells in the female genital tract, a result suggesting that the increased risk of HIV acquisition associated with *P. bivia* may be secondary to the increased presence of target cells. In a separate study, the composition of the vaginal microbiota was shown to modulate the antiviral efficacy of a tenofovir gel microbicide. Although tenofovir reduced HIV acquisition by 61% in women who had a *Lactobacillus*-dominant vaginal microbiota, it reduced HIV acquisition by only 18% in women whose vaginal microbiota comprised primarily *Gardnerella vaginalis* and other anaerobes. This difference in efficacy was due to the ability of *G. vaginalis* to metabolize tenofovir faster than the target cells can take up the drug and convert it into its active form, tenofovir diphosphate. These findings illustrate how microbial ecology can be an important consideration in choosing effective treatment regimens.

RESPONSE TO VACCINATION Second only to the provision of clean water, vaccination has been the most effective public health intervention in the prevention of serious infectious diseases. Its effects are mediated by antigen-specific antibodies and, in some cases, effector T-cell responses. Although vaccines are clearly effective on a population scale, the magnitude of the immune response to vaccines can vary among individuals up to a hundredfold. Although many factors (e.g., genetics, maternal antibody levels, prior antigen exposures) can affect vaccine immunogenicity, the microbiota is now recognized as another important factor. Several cohort studies have associated differences in the fecal microbiota with altered vaccine responses, and the nasal microbiota is thought to contribute to the IgA response to live, attenuated influenza vaccines. These correlations based on clinical data have been partially confirmed in animal studies. The best example is the demonstration that the responses to nonadjuvanted viral subunit vaccines (inactivated influenza and polio vaccines) are reliant on the microbiota, whereas the responses to live or adjuvanted vaccines (live attenuated yellow fever, Tdap/alum, an HIV envelope protein/alum vaccine) are not. A causal role for the microbiome influencing vaccine-induced immunity in humans was demonstrated by comparing microneutralization titers following the inactivated influenza vaccine in individuals treated with or without antibiotics, although an antibiotic-dependent effect was only present in subjects who had low levels of preexisting immunity to influenza. These data suggest that the microbiota may serve as an adjuvant for certain vaccine types and in naïve populations. Incorporation of specific commensal bacteria and/or their products that improve vaccine responses into vaccine formulations may increase overall vaccine efficacy.

MECHANISMS OF MICROBIOME-MEDIATED EFFECTS

As highlighted in the examples above, numerous associations have been made between the microbiome and various disease states. These correlations have often been established at broad taxonomic levels, with little or no insight into causality. Given that most clinical studies of these relationships have a fairly small sample size (often <100) and are simultaneously comparing numerous variables (i.e., each of the bacterial species in the microbiota is effectively a different feature being compared), many of these studies may not be adequately powered and therefore may yield false-positive results. Testing of these correlations

in animal models of disease has been critical in demonstrating a causal relationship between microbes and specific phenotypes. Because microbiome-wide association studies typically result in a long list of bacterial taxa that are correlated with a disease, it has been challenging to know which organism to test further in mechanistic studies. Moreover, even if a specific bacterial species is identified in these analyses, there is potentially enough strain-to-strain variation that the "functional" isolate may need to be recovered from the individuals studied; a publicly available representative of the species may not confer the same phenotype. Despite all these difficulties, a handful of specific microbes have now been linked to disease effects; some examples have been mentioned above. The next layer of challenges relates to identification of the specific mechanisms that underlie these causal relationships. Although the microbiota modulates most facets of host physiology, its impact on the immune system is the best-studied mechanism and helps explain its role in many diseases, particularly those that stem from misdirected immune responses.

REGULATION OF THE IMMUNE SYSTEM

The microbiota is required for the proper development, education, and maintenance of the immune system, a finding underscored by the fact that GF animals have an immature and underdeveloped immune system. Moreover, given that the microbiota has co-evolved with its host, a host-specific microbiota is critical for normal maturation of the immune system: gnotobiotic mice colonized with the microbiota from healthy humans have a small-intestinal immune system indistinguishable from GF mice. This impact on immune ontogeny begins in early life, with maternal transfer of microbially-targeted antibodies and microbe-derived metabolites augmenting neonatal immune development. Some of these early-life microbial exposures must occur during a time-sensitive window, after which subsequent exposures fail to redress the initial deficiency. Examples of these "original sins" are limited in number, but they can have long-lasting physiologic consequences that extend into adult life. In contrast, most host–microbe–immune interactions occur on an ongoing basis throughout life, with microbial perturbations (e.g., antibiotic use, changes in diet) disrupting this homeostatic immunity and potentially altering disease susceptibility.

The microbiota impacts virtually all aspects of host immunity, including its different arms (i.e., innate, adaptive), its varied anatomic niches (e.g., intestinal, skin, lung, bone marrow, CNS), and its overall immunologic tone and responsiveness. Not only does the microbiota influence the development and education of immune cells, but it also plays a critical role in modulating epithelial cell responses that contribute to immune defenses and disease pathogenesis. While the microbiota as a whole is known to drive these varied responses, not all microbes have the same immunomodulatory effects. Indeed, a broad screen of >50 taxonomically diverse commensal bacteria in GF mice demonstrated that most have the capacity to modulate the immune system, with very few bacterial taxa being immunologically quiescent; however, the immunomodulatory effects were often not detected when the same bacterium was administered to a mouse with a normal microbiota, which highlights the functional redundancy within the microbiota. Interestingly, bacterial taxonomy did not correlate with effects on the immune system, a finding that suggests the bioactive molecules may be unique rather than evolutionarily conserved. Given that all the tested bacteria express various canonical ligands (e.g., LPS, peptidoglycan, flagellin) for pattern recognition receptors, such as Toll-like receptors, commensal bacteria either modulate the immune system via a different class of products or their "canonical ligands" have unique structural motifs that trigger distinct signaling pathways—or combination of pathways—that result in education of the immune system.

Efforts are ongoing to define cognate relationships between specific commensal bacteria and their immunomodulatory effects, and approaches are being developed to define specific bacterial factors that are responsible for the phenotypic changes. Complicating factors are that many organisms, particularly those in the phylum Firmicutes, are not readily genetically tractable and that many of the phenotypes are not easy to assess with high-throughput screening. The use of mass spectrometry to detect and profile tens of thousands of different metabolites present in different bodily fluids has offered the promise of deeper insight into microbially mediated processes that underlie disease susceptibility. However, the fact that the overwhelming majority of these metabolites are not annotated, coupled with the sheer volume of data generated, has so far limited the general utility of these untargeted approaches. The few immunomodulatory bacteria and their bioactive molecules that have been identified serve as useful archetypes for how the microbiome influences the immune system and, more generally, host physiology. These commensal-derived products can generally be categorized as endobiotic microbial structures, modified dietary nutrients, and modified host-derived metabolites.

Endobiotic Microbial Immunomodulatory Molecules *B. fragilis* polysaccharide A (PSA) is perhaps the best-studied commensal-derived molecule that has been demonstrated to influence disease outcomes in mouse models. PSA—one of at least eight capsular polysaccharides expressed by *B. fragilis*—has a unique zwitterionic structure that incorporates both a positive and a negative charge within each repeating unit. Studies in which mice have been treated either with isogenic strains of *B. fragilis* that differ in PSA expression or with purified PSA have shown that PSA confers protection—prophylactically and therapeutically—against experimental colitis and MS. PSA is recognized by Toll-like receptor 2 on antigen-presenting cells, particularly plasmacytoid dendritic cells, and—in the setting of inflammation—induces interleukin 10 (IL-10)–producing regulatory T cells (Tregs) that help restrain inflammation.

B. fragilis is also the source of an immunomodulatory glycosphingolipid that, if present during neonatal life, decreases the number of colonic invariant natural killer T (iNKT) cells and improves outcomes in a model of colitis in adulthood. It is not clear whether these glycosphingolipids activate or inhibit iNKT cells; results have been discordant, probably because different glycosphingolipid species have been tested. A chemical synthesis approach confirmed that *B. fragilis* glycosphingolipids have distinct immunomodulatory functions depending on their specific structure.

There are an increasing number of commensal-derived polysaccharides and other large molecules that have been shown to modulate the immune system and/or disease outcomes. Advances in bacterial genetics have facilitated the identification of structural features that contribute to some of these host–microbiota relationships. It is likely that our general understanding of structure–function relationships of commensal-derived products will continue to grow in the coming years, mirroring what has occurred in microbial pathogenesis studies over the past several decades.

Modified Dietary Nutrients As described above, the human diet provides nutrients for the gut microbiota, which can metabolize them into new, bacteria-derived compounds. Perhaps the best example of this is fermentation of undigested dietary fibers into short-chain fatty acids (SCFAs). Several groups have demonstrated that SCFAs, the intestinal levels of which are largely determined by bacterial metabolism, are important for the induction of Tregs, though there is not agreement on which specific SCFA (propionate, acetate, or butyrate) is most relevant. Wild-type mice colonized with bacteria known to induce colonic Tregs have elevated cecal levels of SCFAs. Colonization with any of three *Bacteroides* species (*B. caccae*, *B. massiliensis*, and *B. thetaiotaomicron*) increases levels of acetate and propionate, whereas colonization with *Parabacteroides distasonis* or a mix of 17 human-derived *Clostridium* species elevates levels of all three SCFAs. In all of these cases, though, the SCFAs inhibit histone deacetylase, with a consequent increase in *Foxp3* expression. Notably, microbe-induced SCFA production has not been shown to be critical for Treg induction by any of these organisms. In contrast, there appears to be no correlation between SCFA levels and Treg numbers in mice monocolonized with various Treg-inducing bacterial species. Taken together, these data suggest important heterogeneity in the mechanisms underlying Treg development and do not rule out the possibility of other, redundant mechanisms for Treg induction. In addition to effects on Tregs, SCFAs also promote the epithelial barrier, impact cell proliferation (directionality depends on the specific cell type and SCFA), regulate host metabolism, and provide an energy source to colonocytes.

Although SCFAs represent the best-studied molecules that the microbiota generate from diet, there are many other physiologically important examples. The microbiota metabolizes tryptophan into various products (e.g., kynurenine, indole, and its derivatives) that influence immune function, metabolic diseases, viral infections, and neuronal function, among other things. Desaminotyrosine produced by *Clostridium orbiscindens* confers protection from influenza by inducing type I interferon activity. Modification of unsaturated fatty acids (e.g., linoleic acid) into different isomers regulates specific T-cell subsets embedded in the small-intestinal epithelium. These examples represent an important proof of concept that diet plays an important role in the functional output of the microbiota, not just its composition.

Modified Host-Derived Molecules Bile acids are produced in the liver but then are metabolized by intestinal bacteria to form deconjugated and secondary bile acids. These microbially produced bile acid profiles act through complex signaling pathways to balance the metabolism of lipids and carbohydrates and to affect immune responses. Therefore, bile acids are now being investigated as microbial metabolites that are critical to maintaining human health. As mentioned above, *C. scindens* helps protect mice against CDI through a bile acid–dependent process. Alterations in bile acid profiles due to underlying microbial dysbiosis have also been associated with hepatic and colonic inflammation, hepatic cellular carcinoma, colorectal cancer, and impaired gut motility. Almost all of these relationships have been documented at the level of correlation and, at best, reflect a partial change in phenotype in the setting of bile acid sequestrants (e.g., cholestyramine). Work is ongoing to determine causal relationships between bacterial metabolism of bile acids and changes in host physiology, though the most definitive evidence is that microbe-produced bile acid metabolites influence colonic Treg homeostasis.

In addition to bile acids, the gut microbiota can metabolize many other host-derived molecules, thereby regulating their levels and downstream effects. Taurine enhances NLRP6 inflammasome–induced colonic IL-18 secretion, while histamine, spermine, and putrescine suppress IL-18 secretion; the levels of all of these host-derived metabolites can be regulated by the microbiota. Inosine, the deamination product of adenosine, produced by *Bifidobacterium pseudolongum* enhances efficacy of checkpoint blockade inhibitors in mouse models. While these examples represent the tip of the iceberg, many more examples of bacterial metabolites will undoubtedly be linked to health and disease given the thousands of different bacterial metabolites present throughout the body. However, the clinical relevance of any of these bacterial metabolites remains unknown.

MOVING MICROBIOME SCIENCE FROM BENCH TO BEDSIDE

The numerous microbiome–disease associations identified thus far have generated a great deal of hope that understanding the relevant microbe–host interactions will open the door to unlimited therapeutic applications. Microbiome-based therapies offer several potential benefits. Patients often view such treatment as more "natural" than conventional drug therapy and are therefore more likely to comply with it. Biologically, microbiome-based therapies are more likely to address one of the root causes of disease (microbial dysbiosis) rather than simply affecting the downstream sequelae. Finally, a given microbiome-based therapy may serve as a "polypill" that is effective against several different diseases stemming from similar microbial changes. Despite tremendous interest in therapeutically exploiting the microbiome, there have thus far been few clinical successes along these lines.

The most successful therapeutic application of microbiome science has been the use of FMT, particularly for CDI. As mentioned earlier, FMT involves "transplanting" stool from one individual to a diseased patient, with the idea that the donor microbiota will correct whatever derangement may exist in the ill patient and therefore will alleviate symptoms. Fundamentally, this notion is agnostic as to the specific microbial dysbiosis and holds that any "healthy" microbiota will be curative, though some are now using donor stool from patients with a desired phenotype rather than any healthy individual. The idea of FMT dates to at least the fourth century, when traditional Chinese doctors used a "yellow soup" (fresh human fecal suspension) to successfully treat food poisoning and severe diarrhea. The continued use of FMT through the centuries for the treatment of diarrheal illnesses in both humans and animals, along with the growing appreciation of the importance of the microbiota, laid the groundwork for using FMT to treat CDI. Since the first major prospective trial assessing FMT for recurrent CDI in 2013, most of the numerous studies of FMT for CDI have demonstrated remarkable efficacy, with an average clinical cure rate of ~85%. The donor stool can be fresh or frozen (use of the latter allows biobanking of samples from a limited number of prescreened donors) and can be administered via nasogastric tube, nasoduodenal tube, colonoscopy, enema, or oral capsules; the cure rate is slightly higher with lower-gastrointestinal administration than with upper-gastrointestinal treatment. The optimal screening, preparation, and concentration of infused donor stool have not yet been determined, and there have been cases of antimicrobial-resistant pathogens transmitted by FMT that have led to mortality. The most common adverse effects of FMT include altered gastrointestinal motility (with constipation or diarrhea), abdominal cramps, and bloating, all of which are generally transient and resolve within 48 h. Although controlled studies of the use of FMT in immunosuppressed patients do not yet exist, meta-analyses of case reports and case series have found no serious FMT-related adverse events in >300 immunocompromised patients.

The successful use and the favorable short-term safety profile of FMT for CDI have led to its expanded application for other indications. As of July 2024, >500 trials (listed at *ClinicalTrials.gov*) were investigating the efficacy of FMT for a range of indications, including CDI, IBD (ulcerative colitis and Crohn's disease), obesity, eradication of multidrug-resistant organisms, anxiety and depression, cirrhosis, and type 2 diabetes. The few published studies regarding indications other than CDI have generally included small sample sizes and have offered mixed results. In contrast to the successes in CDI, the results have been more varied for patients with IBD, which is perhaps the second best-studied indication. It is not clear whether these discrepancies are due to heterogeneity in recipients (e.g., in terms of underlying disease mechanisms or endogenous microbiotas), the donor material, and/or the logistical details of FMT administration (e.g., route, frequency, dose). However, these results demonstrate that—under the right circumstances—modulation of the microbiota can be an effective therapy for IBD.

Although FMT offers an important proof of concept that microbiome-based therapies can be effective, treatment is difficult to standardize across large populations because of variability among stool donors and among the endogenous microbiotas of recipients. In addition, FMT is fraught with safety concerns, and its mechanisms of action are unclear. That said, there are now two microbiome-derived therapies conceptually analogous to FMT that are approved by the U.S. Food and Drug Administration (FDA) for treatment of recurrent CDI. FMT likely represents the first generation of microbiome-based therapies; subsequent generations will include the use of more refined bacterial cocktails, single strains of bacteria, or bacterial products and/or metabolites as the therapeutic intervention. The field of probiotics has a complicated history: many different strains have been tested against a multitude of diseases. Several meta-analyses have combined results across bacterial strains and/or disease indications and have generally concluded that the data are not yet convincing enough to support the use of the tested regimens. It should be noted that the tested organisms have generally been chosen based on their presumed safety profile rather than in light of a plausible biologic link to disease. The hope is that more focused, mechanistic microbiome studies will identify specific commensal organisms—and their underlying mechanisms of action—that are involved in disease pathogenesis and that will serve as the basis for the next wave of rationally chosen probiotics, a few of which are currently in clinical trials. The main hurdle in this endeavor has been identifying specific microbes that are causally related to protection from disease. Future therapeutic strategies might include administering a beneficial microbe/microbial product; targeting a deleterious microbe/microbial pathway; or modulating the microbial ecology, potentially by impacting keystone species.

The medical view of microbes has changed radically, moving from the early-twentieth-century notion that we are engaged in a constant struggle with microbes—an "us-versus-them" mentality that focused on the necessity of eradicating bacteria—to the current understanding that we live in a carefully negotiated state of détente with our commensal organisms. Instead of holding a simple view of microbes as enemies to be eliminated with antibiotics, scientists are increasingly recognizing the critical role these organisms play in maintaining human health; loss of these host–microbe interactions in the increasingly sterile environment typical of Western civilization may have predisposed to the increased incidence of autoimmune and inflammatory diseases. The field of microbiome research has made great strides over the past decade in cataloguing the normal microbiota and is now beginning to identify clinically actionable microbe–host relationships.

The explosion of "–omics" technologies (e.g., metagenomics, metatranscriptomics, metabolomics) has enabled the generation of vast amounts of data, but it is not yet clear how best to integrate data sets in order to gain useful insights into host–microbe relationships. The use of FMT has demonstrated that modulation of an individual's microbiota can effectively treat certain diseases; however, models with which to predict specifically how a microbiota will change after modulation—and what potentially untoward effects these changes might have—are still lacking. Implicit in this limitation is our ignorance about what microbial configuration is optimal and how a given microbiota should be rationally altered to obtain an ideal outcome.

Despite initial hyperbolic hype and a few false starts, microbiome research now stands at the forefront of an ability to treat the fundamental basis of many diseases. As the field continues to mature, it will need to move beyond correlations and address causation. The identification of causal microbes and their mechanisms of action will create a "microbial toolbox" from which relevant bioactive strains can be chosen on a per-patient basis to correct specific underlying microbial dysbioses. In the near future, our knowledge base regarding the microbiome and its relationship to health and disease will be robust enough that this information can be applied in making important treatment decisions.

485 Global Issues in Medicine

Joseph J. Rhatigan, Paul E. Farmer*

WHY GLOBAL HEALTH?

Global health has emerged as an important field within medicine. Some scholars have defined global health as the field of study and practice concerned with improving the health of all people and achieving health equity worldwide, with an emphasis on addressing transnational problems. No single review can do much more than identify the leading problems in applying evidence-based medicine in settings of great poverty or across national boundaries. However, this is a moment of opportunity: only relatively recently have persistent calls for global health equity been matched by an unprecedented investment in addressing the health problems of poor people worldwide. To ensure that this opportunity is not wasted, we must strengthen health systems and improve health care delivery to address the true burden and distribution of disease. This chapter introduces the major international bodies that address global health problems; identifies the more significant barriers to improving the health of people who to date have not, by and large, had access to modern medicine; and summarizes population-based data on the most common health problems faced by people living in poverty. Examining specific problems—notably HIV/AIDS **(Chap. 208)** but also tuberculosis **(Chap. 183)**, malaria **(Chap. 231)**, Ebola **(Chap. 216)**, COVID-19 **(Chap. 205)** and key "noncommunicable" chronic diseases (NCDs)—helps sharpen the discussion of barriers to prevention, diagnosis, and care as well as the means of overcoming them. This chapter closes by discussing global health equity, drawing on concepts of social justice.

A BRIEF HISTORY OF GLOBAL HEALTH INSTITUTIONS

Concern about illness across national boundaries dates back many centuries, predating the Black Plague and other pandemics. One of the first organizations founded explicitly to tackle cross-border health issues was the Pan American Sanitary Bureau, which was formed in 1902 by 11 countries in the Americas. The primary goal of what later became the Pan American Health Organization was the control of infectious diseases across the Americas. Of special concern was yellow fever, which had been running a deadly course through much of South and Central America and halted the construction of the Panama Canal. In 1948, the United Nations formed the first truly global health institution: the World Health Organization (WHO). In 1958, under the aegis of the WHO and in line with a long-standing focus on communicable diseases that cross borders, leaders in global health initiated the effort that led to what some see as the greatest success in international health: the eradication of smallpox. Naysayers were surprised when the smallpox eradication campaign, which engaged public health officials throughout the world, proved successful in 1979 despite Cold War tensions.

At the International Conference on Primary Health Care in Alma-Ata (in what is now Kazakhstan) in 1978, public health officials from around the world agreed on a commitment to "Health for All by the Year 2000," a goal to be achieved by providing universal access to primary health care worldwide. Critics argued that the attainment of this goal by the proposed date was impossible. In the ensuing years, a strategy for the provision of selective primary health care emerged. This strategy included four inexpensive interventions collectively known as GOBI: *g*rowth monitoring, *o*ral rehydration, *b*reast-feeding, and *i*mmunizations for diphtheria, whooping cough, tetanus, polio, tuberculosis, and measles. GOBI later was expanded to GOBI-FFF, which also included *f*emale education, *f*ood, and *f*amily planning. Some public health figures saw GOBI-FFF as an interim strategy to achieve "health for all," but others criticized it as a retreat from the bolder commitments of Alma-Ata.

In 1982, UNICEF, led by James Grant, helped usher in a period of sustained and coordinated efforts to reduce childhood mortality using a similar set of interventions among other measures. Over the ensuing two decades, it is estimated that 25 million children's lives were saved in what is often called "The Child Survival Revolution."

The influence of the WHO waned during the 1980s. In the early 1990s, many observers argued that, with its vastly superior financial resources and its close—if unequal—relationships with the governments of poor countries, the World Bank had eclipsed the WHO as the most important multilateral institution working in global health. One of the stated goals of the World Bank was to help poor countries identify "cost-effective" interventions worthy of public funding and international support. At the same time, international financial institutions encouraged many of those nations to reduce public expenditures in health and education in order to stimulate economic growth as part of (later discredited) policies, generally referred to as "structural adjustment," that imposed restrictions on social sector government spending as a condition for access to credit and assistance through the World Bank, the International Monetary Fund, and regional development banks. There was a resurgence of many diseases—including malaria, trypanosomiasis, and schistosomiasis—in Africa. Tuberculosis, an eminently curable disease, remained the world's leading infectious killer of adults. Half a million women per year died in childbirth during the last decade of the twentieth century, and few of the world's largest philanthropic or funding institutions focused on global health equity.

HIV/AIDS, first described in the medical literature in 1981, precipitated a change. In the United States, the advent of this newly described infectious killer marked the culmination of a series of events that dashed previous hopes of "closing the book" on infectious diseases. In Africa, which would emerge as the global epicenter of the pandemic, HIV disease strained tuberculosis control programs, and malaria continued to claim as many lives as ever: at the dawn of the twenty-first century, these three diseases alone killed nearly 6 million people each year. New research, new policies, and new funding mechanisms were called for. The past two decades have seen the rise of important multilateral global health financing institutions such as the Global Fund to Fight AIDS, Tuberculosis, and Malaria; bilateral efforts such as the U.S. President's Emergency Plan for AIDS Relief (PEPFAR); and private philanthropic organizations such as the Bill & Melinda Gates Foundation. With its 194 member states and 150 country offices, the WHO remains important in matters relating to the cross-border spread of infectious diseases and other health threats. In the aftermath of the epidemic of severe acute respiratory syndrome in 2003, the WHO's International Health Regulations—which provide a legal foundation for that organization's direct investigation into a wide range of global health problems, including pandemic influenza, in any member state—were strengthened and brought into force in May 2007.

Even as attention to and resources for health problems in poor countries grow, the lack of coordination among global health institutions remains an issue. The global response to the COVID-19 pandemic revealed both strengths and fundamental flaws in the current state of global health governance. The WHO remains underfunded despite the ever-growing need to engage a wider and more complex range of health issues. This may be what some have called "the golden age of global health," but leaders of major global health organizations must work together to design an effective architecture that will make the most of opportunities to link new resources for and commitments to global health equity with the emerging understanding of disease burden and the unmet need to create robust and resilient national health systems. To this end, new and old players in global health must invest heavily in *discovery* (relevant basic science), *development* of new tools (preventive, diagnostic, and therapeutic), and modes of *delivery* that

*Deceased.

will ensure the equitable provision of health products and services to all who need them.

The adoption of the Sustainable Development Goals (SDGs) in 2015 by the United Nations serves as an example of effective cooperation. The SDGs articulate 17 overarching goals across several domains to be achieved by 2030. Goal 3 specifically relates to global health and contains 13 distinct targets to be met, including reducing maternal and child mortality; ending the epidemics of HIV, tuberculosis, and malaria; and reducing the burden of NCDs.

Included in the SDGs is a commitment to achieve universal health coverage (UHC), providing universal access to high-quality essential health services at an affordable cost worldwide. Championed by the WHO, the World Bank, and many civil society organizations, Goal 3 will measure coverage of 16 essential health services and assess the financial burden of health spending by households in every country.

THE ECONOMICS OF GLOBAL HEALTH

Political and economic concerns have often guided global health interventions. As mentioned, early efforts to control yellow fever were tied to the completion of the Panama Canal. However, the precise nature of the link between economics and health remains a matter for debate. Some economists and demographers argue that improving the health status of populations must begin with economic development; others maintain that addressing ill health is the starting point for development in poor countries. In either case, there is increasing consensus that investments in health care delivery and the control of communicable diseases lead to increased productivity. The question is where to find the necessary resources to start the predicted "virtuous cycle."

During the past two decades, spending on health in poor countries has increased dramatically. According to a study from the Institute for Health Metrics and Evaluation (IHME) at the University of Washington, before the COVID-19 pandemic, total development assistance for health (DAH) worldwide (essentially a measure of "health aid") grew to $38.9 billion in 2018—up from $5.6 billion in 1990—and seemed to reach a plateau. However, the global response to COVID-19 saw the largest yearly increases in DAH ever recorded. Between 2020 and 2021, DAH grew by 86%. It is estimated that in 2021 DAH reached $64.7 billion. In 2021, the leading contributors included the United States, the United Kingdom, Germany, and private foundations.

MORTALITY AND THE GLOBAL BURDEN OF DISEASE

Refining metrics is an important task for global health: only relatively recently have there been solid assessments of the global burden of disease. The first study to look seriously at this issue, conducted in 1990, laid the foundation for the first report on *Disease Control Priorities in Developing Countries* and for the World Bank's 1993 World Development Report *Investing in Health*. Those efforts represented a major advance in the understanding of health status in developing countries. *Investing in Health* has been especially influential: it familiarized a broad audience with cost-effectiveness analysis for specific health interventions and with the notion of disability-adjusted life years (DALYs). The DALY, which has become a standard measure of the impact of a specific health condition on a population, combines absolute years of life lost and years lost due to disability for incident cases of a condition. (See **Fig. 485-1** and **Table 485-1** for an analysis of the global disease burden by DALYs.)

In 2012, the IHME and partner institutions began publishing results from the Global Burden of Diseases, Injuries, and Risk Factors (GBD) study. The GBD study is the most comprehensive effort to date to produce longitudinal, globally ambitious, and comparable estimates of the burden of diseases, injuries, and risk factors. This report reflects the expansion of the available data on health in the poorest countries and of the capacity to quantify the impact of specific conditions on a population. It measures current levels and recent trends for major diseases, injuries, and risk factors worldwide. Since its original publication, the GBD study team has revised and improved the health-state severity weight system, collated published data, and used household surveys to enhance the breadth and accuracy of disease burden data. Updated reports were released in 2013, 2015, 2017, and 2019. The report now includes fact sheets that examine 386 diseases and injuries in depth. As analytic methods and data quality improve, important trends can be identified in a comparison of global disease burden estimates from 1990 to 2019.

GLOBAL MORTALITY

Although the COVID-19 pandemic has led to significant excess deaths, it is instructive to look at the last GBD study's data as a comprehensive baseline of disease burden before the pandemic. In 2019, before the COVID-19 pandemic, of the 56.5 million deaths worldwide, 17% (9.6 million) were due to communicable diseases, maternal and neonatal conditions, and nutritional deficiencies—a marked decrease compared with figures for 1990, when these conditions accounted for 32% of global mortality. Among the fraction of all deaths related to communicable diseases, maternal and neonatal conditions, and nutritional deficiencies, 78% occurred in Sub-Saharan Africa and southern Asia. While the proportion of deaths due to these conditions has decreased significantly in the past decade, there has been a dramatic rise in the number of deaths from NCDs. The leading cause of death worldwide in 2019 was ischemic heart disease, accounting for 9.1 million deaths (16% of total deaths). In high-income countries, ischemic heart disease accounted for 16% of total deaths, and in low-income countries, it accounted for 16%. It is noteworthy that ischemic heart disease was responsible for just 5% of total deaths in Sub-Saharan Africa **(Table 485-2)**. In second place—causing 11% of global mortality—was stroke, which accounted for 8% of deaths in high-income countries, 6% in low-income countries, and 5% in Sub-Saharan Africa. Although chronic obstructive pulmonary disease (COPD) was the third leading cause of death globally and was the fifth leading cause in high-income countries (accounting for 5% of all deaths), this condition did not figure among the top 15 causes in Sub-Saharan Africa. Among the 10 leading causes of death in Sub-Saharan Africa, five were infectious diseases, with HIV/AIDS, lower respiratory infections, diarrheal diseases, and malaria ranking as dominant contributors to disease burden. In high-income countries, however, only 1 infectious disease—lower respiratory infection—ranked among the top 10 causes of death.

The number of deaths among children under 5 years dropped from 16.4 million in 1970 to 11.8 million in 1990 and to 5.0 million in 2019—a decrease that far surpassed predictions. Of childhood deaths in 2021, 2.3 million (46%) occurred in the neonatal period. Just under one-third of deaths among children under 5 years old occurred in southern Asia and slightly more than one-half in Sub-Saharan Africa, but only ~1% occurred in high-income countries.

The global burden of death due to HIV/AIDS and malaria was on an upward slope until 2004, but significant progress has been made since then. Global deaths from AIDS fell from 2.0 million in 2006 to 630,000 in 2022, while malaria deaths dropped from 1.2 million to 608,000 over the same period. Despite these improvements, malaria and HIV/AIDS continue to be major burdens in particular regions, with global implications. Although it has only a minor impact on mortality outside Sub-Saharan Africa and Southeast Asia, malaria is the fifth leading cause of death of children under 5 years of age worldwide. HIV infection ranked 30th in global DALYs in 1990 but was the 11th leading cause of disease burden in 2019, with Sub-Saharan Africa bearing the vast majority of this burden (Fig. 485-1).

The world's population is living longer: global life expectancy has increased significantly over the past 50 years from 58.8 years in 1970 to 73.5 years in 2019. This demographic change, accompanied by the fact that the prevalence of NCDs increases with age, is dramatically shifting the burden of disease toward NCDs, which have surpassed communicable, maternal, nutritional, and neonatal causes. By 2019, 74% of total deaths at all ages and 63% of all DALYs were due to NCDs. Increasingly, the global burden of disease comprises conditions and injuries that cause disability rather than death.

Worldwide, although both life expectancy and years of life lived in good health have risen, years of life lived with disability also have increased. Globally, the total burden of disability increased by 50% between 1950 and 2019. Despite the higher prevalence of diseases

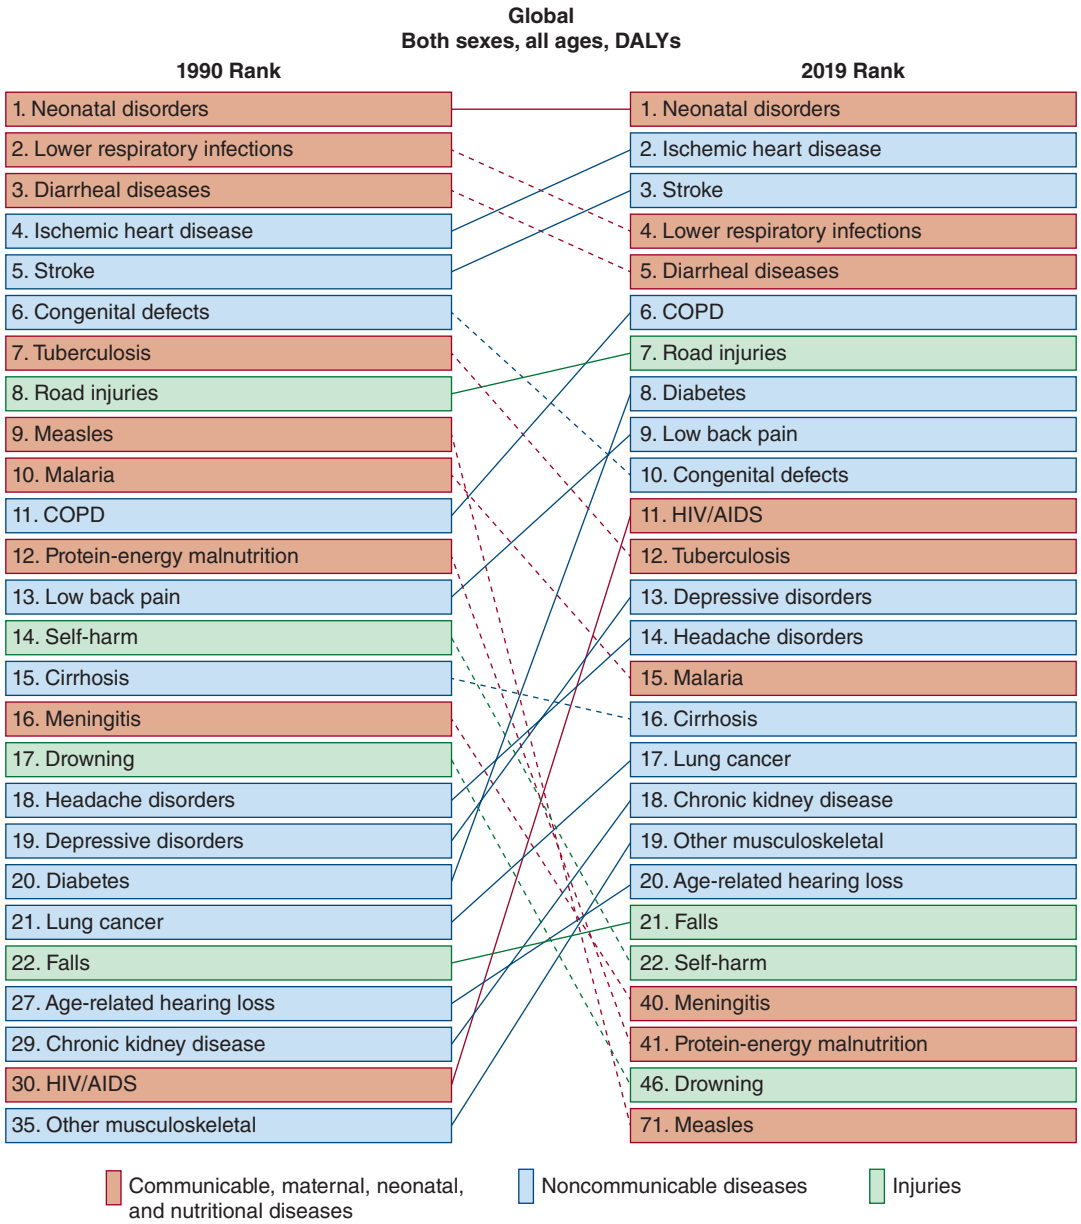

FIGURE 485-1 Global disability-adjusted life-year (DALY) ranks for the top causes of disease burden in 1990 and 2019. COPD, chronic obstructive pulmonary disease. *(From the Institute for Health Metrics and Evaluation [IHME]. GBD Compare. Seattle, WA: IHME, University of Washington, 2023. Available at http://vizhub.healthdata.org/gbd-compare. Accessed Dec 15, 2023.)*

common in older populations (e.g., dementia and musculoskeletal disease) in developed and high-income countries, best estimates from 2019 reveal that disability resulting from cardiovascular diseases, chronic respiratory diseases, and the long-term impact of communicable diseases was greater in low- and middle-income countries. In most developing countries, people lived shorter lives and experienced disability and poor health for a greater proportion of their lives.

HEALTH AND WEALTH

Clear disparities in burden of disease (both communicable and noncommunicable) across country income levels are strong indicators that poverty and health are inherently linked. Numerous studies have documented the link between poverty and health within nations as well as across them. Poverty remains one of the most important root causes of poor health worldwide, and the global burden of poverty continues to be high.

Among the 8 billion persons alive in 2023, 9% (700 million) lived on less than $2.15 per day—a standard measurement of extreme poverty—and half of these individuals lived in Sub-Saharan Africa. While children make up 31% of the overall global population, they account for 50% of persons living in poverty. The extreme poverty rate declined steadily between 1990 and 2019. Before the COVID-19 pandemic, compared with 1990, there were more than 1 billion fewer people living in poverty despite growth in the global population of more than 2 billion during that time. The COVID-19 pandemic led to significant increases in poverty, especially in low- and middle- income countries. The poorest bore the brunt of the economic shocks of COVID-19. The global poorest lost twice as much income as the richest between 2020 and 2022.

RISK FACTORS FOR DISEASE BURDEN

The GBD study found that the three leading risk factors for global disease burden in 2019 were (in order of frequency) high systolic blood pressure, smoking, and high fasting plasma glucose—a substantial change from 1990, when childhood malnutrition was ranked first. Although its prevalence has declined, maternal and childhood malnutrition remain the leading risk factors for death among children < 5 years of age. In an era that has seen obesity become a major health concern in many developed countries, the persistence of undernutrition is cause for consternation. In its rural reaches, no health care initiative, however generously funded, will be effective or comprehensive without addressing undernutrition.

In an analysis that examined how specific diseases and injuries are affected by environmental risk, the WHO estimates that 24% of all

deaths and 28% of deaths among children <5 years of age in 2019 were due to modifiable environmental factors: some 17 million children die every year from causes related to unhealthy environments, including the nearly 500,000 deaths stemming from a lack of access to clean water and sanitation. Many of these modifiable factors lead to child and adult deaths from infectious pathologies; others lead to deaths from malignancies. Risk factors such as indoor air pollution due to use of solid fuels account for 25% of DALYs due to lower respiratory infections

globally. Various forms of unintentional injury and malaria top the list of health problems to which environmental factors contribute.

The third edition of *Disease Control Priorities* (DCP3), published as a set of serial volumes based on content area, provides evidence-based recommendations and cost-effectiveness analyses for numerous interventions, with attention to strategies for strengthening health systems. Cost-effectiveness analyses that compare relatively equivalent interventions in order to facilitate sound decisions under constraint are necessary; however, these analyses, as the DCP3 authors acknowledge, are unreliable when based on an incomplete knowledge of cost and evolving evidence of effectiveness. As both resources and objectives for global health initiatives grew, cost-effectiveness analyses (particularly those based on older evidence) sometimes steered policy makers and public health experts toward low-cost but ultimately ineffective interventions or away from higher-priced but effective ones. Thus, we use the term *global health equity* to emphasize the need to ensure equitable access to high-value health interventions. To illustrate these points, it is instructive to look to HIV/AIDS, which in the course of the last four decades has become one of the world's leading infectious causes of adult death.

HIV INFECTION/AIDS

Chapter 208 provides an overview of the global HIV epidemic today. Approximately 39 million people worldwide were living with HIV infection in 2022, and it was the underlying cause of death for 630,000 people that year. Approximately 67% of all people living with HIV live in Sub-Saharan Africa. Here the discussion will be limited to HIV/AIDS in the developing world. Lessons learned from tackling HIV/AIDS in low-resource settings are highly relevant to discussions of other chronic diseases, including NCDs, for which effective therapies have been developed. In the United States, after the mid-1990s, ART transformed HIV infection from an inescapably fatal disease into a manageable chronic illness. Across high-income countries, improved ART has dramatically prolonged life expectancy for people living with HIV infection, which now approaches that of the general population. This success rate exceeds that obtained with almost any treatment for adulthood cancer or for complications of coronary artery disease. In developing countries, treatment has been offered broadly only since 2003. Before 2003, many arguments were raised to justify not moving forward rapidly with ART programs for people living with HIV/AIDS in resource-limited settings. The standard litany included the price of therapy compared with the poverty of patients, the complexity of the intervention, the lack of infrastructure for laboratory monitoring, and the lack of trained health care providers. Narrow cost-effectiveness arguments that created false dichotomies—prevention *or* treatment rather than their synergistic integration—too often went unchallenged by policy makers, public health experts, and health economists. As a cumulative result of these delays in the face of health disparities both old and new, there were millions of premature deaths.

Disparities in access to HIV treatment did give rise to widespread moral indignation and a new type of health activism. In several middle-income countries, including Brazil, public programs have helped bridge the global access gap. Other innovative projects pioneered by international nongovernmental organizations (NGOs) in diverse settings such as Haiti and Rwanda have established that a simple approach to ART based on intensive community engagement and social and economic support for patients and their community-based health workers can achieve remarkable results **(Fig. 485-2)**.

During the past decade, the availability of ART has increased sharply in the low- and middle-income countries that have borne the greatest burden of the HIV/AIDS pandemic. In 2000, few people living with HIV/AIDS in these nations had access to ART, whereas by 2022, 76% of people living with HIV infection were receiving ART. In light of these dramatic gains, coverage targets have grown more ambitious; for example, in 2014, UNAIDS set the 90-90-90 targets, which aimed to have 90% of people living with HIV know their status, 90% of those with HIV treated with ART, and 90% of those on treatment achieving viral load suppression by 2020. Five countries met these ambitious goals: Botswana, Eswatini, Rwanda, the United Republic of Tanzania, and Zimbabwe. These goals were updated to "95-95-95" targets for 2030, and by 2023, these same five countries had already achieved them.

This scale-up was made possible by several developments: a staggering drop in the cost of generically manufactured ART, the development of a standardized approach to treatment, substantial investments by funders, and the political commitment of governments to afford ART as a public good. Civil-society AIDS activists spurred many of these efforts.

Starting in the early 2000s, a combination of factors, including work by the Clinton HIV/AIDS Initiative (now known as the Clinton Health Access Initiative) and Médecins Sans Frontières, led to the availability of generic ART medications. While first-line ART cost >$10,000 per patient per year in 2000, first-line regimens in low- and middle-income countries are now available for <$45 per year. At the same time, fixed-dose combinations made multidrug regimens easier to administer. Also, around this time, the WHO began advocating a public health approach to the treatment of people with AIDS in low-resource settings; this approach promised—thanks to dropping viremia—to lower transmission rates and, if universally available, to end almost all mother-to-child transmission. Derived from models of care pioneered by the NGO Partners In Health and other groups, this approach proposed the use of standard first-line treatment regimens based on a simple five-drug formulary, with a more complex (and more expensive) set of second-line options in reserve. Clinical protocols were standardized, and intensive training packages for health professionals and community health workers were developed and implemented in many countries. Early rollout efforts were supported by new funding from the Global Fund and PEPFAR. In 2003, lack of access to ART was declared a global public health emergency by the WHO and UNAIDS, and those two agencies launched the 3 by 5 Initiative, setting an ambitious target: to have 3 million people in developing countries on treatment by the end of 2005. Many countries set corresponding national targets and have worked to integrate ART into their national AIDS programs and health systems and to harness the synergies between HIV/AIDS treatment and prevention activities. External funding to

FIGURE 485-2 An HIV and tuberculosis (TB)–co-infected patient in Rwanda before (***left***) and after (***right***) 6 months of treatment.

fight HIV/AIDS in low- and middle-income countries increased dramatically during this period and beyond, rising from $332 million in 1996 to $9.9 billion in 2021. The integration of prevention and care led to a sharp drop in transmission—a 96% decline according to one review of the impact of ART rollout in heavily burdened countries in Africa and the Caribbean.

Further lessons with implications for policy and action have come from efforts now under way among lower-income countries. Rwanda provides an example: since 2000, mortality from HIV disease has fallen by 85% as the country—despite its relatively low gross national income—has provided almost universal access to ART. The reasons for this success include strong national leadership, evidence-based policy, cross-sector collaboration, community-based care, and a deliberate focus on a health-systems approach that embeds HIV/AIDS treatment and prevention in the primary health care service delivery platform. As we will discuss later in this chapter, these principles can be applied to other conditions, including NCDs.

TUBERCULOSIS

Chapter 183 provides a concise overview of the pathophysiology and treatment of tuberculosis. In 2022, an estimated 1.3 million people died from *Mycobacterium tuberculosis* infection; this figure made tuberculosis the second leading single infectious killer after COVID-19 of adults globally. The disease is closely linked to HIV infection in much of the world: of the 10.6 million estimated new cases of tuberculosis in 2022, 890,000 occurred among people living with HIV. A much more substantial proportion of the resurgence of tuberculosis registered in southern Africa is attributed to HIV co-infection. Even before the advent of HIV, however, it was estimated that fewer than one-half of all cases of tuberculosis in developing countries were ever diagnosed. Primarily because of the common failure to diagnose and treat tuberculosis, international authorities devised a single strategy to reduce the burden of disease. In the early 1990s, the World Bank, the WHO, and other international bodies promoted the DOTS strategy (*d*irectly *o*bserved *t*herapy using *s*hort-course isoniazid- and rifampin-based regimens) as highly cost-effective. Passive case-finding of smear-positive patients was central to the strategy, as was an uninterrupted drug supply.

DOTS was clearly effective for most uncomplicated cases of drug-susceptible tuberculosis, but several shortcomings were soon identified. First, the diagnosis of tuberculosis based solely on sputum smear microscopy—a method dating from the late nineteenth century—is not sensitive. Many cases of pulmonary tuberculosis and all cases of exclusively extrapulmonary tuberculosis are missed by smear microscopy, as are most cases of active disease in children. Second, passive case-finding relies on the availability of health care services, which is uneven in the settings where tuberculosis is most prevalent. Third, patients with multidrug-resistant tuberculosis (MDR-TB) are by definition infected with strains of *M. tuberculosis* resistant to isoniazid and rifampin; thus, exclusive reliance on these drugs is unwarranted in settings in which drug resistance is an established problem.

The crisis of antibiotic resistance registered in U.S. hospitals is not confined to the industrialized world or to common bacterial infections. While the great majority of patients sick with and dying from tuberculosis are afflicted with strains susceptible to all first-line drugs, a substantial minority of patients with tuberculosis in some settings are infected with strains of *M. tuberculosis* resistant to at least one first-line antituberculosis drug. Globally in 2021, an estimated 4% of all patients with new *M. tuberculosis* infections and 18% of all previously treated patients were infected with rifampin-resistant or MDR strains; most of these cases resulted from primary transmission. It was clear that poor infection control in hospitals and clinics in the face of delays in the initiation of effective therapy led to explosive and lethal epidemics due to these strains. To improve DOTS-based responses to MDR-TB, global health authorities adopted DOTS-Plus, which adds the diagnostics and drugs necessary to manage drug-resistant disease. Even as DOTS-Plus was being piloted in resource-constrained settings, however, new strains of extensively drug-resistant (XDR) *M. tuberculosis* (resistant to isoniazid and rifampin, any fluoroquinolone, and at least one injectable second-line drug) had already threatened the success of tuberculosis control programs in beleaguered South Africa, for example, where high rates of HIV infection had led to a doubling in the incidence of tuberculosis over the preceding decade. Genetic fingerprinting of cultures of infected sputum and tissues suggest that patients may be infected by more than one strain. Despite the poor capacity for detection of MDR- and XDR-TB in most resource-limited settings, an estimated 450,000 cases of MDR-TB were thought to have occurred in 2021. Approximately 8% of these cases were caused by XDR strains.

TUBERCULOSIS AND AIDS AS CHRONIC DISEASES: LESSONS LEARNED

Strategies effective against MDR-TB have implications for the management of drug-resistant HIV infection and even drug-resistant malaria, which, through repeated infections and a lack of effective therapy, has become a chronic disease in parts of Africa (see "Malaria," below). As new therapies, whether for tuberculosis or for hepatitis C infection, become available, many of the problems encountered in the past will recur. Indeed, examining AIDS and tuberculosis as chronic diseases—instead of simply communicable ones—makes it possible to draw several conclusions, many of them pertinent to global health equity in general.

First, the chronic infections discussed here are best treated with multidrug regimens to which the infecting strains are susceptible. This is true of chronic infections due to many bacteria, fungi, parasites, or viruses; even acute infections such as those caused by *Plasmodium* species are not reliably treated with a single drug.

Second, charging fees for AIDS prevention and care poses insurmountable problems for persons living in poverty, many of whom are unable to pay even modest amounts for services or medications. Like efforts to battle airborne tuberculosis, such services might best be seen as a public good promoting public health. Initially, a subsidy approach will require sustained donor contributions, but many African countries have set targets for increased national investments in health—a pledge that could render ambitious programs sustainable in the long run, as the Rwanda experience suggests. Meanwhile, as local investments increase, the price of AIDS care continues to decrease. The use of generic medications means that ART can now cost <$0.13 per day.

Third, the effective scale-up of pilot projects requires strengthening and sometimes rebuilding of health care systems, including those charged with delivering primary care. In the past, the lack of health care infrastructure has been cited as a barrier to providing ART in the world's poorest regions; however, AIDS resources, which are at last considerable, may be marshaled to rebuild public health systems in Sub-Saharan Africa and other HIV-burdened regions—precisely the settings in which tuberculosis is resurgent. Failure to pursue such a health-systems approach after civil wars ended in Sierra Leone and Liberia accounts for much of their extreme vulnerability to Ebola a decade later.

Fourth, the lack of trained health care personnel, most notably doctors and nurses, still must be addressed. The WHO recommends a minimum of 1 physician per 1000 persons, but many countries, especially in Sub-Saharan Africa, fall far short of that target. Specifically, ~45% of WHO member states report not achieving that target. In Sub-Saharan Africa, there were 0.3 physicians per 1000 people. In contrast, the United States and Cuba report 2.5 and 8.4 doctors per 1000 population, respectively. Similarly, ~50% of WHO member states report having fewer than 3 nurses and midwives per 1000 population. Sub-Saharan Africa bears >20% of the global burden of disease but has access to only 3% of the world's health workers. Further inequalities in health care staffing exist within countries. Rural–urban disparities in health care personnel mirror disparities of both wealth and health. For instance, in Sierra Leone, an estimated 75% of the national health workforce is concentrated in urban areas, where just 44% of the population lives. Even community health workers trained to provide first-line services to rural populations often transfer to urban districts.

In what is termed the "brain drain," many physicians and nurses emigrate from their home countries to pursue opportunities abroad, leaving behind health systems that are understaffed and ill-equipped to deal with either emergencies like Ebola or the usual burden of disease.

One reason doctors and nurses leave Sub-Saharan Africa and other low-income areas is that they lack the tools to practice there. Funding for "vertical" (disease-specific) programs can be used not only to strengthen health systems but also to recruit and train physicians and nurses to underserved regions where they, in turn, can help to train and then work with community health workers in supervising care for patients with AIDS and many other diseases within their communities. Such training should be undertaken even where physicians are abundant, since close community-based supervision represents the highest standard of care for chronic disease, whether in developing or developed countries. The United States, which has a dearth of health care providers in many of its poor and rural communities, has much to learn from Rwanda in this regard.

Fifth, the many barriers to adequate health care and patient adherence that are raised by extreme poverty can be removed only with the deployment of "wrap-around services": food supplements for the hungry, help with transportation to clinics, childcare, and housing. Extreme poverty makes it difficult for many patients to comply with therapy for chronic diseases, whether communicable or not. Experience shows, however, that these many barriers can be more readily surmounted than the extreme poverty itself to which chronic disease and acute infection contribute substantially. Indeed, poverty in its many dimensions is far and away the greatest obstacle to the scale-up of treatment and prevention services.

Finally, there is a need for a renewed basic-science commitment to the discovery and development of vaccines; more reliable, less expensive diagnostic tools; and new classes of therapeutic agents. This need applies not only to HIV, tuberculosis, and malaria—against none of which there is a highly effective vaccine—but also to most other neglected diseases of poverty.

MALARIA

Chapter 231 reviews the etiology, pathogenesis, and clinical treatment of malaria, the world's fifth-ranking infectious killer. In 2022, there were 249 million cases of malaria, and the disease killed 608,000 people; 77% of these deaths occurred among children <5 years old. The poor disproportionately experience the burden of malaria. Sub-Saharan Africa was home to about 94% of all malaria cases and 95% of all deaths. Just 4 countries—Nigeria, the Democratic Republic of the Congo, Uganda, and Mozambique—account for more than half of total malaria deaths globally.

Malaria's human cost has been enormous, with the highest toll among children—especially African children—living in poverty. In 2022, $4.3 billion was spent on malaria worldwide, but the WHO target is more than twice that sum. Macroeconomic analyses estimate that malaria may reduce the per capita gross national product of a disease-endemic country by 50% relative to that of a non–malaria-endemic country. The causes of this drag include impaired cognitive development of children, decreased schooling, decreased savings, decreased foreign investment, and restriction of worker mobility. Microeconomic analyses focusing on direct and indirect costs estimate that malaria may consume >10% of a household's annual income in malaria endemic regions.

In part because of differences in vector distribution and climate, resource-rich countries offer few blueprints for malaria control and treatment that are applicable in tropical (and resource-poor) settings. In 2001, African heads of state endorsed the WHO Roll Back Malaria (RBM) campaign, which prescribes strategies appropriate for Sub-Saharan African countries. In 2008, the RBM partnership launched the Global Malaria Action Plan (GMAP). This strategy integrates prevention and care and calls for the avoidance of single-dose regimens and an awareness of existing drug resistance; the use of insecticide-treated bed nets (ITNs); indoor residual spraying; artemisinin-based combination therapy (ACT); intermittent preventive treatment during pregnancy; prompt diagnosis; and other vector control measures such as larviciding and environmental management.

Over the past two decades, these efforts have dramatically reduced the global burden of malaria resulting in the prevention of 1.7 billion cases and saving 10.6 million lives.

Meeting the challenge of malaria control will continue to require careful study of appropriate preventive and therapeutic strategies in the context of an increasingly sophisticated molecular understanding of pathogen, vector, and host. However, an appreciation of the economic and social devastation wrought by malaria—like that inflicted by diarrhea, AIDS, and tuberculosis—on the most vulnerable populations should heighten the level of commitment to critical analysis of ways to implement proven strategies for prevention and treatment.

Funding from the Global Fund, the Gates Foundation, the World Bank's International Development Association, and the U.S. President's Malaria Initiative, along with leadership from public health authorities, is critical to sustain the benefits of prevention and treatment. Building on the growing momentum of the last decade with adequate financial support, innovative strategies, and effective tools for prevention, diagnosis, and treatment, we may yet achieve the goal of a world largely free of malaria.

EBOLA

Chapter 216 provides an overview of the epidemiology, pathogenesis, and clinical manifestations of Ebola virus and Marburg virus infections. The 2013–2016 outbreak of Ebola virus disease in West Africa was the largest documented Ebola epidemic to date, with >28,000 recorded cases and 11,000 recorded deaths.

Prior to the outbreak, the health systems of the three most affected countries—Liberia, Guinea, and Sierra Leone—were among the world's weakest. Histories of extractive colonial and postcolonial commerce, the conditional aid policies of international financial institutions, recent civil conflict, and underresourced health ministries left this part of West Africa bereft of the means to deliver modern medicine and promote public health. In 2013, Sierra Leone had the world's highest maternal mortality ratio, with 1180 deaths per 100,000 live births. According to one estimate, Liberia had just 51 physicians working in the entire country before the Ebola epidemic, or roughly one physician per 100,000 persons. Clinics and hospitals were scarce across the region, especially in rural areas, and routinely lacked drugs, supplies, electricity, running water, laboratories, and personal protective equipment for the prevention of nosocomial infection. Such deficits were not surprising given these countries' meager public and private expenditures on health.

The unprecedented scale of the West African Ebola epidemic was largely a symptom of these chronically weak health systems. As a result, clinicians, patients' families, and other caregivers—tasked with nursing the sick and interring the dead but lacking the means to do so safely—faced disproportionately high risks of Ebola infection. Health facilities with poor infection control and unsafe burials served as amplifiers of transmission.

The quest to contain Ebola in West Africa was one of the largest global public health efforts at that time, but it was far from ambitious clinically. As in previous Ebola outbreaks, preventing new infections was often prioritized over improving survival among those already infected, leading to substandard care for most West African patients and high case-fatality rates—by WHO estimates, ~70%. However, in settings in which quality supportive and critical care could be provided, clinical outcomes among Ebola-infected patients affirmed that Ebola virus disease is treatable, even in the absence of specific antiviral therapies and experimental drugs.

As with efforts to combat AIDS and tuberculosis, the global response to Ebola reveals the unintended consequences of pitting preventive strategies against therapeutic ones—and the pull of debates about scarcity. Misguided (and often contradictory) public health messaging, distrust of disease-control and social mobilization teams, punitive containment measures, and the unavailability of safe Ebola treatment units capable of delivering effective clinical care deterred individuals from presenting to health facilities, reporting symptomatic patients and their contacts, and cooperating with epidemic response activities. The resulting epidemic of mistrust facilitated the further spread of new infections by impeding surveillance, timely diagnosis, contact tracing, and patient isolation.

In August 2018, a new Ebola outbreak was detected in eastern Democratic Republic of the Congo (DRC) and soon became the world's second largest on record. In June 2020, when it was declared over, it had sickened ~3500 persons and killed two-thirds of them. Containment

was complicated by armed conflict in the affected region, which had long experienced strife, impoverishment, and colonial and postcolonial extraction, feeding a well-founded suspicion of foreign intervention.

Despite these challenges, responders benefitted from the arrival of new tools to prevent, diagnose, and treat Ebola. A new vaccine was extensively deployed using a ring vaccination strategy. There was significant progress in the quality of supportive care provided to patients in DRC, with more routine monitoring, improved access to clinical laboratory services, better staffing of treatment centers, and more aspirational clinical protocols. Nevertheless, the overall case-fatality rate in DRC reveals that these welcome medical innovations did not reach everyone in need of them.

COVID-19

Chapter 205 provides an overview of the epidemiology, pathogenesis, and clinical manifestations of COVID-19 infection. As we near the end of the fourth year of the pandemic, there have been more than 7 million confirmed deaths due to COVID-19 infection and 780 million confirmed cases. Reasonable estimates suggest that the true total of deaths is likely ~18 million. During this period, COVID-19 was among the top five causes of death worldwide. In the early months of the COVID-19 pandemic, many health systems in high-income countries were strained to treat the surge of patients afflicted by it. The pandemic revealed deep structural deficiencies in our collective global ability to recognize and contain such "novel" pathogens. Although SARS-CoV-2 is "novel" in relation to our human immune systems, its rapid march across the globe followed the familiar pattern of many pandemic pathogens before it, such as HIV, tuberculosis, and cholera. It has particularly high attack rates among vulnerable populations, such as those experiencing homelessness and nursing home residents, and in poor communities where insufficient housing, food insecurity, and marginal employment in low-paid service jobs have resulted in inability to safely social distance and quarantine. The United States suffered during the early parts of this pandemic from underinvestment in public health systems that can provide surveillance testing at scale and perform robust contact tracing. On the global level, profound inequities occurred in access to vaccines and therapeutics. The COVID-19 Vaccines Global Access (COVAX) initiative had broad global support and ambitious goals but was unable to meet its targets. This was due, in part, to lack of access to sufficient vaccine doses as a result of excess procurement by high-income countries for their own use. COVAX successfully delivered 2 billion doses of vaccine and is thought to have averted 2.7 million deaths. We share a deep hope that this pandemic may catalyze a broader recognition about the effects of poverty on health, about the need to achieve universal access to health care for all the world's people, and about the urgency of strengthening global public health systems.

"NONCOMMUNICABLE" CHRONIC DISEASES

Although the burden of communicable diseases—especially HIV infection, tuberculosis, and malaria—still accounts for the majority of deaths in resource-poor regions within Sub-Saharan Africa and in the poorest reaches of several first-world cities, 74% of all deaths worldwide in 2022 were attributed to NCDs. Although we use this term to describe cardiovascular diseases, cancers, diabetes, and chronic lung diseases, this usage masks important distinctions. For instance, two significant NCDs in low-income countries, rheumatic heart disease (RHD) and cervical cancer, represent the chronic sequelae of infections with group A *Streptococcus* and human papillomavirus, respectively, and it is in these countries that the burden of disease due to NCDs is rising most rapidly. A little more than three-quarters of deaths attributable to NCDs occur in low- and middle-income countries, which also account for 85% of all early NCD-related deaths—a figure representing ~17 million persons and exceeding the total number of deaths due to AIDS, tuberculosis, and malaria combined. By 2030, NCDs will account for 52 million deaths annually worldwide if no additional action is taken. The recent increase in resources for and attention to communicable diseases is both welcome and long overdue, but developing countries are already carrying a "double burden" of communicable and noncommunicable diseases.

Diabetes, Cardiovascular Disease, and Cancer: A Global Perspective In contrast to tuberculosis, HIV infection, and malaria—diseases caused by single pathogens that damage multiple organs—cardiovascular diseases reflect injury to a single organ system downstream of a variety of insults, both infectious and noninfectious. Some of these insults result from rapid changes in diet and labor conditions; others are of a less recent vintage. The burden of cardiovascular disease in low-income countries represents one consequence of decades of neglect of health systems. Furthermore, cardiovascular research and investment have long focused on the ischemic conditions that are increasingly common in high- and middle-income countries.

Predictions of an imminent rise in the share of deaths and disabilities due to NCDs in developing countries have led to calls for preventive policies to improve diet, increase exercise, and restrict tobacco use, along with the prescription of multidrug regimens for persons at high-level vascular risk. Although this agenda could do much to prevent pandemic NCDs, it will do little to help persons with established heart disease stemming from nonatherogenic pathologies.

The misperception of cardiovascular diseases as a problem primarily of elderly populations in middle- and high-income countries has contributed to the neglect of these diseases by global health institutions, including regionally focused ones. Even in Eastern Europe and Central Asia, where the collapse of the Soviet Union was followed by a catastrophic surge in cardiovascular disease deaths (mortality rates from ischemic heart disease nearly doubled between 1991 and 1994 in Russia, for example), the modest flow of overseas development assistance to the health sector during these troubled years focused on the communicable causes that accounted for <1 in 20 excess deaths during that period.

DIABETES The International Diabetes Federation reports that the number of diabetic adult patients in the world is expected to increase from 537 million in 2022—~1 in 11 adults—to 783 million by 2045. Already, a significant proportion of patients with diabetes, 3 in 4 adults with the condition, live in developing countries where, because those affected are often younger, the complications of micro- and macrovascular disease take a far greater toll. Globally, these complications are a major cause of disability and reduced quality of life: a high fasting plasma glucose level ranks third among risks for disability and global mortality. The GBD 2017 study estimates that diabetes accounted for 1.6 million deaths in 2019; 84% of these deaths occurred in low- and middle-income countries.

CARDIOVASCULAR DISEASE Because systemic investigation of the causes of stroke and heart failure in Sub-Saharan Africa has begun only recently, little is known about the impact of elevated blood pressure in this portion of the continent. Modestly elevated blood pressure in the absence of tobacco use in populations with low rates of obesity may confer little risk of adverse events in the short term. In contrast, persistently elevated blood pressure goes largely undetected, untreated, and uncontrolled in this part of the world. In the cohort of men assessed in the Framingham Heart Study, the prevalence of blood pressures above 210/120 mmHg—severe hypertension—declined from 1.8% in the 1950s to 0.1% by the 1960s with the introduction of effective antihypertensive agents. Although debate continues about appropriate screening strategies and treatment thresholds, Africa's rural health centers, run largely by nurses, must quickly gain access to antihypertensive medications.

The epidemiology of heart failure also reflects inequalities in risk factor prevalence and in access to therapy. The reported burden of this condition has remained unchanged since the 1950s, but the causes of heart failure and the age of the people affected vary across the globe. Heart failure as a consequence of pericardial, myocardial, endocardial, or valvular injury is a leading cause of hospitalization in the United States and Europe, representing ~3% of all hospitalizations, and is estimated to account for a substantial proportion of medical admissions in hospitals in low-income countries as well. In high-income countries, coronary artery disease and hypertension among the elderly account for most cases of heart failure. Among the world's poorest 1 billion people, however, heart failure reflects poverty-driven exposure of children and

young adults to rheumatogenic strains of streptococci and cardiotropic microorganisms (e.g., HIV, *Trypanosoma cruzi*, enteroviruses, *M. tuberculosis*), untreated high blood pressure, and nutrient deficiencies. The mechanisms underlying other causes of heart failure common in these populations—such as idiopathic dilated cardiomyopathy, peripartum cardiomyopathy, and endomyocardial fibrosis—remain unclear.

In stark contrast to the extraordinary lengths to which clinicians in wealthy countries will go to treat ischemic cardiomyopathy among elderly patients, little attention has been paid to young patients with nonischemic cardiomyopathies in resource-poor settings. Nonischemic cardiomyopathies, such as those due to hypertension, RHD, and chronic lung disease, account for >90% of cases of cardiac failure in Sub-Saharan Africa and include poorly understood entities such as peripartum cardiomyopathy (which has an incidence in rural Haiti of 1 per 300 live births) and HIV-associated cardiomyopathy. Lessons learned in the scale-up of chronic care for HIV infection and tuberculosis may be illustrative as progress is made in establishing the means to deliver heart-failure medications to these patients.

Some of the lessons learned from the chronic infections discussed above are, of course, relevant to cardiovascular disease, especially those classified as NCDs but caused by infectious pathogens. Integration of prevention and care remains as important today as in 1960 when Paul Dudley White and his colleagues found little evidence of myocardial infarction in the region near the Albert Schweitzer Hospital in Lambaréné, Gabon, but reported that "the high prevalence of mitral stenosis is astonishing." They termed it a duty to integrate prevention with penicillin prophylaxis and care, including medical management and surgery, when indicated. "The same responsibility," they agreed, "exists for those with correctable congenital cardiovascular defects."

RHD affects almost 40 million people worldwide, with ~2.8 million new cases each year. A meta-analysis of data on heart failure in Sub-Saharan Africa found that RHD was the third most common cause of heart failure in the region. This disease, which may cause endocarditis or stroke, leads to >300,000 deaths per year—almost all occurring in developing countries. Results from 14 low- and middle-income countries included in the Global Rheumatic Heart Disease Registry showed that mortality was significantly higher among patients living in low-income countries and among the less educated. Recent studies in Rwanda and Ethiopia have confirmed a high prevalence of RHD among schoolchildren, including those that are asymptomatic. In part because the prevention of RHD has not advanced since the disease's disappearance in wealthy countries, no part of Sub-Saharan Africa has eradicated RHD despite examples of success in Costa Rica, Cuba, and some Caribbean nations.

Strategies to eliminate RHD may depend on active case-finding, with confirmation by echocardiography, among high-risk groups as well as on efforts to expand access to surgical interventions among children with advanced valvular damage. Partnerships between established surgical programs and areas with limited or nonexistent facilities may help expand the capacity to provide lifesaving interventions to patients who otherwise would die early and painfully. Such partnerships can speed the further development of regional centers of excellence equipped to provide consistent, accessible, high-quality services to those now without them.

CANCER Low- and middle-income countries accounted for ~70% of the 10 million deaths due to cancer worldwide in 2020. By 2040, annual mortality from cancer is expected to increase to >16 million deaths—with developing countries experiencing a sharper increase than developed nations. "Western" lifestyle changes may be responsible for the increased incidence of cancers of the breast, colon, and prostate among populations in low- and middle-income countries, but historic realities, sociocultural and behavioral factors, genetics, and poverty itself already have a profound impact on cancer-related mortality and morbidity rates. Cancer-causing infections, such as human papillomavirus, hepatitis B virus, and *Helicobacter pylori*, are responsible for up to 50% of cancer cases in some countries in Sub-Saharan Africa. Infectious causes of cancer will continue to have a much larger impact in developing countries. Environmental and dietary factors, such as indoor air pollution and high-salt diets, also contribute to increased rates of certain cancers (e.g., lung and gastric cancers). Tobacco use (both smoking and chewing) is the most important source of increased mortality rates from lung, bladder and oral cancers. In contrast to decreasing tobacco use in many developed countries, the number of smokers is growing in developing countries, especially among women and young persons.

For many reasons, outcomes of malignancies are far worse in developing countries than in developed nations. As currently funded, overstretched health systems in poor countries are not capable of early detection; at the time of tissue diagnosis, the majority of patients already have incurable malignancies. Treatment of cancers is available for only a very small number of mostly wealthy citizens in most poor countries, and even when treatment is available, the range and quality of services are often substandard. Yet this need not be the future. Twenty years ago, MDR-TB and HIV infections were widely deemed untreatable in settings of great poverty. The feasibility of creating innovative programs that reduce technical and financial barriers to the provision of care for treatable malignancies among the world's poorest populations is now clear **(Fig. 485-3)**. Several middle-income countries, including Mexico, have expanded publicly funded cancer care to reach poorer populations. This commitment of resources has dramatically improved outcomes for cancers, from childhood leukemia to cervical cancer.

Prevention of Noncommunicable Diseases False dichotomies, including those pitting prevention against care, persist in global health and reflect, in part, outmoded paradigms or a limited understanding of shifts in disease burden and causality as well as the dramatic variations in risk within a single nation. Moreover, such dichotomies or debates are sometimes politicized as a result of vested interests. Although globalization has had many positive effects, one negative effect has been the growth in both developed and developing countries of well-financed lobbies that have aggressively promoted unhealthy dietary changes and increased consumption of alcohol and tobacco. The WHO's 2003 Framework Convention on Tobacco Control represented a major advance, committing all of its signatories to a set of policy measures shown to reduce tobacco consumption.

The WHO estimates that 80% of all cases of cardiovascular disease and type 2 diabetes as well as 40% of all cancers can be prevented through healthier diets, increased physical activity, and avoidance of tobacco. These estimates mask large local variations. Although some evidence indicates that population-based measures can have some impact on these behaviors, it is sobering to note that increasing obesity levels have not been reversed in any population. Tobacco avoidance may be the most important and most difficult behavioral modification of all. In the twentieth century, 100 million people worldwide died of tobacco-related diseases; it is projected that >1 billion people will die of these diseases in the twenty-first century, with the vast majority of those deaths in developing countries. Today, ~80% of the world's 1.1 billion smokers live in low- and middle-income countries. In 2019, tobacco use caused 8.7 million deaths, including deaths due to second-hand smoke. The majority of these deaths occurred in low- and middle-income countries. However, there is well-proven evidence that changes in policy, such as taxes on tobacco and indoor and workplace smoking bans, are effective in decreasing the number of people using tobacco, reducing the amount of tobacco consumed, and preventing young people from starting to use tobacco.

MENTAL AND NEUROLOGIC HEALTH

In 2019, 1 in every 8 people, ~970 million people worldwide, lived with a mental health disorder, including >580 million people suffering from depression and anxiety disorders. One in 4 patients visiting a health service has at least 1 mental, neurologic, or behavioral disorder, but most of these disorders are neither diagnosed nor treated. More than 700,000 people die by suicide every year, and depressive disorders are the second leading cause of years lost to disability in the world today. Most low- and middle-income countries devote <1% of their health expenditures to mental health.

A B

FIGURE 485-3 An 11-year-old Rwandan patient with embryonal rhabdomyosarcoma before (***left***) and after (***right***) 48 weeks of chemotherapy plus surgery. Fifteen years later, she is healthy with no evidence of disease.

Increasingly effective therapies exist for many of the major causes of mental disorders. One of the greatest barriers to delivery of such therapies is the paucity of skilled personnel. Most Sub-Saharan African countries have only a handful of psychiatrists, for example, and almost all of them practice in cities and are unavailable within the public sector or to patients living in poverty. Among the few patients who are fortunate enough to see a psychiatrist or neurologist, fewer still are able to adhere to treatment regimens: several surveys of already diagnosed patients ostensibly receiving daily therapy have revealed that, among the poor, multiple barriers prevent patients from taking their medications as prescribed. In one study from Kenya, no patients being seen in an epilepsy clinic had therapeutic blood levels of antiseizure medications, even though all had been prescribed these drugs. Moreover, many patients in this study had no detectable blood levels of these agents at all. The same barriers that prevent the poor from having reliable access to insulin or ART prevent them from benefiting from antidepressant, antipsychotic, and antiepileptic agents. To alleviate this problem, some authorities are proposing the training of health workers to provide community-based adherence support, counseling services, and referrals for patients in need of mental health services. One such program instituted in Goa, India, used lay counselors and resulted in a significant reduction in symptoms of common mental disorders among the target population.

CONCLUSION: TOWARD GLOBAL HEALTH EQUITY

There is a long way to go before evidence-based internal medicine is applied effectively and equitably among the world's poor. Public health strategies typically operate on the population level, while clinical practice, including the practice of internal medicine, often remains focused on individual patient care. However, global health equity depends on avoiding the false dichotomies of the past: neither public health nor clinical approaches alone are adequate to address the problems of global health. The integration of prevention and care, along with adequate funding, has shown that complex infectious diseases such as HIV/AIDS and tuberculosis are not impossible to manage, even though drug resistance and lack of effective health systems have complicated such work. Beyond what is usually termed communicable disease—i.e., in the arena of chronic diseases such as cardiovascular disease and mental illness—global health is still a nascent, but growing, endeavor. Efforts to address any one of these problems in settings of great scarcity need to be integrated into broader efforts to strengthen failing health systems and alleviate the growing personnel crisis within these systems. Such efforts must include the building of platforms for care delivery that are robust enough to incorporate new preventive, diagnostic, and therapeutic technologies rapidly in response to changes both in the burden of disease and in the needs not met by existing paradigms and systems of care delivery.

Academic medical centers have tried to address this gap as new technologies are introduced and assessed through clinical trials, but the reach of these institutions into settings of poverty is limited in rich and poor countries alike. When such centers link their capacities effectively to the public institutions charged with the delivery of health care to the poor, great progress can be made. For these reasons, scholarly work and practice in the field once known as "international health" and now often designated *global health equity* are changing rapidly. That scholarship and practice is still informed by the tension between clinical practice and population-based interventions, between analysis and action, and between prevention and care.

A number of university hospitals have developed training programs for physicians with an interest in global health. These programs provide training not only in the clinical problems encountered in settings of poverty, but also instruction in public health, health care service delivery, and strategies of health systems strengthening.

At least half of the world's population lacks reliable access to essential health services; the consequence is millions of preventable deaths each year. An absolute majority of these premature deaths occur in Africa, with the poorer regions of Asia not far behind. They include deaths from vaccine-preventable illness, deaths during childbirth, deaths from infectious diseases that might be cured with access to antibiotics and other essential medicines, deaths from malaria that would have been prevented by ITNs and access to therapy, and deaths from waterborne illnesses—in short, from failures of health care delivery. Other excess mortality is attributable to the inadequacy of efforts to develop new preventive, diagnostic, and therapeutic tools.

The development of these tools must be followed quickly by their equitable distribution. Those funding the discovery and development of new tools typically neglect the concurrent need for strategies to make them available to the poor. Indeed, some would argue that the biggest challenge facing those who seek to address this outcome gap is the lack of practical means of delivery in the most heavily affected regions. When new preventive and therapeutic tools are developed without concurrent attention to delivery or implementation, one encounters what are sometimes termed "perverse effects": even as new tools are developed, inequalities of outcome—lower morbidity and mortality rates among those who can afford access, with sustained

high morbidity and mortality among those who cannot—grow in the absence of an equity plan to deliver the tools to those most at risk. Preventing such a future is among the most important goals of global health.

486 Emerging and Re-Emerging Infectious Diseases

David M. Morens, Anthony S. Fauci

EMERGING INFECTIOUS DISEASES: DEFINITION AND CLASSIFICATION

Pathogenic microorganisms and viruses have existed in the environment and in numerous animal species for millions of years. Humans have presumably had endemic infectious diseases since the origins of the human species, about 2 million years ago. However, until about 12,000 years ago, humans lived and moved about in small clans and tribal groups, experiencing limited contact with other humans or animals. During this pre-neolithic era, endemic infections were probably limited mostly to skin and gastrointestinal organisms. Even though contact with the environment and with animals undoubtedly led to sporadic infections with non-endemic pathogens, there was little opportunity for these pathogens to become widely spread among humans, i.e., to become epidemic.

This situation changed dramatically in the early neolithic age, about 10,000 BCE, in association with domestication of animals for food and for labor, planting and fertilization of crops, storage of water, organized disposal or diversion of sewage, growth of large settled villages and towns, labor specialization, and an enormous increase in human crowding and animal–human contacts. These new elements of human societal existence were associated with the emergence and human adaptation of existing enzootic and environmental organisms within populations large enough to sustain human-to-human spread, i.e., to cause emerging epidemics. It is believed that in this period the first significant emerging infectious diseases (EIDs) appeared.

The likelihood that numerous pandemic emergences occurred between the onset of the neolithic era and the era of microbial identification (beginning in the nineteenth century) is suggested by the large number of human pathogens that are today found globally in genetic and phenotypic forms that are identical or highly similar to each other—e.g., skin organisms such as staphylococci **(Chap. 152)**, streptococci **(Chap. 153)**, pneumococci **(Chap. 151)**, and corynebacteria **(Chap. 155)**; enteric pathogens like *Escherichia coli* **(Chap. 166)** and salmonellae **(Chap. 171)**; latently infecting neural viruses like herpesviruses **(Chap. 200)**; and sexually transmitted agents like human papillomavirus **(Chap. 203)**, gonorrhea **(Chap. 161)**, and syphilis **(Chap. 187)**. In some cases, microbial/virologic phylogenetic data allow rough estimation of the times of pathogen emergences, but even without such data, it is obvious that pandemic spread had to have occurred at some time in the past if we are to explain the global prevalence of many human pathogens today. EIDs and indeed pandemic IDs are thus a very old human phenomenon that we have only recently begun to consider.

EIDs have been defined and characterized as shown in **Table 486-1**. The importance of distinguishing between newly emerging IDs and re-emerging IDs (REIDs) has particular significance for clinicians, who usually are not only among the first to encounter the newly emerging group, but also among those with the greatest expertise in recognizing and dealing with the second group. It is also of note (Table 486-1) that subcategories of REIDs include accidental release of pathogens by human activities, e.g., vaccine-derived polioviruses or the sudden 1977 pandemic appearance of a long-extinct 1950s-era H1N1 influenza virus, presumably a result of undisclosed vaccine or other virologic research that led to viral "escape."

EMERGING INFECTIOUS DISEASES: THEIR IMPORTANCE

EIDs have been among the leading causes of death, disability, and social disruption throughout recorded human history **(Table 486-2)**. For example, it is believed by some historians that at least two of the biblical pharaonic plagues (around the thirteenth century BCE) were EIDs. The regionally pandemic "Plague of Athens" (430–425 BCE) is said to have brought about the end of the "Golden Age" of Greece.

TABLE 486-1 Emerging and Re-Emerging Infectious Diseases: Definitions, Categories, and Examples

Emerging infectious diseases (EIDs) are those recognized in humans for the first time, e.g., HIV/AIDS, Nipah virus infection, or severe acute respiratory syndrome (SARS) and COVID-19.

Re-emerging infectious diseases (REIDs) are those that have infected humans in the past and continue to reappear in new locations (e.g., West Nile virus in the United States and Russia in 1999), reappear in resistant or otherwise phenotypically different forms (e.g., influenza, methicillin-resistant *Staphylococcus aureus*, drug-resistant falciparum malaria), or reappear after apparent control or elimination (e.g., poliomyelitis in parts of Africa, cholera in Haiti in 2010 and elsewhere in association with natural disasters, wars, and mass migrations) or under unusual circumstances (e.g., deliberately released agents, including the 2001 anthrax bioterrorism attacks). Important subcategories of REIDs include the following:

- *REIDs related to accidental human release*—e.g., vaccine-derived polioviruses, epizootic vaccinia virus, and the 1979 Sverdlovsk laboratory explosion releasing anthrax spores
- *REIDs caused by human intent to harm (bioterrorism)*—e.g., the 1997 Oregon salad bar poisonings and the 2001 anthrax spore attacks in the United States

Established infectious diseases or *endemic infectious diseases* are those that have been prevalent for a sufficient period of time to allow for a relatively stable and predictable level of morbidity and mortality (e.g., many viral and bacterial respiratory and diarrheal diseases, including respiratory syncytial virus, endemic coronaviruses, noroviruses, pneumococcal disease, drug-susceptible malaria and tuberculosis, and many other tropical diseases such as helminthic and other parasitic diseases, many nosocomial infections).

TABLE 486-2 Selected Emerging Infectious Diseases of Note, 430 BCE to 2024 AD

YEAR	NAME	DEATHS	COMMENTS
430 BCE	"Plague of Athens"	~100,000	First identified transregional pandemic
541	Justinian plague (*Yersinia pestis*)	30–50 million	Pandemic; killed half of then-known world population
1340s	"Black Death" (*Yersinia pestis*)	~50 million	Pandemic; killed at least one-quarter of the known world population
1494	Syphilis (*Treponema pallidum*)	>50,000	Pandemic brought to Europe from the Americas
c. 1500	Tuberculosis	High millions	Ancient disease; became pandemic in Middle Ages
1520	*Hueyzahuatl* (*Variola major*)	3.5 million	Pandemic brought to New World by Europeans
1793–1798	"The American plague"	~25,000	Yellow fever terrorized colonial America
1832	Second cholera pandemic (Paris)	18,402	Spread from India to Europe/Western Hemisphere
1918	"Spanish" influenza	~50 million	Led to additional pandemics in 1957, 1968, 2009
1976–2020	Ebola	More than 15,000 deaths	First recognized in 1976; 29 regional epidemics to 2020
1981	Acute hemorrhagic conjunctivitis	Rare deaths	First recognized in 1969; pandemic in 1981
1981	HIV/AIDS	> 40 million	First recognized in 1981; ongoing pandemic
2002	SARS	774	Near-pandemic
2009	H1N1 "swine flu"	284,000	Fifth influenza pandemic in less than 100 years
2014	Chikungunya	Uncommon but high morbidity	Pandemic, mosquito-borne
2015	Zika	~1000?*	Pandemic, mosquito-borne

*Zika mortality has not been fully established. Most deaths are fetal or related to outcomes of severe congenital infections.

Both the Justinian plague (544 AD) and the Black Death pandemics of bubonic/pneumonic plague of 1347–1349 AD **(Chap. 176)** depopulated large segments of Europe and surrounding regions. The cholera **(Chap. 173)** pandemic of 1831–1832 killed large numbers of Europeans and ushered in the first modern studies to characterize disease and death in modern epidemiologic terms.

The past century has featured three of the most highly fatal pandemics the world has ever experienced: the 1918 H1N1 influenza **(Chap. 206)** pandemic, thought to have been the deadliest pandemic in human history; the human immunodeficiency virus (HIV)/acquired immune deficiency syndrome (AIDS) pandemic **(Chap. 208)**, which so far has killed more than 40 million people; and the COVID-19 pandemic **(Chap. 205)**, which is now (2024) in its fifth year, having killed more than 7 million people so far, and by some estimates as many as 20 million. In addition to the highly fatal and the potentially fatal pandemics of the past century, recent decades featured a seeming Pandora's box of EIDS **(Fig. 486-1)**, including novel pathogenic agents, re-emerging agents, and agents that are known but have re-emerged in entirely new forms, e.g., dengue hemorrhagic fever **(Chap. 215)**, Zika, and numerous antibiotic-resistant bacteria **(Chap. 150)**. It appears that we have entered a new era in which emergences and re-emergences of IDs are increasing in frequency and impact.

RESPONSE OF THE MEDICAL COMMUNITY TO INFECTIOUS DISEASES

Acceptance of the concept of infection—almost complete before 1890—quickly led to treatments such as antitoxins and immune plasmas, soon thereafter to non-vaccinia immunogens, by the 1930s to powerful

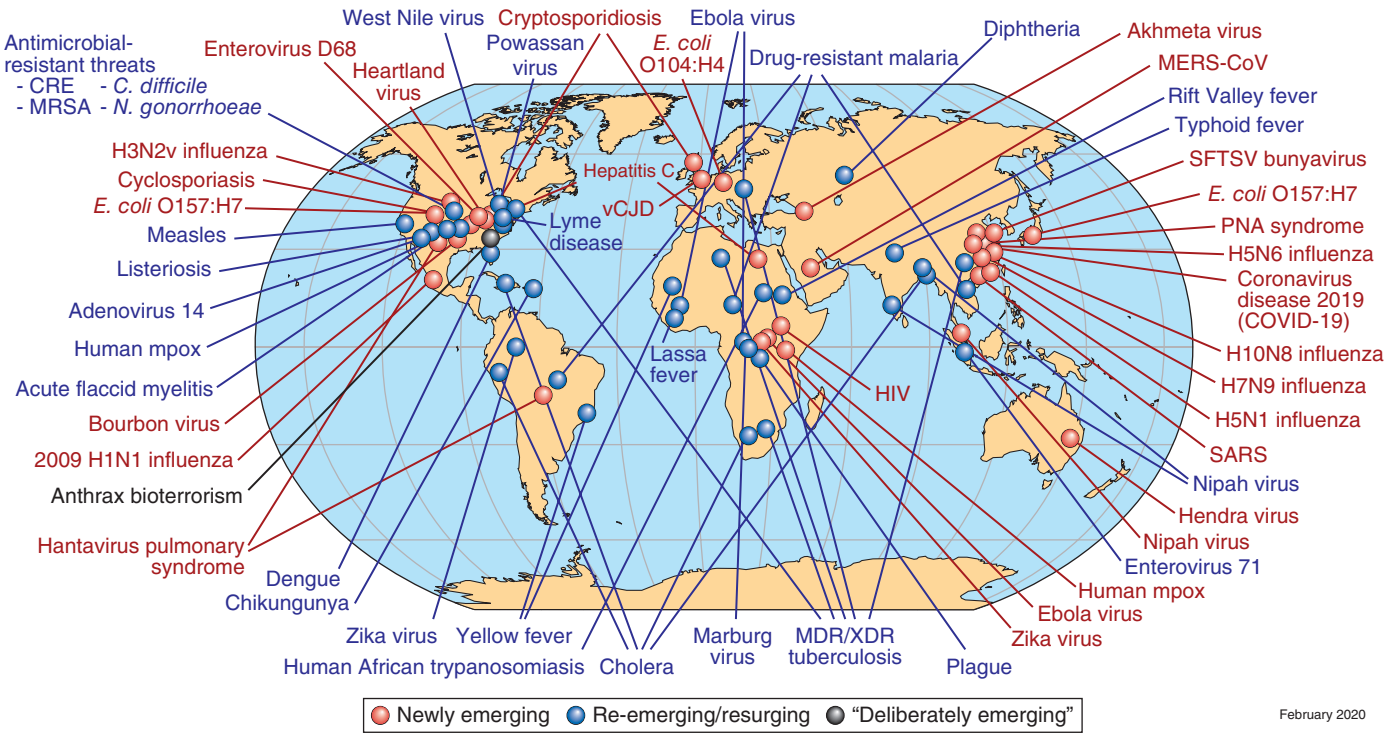

FIGURE 486-1 Selected newly emerging, re-emerging, and human-caused emergences over recent decades. *(Reproduced with permission from DM Morens, AS Fauci: Emerging pandemic diseases: How we got to COVID-19. Cell 182:1077, 2020.)*

antibiotics, and, by the 1950s, to antivirals. Ironically, however, these successes, which many considered miraculous, also led to significant overconfidence. By the 1960s, experts were predicting that infectious diseases would be conquered. In 1981 the U.S. Centers for Disease Control and Prevention was reorganized to pivot away from IDs and toward chronic and lifestyle-associated diseases that caused the greatest U.S. mortality and years of productive life lost (YPLL). Then, before the year was out, the world was shocked by the appearance of the AIDS pandemic, caused by a previously unknown body fluid–transmitted virus: HIV.

Although the AIDS pandemic was an enormous challenge, the biomedical research community, together with the pharmaceutical industry, eventually responded, most importantly by developing effective combination antiretroviral therapies, as well as risk-reduction programs such as needle exchanges and education in safe sexual practices.

A 1992 report of the Institute of Medicine (IOM; now the National Academy of Medicine) drew attention to the enormous problem of emerging infections, coined the term and characterized the scope of EIDs, defined the variables associated with emergences, and made far-reaching recommendations for preparedness, response, research, training, and medical and public health practice. Today, clinicians, scientists, public health officials, and government leaders work together within a global infrastructure of EID awareness, in which preparedness and response capacity have been increasingly successful. Such successes include stopping SARS from becoming globally pandemic and then eradicating its virus as a human pathogen; turning AIDS from an inevitably fatal disease to one associated with a normal lifespan for most patients who take antiviral medication; establishing the United States President's Emergency Plan for AIDS Relief (PEPFAR) program to bring life-saving AIDS treatment to the poorest corners of the world; and success in controlling the 2014–2016 regional Ebola **(Chap. 216)** pandemic in West Africa, without a vaccine or proven treatment, using standard public health measures alone.

This modern global EID control infrastructure includes not only vigorous detection of and response to EIDs, including international health regulations and EID oversight by the World Health Organization (WHO), but also controlling and even eradicating existing diseases. Apart from SARS, mentioned above, in 1980 smallpox **(Chap. 201)** was declared eradicated, a feat considered by some to be the most significant accomplishment in medical history, given the millions killed by the virus over many thousands of years. In 2011, the veterinary disease rinderpest was declared eradicated as well. A number of other important IDs now appear to be either close to eradication—e.g., poliomyelitis **(Chap. 210)**, dracunculiasis **(Chap. 240)**—or significantly controlled globally with eradication at least on the horizon—e.g., measles **(Chap. 211)**, rubella **(Chap. 212)**, yaws **(Chap. 183)**. All aspects of ID control, including controlling and trying to eradicate old emerging and still-re-emerging IDs, as well as preventing and controlling the emergences of new ones, work toward the same goal of reducing the impact of IDs on global human morbidity and mortality.

MECHANISMS OF EMERGENCE

Pathogens that newly emerge into humans are acquired via several different mechanisms. Some emerging pathogens are dead-end infections, i.e., they are not usually transmitted onward to other humans, and thus are not likely to become epidemic. Common examples of such infections are those arising from environmental "point-source exposures," in which many humans are exposed to a pathogen in one place over a very narrow window of time, e.g., coccidioidomycosis **(Chap. 219)** and histoplasmosis **(Chap. 218)** outbreaks associated with excavations, norovirus **(Chap. 209)** outbreaks aboard cruise ships (due to sewage-contaminated water), or bacterial/bacterial toxin contamination of foods in restaurants or at picnic or banquet events. Such point-source emergences tend to be sporadic, unpredictable, and of very short duration, the causative organisms being from the environment and usually well known and easily diagnosed, e.g., norovirus outbreaks identified by epidemiologic and clinical characteristics, or easily tested for, e.g., bacterial culture of enteric pathogens. They are typically short outbreaks of high morbidity but low mortality.

A second category of disease emergence, animal-to-human host switching, is of relevance to both newly emerging and re-emerging diseases and accounts for virtually all novel pandemics (e.g., the influenza pandemic of 1918, HIV/AIDS) and many re-emerging IDs as well (e.g., human mpox, human Rift Valley fever). In the past two decades there has been much theoretical and microbiologic and virologic research on how such zoonotic emergences occur. Current concepts are briefly summarized. Most animal and human pathogens, and especially viruses infecting mammals, are specifically adapted to a narrow host group, such as a single host species—e.g., the many New World hantaviruses, which tend to have been finely adapted to single rodent species over thousands of years. Such pathogens may have a limited ability to infect closely related species, and they are not normally highly transmissible between members of new host species they do infect. Measles, for example, is a human-adapted virus which can infect some primate species, but despite its extraordinary contagiousness for humans, it is not naturally transmitted between primates. How then do pathogen emergences into new host species, and most importantly into humans, occur?

This is an extraordinarily difficult question to answer, since emergences tend to occur in a "black box," out of sight of scientists and epidemiologists, and indeed typically in remote locales. But it is theorized that such emergences result from uncommon constellations of otherwise low-risk molecular genomic and ecologic events **(Chaps. 125 and 126)**, which include pathogens (particularly viruses) with high mutation rates, such as many RNA viruses; intense or unusual human–animal contact; and chance. A theoretical model **(Fig. 486-2)** posits that a virus well adapted to its primary host is likely to be non-adapted or at least far less adapted to other potential hosts, even closely related ones. But since viruses have high mutation rates, there will always be some virions that have mutated to become less well adapted to their own hosts and, by chance, some of these may "accidentally" have acquired an ability to adapt to a new host. Presumably, very few of these mutated viruses come into contact with potential new hosts before they are "purged," but if one or more virions is (1) is not significantly de-adapted to its normal host, (2) is, at the same time, capable of adapting to a new host, and (3) is able to cross a "fitness valley" of de-adaptation to the old host and neo-adaptation to the new host, a host switch may occur (Fig. 486-2). This model attempts to explain why major emergences are relatively uncommon (e.g., despite countless billions of viral mutations occurring daily, looking back over the past 500 years, there has only been about one new recognized influenza pandemic every 30 or so years). It might be said, teleologically, that pathogens are constantly "trying" to emerge, but almost always failing to do so.

A third category of disease emergence relates to mutations that occur in pathogens that are already human adapted, the best-known example being development of antibiotic resistance in a bacterial species previously susceptible to particular antibiotics. Although antibiotic-resistant pathogens live in the soil and other natural environments and have done so since before human-developed antibiotics existed, bacteria are also capable of horizontally transmitting to other bacteria DNA-containing resistance genes, and these may be selected for in Darwinian fashion, e.g., by medical and hospital environments in which antibiotics are administered **(Chap. 147)**. An analogous principle even applies to viruses. Particularly as viruses gain access to larger human populations via crowding and human movement, mutation may lead to a fitness advantage, e.g., to a more transmissible phenotype that may escape natural and vaccine-induced immunity, and may even be associated with increased pathogenicity, as may have happened with the SARS-CoV-2 delta variant in 2022. A similar phenomenon was seen beginning in 2014 with the re-emergence of enterovirus D68 (EV-D68) to cause global epidemics of acute flaccid myelitis.

VARIABLES ASSOCIATED WITH DISEASE EMERGENCE

Whatever the mechanisms of pathogen emergence may be, it has become clear that the determinants of emergence—i.e., variables that provide opportunities for pathogens in disturbed ecosystems to emerge, typically beginning with the host switch of an animal pathogen

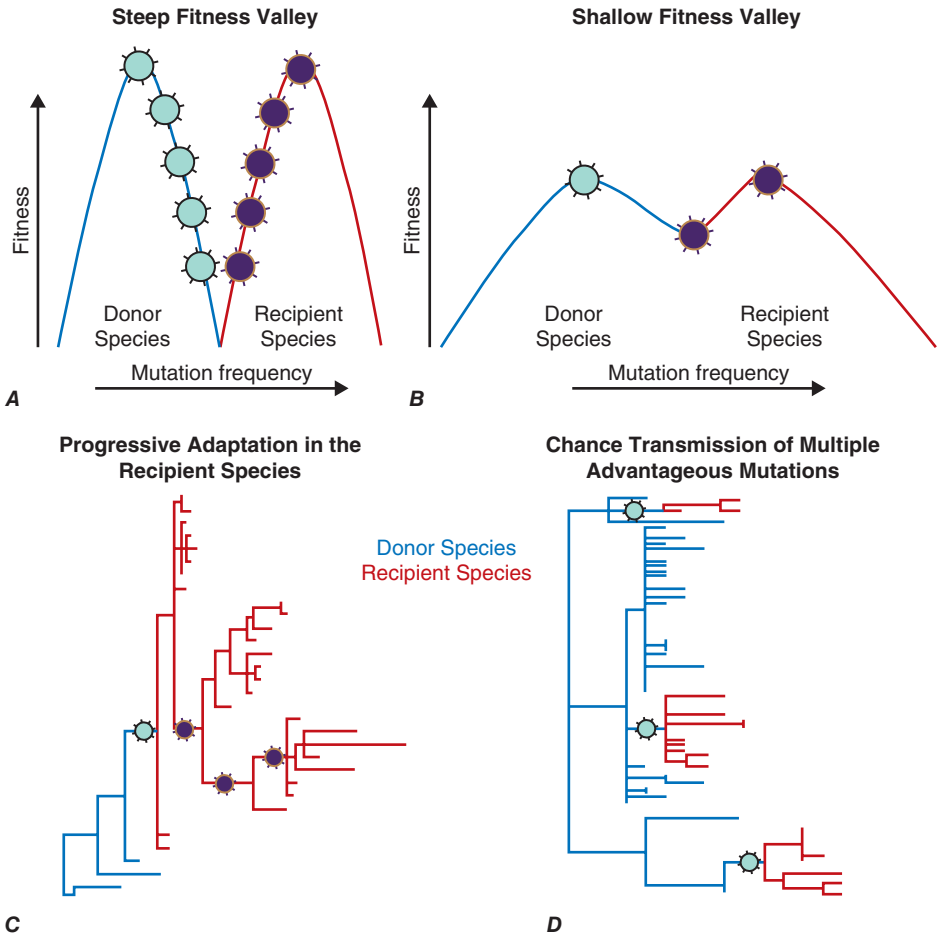

FIGURE 486-2 A theoretical model of how animal-to-human pathogen host-switching might occur, in this case the pathogen being a virus. The light-colored viruses represent those adapted to the transmitting host, and the dark-colored viruses represent those mutating in the direction of the host to which the virus is adapting. ***A*** and ***B*** compare two different situations in which there is a deep virus–host fitness valley (***A***) or a shallow fitness valley (***B***), the valleys representing the degree of challenges that mutable viruses need to overcome to be able to infect new host species. To be able to cross the steep fitness valley, a virus that is at peak adaptation to host 1 must mutate significantly in the direction of de-adaptation to be able to infect host 2, an event that is more likely if the virus has a high natural rate of mutations. In ***B***, a narrow fitness valley is more easily crossed, resulting in a host switch. The phylogenetic trees in ***C*** and ***D*** show the adaptational mutations that necessarily occur for a virus that has crossed a steep fitness valley (shown in ***A***) as it adapts to the new host (***C***). In ***D***, a virus that has crossed a narrow fitness valley (as shown in ***B***) does not "need to" adapt to the new host as significantly (***C***) to be able to initiate and sustain transmission between hosts of the new species. *(Reproduced with permission from DM Morens, AS Fauci: Emerging pandemic diseases: How we got to COVID-19. Cell 182:1077, 2020.)*

within a geographically identified global "hot spot"—are largely related to humans and human activities (Fig. 486-3). Most of the important variables associated with pathogen emergence are either activities of the human host—demographics and behavior including crowding, human movement, sexual practices, and occupation (Fig. 486-3, upper right)—or variables that reflect human degradation of the environment—poverty and social ills, wars, displacements, land use practices, and inadequate public health infrastructure (Fig. 486-3, lower right). Even though HIV clades probably emerged separately and independently more than a century ago, AIDS did not become pandemic until significant viral transmission could be sustained within a modern human-dominated global environment, once composed of remote villages but more recently replaced by urban environments, transnational travel and commercial sex work, meeting places for men who have sex with men, IV drug use, and blood product transfusions. The emergence of hyperendemic dengue and dengue hemorrhagic fever after World War II was associated with urban crowding and domestic water storage. The United States epidemic of hepatitis C (Chaps. 350 and 352), which began in the 1960s, was associated with blood product transfusions and injection drug use. The emergence of hantavirus pulmonary syndrome was associated with construction of human-made peridomestic outbuildings and unfinished basements that housed infected reservoir rodents during the winter. The emergence of Nipah virus (Chap. 204) in Malaysia in 1998 was associated with both deforestation and intensive pig farming practices. The 2003 United States mpox outbreak was associated with unregulated importation of rodent pets from enzootic areas. Emergence in China of both H5N1 and H7N9 poultry influenza A ("bird flu") was associated with crowded live animal markets, and it stopped quickly when these markets were shut down. The 2010 cholera epidemic in Haiti followed a devastating earthquake associated with human displacement, loss of access to safe water, inadequate medical and social support, and the arrival of aid from foreign locales that inadvertently imported cholera organisms.

It should be noted that emergence variables are not always identical between the newly emerging and re-emerging IDs. Re-emergences of known pathogens are more likely to result from societal failures to create and sustain safe human environments, and to disruption of balanced ecosystems in the natural world. Emergences of new pathogens such as pandemic influenza, on the other hand, are sometimes unique and highly improbable events. It is noteworthy that for diseases like influenza, in which transmission is facilitated by crowding and human movement, the intervals between pandemics are about the same today as they were 500 years ago, despite an eightfold increase in the global population and the advent of modern rapid global travel. This suggests that influenza pandemics are rare stochastic events unrelated to the size of the population that spreads them, even though population growth spreads them more widely and more quickly than they once did.

EXAMPLES OF CHALLENGES OF DISEASE EMERGENCE AND HOW THEY ARE BEING MET

The complexities of potential control of pathogen emergence and re-emergence are noteworthy: each emergent disease presents a different challenge, as briefly summarized below for three selected pathogens of global importance.

INFLUENZA A

The reservoir of influenza A viruses is the global pool of wild waterfowl and shorebirds. All human, other mammalian, and poultry-associated influenza viruses are derived from this pool. The 1918 pandemic influenza H1N1 "founder" virus either was derived directly from a waterfowl or had a brief period in another mammalian host before becoming pandemic. Humans immediately transmitted it to domestic pigs in 1918; descendants of those human and pig viruses still exist in whole or in part, having devolved into separate and increasingly divergent lineages over the past century. The three influenza pandemics that have occurred since 1918 were all caused by genetic descendants of the 1918 virus, having been naturally modified by genetic changes of several types. Such mutations make control and prevention difficult. The viruses have multiple mutational mechanisms to circumvent human immunity, including (1) genetic "drift" (point mutations); (2) "shift" (importation of different avian hemagglutinins with or without importation of neuraminidases); (3) intrasubtype reassortments (importation

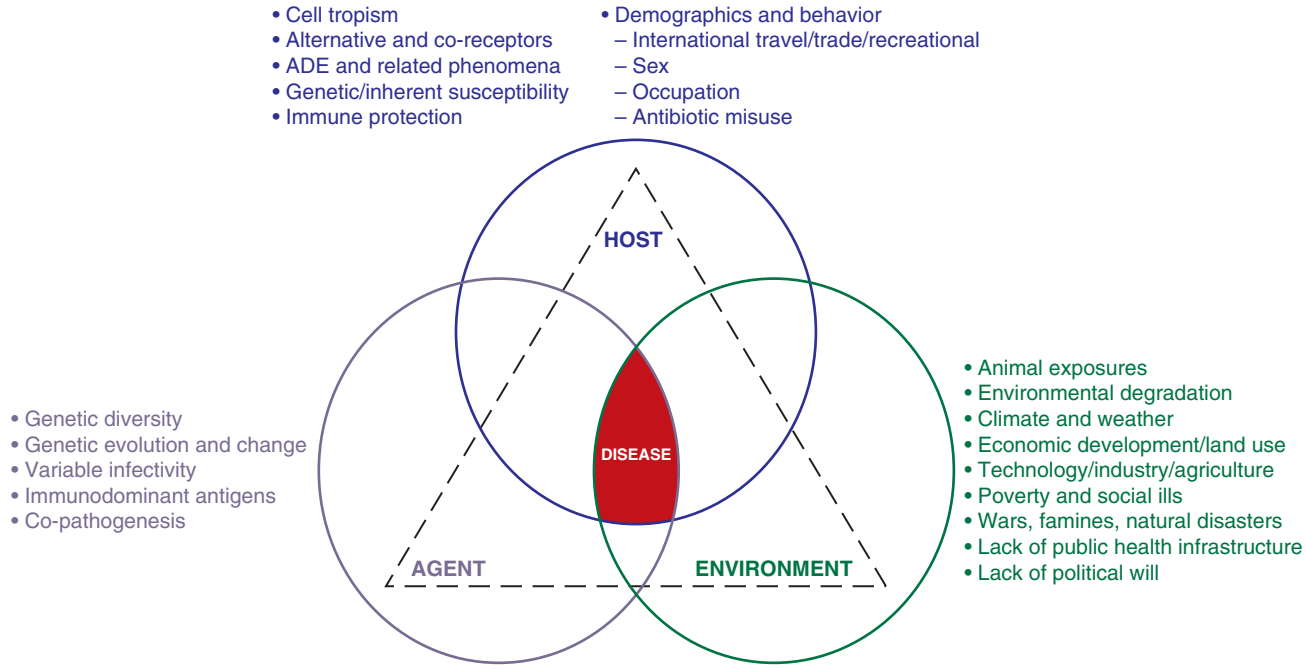

FIGURE 486-3 Infectious agents, hosts, and the environment: determinants of disease emergence, re-emergence and persistence. Factors most closely associated with re-emergences are highlighted, including accidental and purposeful human release of infectious pathogens. *(Reproduced with permission from DM Morens, AS Fauci: Emerging pandemic diseases: How we got to COVID-19. Cell 182:1077, 2020.)*

of whole human hemagglutinin or neuraminidase subtype variants), and (4) glycosylation of external protein sites that can alter viral structure and function. With a broad repertoire of mutational possibilities, a human-adapted virus may repeatedly escape population immunity elicited by natural infection and vaccination, as has been the case with the 1968 pandemic H3N2 virus, which is still causing infections and death, and escaping vaccine immunity, 56 years after its appearance. During this interval it has also periodically, and for unknown reasons, increased in pathogenicity.

Influenza control is further confounded by the fact that influenza A is a nonsystemic virus that replicates on a one-cell-deep layer of respiratory epithelium, without fully encountering the human systemic immune system. Because influenza has a very short incubation period, there is too little time for the virus to fully elicit memory immune cells, the virus only encountering the less specific innate immune system, as well as IgA and IgM antibodies secreted across the epithelium from the systemic circulation (only fully effective in high concentration). It also has an advantage in replicating only in an immune environment of the upper respiratory tract that tolerates multiple continuous antigenic exposures, including brief viral infections, without massive immune responses that could be harmful to the host. Thus, influenza vaccines are at best incompletely effective and protect for only a matter of months. This will be an important challenge in attempts to develop universal influenza vaccines.

It is also noteworthy that pandemic and postpandemic influenza viruses are increasingly better adapted to the modern world. Before 1889, the predominant travel mechanism of influenza spread was by coach, globalization of spread taking as much as a year or more, or failing to occur at all. Until the 1700s, the Americas and Europe did not even appear to have been on the same influenza pandemic cycles. (Although the earliest genetically sequenced influenza viruses date to 1918, scholars have for several centuries presumptively identified influenza pandemics on the basis of characteristic clinical-pathologic signs and symptoms, epidemiologic patterns, and route and rapidity of global spread). In the 1889 pandemic, presumed influenza was spread from East Asia to Europe by rail. The 1918 and 1957 pandemics were spread predominantly by ship, and the 1968 and 2009 pandemics predominantly by air. Influenza spread is ideally suited to human movement and crowding. Furthermore, high rates of presymptomatic and subsymptomatic infection allow the virus to be transmitted by persons who do not know they are infectious or capable of transmitting, thwarting attempts to lower transmission by public health measures.

In short, influenza A is an avian virus emerging out of nature. It remains difficult to prevent or to identify in advance an avian influenza virus with pandemic potential. At this point we have limited ability to control constantly mutating viruses once they have become human-adapted.

SARS AND SARS-CoV2

The sarbecoviruses (SARS-like beta-coronaviruses) are similar to influenza in some respects and different in others. Their natural reservoir is not birds but bats, and the main human host receptor for viral infection is the angiotensin-converting enzyme 2 (ACE2) receptor, as opposed to respiratory tract sialic acid receptors for influenza. Because ACE2 receptors on bats, many other mammals, and humans are quite similar, sarbecoviruses can be thought of as potentially preadapted to humans. It is in part for this reason that many experts predict future emergences of these viruses.

Similar to influenza, SARS-CoV2 is a respiratory virus that does not produce true viremia, has a short incubation period and incomplete exposure to the systemic immune system, and often causes asymptomatic or subsymptomatic infection, bedeviling control with public health measures such as social distancing and isolation. Also similar to influenza, and despite its moderate transmissibility, it can be "superspread" in crowded environments such as restaurants and bars, churches, sports venues, or any crowded place, especially if there is imperfect airflow and humidity. In addition, like influenza, SARS-CoV2 evolves continually (not however by genetic reassortment, but by mutation and recombination), continually escapes population immunity, and is imperfectly prevented by vaccines. As has been the case with influenza, control of emerging SARS-CoV2, and prevention of population spread and large-scale mortality, remains difficult.

DENGUE

A third example of the complexities of emergence and response, in this case re-emergence, is dengue. An *Aedes aegypti*–borne flavivirus, "dengue virus" is actually four closely related viruses (DEN-1, DEN-2, DEN-3, and DEN-4) that interact with each other serologically and with respect to immunity and pathogenicity. Dengue is believed to have emerged more than 400 years ago, perhaps much earlier, and has

been endemic and hyperendemic around the tropical belt ever since, re-emerging sporadically to cause high morbidity and sometimes high mortality. Emergences now occur repeatedly in the U.S. commonwealths of the Northern Mariana Islands and Puerto Rico, in the U.S. territories of Guam, American Samoa, and the United States Virgin Islands, and in the United States–affiliated Federated States of Micronesia. At one time, large-scale dengue epidemics were common in the continental United States, e.g., a major epidemic in Philadelphia in 1780; in recent years smaller outbreaks have occurred in southern states. Despite the fact that all dengue cases occur within a human-to-mosquito-to-human transmission cycle, without direct human-to-human transmission, dengue re-emergences can be so explosive that they mimic the most highly contagious respiratory viruses. During simultaneous 1977 outbreaks of dengue and influenza in Puerto Rico, within-household studies showed greater case-clustering of dengue than of influenza.

Dengue is highly associated with peridomestic water storage (where vector mosquitoes oviposit), lack of sanitation, crowding, and lack of screens and air conditioning. It would seem a simple matter to control dengue by controlling water storage, but even Singapore—a developed country whose residences have screens, air conditioning, excellent sanitation, and public health mosquito police who constantly patrol residences and public places to examine for breeding sites, assessing fines for even minor breeding site violations—is unable to prevent dengue outbreaks from occurring. A difficult problem seems to be that mosquitoes can oviposit in the tiniest and most inconspicuous bits of water, e.g., the slight (several millimeter) indentations in the bases of porcelain toilets where they are bolted to the floor.

Although dengue was historically considered a nuisance disease, shortly after World War II (during which only 4 of more than 90,000 dengue-infected servicemen/service women died) a new and highly fatal clinical form emerged in Southeast Asia and quickly became a significant killer of children. Studied by teams of Thai and American scientists, the new clinical form was classified as dengue hemorrhagic fever (DHF) and, in its most severe form, dengue shock syndrome (DSS), a result of sudden massive extravasation of intravascular fluids into the tissues. But the very same viruses that caused the mild form of dengue were also those that caused DHF and DSS, a puzzle that was unraveled by Halstead and others when it was learned that it was predominantly only with the second of four potential dengue infections (one with each of the four serotypes) that DHF/DSS occurred. Epidemiologic data were consistent with the belief that cross-reactive antibodies elicited by the first dengue infection, unable to neutralize the second virus, actually potentiate viral entry into cells via antibody-dependent enhancement for the acute clinician, dealing with EIDS depends upon ecologic perspectives on infectious disease occurrence.

Only in recent years have science and medicine begun to make an impact on severe dengue disease, including training of clinicians and parents, the widespread availability of oral rehydration solutions that reverse shock syndrome, and several recently developed vaccines. But fear remains that vaccines might potentiate more severe disease, and dengue remains among the greatest re-emerging disease problems for more than 3 billion people.

The three emerging disease examples noted above exemplify the complexity of disease emergence: the role of demographic and environmental variables (live poultry markets in severe human influenza; human-made peridomestic environments in dengue), pathogen interactions (partial immune crosses in influenza and dengue, related to both protection and disease severity, as well as to diagnostic difficulties), complete or partial immune escape (all three pathogens), immunopathogenesis (1918 influenza and dengue), inherent problems in vaccine prevention (all three diseases), animal reservoir hosts of progenitor viruses (all three diseases), viral evolution via mutations (all three diseases), and many other factors.

THE ROLE OF CLINICIANS AND LABORATORIANS IN EID CONTROL

Clinicians and laboratorians are on the front lines of EID control and response efforts, and they must continue to play a leading role in global pandemic preparedness and response. It is typically the astute clinician who first recognizes a new disease, usually because signs and symptoms, or complications, are not typical of similar diseases. For example, in the 1918 influenza pandemic there was never-before-seen pneumonia-associated case-fatality featuring viral infection and bacterial co-pathogenesis, the bacteria being normal oral flora and the pneumonia producing an anatomic pattern, diagnosed clinically or in some cases by x-ray, which was invariably bronchopneumonic. In the 1950s, emergence of dengue hemorrhagic fever was associated with never-before-seen complications, including shock and death, occurring in association with endemic dengue viruses and in epidemiologic patterns that were novel (shock occurring only in infants under one, and in older toddlers and school-aged children, but sparing children between these ages, as well as those in and beyond the older teenage years). In fact, it was the bizarre and unprecedented age-specific mortality patterns of DSS that suggested its pathogenetic mechanisms. That legionellosis **(Chap. 164)**, first identified in 1976, must have been an unknown emerging disease was learned when clinicians were unable to make a pathogen-specific pneumonia diagnosis and laboratories were unable to isolate a pathogen. A similar profile was seen with SARS, emerging in 2002–2003, when adults with respiratory/constitutional symptoms typical of many respiratory viruses experienced an approximate 10% case-fatality rate.

It is not only primary care providers who are in a position to recognize newly emerging diseases. Both emerging acute hemorrhagic conjunctivitis (AHC) in 1969–1970 and emerging human Rift Valley fever (RVF) in 1977 were largely identified by ophthalmologists who observed the unexpected: severe and explosively epidemic conjunctivitis with AHC, and blindness associated with macular infiltrates in RVF. In 1981, it was pathologists who identified *Pneumocystis carinii* (now *jirovecii*) pneumonia in autopsies of previously healthy young men, joining epidemiologists and clinicians in characterizing a new clinical-pathologic syndrome that was eventually recognized as AIDS. And it was pediatric neurologists who played a major role in identifying emergent enterovirus D68–associated acute flaccid myelitis beginning in about 2014. Even looking back in history to a time before the microbial era, we can identify the same phenomenon: it was a "proto-epidemiologist" who first imagined that cervical cancer was the result of a contagious disease when he showed, in the 1840s, that nuns never suffered from it.

Among the skills of medical practitioners related to a key front-line role in dealing with EIDs are the following: (1) abiding curiosity; (2) the ability to sense something out of the ordinary and pursue suspicions, using the medical history, physical examination, and laboratory tests **(Chaps. 8 and 505)**; (3) a sense of the epidemiology of different diseases that allows imagination of how an illness might have been acquired, of the mechanism of acquisition—environmental, respiratory, inoculation (including sexual inoculation), gastrointestinal, occupational, etc. (Fig. 486-3); (4) whether there are family or other case clusters, and whether such clusters represent common-source exposure, zoonotic exposure, or person-to-person transmission; (5) determination of an approximate incubation period and duration of infectivity; (6) a close relationship with the diagnostic laboratory and knowledge of when to seek additional laboratory follow-up; (7) a close relationship with allied practitioners, including specialists, and with disease researchers; (8) a close relationship with public health workers, diligence in promptly reporting reportable diseases and reportable disease syndromes, and awareness of outbreaks that may be occurring in the community; (9) regular reading of the medical literature to stay grounded within and outside of one's specialty; and (10) skill at communicating with and eliciting trust from patients, which appears to maximize the chance of finding clues that may be easily missed.

History tells us that EIDs will certainly continue to appear, including some so novel that they cannot even be imagined. An important component of the biomedical and public health enterprise is the ability to recognize, diagnose, and begin to control EIDs at the earliest possible time, and to limit their spread so that emergences do not evolve into epidemics. This requires coordinated efforts of those in multiple disciplines, communicating with each other rapidly and effectively. It is a part of the significant responsibilities of medical, biomedical, and public health practitioners, who together have the critical skill sets needed to confront the existential threats of EIDs.

487 Primary Care and Global Health

Tim Evans, Kumanan Rasanathan

The twentieth century witnessed the rise of an unprecedented global health divide. Industrialized or high-income countries experienced rapid improvement in standards of living, nutrition, health, and health care **(Chap. 485)**. Meanwhile, in low- and middle-income countries with much less favorable conditions, health and health care progressed much more slowly. The scale of this divide is reflected in the current extremes of life expectancy at birth, with Japan at the high end (84 years) and Chad at the low end (54 years). This 30-year shortfall in Chad reflects the daunting range of health challenges faced by low- and middle-income countries. These nations must deal not only with a complex mixture of diseases (both infectious and chronic) and illness-promoting conditions but also, and more fundamentally, with the fragility of the foundations underlying good health (e.g., sufficient food, water, sanitation, and education) and of the systems necessary for universal access to good-quality health care and public health. In the last decades of the twentieth century, the need to bridge this global health divide and establish health equity was increasingly recognized. The Declaration of Alma-Ata in 1978 crystallized a vision of justice in health, regardless of income, gender, ethnicity, or education, and called for "health for all by the year 2000" through primary health care. While progress since the declaration is remarkable, >45 years later and in the aftermath of a global pandemic of COVID-19, much remains to be done to achieve global health equity.

This chapter looks first at the nature of the health challenges that underlie the health divide in low- and middle-income countries. It then outlines the values and principles of a primary health care approach, with a focus on primary care services. Next, the chapter reviews the experience of low- and middle-income countries in addressing health challenges through primary care and a primary health care approach. Finally, the chapter identifies how current challenges and global context, in particular, the global pandemic, shape an agenda for the renewal of primary health care and primary care, allied to the movement to achieve universal health coverage.

PRIMARY CARE AND PRIMARY HEALTH CARE

The term primary care has been used in many different ways: to describe a level of care or the setting of the health system, a set of treatment and prevention activities carried out by specific personnel, a set of attributes for the way care is delivered, or an approach to organizing health systems that is synonymous with the term primary health care. In 1996, the U.S. Institute of Medicine encompassed many of these different usages, defining primary care as "the provision of integrated, accessible health care services by clinicians who are accountable for addressing a large majority of personal health care needs, developing a sustained partnership with patients, and practicing in the context of family and community."[1] We use this definition of primary care in this chapter. Primary care performs an essential function for health systems, providing the first point of contact when people seek health care, dealing with most problems, and referring patients onward to other services when necessary. As is increasingly evident in countries of all income levels, without strong primary care, health systems cannot function properly or address the health challenges of the communities they serve.

Primary care is only one part of a primary health care approach. The Declaration of Alma-Ata, drafted in 1978 at the International Conference on Primary Health Care in Alma-Ata (now Almaty in Kazakhstan), identified many features of primary care as being essential to achieving the goal of "health for all by the year 2000." However, it also identified the need to work across different sectors, address the social and economic factors that determine health, mobilize the participation of communities in health systems, and ensure the use and development of technology that was appropriate in terms of setting and cost. The declaration drew from the experiences of low- and middle-income countries in trying to improve the health of their people following independence. Commonly, these countries had built hospital-based systems similar to those in high-income countries. This effort had resulted in the development of high-technology services in urban areas while leaving the bulk of the population without access to health care unless they traveled great distances to these urban facilities. Furthermore, much of the population lacked access to basic public health measures. Primary health care efforts aimed to move care closer to where people lived, to ensure their involvement in decisions about their own health care, and to address key aspects of the physical and social environment essential to health, such as water, sanitation, and education.

After the Declaration of Alma-Ata, many countries implemented reforms of their health systems based on primary health care. Most progress involved strengthening of primary care services; unexpectedly, however, much of this progress was seen in high-income countries, most of which constructed systems that made primary care available at low or no cost to their entire populations and that delivered the bulk of services in primary care settings. This endeavor also saw the reinforcement of family medicine as a specialty to provide primary care services. Even in the United States (an obvious exception to this trend), it became clear that the populations of states with more primary care physicians and services were healthier than those with fewer such resources.

Progress was also made in many low- and middle-income countries. However, the target of "health for all by the year 2000" was missed by a large margin. The reasons were complex but partly entailed a general failure to implement all aspects of the primary health care approach, particularly work across sectors to address social and economic factors that affect health and provision of sufficient human and other resources in order to make possible the access to primary care attained in high-income countries. Furthermore, despite the consensus in Alma-Ata in 1978, the global health community rapidly became fractured in its commitment to the far-reaching measures called for by the

[1]Institute of Medicine. Primary Care: America's Health in a New Era (1996).

declaration. Economic recession tempered enthusiasm for primary health care, and momentum shifted to programs concentrating on a few priority measures such as immunization, oral rehydration, breast-feeding, and growth monitoring for child survival. Success with these initiatives supported the continued movement of health development efforts away from the comprehensive approach of primary health care and toward programs that targeted specific public health priorities. This approach was reinforced by the need to address the HIV/AIDS epidemic. By the 1990s, primary health care had fallen out of favor in many global-health policy circles, and low- and middle-income countries were being encouraged to reduce public sector spending on health and to focus on cost-effectiveness analysis to provide a package of health care measures thought to offer the greatest health benefits.

HEALTH CHALLENGES IN LOW- AND MIDDLE-INCOME COUNTRIES

Low- and middle-income countries, defined by a per-capita gross national income of <$12,535 (U.S.) per person per year, account for >85% of the world's population. Average life expectancy in these countries lags far behind that in high-income countries: whereas the average life expectancy at birth for a girl in high-income countries is 83 years, it is only 65 years for a girl in low-income countries. This discrepancy has received growing attention over the past 50 years. Initially, the situation in poor countries was characterized primarily in terms of high fertility and high infant, child, and maternal mortality rates, with most deaths and illnesses attributable to infectious or tropical diseases among remote, largely rural populations. With growing adult (and especially elderly) populations and changing lifestyles linked to global forces of urbanization, a new set of health challenges characterized by chronic diseases, environmental overcrowding, and road traffic injuries has emerged rapidly **(Fig. 487-1)**. The majority of tobacco-related deaths globally now occur in low- and middle-income countries, and the risk of a child's dying from a road traffic injury in Africa is more than twice that in Europe. Thus, low- and middle-income countries in the twenty-first century face a full spectrum of health challenges—infectious, chronic, and injury-related—at much higher incidences and prevalences than are documented in high-income countries and with many fewer resources to address these challenges.

Addressing these challenges, however, does not mean simply waiting for economic growth. Analysis of the association between wealth and health across countries reveals that, for any given level of wealth, there is a substantial variation in life expectancy at birth that has persisted despite overall global progress in life expectancy during the past 40 years **(Fig. 487-2)**. Health status in low- and middle-income countries varies enormously. Nations such as Cuba and Costa Rica have life expectancies and childhood mortality rates similar to or even better than those in high-income countries; in contrast, countries in Sub-Saharan Africa and the former Soviet bloc have at times experienced significant reversals in these health markers, particularly in the 1990s.

As Angus Deaton stated in the World Institute for Development Economics Research annual lecture on September 29, 2006, "People in poor countries are sick not primarily because they are poor but because of other social organizational failures, including health delivery, which are not automatically ameliorated by higher income." This analysis concurs with classic studies of the array of societal factors explaining good health in poor settings such as Cuba and Kerala State in India in the 1980s. Analyses conducted over the past 4 decades indeed show that rapid health improvement is possible in very different contexts. That some countries continue to lag far behind can be understood through a comparison of regional differences in progress in terms of life expectancy over this period **(Fig. 487-3)**.

As average levels of health vary across regions and countries, so too do they vary within countries **(Fig. 487-4)**. Indeed, disparities within countries are often greater than those between high-income

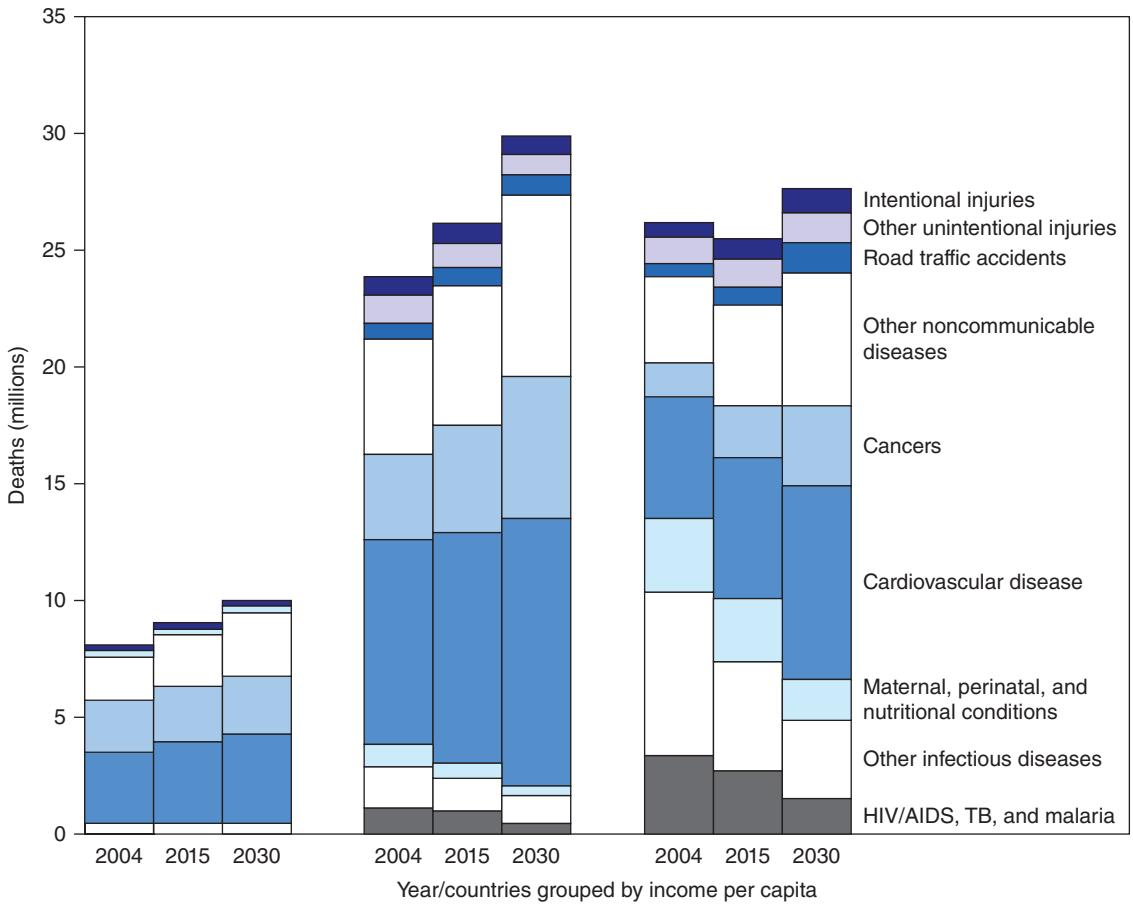

FIGURE 487-1 Projections of disease burden to 2030 for high-, middle-, and low-income countries (*left*, *center*, and *right*, respectively). TB, tuberculosis. *(Reproduced with permission from World Health Organization: The Global Burden of Disease 2004 Update, 2008.)*

and low-income countries. For example, if low- and middle-income countries could reduce their overall childhood mortality rate to that of the richest one-fifth of their populations, global childhood mortality could be decreased by 40%. Disparities in health are mostly a result of social and economic factors such as daily living conditions, access to resources, and ability to participate in life-affecting decisions. In most countries, the health care sector actually tends to exacerbate health inequalities (the "inverse-care law"); because of neglect and discrimination, poor and marginalized communities are much less likely to benefit from public health services than those that are better off. Reforming health systems toward people-centered primary care provides an opportunity to reverse these negative trends.

Health services have failed to make their contribution to reducing these pervasive social inequalities by ensuring universal access to existing, scientifically validated, low-cost interventions such as insecticide-treated bed nets for malaria, taxes on cigarettes, short-course chemotherapy for tuberculosis, antibiotic treatment for pneumonia, dietary modification and secondary prevention measures for high blood pressure and high

cholesterol levels, and water treatment and oral rehydration therapy for diarrhea. Despite decades of "essential packages" and "basic" health campaigns, the effective implementation of what is already known to work with requisite scale and quality appears (deceptively) to be difficult.

Recent analyses have begun to focus on "the how" (as opposed to "the what") of health care delivery, exploring why health progress is slow and sluggish despite the abundant availability of proven interventions for health conditions in low- and middle-income countries. Three general categories of reasons are being identified: (1) shortfalls in performance of health systems; (2) stratifying social conditions; and (3) skews in science.

SHORTFALLS IN PERFORMANCE OF HEALTH SYSTEMS

Specific health problems often require the development of specific health interventions (e.g., tuberculosis requires short-course chemotherapy). However, the delivery of different interventions is often facilitated by a common set of resources or functions: money or financing, trained health workers, and facilities with reliable supplies fit for multiple purposes. Unfortunately, health systems in most low- and middle-income countries are largely dysfunctional across these core functions.

In the large majority of low- and middle-income countries, the level of public financing for health is woefully insufficient: whereas high-income countries spend, on average, >7% of the gross domestic product on health, middle-income countries spend <3%, and low-income countries <2%. External financing for health through various donor channels grew rapidly in the first decade of the twenty-first century but has grown more slowly in the second decade to its current level of $37 billion. While these funds for health are significant, they represent <2% of total health expenditures in low- and middle-income countries and therefore are neither a sufficient nor a long-term solution to chronic underfinancing. In Africa, 70% of health expenditures come from domestic sources. The predominant form of health care financing—charging patients at the point of service—is the least efficient and the most inequitable, tipping millions of households into poverty annually. Health workers, who represent another critical resource, are often inadequately trained and supported in their work, especially in locations with the greatest needs. Recent estimates indicate a shortage of >18 million health workers, constituting a crisis that is greatly exacerbated by the migration of health workers from low- and middle-income countries to high-income countries. Sub-Saharan Africa carries 24% of the global disease burden but has only 3% of the health workforce **(Fig. 487-5)**.

Critical diagnostics and drugs often do not reach patients in need because of supply-chain failures. Moreover, facilities fail to provide good-quality and safe care: new evidence suggests much higher rates of adverse events among hospitalized patients in low- and middle-income countries than in high-income countries. Weak government planning, regulatory, monitoring, and evaluation capacities are associated with rampant, unregulated commercialization of health services and chaotic fragmentation of these services as donors "push" their respective priority programs. With such fragile foundations, it is not surprising that low-cost, affordable, validated interventions are not reaching those who need them.

STRATIFYING SOCIAL CONDITIONS

Health care delivery systems do not exist in a vacuum but rather are embedded in a complex of social and economic forces that often stratify opportunities for health unfairly. Most worrisome are the pervasive forces of social inequality that serve to marginalize populations with disproportionately large health needs (e.g., the urban poor; illiterate mothers). Why should a poor slum dweller with no income be expected to come up with the money for a bus fare needed to travel to a clinic to learn the results of a sputum test for tuberculosis? How can a mother living in a remote rural village and caring for an infant with febrile convulsions find the means to get her child to appropriate care? Shaky or nonexistent social security systems, dangerous work environments, isolated communities with little or no infrastructure, and systematic discrimination against racialized minorities are among the myriad forces with which efforts for more equitable health care delivery must contend.

SKEWS IN SCIENCE

While science has yielded enormous breakthroughs in health in high-income countries, with some spillover to low- and middle-income countries, many important health problems continue to affect primarily low- and middle-income countries whose research and development investments are deplorably inadequate. The past two decades have seen growing efforts to right this imbalance with research and development investment for new drugs, vaccines, and diagnostics that effectively cater to the specific health needs of populations in low- and middle-income countries. For example, the TB Alliance has revitalized a previously "dry" pipeline for new tuberculosis drugs. In 2019, their new drug (pretomanid) received U.S. Food and Drug Administration approval as part of a triple oral regimen (bedaquiline, pretomanid, and linezolid [BPaL]) that treats extensively drug-resistant tuberculosis faster, better, and cheaper. Nevertheless, the global vaccine inequity witnessed during the COVID-19 pandemic is indicative of the need for further efforts to right the research and development balance globally.

As discussed above, the primary constraint on better health in low- and middle-income countries is related less to the availability of health technologies and more to their effective delivery. Underlying these health delivery challenges is a major bias regarding what constitutes legitimate "science" to improve health equity. The lion's share of health research financing is channeled toward the development of new technologies—drugs, vaccines, and diagnostics; in contrast, virtually no resources are directed toward research on how health care delivery systems can become more reliable and overcome adverse social conditions. The complexity of systems and social context is such that this issue of delivery requires an enormous investment in terms not only of money but also of scientific rigor, with the development of new research methods and measures and the attainment of greater legitimacy in the mainstream scientific establishment.

These common challenges to low- and middle-income countries partly explain the resurgence of interest in the primary health care approach and the emergence of a global movement toward universal health coverage, now enshrined as one of the Sustainable Development Goal targets adopted in Agenda 2030 by all countries at the United Nations in September 2015. In some countries (mostly middle-income), significant progress has been made in expanding coverage by health systems based on primary care and even in improving indicators of population health. More countries are embarking on the creation of primary care services despite the challenges that exist, particularly in low-income countries. Even when these challenges are acknowledged, there are many reasons for optimism that low- and middle-income countries can accelerate progress in building primary care as a key vehicle toward achieving universal health coverage.

PRIMARY HEALTH CARE IN THE TWENTY-FIRST CENTURY

The new millennium has seen a resurgence of interest in primary health care as a means of addressing global health challenges but also of familiar obstacles to its implementation. This interest has been driven by many of the same issues that led to the Declaration of Alma-Ata: rapidly increasing disparities in health between and within countries; spiraling costs of health care at a time when many people lack quality care; dissatisfaction of communities with the care they are able to access; and failure to address changes in health threats, especially noncommunicable diseases, pandemics, and challenges arising from accelerated climate change. These challenges require a comprehensive approach and strong health systems with effective primary care. Global health development agencies have partially recognized that sustaining gains in public health priorities such as HIV/AIDS and pandemic preparedness requires not only robust health systems but also the tackling of social and economic factors related to disease incidence and progression. Weak health systems have proved a major obstacle to delivering new technologies, such as COVID-19 vaccines and antiretroviral therapy, to all who need them. We discuss experiences in low- and middle-income countries in relation to primary care in greater detail below. First, we consider the features of primary health care and primary care as currently understood.

REVITALIZATION OF PRIMARY HEALTH CARE

At the 2019 World Health Assembly (an annual meeting of all countries to discuss the work of the World Health Organization [WHO]), a resolution was passed reaffirming the principles of the Declaration of Alma-Ata and the need for national health systems to be based on primary health care. This resolution reframed primary health care as three components: (1) primary care and essential public health functions as the core of integrated health services; (2) empowered people and communities; and (3) multisectoral policy and action. This reframing itself drew on the 2008 WHO World Health Report, which asserted that a primary health care approach was necessary "now more than ever" to address global health priorities, especially in terms of disparities and new health challenges.

The 2008 World Health Report highlighted four broad areas for reform (Fig. 487-6). One of these areas—the need to organize health care so that it places the needs of people first—relates to the necessity for strong primary care in health systems and what this requirement entails. The other three areas also relate to primary care. All four areas require action to move health systems in a direction that will improve health, reduce disparities, and increase satisfaction.

FIGURE 487-6 The four reforms of primary health care renewal. *(Reproduced with permission from World Health Organization: Primary Health Care: Now More Than Ever. World Health Report 2008.)*

Universal Coverage Reforms to Improve Health Equity Despite progress in many countries, most people in the world can receive health care services only if they can pay at the point of service. Disparities in health are caused not only by a lack of access to necessary health services but also by the impact of expenditure on health. More than 100 million people are still being driven into extreme poverty each year by health care costs, with countless others deterred from accessing services at all. Moving toward prepayment financing systems for universal coverage, which ensure access to a comprehensive package of services according to need without precipitating economic ruin, has therefore emerged as a major priority in low- and middle-income countries. Increasing coverage of health services can be considered in terms of three axes: the proportion of the population covered, the range of services underwritten, and the percentage of costs paid (Fig. 487-7). Moving toward universal health coverage requires ensuring the availability of health care services to all, eliminating barriers to access, and organizing pooled financing mechanisms, such as taxation or insurance, to remove user fees at the point of service. It also requires measures beyond financing, including expansion of health services in poorly served areas, improvement in the quality of services provided to marginalized communities, and increased coverage of other social services that significantly affect health (e.g., education).

Service Delivery Reforms to Make Health Systems People-Centered Health systems have often been organized around the needs of those who provide health care services, such as clinicians and policymakers. The result is a centralization of services or the provision of vertical programs that target single diseases. The principles of primary health care, including the development of primary care, reorient care around the needs of the people to whom services cater. This "people-centered" approach aims to provide health care that is both more effective and appropriate.

The increase in noncommunicable diseases in low- and middle-income countries offers a further stimulus for urgent reform of service delivery to improve chronic disease care. As discussed above, large numbers of people currently fail to receive relatively low-cost interventions that have reduced the incidence of these diseases in high-income countries. Delivery of these interventions requires health systems that can address multiple problems and manage people over a long period within their own communities, yet many low- and middle-income countries are only now starting to adapt and build primary care services that can address noncommunicable diseases and communicable diseases requiring chronic care. Even some countries (e.g., Iran) that have had significant success in reducing communicable diseases and improving child survival have been slow to adapt their health systems to rapidly accelerating noncommunicable disease epidemics.

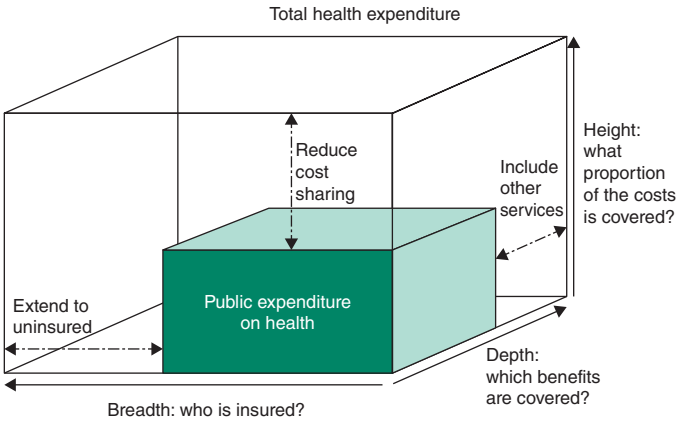

FIGURE 487-7 Three ways of moving toward universal coverage.

People-centered care requires a safe, comprehensive, and integrated response to the needs of those presenting to health systems, with treatment at the first point of contact or referral to appropriate services. Because no discrete boundary separates people's needs for health promotion, curative interventions, and rehabilitation services across different diseases, primary care services must address all presenting problems in a unified way. Meeting people's needs also involves improved communication between patients and their clinicians, who must take the time to understand the impact of the patients' social context on the problems they develop. This enhanced understanding is made possible by improvements in the continuity of care so that responsibility transcends the limited time people spend in health care facilities. Primary care plays a vital role in navigating people through the health system; when people are referred elsewhere for services, primary care providers must monitor the resulting consultations and perform follow-up. All too often, people do not receive the benefit of complex interventions undertaken in hospitals because they lose contact with the health care system once discharged. Comprehensiveness and continuity of care are best achieved by ensuring that people have an ongoing personal relationship with a care team.

Public Policy Reforms to Promote and Protect the Health of Communities Public policies in sectors other than health care are essential to reduce disparities in health and to make progress toward global public health targets. The 2008 final report of the WHO Commission on Social Determinants of Health provided an exhaustive review of the multisectoral policies required to address health inequities at the local, national, and global levels. Advances against major challenges such as HIV/AIDS, tuberculosis, emerging infections, cardiovascular disease, cancers, and injuries require effective collaboration with sectors such as transport, housing, labor, agriculture, urban planning, trade, and energy. The COVID-19 pandemic has underscored the importance of multisectoral action to protect health; countries that have been most successful in managing the pandemic have been those best able to coordinate across their societies to implement nonpharmaceutical health measures and build social solidarity. Similarly, while tobacco control provides a striking example of what is possible if different sectors work together toward health goals, the lack of implementation of many evidence-based tobacco control measures in most countries just as clearly illustrates the difficulties encountered in such multisectoral work and the unrealized potential of public policies to improve health.

Leadership Reforms to Make Health Authorities More Reliable The Declaration of Alma-Ata emphasized the importance of participation by people in their own health care. In fact, participation is important at all levels of decision-making. Contemporary health challenges require models of leadership that acknowledge the role of government but also the many types of organizations involved in health care delivery. Governments need to engage, guide, negotiate, and regulate among these diverse actors, including but not limited to nongovernmental organizations (NGOs), the private sector, professional societies, academia, and patient groups. This difficult task requires concerted investment in leadership and governance capacity, especially if action requires the engagement of different sectors such as local government and education. The complex landscape for leadership at the national level extends to the international level. The increasing transnational character of health as seen by the interdependence of countries with respect to pandemics, climate change, health worker migration, and food security emphasizes the need for more effective global health governance mechanisms.

EXPERIENCES WITH PRIMARY CARE IN LOW- AND MIDDLE-INCOME COUNTRIES

Aspects of the primary health care approach described above, with an emphasis on primary care services, have been implemented to varying degrees in many low- and middle-income countries over the past half-century. As discussed above, some of these experiences inspired and informed the Declaration of Alma-Ata, which itself led many more countries to attempt to implement primary health care. This section describes the experiences of a selection of low- and middle-income countries in improving primary care services that have enhanced the health of their populations.

Before Alma-Ata, few countries had attempted to develop primary care on a national level. Rather, most focused on expanding primary care services to specific communities (often rural villages), making use of community volunteers to compensate for the absence of facility-based care. In contrast, in the post–World War II period, China invested in primary care on a national scale, and life expectancy doubled within roughly 20 years. The Chinese expansion of primary care services included a massive investment in infrastructure for public health (e.g., water and sanitation systems) linked to innovative use of community health workers. These "barefoot doctors" lived in and expanded care to rural villages. They received a basic level of training that enabled them to provide immunizations, maternal care, and basic medical interventions, including the use of antibiotics. Through the work of the barefoot doctors, China brought low-cost universal basic health care coverage to its entire population, most of which had previously had no access to these services.

In 1982, the Rockefeller Foundation convened a conference to review the experiences of China along with those of Costa Rica, Sri Lanka, and the state of Kerala in India. In all of these locations, good health care at low cost appeared to have been achieved. Despite lower levels of economic development and health spending, all of these jurisdictions, along with Cuba, had health indicators approaching—or in some cases exceeding—those of developed countries. Analysis of these experiences revealed a common emphasis on primary care services, with expansion of care to the entire population free of charge or at low cost, combined with community participation in decision-making about health services and coordinated work in different sectors (especially education) toward health goals. During the more than three decades since the Rockefeller meeting, some of these countries have built on this progress, while others have experienced setbacks. Recent experiences in developing primary care services show that the same combination of features is necessary for success. For example, Brazil—a large country with a dispersed population—made major strides in increasing the availability of health care from 1980 to 2010. The Brazilian Family Health Program expanded progressively across the country to reach universal coverage. This program provided communities with free access to primary care teams made up of primary care physicians, community health workers, nurses, dentists, obstetricians, and pediatricians. These teams were responsible for the provision of primary care to all people in a specified geographic area—not only those who access health clinics. Moreover, individual community health workers were responsible for a named list of people within the area covered by the primary care team. Solid evidence indicated that the Family Health Program has contributed to impressive gains in population health, particularly in terms of childhood mortality and health inequities **(Fig. 487-8)**. Nevertheless, systemic inequalities, magnified during the COVID-19 crisis, highlight how continued progress is not guaranteed, and efforts to implement and expand a primary health care approach need to adapt to new health and political challenges.

Chile has also built on its existing primary care services in the past two decades, aiming to improve the quality of care and the extent of coverage in remote areas, above all for disadvantaged populations. This effort has been made in concert with measures aimed at reducing social inequalities and fostering development, including social welfare benefits for families and disadvantaged groups and increased access to early-childhood educational facilities. As in Brazil, these steps have improved maternal and child health and have reduced health inequities. In addition to directly enhancing primary care services, Brazil and Chile have instituted measures to increase both the accountability of health providers and the participation of communities in decision-making. In Brazil, national and regional health assemblies with high levels of public participation are integral parts of the health policy-making process. Chile has instituted a patient's charter that explicitly specifies the rights of patients in terms of the range of services to which they are entitled.

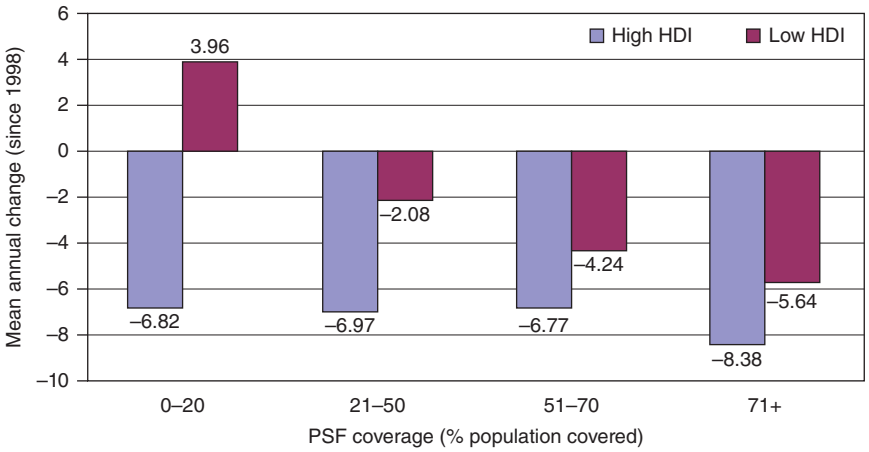

FIGURE 487-8 Improvements in childhood mortality following the Family Health Program in Brazil. HDI, Human Development Index; PSF, Program Saúde da Família (Family Health Program). *(Source: Ministry of Health, Brazil.)*

Other countries that have made recent progress with primary health care include Bangladesh, once one of the poorest countries in the world. Since achieving its independence from Pakistan in 1971, Bangladesh has seen a dramatic increase in life expectancy, and childhood mortality rates are now lower than those in neighboring nations such as India and Pakistan. The expansion of access to primary care services has played a major role in these achievements. This progress has been spearheaded by a vibrant NGO community that has focused its attention on improving the lives and livelihoods of poor women and their families through innovative and integrated microcredit, education, and primary care programs.

The above examples, along with others from the past 40 years in countries such as Thailand, Rwanda, Ethiopia, Turkey, Vietnam, and Oman, illustrate how the implementation of a primary health care approach, with a greater emphasis on primary care, has led to better access to health care services—a trend that has not been seen in many other low- and middle-income countries. This trend, in turn, has contributed to improvements in population health and reductions in health inequities. However, as these nations have progressed, other countries have shown how previous gains in primary care can easily be eroded. In Sub-Saharan Africa, undermining of primary care services contributed to catastrophic reversals in health outcomes catalyzed by the HIV/AIDS epidemic. Countries such as Botswana and Zimbabwe implemented primary health care strategies in the 1980s, increasing access to care and making impressive gains in child health. Both countries were severely affected by HIV/AIDS, with pronounced decreases in life expectancy. However, Zimbabwe has also seen political turmoil, a decline of health and other social services, and the flight of health personnel, whereas Botswana has maintained primary care services to a greater extent and has managed to organize widespread access to antiretroviral therapy for people living with HIV/AIDS.

China provides a particularly striking example of how changes in health policy relevant to the organization of health systems **(Fig. 487-9)** can have rapid, far-reaching consequences for population health. Even as the 1982 Rockefeller conference was celebrating China's achievements in primary care, its health system was unraveling. The decision to open up the economy in the early 1980s led to rapid privatization of the health sector and the breakdown of universal health coverage. As a result, by the end of the 1980s, most people, especially the poorer segments of the population, were paying directly out of pocket for health care, and almost no Chinese had insurance—a dramatic transformation. The "barefoot doctor" schemes collapsed, and the population either turned to care paid for at hospitals or simply became unable to access care. This undermining of access to primary care services in the Chinese system and the resulting increase in impoverishment due to illness contributed to the stagnation of progress in health in China at the same time that incomes in that country increased at an unprecedented rate. Reversals in primary care have meant that China now increasingly faces health care issues similar to those faced by India, although the country has more recently implemented measures to restore universal health coverage, with significant success. In both countries, rapid economic growth has been linked to lifestyle changes and noncommunicable disease epidemics. The health care systems of the two nations share two negative features that are common when primary care is weak: a disproportionate focus on specialty services provided in hospitals and unregulated commercialization of health services. China and India both saw expansion of private hospital services that cater to middle-class and urban populations who can afford care; at the same time, hundreds of millions of people in rural areas struggled to access basic services. Even in the wealthier groups, a lack of primary care services has been associated with late presentation with illness and with insufficient investment in primary prevention approaches. This neglect of prevention poses a risk of large-scale epidemics of cardiovascular disease, which could endanger continued economic growth. In addition, the health systems of both countries now depend for the majority of their funding on out-of-pocket payments by people when they use services. Thus, substantial proportions of the population must sacrifice other essential goods as a result of health expenditure and

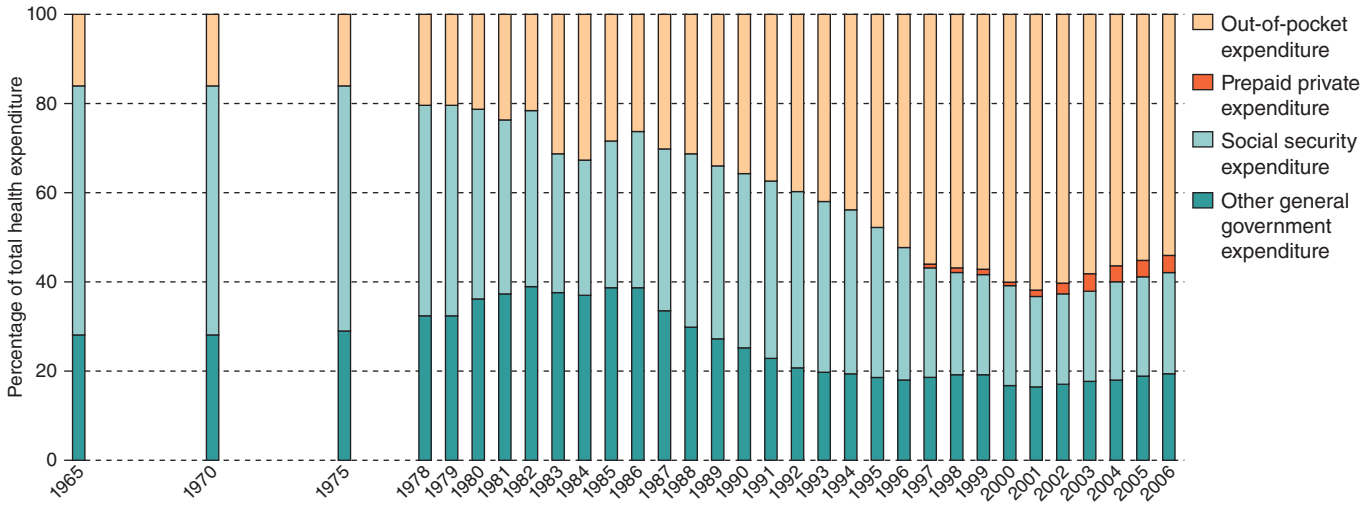

FIGURE 487-9 Changes in source of health expenditure in China over the past 40 years. *(Reproduced with permission from World Health Organization: Primary Health Care: Now More Than Ever. World Health Report 2008.)*

may even be driven into poverty by this cost. The commercial nature of health services with inadequate or no regulation has also led to the proliferation of charlatan providers, inappropriate care, and pressure for people to pay for expensive and sometimes unnecessary care.

Faced with these problems, China and India have implemented measures to strengthen primary health care. China has increased government funding of health care, has taken steps toward restoring health insurance, and has enacted a target of universal access to primary care services. India has similarly mobilized funding to greatly expand primary care services in rural areas and in urban settings. Both countries are increasingly using public resources from their growing economies to fund primary care services.

These encouraging trends are illustrative of new opportunities to implement a primary health care approach and strengthen primary care services in low- and middle-income countries. Linked to goal number 3 of the UN Sustainable Development Goals, Over the past decade, nearly all countries have adopted universal health coverage—the provision of quality health services in a timely manner at affordable cost—and the primary health care approach remains key to achieving this.

OPPORTUNITIES TO BUILD PRIMARY CARE IN LOW- AND MIDDLE-INCOME COUNTRIES

To reach global health targets, health systems must be strengthened. More money is currently being spent on health than ever before. In 2020, global health spending totaled $9 trillion (U.S.)—more than double the amount spent a decade earlier. Although most expenditure occurs in high-income countries, spending in many emerging middle-income countries has rapidly accelerated, as has the allocation of monies for this purpose by both governments in, and donors to, low-income countries. These twin trends—greater emphasis on building health systems based on primary care and allotment of more money for health care—provide opportunities to address many of the challenges discussed above in low- and middle-income countries.

Accelerating progress requires a better understanding of how global health initiatives (GHIs) can more effectively facilitate the development of primary care in low-income countries. Recent reviews including the WHO Maximizing Positive Synergies Collaborative Group and the Wellcome Trust Future of GHIs have assessed the impact on country health systems of diverse GHIs such as the Global Fund to Fight AIDS, Tuberculosis and Malaria; the Global Alliance for Vaccines and Immunization; the U.S. President's Emergency Plan for AIDS Relief; and the Global Financing Facility of the World Bank. While evidence of improved access to targeted health services is encouraging, systemic concerns related to increasing domestic resources for health and accelerating comprehensive primary care remain. If GHIs implement programs that work in tandem with other components of national health systems without undermining staffing and procurement of supplies, they have the potential to contribute substantially to the capacity of health systems to provide comprehensive primary care services.

In the context of the recent pandemic, GHIs appear even more important. The imperative of vaccinating the world's population against SARS-CoV-2 led to the creation of the multi-billion-dollar COVAX facility that failed to ensure equitable access to COVID-19 vaccines. After the pandemic, the need to recover essential health services, particularly for mothers and children, underlines the importance of GHIs like the Global Financing Facility for every mother and child as catalysts for universal access to life-saving services. The general trend is to coordinate this funding in order to reduce fragmentation of national health systems and to concentrate more on strengthening these systems. Comprehensive primary care in low-income countries must inevitably deal with the rapid emergence of chronic diseases and the growing prominence of injury-related health problems; thus, international health development assistance must become more responsive to these needs.

Beyond funding for health services, other opportunities exist. Increased social participation in health systems can help build primary care services. In many countries, political pressure from community advocates for more holistic and accountable care as well as entrepreneurial initiatives to scale up community-based services through NGOs have accelerated progress in primary care without major increases in funding. Participation of the population in the provision of health care services and in relevant decision-making often drives services to cater to people's needs as a whole rather than to narrow public health priorities.

Participation and innovation can help address critical issues related to the health workforce in low- and middle-income countries by establishing effective people-centered primary care services. Many primary care services do not need to be delivered by a physician or a nurse. Multidisciplinary teams can include paid community workers who have access to a physician if necessary but who can provide a range of health services on their own. In Ethiopia, >38,000 community health workers have been trained and deployed to improve access to primary care services, and there is increasing evidence that this measure is contributing to better health outcomes. In India, >600,000 community health advocates have been recruited as part of expanded rural primary care services. In Niger, the deployment of community health workers to deliver essential child health interventions (as a component of integrated community case management) has had impressive results in reducing childhood mortality and decreasing disparities. After the Declaration of Alma-Ata, experiences with community health workers were mixed, with particular problems regarding levels of training and lack of payment. Current endeavors are not immune from these concerns. However, with access to physician support and the deployment of teams, some of these concerns may be addressed. Growing evidence from many countries indicates that shifting appropriate tasks to primary care workers who have had shorter, less expensive training than physicians will be essential to address the human resources crisis.

Finally, recent improvements in information and communication technologies, particularly mobile phone and Internet systems, have created the potential for systematic implementation of e-health, telemedicine, and improved health data initiatives in low- and middle-income countries. These developments raise the tantalizing possibility that health systems in these countries, which have long lagged behind those in high-income countries but are less encumbered by legacy systems that have proved hard to modernize in many settings, could leapfrog their wealthier counterparts in exploiting these technologies. Although the challenges posed by poor or absent infrastructure and investment in many low- and middle-income countries cannot be underestimated and will need to be addressed to make this possibility a reality, the rapid rollout of mobile networks and their use for health and other social services in many low-income countries where access to fixed telephone lines was previously very limited offer great promise in building primary care services in low- and middle-income countries. To a partial extent, this potential has been demonstrated and even realized in many countries during the COVID-19 pandemic, with greatly increased uptake of the use of telemedicine and clinical support via digital means.

CONCLUSION

As concern continues to mount about glaring inequities in global health, there is a growing commitment to redress these egregious shortfalls, as exemplified by the central place of equity in the United Nations' Sustainable Development Goals adopted in 2015, including a specific target on the achievement of universal health coverage in all countries by 2030. This commitment begins first and foremost with a clear vision of the fundamental importance of health in all countries, regardless of income. The values of health and health equity are shared across all borders, and primary health care provides a framework for their effective translation across all contexts.

The translation of these fundamental values has its roots in four types of reform that reflect the distinct but interlinked challenges of (re)orienting a society's resources on the basis of its citizens' health needs: (1) organizing health care services around the needs of people and communities; (2) harnessing services and sectors beyond health care to promote and protect health more effectively; (3) establishing sustainable and equitable financing mechanisms for universal health coverage; and (4) investing in effective leadership to steward change locally, nationally and across borders. This common primary health

care agenda highlights the striking similarity, despite enormous differences in context, in the nature and direction of the reforms that national health systems must undertake to promote greater equity in health. This shared agenda is complemented by the growing reality of global health interconnectedness due, for example, to shared microbial threats, bridging of ethnolinguistic diversity, flows in migrant health workers, and mobilization of global funds to support the neediest populations. Embracing solidarity in global health while strengthening health systems through a primary health care approach is fundamental to sustained progress in global health.

The shortfalls in health system performance, stratification of social conditions leading to unfair differences in health, and skews in science that undermine the realization of "Health for All" have never been more glaringly visible than during the COVID-19 pandemic. But they also have never commanded such global political attention at the highest level. Out of this crisis, then, is a once-in-a-lifetime opportunity to recast global and national systems to enable the genuine implementation of the primary health care approach in all countries.

488 Biology of Aging

Rafael de Cabo, David G. Le Couteur

The increase in older people over the past few decades is one of the most significant changes in human history. For the first time, people over the age of 65 years now exceed children under the age of 5 years (Fig. 488-1). Aging is associated with an exponential increase in the incidence of many chronic diseases (Fig. 488-2). This has significant implications for the delivery of health services and aged care in all nations.

Older people are living even longer due to advances in medical care but at the cost of longer periods of frailty and disability and of iatrogenic burdens associated with intensive medical care of multiple diseases, such as polypharmacy. Establishing the relationship between aging and disease, particularly noncommunicable disease, is one of the most important goals for biomedical research. Studies in animal models confirm that aging is malleable. The "longevity dividend" refers to the concept whereby an intervention that slows the aging process is likely to delay the onset of a wide range of age-related diseases and syndromes, as well as potentially increasing years of healthy lifespan ("health span").

DEFINITIONS OF AGING

Aging is a progressive process associated with deterioration in structure and function, leading to increased susceptibility to disease and mortality, and often associated with impaired reproductive capacity. There are statistical, biological, and phenotypic components to most definitions of aging (Fig. 488-3).

THEORIES OF AGING

MUTATION ACCUMULATION AND ANTAGONISTIC PLEIOTROPY

Evolutionary theories of aging attempt to explain why aging, which impairs health and survival, has evolved, and why there is so much variability in lifespan across taxa. Aging is generally considered to be nonadaptive. This means aging has not been shaped by evolution or genetically programmed. However, many genes influence the aging process, and the initiating process of aging is most likely to involve stochastic, nonprogrammed changes in nuclear maintenance that influence gene expression and repair. Many theories of aging are based on the concept that, in the wild, mortality is secondary to extrinsic causes, such as predation, injury, and infection, and evolutionary selection pressure is generated by early life survival and reproductive success. There is minimal selection pressure to maintain health and extend life beyond early reproductive years and inevitable death from extrinsic causes. In fact, traits may evolve that are beneficial in early life and for reproduction but become harmful if the animal lives to an older age. These theories were set out by the classic "mutation accumulation" (John B.S. Haldane) and "antagonistic pleiotropy" (George C. Williams) theories of aging.

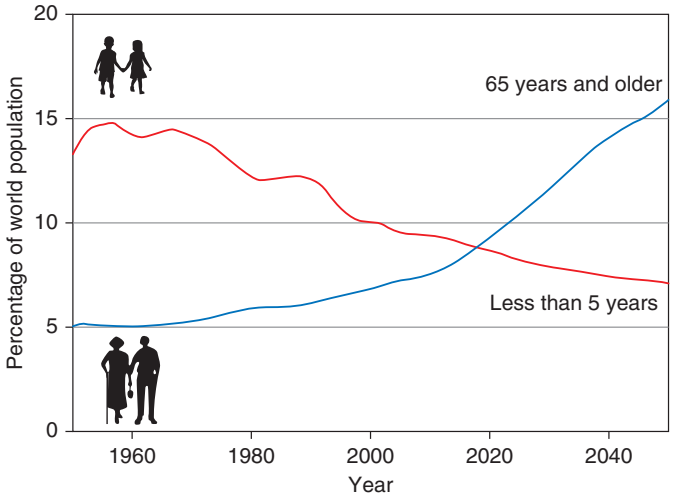

FIGURE 488-1 Globally, people over the age of 65 years now exceed children under the age of 5 years.

DISPOSABLE SOMA THEORY

There is often a trade-off between aging and reproduction. Animals with high extrinsic mortality tend to have short lives, small bodies, and greater reproductive output, while animals with low extrinsic mortality, such as humans and other primates, tend to have longer lives, larger bodies, and fewer offspring. The disposable soma theory of aging (Thomas Kirkwood) explicitly hypothesizes that evolution selects strategies that prioritize utilization of finite resources to maintain germ cells necessary for reproduction rather than for maintenance of the soma (nongerm cells), hence leading to age-related accumulation of damage to the soma.

INFORMATION THEORY OF AGING

This theory has its foundations in studies of aging biology and the role of DNA methylation in aging and as an "aging clock." With aging, there are marked changes in the epigenome (an analog information system), which have profound effects of gene expression (an information retrieval system). By contrast, the DNA code (a digital information system) is relatively stable with aging.

COMPARATIVE AGING ACROSS SPECIES

NEGLIGIBLE SENESCENCE AND PROGRAMMED AGING

There are some animals that undergo "negligible senescence," meaning that there are no obvious biological changes of aging and the rate of mortality does not increase with time. These include some strains and species of clams, sharks, hydra, and worms. The longest living vertebrate is the Greenland shark, which may live up to nearly 400 years of age. On the other hand, there are a few animals that undergo programmed aging and death. These are the semelparous animals such as Pacific salmon and marsupial mice (Fig. 488-4).

GRANDMOTHER EFFECT

There are species, including humans, where evolution could influence late-life survival through what is called the grandmother effect. In these species, survival of offspring depends on the care provided by their long-lived grandmothers. This also explains the development of extended postreproductive survival in humans.

BIOLOGICAL HALLMARKS OF AGING

Aging is associated with a range of molecular processes that are remarkably similar between species. These "hallmarks of aging" are the mechanistic pathways that cause aging. The processes are highly interconnected, and impairment of one process will impact the others. The hallmarks include those that act at the various biological strata and together erode various pillars of health (Fig. 488-5).

Interventions that alter the behavior of each of these pathways (via genetic manipulation, pharmacologic treatments, or nutritional interventions) influence aging and lifespan of laboratory animals such as mice, fruit flies (*Drosophila melanogaster*) or worms (*Caenorhabditis elegans*). Each of the hallmarks is a potential target for pharmacotherapies that might delay aging and the onset of age-related morbidity and increase both health span and lifespan.

GENOMIC INSTABILITY

The integrity of DNA is vulnerable to many exogenous (e.g., irradiation, chemicals, transposons) and endogenous (e.g., oxidative stress)

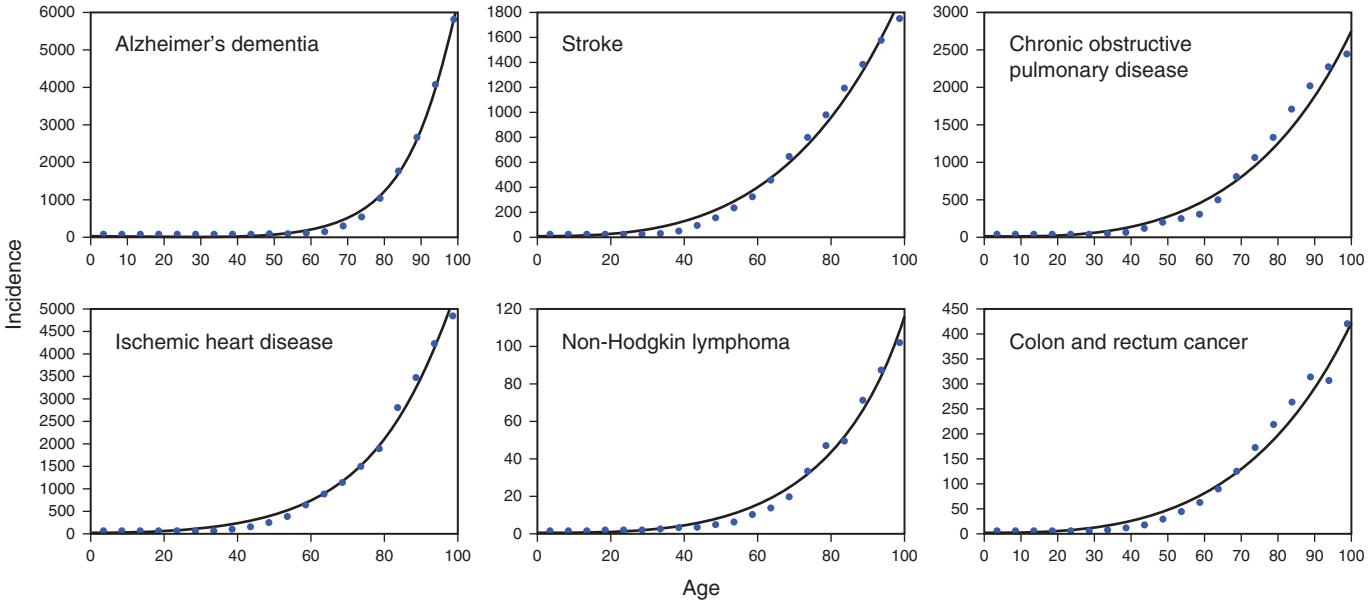

FIGURE 488-2 Many noncommunicable diseases have an exponential increase in incidence with age. Aging biology is likely to be an integral part of the mechanisms for these diseases.

stresses that generate largely random DNA lesions such as point mutations, translocations, and chromosomal anomalies. Mitochondrial DNA is especially susceptible to damage with aging because of its proximity to free radicals produced during oxidative phosphorylation and lack of histones and repair mechanisms. Genetic manipulation of nuclear and mitochondrial DNA repair mechanisms shortens lifespan in mice, while human premature aging syndromes are associated with deficiencies in genes necessary for nuclear maintenance. For example, Werner's syndrome is caused by mutations in a recQ helicase gene (*WRN*) required for repair of double-stranded breaks, and Hutchinson-Guildford progeria syndrome is caused by mutations in the lamin A gene (*LMNA*) required for structural support of the nucleus.

TELOMERE ATTRITION

Telomeres are repeat sequences at the ends of linear chromosomes that counter the inability of DNA polymerase to replicate the tips of chromosomes. In humans, telomeres consist of a redundant TTAGGG sequence repeated several thousand times. Some cells (e.g., germ cells, tumor cells) contain telomerase, which can reform telomeres that are shortened during replication. In most cells, after multiple divisions, the telomeres are truncated to a point where cell division cannot continue. In cell culture, this number of divisions is called the Hayflick limit, and cells that cannot undergo further division are said to have entered a phase of "replicative cellular senescence." Some studies in humans have found that telomere length in blood cells decreases with age, while mice that have been genetically manipulated to have short or long telomeres have decreased and increased lifespans, respectively. In humans, telomerase deficiency is associated with pulmonary fibrosis and aplastic anemia.

EPIGENETIC ALTERATIONS

Gene expression is regulated by DNA methylation, histone modification, chromatin remodeling, and noncoding RNAs. These all change with age, leading to altered transcription of genes, especially those involved with inflammation, mitochondrial function, and autophagy pathways. There are consistent age-related changes in the pattern of DNA methylation in human blood samples that have been called "epigenetic clocks" (e.g., "Horvath epigenetic clock") because they reflect chronologic age. Histones are proteins that package DNA into nucleosomes, thus influencing DNA available for transcription. The sirtuins are a family of NAD-dependent proteins that regulate histones through deacetylation and have significant effects on aging and lifespan. For example, overexpression of sirtuins and activation by drugs such as resveratrol increase lifespan in model organisms. De-repression of retrotransposons has been implicated in aging, and nonreverse transcriptase inhibitors decrease this and delay aging in mice.

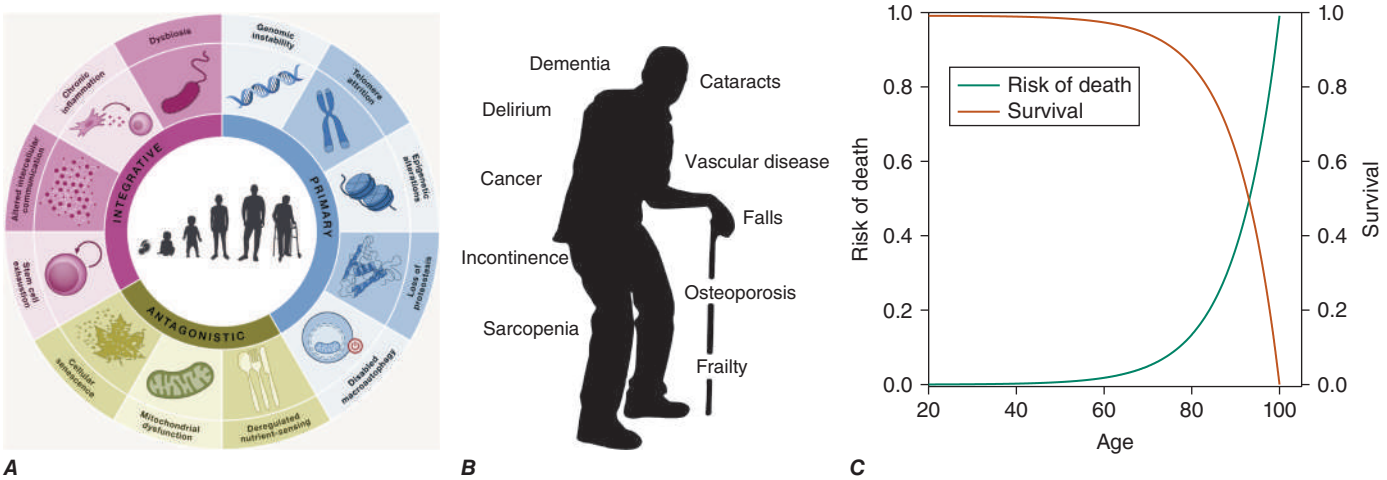

FIGURE 488-3 Definitions of aging often include (***A***) a biological component encapsulated by the 12 hallmarks of aging, (***B***) a phenotypic component that includes many chronic diseases and syndromes of aging, and (***C***) a statistical component that in most species involves an exponential (Gompertz) increase in the risk of mortality with age.

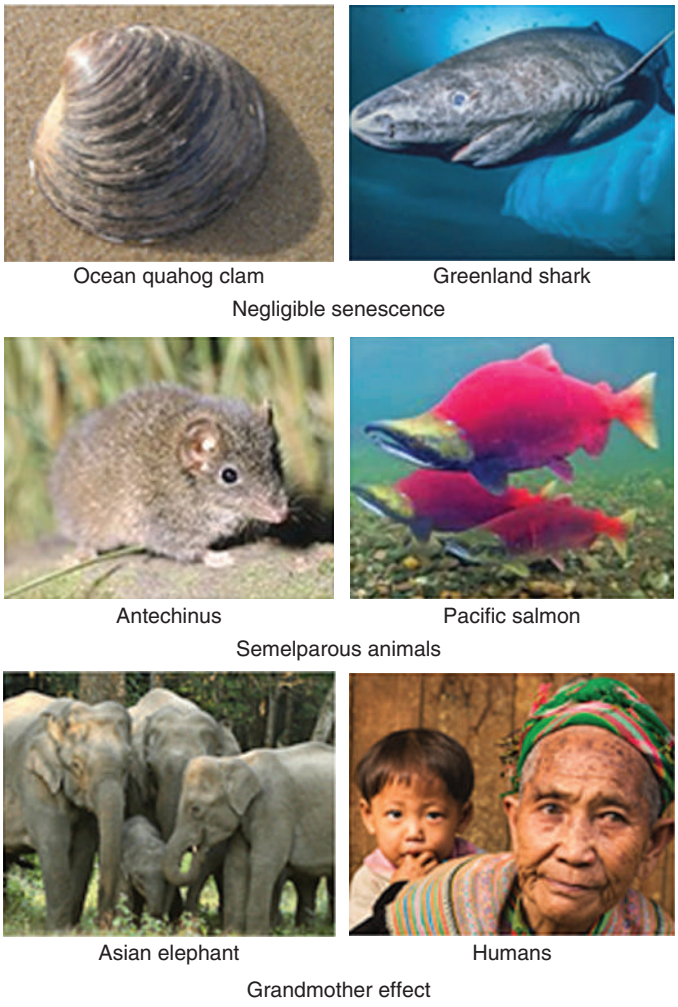

FIGURE 488-4 Some animals undergo negligible senescence, while others such as the semelparous animals undergo programmed aging and death. In some long-lived species, including humans, there is a prolonged postreproductive period that can evolve because of the beneficial effects of grandmothers on survival of infants.

LOSS OF PROTEOSTASIS

Damaged proteins in cells are removed by the autophagy-lysosomal system and ubiquitin-proteosome system. These processes are impaired with aging, which can lead to intracellular and extracellular aggregates of damaged proteins and other cellular components such as lipofuscin, Lewy bodies, neurofibrillary tangles, and amylin **(Fig. 488-6)**.

DISABLED MACROAUTOPHAGY

Autophagy refers to the sequestration and digestion of proteins (i.e., proteostasis), nonprotein macromolecules (e.g., glycogen), and organelles (e.g., mitochondria, "mitophagy"). Autophagy and the expression of autophagy-related genes decline with old age. Autophagy is activated by caloric restriction (CR), spermidine, and inhibition of mechanistic target of rapamycin (mTOR) that all are associated with delayed aging. Loss of function of genes that are associated with autophagy in humans is associated with increased susceptibility to a range of age-related diseases.

DEREGULATED NUTRIENT SENSING

Nutrition has a profound effect on aging in all species. One of the most important nutritional interventions that influences aging is CR. CR involves providing animals with less food (usually ~30–50% less than eaten by ad libitum fed controls). When this is maintained over a lifetime, lifespan is increased, and many age-related pathologies and diseases are delayed. There are several interconnected pathways that mediate the effects of nutrition and CR on aging and age-related health through a wide range of downstream effects **(Fig. 488-7)**. Drugs that act on these pathways to replicate CR are called CR-mimetics and increase lifespan regardless of calorie intake. These key pathways include the following:

1. Insulin and insulin-like growth factor (IGF)-1 signaling pathway (IIS), including growth hormone (GH). Animals with genetic downregulation of this pathway have longer lifespans, including the very long-living Methuselah mice with knock out of the receptor for GH. Humans with GH receptor deficiency (Laron syndrome) have less incidence of cancer and diabetes. Many of the downstream effects on aging pathways are mediated by FOXO (forkhead box O) transcription factors. Genetic variation in some FOXO genes is associated with longevity in humans.
2. mTOR pathway. This pathway is activated by amino acids via tRNA and the IIS and therefore can be manipulated by dietary protein intake. Inactivation of mTOR by dietary restriction or rapamycin is associated with reduced protein synthesis and increased autophagy, leading to increased lifespan.
3. Sirtuins. The sirtuins are a class of seven proteins that respond to dietary energy via the cofactor NAD. Sirtuins regulate gene expression via deacetylation of histone and nonhistone proteins and have been shown to impact many processes related to aging, including apoptosis, inflammation, DNA damage/repair, and mitochondrial biogenesis. Increased sirtuin activity induced by genetic manipulation, resveratrol, or NAD supplementation has been associated with increased lifespan.
4. AMP-activated protein kinase (AMPK) responds to dietary energy restriction via cellular levels of AMP. Activation of AMPK with metformin increases lifespan in animals, and observational studies in humans suggest that metformin impacts age-related conditions. Human clinical trials of metformin are underway to determine its effects on aging.
5. Fibroblast growth factor 21 (FGF21) responds to dietary protein, with protein restriction leading to increased production and release into the blood. FGF21 promotes AMPK signaling and insulin sensitivity, and overexpression in mice increases lifespan.

MITOCHONDRIAL DYSFUNCTION

Age-related changes in mitochondria include increased electron leakage and decreased ATP production, primarily due to impaired complex IV activity. Mitochondrial DNA damage accumulates with age, and mitochondria may become swollen with disrupted cristae. Impaired mitochondrial function leads to increased generation of superoxide radicals and hydrogen peroxide, which are potent oxidants. Consequently, aging is associated with the accumulation of oxidative damage to fat, proteins, and DNA. This forms the basis of the free radical theory of aging. Antioxidants have been investigated as a method to delay age-related oxidative stress but have been ineffective in delaying aging. On the other hand, many of the nutritional and pharmacologic interventions that delay aging are associated with increased mitochondrial biogenesis, usually via their effect on the PGC1α transcription factor.

CELLULAR SENESCENCE

Senescent cells have stopped dividing because of either telomere shortening or other damage mediated by the INK4/ARF system. Senescent cells (sometimes called zombie cells) accumulate in various tissues with increasing age. They produce a range of inflammatory cytokines including interleukin 6 (IL-6) and tumor necrosis factor α (TNF-α), collectively called the senescence-associated secretory phenotype (SASP), which contributes to systemic inflammation. Elimination of senescent cells that express INK4 and several drugs that eradicate senescent cells called senolytics (e.g., dasatinib, quercetin, fisetin) delay the progression of age-related pathologies.

STEM CELL EXHAUSTION

The numbers of stem cells decline with aging, probably secondary to replicative senescence and telomere shortening. Transplantation of pluripotent stem cells from young donors to old recipients extends lifespan in mice and may improve frailty in humans. Another strategy involves induction of genes that regulate stem cells (Yamanaka OSKM factors:

FIGURE 488-5 The hallmarks of aging include 12 processes that form the foundations of the biological changes of aging and age-related diseases and syndromes.

OCT4, SOX2, KLF4, MYC), which delays aging in progeria mouse models. After bone marrow transplantation, no evidence suggests that the recipient runs out of donor stem cells even though the stem cell population could be compromised numerically and due to the age of the donor. Can the stem cells renew themselves in the new host?

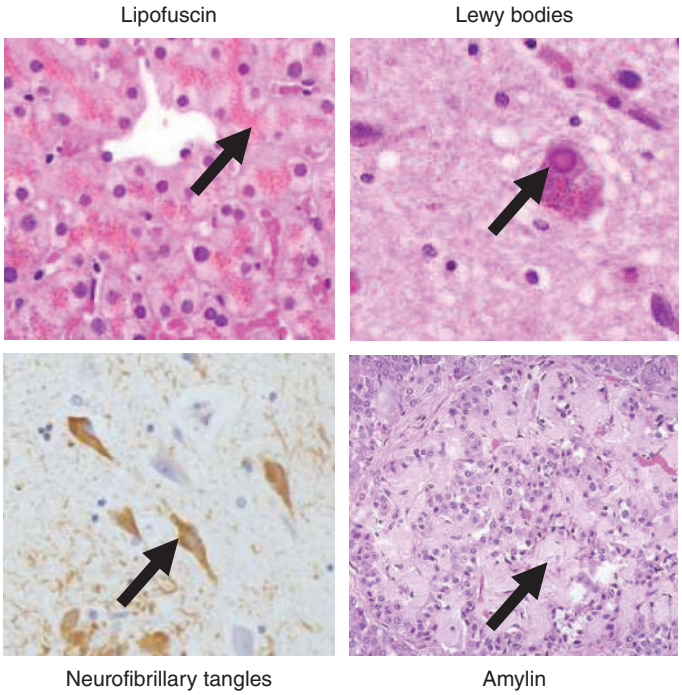

FIGURE 488-6 Impaired proteostasis with old age contributes to the accumulation of aggregates often associated with disease (lipofuscin in the liver, Lewy bodies in the substantia nigra, neurofibrillary tangles in neurons, and amylin in pancreatic islets).

ALTERED INTRACELLULAR COMMUNICATION

Many signaling pathways undergo changes with old age including insulin/IGF-1, dopaminergic, sex hormones, growth differentiation factor 11 (GDF11), and the renin-angiotensin system. These and other bloodborne factors might explain some of the antiaging effects of blood transfusions. Age-related changes are also noted in the extracellular matrix, including increased fibrosis, that impact cell-to-cell communication.

CHRONIC INFLAMMATION

Aging is associated with low-grade activation of the innate immune system, leading to elevated levels of IL-6 and TNF-α and often elevated C-reactive protein and erythrocyte sedimentation rate (ESR) with a lower lymphocyte-to-neutrophil ratio. This has been called "inflammaging." This may be secondary to several factors including the SASP, chronic infection with cytomegalovirus, obesity, leaky gut, and activation of the nuclear factor κB (NF-κB) pathway. Inflammation is a key factor in the pathogenesis of many chronic diseases and, in particular, frailty.

DYSBIOSIS

Complex changes occur in the gut microbiome with old age in humans. The degree of microbial heterogeneity declines, and changes are seen in some species and phyla (e.g., Bacteroidetes, *Akkermansia*). Fecal microbiome transplantation and various probiotics have some effects on aging in mice.

GEROSCIENCE

Old age is the major risk factor for many chronic diseases. The nature of the relationship has been the source of debate for millennia. On one hand, it has been argued that aging is similar to any other disease and, therefore, is amenable to therapeutic interventions. On the other hand, it has been argued that aging is an inevitable and untreatable process that increases the risk for other diseases.

Regardless, there is a marked and often exponential increase in the prevalence and incidence of most chronic diseases with age (Fig. 488-2), and there are several conditions that are generally considered to be primarily age-related disorders, including dementia, sarcopenia, frailty, and osteoporosis. These conditions are very rare below the age of 50 years.

Geroscience refers to the study of the relationship between aging biology and disease. Aging leads to impairment of many physiologic systems that will increase susceptibility to disease. For example, aging is associated with marked changes in immune function. Immunosenescence refers to age-related deterioration of the responsiveness of the immune system to infection and other antigenic challenges, caused by thymic involution with reduced naïve T cells and impaired memory T cells, a reduction in hematopoietic stem cells, and impaired antigen-presenting cell function. Aging is associated with many endocrine changes, most notably a reduction in sex steroids and GH, which contributes to sarcopenia and osteoporosis. Vascular changes including increased arterial stiffness leading to high peripheral vascular resistance and microvascular pathology have an obvious link with cardiovascular disease, but also probably contribute to other conditions such as dementia, osteoarthritis, and sarcopenia.

Although the usual dogma is that aging is a process that increases susceptibility to diseases, the relationship between chronic disease and aging may be much more fundamental. The pathogenesis of most chronic diseases includes one or more of the hallmarks of aging, and differences between disease and normal aging are defined by a quantitative difference in the expression of these hallmarks and the tissues that are affected. Likewise, the difference between aging and

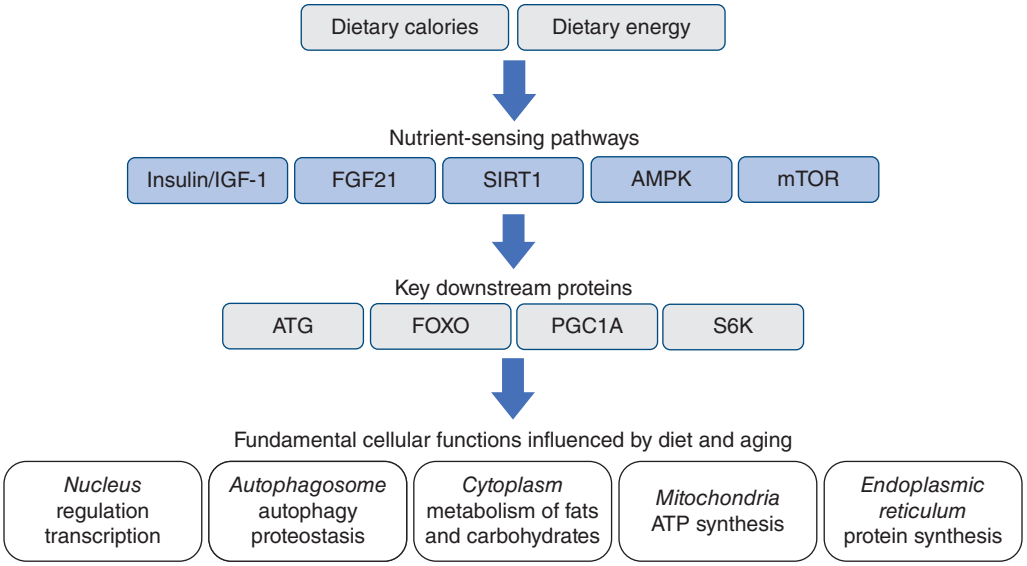

FIGURE 488-7 Nutrient sensing pathways. The main molecular switches that respond to changes in dietary intake (*blue boxes*: insulin/IGF-1, mTOR, AMPK, SIRT1, FGF21) influence a range of downstream intermediaries (some of these are shown in the *gray boxes*). These regulate key cellular processes (*white boxes*) including metabolism, autophagy, mitochondria, and protein synthesis.

disease in terms of the clinical features is often based on quantitative differences. Therefore, there is a continuum between aging and many chronic diseases. These are often separated by so-called "prediseases" or "subclinical diseases," which are evidence for this continuum. Then, chronic disease can be considered a manifestation of aging that is predominant in a particular tissue. The presence of several chronic diseases, termed *multimorbidity*, represents aging changes that are more advanced in several tissues. Frailty can be defined as a multisystem aging syndrome where aging changes are present in most tissues, leading to multiple deficits and impaired function.

STRATEGIES THANT INCREASE HEALTH SPAN AND DELAY AGING

Aging is an intrinsic feature of human life whose manipulation has fascinated humans ever since becoming conscious of their existence. Several long-term experimental interventions (e.g., resveratrol, rapamycin, spermidine, and metformin) may open doors for pharmacologic strategies. Surprisingly, most of the effective aging interventions proposed to date converge on only a few molecular pathways: nutrient signaling, mitochondrial proteostasis, and the autophagic machinery.

Lifespan is inevitably accompanied by a gradual functional decline, steady increase of several chronic diseases, and ultimately death. For millennia, it has been a dream of mankind to prolong both lifespan and health span. Developed countries have profited from advances in medical care and technology, improvements in their public health care systems, and better living conditions derived from their socioeconomic power—to achieve remarkable increases in life expectancy during the past century. In the United States, the percentage of the population aged ≥65 is projected to increase from 13% in 2010 to 19.3% in 2030. However, old age remains the leading risk factor for major life-threatening disorders. The number of people suffering from age-related diseases is anticipated to almost double over the next two decades. The prevalence of age-related pathologies represents a major threat and an economic burden that urgently needs effective interventions.

Molecules, drugs, and other interventions that might decelerate aging processes continue to be a major focus among the general public and scientists of all biological and medical fields. Over the past three decades, this interest has taken root because many of the molecular mechanisms underlying aging are interconnected and linked with pathways that cause diseases, including cancer and cardiovascular and neurodegenerative disorders. Unfortunately, results often lack reproducibility because of the unavoidable problem of the time needed to assess the effectiveness of antiaging interventions in mammals. Experiments lasting the lifetime of animal models are prone to develop artifacts, increasing the possibilities and time windows for experimental discrepancies. Some inconsistencies in the field arise from overinterpreting the results of animal models with shortened lifespan and scenarios of accelerated aging.

Molecules, drugs, and other interventions have been proposed to have antiaging properties throughout history and into the present. In the following sections, interventions will be restricted to those that meet the following highly selective criteria: (1) promotion of lifespan and/or health span, (2) validation in at least three model organisms, and (3) confirmation by at least three different laboratories. These include CR and intermittent fasting regimens, some pharmacotherapies (resveratrol, rapamycin, spermidine, and metformin), and exercise.

CALORIC RESTRICTION

One of the most important and robust interventions that delays aging is CR. This outcome has been recorded in rodents, dogs, worms, flies, yeasts, monkeys, and prokaryotes. CR is defined as a reduction in the total caloric intake, usually of ~30%, and without malnutrition. CR reduces the nutrient-mediated release of growth factors, such as GH, insulin, and IGF-1, which have been shown to accelerate aging and enhance the probability for mortality in many organisms. Yet, the effects of CR on aging were first discovered by McCay in 1935, long before the discovery of these hormones and growth factors and signaling properties. Some of the pathways that mediate this remarkable response of CR have been elucidated in experimental models. These include the nutrient-sensing pathways (mTOR, AMPK, insulin/IGF-1, and sirtuins) and the family of FOXO transcription factors (orthologs are found in *D. melanogaster* and *C. elegans*). The transcription factor Nrf2 appears to confer most of the anticancer properties of CR in mice, even though it is dispensable for lifespan extension.

The effects of CR in monkeys have been assessed in two studies with different outcomes: one study observed prolonged life, while the other did not. In these monkey studies, there were key differences in the onset of the intervention, diet composition, feeding protocols, and genetic background that may explain this discordance. However, both studies confirmed that CR increases health span by reducing the risk for diabetes, cardiovascular disease, and cancer. In humans, CR is associated with extended lifespan and increased health span. This is most convincingly demonstrated in Okinawa, Japan, where one of the most long-lived human populations resides. In comparison to the rest of the Japanese population, Okinawan people usually combine an above-average amount of daily exercise with a below-average food intake. However, when Okinawan families moved to Brazil, they adopted a Western lifestyle that affected both exercise and nutrition,

causing a rise in weight and a reduction in life expectancy by nearly two decades. In the Biosphere II project, volunteers lived together for 24 months undergoing an unforeseen severe CR that led to improvements in insulin, blood sugar, glycated hemoglobin, cholesterol levels, and blood pressure—all outcomes that would be expected to benefit lifespan. CR changes many aspects of human aging that might influence lifespan such as the transcriptome, hormonal status (especially IGF-1 and thyroid hormones), oxidative stress, inflammation, mitochondrial function, glucose homeostasis, and cardiometabolic risk factors. Epigenetic modifications are also an emerging target for CR. The first clinical trial of CR in people at average weight (a body mass index between 20 and 25) started in 2007. The Comprehensive Assessment of Long-Term Effects of Reducing Intake of Energy (CALERIE) included 143 adults between the ages of 21 and 50 years intending to reduce their caloric intake by 25% of their typical intake for 2 years; also included was a group of 75 people who remained on their normal diets and caloric intake. CALERIE has provided evidence for improvements to the quality of life, immune health, cardiometabolic integrity, liver function, and skeletal muscle quality, even though the participants only reached a moderate level of CR (11.9 ± 0.7%) over the 2-year span. CR in this clinical trial also led to a reduction in the rate of biological aging measured by a series of common clinical biomarkers of preservation of physiologic and functional integrity (e.g., liver enzymes, albumin, fasting blood glucose, insulin, and blood pressure). At the molecular level, gene expression analyses in a subset of CALERIE participants indicate that CR induces the regulation of core longevity pathways linked to the preservation of mitochondrial function and stability, lowering chronic inflammation and reducing oxidative stress.

PERIODIC FASTING

It must be noted that maintaining CR while avoiding malnutrition over a long period of time is not only arduous in humans but also linked with substantial side effects. For instance, prolonged reduction of calorie intake may decrease fertility and libido, impair wound healing, reduce the potential to combat infections, and lead to amenorrhea and osteoporosis. How can CR be translated to humans in a socially and medically acceptable way? A whole series of periodic fasting regimens are asserting themselves as suitable strategies, among them (1) the alternate-day fasting diet, (2) the "5:2" intermittent fasting diet, (3) a 48-h fast once or twice each month, and (4) daily time-restricted feeding (TRF). Periodic fasting is psychologically more viable, lacks some of the negative side effects of CR, and is only accompanied by minimal weight loss. All these dietary interventions involve a substantial reduction of caloric intake for a defined period and typically lead to an elevation of circulating ketone bodies during those low-calorie intake periods, illustrating the metabolic switch from the utilization of glucose as a fuel source to the use of fatty acids and ketone bodies. This metabolic shift results in a reduction in the respiratory exchange ratio (the ratio of carbon dioxide produced to oxygen consumed), indicating greater metabolic flexibility and energy production efficiency from use of fatty acids and ketone bodies.

It is striking that many cultures implement periodic fasting rituals, for example, some Buddhists, Christians, Hindus, Jews, Muslims, and practitioners of African animistic religions. It could be speculated that a selective advantage of fasting versus nonfasting populations is conferred by health-promoting attributes of religious routines that periodically limit caloric intake. Indeed, several lines of evidence indicate that intermittent fasting regimens exert antiaging effects. For example, improved morbidity and longevity were observed among Spanish nursing home residents who underwent alternate-day fasting. Rats subjected to alternate-day fasting live up to 83% longer than control animals fed ad libitum, and even one 24-h fasting period every 4 days is sufficient to generate lifespan extension.

Repeated fasting and eating cycles may circumvent the negative side effects of sustained CR. This strategy may even yield health benefits despite overeating behavior during the nonfasting periods. In a landmark experiment, mice fed a high-fat diet in a time-restricted manner, i.e., with regular fasting breaks, showed reduced inflammation markers, did not develop fatty liver, and were slim in comparison to mice fed ad libitum despite equivalent total calories consumed. From an evolutionary point of view, this kind of feeding pattern may reflect mammalian adaptation to food availability: overeating in times of nutrient availability (e.g., after a hunting success) and starvation in times of food scarcity. This is how some indigenous peoples who have avoided Western lifestyles live today; those who have been investigated show limited signs of age-induced diseases such as cancer, neurodegeneration, diabetes, cardiovascular disease, and hypertension.

Fasting exerts beneficial effects on health span by minimizing the risk of developing age-related diseases, including hypertension, neurodegeneration, cancer, and cardiovascular disease. The most effective and rapid repercussion of fasting is a reduction in hypertension. Two weeks of water-only fasting resulted in blood pressure <120/80 mmHg in 82% of subjects with borderline hypertension. Ten days of fasting cured all hypertensive patients who had been taking antihypertensive medication previously. Periodic fasting also dampens the consequences of many age-related neurodegenerative diseases in mouse models of Alzheimer's disease, Parkinson's disease, Huntington's disease, and frontotemporal dementia, but not amyotrophic lateral sclerosis. Fasting cycles are as effective as chemotherapy against certain tumors in mice. When combined with chemotherapy, fasting protects mice against the negative side effects of chemotherapeutic drugs, while enhancing efficacy against tumors. Combining fasting and chemotherapy rendered 20–60% mice cancer-free when inoculated with highly aggressive tumors like glioblastoma or pancreatic tumors, which have 100% mortality even with chemotherapy.

PHARMACOLOGIC INTERVENTIONS TO DELAY AGING AND INCREASE LIFESPAN

Virtually all obese people know that stable weight reduction will lower their risk of cardiometabolic disease and enhance their overall survival, and yet only 20% of overweight individuals are able to lose 10% weight for a period of at least 1 year. Even in the most motivated people (e.g., the "Cronies" who deliberately attempt long-term CR to extend their lives), long-term CR is extremely difficult to adhere to. Thus, much focus has been directed at the possibility of developing medicines that replicate the beneficial effects of CR but without the need for reducing food intake ("CR-mimetics," Fig. 488-8).

- *Resveratrol.* Resveratrol, an agonist of SIRT1, is a polyphenol that is found in grapes and red wine. The potential of resveratrol to promote lifespan was first identified in yeast, and it has gathered fame since, at least in part, because it has been suggested to be responsible for the so-called French paradox whereby wine reduces some of the cardiometabolic risks of a high-fat diet. Resveratrol has been reported to increase lifespan in many lower-order species such as yeast, fruit flies, worms, and fish, as well as mice on high-fat diets. In monkeys fed a diet high in sugar and fat, resveratrol had beneficial

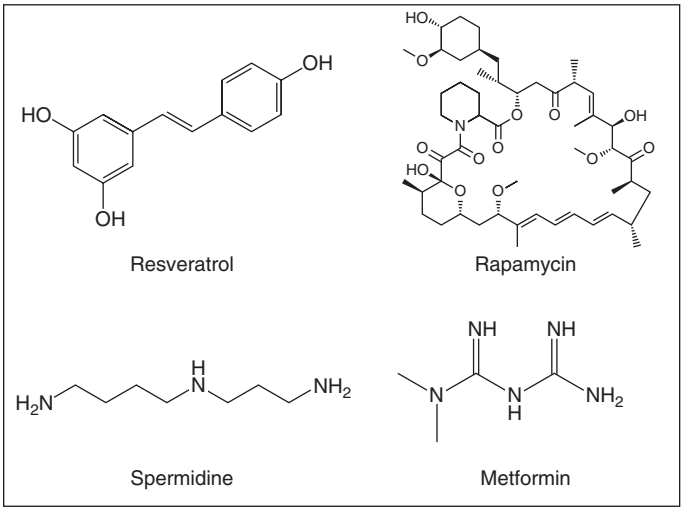

FIGURE 488-8 Chemical structure of four agents (resveratrol, rapamycin, spermidine, and metformin) that have been shown to delay aging in experimental animal models.

outcomes related to inflammation and cardiometabolic parameters. Some studies in humans have also shown improvements in cardiometabolic function, while others have not. Studies in animals and humans reveal that resveratrol mimics some of the metabolic and gene expression changes of CR. In most experimental models, resveratrol induces beneficial health effects by suppressing inflammation, oxidative damage, tumorigenesis, and immunomodulatory activities. Resveratrol also leads to improvements in mitochondrial function and protection against obesity, cancer, and cardiovascular dysfunction.

- *Rapamycin*. Rapamycin, an inhibitor of mTOR, was originally discovered on Easter Island (Rapa Nui, hence its name) as a bacterial secretion with antibiotic properties. Before its emergence in the antiaging arena, rapamycin was known as an immunosuppressant and cancer chemotherapeutic in humans. Rapamycin extends lifespan in all organisms tested so far, including yeast, flies, worms, and mice. However, the potential utility of rapamycin in lifespan extension in humans is likely to be limited by adverse effects related to immunosuppression, impaired wound healing, proteinuria, and hypercholesterolemia, among others. An alternative strategy may be the implementation of intermittent rapamycin treatment, which was found to increase mouse lifespan.
- *Spermidine*. Spermidine is a physiologic polyamine that induces autophagy-mediated lifespan extension in yeast, flies, and worms. Endogenous spermidine levels decrease during life in virtually all organisms including humans, with the remarkable exception of centenarians. Oral administration of spermidine or upregulation of bacterial polyamine production in the gut leads to lifespan extension in short-lived mouse models. The lifespan effects of spermidine are mediated through the inhibition of histone acetylases and the activation of autophagy genes, such as *atg7*, *atg11*, and *atg15* (Morselli et al., 2009). Spermidine has also been found to have beneficial effects on neurodegeneration and cardioprotection through activation of autophagy. Spermidine supplementation is safe in humans and has been associated with positive effects on cognitive function of older adults and on blood pressure maintenance.
- *Metformin*. Metformin, a biguanide first isolated from the French lilac, is widely used for the treatment of type 2 diabetes. Metformin decreases hepatic gluconeogenesis and increases insulin sensitivity. Other actions of metformin include AMPK activation, leading to mTOR inhibition and lower mitochondrial complex I activity, and activation of the transcription factor SKN-1/Nrf2. Metformin increases lifespan in different mouse strains including female mice predisposed to high incidence of mammary tumors. At a biochemical level, metformin supplementation is associated with reduced oxidative damage and inflammation and mimics some of the gene expression changes seen with CR. Based on experimental data on the positive outcomes in model organisms and the evidence emerging from epidemiologic studies, a clinical trial known as TAME (Targeting Aging with Metformin) has been initiated to assess whether metformin can delay the onset of age-related diseases beyond its effects on glucose metabolism. TAME is planning to enroll 3000 subjects, ages 65–79, in a multicenter trial in the United States.

EXERCISE AND PHYSICAL ACTIVITY

In humans and animals, regular exercise reduces the risk of morbidity and mortality. Given the marked increase in cardiovascular disease in the elderly, the effects of exercise on human health may be even stronger than those seen in laboratory mice, as mice do not develop atherosclerosis and have a far lower incidence of age-related cardiovascular disease. An increase in aerobic exercise capacity, which declines during aging, is associated with favorable effects on blood pressure, lipids, glucose tolerance, bone density, and depression in older people. Likewise, exercise training protects against aging disorders such as cardiovascular disease, diabetes mellitus, and osteoporosis. Exercise is the only intervention that can prevent or even reverse sarcopenia (age-related muscle wasting). Even moderate or low levels of exercise (30-min walking per day) have significant protective effects in obese subjects. In older people, regular physical activity has been found to increase the length of stay in independent living.

While clearly promoting health and quality of life, regular exercise does not extend lifespan. Furthermore, the combination of exercise with CR has no additive effect on maximal lifespan in rodents. However, alternate-day fasting with exercise is more beneficial for muscle mass than either treatment alone. In nonobese humans, exercise combined with CR has synergistic effects on insulin sensitivity and inflammation. From an evolutionary perspective, the responses to hunger and exercise are linked: when food is scarce, increased activity is required to hunt and gather.

HORMESIS

Paradoxically, the term *hormesis* describes the protective effects conferred by the exposure to low doses of stressors or toxins (or as Nietzsche stated, "What does not kill me makes me stronger"). Adaptive stress responses elicited by noxious agents (chemical, thermal, or radioactive) precondition an organism, rendering it resistant to subsequent higher and otherwise lethal doses of the same trigger. Hormetic stressors have been found to influence aging and lifespan, presumably by increasing cellular resilience to factors that might contribute to aging such as oxidative stress.

Yeast cells that have been exposed to low doses oxidative stress exhibit a marked anti-stress-like response that inhibits death following exposure to lethal doses of oxidants. During ischemic preconditioning in humans, short periods of ischemia protect the brain and the heart against a more severe deprivation of oxygen and subsequent reperfusion-induced oxidative stress. Similarly, the lifelong and periodic exposure to various stressors can inhibit or retard the aging process. Consistent with this concept, heat or mild doses of oxidative stress can lead to lifespan extension in *C. elegans*. CR can also be considered as a type of hormetic stress that results in the activation of antistress transcription factors (e.g., Rim15, Gis1, and Msn2/Msn4 in yeast, Nrf2 and FOXO in mammals) that enhance the expression of free radical–scavenging factors and heat shock proteins.

CONCLUSIONS

Clinicians need to understand aging biology to better manage and care for the elderly. Moreover, strategies based on aging biology are needed that delay aging, reduce the onset of age-related disorders, and increase health span for future generations. Dietary interventions and drugs that act on nutrient-sensing pathways are being developed and, in some cases, are already being tested in humans. Well-controlled human clinical trials have started to recapitulate the preclinical evidence of intermittent fasting on obesity, diabetes mellitus, cardiovascular disease, cancers, and neurologic disorders. While most animal studies show that intermittent fasting improves health throughout the lifespan, most human studies are focused on relatively short-term interventions over a few days or months. While intriguing, it remains to be seen whether people will be willing to maintain strict intermittent fasting regimens over long periods of time or if short-term clinical benefits can be obtained in combination with other therapeutic approaches.

489 Caring for the Geriatric Patient

Joseph G. Ouslander, Bernardo Reyes

DEMOGRAPHICS OF AGING AND ITS IMPLICATIONS FOR CARE OF OLDER ADULTS

The United States and other countries will continue to experience a rapid increase in the number of older adults who seek health care. The most rapidly growing segment of the population in the United States and many other developed countries is those older than 80 **(Fig. 489-1)**. According to the United Nations 2022 Aging Report, 1 in 6 people worldwide will be 65 years old or older by the year 2050. The sex and gender composition of the aging population around the world is also expected to change. Although females outlive males, an improvement in the survival of the oldest-old males could result in a more balanced gender distribution in the geriatric population in the future.

In high-income countries, consumption of health care resources will be most affected by the shift in the age distribution of the population over the next several decades. The World Health Organization continues to work actively to raise awareness of the changes necessary in current health care systems beyond increments in their budgets. As life span increases, efforts should continue to focus on promoting healthy aging to reduce the burden of disability in health care systems all over the world.

The geriatric population requires different approaches to care for several reasons. The wide variations seen in aging make it difficult to develop age-related guidelines for diagnosis and treatment. For example, acute illnesses are most often not treated in isolation but in the context of multiple comorbidities. Close to half of those older than 80 have three chronic conditions, and about one-third have four or more chronic conditions **(Fig. 489-2)**. Functional disabilities are prevalent **(Fig. 489-3)**, which require careful attention in the evaluation of the older patient, along with assessment of social support available for assistance when needed for independent and safe living.

Effectively caring for the geriatric population requires consideration of several key principles:

1. Aging is not a disease; normal aging changes generally do not cause symptoms but do increase susceptibility to many diseases and conditions due to diminished physiologic reserve.
2. Medical conditions are commonly multiple ("multimorbidity") and multifactorial in origin, requiring a comprehensive approach to evaluation and management.
3. Many potentially reversible and treatable conditions are underdiagnosed and underevaluated in this population, such as fall risk, urinary incontinence, and elder abuse and neglect; simple screening tools can help detect them.
4. Cognitive and affective disorders (e.g., mild cognitive impairment, dementia, depression, anxiety) are common and may be undiagnosed in early stages; simple screening tools can help detect them.
5. Iatrogenic illnesses are common, especially related to adverse drug reactions, immobility, and related deconditioning, as well as other complications.
6. Focus on functional ability and quality of life, as opposed to cure, are key goals of care.
7. Social history, social support, and patient preferences are critical to treating older people in a safe and person-centered manner.
8. Effective geriatric care requires multidisciplinary collaboration among many different disciplines.
9. Geriatric care is provided most commonly outside the hospital (e.g., outpatient clinics and offices, at home, in skilled nursing and assisted living settings), and attention to care transitions between settings is essential for effective care.
10. Ethical issues, palliative care, and end-of-life care are critical aspects of caring for the geriatric population.

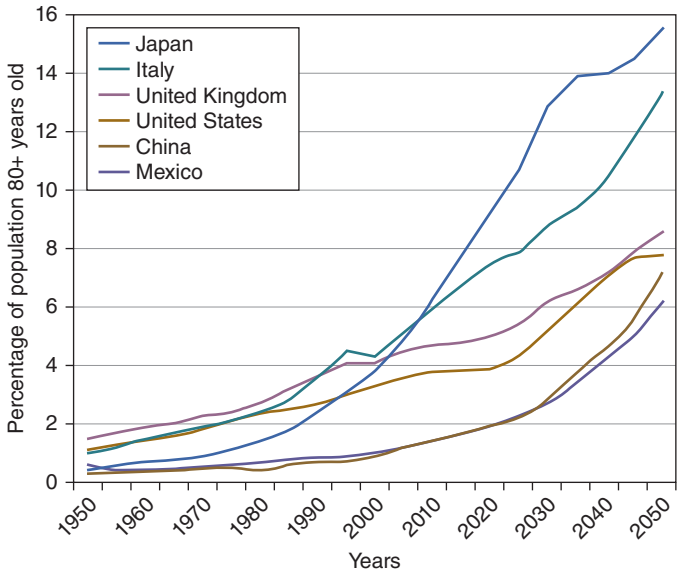

FIGURE 489-1 Percentage of the population age >80 years from 1950 to 2050 in representative nations. *(Updated data available at: https://esa.un.org/unpd/wpp/Graphs/DemographicProfiles/. Accessed December 30, 2016.)*

Another way to summarize key concepts of caring for older adults is using the "5M's of geriatrics" (mentation, medication, mobility, multicomplexity, and matters most) This framework organizes care of older adults in a person-centered manner instead of a disease-driven paradigm. The intention of the 5M's is to optimize the utilization of existing resources during the hospitalization of older adults, as well as to focus on key geriatric issues in all settings of care. At the core of the 5M's is what *matters* most to the patient in terms of goals of care and everyday living **(Fig. 489-4)**. *Mobility* is critical to individual function, quality of life, and fall risk, and ranges from the ability to move around the community to walking and transferring from a chair. Because mild cognitive impairment, dementia, delirium, and depression are all common in older adults, *mentation* is a core area for geriatric assessment. Polypharmacy and prescription of potentially inappropriate and harmful medications remain common; thus, careful *medication* reconciliation and consideration of deprescribing are core aspects of care for all older adults. Many older adults have complex clinical issues in more than one of the four M's just discussed, as well as geriatric syndromes (e.g., falls, incontinence), thus focusing attention on multiple comorbidities and *multicomplexity*. In addition to these 5M's, *social determinants of health* play a critical role in providing comprehensive care to older people.

In this chapter, these key principles serve as the background for the clinical recommendations for managing older adults. The reader is referred to textbooks of geriatric medicine for more details on each of the principles and the management of common diseases and conditions in this population.

FUNDAMENTALS OF GERIATRIC CARE

PERSON-CENTERED CARE

Person-centered care is a critical concept in caring for older people because of the complexity of their medical, functional, and psychosocial problems and, in many instances, the lack of rigorous data on the most effective strategies for caring for specific conditions in patients with multimorbidity. For almost any condition, from common disorders such as hypertension and diabetes to geriatric syndromes such as fall risk and urinary incontinence, the answer to how best to treat medical conditions in an older patient is "it depends." It depends not only on evidence-based medicine but also on careful weighing of many factors that can be important to individual older people.

The American Geriatrics Society (AGS) identifies the following elements as key to person-centered care: (1) an individualized, goal-oriented care plan based on the person's preferences; (2) ongoing review of the person's goals and care plan; (3) information sharing and

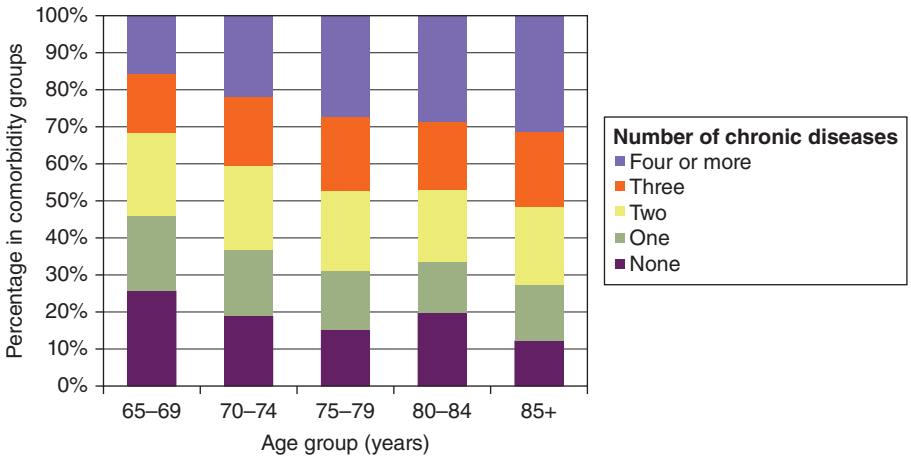

FIGURE 489-2 Prevalence of comorbidity by age group in persons ≥65 years old living in the United States and enrolled in Medicare Parts A and B in 1999. *(From JL Wolff et al: Arch Intern Med 162:2269, 2002.)*

integrated communication; (4) education and training for providers and, when appropriate, the person and those important to the person; and (5) performance measurement and quality improvement using feedback from the person and caregivers. In everyday practice with complex older patients, it is essential to have a comprehensive approach that addresses medical conditions, geriatric syndromes, improving or maintaining function and independence, quality of life, comfort, and dignity.

Several tools are available to assist in implementing evidence-based and person-centered care, including estimation of prognosis (e.g., "ePrognosis") and "Choosing Wisely" recommendations from the AGS and AMDA—The Society for Post-Acute and Long-Term Care Medicine. Examples of these recommendations that are relevant to internal medicine practice are illustrated in **Table 489-1**.

COMPREHENSIVE GERIATRIC ASSESSMENT

General Principles of Geriatric Assessment Comprehensive geriatric assessment addresses all of the components required for Medicare's annual wellness visit and more. In addition to management of common medical conditions and syndromes in older people (see below), a series of screening questions can be useful as a "geriatric review of systems" in clinical practice because of the importance and high prevalence of functional impairments and disabilities, limited social support to assist with functional limitations, cognitive and affective disorders, and geriatric conditions that may go undetected and cause patient safety issues and complications **(Table 489-2)**. Positive responses to one or more of the screening questions for each item should prompt consideration of further assessments, many of which can be accomplished using standard and validated tools available on the Internet, such as activities of daily living scales, depression scales, sleep questionnaires, and mental status examinations.

One very useful component of the geriatric assessment is the *foot exam*. Improper footwear and foot deformities, especially painful ones, are a major cause of falling (see below). If a person is not wearing socks, this may be an indication they have difficulty putting them on due to hip arthritis or another condition. Inspection between the toes is important to detect poor hygiene and ulcers, especially in diabetics. Poorly trimmed and/or fungal-infected toenails suggest that the individual cannot trim their toenails, has no one to help them do it, and does not have access to a podiatrist or regular pedicures. Other unique aspects of comprehensive geriatric assessment are described below.

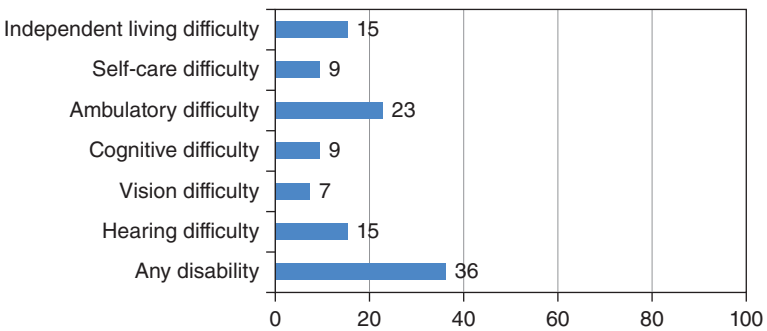

FIGURE 489-3 Percentage of people age 65+ with various disabilities. *(Source: U.S. Census Bureau, American Community Survey, 2013. Available at https://aoa.acl.gov/Aging_Statistics/Profile/2014/index.aspx. Accessed December 30, 2016.)*

Evaluation of Medical Decision-Making Capacity Key aspects of decision-making in older adults are illustrated in **Fig. 489-5**. Including the patient in the consent process for any treatment is the foundation of patient autonomy and person-centered care. Because aging is associated with an increasing potential to develop cognitive impairment, the determination of decision-making capacity is important not only to protect the patients against potential abuse but also to preserve autonomy when possible and, when it is not, to ensure an appropriate surrogate decision-making process is followed. Assessing for capacity is usually triggered by specific circumstances (e.g., the need for invasive diagnostic testing or surgery). Determination of decision-making capacity limited to medical circumstances should be differentiated from declaring a patient "incompetent" to make all decisions. Declaring someone incompetent is a legal definition and usually is reserved for court settings. Another caveat about evaluating decision-making capacity is distinguishing lack of capacity from poorly presented information, sensory impairment, language barriers, and/or low level of literacy. Diversity in values and beliefs can influence the perception of capacity for different cultures. Moreover, clinicians should be aware of the possibility of undue influence where caregivers might have secondary gain (financial or other) from taking control over decision-making on behalf of an older adult. The clinician should corroborate that the patient has received all the necessary information, comprehends the information provided, and has no major auditory or visual impairments. For geriatric patients, it is important to determine if the patient uses hearing aids or prescription glasses and ensure they are available for their use. Processing speed can slow with age and should be considered while completing a capacity assessment. Lastly, an important determinant of capacity is the presence of acute illness that could produce a transient alteration of cognition. Therefore, if the decision-making is deferred to a surrogate, this should be limited to procedures and treatments that are needed urgently.

Standard tests of cognitive function correlate poorly with the capacity to consent for specific interventions. Several standardized tools have been validated to determine decision-making capacity. The MacArthur Competence Assessment Tool–Treatment (MacCAT-T) is one of the several resources for determining decision-making capacity. It is a structured tool that has been validated, but it is lengthy and can be difficult to administer in some patients. The Capacity to Consent to Treatment Instrument (CCTI) is another tool that has been validated in patients with mild to moderate Alzheimer's disease.

Evaluation of the Older Driver For many older adults in the United States, driving is essential for maintaining independence, and driving cessation is associated with negative outcomes including social isolation and depression. On the other hand, older adults are at higher risk of being involved in fatal crashes than younger counterparts, with up to a ninefold higher risk for those ≥85 years old. Older people should be routinely assessed for their driving status and whether they have been involved in motor vehicle crashes in addition to assessment for sensory, functional, and cognitive impairments that can make driving unsafe **(Table 489-3)**. In

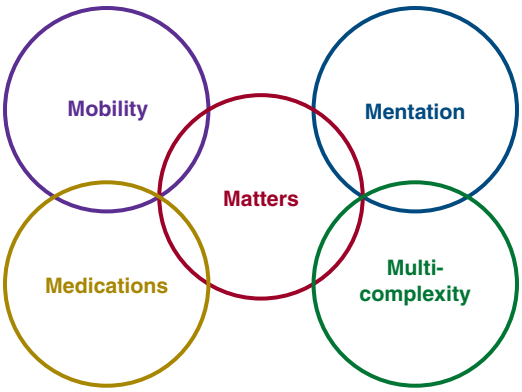

FIGURE 489-4 The 5M's of geriatrics.

addition to common geriatric conditions, several different types of drugs can impair various aspects of driving performance and should be carefully considered in older people who continue to drive, including antianxiety agents, narcotic analgesics, antipsychotics, anticonvulsants, and drugs with strong anticholinergic properties.

Suspected driving impairment can be a source of conflict between the patient (who wants to maintain independence), the family (who may want their relative to continue driving due to lack of other transportation, or may be concerned about their safety, or both), and the physician (who is concerned about all who are at risk from a car crash). These decisions involve liability since local governments might not require driving retesting for all older drivers, but in some states, physicians are required to report older people who they believe are unsafe drivers. Evaluation of driving should be aimed to correct any reversible cause of losing driving skills, such as vision and hearing impairment. Although tests of executive function such as the Trails B have been associated with poor driving performance, no single screening test predicts unsafe driving. A combination of neuropsychological testing by a psychologist and on-road testing by a trained occupational therapist can provide the physician with essential input in making the difficult decision on driving cessation. The AGS and the U.S. Department of Transportation's National Highway Traffic Safety Administration have updated the "Physician's Guide to Assessing and Counseling Older Drivers," which can be helpful to practicing clinicians and is available on the AGS website.

TABLE 489-1 Examples of Choosing Wisely Recommendations Helpful in Implementing Person-Centered Care in Complex Geriatric Patients

- Don't recommend percutaneous feeding tubes in patients with advanced dementia; instead, offer oral assisted feeding.
- Don't use antipsychotics as the first choice to treat behavioral and psychological symptoms of dementia.
- Avoid using medications other than metformin to achieve hemoglobin A_{1c} <7.5% in most older adults; moderate control is generally better.
- Don't use benzodiazepines or other sedative-hypnotics in older adults as first choice for insomnia, agitation, or delirium.
- Don't use antimicrobials to treat bacteriuria in older adults unless specific urinary tract symptoms are present.
- Don't prescribe cholinesterase inhibitors for dementia without periodic assessment for perceived cognitive benefits and adverse gastrointestinal effects.
- Don't recommend screening for breast, colorectal, prostate, or lung cancer without considering life expectancy and the risks of testing, overdiagnosis, and overtreatment.
- Don't routinely prescribe lipid-lowering medications in individuals with a limited life expectancy.
- Don't obtain a *Clostridioides difficile* toxin test to confirm "cure" if symptoms have resolved.
- Don't recommend aggressive or hospital-level care for a frail elder without a clear understanding of the individual's goals of care and the possible benefits and burdens.

Interpretation of Diagnostic Tests Physiologic changes associated with aging can affect the results of some common diagnostic tests. The large variation of many physiologic measures that are associated with normal aging makes establishing what is "normal" for many tests challenging. For this reason, the results of several diagnostic tests must be interpreted cautiously. Ambulatory cardiac monitoring may identify a variety of arrhythmias in older adults. Such arrhythmias must be linked to symptoms or adverse outcomes if left untreated before considering the use of potentially toxic medications or invasive procedures.

Advanced imaging also could demonstrate incidental abnormalities. Although a significant portion of these findings are benign, the rate of malignancy among incidental findings in the colon and extracolonic structures, as well as ovarian and thyroid gland, is ~20%. Musculoskeletal imaging, such as magnetic resonance imaging (MRI) of the spine, may reveal multiple abnormalities that may or may not be related to symptoms.

Unless further evaluation would not lead to a change in the goals of care and treatment plan, abnormal diagnostic tests require further evaluation in older patients. Examples include low hemoglobin levels, abnormal thyroid function tests, age-/sex-/weight-adjusted creatinine clearance, and elevated liver function tests. None of these abnormal findings are the result of normal aging and generally indicate the presence of a disorder that may or may not be reversible.

PREVENTION IN OLDER ADULTS

Age-Appropriate Screening Screening tests for specific diseases, as opposed to screening for geriatric conditions, require a careful person-centered approach. The focus of preventive medicine depends heavily on the ability to identify those who are at risk for specific conditions, as well as the time to benefit from interventions when considering the individual's life expectancy **(Chap. 6)**. Several professional societies have provided guidance regarding specific tests in older adults (Table 489-3). An important caveat about screening to prevent disease in older patients (e.g., colonoscopy for colon cancer, Pap smears, prostate-specific antigen testing) is that abnormal results may lead to subsequent testing and treatment among individuals who will not suffer morbidity or mortality from the disease because of limited life expectancy. Thus, geriatric patients pose a significant challenge in deciding what screening tests could offer a reasonable ratio of benefit and risk as well as being cost-effective. As an example, the U.S. Preventive Services Task Force recommends colorectal cancer screening up to the age of 75 years. Due to the limited net benefit, for those between 76 and 85 years old, the recommendation is to only consider colonoscopy if they have never been screened and are healthy enough to undergo treatment if colon cancer is detected.

Vaccinations The use of vaccines in older adults is aimed at creating immunity against common infections that could lead to serious complications and rebuilding previously obtained immunity. The U.S. Centers for Disease Control and Prevention (CDC) recommends routine vaccination against influenza, pneumococcus, and shingles as they are prevalent in this age group. CDC's recommendations on vaccination for COVID-19 and its variants, as well as respiratory syncytial virus, should be reviewed regularly because of frequent updates. Other countries in Europe and Asia have similar trends in vaccinations with small variances.

Sexually Transmitted Diseases Although most sexually transmitted diseases (STDs) occur in younger people **(Chap. 141)**, some older adults do have high-risk sexual behavior. Most Americans remain sexually active in their 60s and 70s, and up to a quarter of individuals in their 80s consider themselves sexually active. Sexually active older adults may have a lower awareness of the need for safe sexual practices, such as the risks of multiple sexual partners and condom use. The incidence of STDs in older people is still relatively low. Nonetheless, patients presenting with symptoms compatible with syphilis or

TABLE 489-2 Examples of Screening Questions and Tools and Strategies for Further Evaluation of Social Support, Functional Status, Geriatric Syndromes, and Cognition and Affect

GERIATRIC ASSESSMENT DOMAINS		RECOMMENDED SCREENS	FURTHER ASSESSMENT FOR POSITIVE SCREEN
SOCIAL	**Social Support**	Do you live alone? Do you have a caregiver? Are you a caregiver?	• Consider referral to a social worker • Refer to area agency on aging
	Elder Neglect/Abuse	Do you ever feel unsafe where you live? Has anyone ever threatened or hurt you? Has anyone been taking your money without your permission?	• Consider referral to a social worker and/or adult protective services
	Advance Directives	Would you like information or forms for a power of attorney for health care? Would you like information on a living will?	• Discussion on advance directives • Physician Orders for Life-Sustaining Treatment (POLST) (or MOLST or POST)
FUNCTIONAL	**Functional Status**	Do you need assistance with shopping or finances? Do you need assistance with bathing or taking a shower?	• Instrumental Activities of Daily Living (ADL) Scale • Basic ADL Scale
	Driving	Do you still drive? If yes: While driving, have you had an accident in the past 6 months? Driving concerns by family member?	• Vision testing • Consider occupational therapy and/or formal driving evaluation
	Vision	Do you have trouble seeing, reading, or watching TV? (with glasses, if used)	• Vision testing • Consider referral for eye exam
	Hearing	Do you have difficulty hearing conversation in a quiet room? Unable to hear whisper test 6 inches away?	• Check for cerumen in ear canals and remove if impacted • Hearing Handicap Inventory • Consider audiology referral
GERIATRIC SYNDROMES	**Medications**	Do you take five or more routine medications? Do you understand the reason for each of your medications?	• Match medications with diagnoses • Consider reducing doses, stopping drugs, adherence aides, and/or consultation with a pharmacist
	Fall Risk	Have you fallen in the past year? Are you afraid of falling? Do you have trouble climbing stairs or rising from chairs?	• "Get Up and Go" test • Consider full fall assessment • Consider physical therapy evaluation • Consider home safety assessment
	Continence	Do you have any trouble with your bladder? Do you lose urine or stool when you do not want to? Do you wear pads or adult diapers?	• Consider full continence assessment • 3IQ Questionnaire (women) • AUA 7 symptom inventory (men)
	Weight Loss	Weight <100 pounds or Unintentional weight loss ≥10 pounds over 6 months?	• Assess for common risk factors for malnutrition • Consider referral to dietician for nutritional evaluation
	Sleep	Do you often feel sleepy during the day? Do you have difficulty falling asleep at night?	• Epworth Sleepiness Scale or Pittsburgh Sleep Index • Consider referral for sleep evaluation
	Pain	Are you experiencing pain or discomfort?	• Pain assessment
	Alcohol Abuse	Do you drink >2 drinks/day?	• AUDIT-C
COGNITION AND AFFECT	**Depression**	Do you often feel sad or depressed? Have you lost pleasure in doing things over the past few months?	• PHQ-9 or Geriatric Depression Scale • Screen for suicide risk
	Cognition	Self-reported memory loss? Cognitive screen positive? (three-item recall and Clock Draw test "Mini-Cog") Confusion Assessment (CAM) for delirium	• Montreal Cognitive Assessment or Mini Mental State Examination • If diagnosis is unclear, consider neuropsychological testing

Abbreviations: 3IQ, Three Incontinence Questions; AUA, American Urological Association; AUDIT-C, Alcohol Use Disorders Identification Test; MOLST, Medical Orders for Life-Sustaining Treatment; PHQ, Patient Health Questionnaire; POST, Physician Orders for Scope of Treatment.

gonococcal infection (cervicitis, urethritis, proctitis, epididymitis) should be screened for high-risk sexual behavior and educated if necessary. Clinical symptoms of herpes simplex infection and the possibility of becoming contagious also decrease with age. As ulcerative lesions are less frequent, herpes simplex virus 2–specific serologic testing should be considered for patients with recurrent nonspecific genital symptoms. Therapy should not be started unless the patients are symptomatic.

In the United States alone, 450 per 100,000 persons above the age of 55 are infected with HIV. Since the introduction of highly active antiretroviral therapy, the life expectancy of patients with HIV has increased, resulting in a significant increase in the number of older adults living with the disease. De novo infections have also contributed to the rising number of HIV cases in older adults. See **Chap. 208** for details on HIV infection.

TREATMENT OF COMMON DISEASES IN THE GERIATRIC POPULATION

HYPERTENSION

In the United States, 70% of older adults have hypertension. Several clinical trials have demonstrated the benefits of hypertension treatment on risk reduction of cardiovascular events in older people. Nonetheless, blood pressure targets remain controversial. The balance between the cardiovascular protective benefits versus the risk of treatment-related adverse events must be considered in individual patients based on their

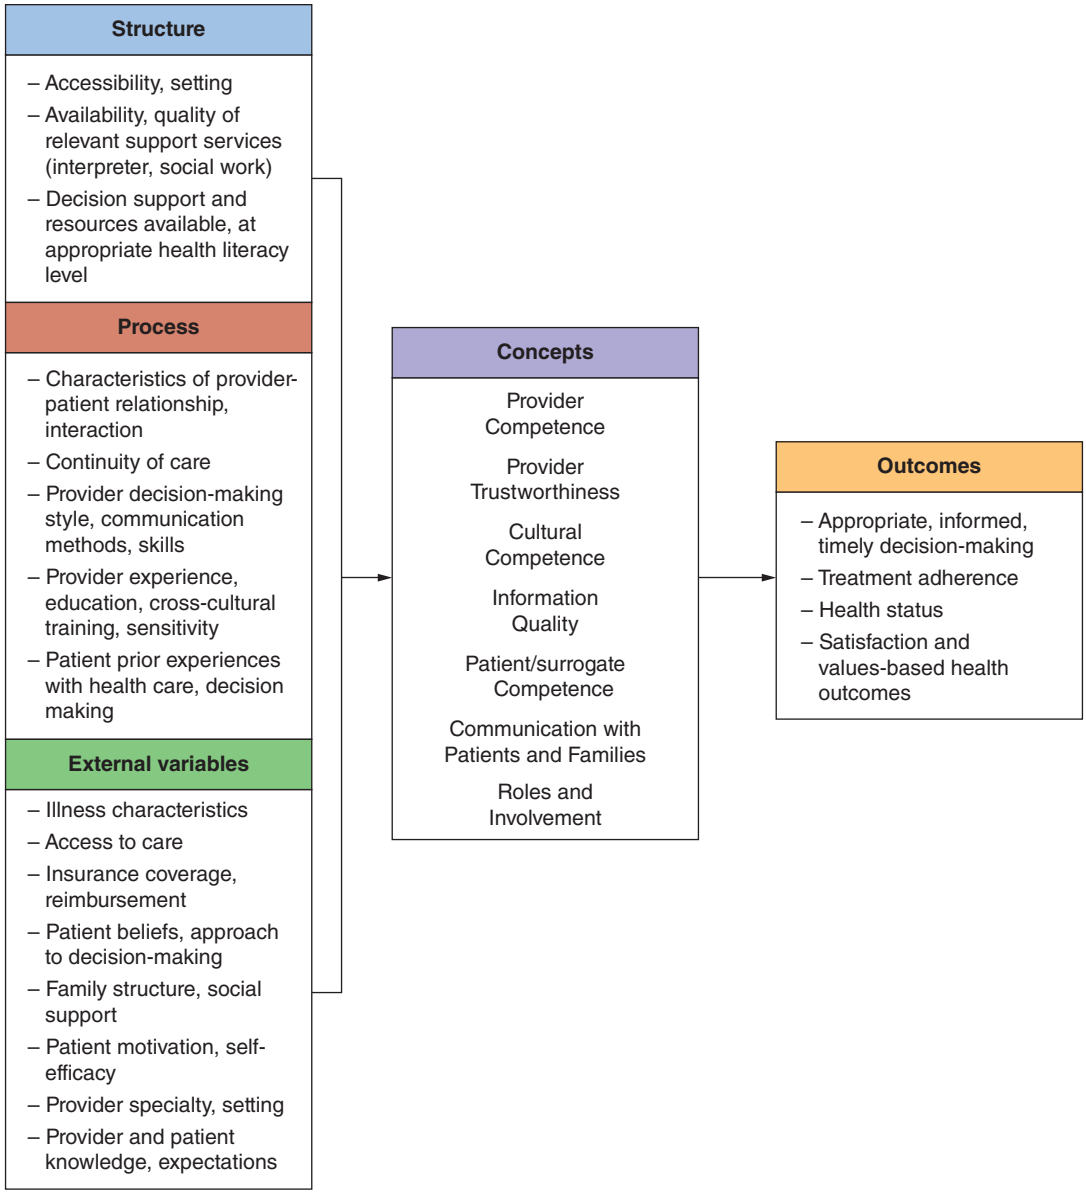

FIGURE 489-5 Key aspects of decision-making in older adults. *(Reproduced with permission from SM Dy, TS Purnell: Key concepts relevant to quality of complex and shared decision-making in health care: A literature review. Soc Sci Med 74:582, 2012.)*

comorbidities and level of function. For example, hypotension and postural hypotension related to antihypertensive therapy are common causes of syncope, falls, and related injuries in the geriatric population, especially those with multimorbidity. In addition to cardiovascular disease prevention, control of systolic blood pressure (SBP) may reduce the burden of white matter changes in the brain, which are associated with gait abnormalities and cognitive decline. A secondary analysis of the SPRINT trial (see below) suggests that intensive treatment of systolic blood pressure might reduce the risk of dementia and mild cognitive impairment (MCI) among those at higher risk for such conditions. The European Society of Cardiology/European Society of Hypertension guidelines recommend pharmacologic treatment for individuals 80 years old or older if SBP is 160 mmHg or higher. In contrast, the American College of Physicians recommends starting treatment if SBP is 150 mmHg or higher.

Two large studies (HYVET and SPRINT) have shed some light on these issues. HYVET was a multicenter study conducted in several countries involving ~3800 patients ≥80 years old. The study demonstrated that active treatment of hypertension with a target of ≤150 mmHg significantly reduced not only the risk of stroke and heart failure but also the mortality risk. As with other large hypertension studies like ALLHAT, a linear association was noted between blood pressure and stroke reduction. Nonetheless, in the HYVET study, this association was less prominent as age increased. SPRINT was another large randomized trial targeting lowering SBP to targets of <140 versus 120 mmHg (measured with an automated device) with a subgroup analysis in those aged 75 and older. Significant reductions were documented in the primary endpoint, which was a composite of cardiovascular disease events (including myocardial infarction, acute coronary syndrome, heart failure, stroke, or death from cardiovascular causes). However, it is critical to recognize that patients with diabetes, a history of stroke or heart failure, SBP <110 mmHg after 1 min of standing, as well as people with several other comorbidities, were excluded from the SPRINT trial, and aggressive treatment in the setting of these comorbidities may incur more risk of adverse effects. In addition, the reduction in adverse outcomes detected during the study was not observed long term.

Overall, these data strongly suggest a person-centered approach to hypertension in the heterogeneous older population. For older patients with minimal comorbidity, no postural hypotension, and low risk of falls and volume depletion, the benefit-risk ratio favors lower targets for SBP (<130 mmHg measured by a hand sphygmomanometer). Aggressive targets also may be more beneficial for patients with concomitant nonvalvular atrial fibrillation or coronary artery disease. However, for those with diabetes, heart failure, or postural hypotension, treatment of hypertension with higher SBP targets (e.g., <150 mmHg)

TABLE 489-3 Recommendations for Primary Prevention Screening for Specific Diseases in Older Adults from Different Professional Societies

TYPE OF SCREENING	TEST	FREQUENCY	PROFESSIONAL SOCIETY ISSUING RECOMMENDATIONS		
			USPSTF[a]	ACS[b]	ACP[c]
Colorectal	Fecal occult blood test or fecal immunochemical test (FIT) or Sigmoidoscopy or Colonoscopy	Annual Every 5 y Every 10 y	Screen all adults age 50–75; prognosis may support screening individuals of age 76–85 if never screened; not recommended for adults over age 85	Screen all adults age >50; discontinuing screening is reasonable in people with severe comorbidity that would preclude treatment	Screen all adults age 50–75 People with life expectancy <10 y should not be screened
Breast	Mammography	Every 1–2 y	Biennial screening of all women age 50–74; evidence of benefits and harms is insufficient for women age >75	Annual screening starting at age 40; continue while in good health	ECOG[d] Annual screening starting at age 40 y
Cervical	Pap smear HPV test	Pap only, every 3 y HPV + Pap, every 5 y	Screen women age 21–65; discontinue at age 65 if adequate prior screening	Screen women age 21–65; discontinue at age 65; discontinue at age 65 if regular screening normal	Screening should stop at age 65 if evidence of negative adequate prior screening
Lung	Low-dose CT scan	Annual	Screen age 55–80 current and former smokers with a 30+ pack-year smoking history; discontinue screening once a person has not smoked for 15 years or develops a health problem that limits their ability or willingness to have curative surgery	Screen 55–74-y-old current and former smokers in good health with a 30+ pack-year smoking history	ACCP[e] In settings that can deliver the comprehensive care provided to National Lung Screening Trial participants, offer screening to people age 55–74 who are current and former smokers with 30+ pack-year smoking history
Prostate	Prostate-specific antigen (PSA)	1–2 y	Do not screen men for prostate cancer with PSA if age 70 y or older	Screen men age 50 and over with a life expectancy >10 y after discussion about the risks, benefits, and uncertainties of PSA screening Follow-up screening should occur annually if PSA >2.5 ng/mL or biennially if PSA <2.5 ng/mL	AUA[f] Biennial PSA screening in men age 55–69 y with life expectancy >10–15 y, after shared decision-making discussions accounting for values and preferences
Osteoporosis	Dual-energy x-ray absorptiometry (DEXA) Measure height, preferably with a wall-mounted stadiometer	Perform bone mineral density testing 1–2 y after initiating medical therapy for osteoporosis and every 2 y annually thereafter	USPSTF[a]	NOF[g]	
			Screen women age 65; the current evidence is insufficient to assess the balance of benefits and harms of screening for osteoporosis to prevent osteoporotic fractures in men	Screen women age 65 and older and men age 70 and older; postmenopausal women and men age 50–69, based on risk factor profile; postmenopausal women and men age 50 and older who have had an adult-age fracture	
Carotid disease	Carotid ultrasound	Once	SOCIETY OF VASCULAR SURGERY		
			Age over 65, coronary artery disease, need for coronary bypass, symptomatic lower extremity arterial occlusive disease, history of tobacco use, and high cholesterol would be appropriate risk factors to prompt ultrasound in patients with a bruit		
Coronary artery disease (CAD)	Coronary calcium score (CCS)	Once	SCCT[h]	AHA/ACC[i]	
			Do not use CCS for patients with known CAD	CCS of 0 may have a strong negative predictive value for coronary events in older adults	
Abdominal aortic aneurysm	Abdominal ultrasound	Once	USPSTF[a]	AAFP[j]	
			The USPSTF recommends one-time screening for abdominal aortic aneurysm with ultrasonography in men aged 65–75 y who have ever smoked; there is insufficient evidence to recommend screening for women even if they have ever smoked	Recommended for men aged 65–75 y who have ever smoked	
Diabetes	Fasting blood glucose, glucose tolerance test, or hemoglobin A_{1c}	Annually	USPSTF[a]	ADA[k]	
			No evidence to screen for diabetes after the age of 70; recommendation being reviewed at the time of this publication	Screen people 45 y and older

Abbreviation: CT, computed tomography.

is probably a safer approach. In addition to diet, exercise, and sodium restriction, specific pharmacologic approaches most often depend on co-occurring conditions, such as coronary artery disease, heart failure, and atrial fibrillation (see Chap. 288).

DIABETES

The prevalence of type 2 diabetes in the older adult population is now >25% and is expected to increase due to adverse lifestyle changes and an increased incidence of obesity. In addition, advances in the care for type 1 diabetes have increased the number of individuals living beyond the age of 64 with this chronic illness.

Those between the ages of 65 and 74 have the highest rates of complications associated with diabetes. However, older diabetic patients are at significant risk of hypoglycemia because of potential medication errors, progressive renal insufficiency, and inconsistent oral intake. Diabetic patients age 75 or older have twice the risk of visiting the emergency department due to hypoglycemia. Hypoglycemic episodes are associated with progressive cognitive decline in older adults, especially those with existing cognitive impairment. On the other hand, chronically uncontrolled diabetes is associated with an increased risk of all-cause dementia.

Data from randomized clinical trials suggest that intensive glycemic control does not reduce major macrovascular events in older adults. Thus, the AGS guideline on diabetes in older adults (see "Further Readings") and the Choosing Wisely recommendations (Table 489-1) suggest that, in most older adults, the harms associated with a hemoglobin A_{1c} (HbA_{1c}) target <7.5% are likely to outweigh the benefits. These recommendations are consistent with the American Diabetes Association guidelines from 2023 that recommend an HbA_{1c} target of 7 or 7.5% for older adults with intact cognition and functional capacity and few comorbidities. The goals of treating diabetes in the geriatric population should be tailored to the patient's functional status, coexisting geriatric syndromes, social support, personal goals, perception of risk, and life expectancy. Insulin should be avoided when possible, and in particular, long-term use of sliding-scale insulin should be avoided because of the relatively high incidence of hypoglycemia, the challenges and discomforts of repeated glucose measurements, and the high burden it can place on caregivers. For those who do requires insulin, the use of continuous glucose monitoring may be useful.

For specifics of treatment options, see **Table 489-4 and Chap. 416**. Regardless of the therapeutic goals for HbA_{1c}, older diabetic patients should be regularly examined for neuropathy and retinopathy. Neuropathy can lead to unhealing foot lesions and other podiatric conditions. Retinopathy can lead to vision loss and require ophthalmologic intervention. In addition, lifestyle management is an important component of the plan of care. Diabetic older adults should exercise regularly to the extent possible and should have an adequate protein intake to try to maintain muscle mass.

TABLE 489-4 Recommendations and Considerations for Pharmacologic Therapy of Diabetes in Older Adults

MEDICATION	RECOMMENDATIONS AND CONSIDERATIONS
Metformin	• Metformin is the first-line agent for older adults with type 2 diabetes • Low risk of hypoglycemia • Recent studies suggest it may be used safely in patients with estimated glomerular filtration rate ≥30 mL/min/1.73 m^2 • Use with caution in patients with advanced renal insufficiency or significant heart failure • Can cause gastrointestinal symptoms with lower appetite
Sodium-glucose cotransporter 2 (SGLT-2) inhibitors	• Offer an oral route, which may be convenient for older adults • Low risk of hypoglycemia and hypotension • Strong evidence for renal protection and improved outcomes among patients with congestive heart failure • Caution when combined with other therapies such as diuretics
Thiazolidinediones	• If used at all, should be used very cautiously in those with, or at risk for, congestive heart failure and those at risk for falls or fractures
Sulfonylureas	• Associated with hypoglycemia and should be used with caution • Shorter-duration sulfonylureas such as glipizide are preferred • Leads to severe and persistent hypoglycemia in the settings of acute kidney injury • Glyburide is longer duration and contraindicated in older adults
Dipeptidyl peptidase 4 (DPP-4) inhibitors	• Few side effects and minimal hypoglycemia, but costs may be a barrier • No evidence of increase in major adverse cardiovascular events
Glucagon-like peptide 1 (GLP-1) agonist	• GLP-1 receptor agonists are injectable, which requires visual, motor, and cognitive skills • Associated with nausea, vomiting, diarrhea, and weight loss, which may not be desirable in some older patients, particularly those with cachexia
Insulin therapy	• Use oral medications whenever possible • Administration requires that patients or their caregivers have good visual and motor skills and cognitive ability • Insulin doses should be titrated to meet individualized glycemic targets and to avoid hypoglycemia • Once-daily basal insulin injection therapy is associated with minimal side effects and may be a reasonable option in many older patients • Multiple daily injections of insulin may be too complex for the older patient with advanced diabetes complications, life-limiting comorbid illnesses, or limited functional status • Avoid sliding scale in postacute and long-term care facilities except during periods of instability associated with acute illness; risk of hypoglycemia is high; glucose checks, insulin administration, and documentation require excessive staff time, and most patients do not like frequent fingersticks

Source: Based on recommendations from the American Diabetes Association 2020 and JS Custódio et al: Drugs Aging 37:399, 2020.

HYPERLIPIDEMIA

While good evidence exists regarding the benefits of statins for secondary prevention among those ≥75 years old, the use of these medications for primary prevention has been controversial. The use of statins in those older than 75 or 80 for primary prevention of cardiovascular events and mortality is the subject of ongoing debate in the geriatric literature. Secondary analyses of large clinical trials have demonstrated primary prevention and disability-free survival benefits with statin use among selected subgroups of older adults. Two other factors make the use of statins in older adults controversial. First, the major benefits have been demonstrated over long-term use; thus, life expectancy is a limiting factor for meaningful change in outcomes. Second, although many older adults on statins complain of muscle pain, the risk of myositis and rhabdomyolysis is increased mostly with the coexistence of other risk factors.

On the other hand, statins are safe to use in older adults, especially at moderate to low doses. Adverse effects of statins on cognitive function appear to be uncommon. Relatively healthy adults older than 75 with a life expectancy of >10 years may benefit from statin use, and the approach to hyperlipidemia should be person-centered in this population, as discussed for both hypertension and diabetes. In addition, current scientific evidence supports the use of moderate- to high-dose statins in older adults after an acute cardiovascular event (myocardial infarction, stroke) to prevent a recurrence. Even among cognitively and functionally impaired adults, another event could cause further impairment that interferes with function and quality of life. This is not true, however, for individuals at the end of life. A substantial proportion of older people (close to a third) are maintained on statins at the end of life. In a pragmatic clinical trial including older adults

with a life expectancy of up to 1 year taking statin discontinuation was associated with improved quality of life and reduction of polypharmacy burden without increased risk of cardiovascular complications. Thus, discontinuation of statins in this situation is strongly recommended.

OSTEOARTHRITIS AND CHRONIC PAIN

By far, the most common cause of chronic pain in older people is osteoarthritis (OA). The approach to the management of symptomatic OA in older people differs from the approach in younger patients **(Chaps. 382 and 383)** because of the substantial toxicity of nonsteroidal anti-inflammatory drugs (NSAIDs) in this population. *Nonpharmacologic interventions, briefly discussed below, should be the first line of treatment*. While some patients older than 65 can tolerate NSAID use with concomitant protection from gastrointestinal (GI) bleeding with a proton pump inhibitor (PPI), this regimen exposes patients to two drugs with numerous potential adverse drug effects. NSAIDs are well known to be associated not only with GI bleeding but also with worsening renal function as well as fluid retention, hypertension, and exacerbation congestive heart failure. In addition, a substantial number of older patients are on anticoagulants or platelet aggregation inhibitors, which could further increase the risk of bleeding from NSAIDs. PPIs are associated with a higher incidence of pneumonia, osteoporosis, and *Clostridioides difficile*–associated diarrhea, and they may be associated with a higher risk of dementia.

Thus, in older patients with multimorbidity who have painful OA, the risks of NSAIDs most often outweigh the benefits, and older patients should be discouraged from taking nonprescription NSAIDs without consulting their primary care clinician. Topical NSAIDs are better tolerated, and 4 or 5% lidocaine patches and other nonprescription analgesic creams (e.g., 1% diclofenac) may also be effective. Acetaminophen in doses of 1 g 2–3 times daily should be the basis of pharmacologic treatment. Failure to respond could be followed up with careful trials of tramadol or a narcotic agent (started in a short-acting preparation) with appropriate attention to avoiding narcotic-induced constipation. Tramadol has less addiction potential and side effects than more potent narcotics and can be very effective for some older people. However, it is contraindicated in patients with seizure disorders and must be used cautiously with selective serotonin reuptake inhibitor and serotonin-norepinephrine reuptake inhibitor drugs to prevent serotonergic toxicity. Another pharmacologic option that can be very useful in older people with primary or secondary muscular pain due to an arthritic condition, especially those with dysphoria or depression (common in people with chronic pain), is a trial of duloxetine. Duloxetine is approved for the treatment of depression as well as pain, but it must be started in low doses (e.g., 20 mg) and titrated up to a maximum of 60 mg, if needed, over several weeks.

Although the prescription of narcotics is getting increasingly cumbersome because of high rates of abuse, this should not deter the prescription of these agents to relieve pain and disability in older patients, especially postsurgical pain. If opioids are prescribed, a bowel regimen consisting of adequate fluid, a bulk-forming agent, and use a stimulant such as senna or polyethylene glycol is highly recommended for people who have not had a movement to avoid severe constipation. Note that although docusate is often prescribed, its efficacy is highly variable. In addition, as in any other population, there should be close monitoring of issues such as diversion and abuse or addiction.

Many older patients respond well to various nonpharmacologic interventions, including stretching, strengthening, timely and appropriate use of heat and ice, massage (including the use of "massage guns"), swimming and whirlpool therapy, bracing, acupuncture, and therapeutic electrical stimulation These interventions are best carried out under the supervision of physical therapists or other professionals with appropriate expertise to avoid injury. Although now frequently offered by telehealth, they will not be optimally effective unless a trained therapist teaches the technique and assesses its proper use periodically in person. Surgical interventions, including replacement of major joints, have improved over the past several years, and even older patients with multimorbidity may benefit in terms of function and quality of life. Total knee replacement, for example, is effective in generally healthy older patients and should be considered in selected higher-risk patients. "Pre-habilitation," with targeted strengthening and endurance exercises, and willingness to go through several weeks of postoperative physical therapy should be prerequisites for referring older patients for joint replacement.

CANCER

More than half of new cases of cancer and mortality associated with it occur after the age of 65. Data regarding older adults with multiple comorbid conditions and their response to cancer treatment are limited. While only ~10% of clinical trials have had age-stratification analyses, the available evidence suggests that age alone is not a predictor of harm. Nonetheless, making treatment decisions is challenging due to both shorter life expectancy in older adults and the cumulative effect of multiple comorbidities. Thus, a person-centered approach that integrates the principles of geriatric and palliative care is essential.

Older adults generally experience decreases in functional status after receiving chemotherapy. Most of this negative effect appears to be related to comorbidity and baseline functional status, rather than due to age alone. For this reason, specialists in geriatric oncology have proposed using comprehensive geriatric assessment, covering many of the issues addressed in Table 489-3, as a strategy to better predict which older adults will tolerate and benefit most from cancer treatment. Tools such as the Chemotherapy Risk Assessment Scale for High-Age Patients have been validated to estimate the risk of chemotoxicity. Lack of social support has been associated with poor outcomes after radiation and chemotherapy, especially in older women. Other important issues in cancer treatment planning include the availability of transportation for treatments, economic and insurance status, the patient's ability to follow treatment plans, and family and social support available during therapy, when adverse effects and functional decline may occur.

Newer treatment options such as immunotherapy have shown promising results in the general population with lung and bladder cancer as well as lymphomas. Unfortunately, older adults are underrepresented in clinical trials using these agents, and there is a lack of robust evidence regarding tolerability and efficacy.

ANEMIA

Low hemoglobin or hematocrit is common in older adults but is not a normal age-related change. All anemic older adults should have a basic evaluation including a complete blood count, examination of a peripheral red blood cell smear, reticulocyte count, and measurement of iron, iron-binding capacity, and transferrin saturation. A serum ferritin level can help distinguish iron deficiency anemia from the anemia of chronic disease, two common forms of anemia in older adults. Iron deficiency is the most common cause of anemia in the older population, with other nutritional anemias (e.g., B_{12} deficiency) and myelodysplasia each accounting for a smaller percentage. Anemia of chronic disease is common in older people who have several chronic illnesses. The etiology of the anemia in older adults cannot be specifically explained in more than a third of the cases, and this unexplained anemia is generally normocytic, mild in degree, with a low reticulocyte count, and associated with normal or low erythropoietin levels in the face of inadequate production of new red cells. Anemia is frequently asymptomatic, but severe cases could present with symptoms such as generalized weakness and functional decline, shortness of breath, chest pain, or syncope. The unexplained anemia of aging appears to be responsive to erythropoietin, but it is unclear whether correction of the anemia improves outcomes. Thresholds for transfusion of packed red cells among older adults should be based on symptoms and associated conditions. For example, for geriatric patients suffering acute blood loss anemia after an orthopedic procedure, transfusion is indicated when hemoglobin is <8 mg/dL (instead of 7 mg/dL). Similarly, older patients with active cardiovascular disease, such as angina or heart failure, may need to be transfused at levels <8 or 9 mg/dL. For details of the general evaluation and management of anemia, please refer to **Chap. 66**.

HEART FAILURE

Although the incidence of heart failure (HF) has decreased over the years, the prevalence has seen an uptrend. This paradoxical

epidemiologic trend is explained by longer survival. As many as 20% of individuals ≥80 years old carry a diagnosis of HF, with two-thirds of those having preserved ejection fraction. The management of HF is discussed in detail in **Chaps. 264 and 265**. The treatment of HF in frail older adults depends on cardiac ejection fraction (preserved vs reduced) and is limited by tolerability of low-sodium diets, fluid restriction, and adverse effects of medication. Medications such as diuretics, beta-blockers, angiotensin-converting enzyme inhibitors, and angiotensin receptor blockers may be poorly tolerated due to hypotension, electrolyte imbalances, volume depletion, and orthostatic hypotension. Newer therapies such as angiotensin receptor–neprilysin inhibitors, mineralocorticoid receptor antagonists, and sodium-glucose cotransporter 2 inhibitors (SGLT2i) have been shown to improve outcomes in older adults with specific types of HF. Thus, echocardiography to check ejection fraction is essential in the management of older people with HF. In contrast with other chronic disease processes, older adults have been well represented in clinical trials with these newer agents, allowing multiple subanalyses that have proven efficacy.

GERIATRIC SYNDROMES AND CONDITIONS

In this section, selected geriatric syndromes and conditions likely to be encountered by internists in hospitals, clinics, and postacute and long-term care (LTC) settings are discussed. For a more thorough discussion of these and other syndromes and conditions, the reader is referred to textbooks that focus specifically on geriatrics and gerontology (see "Further Reading").

FALLS

Epidemiology and Impact Among all geriatric syndromes, falls are probably the most common that internists will encounter. Falls are responsible for potentially devastating consequences for function and quality of life, as well as mortality. About one in three older community-dwelling and one in two older LTC facility residents fall annually, with many more at risk for falls. The consequences of falls include fear of falling with adverse effects on quality of life, painful injuries including hip and wrist fractures, subdural hematomas, and death. Falls are associated with loss of function and death within the year after a fall. With the increasing prescription of anticoagulants, falling presents a frequent conundrum in balancing the risks and benefits of anticoagulation. For these reasons, internists should regularly screen older people for falling using questions such as, "Have you fallen in the past year?" "Are you afraid of falling?" "Do you have trouble climbing stairs or rising from chairs?" (Table 489-2).

Evaluation The risks and causes of falls are multifactorial. Most older people at risk for a fall or who have suffered a fall have more than one potential underlying risk factor or cause. Many falls are labeled as "mechanical" and attributed to simply tripping or slipping. It is essential to recognize, however, that older people who trip or slip may have a variety of underlying reversible conditions that could have contributed to the event. Thus, a thorough evaluation of all falls is warranted. In addition to evaluating the patient who has fallen for injury, it is critical to determine, to the extent possible, whether the patient had a syncopal episode or a seizure, which dictates a very different approach to evaluation and management. As many as half of "unexplained falls" in older people with dementia (e.g., found on the floor) may be due to near-syncope or syncope related to postural hypotension.

Figure 489-6 illustrates an overview of the approach to an older person who reports a history of one or more falls in the past 6 months, and **Table 489-5** provides more detail on the immediate evaluation of an older person who has fallen. **Chap. 28 provides more detail on the evaluation of gait and balance disorders.**

Management **Table 489-6** illustrates approaches to the management of falls. Immediately after a fall, injuries and underlying acute illnesses should be identified and treated. It is common practice for older patients who come to an emergency department with a history of a fall to have a brain imaging study. While this is understandable from a potential liability standpoint, it is also reasonable to avoid such studies if no history or signs of head trauma, neurologic symptoms or signs, or anticoagulation is noted and to monitor the patient carefully over the next 48–72 h for the development of specific indications for a brain imaging study.

Because the causes of and risk factors for falls are often multifactorial, management commonly requires multiple interventions in the same patient. Among the most common and effective interventions are physical therapy for strengthening and balance; Tai Chi has also been shown to be effective in multiple trials. Although many older people who fall are vitamin D deficient, the role of vitamin D replacement in preventing falls or preventing injuries from falls when combined with interventions such as strength and balance training remains unclear. The risk/benefit ratio probably favors vitamin D replacement with at least 800 IU per day, but high-dose vitamin D (60,000 IU in one oral dose monthly) has been associated with an increase in the risk of falls. Patients who suffer a fracture after a fall should be investigated and treated for osteoporosis. Patients at high risk for recurrent falls and injuries should be encouraged to use a fall alert system; selected patients may benefit from hip protectors.

All older patients at fall risk should have an environmental evaluation for potential hazards and home improvements and a fall-alert system that can help prevent lying on the floor for many hours with the risk of rhabdomyolysis.

In older people at high fall risk and with atrial fibrillation or flutter, the risk of life-threatening bleeding associated with anticoagulants is substantially lower than the risk of stroke. Because of the devastating effects a stroke can have on function and quality of life, anticoagulation is generally preferred. Patients with this combination should also strongly consider insertion of a left atrial appendage closure device.

POLYPHARMACY

Epidemiology and Impact Polypharmacy is defined as the prescription of multiple medications using various thresholds (generally ranging from five up to nine simultaneous drugs) and has been identified as a major challenge in the geriatric population for decades. About 40% of the U.S. population age 65 and older take five to nine medications, and close to 20% take 10 or more. Polypharmacy is an increasingly complex challenge because of the rising prevalence of multimorbidity, a plethora of clinical practice guidelines, the proliferation of medications that can effectively treat common geriatric conditions, and rising patient and family demand for medications due in part to television advertising and information available on the Internet. For example, based on several condition-specific clinical practice guidelines (which do not account for multimorbidity), an 80-year-old person with multimorbidity including diabetes, chronic obstructive lung disease, hypertension, osteoporosis, and degenerative joint disease might be prescribed an extremely complicated nonpharmacologic regimen and over a dozen medications with the potential for multiple drug-drug and drug-disease interactions and high out-of-pocket costs.

Polypharmacy increases the risks associated with age-related changes in the pharmacology of many drugs and the risk of adverse drug events. Such events cause >100,000 hospitalizations per year; the main culprits are warfarin and other antiplatelet agents as well as insulin and other hypoglycemic agents. Other categories of drugs are also involved, including cardiovascular drugs that can cause electrolyte and volume disturbances and hypotension, falls, and syncope; central nervous system drugs associated with altered mental status and falls; and antimicrobials, which cause allergic reactions, diarrhea, and other adverse drug effects.

Evaluation Because many older patients see multiple specialists, internists should perform careful medication reconciliation at each office or clinic visit and especially at the time of care transitions, including acute hospitalization, hospital discharge, admission to a long-term care facility or home health program, and discharge from a postacute care facility to home. At each transition, all medications should be considered in terms of unclear diagnosis or indication, uncertain dose or route of administration, stop date, hold parameters, lab tests needed for monitoring, dosages different than the last care setting, medication

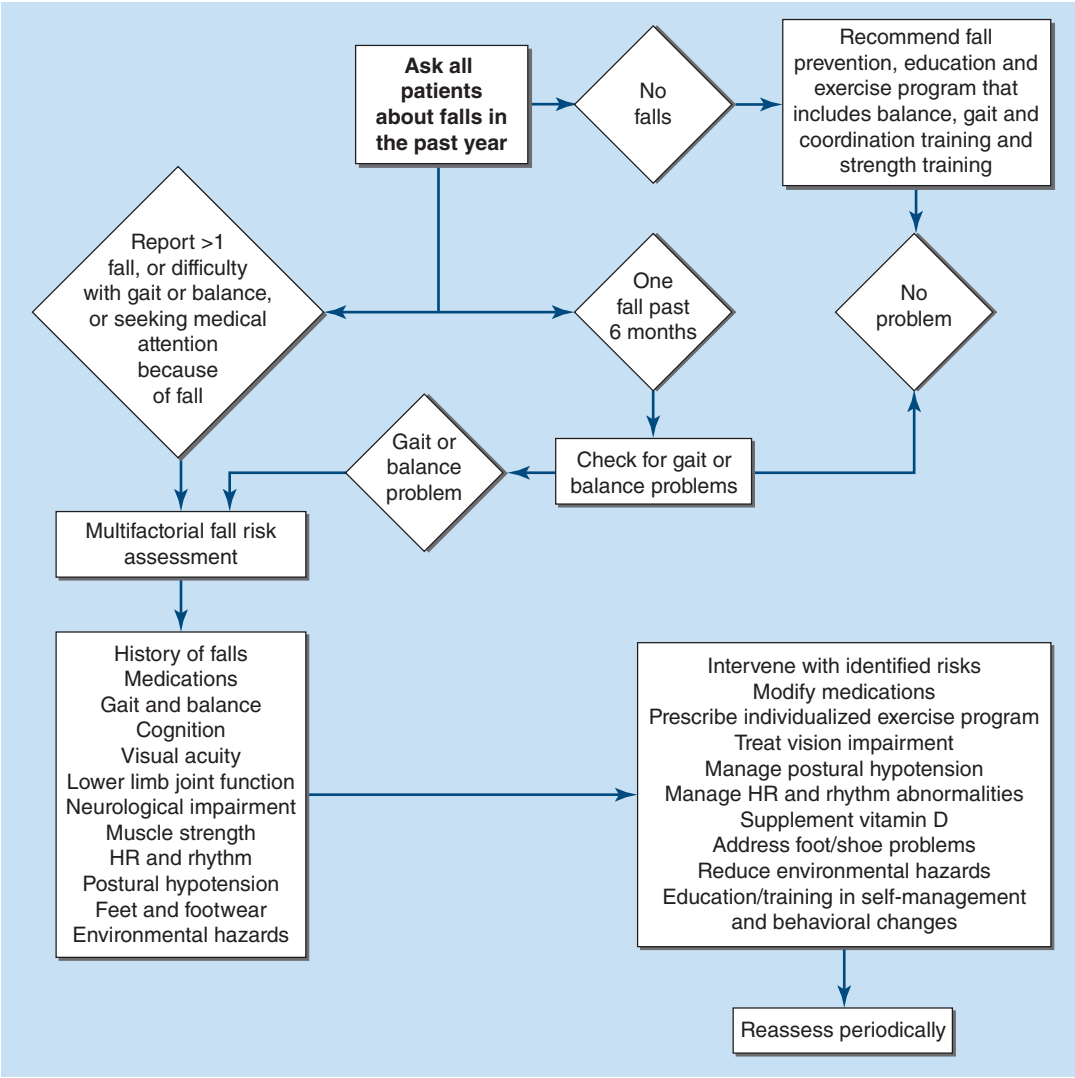

FIGURE 489-6 Algorithm depicting assessment and management of falls in older patients. HR, heart rate. *(Reproduced with permission of American Geriatrics Society. American Geriatrics Society and British Geriatrics Society: Clinical Practice Guideline for the Prevention of Falls in Older Persons. New York, American Geriatrics Society, 2010.)*

duplication, medications that should be restarted, and the potential for drug-drug and drug-disease interactions. Possible adverse drug effects, effectiveness of drug therapy, and adherence should be evaluated.

Management Internists should serve as the "quarterback" for all prescribing to help ensure adherence and minimize the potential for adverse drug effects. Table 489-7 lists several general recommendations for geriatric prescribing that should help make drug therapy more effective and safer in older patients, especially those with multimorbidity, and Fig. 489-7 illustrates a stepwise approach to optimizing medication management. Clinical pharmacists can be extremely helpful in achieving these recommendations and goals. **Chap. 71 also provides information on the general principles of clinical pharmacology.**

While undertreatment of certain conditions may occur in older people (e.g., osteoporosis, depression, and overactive bladder), more attention is now being paid to "deprescribing." Deprescribing must be done carefully, especially at the time of care transitions, when indications for specific drugs and patient preferences may not be clear. The AGS's updated Beers criteria include a comprehensive list of drugs that may be inappropriate in older people and the rationale for this rating. The Screening Tool of Older Persons' Prescriptions (STOPP) criteria are also useful in identifying drugs that should be reconsidered in older people.

Several commonly prescribed drugs should be considered for deprescribing efforts, including (1) diuretics and hypotensive agents when patients have systolic hypotension or postural hypotension that can precipitate near-syncope and falls; (2) overreliance on antianxiety and hypnotic medications, especially benzodiazepines; (3) psychotropic and other drugs with anticholinergic activity that can cause dry mouth and constipation and increase the long-term risk of cognitive impairment; (4) PPIs with unclear indications because of numerous reported potential adverse drug effects, including increased risk of pneumonia, osteoporosis, and dementia; (5) cholinesterase inhibitors and memantine in patients with severe cognitive impairment who have been on them for years; (6) hypoglycemic agents in patients with multimorbidity who should not have tightly controlled blood sugar with increased risk of hypoglycemia; and (7) statins and prophylactic aspirin in patients with severe chronic illness who are near the end of life.

Careful deprescribing is a critical aspect of person-centered care in the geriatric population. Several general principles, including those in Table 489-7 and Figure 489-7, may assist with deprescribing efforts. The AGS's comprehensive Deprescribing Toolkit and the *deprescribing.org* website can be very helpful these efforts.

COGNITIVE IMPAIRMENT: DELIRIUM AND DEMENTIA

The reader is referred to other chapters in this text **(Chaps. 442–445)** on cognitive impairment. Because these conditions are so prevalent in the older population, selected aspects highly relevant to geriatrics are briefly discussed here.

Epidemiology and Impact Delirium occurs in up to 40% of hospitalized older patients and is associated with increased morbidity, length of hospital stays, need for institutional care, health care utilization, and mortality in this population. An even higher incidence of delirium can be seen in older patients with underlying cognitive

TABLE 489-5 Evaluating the Older Person Who Falls—Immediate Postfall Evaluation

History

- Circumstances surrounding the fall
  - Relationship to changes in posture, turning of head, after a meal or medication intake, rushing to the toilet, nocturia, straining to urinate or defecate
  - Accidental trip or slip (note that many correctable factors can contribute to a reported "mechanical" fall—see text)
  - Hazards in the living environment (loose rugs, cords, unsafe steps, slippery floors, etc.)
- Premonitory or associated symptoms
  - Dizziness (lightheadedness vs vertigo); cardiovascular (postural lightheadedness, palpitations, chest pain, shortness of breath); focal neurologic symptoms suggestive of stroke or transient ischemic attack (weakness, sensory disturbance, dysarthria, ataxia, aphasia); symptoms of a seizure (witnessed clinic movements, incontinence of urine or stool, tongue biting)
  - Symptoms over the previous few days that may have led to volume depletion (poor food/fluid intake, nausea/vomiting, diarrhea, urinary frequency/polyuria)
- Exclude loss of consciousness or seizure (may be difficult without a witness)
- Medications—chronic and within the few hours before the fall
  - Diuretics and other antihypertensive drugs
  - Nitrates
  - Drugs that cause bradycardia—beta blockers; cholinesterase inhibitors
  - Psychotropics—antipsychotics, hypnotics, sedatives, antidepressants
  - Antiparkinsonian drugs
  - Hypoglycemic drugs
- Excessive alcohol intake

Physical Examination

- Exclude physical injury
  - Head trauma, hip range of motion, pubic bone tenderness, wrist pain, other signs of trauma
  - Bruising in patients on anticoagulants/platelet inhibitors
- Exclude acute illness
  - Vital signs
  - Postural vital signs (if feasible/safe)
  - Fingerstick glucose in diabetics
  - Poor skin turgor suggesting volume depletion (over chest; other areas unreliable)
  - Signs of an acute respiratory, cardiovascular, or abdominal condition
  - Focal neurologic signs suggestive of stroke
- Signs of conditions that increase risk for falls
  - Poor visual acuity; use of bifocals
  - Limited range of motion of neck (to detect possible cervical arthritis/disk disease)
  - Cardiovascular—arrhythmias, carotid bruits, aortic stenosis, mitral insufficiency, heart failure
  - Degenerative joint disease in lower extremities causing pain, limited range of motion, and/or deformity
  - Podiatric conditions (calluses; bunions; ulcerations; poorly fitted, inappropriate, or unsafe shoes)
  - Neurologic signs—lower extremity muscle weakness; peripheral neuropathy; tremor, rigidity, and/or bradykinesia suggestive of undiagnosed Parkinson's disease; cerebellar signs (abnormal heel to shin or heel tapping); abnormal reflexes that could reflect upper motor neuron disorder such as spinal cord compression or subdural hematoma; cognitive deficits that can result in poor judgement
  - Observation of gait and balance—simple Get Up and Go test (see text) with observation for short steps, poor foot elevation, wide-based gait, multiple steps to turn 180 degrees; other abnormalities that might suggest normal pressure hydrocephalus (especially in combination with symptoms of incontinence and/or cognitive impairment)

Laboratory and/or Imaging Studies

- Should be guided by history and physical examination—common examples include:
  - Complete blood count, basic metabolic panel to exclude/verify acute illness
  - Urinalysis (only when additional symptoms of urinary tract infection present)
  - Electrocardiogram (in patients suspected of acute coronary syndrome or with significant known cardiovascular disease)
  - X-rays to exclude fractures
  - Brain imaging if signs present to exclude subdural hematoma, stroke
  - Cardiac monitoring in patients with history suggestive of syncope or near-syncope
  - Electroencephalography in patients with history suggestive of seizure

Source: Adapted from RL Kane et al (eds): *Essentials of Clinical Geriatrics*, 8th ed. New York, McGraw-Hill, 2018.

impairment after surgery or while in the intensive care unit. While most episodes of delirium clear within a few days if the underlying cause(s) is identified and treated, delirium may persist for weeks or, in a few cases, for months after an acute hospitalization.

Normal aging does not cause impairment of cognitive function of sufficient severity to render an individual dysfunctional, which is the hallmark of dementia syndrome. Slowed thinking and reaction time, mild recent memory loss, and impaired executive function can occur with increasing age and may or may not progress to dementia. **Figure 489-8** illustrates the prevalence of memory impairment with increasing age. Just over 20% of people over age 70 in the United States have cognitive impairment without dementia, generally referred to as MCI. Up to 15–20% of those diagnosed with MCI will progress to dementia over a year; thus, most people with MCI will progress to dementia within 5 years. Therapeutic implications of MCI are subjects of intensive research. No nonpharmacologic or pharmacologic intervention has been shown to prevent the progression of dementia.

The definitions of Alzheimer's disease and related dementias have been updated by the American Psychiatric Association. The prevalence of dementia increases with age; by age 85, between 30 and 40% of

TABLE 489-6 Examples of Management for Underlying Causes of Falls in Older Patients

CAUSES	EXAMPLES OF TREATMENT
Cardiovascular	
Arrhythmias	Antiarrhythmic medication, ablation, pacemaker (depending on nature of arrhythmia)
Aortic stenosis with syncope or near syncope	Valve surgery (transcatheter procedure if appropriate)
Postural hypotension	Reduce or eliminate hypotensive drugs Hydration, support stockings Medication (Proamatine [midodrine], fludrocortisone, droxidopa) Adaptive behaviors (e.g., pausing and getting up slowly)
Hypertension	Manage carefully to avoid hypotension and near syncope; control may be important in patients with periventricular white matter changes in preventing further gait disturbance
Neurologic	
Autonomic dysfunction with postural hypotension	As above
Cervical spondylosis (with spinal cord compression)	Neck brace; physical therapy; consider surgery
Parkinson's disease	Antiparkinsonian drugs
Visual impairment	Ophthalmologic/optometric evaluation and specific treatment
Seizure disorder	Anticonvulsants
Normal-pressure hydrocephalus	Surgery (ventricular-peritoneal shunt)
Dementia	Supervised activities Hazard-free environment
Benign positional vertigo	Habituation exercises Anti-vertiginous medication
Others	
Foot disorders	Podiatric evaluation and treatment
Gait and balance disorders	Properly fitted shoes Physical therapy Exercise with balance training (including Tai Chi where available)
Muscle weakness, deconditioning	Lower extremity strength training
Drug adverse effects (e.g., sedatives, alcohol, other psychotropic drugs, antihypertensive)	Elimination of drug(s) when feasible
Vitamin D deficiency	Vitamin D supplementation
Recurrent falls	Fall alert system for those who live alone; hip protectors in selected patients

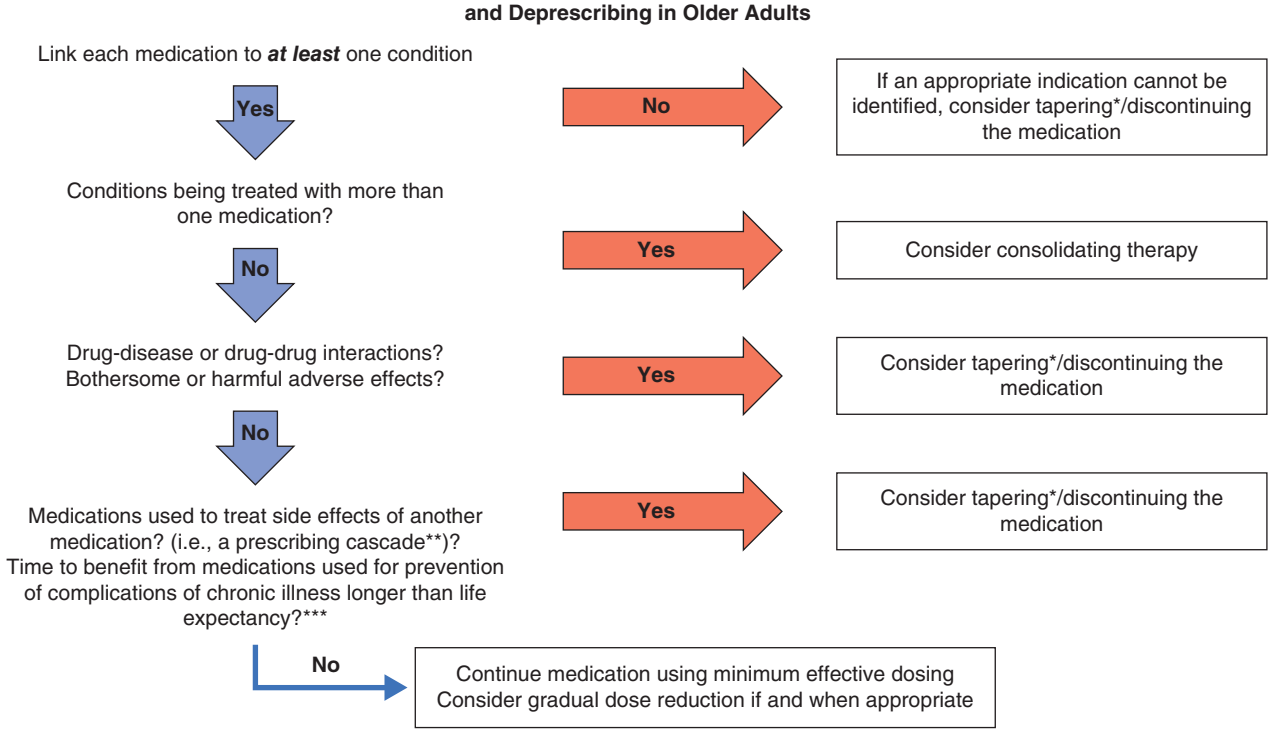
TABLE 489-7 General Recommendations for Geriatric Prescribing

1. Evaluate geriatric patients thoroughly to identify all conditions that could (a) benefit from drug treatment; (b) be adversely affected by drug treatment; and (c) influence the efficacy of drug treatment.
2. Manage medical conditions without drugs as often as possible.
3. Know the pharmacology of the drug(s) being prescribed.
4. Consider how the clinical status (e.g., renal function, hydration) of each patient could influence the pharmacology of the drug(s).
5. Avoid potentially serious adverse drug-drug interactions.
6. For drugs or their active metabolites eliminated predominantly by the kidney, use a formula to approximate age-related changes in renal function and adjust dosages accordingly; the Cockcroft-Gault formula (below) is probably safer as it tends to underestimate creatinine clearance.

$$\text{Creatinine clearance} = \frac{(140 - \text{age}) \times \text{body weight (kg)}}{72 \times \text{serum creatinine level}} (\times 0.85 \text{ for women})$$



7. If there is a question about drug dosage, start with smaller doses and increase gradually until the drug is effective or intolerable side effects are observed.
8. Drug blood concentrations can be helpful in monitoring several potentially toxic drugs used in the geriatric population.
9. Help to ensure adherence by:
   a. Making drug regimens and instructions as simple as possible
   b. Using the same dosage schedule for all drugs whenever feasible (e.g., once or twice per day)
   c. Timing the doses in conjunction with a daily routine
   d. Paying attention to impaired cognitive function, diminished hearing, and poor vision when instructing patients and labeling prescriptions
   e. Instructing relatives and caregivers on the drug regimen
   f. Enlisting other health professionals (e.g., home health aides, pharmacists) to help ensure compliance
   g. Making sure the older patient can get to a pharmacist (or vice versa), can afford the prescriptions, and can open the container
   h. Using aids (e.g., special pillboxes and drug calendars) whenever appropriate
   i. Performing careful medication adjudication and patient/family education at the time of every hospital discharge
   j. Keeping updated medication records and review them at each visit
   k. Reviewing knowledge of and adherence with drug regimens regularly
10. Monitor older patients frequently for adherence, drug effectiveness, and adverse effects, and adjust drug therapy accordingly.

patients have a dementia syndrome. Alzheimer's disease and vascular dementia, which often occur together based on pathologic studies, account for most dementias in older people. Dementia with Lewy bodies accounts for up to 25% of dementia and is characterized by parkinsonian features early in the disease (as opposed to dementia in Parkinson's disease, which generally occurs years after the onset of Parkinson's), personality changes, alterations in alertness and attention, and visual hallucinations that can cause paranoia. Although most dementia syndromes are slowly progressive over several years, dementia is a terminal illness among patients who do not succumb to other comorbidities and results in a devastating loss of cognition and function in the later stages.

Evaluation Regardless of setting, the new onset of delirium should be treated as a medical emergency because it can be the manifestation of an underlying critical illness. The first step in the evaluation is to identify predisposing and precipitating factors such as hearing or visual impairment, symptoms of depression, laboratory abnormalities, uncontrolled pain, infections, exacerbation of chronic illnesses, and history of alcohol or other substances use. The most validated evaluation for delirium is the Confusion Assessment Method, which requires an acute onset and fluctuating course *and* inattention *and* disorganized thinking *or* altered level of consciousness. Because the causes and risk factors for delirium are multifactorial, evaluation requires a careful history, physical examination, and selected laboratory studies based on the findings.

The benefits of screening older community-dwelling adults for cognitive impairment are controversial, but many interventions may benefit patients and families early in the course of the disease (see below). Older patients in outpatient settings with complaints (or family reports) of early signs of cognitive impairment benefit from neuropsychological testing, which can help differentiate between MCI and dementia and identify concomitant factors such as depression and anxiety. The Mini-Cog is a sensitive screening tool for cognitive impairment and consists of a three-item recall test and clock drawing. Further evaluation of dementia includes a comprehensive history and physical examination, functional status assessment (since the diagnosis depends on impaired function), a brain imaging study, and selected laboratory tests, including a complete blood count, comprehensive metabolic panel, thyroid

*Many types of drugs should be tapered to avoid withdrawal with sudden discontinuation, e.g., antidepressants, sedatives, hypnotics, analgesics.

**A common example of a prescribing cascade is treating edema associated with amlodipine with a diuretic.

***Common examples are continuing statins and inappropriate goals resulting in overtreatment of hypertension and diabetes causing hypotension and hypoglycemia in people with very limited life expectancy.

FIGURE 489-7 General approach to optimizing medication management and deprescribing in older adults. This algorithm illustrates a stepwise approach to optimizing medication management.

function tests, vitamin B_{12} level, and, if suspected, tests for syphilis and human immunodeficiency virus antibodies.

Management Table 489-8 lists pharmacologic and nonpharmacologic management strategies for various underlying risk factors and causes of delirium. Every attempt should be made to avoid or discontinue any medication that may be worsening cognitive function in a delirious geriatric patient. This may not be possible, and in some patients, psychotropic drugs may be needed to treat delirium if the patient is a danger to themselves or others and/or if delusions and hallucinations are present. Low-dose risperidone (0.25–0.5 mg) or quetiapine (12.5–50 mg at night to take advantage of sedation) may be effective; more sedating antipsychotics and benzodiazepines should be avoided unless the goal is to put the patient to sleep for a short time. If a benzodiazepine is used, it should be short-acting (e.g., lorazepam) and in a low dose; alprazolam should be avoided as many patients become dependent on it long-term. Overall, multifactorial-proactive interventions and geriatric consultation have been associated with decreased incidence and duration of delirium in the hospital setting.

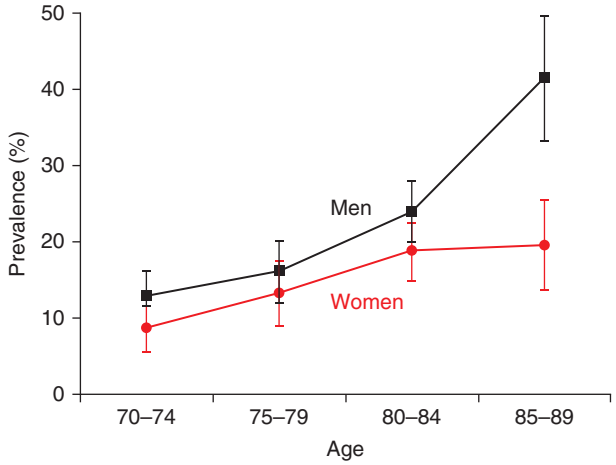

FIGURE 489-8 Prevalence of mild cognitive impairment by age and sex in Olmsted County, Minnesota. *(Reproduced with permission from RC Petersen et al: Prevalence of mild cognitive impairment is higher in men. The Mayo Clinic Study of Aging. Neurology 75:889, 2010.)*

Many nonpharmacologic interventions for older people with dementia, their families, and other caregivers may be beneficial (Table 489-9). Four basic approaches to the pharmacologic treatment of dementia are employed: (1) avoidance of drugs that can worsen cognitive function, mainly those with strong anticholinergic activity; (2) use of agents that enhance cognition and function; (3) drug treatment of coexisting depression, which is common throughout dementia; and (4) pharmacologic treatment of complications such as paranoia, delusions, psychosis, and behavioral symptoms such as agitation (verbal and physical). The use of antipsychotics to treat the neuropsychiatric symptoms of dementia is controversial. Most experts and guidelines recommend avoiding these drugs and using nonpharmacologic strategies unless patients are a danger to themselves and others or if nonpharmacologic interventions have failed. Patients with new or worsening behavioral symptoms associated with dementia should have a medical evaluation to identify potentially treatable precipitating conditions. Pain may be especially hard to detect, and if suspected, a therapeutic trial of acetaminophen should be considered.

The effectiveness of cholinesterase inhibitors and memantine in improving function and quality of life in patients with various types

TABLE 489-8 Evaluation and Management of Delirium

CONTRIBUTING FACTORS	APPROACHES TO EVALUATION AND MANAGEMENT
Drugs	Consider the etiologic role of newly initiated drugs, increased doses, interactions, over-the-counter drugs, and alcohol; consider especially the role of high-risk drugs: lower the dose, discontinue the drug, or substitute a less psychoactive medication. Consider withdraw from chronic medications. Pay special attention to psychotropic medications.
Electrolyte disturbances	Assess for and treat, especially, dehydration, hyponatremia and hypernatremia, and hypothyroidism
Infection	Urinary tract infections, pneumonia, soft tissue infection
Visual/hearing impairment	Encourage the use of glasses and hearing aids if available
Urinary and fecal disorders	Treat urinary retention and fecal impaction
Pulmonary disorders	Correct hypoxemia
Prevent or Manage Complications	
Urinary incontinence	Scheduled toileting
Immobility and falls	Encourage early mobilization to maintain baseline mobility
Pressure ulcers	Mobility and repositioning, nutrition
Sleep disturbances	Sleep hygiene, avoid sedatives, avoid unnecessary awakenings
Feeding disorders	Feeding assistance if necessary, aspiration precautions, liberalize diet if possible
Maintain Patient Comfort and Safety	
Behavioral interventions	Staff education regarding de-escalation techniques for treatment of hyperactive delirium; facilitate family visitation if possible
Pharmacologic interventions	*Only* if patients become a threat to themselves or others and other interventions have failed
Restore Function	
Hospital environment	Adequate lighting, reduce noise
Cognitive reconditioning	Reorient patient frequently
Physical reconditioning	Physical and occupational therapy
Discharge planning	Assess new needs based on predischarge functional status, evaluate social support, coordinate transitions of care, medication reconciliation

TABLE 489-9 Key Principles in the Management of Dementia

- Optimize the patient's physical and mental function through physical activity and mind plasticity principles and activities
  - Treatment underlying medical and other conditions (e.g., hypertension, Parkinson's disease, depression)
  - Avoid use of drugs with central nervous system side effects (unless required for management of psychological or behavioral disturbances—see **Chap. 31**)
  - Assess the environment and suggest alterations, if necessary
  - Encourage physical and mental activity
  - Avoid situations stressing intellectual capabilities; use memory aids whenever possible
  - Prepare the patient for changes in location
  - Emphasize good nutrition
- Identify and manage behavioral symptoms and complications
  - Driving (consider a formal driving evaluation)
  - Wandering
  - Dangerous driving
  - Behavioral disorders
  - Depression
  - Agitation or aggressiveness
  - Psychosis (delusions, hallucinations)
  - Malnutrition
  - Incontinence
- Provide ongoing care
  - Reassessment of cognitive and physical function
  - Treatment of medical conditions
- Provide information to patient and family
  - Nature of the disease
  - Extent of impairment
  - Prognosis
- Provide social service information to patient and family
  - Local Alzheimer's association
  - Community health care resources (day centers, homemakers, home health aides)
  - Legal and financial counseling
  - Use of advance directives
  - Provide family counseling for:
    - Setting realistic goals and expectations
    - Identification and resolution of family conflicts
    - Handling anger and guilt
    - Decisions on respite or institutional care
    - Legal concerns
    - Ethical concerns
    - Consideration of palliative and hospice care
- Protect the caregiver from effects of caregiver stress

Source: Reproduced with permission from RL Kane et al (eds): *Essentials of Clinical Geriatrics*, 8th ed. New York, McGraw-Hill, 2018.

of dementia is controversial, and the potential benefits of these drugs versus their risks and costs must be weighed carefully to provide optimal person-centered care. The best evidence for the effectiveness of cholinesterase inhibitors is in delaying the progression of Alzheimer's disease and increasing the time before institutional placement is needed. GI side effects can be problematic and include nausea, vomiting, and diarrhea; nightmares can be bothersome as well. In addition to these bothersome side effects, cholinesterase inhibitors can cause bradycardia and have been associated with syncope, injurious falls, and pacemaker placement. Memantine can cause dizziness, headache, confusion, and constipation. In one study, vitamin E was more effective than memantine in preventing functional decline in patients with Alzheimer's disease.

The diagnosis and management Alzheimer's disease and related disorders is changing rapidly because of the recent availability of more accurate biomarker testing and antiamyloid antibody therapy. Plasma p-tau 217 has been shown to be reasonably accurate in identifying amyloid-β and predicting cognitive decline in people with Alzheimer's disease. Antiamyloid antibodies have been approved by the U.S. Food and Drug Administration and can clear amyloid on positron emission tomography scan imaging. However, none have been shown to have major impacts on cognition as of the end of 2024. In addition, they have side effects, including intracerebral hemorrhage, and a high out-of-pocket cost **(see Chap. 442)**.

URINARY INCONTINENCE AND OVERACTIVE BLADDER

Epidemiology and Impact Urinary incontinence is curable or controllable in many older patients, especially those who have adequate mobility and mental functioning. Even when it is not curable, incontinence can be managed in a manner that keeps people comfortable, makes life easier for caregivers, and minimizes the costs of caring for the condition and its complications. Approximately one in three women and 15–20% of men older than age 65 years have some degree of urinary incontinence. Between 5 and 10% of community-dwelling older adults have incontinence more often than weekly and/or use a pad for protection from urinary accidents. The prevalence is as high as 60–80% in many nursing homes, where residents often have both urinary and stool incontinence. Many older people (~40%) suffer from "overactive

bladder" (OAB), which may or may not include symptoms of incontinence. Symptoms of OAB include urinary urgency (with or without incontinence), urinary frequency (voiding every 2 h or more often), and nocturia (awakening at night to void). If nocturia alone is the predominant symptom, the patient should be asked about sleep disorders (see next section). The pathophysiology, evaluation, and management of OAB are essentially the same as for urge urinary incontinence.

Incontinence and OAB are associated with social isolation and depression and can be a precipitating factor in the decision to seek nursing home care when it cannot be managed in a manner that maintains hygiene and safety. In addition to predisposing to skin irritation and pressure ulcers, the most important potential complications of urinary incontinence and OAB are falls and resultant injuries related to rushing to get to a toilet. Older people with gait disorders, especially those with OAB and multiple episodes of nocturia or nocturnal incontinence, are at especially high risk for falls and related injuries. In addition to the bother of the condition to the older person or a caregiver, fall risk is a compelling reason for undertaking a diagnostic evaluation and specific treatment for incontinence and OAB in the geriatric population.

Evaluation Internists should ask older people about symptoms of urinary incontinence because these symptoms are often hidden out of embarrassment or fear. Simple questions can help identify incontinent patients, such as "Do you have trouble with your bladder?" "Do you ever lose urine when you don't want to?" "Do you ever wear padding to protect yourself in case you lose urine?" (Table 489-2). A substantial number of older people will respond "no" to the first two questions but "yes" to the third one.

Several points are worth noting for the practicing internist. The history and physical examination should focus on identifying potentially reversible causes and contributing factors **(Table 489-10)** and identifying the specific lower urinary tract symptoms. A simple, three-item validated questionnaire can assist in distinguishing between the most common types of incontinence **(Fig. 489-9)**. Key aspects of the history and physical exam are outlined in **Table 489-11**. Among older women, the most common symptoms are a mixture of urge and stress incontinence **(Fig. 489-10)**; the urge is usually the more bothersome. Stress incontinence can often be objectively observed during a physical examination with a comfortably full bladder by having the patient cough in the standing position; leakage of urine simultaneously with

TABLE 489-10 Reversible Conditions That Cause or Contribute to Urinary Incontinence and Overactive Bladder Symptoms in Older People

CONDITION	MANAGEMENT
Lower urinary tract conditions	
Urinary tract infection (symptomatic with frequency, urgency, dysuria, etc.)	Antimicrobial therapy
Atrophic vaginitis/urethritis	Topical estrogen (not a primary treatment for incontinence but may help prevent recurrent infections and ameliorate symptoms of overactive bladder; oral estrogens can cause or worsen incontinence)
Stool impaction with irritation of bladder/urethral innervation and/or partial bladder outlet obstruction	Disimpaction; appropriate use of stool softeners, bulk-forming agents, and laxatives if necessary; implement bowel regimen
Increased urine production	
Metabolic (hyperglycemia, hypercalcemia)	Better control of diabetes mellitus
	Therapy for hypercalcemia depends on underlying cause
Excess caffeine or fluid intake	Reduction in intake of caffeinated beverages; reduction in fluid intake (most older people with incontinence or overactive bladder self-restrict fluid intake)
Volume overload with increased urine production at night	Support stockings
Venous insufficiency with edema	Leg elevation
	Sodium restriction
	Diuretic therapy (late afternoon dose may be effective)
Congestive heart failure	Medical therapy
Impaired ability or willingness to reach a toilet	
Delirium	Diagnosis and treatment of underlying cause(s)
Chronic illness, injury, or restraint that interferes with mobility	Regular toileting
	Use of toilet substitutes
	Environmental alterations (e.g., bedside commode, urinal)
	Remove restraints if possible
Psychological (depression, anxiety)	Appropriate nonpharmacologic and/or pharmacologic treatment
Drug side effects	Remove offending drug(s) if feasible; modification of dose, frequency, or timing may also reduce symptoms for some drugs:
	Diuretics (polyuria, frequency, urgency)
	Anticholinergics (constipation, incomplete bladder emptying)
	Psychotropic drugs
	Tricyclic antidepressants (anticholinergic effects)
	Antipsychotics (immobility, sedation)
	Sedative-hypnotics (immobility, sedation)
	Narcotic analgesics (constipation, incomplete bladder emptying)
	α-Adrenergic blockers (urethral relaxation)
	α-Adrenergic agonists (urethral contraction and potential incomplete bladder emptying)
	Cholinesterase inhibitors (urinary frequency, urgency)
	Angiotensin-converting enzyme inhibitors (cough precipitating stress incontinence)
	Calcium channel blockers, gabapentin, pregabalin, glitazones (edema with nocturia)
	Alcohol (polyuria, frequency, urgency, sedation, delirium, immobility)
	Caffeine (polyuria, bladder irritation)

Source: Reproduced with permission from RL Kane et al (eds): *Essentials of Clinical Geriatrics*, 8th ed. New York, McGraw-Hill, 2018.

The 3IQ is a patient questionaire that helps your doctor distinguish urge incontinence from stress incontinence. It should take no more than a couple of minutes. Complete the quiz and bring it to your next appointment.

1. During the last 3 months, have you leaked urine (even a small amount)?

☐ **Yes** ☐ **No** (if this response is marked, the 3IQ test is complete)

2. During the last 3 months, did you leak urine (check all that apply):

☐ When you were performing some physical activity, such as coughing, sneezing, litting, or exercising?

☐ When you had the urge or the feeling that you needed to empty your bladder, but you could not get to the toilet fast enough?

☐ Without physical activity and without sense of urgency?

3. During the last 3 months, did you leak urine most often (check only one):

☐ When you were performing some physical activity, such as coughing, sneezing, litting, or exercising?

☐ When you had the urge or the feeling that you needed to empty your bladder, but you could not get to the toilet fast enough?

☐ Without physical activity and without sense of urgency?

☐ About equally as often with physical activity as with a sense of urgency?

Definitions of type of urinary incontinence are based on responses to question 3.

Response to Question 3	Type of incontinence
Most often with physical activity	Stress only or stress predominant
Most often with the urge to empty the bladder	Urge only or urge predominant
Without physical activity or sense of urgency	Other cause only or other cause predominant
About equally with physical activity and sense of urgency	Mixed

FIGURE 489-9 The 3 Incontinence Questions (3IQ) Assessment Tool. *(From Annals of Internal Medicine, JS Brown et al: The sensitivity and specificity of a simple test to distinguish between urge and stress urinary incontinence. 144 (10):715, 2006. Copyright © 2006 American College of Physicians. All Rights Reserved. Reprinted with the permission of American College of Physicians, Inc.)*

coughing indicates that stress incontinence is present. Older men commonly have symptoms associated with OAB and/or symptoms of voiding difficulty (hesitancy, poor or intermittent urinary stream, postvoid dribbling); the OAB symptoms are usually more bothersome. These symptoms overlap with those of both benign and malignant disorders of the prostate, and many internists may choose to consult a urologist for further management **(Chap. 92)** because a urinary flow rate and postvoid residual determination, and further evaluation if malignancy is suspected, help determine therapy.

Most older patients with symptoms of incontinence or OAB should have a postvoid residual determination, especially men, diabetics, those with neurologic disorders, and those with symptoms of voiding difficulty because incomplete bladder emptying is common in older patients and is difficult to detect by history and physical examination alone. There is no specific cutoff for an abnormal postvoid residual; the test must be done with a full bladder, and straining during the test can alter the results. In older patients, a postvoid residual between 0 and 100 mL is normal, a residual between 100 and 200 mL must be interpreted based on symptoms, and a value >200 mL is abnormal and usually influences treatment. Incomplete bladder emptying is a common contributing factor in urinary frequency and nocturia if bladder sensory function is intact or hypersensitive.

Management Some patients should be referred for further urologic, gynecologic, and/or urodynamic evaluation. Examples include a history of lower urinary tract surgery or radiation or recurrent symptomatic urinary tract infections, marked pelvic prolapse on physical examination of a woman, suspected prostate cancer, and sterile hematuria.

Potentially reversible conditions should be addressed, including the many types of medications that can affect bladder function, which should be eliminated if possible (Table 489-10). **Table 489-12** lists treatments for different types of incontinence. Many patients respond well to properly taught and adhered to behavioral interventions. Physical therapists and nurses who specialize in treating lower urinary tract symptoms can be very helpful and should be consulted if available. Pharmacologic treatment of incontinence and OAB is dictated by the innervation of the lower urinary tract. α-Adrenergic stimulation increases tone in the smooth muscle of the urethra; thus, α-agonists have been used to treat stress incontinence in women (although none are approved by the U.S. Food and Drug Administration for this indication), and α-blockers are used to decrease urethral tone in men with OAB associated with prostate enlargement. Anticholinergic/antimuscarinic agents and β_3-agonists inhibit bladder contraction and are used for OAB and urge incontinence. The latter do not have the bothersome anticholinergic effects of antimuscarinic drugs. In men with OAB and normal postvoid residual who do not respond to an α-blocker (with or without a 5α-reductase inhibitor), adding an antimuscarinic or β_3-adrenergic agent may improve symptoms with a very low risk of causing urinary retention. Patients with severe cognitive impairment and/or immobility can often be managed effectively by prompted voiding (during the daytime) and/or incontinence undergarments, as long as comfort, dignity, and safety are maintained.

Older people with incontinence or OAB who have gait disorders or a history of falling should be encouraged to use a urinal, bedside commode, or external catheter. If they insist on walking to the bathroom, they should have a clearly lit and uncluttered path to do so.

TABLE 489-11 Key Aspects of the History and Physical Examination of an Older Patient with Symptoms of Urinary Incontinence and Overactive Bladder

History
Active medical conditions, especially neurologic disorders, diabetes mellitus, congestive heart failure, venous insufficiency
Medication review for drugs that can contribute (see Table 489-10)
Fluid intake pattern
Type and amount of fluid (especially caffeine and fluids before bedtime)
Past genitourinary history, especially childbirth, surgery, dilatations, urinary retention, recurrent urinary tract infections
Symptoms of incontinence
Onset and duration
Type—stress vs urge vs mixed vs other (see Fig. 489-10)
Frequency, timing, and amount of incontinence episodes and of continent voids (a voiding diary may be useful)
Other lower urinary tract symptoms
Irritative—dysuria, frequency, urgency, nocturia
Voiding difficulty—hesitancy, slow or interrupted stream, straining, incomplete emptying
Other—hematuria, suprapubic discomfort
Other symptoms
Neurologic (indicative of stroke, dementia, parkinsonism, normal-pressure hydrocephalus, spinal cord compression, multiple sclerosis)
Psychological (depression)
Bowel (constipation, stool incontinence)
Symptoms suggestive of volume-expanded state (e.g., lower extremity edema, shortness of breath while horizontal or with exertion)
Environmental factors
Location of bathroom
Availability of toilet substitutes (e.g., urinal, bedside commode)
Perceptions of incontinence
Patient's concerns or ideas about underlying cause(s)
Most bothersome symptom(s)
Interference with daily life
Severity (e.g., "Is it enough of a problem for you to consider surgery?")
Physical Examination
Mobility and dexterity
Functional status compatible with ability to self-toilet
Gait disturbance (e.g., that may suggest parkinsonism, normal-pressure hydrocephalus)
Mental status
Cognitive function compatible with ability to self-toilet
Motivation
Mood and effect
Neurologic
Focal signs (especially in lower extremities) that could suggest a central nervous system condition
Signs of parkinsonism
Sacral arc reflexes (e.g., loss of perianal sensation or an anal wink in response to perianal stimulation)
Abdominal
Bladder distension[a]
Suprapubic tenderness
Lower abdominal mass
Rectal
Perianal sensation
Sphincter tone (resting and active)
Impaction
Masses
Size and contour of prostate (neither is diagnostic of urethral obstruction)
Pelvic
Perineal skin condition
Perineal sensation
Atrophic vaginitis (friability, inflammation, bleeding)
Pelvic prolapse or mass
Other
Lower extremity edema or signs of congestive heart failure (if nocturia is a prominent complaint)

[a]Clinically significant degrees of urinary retention may be difficult to detect on physical examination; many incontinent patients should have a postvoid residual determination done by ultrasound (see text).

Source: Reproduced with permission from RL Kane et al (eds): *Essentials of Clinical Geriatrics*, 8th ed. New York, McGraw-Hill, 2018.

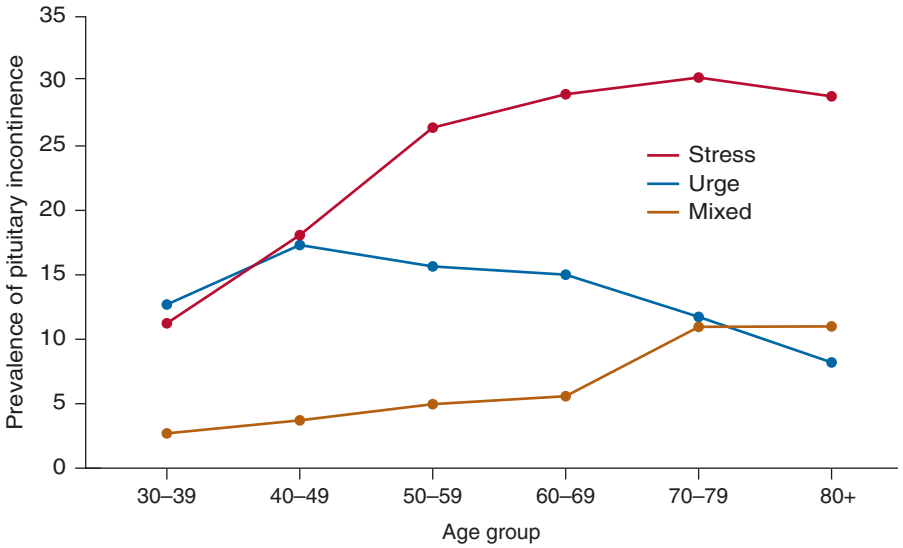

FIGURE 489-10 Rates of urge, stress, and mixed incontinence, by age group, in a sample of 3552 women. *Based on a sample of 3553 participants. *(Adapted from JL Melville, W Katon, K Delaney, K Newton: Urinary incontinence in US women: A population-based study. Arch Intern Med 165:537, 2005.)*

SLEEP DISORDERS

Sleep disorders are discussed in more detail for the general adult population in Chap. 33. Because they are so common and have some unique features in older patients, they are discussed briefly here.

Epidemiology and Impact Aging is associated with multiple changes in sleep architecture as well as multiple diseases and disorders that can disrupt sleep. Thus, complaints of sleep difficulty are common in older adults. Consequences of sleep difficulty include lower health-related quality of life, increased medication use, more cognitive decline, and greater health care utilization. Four types of primary sleep disorders are common in the geriatric population: insomnia, sleep-disordered breathing due to obstructive sleep apnea (OSA), restless leg syndrome (RLS), and periodic leg movements in sleep (PLMS). Complaints of bothersome insomnia—the inability to fall asleep or stay asleep despite a conducive environment—increase with age and occur in close to 30% of people older than 65. Insomnia is commonly associated with depression, anxiety, alcohol intake, and ingestion of caffeinated beverages later in the day. OSA occurs in ~10% of older adults but is probably underreported and underdiagnosed. It is associated with medical comorbidities, such as obesity and congestive heart failure. RLS occurs in 5–10% of adults, and its prevalence increases in those older than 70. It is almost twice as common in women than in men. Family history, iron deficiency, and intake of antihistamines and most antidepressants are risk factors. PLMS can be found in up to 45% of older people but is often of unknown clinical consequence and remains undiagnosed.

TABLE 489-12 Primary Treatments for Different Types of Geriatric Urinary Incontinence

TYPE OF INCONTINENCE	PRIMARY TREATMENTS
Stress	Pelvic muscle (Kegel) exercises
	Other behavioral interventions including timed voiding and double voiding to avoid residual urine
	α-Adrenergic agonist (none are approved by the U.S. Food and Drug Administration for this purpose)
	Topical estrogen to strengthen periurethral tissue (not effective alone; oral estrogens contraindicated)
	Periurethral injections to provide bulking and support
	Surgical bladder neck suspension or sling for severe incontinence, based on patient preference
Urge and overactive bladder symptoms	Pelvic muscle (Kegel) exercises
	Other behavioral interventions: timed voiding and double voiding to avoid residual urine
	Antimuscarinic and β-3-adrenergic drugs
Incontinence with incomplete bladder emptying	α-Adrenergic antagonists in men with a 5α-reductase inhibitor if the prostate is enlarged); an antimuscarinic or β-3-adrenergic drug can be added if unresponsive to the α-adrenergic agonist
	Bladder training, double voiding
	Intermittent catheterization
	Indwelling catheterization in selected patients in whom risks and discomforts of urinary retention outweigh risks of a chronic indwelling catheter
Incontinence with impaired physical and/or cognitive function	Behavioral interventions (prompted voiding, habit training)
	Environmental manipulation including use of urinal or bedside commode, safe lit path to bathroom)
	Incontinence undergarments and pads

Source: Reproduced with permission from RL Kane et al (eds): *Essentials of Clinical Geriatrics*, 8th ed. New York, McGraw-Hill, 2018.

Evaluation Older people should be screened for sleep difficulty with questions such as, "Do you often feel sleepy during the day?" and "Do you have difficulty falling asleep at night?" Further evaluation of the nature and impact of the complaints can be accomplished with standardized questionnaires (Table 489-3). Patients with significant sleep complaints should be asked about conditions that can interrupt sleep, such as nocturia, gastroesophageal reflux, cough due to reflux, chronic sinusitis with postnasal drip, chronic pain, and caffeine or alcohol intake. Specific questions characterizing the complaints should include inquiring about loud snoring (for OSA), the urge to move legs associated with uncomfortable sensations (RLS), and leg movements during sleep (PLMS; which may result in kicking a bed partner).

Management Patients suspected of having OSA, RLS, or PLMS should be referred for formal sleep evaluation. While hypnotics are among the most commonly prescribed drugs in the geriatric population, nonpharmacologic management of sleep should be the initial and primary approach, as many patients can benefit from properly taught and adhered to sleep hygiene interventions (Table 489-13). Benzodiazepine hypnotics should be avoided whenever feasible because they are associated with next-day hangover effects, which may manifest as cognitive impairment and can precipitate falls and car crashes and rebound insomnia. Patients with sleep-onset insomnia may respond to melatonin or low-dose trazadone, both of which are safer than using a benzodiazepine chronically.

FRAILTY

Definition, Epidemiology, and Impact The term *frail* is often used to describe older adults. However, over the past several years, *frailty* has been defined as a specific syndrome, and the word *frail* is more appropriately used to describe people who meet frailty criteria. Frailty is a state of increased vulnerability characterized by a decline in physiologic reserve and function across multiple systems. Many different definitions and tools to define frailty exist. Fried criteria based on the Cardiovascular Health Study (see below) and the Frailty Index (a list of several specific diagnoses developed by Rockwood and colleagues) have been used to screen for frailty in clinical settings. The importance of screening for frailty is to mitigate disability and adverse health outcomes as well as for the assessment of benefits and risks of treatment decisions. The prevalence of frailty is higher among women and increases with age. The overall prevalence of frailty in community-dwelling adults aged 65 and older varies considerably but, on average, is 10–14% depending on the definition. The prevalence of frailty

TABLE 489-13 Nonpharmacologic Management of Insomnia in Older Adults

Sleep Hygiene Rules
Check effect of medication on sleep and wakefulness
Avoid caffeine, alcohol, and cigarettes after lunch
Limit liquids in the evening
Keep a regular bedtime-waketime schedule
Avoid naps or limit to 1 nap a day, no longer than 30 min
Spend time outdoors (without sunglasses), particularly in the late afternoon or early evening
Exercise—but limit exercise immediately before bedtime
Instructions for Stimulus-Control Therapy
Only go to bed when tired or sleepy
If unable to fall asleep within 20 min, get out of bed (and bedroom if possible); while out of bed, do something quiet and relaxing
Only return to bed when sleepy
If unable to fall asleep within 20 min, again get out of bed
Repeat these behaviors until able to fall asleep within a few minutes
Get up at the same time each morning (even if only a few hours of sleep)
Avoid naps

Source: Adapted from JB Halter et al (eds): *Hazzard's Geriatric Medicine and Gerontology*, 8th ed. New York, McGraw-Hill, 2022.

increases with age, reaching close to 16% in individuals age 80–84 and 26% in those aged 85 or older. In older hospitalized patients and institutionalized older people, the frailty prevalence varies from about 27% to up to 80%. Irrespective of the definition, the prevalence of frailty shows a U-shaped relationship with body mass index (BMI), with higher levels of frailty in individuals with both low and very high BMI.

Pathophysiology Frailty is a three-dimensional process that involves changes at the cellular, physiologic, and phenotypical levels. At the cellular level, frailty manifests as changes in mitochondrial function, the development of oxidative stress and DNA damage, telomere shortening, and stem cell exhaustion. These changes at the cellular level result in physiologic alterations including inflammation, cell mediator dysfunction such as low production of nitric oxide by the endothelium, sarcopenia, and energy unbalance. Fried and colleagues conceptualize frailty as a vicious circle of declining energetics and reserve, whose elements represent both the diagnostic criteria for the syndrome identification and the core elements of its pathophysiology. The process manifests phenotypically as an overall decline in physical function and cognitive impairment. In particular, the phenotype of frailty has been defined by Fried and colleagues by the five following characteristics: unintentional weight loss, weakness, exhaustion, slowness, and low activity (with specific operational definitions of each).

Management Although there is conflicting evidence regarding the effectiveness of specific interventions to treat or prevent frailty, person-centered physical activity programs and nutritional supplementation appear to improve components of frailty such as muscle strength, gait speed, and overall mobility. In addition, optimizing the management of chronic conditions, medication management including mitigation of polypharmacy, and identifying the individual's priorities could lead to reversing or slowing the progression of frailty. The growing field of "geroscience" is actively studying drugs including metformin and a variety of senolytic agents for their potential effects on preventing or mitigating frailty.

ELDER ABUSE AND NEGLECT

Epidemiology and Impact The incidences of elder abuse neglect and self-neglect are unknown because they are often unrecognized. The best data suggest that the incidence over 12 months is at least 8–10%. Abuse and neglect can result in physical injuries and related pain, worsening of chronic medical conditions, dehydration and pressure ulcers, emotional distress, and loss of income and savings.

Evaluation Because abuse and neglect are underreported, are unsuspected, and have such devastating consequences, older adults should be screened (without the presence of caregivers) with questions such as, "Do you ever feel unsafe where you live?" "Has anyone ever threatened or hurt you?" "Has anyone been taking your money without your permission?" (Table 489-2). **Table 489-14** outlines the definitions, symptoms and signs, and key aspects of evaluating suspected abuse and neglect.

Management In addition to treating the physical, medical, and emotional consequences, patients suspected of elder abuse or neglect should be reported to the appropriate local or state agency to investigate and ensure the patient's safety. The reader is referred to two reviews of this topic for further information on specific aspects of management.

COVID-19

The COVID-19 pandemic disproportionately affected the older population, especially those residing in nursing homes and assisted living facilities. Compared with those between the ages of 18 and 29 years old, older adults are at greater risk for adverse outcomes after infection with COVID-19, especially those with multiple comorbidities. Internists should regularly refer to the CDC guidelines on vaccination as they are frequently updated. (See **Chap. 205** for more details on managing COVID-19). The COVID-19 epidemic had devastating and persistent effects on nursing home staffing and heightened awareness of changes that are essential for long-term care quality in the United States (see National Academies of Sciences, Engineering, and Medicine report in "Further Reading").

END-OF-LIFE AND PALLIATIVE CARE

End-of-life and palliative care are critical aspects of caring for the geriatric population and require a comprehensive, person-centered approach; they are addressed in detail in **Chap. 13**, and pain management is addressed in **Chap. 14**. For older patients, limited life expectancy is a critical factor to consider when making end-of-life care decisions. General principles of decision-making are especially relevant when considering palliative and/or end-of-life care in older patients (Fig. 489-5). Decision-making becomes complicated, however, among older patients with multimorbidity. Without a clear terminal diagnosis, when to start palliative care/end-of-life care could be challenging. While it is sometimes clear when an older patient has a terminal condition, such as end-stage congestive heart failure or chronic obstructive pulmonary disease, many older patients with multimorbidity have combinations of conditions of varying severity. Moreover, neurogenerative disorders, including most forms of dementia, Parkinson's disease, and patients with multiple strokes, commonly have a gradually progressive course, and it can be challenging to determine when discussions about palliative and end-of-life care should be initiated. Dementia, however, should be considered a terminal illness in the advanced stages.

Internists should play a pivotal role in making the decision when to initiate these discussions and should be proactive in encouraging patients and their families to execute advance directives before a health care crisis occurs. There are good data that bear on some of the decisions. For example, the survivability of cardiopulmonary resuscitation (CPR) in hospitalized patients age 65 and older is <20%; among the old-old with multimorbidity, it is much lower. The survivability of CPR in nursing home residents is almost zero, making it a futile intervention for most in this setting. Data and recommendations from major organizations suggest that enteral feeding tubes should not be placed in patients with end-stage dementia (Table 489-1). Tools for the estimation of prognosis such as *ePrognosis.com*, for holding conversations with older people and their families about advance care planning, and for documentation of advance directives (e.g., living will, durable power of attorney for health care, Physician Orders for Life-Sustaining Treatments [POLST], and other order sets) will assist internists in paying careful attention to factors that contribute to person-centered care and in dealing with these challenging issues in end-of-life geriatric care.

TABLE 489-14 Elder Abuse and Neglect

CATEGORY	DEFINITION AND EXAMPLES	SYMPTOMS AND SIGNS	KEY ASPECTS OF EVALUATION
Physical abuse	Acts of violence that may result in pain, injury, or impairment • Pushing, slapping, hitting, force-feeding • Improper positioning or use of restraints • Improper use of medications	Abrasions Lacerations Bruises Fractures Use of restraints Burns Pain Depression Delirium or onset or worsening of dementia-related behavioral symptoms	The interview should be conducted alone with the patient; it may reveal discordant histories or findings inconsistent with the history provided by the caregiver. Ankles and wrists should be examined for abrasions suggestive of the use of restraints. Findings that are discordant with the mechanism of injury reported or multiple injuries in various stages of healing should raise the suspicion of abuse. Injuries to the head, neck, and upper arms occur in victims of physical elder abuse but must be distinguished from accidental injuries. Jaw and zygomatic fractures are more likely to be sustained from a punch than from a fall, which more typically result in fractures to orbital and nasal bones.
Psychological or verbal abuse	Conduct that causes mental or emotional distress • Verbal harassment or intimidation • Threats of punishment or deprivation • Isolation	Direct observation of verbal abuse Subtle signs of intimidation, such as deferring questions to a caregiver or potential abuser Evidence of isolation Depression, anxiety, or both	Assess the size and quality of the patient's social network (beyond the suspected abuser). Conduct standardized assessments of depression, anxiety, and cognition, directly or through referral. Ask specifically about verbal or psychological abuse with questions such as, "Does your relative/caregiver ever yell or curse at you?"; "Have you been threatened with being put into a nursing home?"; or "Are you ever prevented from seeing friends and family members whom you wish to see?"
Financial abuse	Misuse of the person's income or resources for the financial or personal gain of a caregiver or advisor • Stealing money or possessions • Denying a home • Coercing to sign contracts or spend money	Inability to pay for medicine, medical care, food, rent, or other necessities Failure to renew prescriptions, adhere to medication regimens or other treatments, or keep medical appointments Malnutrition, weight loss, or both, without an obvious medical cause Evidence of poor financial decision-making Firing of home care or other service providers by abuser Unpaid utility bills Initiation of eviction proceedings	Ask about financial exploitation with questions such as, "Has money or property been taken from you without your consent?"; "Have your credit cards or automated teller machine card been used without your consent?"; and "At the end of the month, do you have enough money left for food and other necessities?" Abrupt changes in financial circumstances of the caregiver in either direction may herald an increased risk of financial exploitation or exploitation already under way. Abuse of the power of attorney; if the person with power of attorney or health care proxy is suspected of not acting in the best interest of the patient, documents necessary to ensure that the assumption of fiduciary responsibilities is authorized.
Sexual abuse	Sexual coercion or assault	Bruising, abrasions, lacerations in the genital or anal areas or abdomen Newly acquired sexually transmitted diseases, especially in nursing home Urinary tract infection	Inquire directly about sexual assault or coercion. For patients with dementia, direct queries to caregivers about hypersexual behavior as part of a larger history regarding dementia-related behaviors and assess patient's capacity for decision-making about sexual activity. If indicated, refer to an emergency department for assessment for sexual assault and collection of specimens (forensic evidence should be collected by experienced professionals, such as nurses who have undergone Sexual Assault Nurse Examiners [SANE] training).
Neglect (by caregiver or self-neglect)	Failure to provide the materials, supplies, food and drink, or services necessary for optimal functioning or to avoid harm	Malnutrition Dehydration Poor hygiene Pressure ulcers Nonadherence to medication regimen or other treatments Worsening of dementia-related behavioral symptoms	Interview primary caregiver about their understanding of the nature of the patient's care needs and how well care is being rendered. Neglect by a caregiver may be intentional or unintentional. Assess hygiene, cleanliness, and appropriateness of dress. Examine the skin for pressure ulcers, infections, and infestations. Assess nutrition and hydration, including measuring body mass index and blood urea nitrogen and creatinine to assess hydration.

MODELS OF GERIATRIC CARE

Several innovative models of care have been developed over the past three decades designed to provide high-quality and effective care for the burgeoning geriatric population with multimorbidity, functional and cognitive impairment, and challenges with social support. These include outpatient comprehensive geriatric assessment programs, inpatient acute care for the elderly (ACE) units, consultation and co-management services, and home-based programs. These models of care are assuming greater importance in the emerging era of value-based health care services.

CARE TRANSITION INTERVENTIONS

Improving transitions of care between settings has become a major focus of governments, health systems, hospitals, postacute care (PAC) and LTC organizations and programs, physicians, and other health care professionals. Geriatric patients are especially vulnerable to complications at the time of discharge from an acute medical or psychiatric hospital, as well as at the time of discharge from a PAC facility (skilled nursing facility [SNF], acute rehabilitation or long-term hospital) or home care program. With the increasing role of hospitalists, and others who specialize in SNF care, medical care for geriatric patients has become fragmented at the time of transitions, creating opportunities for communication problems and medical errors. Changes in reimbursement and financial penalties for high rates of hospital readmissions have driven the development of many care transition interventions (Table 489-15).

INTERPROFESSIONAL TEAMS AND CO-MANAGED CARE

The complexity of caring for the aging population is more evident during hospitalizations due to a new acute illness or exacerbation of

TABLE 489-15 Examples Care Transitions Interventions

INTERVENTION	WEBSITE	CORE INTERVENTIONS
Re-Engineered Discharge (Project RED) (Jack et al: 2009)	*https://www.bu.edu/fammed/projectred/*	"Discharge advocate" performs the following: • Facilitates patient education and understanding • Performs medication reconciliation • Coordinates postdischarge appointments and communication with primary care provider (PCP) • Calls patient 2–3 days after discharge
Transitional Care Model (Naylor et al: 2004; Naylor et al: 1999)	*https://www.nursing.upenn.edu/ncth/transitional-care-model/*	Advanced practice nurse performs the following: • Coordinates patient care before and after discharge • Assesses each patient's needs; engages and activates the patient and family • Facilitates communication among patient, family, and health care providers • Conducts regular home visits and telephone support after discharge
Care Transitions Program® (Coleman et al: 2004)	*http://www.caretransitions.org*	"Transition coach" performs the following: • Facilitates improved self-management skills including medication management and how to respond to warning signs/symptoms • Makes postdischarge home visits and phone calls
Better Outcomes for Older Adults through Safe Transitions (BOOST) (Hansen et al: 2013)	*https://www.hospitalmedicine.org/clinical-topics/care-transitions/*	Includes toolkit facilitating the following: • Comprehensive identification and assessment of high-risk patients • Patient/caregiver education • Enhanced communication with posthospitalization care providers • Follow-up phone call with patient after discharge
Interventions to Reduce Acute Care Transfers (INTERACT) (Ouslander et al: 2013)	*http://www.interact-pathway.com*	Includes tools for skilled nursing, assisted living, and home health care, including: • Quality improvement • Communication • Decision support • Advance care planning

preexisting chronic conditions. Interprofessional teams integrate different areas of expertise to provide patient-centered care. Physicians should understand and respect the roles of nurses; physical, occupational, and speech therapists; nutritionists; pharmacists; psychologists; social workers; clergy; and other direct care staff. The evolution of interprofessional teams has resulted in a comprehensive approach to care by opening channels of communication between health professionals from different disciplines.

Co-managed medicine is an example of how enhanced communication between different providers improves outcomes, avoids common complications, and saves resources. In the era of person-centered and value-based care, effective co-managed medicine appears to deliver consistently high-quality care at a lower cost. Collaborations between internists and geriatricians are examples of this strategy. Hip fracture and trauma co-management programs also have been developed in many academic and community hospitals and are demonstrating some success in reducing complications and length of stay in older trauma patients.

AGE-FRIENDLY HEALTH SYSTEMS

A new framework for providing comprehensive, integrated, and person-centered care across settings of care has been developed called "age-friendly health systems." Health systems participating in the development of age-friendly programs focus on the 5M's discussed previously (Fig. 489-4) as a strategy to achieve high-quality care across the system. Strategies are implemented to educate and facilitate all system health care providers to focus on the 5M's of geriatrics under the leadership and mentorship of specially trained geriatrics health professionals.

490 Approach to Medical Consultation

Jeffrey S. Berns, Jack Ende

Effective health care requires teams of generalists and specialists with complementary expertise. Many clinical conditions require the input of more than one clinical provider, either because the diagnosis and recommended treatment is uncertain or because the required diagnostic procedure or management lie outside the principal provider's area of expertise.

To *consult* is to seek advice from someone with expertise in a particular area, whereas *consultation* refers to the meeting or comparable outcome arising from that request. Medical consultation takes several forms. Its most traditional forms include in-hospital consultation, in which physicians provide recommendations, typically recorded in the medical record, or perform procedures for a hospitalized patient, and outpatient consultations, in which patients are seen in the office setting. More contemporary forms of consultation include e-consultations, telemedicine evaluations (see "Consultation Involving Telemedicine," below), and remote medical second opinions. In these forms, the consultant may not actually see the patient but, nonetheless, assumes the responsibility of evaluating the patient's clinical condition, assessing and analyzing pertinent clinical data, and offering a synthesis and appropriate recommendations.

While forms of medical consultation evolve, basic responsibilities associated with medical consultation endure. These responsibilities can be divided into those that fall to the requesting physician or nonphysician practitioner; the consultant, who provides the consultation; and the health system, hospital, or organization that must support this important medical encounter **(Table 490-1)**.

RESPONSIBILITIES OF THE REQUESTING CLINICIAN

Before requesting a consultation, the physician or other provider should ensure that the patient endorses the purpose of the consultation, understands the role of the consultant, and anticipates the likely outcomes of the encounter. Further responsibilities of the requesting physician include being specific and communicating clearly the reason for the consultation. Vague messages such as "Please evaluate" are not as helpful as more specific inquiries such as "What is the cause of the declining kidney function?" or "How should this asymptomatic pulmonary nodule be evaluated?" To the extent possible, the requesting physician should provide the relevant clinical information, summarized as succinctly as possible. Urgency should be clearly conveyed, typically with a phone call or other direct communication.

The requesting physician should be explicit regarding the intended outcome of the consultation, i.e., is this for a single evaluation or ongoing co-management? Communication between the requesting and the consulting physicians is paramount. Whether this communication includes direct contact is less important than that the relevant information and desired outcome be explicit and clear, regardless of communication medium. Consultations should be requested for clinical purposes and always directed to qualified consultants; they should not be driven by entrepreneurial or relationship-building purposes. Another responsibility of the referring physician is not to "overconsult." Medical care should be focused on value, not volume.

TABLE 490-1 Stakeholder Responsibilities in the Medical Consultation Process

REFERRING PHYSICIAN OR PROVIDER	CONSULTANT PHYSICIAN	HEALTH SYSTEM, HOSPITAL, OR CARE ORGANIZATION
• Ensure patient participation and engagement • Be specific regarding clinical question and desired outcome • Communicate level of urgency • Avoid consulting for nonclinical purposes	• Maintain standards of professionalism, including those pertaining to availability, communication, respect, and collegiality • Appreciate levels of urgency and respond appropriately • Assemble and develop one's own database • Be specific in synthesis and recommendations • Understand desired outcomes, including arrangements for follow-up • Communicate with referring provider in whatever manner is mutually desirable	• Maintain adequate specialty workforce to enable appropriate access • Support systems for efficient exchange of clinical information • Develop culture of collegiality and team-based care

RESPONSIBILITIES OF THE CONSULTANT

Just as the referring physician should attend to clear and explicit communication, so too should the consultant follow the precepts of effective interactions between professionals, which include courtesy, availability, and clarity. Particularly on the inpatient service, where consultants may receive several requests each day, it is important that the incoming consultations are triaged and dispatched as clinically appropriate. Consultants also need to determine the requested level of involvement going forward and not assume that long-term co-management is being sought. While consultants can and should make use of available clinical data, they should also assemble independently their own database, including taking a history, performing a physical exam, and reviewing pertinent laboratory, imaging, and pathology studies. Absent that, they may be unable to provide an independent and actionable synthesis. Just as the referring physician needs to be clear and concise, so too should the consultant be specific and focused in the recommendations provided. "Possible malignant ascites" is less helpful than, "I will arrange for paracentesis to exclude the possibility of malignant ascites." For the most part, recommendations to "consider" some diagnosis or test are less helpful than more specific and concrete advice. Some referring physicians wish to be called after a patient is seen; others prefer that communication be handled as part of the medical record. How this communication is handled must also align with the complexity and urgency of the consultation and clinical circumstances.

RESPONSIBILITIES OF HEALTH SYSTEMS, HOSPITALS, AND MEDICAL ORGANIZATIONS

Health systems, hospitals, and medical organizations also have responsibilities in the consultation process. This responsibility includes ensuring that qualified consultants are accessible and available on the medical staff. Consultations within a single system are aided by common shared electronic medical records, particularly when consultations originate in the hospital, but then also involve care in the outpatient setting. Finally, health care entities should strive to foster a culture of team-based care and collegiality. Reimbursement for consultations varies among payors and may have implications for self-pay or unreimbursed expenses for providers or health systems. While it is important to understand reimbursement models, the clinical needs of the patient should be prioritized.

SPECIAL ISSUES IN MEDICAL CONSULTATION

Curbside Consults Curbside consults are requests from one physician to another for an informal and unwritten opinion about a specific patient care matter. They are typically limited in scope, mostly regarding management or questions regarding procedures, and developed from information provided by the consulting physician and perhaps the medical record (such as labs and imaging studies). Although

often viewed as convenient, efficient, and a common aspect of clinical care, without a comprehensive review of the record or any direct contact with the patient, curbside consults have been found to often be incomplete or even flawed. It is not uncommon for the question being asked to be deemed too complex for a curbside consult or for it not to be the actual or only issue the consultant feels needs to be addressed. As a general rule, curbside consults should be avoided. While medicolegal liability is often cited as a reason to limit curbside consults, the risk is actually negligible as U.S. courts have ruled that curbside consults do not establish a doctor-patient relationship necessary for creating the basis for medical malpractice litigation. An important exception, however, is when a curbside consult is provided by a resident or fellow in training; in this circumstance, the trainee's supervising physician, whether aware of the curbside consult or not, is responsible for the recommendations of the trainee.

Advice Related to curbside consultation, but decidedly different, are instances when one physician reaches out to another, often one in another specialty, for advice. Examples include an internist turning to a radiologist for guidance on what is the most appropriate imaging study to diagnose a deep tissue abscess; a general internist asking a gastroenterologist for advice on management of acute diverticulitis; a hospitalist asking a neurologist for guidance on management of a patient with Parkinson's disease who is NPO; or a nephrologist asking an infectious disease specialist about immunizations in a kidney transplant recipient.

Outreach such as this is typically triggered by a specific patient encounter, but the request is more for general information that the requesting physician may use for the encounter at hand as well as for similar encounters going forward. Thus, reaching out for advice differs from formal consultation and from curbside consultation, which are specific for a particular patient. As such, requests for advice fall within the realm of collegial communication and not necessarily within that of clinical consultation per se.

Second Opinions Physicians may find themselves providing consultations requested by patients who have already been evaluated for the same problem by another physician. Not a "consult" in the usual context of one physician referring a patient to another, the service provided by the consultant is, nonetheless, very much aligned with a physician-referred consult. Second opinions, which often are encouraged by the patient's physician, may be sought by patients for reassurance that a diagnosis and treatment recommendation are correct, out of dissatisfaction with the initial physician, or with the hope of an entirely different opinion and recommendation. The physician providing the second opinion should strive to understand the patient's motivations for seeking the additional opinion. While a second opinion may have been initiated by the patient rather than referral from another physician, it is recommended that the consulting physician communicate with the patient's primary physician, as would be done following a standard consultation, unless the patient insists otherwise. In addition, professional behavior in how the consulting physician refers to the recommendations or actions of previous physicians is important, including when there is disagreement. Likewise, it is important that a transfer of care from the prior physician to the one providing a second opinion be enacted only if specifically requested by the patient or the physician who encouraged the second opinion.

Consults Involving Advanced Practice Providers Increasingly, specialist physicians may find themselves being consulted by nurse practitioners and physician assistants rather than other physicians. Whether the quality of the information provided to the consultant physician by these providers is different from physician-to-physician referrals has not been studied. Consulting physicians should know whether they should respond back to the advanced practice provider or to the supervising physician, if there is one. As with physician-to-physician consults, it is also important for the consultant to know whether the individual calling for the consult has an ongoing role in the care of the patient or is simply covering for a limited period of time. Finally, the consultant, if responding back to the advanced practice provider, should make sure that the information provided meets the needs of that provider and that questions are answered as they would be if responding back to another physician.

Consultation Involving Telemedicine and Electronic Health Records (EHRs) Consultations making use of EHRs, patient portals, and various forms of telecommunication technology, including video conferencing or cell phone communication, can improve access to care, reduce cost, and improve outcomes. This is particularly true when employed in geographic areas of health care shortage and when the clinical issues can be handled without direct contact with the patient, i.e., radiology or dermatology. However, the absence of direct contact between patient and consultant introduces special issues related to diagnostic accuracy and physician-patient relationship. Regulatory, liability, security, and confidentiality issues arise as well, as do concerns about disparities related to access to telemedicine technologies and willingness and ability to use them among some patient populations.

491 Medical Disorders During Pregnancy

Sarah Rae Easter, Robert L. Barbieri

Each year, ~3.7 million births occur in the United States, and >130 million births occur worldwide. A significant proportion of births are complicated by medical disorders. Advances in medical care and fertility treatment have increased the number of people with serious medical problems seeking pregnancy. Medical problems that interfere with the physiologic adaptations of pregnancy increase the risk for poor pregnancy outcome. Conversely, in some instances, pregnancy events may have implications for an individual's long-term health.

HYPERTENSION

(See also Chap. 288) Cardiac output increases by 40% in pregnancy, with most of the increase due to an increase in stroke volume. Heart rate increases by ~10 beats/min during the third trimester. In the second trimester, systemic vascular resistance decreases, and this decline is associated with a fall in blood pressure. A blood pressure of systolic ≥140 and/or diastolic ≥90 mmHg on two measurements 4 h apart after 20 weeks' gestation is abnormal and is associated with an increase in perinatal morbidity and mortality. Hypertension during pregnancy is classified as preeclampsia, gestational hypertension, or chronic hypertension. These classifications are distinguished based on timing in pregnancy and the presence of associated features (see below). The prevalence of hypertensive disorders in pregnancy (HDP) is rising. The Centers for Disease Control and Prevention (CDC) estimated that in 2019, 16% of deliveries in the United States were complicated by a HDP.

PREECLAMPSIA

Approximately 5–7% of all pregnant women develop *preeclampsia*, the new onset of hypertension (blood pressure ≥140/90 mmHg) and proteinuria (either a 24-h urinary protein >300 mg/24 h or a

protein-creatinine ratio ≥0.3) after 20 weeks of gestation. Preeclampsia can be diagnosed without proteinuria in the presence of symptoms or laboratory abnormalities raising concern for end-organ damage. Specific clinical features qualify as evidence of severe disease, including severe hypertension (blood pressure ≥160/110 mmHg), new-onset symptoms (headache not responsive to medications, visual changes, or unremitting severe epigastric pain), pulmonary edema, or laboratory abnormalities signifying thrombocytopenia (platelets $<100 \times 10^9$/L), renal insufficiency (creatinine >1.1 mg/dL), or liver impairment (elevation of transaminases to twice the normal concentration). Eclampsia is diagnosed when a pregnant person with preeclampsia develops generalized seizures. The *HELLP syndrome* (*h*emolysis, *e*levated *l*iver enzymes, *l*ow *p*latelets) is a special subtype of preeclampsia with severe features and is a major cause of morbidity and mortality. Coagulopathy, cerebrovascular accidents (CVAs), hepatic capsule rupture, and placental abruption are additional end-organ complications of preeclampsia.

The precise pathophysiology of preeclampsia remains unknown, but chronic uteroplacental ischemia, an exaggerated maternal inflammatory response, and/or imbalance of angiogenic factors likely contribute to the clinical syndrome. In preeclampsia, there is excess production of an antiangiogenesis factor, soluble fms-like tyrosine kinase 1 (sFlt-1), and decreased production of an angiogenic factor, placental growth factor (PlGF). A ratio of circulating sFlt-1/PlGF ≥40 is associated with an increased risk of developing preeclampsia with severe features in the 2 weeks following the measurement. Abnormalities of cerebral circulatory autoregulation explain some of the neurologic manifestations of the disease and can increase the risk of stroke at even modestly elevated blood pressures. In the absence of treatment, 1 in 100 cases of preeclampsia may progress to *eclampsia*—new-onset generalized tonic-clonic seizures in a patient with preeclampsia. Low-dose aspirin initiated between 12 and 14 weeks of gestation reduces the risk in women at high risk of developing preeclampsia.

GESTATIONAL HYPERTENSION

The development of elevated blood pressure after 20 weeks of pregnancy in the absence of preexisting chronic hypertension or proteinuria is referred to as *gestational hypertension*. Gestational hypertension with severe features of the disease is best classified as preeclampsia. Both gestational hypertension and preeclampsia are associated with an increased risk of developing chronic hypertension, cardiovascular disease, chronic kidney disease, or diabetes mellitus later in life.

TREATMENT

Preeclampsia

The management of preeclampsia is challenging because it requires the clinician to balance the health of the mother with the health of the fetus. The definitive treatment of preeclampsia is delivery of the fetus and placenta, but preterm delivery exposes the fetus to the risks of prematurity. In preeclampsia without severe features, delivery at 37 weeks is recommended. People with preeclampsia without severe features may be managed expectantly until 37 weeks with close monitoring for development of severe features or laboratory abnormalities, frequent fetal surveillance, and limited physical activity to reduce blood pressure.

Expectant management of preeclampsia with severe features remote from term affords some benefits for the fetus but at significant risk to the mother. For women with preeclampsia with severe features, delivery is recommended unless the patient is <34 weeks and eligible for expectant management in a tertiary hospital setting. Indications for delivery prior to 34 weeks include unremitting symptoms, development of laboratory abnormalities, or severe range blood pressures refractory to medical management. The goal of prolonging pregnancy to this gestational age is to improve neonatal outcomes. Therefore, concerns about fetal well-being, such as severe fetal growth restriction or placental abruption, may also prompt delivery before 34 weeks. Timely management of blood pressures ≥160/110 mmHg reduces the risk of CVAs. Labetalol and hydralazine IV are the first-line agents to manage severe hypertension in preeclampsia with consideration of oral agents once blood pressure is controlled.

Women who have had preeclampsia are at increased risk of cardiovascular disease later in life. Interventions to reduce cardiovascular risk can be initiated in health encounters following birth.

CHRONIC HYPERTENSION

Pregnant people with chronic hypertension are at increased risk for superimposed preeclampsia and placental complications such as fetal growth restriction and placental abruption. These complications may necessitate preterm birth, which is associated with newborn respiratory distress syndrome. People with chronic hypertension should have a thorough prepregnancy evaluation to identify remediable causes of hypertension and to transition off antihypertensive agents associated with adverse outcomes in pregnancy. Angiotensin-converting enzyme inhibitors and angiotensin-receptor blockers are contraindicated in pregnancy because of an increased risk of stillbirth and congenital fetal anomalies. Labetalol and extended-release nifedipine are the most commonly used medications for the treatment of chronic hypertension in pregnancy. The optimal target blood pressure is <140/90 mmHg, which reduces the risk of developing preeclampsia and preterm birth. A preconception or early pregnancy assessment for end-organ impacts of hypertension, including the presence of proteinuria, may help differentiate the effects of chronic hypertension from those of superimposed preeclampsia.

RENAL DISEASE

Normal pregnancy is characterized by a 40% increase in glomerular filtration rate and creatinine clearance secondary to a rise in renal plasma flow. Patients with underlying renal disease may expect a worsening of existing hypertension or development of preeclampsia during pregnancy. A prepregnancy serum creatinine level ≥133 µmol/L (≥1.5 mg/dL) and low C4 levels are associated with adverse pregnancy outcomes. Certain pathologies, such as those associated with glomerular disease, increase the risk of adverse outcomes. Neither hemodialysis nor prior renal transplant is a contraindication to pregnancy, but both require close multidisciplinary management. When renal disease worsens during pregnancy, close collaboration between the internist and the maternal-fetal medicine specialist is essential so that decisions regarding delivery can be weighed to balance the sequelae of prematurity for the neonate versus long-term sequelae for the mother with respect to future renal function.

CARDIAC DISEASE

Cardiac disease is the leading cause of maternal mortality in the United States. Prepregnancy cardiac disease and cardiac disease caused by pregnancy are both major contributors. Patient education, risk stratification, optimization of hemodynamics, and multidisciplinary planning with a pregnancy heart team are the tenets of management. Patients with pulmonary hypertension **(Chap. 294)**, severe ventricular dysfunction (ejection fraction <30% or New York Heart Association class III–IV), severe mitral or aortic stenosis, severe aortic dilation, or Fontan circulation with severe complications are at the highest risk of maternal mortality. Pregnancy is contraindicated in these women, with termination of pregnancy as an option to reduce maternal risk. Risk stratification including a detailed history with attention to symptoms, echocardiography, and cardiopulmonary exercise testing guides monitoring and management for most patients. Contemporary guidelines support continuing most nonteratogenic prepregnancy medications and reserving cesarean delivery for obstetric indications with few exceptions.

VALVULAR HEART DISEASE

(See also Chaps. 272–279.)

Mitral Stenosis The pregnancy-induced increase in blood volume, cardiac output, and tachycardia can increase the transmitral pressure gradient and cause pulmonary edema or tachyarrhythmias in

women with mitral stenosis. People with moderate to severe mitral stenosis (mitral valve area ≤1.5 cm^2) who are planning pregnancy and have either symptomatic disease or pulmonary hypertension should undergo valvuloplasty prior to conception, preferably with percutaneous balloon valvotomy. Careful control of heart rate and avoidance of hypovolemia, especially during labor and delivery, mitigate the risk of tachycardia and reduced ventricular filling times on cardiac function. The immediate postpartum period is a time of particular concern secondary to rapid volume shifts.

Aortic Stenosis People with aortic stenosis, a mean valve gradient <25 mmHg, and normal left ventricular function are likely to tolerate pregnancy. Symptomatic aortic stenosis or severe aortic stenosis with a peak gradient >50 mmHg should be evaluated for correction prior to pregnancy.

Mitral and Aortic Regurgitation The pregnancy-induced decrease in systemic vascular resistance reduces the risk of cardiac failure with these conditions, especially in those with chronic lesions. As a general rule, regurgitant lesions are well tolerated in pregnancy with acute onset of mitral or aortic regurgitation as an exception.

Mechanical Heart Valves People with mechanical heart valves are at high risk of valve thrombosis in pregnancy and warrant special consideration. Use of warfarin in pregnancy is limited to this population and avoided in the first trimester due to its association with fetal chondromalacia punctata. The risk of serious neonatal bleeding and associated neurologic injury persists throughout pregnancy, but the superiority of warfarin in preventing valve thrombosis merits its use in the second and third trimesters. Bridging from warfarin to heparin infusion at 36 weeks' gestation minimizes bleeding risk and facilitates neuraxial analgesia at delivery.

CONGENITAL HEART DISEASE

(See also Chap. 280) Reparative surgery has markedly increased the number of adults with congenital heart disease seeking pregnancy with a variety of disease-specific management considerations and outcomes. Repaired septal defects are comparatively low risk, whereas unrepaired septal lesions or repaired complex lesions such as tetralogy of Fallot may warrant additional surveillance by a pregnancy heart team to ensure that pregnancy is tolerated. People with complications in the setting of lower risk disease or with high-risk disease including uncomplicated Fontan circulation, systemic right ventricle, or cyanotic disease require delivery at a tertiary care center with subspecialty expertise. In *Eisenmenger's syndrome*, i.e., the combination of pulmonary hypertension with right-to-left shunting due to congenital abnormalities (Chap. 280), maternal and fetal deaths occur frequently, informing the recommendation for termination of pregnancy. The presence of a congenital cardiac lesion in the mother increases the risk of congenital cardiac disease in the newborn and is the basis for the recommendation to screen for fetal congenital heart disease with fetal echocardiography.

AORTOPATHY

The physiologic cardiovascular adaptations of pregnancy can predispose to aortic dissection, the majority of which occur in people with underlying aortopathies (Chap. 291). Although dissection may occur in the absence of aortic root enlargement in some genetic syndromes, sequential transthoracic echocardiographic (TTE) monitoring during pregnancy for evolution of the aortic root diameter is the mainstay of monitoring those at risk. Aortic magnetic resonance imaging (MRI) without gadolinium is useful to define thoracoabdominal aortic pathology in high-risk diseases. For most diseases, an aortic root diameter <40 mm portends a favorable pregnancy outcome, whereas a diameter >50 mm is an indication for prepregnancy repair. Beta blockers are a mainstay of therapy for most patients. A high clinical suspicion for dissection in patients presenting with chest pain is mandatory.

Marfan Syndrome (See also Chap. 425) This autosomal dominant disease is associated with an increased risk of aortic dissection and rupture. An aortic root diameter >40 mm is associated with an increased risk of aortic dissection, and an aortic root diameter >45 mm is an indication for surgical treatment. Operative vaginal delivery to limit the aortic wall stress associated with Valsalva should be considered for women with an aorta of 40–45 mm.

Ehlers-Danlos Syndrome (EDS) (See also Chap. 425) Vascular EDS (vEDS, type IV) is an autosomal dominant disease associated with an increased risk of uterine or vascular rupture that may cause death. For people with vEDS, pregnancy is relatively contraindicated because of this risk.

CARDIAC COMPLICATIONS IN PREGNANCY

Arrhythmias New-onset arrhythmias in healthy patients or patients with cardiac disease are common cardiac complications. Treatment is generally the same as in the nonpregnant patient, and fetal tolerance of medications such as beta blockers, calcium channel blockers, and common antiarrhythmics is acceptable. Pharmacologic or electric cardioversion may be performed to improve cardiac performance and reduce symptoms according to standard indications.

Peripartum Cardiomyopathy (PPCM) (Chap. 269) This uncommon but life-threatening condition should be considered in patients presenting in the third trimester or postpartum period with unexplained cardiogenic pulmonary edema. Treatment is directed toward symptomatic relief and improvement of cardiac function. The majority of patients recover completely. The subset of patients with left ventricular ejection fraction <30% are at high risk of progressive dilated cardiomyopathy. People with a history of PPCM may carry a genetic mutation that influences cardiac function. Approximately 10% of people with a history of PPCM have a truncating mutation in the *titin* gene encoding the sarcomere protein and experience higher rates of ongoing cardiomyopathy. Recurrence in a subsequent pregnancy is a risk, with a left ventricular ejection fraction of <50% 12 months postpartum as the threshold to advise against another pregnancy.

ENDOCRINE AND METABOLIC DISORDERS

The fetoplacental unit induces major metabolic changes to shunt glucose and amino acids to the fetus while the mother uses ketones and triglycerides to fuel her metabolic needs. The use of glucose by the fetus leads to a maternal state of accelerated ketosis during maternal fasting, characterized by lower glucose concentrations and higher hydroxybutyrate and acetoacetate levels. These metabolic changes are accompanied by maternal insulin resistance that increases during the course of pregnancy caused in part by placental production of steroids, a growth hormone variant, and placental lactogen.

DIABETES MELLITUS

(See also Chaps. 415–417) Pregnancy complicated by pregestational diabetes mellitus (pgDM), either type 1 or type 2 diabetes, complicates ~1% of pregnancies and is associated with increased maternal and perinatal morbidity and mortality rates. The prevalence of pgDM is greater among patients who are obese compared to normal weight (2.2 vs 0.5%). The metabolic changes of pregnancy can precipitate hyperglycemia requiring increased insulin needs, development of diabetic ketoacidosis, or hypoglycemia. Impaired glycemic control during the critical first 5–8 weeks of embryonic growth leads to an increased risk of spontaneous abortion and congenital malformations and highlights the importance of prepregnancy glycemic control. pgDM increases the risk of stillbirth, preeclampsia, and large for gestational age infants. Macrosomia increases the risk of shoulder dystocia and birth trauma, including brachial plexus injury and obstetric lacerations. Neonates are at risk of hypoglycemia, hyperbilirubinemia, polycythemia, and respiratory distress. An assessment of end-organ complications of pgDM including nephropathy, retinopathy, and neuropathy is essential to understanding the patient's risk profile.

GESTATIONAL DIABETES

Gestational diabetes mellitus (GDM) occurs in ~8% of pregnancies, and screening for GDM is a routine part of prenatal care, recommended by the U.S. Preventive Services Task Force with a B recommendation. The typical two-step strategy to diagnose GDM is performed at 24–28 weeks of

gestation and involves the initial administration of a 50-g oral glucose challenge with a single serum glucose measurement at 60 min. Plasma glucose >7.2 mmol/L (>130 mg/dL) warrants administration of a 100-g oral glucose tolerance test (GTT) with plasma glucose measurements obtained in the fasting state and at 1, 2, and 3 h. Normal plasma glucose concentrations at these time points are <5.3 mmol/L (<95 mg/dL), <10 mmol/L (<180 mg/dL), <8.6 mmol/L (<155 mg/dL), and <7.8 mmol/L (<140 mg/dL) as the upper norms. Two elevated glucose values indicate a positive GTT diagnostic of GDM. GDM increases the risks of maternal and neonatal complications similar to those seen with pregestational diabetes. Treating GDM reduces the risk of preeclampsia, birth weight >4000 g, and shoulder dystocia.

TREATMENT

Diabetes Mellitus in Pregnancy

Preconception counseling to optimize glycemic control and assess for end-organ complications of pgDM is a cost-effective and evidence-based intervention. Guidelines encourage people with pgDM considering pregnancy to initiate insulin prior to pregnancy, targeting a preconception hemoglobin A_{1c} <6% to reduce the risk of fetal congenital malformation. Insulin is the preferred medical therapy for pgDM in pregnancy due to its safety profile and lower rates of treatment failure compared to oral hypoglycemic medications.

Once pregnancy is established, glucose control should be managed more intensively than in the nonpregnant state with assessment of blood glucose when fasting and either 1 or 2 h after a meal at a minimum. Fasting blood glucose levels should be maintained at <5.3 mmol/L (<95 mg/dL), with postprandial targets of <7.8 mmol/L (140 mg/dL) or <6.7 mmol/L (120 mg/dL) at 1 and 2 h, respectively. Continuous glucose monitoring is an evidence-based intervention to improve neonatal outcomes in type 1 diabetes. Sequential measurement of hemoglobin A_{1c} is of minimal utility for monitoring glucose control during pregnancy because of the higher rate of red blood cell turnover during pregnancy and resultant falsely low values. Average daily insulin needs increase from 0.7–0.8 units/kg in the first trimester to 0.8–1 units/kg in the second trimester and 0.9–1.2 units/kg in the third trimester. Most management strategies utilize a combination of basal insulin with short-acting insulin at mealtime or continued use of a prepregnancy insulin pump in appropriately selected patients.

Glycemic control may become more difficult to achieve as pregnancy progresses due to an increase in insulin resistance. Attention to glycemic control and frequent fetal surveillance including ultrasounds are mainstays of management in the third trimester. Ultrasound identification of a large for gestational age fetus or polyhydramnios on antenatal ultrasound can be indicators of suboptimal glycemic control. Tight glycemic control at delivery minimizes the risk of neonatal hypoglycemia due to fetal hyperinsulinemia caused by elevated maternal glucose levels. Infants of mothers with pgDM have higher rates of preterm birth, although preterm delivery is generally reserved for poor glycemic control, worsening maternal renal disease, or active proliferative retinopathy in addition to the usual obstetric indications. Induction of labor may be recommended in the early term period of 37–39 weeks of gestation. Cesarean delivery is reserved for cases of suspected macrosomia based on an estimated fetal weight of 4500 g or greater to minimize the risk of shoulder dystocia and associated birth trauma.

TREATMENT

Gestational Diabetes

Treatment of GDM begins with nutritional therapy to optimize normoglycemia and gestational weight gain, which is effective in the majority of women. Insulin is the preferred therapy for patients who exceed the aforementioned targets despite nutritional therapy. Metformin and glyburide are alternatives for patients who decline or cannot reliably take insulin. Contemporary data demonstrate lower mean birth weights, gestational weight gain, and rates of preeclampsia with metformin compared to both glyburide and insulin. The unknown long-term developmental and metabolic effects of metformin, including higher adiposity measurements in children exposed to metformin in utero, inform the preference for insulin.

GDM confers a 7- to 10-fold increase in the risk of developing type 2 diabetes later in life, with a 10% risk within 5 years of delivery. All people with GDM should have a 2-h 75-g GTT to screen for diabetes or impaired glucose tolerance 4–12 weeks following birth. The increased long-term risks of diabetes and cardiovascular disease and the need for regular follow-up with a primary care provider should be emphasized for all people with GDM. Following birth, exercise, weight loss, and treatment with metformin reduce the risk of developing diabetes in these at-risk patients.

OBESITY

(See also Chap. 414) Pregnant people who are obese have an increased risk for GDM, preeclampsia, cesarean delivery, congenital malformations, stillbirth, and neonatal death. A growing body of literature suggests the in utero effects of excess adipose tissue may cause changes in fetal metabolic programming that lead to adverse health outcomes in adult life. People contemplating pregnancy should attempt to attain a healthy weight prior to conception, recognizing that even a 10% reduction in weight may significantly reduce many of these risks. Those undergoing bariatric surgery should be counseled to avoid conception for 12–18 months after surgery until weight stabilizes. Bariatric surgery reduces the risks for some complications but requires increased laboratory surveillance for micronutrient deficiencies in pregnancy with appropriate supplementation. All women should be counseled to avoid weight gain in excess of the National Academy of Medicine guidelines (25–35 lb for normal weight, 15–25 lb for overweight, and 11–20 lb for obese women) with the knowledge that excess gestational weight gain increases the risk of macrosomia and cesarean delivery, independent of the presence of comorbid diabetes.

THYROID DISEASE

(See also Chap. 394) The estrogen-induced increase in thyroxine-binding globulin increases circulating levels of total T_3 and total T_4 in pregnancy. Placental human chorionic gonadotropin (hCG) directly stimulates the thyroid, causing an increase in free T_3 and T_4, especially in the first trimester. Interpretation of the measurement of free T_4, free T_3, and thyroid-stimulating hormone (TSH) should use trimester-specific ranges. People with a history of Graves' disease have an increased risk of fetal goiter and neonatal Graves' disease independent of treatment status due to the transplacental passage of thyroid-stimulating antibodies and stimulation of the fetal thyroid.

TREATMENT

Hyperthyroidism

Options for the treatment of symptomatic hyperthyroidism in pregnancy include beta blockers, propylthiouracil, and methimazole. Methimazole crosses the placenta to a greater degree than propylthiouracil and has been associated with fetal aplasia cutis. Propylthiouracil can be associated with maternal liver failure. Some experts recommend propylthiouracil in the first trimester and the option of continuing propylthiouracil or switching to methimazole thereafter. Radioiodine should not be used during pregnancy, either for scanning or for treatment, because of effects on the fetal thyroid.

TREATMENT

Hypothyroidism

The goal of therapy for hypothyroidism is to maintain the serum TSH in the normal range, and thyroxine is the drug of choice. The dose of thyroxine required to keep the TSH in the normal range

rises during pregnancy. Since the increased thyroxine requirement occurs as early as the fifth week of pregnancy, one approach is to increase the thyroxine dose by 30% (two additional pills weekly) as soon as pregnancy is diagnosed and then adjust the dose according to TSH.

HEMATOLOGIC DISORDERS

Pregnancy has been described as a state of physiologic anemia. Red blood cell mass increases in pregnancy but to a lesser degree than plasma volume. This differential increase results in a lower hemoglobin concentration and so-called dilutional anemia. However, iron, folate, and vitamin B_{12} deficiencies are common causes of correctable anemia during pregnancy. Transfer of iron to the fetal compartment may explain why iron deficiency anemia is detected in ~11% of pregnant people in the third trimester. Screening for anemia is recommended in the first trimester and at 24 to 28 weeks' gestation. Measurement of ferritin can help detect iron deficiency before anemia is diagnosed. Iron replacement therapy is recommended in pregnancy.

Hemoglobinopathy screening is recommended for all pregnant women with testing of mean corpuscular volume, mean corpuscular hemoglobin, ferritin, and hemoglobin analysis **(Chap. 103)**. Hemoglobinopathies can be associated with increased maternal and fetal morbidity and mortality, with sickle cell disease as a particularly high-risk entity in pregnancy. Management is tailored to the specific hemoglobinopathy and is generally the same for both pregnant and nonpregnant women. Prenatal diagnosis of hemoglobinopathies in the fetus is readily available and should be discussed with prospective parents either prior to or early in pregnancy.

Thrombocytopenia occurs in 5–10% of pregnancies. The majority of cases are benign gestational thrombocytopenias, but the differential diagnosis should include immune thrombocytopenia **(Chap. 120)**, preeclampsia, and thrombotic thrombocytopenic purpura. Benign gestational thrombocytopenia is unlikely if the platelet count is <100,000/μL.

DEEP VENOUS THROMBOSIS AND PULMONARY EMBOLISM

(See also Chap. 290) Pregnancy is associated with venous stasis, endothelial injury, and a hypercoagulable state. During pregnancy, circulating coagulation factors II, VII, VIII, IX, X, and XII, fibrinogen, and von Willebrand factor increase, and protein S and antithrombin III decrease. Inherited thrombophilias and the presence of antiphospholipid antibodies increase the risk of venous thromboembolism (VTE) in pregnancy and often require prophylactic anticoagulation during pregnancy and the postpartum period to mitigate risk. Deep venous thrombosis (DVT) or pulmonary embolism (PE) occurs in about 1 in 500 pregnancies, with the highest risk in the postpartum state. In general, all diagnostic and therapeutic modalities afforded to the nonpregnant patient should be utilized in pregnancy.

TREATMENT

Venous Thromboembolism

Aggressive diagnosis and management of suspected DVT or PE optimize outcomes for both patient and fetus. Anticoagulant therapy with low-molecular-weight heparin (LMWH) or unfractionated heparin is indicated in pregnant people with VTE. Anticoagulants increase the risk of epidural hematoma in the setting of neuraxial analgesia (e.g., epidural or spinal anesthesia) in labor and must be withheld prior to placement. To ensure patient access to neuraxial analgesia in labor, prophylactic LMWH can be stopped 12 h before placement of an epidural catheter, whereas therapeutic LMWH can be discontinued for a full 24 h. Transition to unfractionated heparin as delivery approaches can shorten the time between anticoagulant administration and epidural placement. Unfractionated heparin can be used with an epidural catheter in place in those at highest risk of worsening thromboembolic disease.

NEOPLASIA

Cancer complicates ~1 in 1400 pregnancies. The four cancers that occur most commonly in pregnancy are cervical cancer, breast cancer, melanoma, and lymphoma. Also, cancer rates in pregnancy vary across the globe depending on local medical practices and exposures. In addition to cancers developing in other organs, gestational trophoblastic tumors can arise from the placenta.

Pregnancy has relatively little or no impact on the natural history of malignancies, despite the hormonal influences. People with a history of active or treated hormonally responsive breast cancer who choose to pursue pregnancy have similar rates of cancer-related events as those who do not. Spread of the cancer to the fetus (so-called vertical transmission) is exceedingly rare. However, managing cancer in a pregnant people is complex, with competing interests for mother and fetus. Generally, the management that optimizes maternal physiology is also best for the fetus. The best way to approach management of a pregnant woman with cancer is to ask, "What would one do in this clinical situation if she was not pregnant? Then, which, if any, aspect of those plans needs to be modified because she is pregnant?"

TREATMENT

Malignancy

Exposure of the developing fetus to therapeutic doses of ionizing radiation may cause adverse effects and is generally avoided during pregnancy.

Chemotherapy is associated with adverse fetal effects, but the significance of these depends on the specific agent and gestational age. Cytotoxic chemotherapy should virtually never be given in the first trimester due to risk of spontaneous abortion or malformation. If avoiding chemotherapy during this vulnerable time period could compromise maternal health, patients should be counseled about the role of therapeutic abortion to avoid serious neonatal sequelae.

A variety of single agents and combinations have been administered in the second and third trimesters, without a high frequency of toxic effects to the pregnancy or the fetus. Whether the association between chemotherapy and outcomes such as fetal growth restriction is due to the therapy or underlying malignancy is unknown. Literature supporting the short- and long-term neonatal safety of common agents is growing. For malignancies diagnosed closer to term or slowly progressive malignancies, delaying treatment until after delivery to avoid fetal exposure to chemotherapy may be desirable. If delaying therapy may compromise maternal prognosis, then treatment might be initiated after the first trimester of pregnancy with plans to deliver the fetus preterm to avoid excess cumulative exposure to chemotherapy. Neonatal prognosis is most closely linked to gestational age at delivery. Decisions regarding timing of delivery should contextualize this within the natural history of the disease, safety of the proposed treatment, and the person's goals of care.

NEUROLOGIC DISORDERS

Neurologic complaints such as headaches or neuropathies are common in pregnancy, and differentiating bothersome symptoms from life-threatening pathology is challenging **(Chap. 437)**. While most complaints are benign, *cerebrovascular accidents* (CVAs) should be high on the differential diagnosis and evaluated with MRI without gadolinium or a head computed tomography (CT) in cases of suspected stroke. Noncontrast MRI is more sensitive than CT in identifying early and small infarcts and cerebral venous thrombosis.

Exclusion of preeclampsia is important for any patient presenting with a headache after 20 weeks of gestation with a low threshold to assess for CVA due to the comparatively high prevalence in this population. Headache in preeclampsia can be associated with the *posterior reversible encephalopathy syndrome* (PRES), which is on the spectrum of *reversible cerebral vasoconstriction syndromes* (RCVS) that can present in pregnancy or the postpartum period with neurologic complaints. Peripheral nerve disorders associated with pregnancy include

Bell's palsy (idiopathic facial paralysis) **(Chap. 452)**, *carpal tunnel syndrome* (median nerve entrapment), or *meralgia paresthetica* (lateral femoral cutaneous nerve entrapment). *Restless leg syndrome* (RLS) is the most common peripheral nerve and movement disorder in pregnancy, affecting up to 20% of patients. If serum ferritin is low, oral iron supplementation is a first-line treatment option.

Pregnancy is safe for most people with neurologic disorders, with management considerations focusing on medication safety, the impact of pregnancy on the disease, and potential neonatal consequences. For those with *epilepsy* planning pregnancy, lamotrigine and levetiracetam are first-line monotherapies due to the abundance of safety data. Valproate is known to be associated with congenital malformations and should be discontinued in favor of another medication for people planning to conceive. Folic acid supplementation of 4 mg daily is recommended for those taking antiepileptic drugs (AEDs). Escalating doses of AEDs may be required due to increased clearance in pregnancy and guided by monthly monitoring of AED levels.

Patients with preexisting *multiple sclerosis* **(Chap. 455)** experience a gradual decrease in the risk of relapses as pregnancy progresses and, conversely, an increase in attack risk during the postpartum period. Prior to conception, disease-modifying therapies (DMTs) should be used to gain control of the disease. DMTs are typically withheld in pregnancy due to the decreased risk of relapse alongside limited neonatal safety data. Relapses should be treated with glucocorticoids, which may be given prophylactically after birth to reduce the risk of postpartum relapse. Finally, certain tumors, particularly pituitary adenoma **(Chap. 392)** and meningioma, may manifest during pregnancy because of accelerated growth, possibly driven by hormonal factors. Neuroimaging with noncontrast MRI may be required for women with a history of central nervous system (CNS) tumors to facilitate neuraxial analgesia.

GASTROINTESTINAL AND LIVER DISEASE

Up to 90% of pregnant people experience nausea and vomiting during the first trimester of pregnancy. *Hyperemesis gravidarum* (HG) is a severe form that prevents adequate fluid and nutritional intake and may require hospitalization to prevent dehydration and malnutrition. GDF15, which is produced by the placenta and is known to suppress appetite, may be involved in the pathogenesis of HG. Thiamine and folate supplementation and monitoring of electrolytes for evidence of refeeding syndrome should be considered in severe cases with evaluation for supplemental enteral nutrition in refractory disease.

Exacerbation of *inflammatory bowel disease* is common, and medical management, including the use of anti–tumor necrosis factor agents, parallels the nonpregnant state **(Chap. 337)**. Pregnancy is a risk factor for development or worsening of gallbladder disease such as cholelithiasis. This aggravation may be due to pregnancy-induced alteration in the metabolism of bile and fatty acids. *Intrahepatic cholestasis of pregnancy* is generally a third-trimester event presenting with profound pruritus and confirmed with an elevated level of bile acids with or without transaminitis. The association between cholestasis and stillbirth merits increased fetal surveillance and delivery before term. Symptoms can be improved with the use of ursodiol.

Acute fatty liver is a rare complication of pregnancy on the spectrum with HELLP syndrome and preeclampsia. Acute fatty liver of pregnancy is generally distinguished by markedly increased serum levels of bilirubin and ammonia and by hypoglycemia. Management of acute fatty liver of pregnancy includes delivery accompanied by supportive care. Most people recover within 7–10 days after delivery, but reports of fulminant liver failure requiring transplant underscore the importance of prompt diagnosis and management. The association between acute fatty liver in pregnancy and long-chain 3-hydroxyacyl CoA dehydrogenase (LCHAD) deficiency in the fetus inform the recommendation for close monitoring in the newborn with consideration of genetic testing.

All pregnant people should be screened for *hepatitis B virus* with HBsAg testing and *hepatitis C virus* **(Chap. 350)**. All infants receive hepatitis B vaccine, but infants born to mothers who are carriers of hepatitis B surface antigen should also receive hepatitis B immune globulin as soon after birth as possible to decrease the risk of vertical transmission. The presence of the hepatitis B E antigen in the mother and high viral load increase the risk of vertical transmission. Strategies to decrease vertical transmission of hepatitis C are limited to avoiding procedures (i.e., amniocentesis) that increase the risk. Postpartum referral to a specialist for consideration of potentially curative therapy is indicated.

INFECTIONS

BACTERIAL INFECTIONS

All pregnant patients are screened prenatally for syphilis, gonorrhea, and chlamydial infections, and the detection of any of these should result in prompt evaluation and treatment **(Chaps. 161, 187, and 194)**. Other than *bacterial vaginosis*, the most common bacterial infections during pregnancy involve the urinary tract **(Chap. 140)**. All pregnant people should be screened with a urine culture for *asymptomatic bacteriuria* at the first prenatal visit. Pregnancy is an indication for treatment of asymptomatic bacteriuria to avoid pyelonephritis. Progesterone-mediated ureteral and bladder smooth muscle relaxation, coupled with compression effects of the enlarging uterus, promote stasis and increase the risk of these conditions. Pregnant women who develop pyelonephritis should be treated with inpatient IV antibiotic administration due to the elevated risk of urosepsis and acute respiratory distress syndrome in pregnancy-associated pyelonephritis. Pregnant people with recurrent urinary tract infections or one episode of pyelonephritis should receive daily antibiotic suppressive treatment throughout the remainder of their pregnancy. Options for suppressive treatment include nitrofurantoin (50 or 100 mg at bedtime) or cephalexin (250 or 500 mg at bedtime).

VIRAL INFECTIONS

All pregnant people should be screened for hepatitis B virus, hepatitis C virus, and HIV as well as immunity to rubella and varicella. Screening for varicella immunity begins with obtaining a history of varicella immunization or infection. Testing for antibodies to varicella is reserved for cases where there is no history of prior immunization or infection, because the available varicella antibody test has low sensitivity and does not reliably detect antibodies in people who have been immunized.

Influenza **(See also Chap. 206)** Pregnant people with influenza are at increased risk of serious complications and death. All people who are pregnant or plan to become pregnant in the near future should receive inactivated influenza vaccine. The prompt initiation of antiviral treatment is recommended for pregnant people in whom influenza is suspected. Treatment can be reconsidered once the results of high-sensitivity tests are available. Prompt initiation of treatment lowers the risk of admission to an intensive care unit and death.

COVID-19 Pregnancy is a risk factor for severe COVID-19 infection. All unvaccinated people planning pregnancy or who are pregnant should receive a COVID-19 vaccine.

Cytomegalovirus Infection The most common cause of congenital viral infection in the United States is cytomegalovirus (CMV) **(Chap. 200)**. As many as 50–90% of women of childbearing age have antibodies to CMV, but only rarely does CMV reactivation result in neonatal infection. More commonly, primary CMV infection during pregnancy creates a risk of congenital CMV. No currently accepted treatment of CMV infection during pregnancy has been demonstrated to protect the fetus effectively. Severe CMV disease in the newborn is characterized most often by petechiae, hepatosplenomegaly, and jaundice. Chorioretinitis, microcephaly, intracranial calcifications, hepatitis, hemolytic anemia, and purpura may also develop. CNS involvement can result in the development of psychomotor, ocular, auditory, and dental abnormalities over time. People with a primary CMV infection should delay conception for 6 months.

Herpesvirus Infection **(See also Chap. 197)** The acquisition of genital herpes during pregnancy is associated with spontaneous

abortion, prematurity, and congenital and neonatal herpes. Disseminated neonatal herpes carries with it high mortality and morbidity rates from CNS involvement. A cohort study of pregnant people without evidence of previous herpesvirus infection demonstrated that ~2% acquired a new herpesvirus infection during the pregnancy and ~60% of the newly infected women had no clinical symptoms. The risk of transmission was increased in those with infections closer to delivery. The risk of active genital herpes lesions at term can be reduced by prescribing acyclovir (400 mg three times daily) for the last 4 weeks of pregnancy to all people who had an episode of genital herpes during the pregnancy. Those with active genital herpes lesions at the time of presentation in labor should be delivered by cesarean section.

Rubella (See also Chap. 212) Rubella virus is a known teratogen; first-trimester rubella carries a high risk of fetal malformations, although the risk significantly decreases later in pregnancy. Congenital rubella infection may be diagnosed by percutaneous umbilical-blood sampling with the detection of IgM antibodies in fetal blood. All pregnant people or those considering pregnancy should be tested for their immune status to rubella.

Parvovirus Infection (See also Chap. 202) Infection with human parvovirus B19 may occur during pregnancy with the possibility of fetal transmission in the absence of immunity. It rarely causes significant maternal sequelae but can lead to erythroid aplasia in the fetus with resultant anemia, fetal hydrops, and death. Management includes screening for fetal anemia with Doppler assessment of the middle cerebral artery and consideration of intrauterine transfusion of red blood cells to the fetus to avoid the physiologic consequences of anemia while awaiting recovery of the fetal bone marrow.

HIV Infection (See also Chap. 208) The predominant cause of HIV infection in children is transmission of the virus from mother to newborn during the perinatal period. All pregnant women should be screened for HIV infection. Factors that increase the risk of mother-to-newborn transmission include high maternal viral load, low maternal CD4+ T-cell count, prolonged labor, prolonged duration of membrane rupture, and the presence of other genital tract infections, such as syphilis or herpes. Antiretroviral therapy (ART) has decreased the rate of perinatal transmission from 20% to ~1%. For those receiving antepartum ART, viral load guides the decision for vaginal versus cesarean delivery and need for adjunct intrapartum zidovudine. People with an undetectable viral load are at the lowest risk of transmission and require no additional therapy, whereas those without antepartum ART exposure or with viral loads >1000 copies/mL at delivery require IV zidovudine and a prelabor cesarean delivery, typically scheduled at 38 weeks. Cesarean delivery should be reserved for obstetric indications for women with ≥50 but ≤1000 copies/mL, and intrapartum zidovudine can be considered.

Zika Virus Zika virus (ZIKV) can be transmitted from mother to fetus throughout gestation and often results in severe microcephaly, CNS malformations, and fetal death. Symptomatic pregnant people with relevant epidemiologic exposure within 2 weeks of symptom onset should have serum and urine tested for ZIKV and dengue nucleic acids by nucleic acid amplification test and IgM serology. Sequential obstetrical ultrasound is recommended to assess for fetal growth and anomalies. Couples considering pregnancy should avoid travel to areas with known mosquito transmission of ZIKV.

VACCINATIONS

(See also Chap. 129) For rubella-nonimmune individuals contemplating pregnancy, measles-mumps-rubella vaccine should be administered, ideally at least 3 months prior to conception, but otherwise in the immediate postpartum period. All pregnant people should be vaccinated against influenza and COVID-19. Administration of one dose of the tetanus, diphtheria, and pertussis (Tdap) vaccine between 27 and 36 weeks of gestation is recommended to promote maternal IgG production and reduce the risk of neonatal pertussis due to transplacental passage of IgG.

MATERNAL MORTALITY

Maternal death is defined as death occurring during pregnancy or within 42 days of completion of pregnancy from a cause related to or aggravated by pregnancy, but not due to accident or incidental causes. The maternal mortality rate is the number of maternal deaths per 100,000 live births. From 1935 to 2007, the U.S. maternal mortality rate decreased from nearly 600/100,000 births to 12.7/100,000 births, rising thereafter. In 2021, the U.S. maternal mortality rate was 32.9/100,000 births. An increasingly complex patient population, with multiple comorbidities, and the COVID-19 pandemic likely contributed to the high rate of maternal death in 2021. There are significant racial and ethnic disparities in the maternal mortality rate, with a nearly fourfold increased risk of death for non-Hispanic black women compared to non-Hispanic white women (69.9 vs 26.6 deaths per 100,000 live births, respectively) (Chap. 11). Women over 40 years of age had a maternal mortality rate of 139 per 100,000 live births.

Pregnancy-related death is defined as the death of a person while pregnant or within 1 year of the end of pregnancy from any cause related to or aggravated by pregnancy. Cardiovascular disease, including cardiomyopathy, accounted for nearly a third of pregnancy-related deaths from 2014 to 2017 followed by infection, noncardiovascular medical conditions, hemorrhage, and thrombotic events. The relative contribution of medical disease to pregnancy-related death, coupled with knowledge that one in three pregnancy-related deaths occur 1 week to 1 year after delivery, highlights the role of the specialist in internal medicine in reducing maternal mortality.

In some countries in sub-Saharan Africa and southern Asia, the maternal mortality rate is >500/100,000 live births. The most common causes of maternal death in these countries are maternal hemorrhage, hypertensive disorders, infection, obstructed labor, and complications from unsafe pregnancy termination. The health interventions that have the greatest impact on maternal health include improving the following components of the health system: (1) access to contraceptive services in order to space births and limit total family size; (2) access to safe pregnancy termination; (3) presence of trained birth attendants at all deliveries; and (4) transportation to emergency obstetrical centers that can provide intensive medical and surgical services, including cesarean delivery. Maternal death is a global public health tragedy that could be mitigated with the application of modest resources.

SUMMARY

With improved diagnostic and therapeutic modalities as well as advances in the treatment of infertility, more patients with serious medical complications will be seeking to become pregnant and will require complex obstetric care. Improved outcomes of pregnancy in these people will be best attained by a multidisciplinary team of internists, maternal-fetal medicine (high-risk obstetrics) specialists, pediatricians, and anesthesiologists assembled to counsel these patients about the risks of pregnancy and to optimize interconception care. The importance of preconception counseling and the impact of events of pregnancy on lifelong disease cannot be overstated. It is the responsibility of all physicians caring for women in the reproductive age group to assess their patients' reproductive plans as part of their overall health evaluation and to integrate pregnancy-related diagnoses into their assessment of future risk for cardiovascular disease.

492 Medical Evaluation of the Patient Undergoing Noncardiac Surgery

Prashant Vaishnava, David I. Sahar, Kim A. Eagle

Cardiovascular and pulmonary complications continue to account for major morbidity and mortality in patients undergoing noncardiac surgery. Emerging evidence-based practices dictate that the internist should perform an individualized evaluation of the surgical patient to provide an accurate preoperative risk assessment and stratification that will guide optimal perioperative risk-reduction strategies. This chapter reviews cardiovascular and pulmonary preoperative risk assessment, emphasizing the goal-directed management of patients at elevated risk for adverse cardiovascular outcomes in the perioperative period. In addition, perioperative management of diabetes mellitus and prophylaxis of endocarditis and for venous thromboembolism are reviewed.

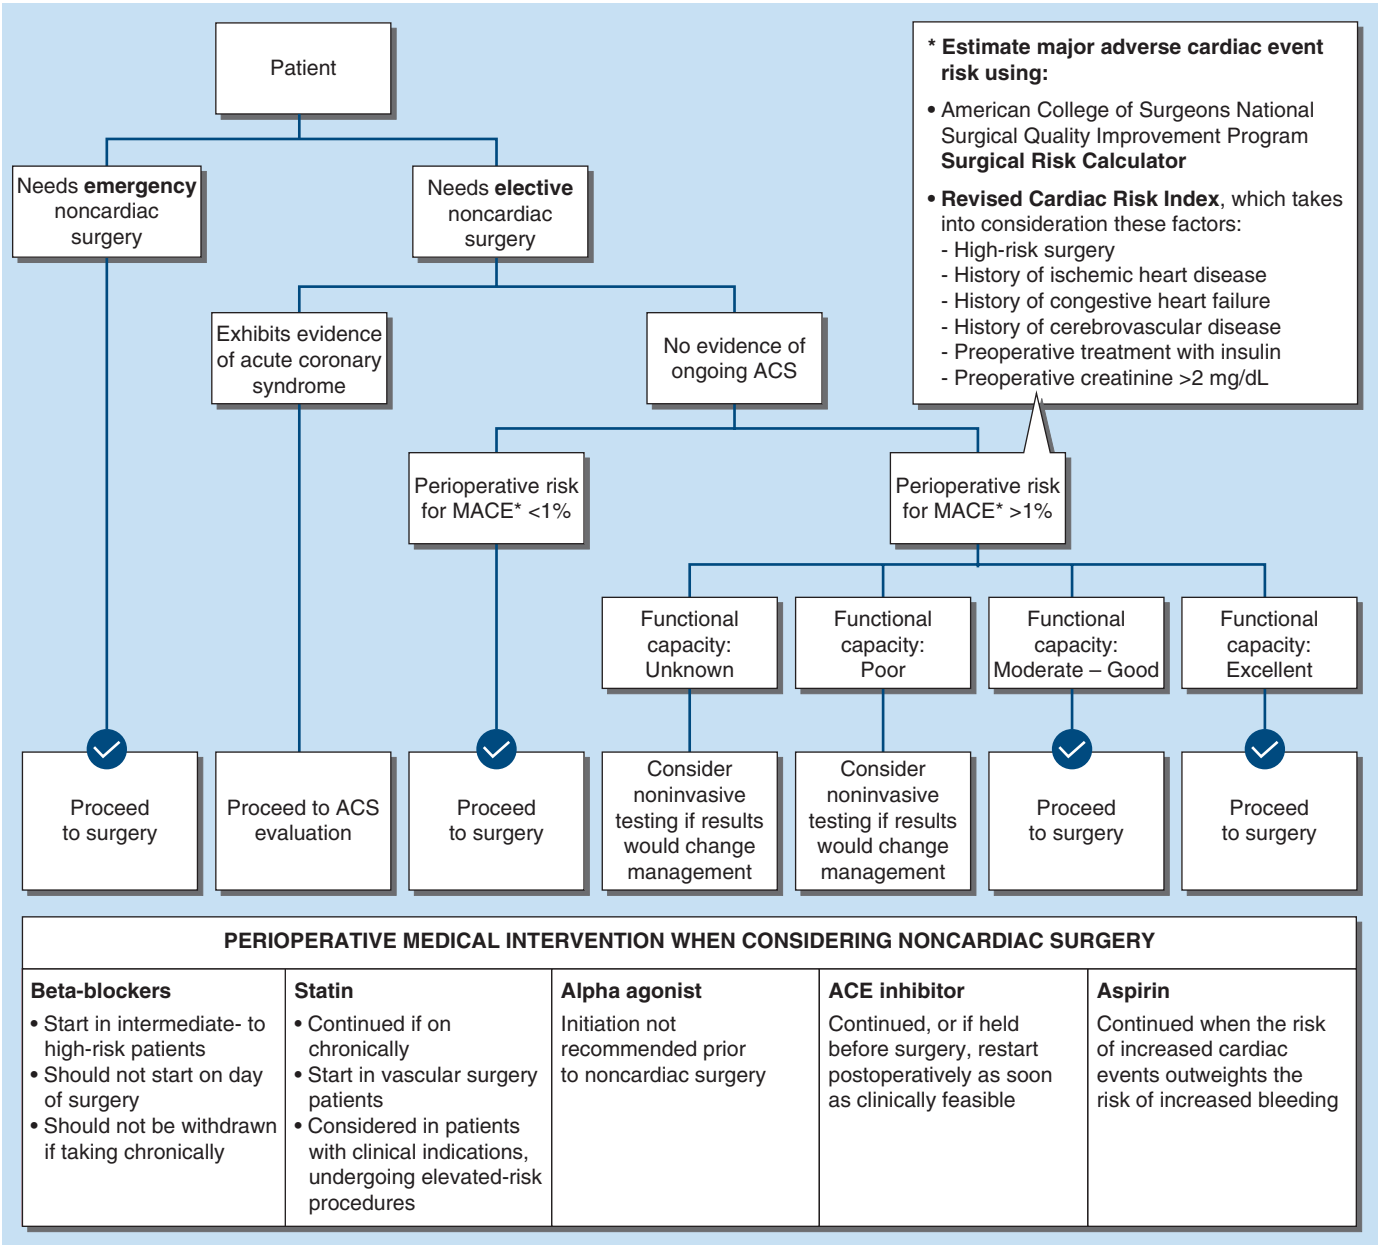
EVALUATION OF INTERMEDIATE- AND HIGH-RISK PATIENTS

Simple, standardized preoperative screening questionnaires, such as the one shown in **Table 492-1**, have been developed for the purpose of identifying patients at intermediate or high risk who may benefit from a more detailed clinical evaluation. Evaluation of such patients for surgery should always begin with a thorough history and physical examination and with a 12-lead resting electrocardiogram, in accordance with the American College of Cardiology/American Heart Association guidelines. The history should focus on symptoms of occult cardiac or pulmonary disease. The urgency of the surgery should be determined, as true emergency procedures are associated with unavoidably higher morbidity and mortality risk. Preoperative laboratory testing should be carried out only for specific clinical conditions, as noted during clinical examination. Thus, healthy patients of any age who are undergoing elective surgical procedures without coexisting medical conditions should not require any testing unless the degree of surgical stress may result in unusual changes from the baseline state.

PREOPERATIVE CARDIAC RISK ASSESSMENT

A stepwise approach to cardiac risk assessment and stratification in patients undergoing noncardiac surgery is illustrated in **Fig. 492-1**. The evaluation begins with characterization of the combined surgical and clinical risk into categories of low (<1%) and elevated risk for major adverse cardiovascular events (MACEs). Select surgeries are associated with very low risk for MACE; these surgeries and procedures include select ophthalmologic surgeries (e.g., cataract surgery), select endoscopic procedures, and select superficial procedures. Patients undergoing these low-risk procedures should proceed to surgery without further testing. Clinical risk may be estimated with the American College of Surgeons' National Surgical Quality Improvement Program (NSQIP) risk calculator (*http://www.riskcalculator.facs.org*) or with calculation of the Revised Cardiac Risk Index (RCRI). Additional tools include the Surgical Outcome Risk Tool (SORT) or the American University of Beirut (AUB)-HAS2 Cardiovascular Risk Index. The former is based, in part, on the American Society of Anesthesiologists Physical Status (ASA-PS) grade; the latter provides for estimation of 30-day death, myocardial infarction (MI), or stroke risk.

Previous studies have compared several cardiac risk indices. The American College of Surgeons' NSQIP prospective database has identified five predictors of perioperative MI and cardiac arrest based on increasing age, American Society of Anesthesiologists class, type of surgery, dependent functional status, and abnormal serum creatinine level. However, given its accuracy and simplicity, the RCRI **(Table 492-2)** is often the favored risk index. The RCRI relies on the presence or absence of six identifiable predictive factors: high-risk surgery, ischemic heart disease, congestive heart failure, cerebrovascular disease, diabetes mellitus treated with insulin, and renal insufficiency with a creatinine >2.0 mg/dL. Each of these predictors is assigned one point. The risk of major cardiac events—defined as MI, pulmonary edema, ventricular fibrillation or primary cardiac arrest, and complete heart block—can then be predicted. Based on the presence of none, one, two, three, or more of these clinical predictors, the rate of development of one of these four major cardiac events is estimated to be 0.4%, 0.9%, 7%, and 11%, respectively **(Fig. 492-2)**. The clinical utility of the RCRI is to identify patients with three or more predictors who are at very high risk (≥11%) for cardiac complications and who may benefit from further risk stratification with noninvasive cardiac testing, initiation of preoperative preventive medical management, or avoidance of surgery.



For patients at elevated combined clinical and surgical risk for MACE, the stepwise perioperative cardiac assessment for coronary

TABLE 492-1 Standardized Preoperative Questionnaire[a]

1. Age, weight, height
2. Are you:
   Female and 55 years of age or older or male and 45 years of age or older?
   If yes, are you 70 years of age or older?
3. Do you take anticoagulant medications ("blood thinners")?
4. Do you have or have you had any of the following heart-related conditions?
   Heart disease
   Heart attack within the last 6 months
   Angina (chest pain)
   Irregular heartbeat
   Heart failure
5. Do you have or have you ever had any of the following?
   Rheumatoid arthritis
   Kidney disease
   Liver disease
   Diabetes
6. Do you get short of breath when you lie flat?
7. Are you currently on oxygen treatment?
8. Do you have a chronic cough that produces any discharge or fluid?
9. Do you have lung problems or diseases?
10. Have you or any blood member of your family ever had a problem other than nausea with any anesthesia?
    If yes, describe:
11. If female, is it possible that you are pregnant?
    Pregnancy test:
    Please list date of last menstrual period:

[a]University of Michigan Health System patient information report. Patients who answer yes to any of questions 2–9 should receive a more detailed clinical evaluation.

PERIOPERATIVE MEDICAL INTERVENTION WHEN CONSIDERING NONCARDIAC SURGERY

Beta-blockers	Statin	Alpha agonist	ACE inhibitor	Aspirin
• Start in intermediate- to high-risk patients • Should not start on day of surgery • Should not be withdrawn if taking chronically	• Continued if on chronically • Start in vascular surgery patients • Considered in patients with clinical indications, undergoing elevated-risk procedures	Initiation not recommended prior to noncardiac surgery	Continued, or if held before surgery, restart postoperatively as soon as clinically feasible	Continued when the risk of increased cardiac events outweighs the risk of increased bleeding

FIGURE 492-1 Composite algorithm for cardiac risk assessment and stratification in patients undergoing noncardiac surgery. Preoperative evaluation involves a stepwise clinical evaluation. Those individuals requiring emergency surgery should proceed without further risk stratification. Acute coronary syndrome (step 2) should be evaluated and treated according to goal-directed medical therapy. For patients awaiting nonemergent surgeries and without acute coronary syndrome, perioperative risk is a combination of clinical and surgical risk. Select procedures and surgeries (e.g., select endoscopic procedures) are associated with low (<1%) perioperative risk, and no further clinical testing is generally necessary. For those procedures associated with elevated risk, an assessment of functional capacity informs the decision for further testing. Those individuals with moderate or greater functional capacity do not require further testing and should proceed to surgery. Individuals with poor or unknown functional capacity may require pharmacologic stress testing if it would change decision-making or perioperative care. ACE, angiotensin-converting enzyme; ACS, acute coronary syndrome; MACE, major adverse cardiovascular event. *(Reproduced with permission from AY Patel et al: Cardiac risk of noncardiac surgery. J Am Coll Cardiol 66:2140, 2015.)*

artery disease (CAD) proceeds with consideration of functional capacity. Participation in activities of daily living offers an expression of functional capacity, often expressed in terms of metabolic equivalents (METs). For predicting perioperative events, poor exercise tolerance has been defined as the inability to walk four blocks or climb two flights of stairs at a normal pace or to meet a MET level of 4 (e.g., carrying objects of 15–20 lb. or playing golf or doubles tennis) because of the development of dyspnea, angina, or excessive fatigue (Table 492-3). Patients with moderate or greater (≥4 METs) functional capacity (e.g., climbing up a flight of stairs, walking up a hill, or walking on level ground at 4 mph) generally should not undergo further noninvasive cardiac testing prior to elective noncardiac surgery. Those patients with poor (<4 METs) or unknown functional capacity should undergo pharmacologic stress testing if the results of such testing would impact decision-making or perioperative care.

PREOPERATIVE NONINVASIVE CARDIAC TESTING FOR RISK STRATIFICATION

There is little evidence to support widespread application of preoperative noninvasive cardiac testing for all patients undergoing major surgery. The current paradigm to guide the need for noninvasive cardiac testing is to perform such testing in patients with poor or unknown capacity if it would alter clinical management or modify perioperative care. Options for pharmacologic stress testing include dobutamine stress echocardiography or myocardial perfusion imaging with coronary vasodilator stress (dipyridamole, adenosine, or regadenoson) with thallium-201 and/or technetium-99m. Similarly, there is a limited

TABLE 492-2 Clinical Markers Included in the Revised Cardiac Risk Index

High-Risk Surgical Procedures
Vascular surgery (except carotid endarterectomy)
Major intraperitoneal or intrathoracic procedures
Ischemic Heart Disease
History of myocardial infarction
Current angina considered to be ischemic
Requirement for sublingual nitroglycerin
Positive exercise test
Pathological Q waves on ECG
History of PCI and/or CABG with current angina considered to be ischemic
Congestive Heart Failure
Left ventricular failure by physical examination
History of paroxysmal nocturnal dyspnea
History of pulmonary edema
S_3 gallop on cardiac auscultation
Bilateral rales on pulmonary auscultation
Pulmonary edema on chest x-ray
Cerebrovascular Disease
History of transient ischemic attack
History of cerebrovascular accident
Diabetes Mellitus
Treatment with insulin
Chronic Renal Insufficiency
Serum creatinine >2 mg/dL

Abbreviations: CABG, coronary artery bypass grafting; ECG, electrocardiogram; PCI, percutaneous coronary intervention.

role for perioperative coronary computed tomography angiography (CCTA) in patients undergoing noncardiac surgery. While some investigators have shown in observational studies that CCTA may improve prediction of MACEs perioperatively when compared to RCRI, there are few data to demonstrate that such improved prognostication translates to improved outcomes. Furthermore, coronary revascularization before noncardiac surgery is not recommended for the express purpose of reducing perioperative cardiac events. That said, revascularization before noncardiac surgery should be considered in patients if it would

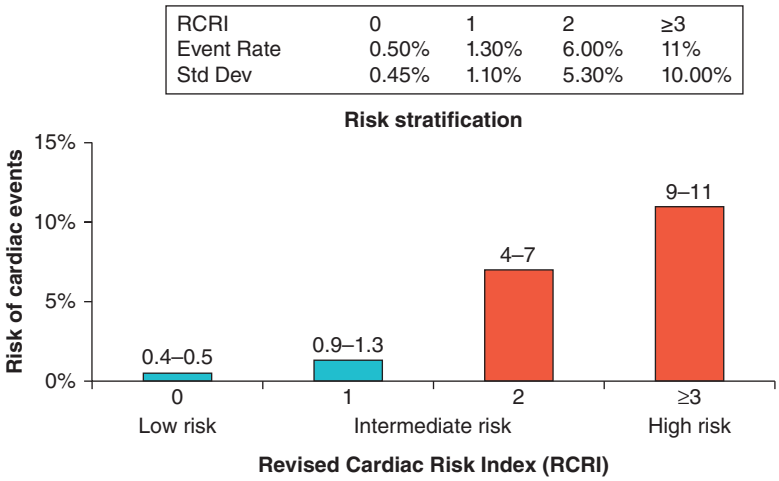

FIGURE 492-2 Risk stratification based on the Revised Cardiac Risk Index; derivation and prospective validation of a simple index for prediction of cardiac risk in patients undergoing major noncardiac surgery. Cardiac events include myocardial infarction, pulmonary edema, ventricular fibrillation, cardiac asystole, and complete heart block. *(Adapted from TH Lee et al: Circulation 100:1043, 1999.)*

TABLE 492-3 Assessment of Cardiac Risk by Functional Status

Risk	Higher	• Has difficulty with adult activities of daily living
		• Cannot walk four blocks or up two flights of stairs or does not meet a MET level of 4
		• Is inactive but has no limitations
		• Is active: easily does vigorous tasks
	Lower	• Performs regular vigorous exercises

be indicated regardless of the surgery planned and instead according to clinical practice guidelines. In the Coronary Artery Revascularization Prophylaxis trial, there were no differences in perioperative and long-term cardiac outcomes with or without preoperative coronary revascularization; of note, patients with left main disease were excluded.

RISK MODIFICATION: PREVENTIVE STRATEGIES TO REDUCE CARDIAC RISK

Perioperative Coronary Revascularization *Prophylactic* coronary revascularization with either coronary artery bypass grafting (CABG) or percutaneous coronary intervention (PCI) provides no short- or mid-term survival benefit for patients *without* left main CAD or three-vessel CAD in the presence of poor left ventricular systolic function and is *not recommended* for patients with stable CAD before noncardiac surgery. Although PCI is associated with lower procedural risk than is CABG in the perioperative setting, the placement of a coronary artery stent soon before noncardiac surgery may increase the risk of bleeding during surgery if dual antiplatelet therapy (DAPT) (aspirin and $P2Y_{12}$) is administered; moreover, stent placement shortly before noncardiac surgery increases the perioperative risk of MI and cardiac death due to stent thrombosis if such therapy is withdrawn prematurely **(Chap. 287)**. It is recommended that, if possible, elective noncardiac surgery be delayed for 6 months after elective PCI and 12 months after acute coronary syndrome. Contemporary stent platforms allow for greater flexibility in the earlier interruption of DAPT; accordingly, time sensitive noncardiac surgery could be a consideration as soon as 1 month of treatment with DAPT has passed. For patients who *must* undergo noncardiac surgery early (>14 days) after PCI, balloon angioplasty without stent placement appears to be a reasonable alternative because DAPT is not necessary in such patients.

PERIOPERATIVE PREVENTIVE MEDICAL THERAPIES The goal of perioperative preventive medical therapies with β-adrenergic antagonists, hydroxymethylglutaryl-coenzyme A (HMG-CoA) reductase inhibitors (statins), and antiplatelet agents is to reduce perioperative adrenergic stimulation, ischemia, and inflammation, all of which are heightened during the perioperative period.

β-ADRENERGIC ANTAGONISTS The use of perioperative beta blockade should be based on a thorough assessment of a patient's perioperative clinical and surgery-specific cardiac risk (e.g., as with the RCRI). The paradigm for beta blockade in the perioperative period has shifted in recent years owing, first, to the publication of the PeriOperative Ischemic Evaluation (POISE) trial demonstrating that, while perioperative beta blockade reduces the perioperative risk for MI, this is at the expense of increased death and stroke. Regarding POISE, this trial has been scrutinized for the use of an excessive dose of beta blocker in the perioperative period and one that may not be reflective of clinical practice, nor one that was titrated in the days or weeks preceding the procedure or surgery. Second, research misconduct has discredited the Dutch Echocardiographic Cardiac Risk Evaluation Applying Stress Echocardiography (DECREASE) family of studies, which previously contributed to the bedrock of data supporting the use of perioperative beta blockade but have now been retracted.

Current guidelines emphasize the following key points:

1. Continuation of beta blockade in patients undergoing surgery and who have been receiving such therapy chronically.
2. Avoidance of beta-blocker withdrawal or initiation on the day of surgery.
3. Consideration of initiation of beta-blocker therapy perioperatively (ideally far enough in advance to assess safety and tolerability) in very select high-risk patients, namely, those with intermediate- or high-risk ischemia or three or more RCRI risk factors.

HMG-COA REDUCTASE INHIBITORS (STATINS) A number of prospective and retrospective studies support the perioperative prophylactic use of statins for reduction of cardiac complications in patients with established atherosclerosis. For patients undergoing noncardiac surgery and currently taking statins, statin therapy *should be continued* to reduce perioperative cardiac risk. Initiation of statin therapy is *reasonable* for patients undergoing vascular surgery independent of clinical risk. There is equipoise about the perioperative initiation of statin therapy in patients undergoing other elevated-risk procedures. In the Lowering the Risk of Operative Complications Using Atorvastatin Loading Dose (LOAD) randomized, placebo-controlled trial, the use of 80 mg of atorvastatin within 18 h before surgery and then followed by 40 mg daily for 7 days in statin-naïve patients (24% of whom had a history of cardiovascular disease) did not reduce the risk of major adverse events.

ANGIOTENSIN-CONVERTING ENZYME (ACE) INHIBITORS It is important to maintain continuity of therapy with inhibitors of the renin-angiotensin-aldosterone system (when such therapy is used for the treatment of heart failure or hypertension).

ORAL ANTIPLATELET AGENTS The 4- to 6-week period following implantation of an intracoronary stent (bare metal or drug eluting) constitutes the period of time of greatest risk for the development of stent thrombosis. If possible, noncardiac surgery should be avoided in this vulnerable period. The duration of DAPT thereafter is dictated by the circumstances in which PCI was performed and whether the indication was stable ischemic heart disease or acute coronary syndrome. For the former among patients treated with a drug-eluting stent (DES), DAPT should be given for at least 6 months. For the latter, DAPT should be given for at least 12 months. However, DAPT may be interrupted to allow for noncardiac surgery 30 days after bare metal stent (BMS) and 6 months after DES, respectively. Elective, noncardiac surgery should be delayed for 5 days since the last dose of clopidogrel; 7 days since the last dose of prasugrel; and 3–5 days since the last dose of ticagrelor. The use of cangrelor, an intravenous reversible $P2Y_{12}$ receptor antagonist, may be an appealing bridging strategy, although studies of its use in those undergoing cardiac and noncardiac surgery are limited. If $P2Y_{12}$ inhibitor therapy (clopidogrel, prasugrel, or ticagrelor) is interrupted or discontinued in patients who have received intracoronary stents, aspirin should be continued perioperatively (save select circumstances where the risk of bleeding may be catastrophic as in neurosurgical or spinal procedures) and the $P2Y_{12}$ receptor inhibitor should be restarted as soon as possible postoperatively. Decisions surrounding antiplatelet management in the perioperative setting among patients who have received intracoronary stents are complex and should involve multidisciplinary decision-making.

α_2 AGONISTS Based on the results of POISE-2 (a large multicenter, international, blinded randomized clinical trial of aspirin and clonidine), α_2 agonists for prevention of cardiac events are not recommended in patients who are undergoing noncardiac surgery. In this trial, clonidine increased the rate of nonfatal cardiac arrest and clinically important hypotension, while reducing the rate of death or nonfatal MI.

CALCIUM CHANNEL BLOCKERS Evidence is lacking to support the use of calcium channel blockers as a prophylactic strategy to decrease perioperative risk in major noncardiac surgery.

SODIUM-GLUCOSE COTRANSPORTER 2 INHIBITORS The use of sodium-glucose cotransporter 2 (SGLT-2) inhibitors has grown in recent years owing to their beneficial impact in patients with and without type 2 diabetes mellitus and with heart failure with either reduced or preserved ejection fraction. However, euglycemic diabetic ketoacidosis is a known, but rare, complication with this therapy and one that may be precipitated by changes and fasting in the perioperative state. Accordingly, SGLT-2 inhibitor therapy should be interrupted for at least 3–4 days prior to scheduled noncardiac surgery.

TABLE 492-4 Gradation of Mortality Risk of Common Noncardiac Surgical Procedures

Higher	• Emergent major operations, especially in the elderly • Aortic and other noncarotid major vascular surgery (endovascular and nonendovascular) • Prolonged surgery associated with large fluid shift and/or blood loss
Intermediate	• Major thoracic surgery • Major abdominal surgery • Carotid endarterectomy surgery • Head/neck surgery • Orthopedic surgery • Prostate surgery
Lower	• Eye, skin, and superficial surgery • Endoscopic procedures

ANESTHETICS Mortality risk is low with safe delivery of modern anesthesia, especially among low-risk patients undergoing low-risk surgery (Table 492-4). Inhaled anesthetics have predictable circulatory and respiratory effects: all decrease arterial pressure in a dose-dependent manner by reducing sympathetic tone and causing systemic vasodilation, myocardial depression, and decreased cardiac output. Inhaled anesthetics also cause respiratory depression, with diminished responses to both hypercapnia and hypoxemia, in a dose-dependent manner; in addition, these agents have a variable effect on heart rate. Prolonged residual neuromuscular blockade also increases the risk of postoperative pulmonary complications due to reduction in functional residual lung capacity, loss of diaphragmatic and intercostal muscle function, atelectasis, and arterial hypoxemia from ventilation–perfusion mismatch.

Several meta-analyses have shown that rates of pneumonia and respiratory failure are lower among patients receiving neuroaxial anesthesia (epidural or spinal) rather than general anesthesia. However, there were no significant differences in cardiac events between the two approaches. Evidence from a meta-analysis of randomized controlled trials supports postoperative epidural analgesia for >24 h for the purpose of pain relief. However, the risk of epidural hematoma in the setting of systemic anticoagulation for venous thromboembolism prophylaxis (see below) and postoperative epidural catheterization must be considered.

PREOPERATIVE PULMONARY RISK ASSESSMENT

Perioperative pulmonary complications occur frequently and lead to significant morbidity and mortality. Clinical practice guidelines recommend the following:

1. All patients undergoing noncardiac surgery should be assessed for risk of pulmonary complications (Table 492-5).
2. While select studies have suggested that quitting smoking shortly before surgery increases the risk for postoperative complications through increased sputum production and/or decreased cough, meta-analysis of the available data has challenged this, and all patients should be advised of the imperative to stop smoking presurgically.
3. Patients undergoing emergency or prolonged (3–4 h) surgery; aortic aneurysm repair; vascular surgery; major abdominal, thoracic, neurologic, head, or neck surgery; and general anesthesia should

TABLE 492-5 Predisposing Risk Factors for Pulmonary Complications

TABLE 492-6 Risk Modification to Reduce Perioperative Pulmonary Complications

Preoperatively
• Smoking cessation
• Training in proper lung expansion techniques
• Inhalation bronchodilator and/or steroid therapy, when indicated
• Control of infection and secretion, when indicated
• Weight reduction, when appropriate
Intraoperatively
• Limited duration of anesthesia
• Avoidance of long-acting neuromuscular blocking drugs, when indicated
• Prevention of aspiration and maintenance of optimal bronchodilation
Postoperatively
• Optimization of inspiratory capacity maneuvers, with attention to:
• Mobilization of secretions
• Early ambulation
• Encouragement of coughing
• Selective use of a nasogastric tube
• Adequate pain control without excessive narcotics

Source: From VA Lawrence et al: Ann Intern Med 144:596, 2006, and WF Dunn, PD Scanlon: Mayo Clin Proc 68:371, 1993.

be considered to be at elevated risk for postoperative pulmonary complications.

4. Patients at higher risk of pulmonary complications should undergo incentive spirometry, deep breathing exercises, cough encouragement, postural drainage, percussion and vibration, suctioning and ambulation, intermittent positive-pressure breathing, continuous positive airway pressure, and selective use of a nasogastric tube for postoperative nausea, vomiting, or symptomatic abdominal distention to reduce postoperative risk. Multiple pulmonary risk indices are available to estimate the postoperative risk of respiratory failure, pneumonia, and other pulmonary complications; among these is the ARISCAT risk index, which accounts for the following seven risk factors: age, low preoperative oxygen saturation, respiratory infection within the preceding month, upper abdominal or thoracic surgery, surgery lasting >2 h, hemoglobin <10 g/dL, and emergency surgery **(Table 492-6)**.
5. Preoperative spirometry and chest radiography should not be used routinely for predicting risk of postoperative pulmonary complications but may be appropriate for patients with chronic obstructive pulmonary disease or asthma.
6. Spirometry is of value before lung resection in determining candidacy for coronary artery bypass; however, it does not provide a spirometric threshold for extrathoracic surgery below which the risks of surgery are unacceptable.
7. Pulmonary artery catheterization, administration of total parenteral nutrition (as opposed to no supplementation), or total enteral nutrition has no consistent benefit in reducing postoperative pulmonary complications.

PERIOPERATIVE MANAGEMENT AND PROPHYLAXIS

DIABETES MELLITUS

(See also Chaps. 415-417) Many patients with diabetes mellitus have significant symptomatic or asymptomatic CAD and may have silent myocardial ischemia due to autonomic dysfunction. Intensive (vs lenient) glycemic control in the perioperative period is generally not associated with improved outcomes and may increase the risk of hypoglycemia. Practice guidelines advocate a target glucose range of 100–180 mg/dL in the perioperative period. Oral hypoglycemic agonists should not be given on the morning of surgery. Perioperative hyperglycemia should be treated with IV infusion of short-acting insulin or subcutaneous sliding-scale insulin. Patients whose diabetes is diet controlled may proceed to surgery with close postoperative monitoring.

INFECTIVE ENDOCARDITIS

(See also Chap. 133) Prophylactic antibiotics should be administered to the following patients before dental procedures that involve manipulation of gingival tissue, manipulation of the periapical region of teeth, or perforation of the oral mucosa: those with prosthetic cardiac valves (including transcatheter prosthetic valves); prosthetic material used in valve repair (annuloplasty ring or artificial chord); previous infective endocarditis; cardiac transplant recipients with valvular regurgitation from a structurally abnormal valve; and unrepaired cyanotic congenital heart disease or repaired congenital heart disease, with residual shunts or valvular regurgitation at the site adjacent to the site of a prosthetic patch or prosthetic device.

AORTIC STENOSIS

Previous American College of Cardiology/American Heart Association guidelines have cautioned against surgery in patients with severe aortic stenosis, citing a 10% mortality risk. More recent guidance, rooted in contemporary data, offers greater latitude for noncardiac surgery in appropriately selected patients with severe aortic stenosis. In an analysis of patients undergoing moderate- or high-risk surgery at the Mayo Clinic from 2000 to 2010, there was no significant difference in 30-day mortality between those with severe aortic stenosis and matched controls (5.9 vs 3.1%, $p = .13$); however, those with severe aortic stenosis had more MACEs (18.8 vs 10.5%, $p = .01$), mainly due to heart failure. In sum, severe aortic stenosis is associated with adverse outcomes in patients undergoing noncardiac surgery; however, in contemporary cohorts, this risk is less than has previously been stated. Patients with severe symptomatic aortic stenosis should generally undergo aortic valve intervention (surgical aortic valve replacement or transcatheter aortic valve implantation) if noncardiac surgery can be deferred. Asymptomatic patients with severe aortic stenosis and preserved ejection fraction can generally safely undergo low- or intermediate-risk noncardiac surgery. Balloon valvotomy is usually not recommended but may serve a role in the minority of patients who need "bridging" to a necessary surgery or procedure.

VENOUS THROMBOEMBOLISM

(See also Chap. 290) Perioperative prophylaxis of venous thromboembolism should follow established guidelines of the American College of

Chest Physicians. Aspirin is not supported as a single agent for thromboprophylaxis. Low-dose unfractionated heparin (≤5000 units SC bid), low-molecular-weight heparin (e.g., enoxaparin, 30 mg bid or 40 mg qd), or a pentasaccharide (fondaparinux, 2.5 mg qd) is appropriate for patients at moderate risk; unfractionated heparin (5000 units SC tid) is appropriate for patients at high risk. The use of direct oral anticoagulants may be an alternative to the use of prophylactic doses of low-dose unfractionated heparin and low-molecular-weight heparin; among patients immobilized after nonmajor orthopedic surgery, rivaroxaban 10 mg once daily when compared to enoxaparin was associated with a decrease in venous thromboembolic events, without a significant change in bleeding. Graduated compression stockings and pneumatic compression devices are useful supplements to anticoagulant therapy or as alternatives to anticoagulant therapy in patients at excessive bleeding risk.

493 Point-of-Care Ultrasound

Wilma Chan, Nilam J. Soni, Paul H. Mayo

DEFINITION

Point-of-care ultrasound (POCUS) is defined as the acquisition, interpretation, and clinical integration of ultrasonographic views by a treating clinician in real time at the patient's bedside. POCUS is distinct from consultative ultrasound where a clinician orders an ultrasound exam, a sonographer acquires a comprehensive set of images, an imaging specialist (most often a radiologist or cardiologist) interprets the images, and the ordering clinician receives an ultrasound report and integrates findings into clinical decision-making **(Fig. 493-1)**. The goal of POCUS is not to replace the imaging specialist or the high-resolution data provided by computed tomography (CT) or magnetic resonance imaging (MRI), but rather to improve diagnostic and therapeutic decisions made by the treating clinician at the bedside.

POCUS became part of trauma care in emergency departments in the 1980s, and subsequently, many specialties began incorporating POCUS into patient care. The 1999 House of Delegates from the American Medical Association passed a resolution (AMA HR. 802) enabling each specialty to define its own scope and appropriate use of POCUS. Specialty-based guidelines emerged supporting credentialing processes and defining standard scanning protocols to answer focused diagnostic questions. Common clinical scenarios, such as acute dyspnea, abdominal pain, and shock, can be rapidly characterized using POCUS **(Table 493-1)**.

In internal medicine, there has been expanding interest in POCUS since the 2000s. POCUS can enhance diagnostic accuracy, treatment, monitoring, and screening of patients, as well as improve patient and clinician confidence and procedural safety **(Fig. 493-2)**.

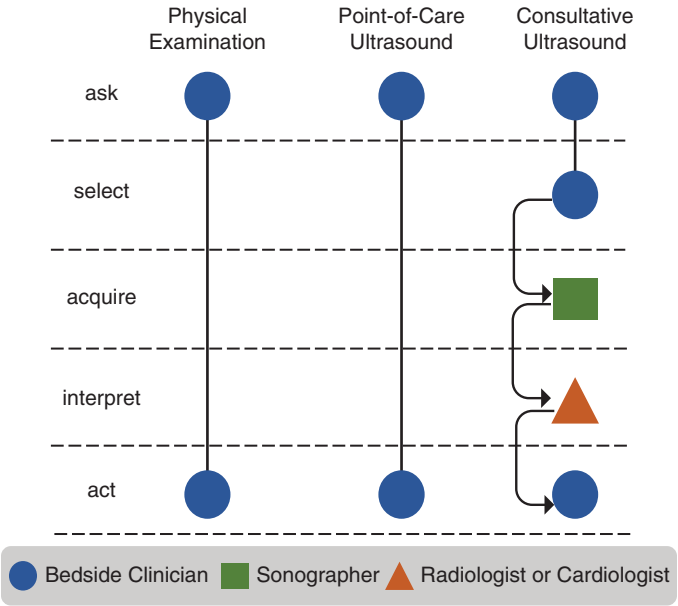

FIGURE 493-1 Workflow schematic comparing point-of-care ultrasound to physical examination and consultative ultrasound. Medical decision-making begins with asking a targeted question, selecting the diagnostic modalities, acquiring and interpreting images or other data, and ultimately, acting to incorporate the new findings into the patient's care. The three different shapes represent various personnel in this process, and *curved arrows* demonstrate the exchange of information among providers across different stages. *(Reproduced with permission from NJ Soni, BP Lucas: Diagnostic point-of-care ultrasound for hospitalists. J Hosp Med 10, 2014.)*

Portable ultrasound machines are categorized as cart-based machines versus handheld devices with wired or wireless probes connected to a tablet or mobile phone. Linear, curvilinear, and phased-array probes are commonly available, and multifunctional probes are emerging. Linear high-frequency probes have excellent image resolution but limited penetration, so they are used primarily to examine superficial structures. Deeper structures are visualized with curvilinear or phased-array probes, which have a lower frequency. Portable ultrasound devices offer two-dimensional or gray-scale imaging, and color flow and spectral Doppler imaging. Important considerations when purchasing an ultrasound machine include portability, image resolution, screen size, probe types, imaging modes, battery life, disinfection, image archiving capability, and warranty.

COMMON APPLICATIONS

CARDIAC

In the 1990s, clinicians began to perform focused cardiac POCUS exams to guide immediate management, especially for urgent and life-threatening conditions. In intensive care units and emergency departments, cardiac POCUS is routinely used to rapidly categorize shock states and acute respiratory failure. In outpatient settings, it is often used for serial monitoring of stable patients with chronic forms of heart disease.

A limited or focused cardiac POCUS exam includes five core views: parasternal long-axis, parasternal short-axis (mid-ventricular or papillary muscle level), apical four-chamber, subcostal four-chamber, and inferior vena cava views. Clinicians with comprehensive training in echocardiography, including cardiologists and intensivists certified by the National Board of Echocardiography, may perform advanced Doppler measurements of cardiac pressures and function. Cardiac POCUS and consultative echocardiography are complementary techniques where the clinical situation and operator skill determine which approach is most appropriate.

Cardiac POCUS exams can guide immediate and ongoing clinical decision-making when performed serially. To categorize shock states, left ventricular systolic function can be qualitatively categorized as normal **(Video 493-1)**, hyperdynamic **(Video 493-2)**, moderately reduced **(Video 493-3)**, or severely reduced **(Video 493-4)**. Other findings detected by cardiac POCUS that can change immediate management include acute right ventricular failure **(Video 493-5)**, cardiac tamponade **(Video 493-6)**, and gross valvular abnormalities, including severe regurgitation of the tricuspid **(Video 493-7)**, mitral **(Video 493-8)**, and aortic **(Video 493-9)** valves, as well as large valvular vegetations **(Video 493-10)**.

Competence in basic cardiac POCUS has become a mandatory component of an increasing number of specialties, including emergency medicine, pulmonary medicine, critical care medicine, and anesthesiology.

LUNG AND PLEURA

Historically, thoracic ultrasonography, comprised of lung and pleural ultrasound, was established by clinicians specialized in critical care, pulmonary, and emergency medicine. The pleural surface can be imaged through the intercostal spaces using high-frequency probes, while low-frequency probes penetrate deeper, allowing visualization of structures in the thorax. Ultrasound is superior to chest x-ray for detection of pneumothorax, early interstitial processes, and small pleural effusions and is superior to chest CT for characterization of early complex pleural effusions.

Pleural fluid is seen as a relatively hypoechoic space bounded by the diaphragm, chest wall, and atelectatic lung **(Video 493-11)**. Pleural effusions are quantified as small **(Video 493-12)**, moderate **(Video 493-13)**, or large **(Video 493-14)**, and qualitatively assessed as simple, homogeneously echogenic, complex nonseptated **(Video 493-15)**, or complex septated **(Video 493-16)**. Ultrasound guidance to identify an

TABLE 493-1 Comparison of Physical Examination Versus Point-of-Care Ultrasound Findings for Common Pathologies

PATHOLOGY	PHYSICAL EXAMINATION					POINT-OF-CARE ULTRASOUND

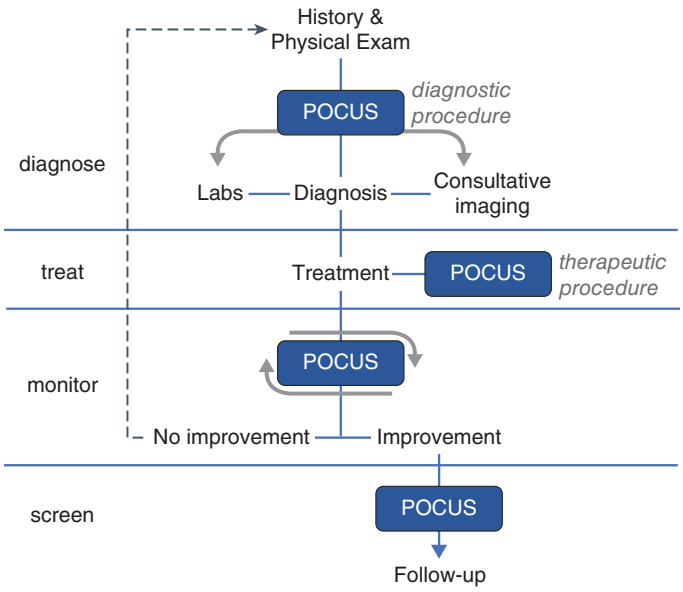

FIGURE 493-2 Clinicians can use point-of-care ultrasound (POCUS) as part of a patient's diagnosis, treatment, monitoring, and screening. A patient encounter begins with the history and physical examination, followed by a focused bedside ultrasound exam to narrow the differential diagnosis and guide workup. Treatment plans can include bedside procedures that are performed with ultrasound guidance. Serial POCUS exams can monitor disease processes and guide ongoing treatment decisions. Screening POCUS exams can detect asymptomatic, potentially treatable conditions. *(Reproduced with permission from NJ Soni, BP Lucas: Diagnostic point-of-care ultrasound for hospitalists. J Hosp Med 10:120, 2015.)*

optimal site for pleural drainage reduces the risk of pneumothorax and bleeding complications.

Normal air-filled lung tissue reflects sound waves, thereby preventing visualization of aerated lung parenchyma. Two hallmarks of normal aeration of lung on ultrasound include lung sliding **(Video 493-17)**, which results from respirophasic movement of the parietal and visceral pleural interface, and A-lines, which are horizontally orientated reverberation artifacts seen deep to the pleural line of air-filled lungs **(Video 493-18)**. Interstitial abnormalities manifest as B-lines, which are vertically orientated hyperechoic lines emanating from the pleural line to the bottom of the screen **(Video 493-19)**. Depending on their density and distribution, B-lines can support a diagnosis of cardiogenic pulmonary edema, pneumonitis, acute respiratory distress syndrome, or interstitial lung diseases. Consolidation results in lung that is tissue dense on ultrasound. Mobile air bronchograms and blood flow detected by color flow Doppler are associated with pneumonia when seen in an area of consolidation **(Video 493-20)**. Similar to chest x-ray and chest CT, identification of consolidation by lung ultrasound does not specify a diagnosis of pneumonia, and clinical correlation is required.

ABDOMEN

Evaluation of peritoneal free fluid is a common abdominal POCUS application. POCUS cannot specify the type of fluid (i.e., ascites, blood, urine, bile, chyme) but can detect as little as 100–500 mL of peritoneal free fluid. When ascites is present **(Video 493-21)**, POCUS can identify a safe site for paracentesis, improving procedural success and complication rates compared to landmark-based techniques. POCUS eliminates attempts at paracentesis when an insufficient volume of ascites is present **(Video 493-22)**. The best site, depth, and angle for needle insertion is determined using the ultrasound probe followed by color flow Doppler examination of the proposed trajectory of needle insertion to avoid injury to abdominal wall blood vessels **(Video 493-23)**.

POCUS is used in the initial evaluation of acute renal failure and decreased urine output. Bladder ultrasound can rapidly identify presence or absence of urine in the bladder and confirm appropriate placement and function of a urinary catheter **(Videos 493-24 and 493-25)**. Bladder ultrasound is more reliable than automated bladder scanners for urinary retention, as bladder scanners can falsely report pelvic free fluid (i.e., ascites, cysts, small bowel obstruction) as elevated bladder volume. POCUS is effective to evaluate kidney size and echogenicity; identify renal cysts, large stones, and masses; and detect and grade hydronephrosis **(Videos 493-26 to 493-28)**, thereby identifying obstructive uropathy.

POCUS can diagnose an abdominal aortic aneurysm (AAA) with high sensitivity and specificity **(Videos 493-29 and 493-30)**. A protocol that emphasizes complete visualization of the abdominal aorta from celiac trunk through the iliac bifurcation in both transverse and longitudinal planes can provide a reliable evaluation of the aorta. POCUS use for AAA screening may reduce morbidity and mortality among high-risk patients.

POCUS has utility for evaluation of small-bowel function. Normally, the small bowel is partially filled with air that obscures visualization due to scattering of sound waves. When a small-bowel obstruction (SBO) develops, the air-filled loops of bowel become fluid-filled, permitting visualization of the bowel walls. Diagnostic criteria for SBO by ultrasound include dilation of the bowel (diameter >2.5 cm), fluid-filled small-bowel loops (confirmed by appearance of plicae circularis at the perimeter), and hyperactive to-and-fro peristalsis within loops of small bowel **(Video 493-31)**. Combining patient history, physical examination, and a systematic survey of all four quadrants by ultrasound, clinicians can diagnose SBO rapidly and reliably. For a new diagnosis of SBO, POCUS can expedite early intervention and surgical consultation. For recurrent SBO, POCUS can reduce repeat radiation exposure by CT scans and expedite initiation of medical management.

LOWER EXTREMITY DEEP-VEIN THROMBOSIS

Two-dimensional compression ultrasound is a rapid and accurate diagnostic technique for deep-vein thrombosis (DVT) that clinicians can learn after brief training programs. A point-of-care lower extremity compression ultrasound exam yields similar diagnostic accuracy for detection of DVTs as traditional duplex or triplex ultrasound exams. DVTs commonly form at venous junctions because of high turbulence, and hence, compression ultrasound is performed at major branchpoints of the venous system. A perpendicular compression technique is required to ensure complete venous compression with wall-to-wall touching. A noncompressible vein is diagnostic of DVT **(Video 493-32)**, and visualization of intraluminal clot is not required to diagnose a DVT.

SKIN AND SOFT TISSUE

POCUS allows rapid differentiation between skin and soft tissue infections (SSTIs) and reactive lymph nodes, seromas, hematomas, hernias, thrombophlebitis, DVT, cysts, and bursitis. For SSTIs, POCUS can reduce unnecessary attempts at incision and drainage and avoid delays in surgical intervention. SSTIs range from cellulitis to phlegmon, abscess, and necrotizing fasciitis. POCUS can accurately distinguish abscess from cellulitis, but diagnostic accuracy is more variable for necrotizing fasciitis. To diagnose cellulitis, POCUS identifies subcutaneous edema described as "cobblestoning" **(Video 493-33)**. Abscesses appear as irregular, enclosed areas superficially with compressible material and absent central flow on color Doppler **(Video 493-34)**.

VASCULAR ACCESS

Current evidence supports use of ultrasound guidance for insertion of central venous catheters (CVCs) in the femoral, internal jugular, and axillary veins. Ultrasound guidance for insertion of internal jugular CVCs improves procedure success rates and reduces complications, particularly pneumothorax and arterial punctures. A preprocedure ultrasound survey identifies potential vessels to cannulate and can reveal unsuspected venous thrombosis, atypical anatomy, and venous stenosis. During insertion, real-time visualization of the needle tip reduces procedure attempts and needle redirections, which reduces the risk of complications. Sonographic confirmation of the guidewire in the target vein provides a safety check prior to venous dilation and insertion of the CVC.

For peripheral intravenous (PIV) catheter insertion, ultrasound can increase cannulation success rates while reducing puncture attempts, time to cannulation, and trauma to surrounding structures,

particularly in patients with anticipated difficult PIV placement or after failed attempts using standard techniques. Ultrasound identifies peripheral veins that are large, linear, and superficial, and real-time ultrasound guidance allows visualization of the needle tip entering the vessel lumen.

TRAINING

PATHWAYS

Ultrasound training is a longitudinal process for clinicians as they progress through medical school, residency, and fellowship and enter clinical practice. Training recommendations for POCUS have been developed for different stages of medical education but with varying definitions of competence. Regardless of the clinical rank of the learner, competence in POCUS requires mastery of ultrasound knowledge (e.g., clinical indications, applications, limitations, artifacts), image acquisition, image interpretation, and clinical integration. Image acquisition and interpretation skills are learned at varying rates and require deliberate practice.

CERTIFICATION

Currently, there is no widely accepted certification for POCUS. Some residency and fellowship training programs, such as critical care and emergency medicine, require comprehensive training in POCUS, and hospitals generally grant POCUS privileges to physicians with board certification in these specialties. In contrast, internal medicine residency training does not require comprehensive POCUS training, and board certification in internal medicine does not imply competence in POCUS. Several internal medicine residency programs and professional societies have developed POCUS training courses.

CREDENTIALING AND PRIVILEGES

Clinical privileges are governed by the rules and regulations of individual hospitals. A hospital's credentialing and privileging committee is responsible for developing criteria for granting privileges for POCUS use, which may be guided by specialty-specific guidelines. Some hospitals will designate a local POCUS expert to assess competence in POCUS prior to granting privileges for POCUS use in patient care. Hospital credentialing and privileging bodies may designate POCUS as a core privilege of a specialty (e.g., emergency medicine privileges include POCUS use) or as add-on privileges separate from the primary specialty's skills. Some well-established POCUS applications, such as ultrasound-guided CVC insertion, are commonly designated as core privileges when use of ultrasound guidance is standard of care. In contrast, less common POCUS applications, such as peripheral nerve blocks, may be designated as add-on privileges.

FUTURE DIRECTIONS

The increasing portability and affordability of ultrasound devices have allowed internal medicine clinicians to incorporate POCUS into frontline patient care. Increasing POCUS use in internal medicine requires development of effective training programs during residency training and for internists in-practice. Tele-ultrasound has shown promise for training clinicians and delivering patient care remotely. In the coming years, artificial intelligence will facilitate both POCUS training and use in clinical care, and remote serial monitoring of common conditions like heart failure may be possible with patients' use of POCUS.

494 Improving Health and Health Care Using Behavioral Economics

Kevin G. Volpp, George Loewenstein, David A. Asch

Tobacco use, physical inactivity, unhealthy diet, excessive alcohol use, and other individual behaviors are estimated to underlie 40% of premature mortality in the United States. Approximately 75% of the $4.3 trillion currently spent on health care in the United States is attributable to cancer, heart disease, type 2 diabetes, and obesity, and each of these conditions is strongly influenced by behavior. Nearly one-half of patients prescribed medications to lower their cholesterol within 1 year following myocardial infarction stop taking these drugs—even when they are provided free of charge. Despite great advances in the science and technology of health care, a large gap separates theoretically achievable goals in health and health care from what individuals and populations actually achieve. Human behavior is both a major contributor to health problems and a barrier to the successful implementation of solutions to address them.

Recognizing that there are many reasons people do not take action to improve their health, behavior change experts have focused efforts both on strategies targeting individual behavior, such as diet and exercise, medication adherence, and smoking cessation, as well as policy-related work such as identifying problems with the existing system of health insurance, including the design of patient benefits and payments to clinicians and hospitals.

Existing policies presuppose that health care decisions are based on rational self-interest and that people have advanced computational capacity. Rational people, it is assumed, will dispassionately assess the net present value of the costs and benefits of alternative courses of behavior and pursue the best path forward. These approaches often break down when exposed to realities of human behavior such as limited attention, overconfidence, and problems of self-control. It is not just the magnitude of costs and benefits that matters, but also other critical features, such as their timing, frequency, saliency, and framing. Acknowledging these complexities has implications not only for understanding health-related behaviors, but also for intervention design. Public health programs, including those involving financial incentives, are more likely to achieve their goals if designed based not on how perfectly rational people *ought* to make health decisions but rather on how humans *actually* make them. The field of behavioral economics uses insights from psychology to identify ways that human decision-making often falls short of the ideal. The field aims to offer a more realistic account of human behavior, providing a natural framework for efforts to encourage changes in behavior.

CONCEPTS OF CLASSICAL ECONOMICS AND HOW THEY DIFFER FROM BEHAVIORAL ECONOMICS

Classical economics posits that individuals are rational utility maximizers, meaning that they are able to dispassionately identify alternative decisions, calculate the probabilities of and utility/disutility for each potential outcome, and then implement the decision that has the highest net present value. When it comes to health behaviors, classical economic theory would assume that if people are obese they must have decided that the costs of obesity are outweighed by the benefits of the behaviors that lead to it, and that if people smoke they must have decided that the pleasures of doing so outweigh the costs. This assumption of rational utility maximization has two major consequences for public policy, both of which are applicable in the health domain.

The first is that conventional economic thinking radically limits the range of situations in which it makes sense to intervene at a policy level. If someone has made a considered and rational decision to smoke, it becomes harder to justify government interventions to change that decision as long as their actions don't directly harm others. Under the assumptions of conventional economics, regulatory interventions such as targeted taxes and subsidies are considered appropriate only in situations characterized by externalities (costs that an individual's actions impose on others such as second-hand cigarette smoke), the presence of "market failures" (e.g., monopolies), or the presence of certain types of information asymmetries.

The second is that standard economics offers a relatively restricted array of policy tools, including taxes, subsidies, and mandates regarding patient education and information provision, and makes unrealistic assumptions about how each of these approaches will influence the behavior of individuals.

Behavioral economics builds on conventional economics by enriching its conception of individual behavior, offering enhancements on each of these dimensions. First, it broadens the range of situations in which policy interventions make sense by introducing the notion of "internalities." While externalities are costs (or benefits) individual behaviors impose on others, internalities are the costs individuals impose on themselves—typically their future selves. While interventions to address smoking and obesity can be justified on externality grounds (e.g., the health care costs are borne by individuals other than the immediately affected individual), they can also be justified on grounds of internalities—e.g., people often irrationally discount the delayed consequences of their behavior. In that sense, people might want to be protected not just from others, but from the decisions of their prior selves. Policy intervention can be further justified by the ubiquitous exploitation of individual weaknesses by businesses. Commercial enterprises may take advantage of such vulnerabilities for individual profit rather than customer health, such as with the formulation of tempting but unhealthy processed foods, the selling or prescribing of addictive substances such as cigarettes or opioids, or the pricing of meal "deals" that do not account for the health consequences of economically predatory offers. This behavior is found across industries: Credit card companies and automobile manufacturers lure new customers with "$0 down" and fleeting but appealing teaser rates of "0% interest," playing on the common propensity to focus on the present rather than on the future, as well as on people's overoptimism when it comes to their own future finances. Banks earn revenue by charging high fees for minor mistakes such as account overdrafts or breaches of minimum balance rules, often hiding the description of such fees in small print and complicated jargon. States market lottery tickets that return $0.45 on the dollar and promote these games in ways that ignore more realistic expectations using one-sided messages such as "you can't win if you don't play" rather than, for example, the equally accurate message, "you can't lose if you don't play."

Second, behavioral economics substantially broadens the range of potential policy interventions beyond those offered by traditional economics. Behavioral economics has become best known for the concepts of "libertarian paternalism" and "asymmetric paternalism." In contrast to "heavy-handed" paternalism, asymmetric paternalism attempts to protect people without limiting freedom of choice. That is, it is asymmetric because it seeks to help individuals who are prone to making irrational decisions without restricting the freedom of choice of those making informed, deliberate decisions. For example, arranging the presentation of food in a cafeteria line so that the healthy foods appear first is likely to increase the amount of healthy food chosen, without depriving those who want the unhealthy foods of the opportunity to purchase them. People who believe that individuals behave optimally should not object to asymmetric paternalism because it does not limit freedom, but those who acknowledge the limits of human rationality should endorse such measures, assuming that they are designed with individuals' interests at heart. Frequently, these measures are called "nudges."

A nudge has been defined as "any aspect of the choice architecture that alters people's behavior in a predictable way without forbidding any options or significantly changing their economic incentives. To count as a mere nudge, the intervention must be easy and cheap to avoid." The most prominent, and to date successful, application of nudges has been the use of defaults to increase enrollment in defined contribution

retirement savings plans and, secondarily, the use of automatic escalation to encourage higher savings rates. These ideas and research findings have had a major impact on retirement savings policies worldwide. Building on this success story in savings, and bolstered by the establishment of so-called "nudge units" worldwide, the nudge agenda has positioned behavioral economics at the center of public policy.

The applicability of behavioral economics to policy, including health-related policies, however, goes well beyond nudges. Many health-relevant insights from behavioral economics do not fit the definition of a nudge. For example, there have been incentive programs aimed at changing health behaviors for maximum cost-effectiveness, improvements in the delivery of health-related information, such as nutrition labels, and new designs for physician incentives or health insurance. A common theme of this work is its harnessing of predictable decision errors that usually harm people to, instead, help them to achieve longer-term health goals or other socially valuable purposes, much the way some martial arts redirect an adversary's strength against him. Many of the same messages, incentives, and choice structures used so effectively to lure people into self-destructive health behaviors can be redirected to attract them to healthier choices that improve their long-term health and well-being. In addition, some features of human decision-making that are not recognized by traditional economics but are not really examples of decision errors, such as our propensity to experience regret when we make a bad choice and our aversion to putting ourselves into such situations (a phenomenon known as "regret aversion"), can also be exploited in the service of improving health behaviors and outcomes.

There is a common misconception that if you deploy financial incentives in order to promote behavior change, then you are engaged in behavioral economics. But that kind of activity is not behavioral economics; it is simply economics. Indeed, a large number of everyday transactions, such as being paid to go to work or getting a fine for parking in the wrong place, reflect traditional economic incentives to encourage or discourage certain behaviors. However, introducing incentives in situations, such as those characterized by internalities, in which traditional economics would suggest the incentives are unnecessary *can* be viewed as applications of behavioral economics.

Perhaps more importantly, a central lesson from the field of behavioral economics is that how incentives are delivered can matter more than their objective magnitude. There are ways of delivering large incentives that make them ineffective in changing behavior, and there are ways that can greatly magnify the effectiveness of comparatively small incentives. This observation is a source of optimism because it suggests that, with careful design, we can leverage relatively small investments to improve public health.

USING BEHAVIORAL ECONOMICS TO PROMOTE SELF-BENEFICIAL HEALTH BEHAVIORS

Over the past several decades, behavioral economics has described various ways in which people's decisions differ from standard economic models (Table 494-1). The article "Prospect Theory" by Kahneman and Tversky in 1979 is widely credited with being seminal in the development of behavioral economics. Prospect theory provides an overarching conceptual framework for describing observations about human behaviors that could not be explained by expected utility theory.

Although these deviations from expected utility theory can be seen as psychological foibles and errors, the real value of this work has come less from identifying these errors and more from recognizing that they occur in predictable ways (Table 494-2). Indeed, it is the predictability and reliability of a number of key features of human decision-making identified by behavioral economics, including but not limited to those connected to prospect theory, that allow them to be used in order to promote self-advantageous health-related behaviors.

Loss Aversion and Framing Effects Key tenets of prospect theory include the following: (1) how people feel about a set of possible outcomes depends on their starting point; this is the notion of reference-dependence in which decision-makers evaluate outcomes as gains or losses depending on their starting point; (2) people dislike losses much more than they like equivalent-sized gains, a phenomenon known as "loss aversion"; and (3) there is diminished sensitivity to both gains and losses (Fig. 494-1).

TABLE 494-1 Traditional Versus Behavioral Economics

TRADITIONAL ECONOMICS	BEHAVIORAL ECONOMICS
Core theory: Expected utility maximization	Core theory: Prospect theory
Assumes perfect rationality	Recognizes that people make decision errors
Starting point independent	Assessment depends on your starting point
Framing doesn't matter	Framing affects assessment even when utilities are the same
Stable preferences	Time-inconsistent preferences
People discount the future at constant rates	People discount the near future to a greater degree and have time-inconsistent discounting
Intervene only when my actions adversely affect others (negative externalities)	Consider interventions when people will harm their future selves (internalities)
Regulations and policies generally geared to protecting people from the actions of others	Regulations and policies often geared to protecting people from themselves

One example of how we can apply the insights of loss aversion can be seen in designing provider payment systems. Financial incentives to physicians to achieve quality goals might be presented—"framed" in the language of behavioral economics—as either rewards (in which physicians receive a bonus if, for example, they increase their colorectal cancer screening rates or increase the percentage of their patients who reach a glycosylated hemoglobin target) or penalties (in which physicians would fail to receive an expected payment if they do not meet these targets). Classical economists would consider equivalently sized rewards and penalties as identically motivating, because each reflects a structure in which one receives $X for a certain outcome (Fig. 494-1). However, loss aversion implies that whether the same incentive is framed as a gain or as a loss can make a big difference. A number of studies have shown that people have a "loss aversion ratio" in a range of 1.5 to 2.5. That means that a potential penalty of $1000 for failing to meet a quality target ought to be about as potent a motivator as a potential reward of $1500 to $2500 for meeting the same target. That multiplier is nonsensical from the standpoint of classical economics, but as an empirically verifiable descriptor of human behavior, it can be exploited in the designs of programs for clinicians or patients to improve health.

All of us—including physicians—are highly susceptible to how information is framed. In a set of experiments, patients, students, and physicians were presented with cases of lung cancer that could be treated either by surgery or radiation therapy. Among all three groups, the choice of surgery was more popular when its outcomes were framed

TABLE 494-2 Key Decision Errors and Suggestions for Addressing Them

Present-biased preferences	Provide feedback and rewards quickly
Nonlinear probability weighting	Motivate people with probabilistic rewards (lotteries)
Overoptimism and loss aversion	Get people to precommit and put money at risk as an effective motivational tool
Peanuts effect	Deliver rewards in bundles, avoiding many small rewards
Narrow bracketing	Frame rewards in terms of effort per day rather than per month or year
Regret aversion	Help people anticipate the regret of poor choices
Defaults/status quo bias	Change the architecture or environment of choice to shift the path of least resistance to favor healthy decisions
Rational-world bias	Move beyond the assumption that simply providing information will lead to desired behaviors

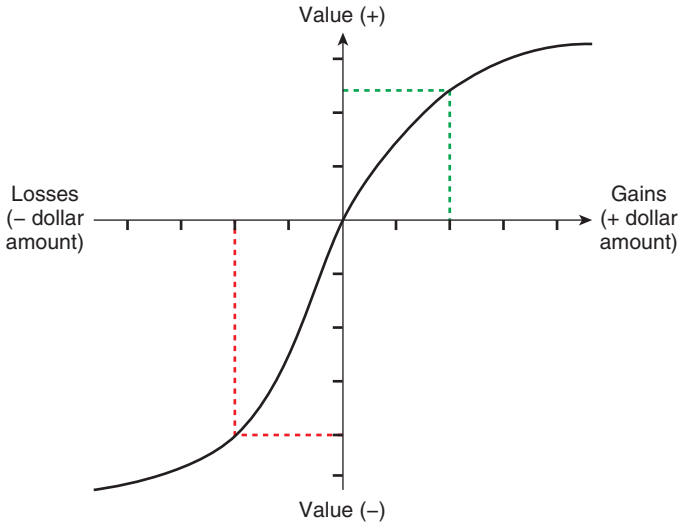

FIGURE 494-1 Prospect theory. *(Adapted from D Kahneman: Thinking, Fast and Slow. New York, NY: Farrar, Straus and Giroux, 2011.)*

in terms of the probability of survival (e.g., a 68% chance of living for >1 year) rather than in terms of the probability of death (e.g., a 32% chance of dying by the end of 1 year). We can say that such sensitivity to framing is irrational since a 68% chance of survival is logically equivalent to a 32% chance of dying—but these irrational decisions fall into predictable patterns of behavior, and that predictability can be used to influence those decisions. This means that clinicians have enormous opportunities to lead patients toward particular decisions by framing the outcomes of those decisions in specific ways, even as they remain truthful. Such an understanding could lead to the view that clinicians should be careful to balance their framing (for example, by following up the statement of 68% chance of survival with a statement like, "That means there is a 32% chance of death") in order to provide information in a way unlikely to lean toward a particular choice. Alternatively, if clinicians' roles go beyond neutral informant to trusted advisor, perhaps clinicians should deliberately frame outcomes in ways that encourage a particular choice—a much more paternalistic stance. Patients often rely on clinicians to help them make the best decisions, and that reliance may justify using the principles of behavioral economics strategically in some settings, even if the same actions in other settings might be seen as paternalistic, anti-libertarian, or coercive.

Loss Aversion and Overoptimism The power of loss aversion can be most effectively leveraged when combined with a well-documented decision error: overoptimism, or unrealistically high expectations about future outcomes. Overoptimism is especially pronounced in the context of people's predictions about their own likelihood of exerting self-control, sometimes referred to as the "false hope syndrome." The optimism that "*This* time, my efforts at weight loss will succeed!" or "*This* year, I will follow my New Year's resolutions!" often reveals itself to be false. Although in some contexts overoptimism seems to be beneficial, it can also result in suboptimal patterns of behavior. For example, people prefer paying a flat rate for gym memberships even though they would spend less if they were to pay on a per-visit basis, in part because they overestimate their future gym attendance. Indeed, many people enter into commercial weight loss programs and pay for a full year up front because they are overly optimistic about their chances of success.

Loss aversion can produce a variety of undesired behaviors, from excessive risk aversion to the tendency for people to hold on to losing investments, such as houses or stocks. However, loss aversion can advance individual or social goals. Framing reward outcomes in terms of losses by "fronting" a sum of money that gets lost if goals are not met is often more motivating than providing equivalent gains for meeting goals (the economic but not psychological equivalent). Yet, despite the greater behavioral potency of losses, program administrators are often reluctant to use loss framing, perhaps because such programs can seem more punitive than organizations may wish to appear. However, it is possible to take advantage of loss aversion by designing programs in which people voluntarily put their own money at risk in the service of achieving health-behavior goals that they themselves desire. "Deposit contracts," in which people seeking to change their own behavior put down money that they would lose if they are not successful in meeting their goals, leverage overoptimism and loss aversion to encourage behavior.

Peanuts Effects The prospect theory value function assumes diminishing marginal utility, which means that small gains and losses are disproportionately motivating relative to larger ones (e.g., two $500 rewards would be more potent than one $1000 reward). However, this may be too simple for small rewards (e.g., two $5 rewards may be less motivating than one $10 reward). This "peanuts effect" may be part of the reason why charities and retailers often describe costs in terms of "pennies a day." This observation challenges the expected efficacy of programs that emphasize efforts to repeatedly achieve small changes such as in weight loss programs. It is easy for a patient to rationalize that no single cigarette causes lung cancer, that no single snack leads to obesity, or that no single trip to the gym prevents heart disease. If self-destructive patterns of behavior, such as cigarette smoking, weight gain, or cell phone use while driving, are seen as individual instances rather than parts of a composite whole, it is easier to understand how they can be seen as acceptable. The pleasure of smoking a cigarette or eating a dessert and the convenience and engagement of conducting business or socializing via text in otherwise "dead" travel time are immediate and tangible, but the marginal costs—increased risks of developing lung cancer, being overweight, or having a car accident—seem inappreciably small. Across a lifetime or a population, however, the cumulative costs and/or probabilities are not small at all.

The tendency to underweight small outcomes can also be used to people's advantage, such as by inducing people to put away small sums for retirement savings in short cycle lengths or to make small periodic investments in their health via medication adherence. In each of these efforts, we need to think asymmetrically. In our incentive programs we should provide frequent (often daily) feedback on rewards because of present-biased preferences, but if we are *delivering* financial rewards, we want to aggregate them so that the rewards appear substantial enough to warrant attention. To use the peanuts effect to advantage, one might alert people to their rewards daily but then deliver them monthly to create larger aggregate payments.

PRESENT-BIASED PREFERENCES

Another central observation from behavioral economics is the concept of hyperbolic discounting, or "present bias." It is standard in conventional economics to assume that people discount the future; for example, $1000 today is worth more than $1000 a year from now, since money can be invested and earn interest. However, people tend to discount outcomes that are close in time more steeply than outcomes that are farther off in time; the degree of time discounting is disproportionately greater for short time delays than for long ones, in contrast to the assumption of standard economic models.

The medical implications of present bias are profound. For example, most people would desperately like to avoid a stroke, and many patients with hypertension have an understanding that taking their antihypertensive medications is one of the best ways to avoid a stroke in the future. While the classical economist would see daily adherence to antihypertensive treatment as a trivial cost to avoid the major cost of a future stroke, the stroke that is avoided is far in the future and uncertain; moreover, the stroke that is prevented is never noticed. In contrast, even the relatively small effort required to stay on antihypertensive medication is incurred in the present and comes without any immediate compensatory benefit. To the extent that patients overly discount the future harms of a later stroke, they will be less motivated to invest today in their own medication adherence. To the classical economist, these patients are behaving irrationally because they are failing to make small investments that, if they did the calculations, would clearly make them more likely to be substantially better off; this reasoning is

parallel to how classical economists judge people who undersave for retirement (the vast majority of Americans) to be irrational. To the behavioral economist, these errors are targets for therapy, in the way that we can see genetic mutations or defects in chemical pathways as therapeutic targets in the management of illness.

Present bias is somewhat subtler than simply steep discounting of the future. In fact, it reflects *two* behavioral tendencies: (1) the tendency to overweight immediate costs and benefits relative to those occurring in the future, as just discussed, and (2) the tendency to take a more evenhanded approach to *future* costs and benefits. People are much more willing to begin dieting *tomorrow*, because the overweighting of immediate costs deters us from the immediate deprivation of dieting, and the more balanced perspective on delayed deprivation makes us willing to impose these costs on ourselves in the future.

Although present-biased preferences typically promote unhealthy behaviors, policymakers can use them for beneficial effects. The motivational impact of benefits and costs, such as rewards for good behavior and punishments for bad behavior, can be increased substantially if they are made immediate. These consequences should coincide as closely as possible with the timing of the behaviors they are meant to encourage or deter. Funds for this could be provided by employers or insurers, for whom this might be a cost-effective way to improve worker health and productivity.

Such programs have been shown to have dramatic effects in the area of addiction to drugs such as opiates and cocaine. This success is particularly striking, because many individuals with such addictions already face major adverse consequences, such as loss of livelihood and disenfranchisement from their families; yet these costs are often insufficient to motivate abstinence. Similarly, small incentives offered on proof of abstinence from tobacco have succeeded in tripling smoking-cessation rates where the far larger (but delayed) incentives in terms of improved health have failed. Small, daily incentives have significantly increased behaviors ranging from weight loss to fruit and vegetable consumption in part because they bring immediate rewards (money, excitement) to situations in which the benefits of avoiding ill health are typically distant and uncertain.

Thus, rather than requiring individuals to make decisions based on consideration of their long-term best interests, it might be useful to change short-term incentives so that beneficial actions are easier and more attractive to choose or small costs—"hassle factors"—are put in the way of behaviors adverse to health. Some school districts and employers have begun to use this approach by removing various products such as soda and candy from vending machines so that the cost of obtaining them now includes a walk off campus, while healthier food and beverage options are immediately and readily available.

Regret Aversion People dislike regretting decisions they have made, often voicing laments such as, "If only I had …. " Contemporary rhetoric recasts one form of regret aversion as "FOMO," the fear of missing out. Moreover, people are sufficiently far-sighted to anticipate possible future regret and seek to make decisions today that reduce that risk in the future. The avoidance of anticipated regret is a useful exception to present-biased preferences.

Regret aversion helps to explain the success of the Dutch postal code lottery, in which winning postal codes are selected and those living within the selected areas who purchased tickets receive prizes. Those who did not purchase tickets learn that they would have won had they done so. Individuals see their neighbors winning large prizes that they do not share, or fear that this will occur, and their desire to avoid future regret drives subsequent lottery participation.

Anticipated regret has been shown to affect a variety of preventive behaviors, such as the significant increase in vaccination use among people who experienced illness after failing to get vaccinated. Lottery-based incentive programs where eligibility is conditioned on adherence (for example, you aren't eligible to play the lottery unless you had taken your medication or checked your blood pressure the previous day) can incorporate regret aversion into their design by notifying both winners and losers. Those whose number comes up but are ineligible for a reward because of nonadherence are told they would have won had they only taken their medication, checked their blood pressure, or done whatever it was the lottery program was designed to promote. Because people hate the feeling of regret, they are more likely to engage in behaviors to avoid that feeling. Indeed, the advertising campaigns of some traditional lottery systems take advantage of regret aversion. Many people play the same favorite number when they buy lottery tickets. It easy to imagine the disappointment you would feel if you missed buying a ticket one week and that was the week your favorite number came through. Advertising slogans like "don't let your number win without you" keep people in the game in order to escape that feeling of regret. The same techniques used to promote the marketing of lottery tickets can be deployed toward health promotion. The pattern of effectiveness of a recent effort using a regret-based lottery incentive in Philadelphia to increase COVID vaccination rates highlights the importance of marketing, as larger effects were observed when the program was first announced and received extensive media coverage than in subsequent rounds of the intervention.

Defaults Although many interventions playing on behavioral economics do not qualify as "nudges," nudges remain a powerful way to influence choice. Traditional economic thinking ignores the power of the default option—the path that is "selected" when no selection is made. However, the default bias, or status quo bias, reflects our tendency to take "the path of least resistance"—to continue doing what we have been doing, or to do what comes automatically, even when superior alternatives exist. Defaults have been blamed for a wide range of suboptimal outcomes, from the failure of employees to put aside retirement funds in companies whose default contribution rate is zero, to suboptimal allocation between investment alternatives, to excessive consumption of French fries and large sodas as part of defaulted "supersized" meals at fast-food franchises. Likewise, countries and states that have "opt-in" policies for organ donation—that is, the default is nonparticipation—tend to have lower donation rates than those with opt-out defaults or (as is increasingly viewed as the best compromise) those in which citizens are required to make an active choice about whether they want to be listed as a donor. Defaults that prioritize comfort over so-called "heroic measures" have been shown to increase the rate at which patients with terminal lung diseases choose comfort-oriented plans of care. Although already employed extensively, judiciously selected defaults could be used more widely to encourage the choice of beneficial health options.

If used tactically, a choice architect (the person who makes decisions on how choices are presented to the end user) can utilize defaults such as changing scheduled automatic prescription refills from 30 to 90 days (or longer) for patients requiring lifelong chronic-disease therapy or changing the default option in fast-food restaurants in combination meals from large sodas to small sodas or water or from French fries to carrots unless you ask for French fries, to help propel people toward self-beneficial behaviors. A default toward prescription of generic medications embedded in a health system electronic order entry system moved generic prescribing to nearly 100% in a context in which previous attempts at physician education had shown no effect at all. Changing the default framing of an invitation to patients with poorly controlled diabetes to join a free remote glycemic monitoring program tripled enrollment from ~13% to 37%.

Such approaches cost nothing, since a default has to be set one way or another, preserve freedom of choice, and could change behavior substantially. We miss out on many opportunities to nudge people toward healthier lifestyles when we do not consider the default option as a tactical choice to be actively incorporated into an overall health-promoting strategy.

The Rational-World Bias Perhaps the most consequential decision error affecting health-related behaviors is the tendency of public health officials and private-sector benefit designers to make policy decisions based on the assumption that people's choices are deliberative and rational. This in turn leads to assumptions that information provision is all that is needed for optimal decision-making and that, when financial incentives are offered, the amount is all that really matters.

One significant manifestation of the rational-world bias is the complexity of health insurance plans. Health insurance is complicated for many reasons, but one reason is that health care itself is complicated. Health insurance plans are full of deductibles and copayments and other financial incentives that are designed by economists and actuaries to encourage insured patients to direct their care in specific cost-minimizing and health-maximizing ways. For these built-in incentives to exert their desired influence, however, patients need to understand the incentives they are facing, and there is considerable evidence that they do not. This complexity of insurance benefit design, rather than creating perfectly tailored incentives, is part of insurance design's undoing—because an incentive that cannot be understood cannot be effective. Most consumers lack an understanding of the most basic insurance concepts, such as deductibles, copays, and coinsurance, and, when given even a simplified version of a traditional insurance plan, are unable to compute the costs they would incur for basic services.

Giving a nod to the benefits of simplicity, the Affordable Care Act (ACA) in the United States requires insurance plans to be presented in a standardized document that describes plan features such as premiums, deductibles, and coinsurance. However, describing something that is inherently complex in simple terms raises the risk of glossing over important subtleties. A more productive approach would be to provide consumers with a truly simplified insurance product. For example, insurers might create a plan designed with copayments only, since copayments are most easily understood by consumers: copayments are analogous to paying a price for a good or service when shopping, whereas coinsurance and deductibles make it difficult for people to estimate how much their care would cost. It is difficult, if not impossible, for a consumer to estimate 10% coinsurance on a hospital stay or an emergency room visit since they have no idea of the full amount on which the 10% will be calculated. For medical markets and patient cost-sharing elements embedded in plan design to affect decision-making *ex ante*, consumers need some way of accurately gauging not only benefits and risks of treatments but also the costs. This should occur before receiving a diagnostic test or treatment as opposed to what typically happens now: a medical bill is received after the fact.

Another manifestation of the rational-world bias is the more insidious and pervasive belief that if only people knew more about how to advance their health they would do so. This error leads to making education the centerpiece of many health interventions, even though public health experts have long recognized that knowledge alone rarely translates to health-enhancing behavior. For example, nearly everyone knows the health hazards of smoking. While raising and maintaining awareness of the dangers of smoking is an important goal, the financial budgets of the Centers for Disease Control and Prevention, or the time budgets of clinicians, might be more efficiently allocated toward efforts to change behavior that do not presume that the deficit is a lack of knowledge. In cases where the deficit is not in knowledge but in behavior, reliance on education as a primary avenue for reducing health risks may divert efforts and resources from other activities that might be much more effective.

APPLICATIONS

Weight Loss Efforts to combat obesity using incentives started in the 1970s. This early work was motivated by the observation that participants who deposited money and other valuables with a therapist and signed contracts in which return of their valuables was contingent on progress toward prespecified goals lost tremendous amounts of weight. Even though participants received no training in weight loss or maintenance strategies, participants lost an average of 32 pounds. This small initial study lacked control groups and long-term follow-up but provided an important proof of concept.

In the first systematic study of deposit or precommitment contracts, participants responding to an advertisement for a weight loss program were informed that study participation required a deposit of $200 (1974 dollars), which would be fully refunded contingent on satisfactory weight loss. After an 11-session, 10-week program, those who received incentives for losing weight or for limiting calories lost significantly more weight than those who received incentives for attending sessions. Of the participants in the former two groups, 70% lost >15 pounds. A major limitation to this approach was that only 15% of the prospective participants who responded to the initial newspaper advertisement ended up enrolling, suggesting that deposit contracts that require commitment of substantial funds up front are effective for participants, but this likely deters a substantial portion of high-risk participants, and effectiveness may reflect selection of highly motivated individuals.

Subsequent studies confirmed that deposit contract participants lose significant weight.

Paying participants for weight loss using direct payments was less effective than deposit contracts. In a randomized trial, cash payments up to $25 per week for making 100% of proportional progress toward goal, $12.50 for 50% of goal, and $2.50 for not gaining weight did not result in greater weight loss in the payment group than among control subjects.

Studies that have shown no effects on either initial weight loss or maintenance typically have used incentives of small magnitude or were targeted at behaviors like attendance at weight loss programs that, by themselves, do not ensure weight loss. In recent years, weight loss incentives have become a common feature in programs used by employers and health plans, though deposit contracts have not been widely used.

Both daily lottery-type incentives and precommitment (deposit) contract incentives promote initial weight loss over 16 weeks (lottery = 13.1 pounds; p = .014 for lottery vs control; deposit contract = 14.0 pounds; p = .003 vs control; **Fig. 494-2**). However, as is the case in many weight loss studies, following the termination of incentives, participants regained most of the weight they had lost over the following 3 months. Longer trials (8 months) found no difference in effectiveness of deposit contracts for continuous 8-month weight loss versus 6-month weight loss with 2 months of maintenance, but both were successful in achieving a mean weight loss of ~10 pounds. A study that examined weight loss over 18 months using daily lotteries found modest weight loss of 5.4 pounds more than the usual care control group, but neither lottery incentives, environmental change strategies, nor the combination were significantly more effective than usual care.

Many employers use premium adjustments (increases or decreases to health insurance payments) as their standard approach to using financial incentives for health promotion. In one study, participants were randomly assigned to a control group with no other intervention or one of three financial incentive groups. Two intervention groups were offered a premium reduction of $550 if they achieved their weight loss goal by 1 year. The "delayed" group would receive the premium adjustment in the following year, spread across each pay period. The "immediate" group would have their premiums adjusted as soon as the weight loss goal was met. A third intervention group was offered a daily lottery with about a 1 in 5 chance of winning $10 and a 1 in 100 chance of winning $100. To be eligible to win each day, participants had to weigh in and be on track to lose 5% of their initial weight by 6 months, with maintenance for the subsequent 6 months. After 1 year in the program, none of the intervention approaches showed a significant degree of weight loss. The control group gained <0.1 kg.

The relative ineffectiveness of premium-based financial incentives is not surprising given their design. Premium adjustments are

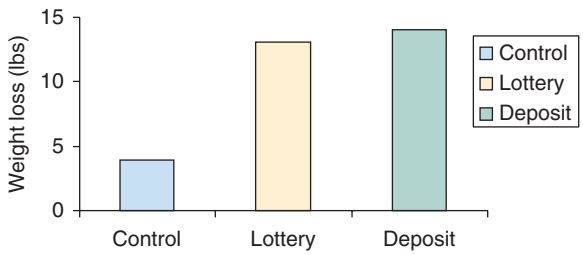

FIGURE 494-2 Weight loss in incentives versus control. *(Figure created using data from KG Volpp et al: Financial incentive-based approaches for weight loss: A randomized trial. JAMA 300:2631, 2008.)*

logistically appealing because the infrastructure to do so is already in place; however, there is little evidence for their effectiveness, and theory argues against it. Such incentives are typically deducted from, and therefore hidden, in paychecks that are directly deposited in bank accounts and may go unnoticed by the individual. While a $550 incentive seems like a large amount, it is only $20 in each biweekly paycheck. Typically, these incentives are administered on an all-or-nothing basis contingent on meeting a specific threshold such as a body mass index of ≤25 kg/m^2, meaning that those who are close to that target may be motivated by a goal within reach, but those who are farther away (and have the most weight to lose and the most health to gain) may be less motivated (perhaps even demotivated) by a goal that does not seem attainable. While data suggest that longer-term weight loss is more reliably attained through bariatric surgery or glucagon-like peptide 1 (GLP-1) medications, these are much higher cost alternatives (GLP-1 medications currently cost about $20,000 a year per person) that carry both known and unknown risk. The best evidence and theory suggest that the standard approach of using premium-based incentives is not very effective and that employers should consider alternative delivery channels for financial incentives.

A common problem employers and health plans struggle with is getting high levels of engagement among employees/health plan members. Weight Watchers, the largest commercial weight loss program in the United States, worked with a team of academic investigators to conduct a randomized controlled trial involving >23,000 participants testing the impact of offering employer subsidization of Weight Watchers membership fees of 50%, 80%, 100%, or 50% that could turn into 100% conditional on attending at least three Weight Watchers classes a month. Higher subsidies led to significantly higher program enrollment. The 100% subsidy produced the highest enrollment (7.7%), significantly higher than each of the lower subsidies (vs 80% subsidy: 6.2%, p = .002; vs 50% subsidy: 3.9%, p <.0001; vs hybrid: 3.7%, p <.0001). Enrollment in the 80% subsidy group was significantly higher than both lower subsidy groups (vs 50% subsidy: 3.9%, p <.0001; vs hybrid: 3.7%, p <.0001). Among enrollees, however, there were no differences among the four groups in attendance or weight loss. In all groups, overall weight loss was modest, with a mean weight loss ranging from 2.6 pounds in the 100% subsidy arm to 4.0 pounds in the hybrid subsidy arm. In all arms, attendance rates dropped steadily over time, suggesting that while the hypothesized trade-off between higher subsidies and lower ongoing engagement in the program did not exist, subsidies that lower the cost of participating are insufficient to achieve high levels of ongoing engagement **(Fig. 494-3)**.

In another study, 281 overweight and obese adults were randomly assigned to a control group or one of three incentive groups for a 13-week physical activity program. All participants were given a goal of achieving 7000 steps a day, tracked automatically using their smart phones. Participants in each of the three incentive arms were offered the same magnitude incentive, $1.40 per day, and were told that accumulated earnings would be sent via a check at the end of each month. However, the incentive in each group was framed differently. In the standard gain incentive group, participants were told that they could earn $1.40 each day they achieved the goal. In the regret lottery incentive group, participants were in a daily regret lottery in which they had an 18 in 100 chance of winning $5 and a 1 in 100 chance of winning $50, which averages to $1.40 per day. In the loss framing incentive group, participants were told at the beginning of each month that $42 had been placed in a virtual account and that they would lose $1.40 each day the goal was not achieved. During the 13-week intervention, participants in the control, standard gain, and regret gain arms achieved their daily step goal ~30%, 35%, and 36% of the time, respectively, but the gain-framed incentive arms were not significantly different from the control arm. However, participants in the loss framing group achieved the goal 45% of the time, a 50% relative increase, which was significantly greater than the control arm (p = .001). This study was one of the first to create a loss frame without requiring participants to put their own money at risk using a deposit contract, important because as previously noted fewer people are willing to engage in deposit contract-based incentives than reward-based incentives.

Experience with behavioral economics and weight loss provides several general lessons that are transferable to other health applications. While early studies mainly tested the impact of the magnitude of financial incentives, later studies have revealed that the design of the incentive strategy is at least as important. Designs can vary on a wide range of factors, including the timing and frequency of incentives, the setting of targets, the certain or probabilistic nature of incentives, the delivery channel of incentives, and the framing of incentives as gains or losses. Classical economists would see only the size of the incentive as an available lever for motivation, but behavioral economists face a much larger set of considerations in designing and testing effective approaches.

Medication Adherence Numerous studies have shown that at least a third of patients fail to adhere to medication regimens. Structural approaches to improving medication adherence such as changing some of the underlying defaults such as switching from 30-day

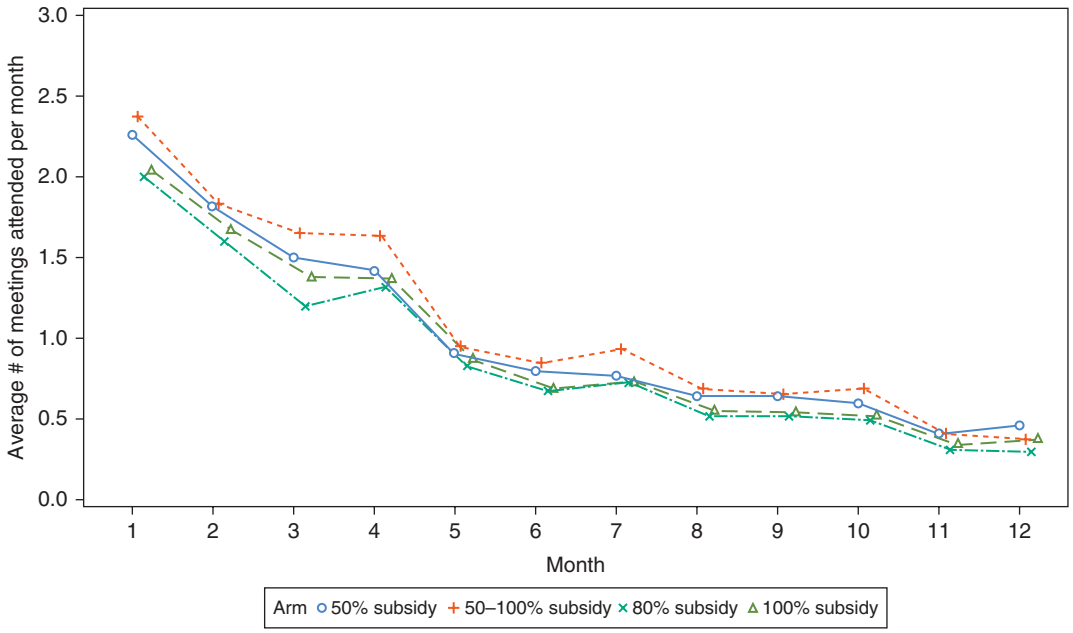

FIGURE 494-3 Attendance rates at Weight Watchers over time in different subsidy groups. *(Reproduced with permission from LK John et al: The effect of cost sharing on an employee weight loss program: A randomized trial. Am J Health Promot 32:170, 2018.)*

prescriptions to 90-day prescriptions for chronic conditions have great promise. A recent study indicated that changing to a default 90-day prescription increased adherence from 70.6% preintervention to 90.1% postintervention (p <.001). It is logical that adherence rates are higher over a year if people need 3 refills instead of 11—the latter provides more opportunities to forget, experience delays, or fall off the wagon. Automatic refills through prescription mail order might similarly help people stay adherent, giving them one less thing to think about or fail to think about.

More widely, 90-day prescriptions or automatic refills could be set up as the default, and patients or their providers could opt out if desired. However, opt-out defaults are not always possible. A large pharmacy benefits manager wanted to encourage automatic refills for patients on long-term medication but could not have members opt out of such a system because of the potential that those who missed the implications of the opt-out would be upset about finding credit card charges for automatic refills. Using active choice—i.e., requiring customers to make an explicit decision rather than only providing the service to those who proactively opt in—the company also presented options in a way that highlighted the convenience of automatic refills: "We can send your refills to you automatically or you can get your refills manually if you prefer." This resulted in more than twice as many patients choosing to be in the automatic-refill program as compared with opt-in.

A feature of many health insurance plans is that they require patients to pay some costs out of pocket and hence discourage the use of high-value care, such as the use of statins by patients with diabetes—care that is widely seen as worth its cost. Support for the use of health insurance deductibles that require patients to have "skin in the game" for their health expenditures derives from insurance theory as well as the seminal RAND health insurance experiment, which demonstrated that these deductibles help overcome moral hazard and thereby reduce the consumption of health care services. Copayments, deductibles, and the growth of high-deductible health plans make consumers more cost conscious with the intent that this makes them better shoppers for health care services.

However, while deductibles and copayments can reduce overutilization of some lower-value health care services, deductibles and copayments make considerably less sense for medications and services that are high value and low cost—e.g., when patients receive medications to manage their hypertension, diabetes, or hyperlipidemia. Given that deductibles and copayments are designed to reduce utilization, why would we apply them to antihypertensives or statins or insulin given the high health value of these drugs? As the RAND health insurance study showed, high-deductible health plans are as likely to discourage the use of high-value services as the use of low-value services. Because patients have imperfect knowledge about which tests or services are high or low value and the relationship between price and quality, such plans discourage spending on *all* tests and services, including those of high value.

Value-based insurance design—which involves discounting, or making free, services deemed high in value—is an attempt to sharpen the blunt incentives inherent in deductibles and copayments. Value-based insurance design was inspired by research that showed the use of higher copayments significantly reduced the use of services such as prescriptions but ultimately raised costs because lower rates of medication nonadherence led to higher rates of emergency department visits and adverse outcomes. Extrapolating from these results, it was natural to conclude that lowering cost sharing for high-value activities, such as medications for chronic conditions, would increase adherence and potentially thereby reduce costs. The ACA incorporates a kind of value-based insurance design in its requirement that preventive services be offered to patients at no charge.

By and large, value-based insurance design has not delivered on the hope that it would both save money and significantly improve health. From the perspective of the purchaser (for example, the employer or insurer), the economic impact of value-based insurance design depends on whether it can make enough people adherent who were previously nonadherent—and on the health and cost consequences of that improved adherence—to offset the loss of the copayments from those who were already adherent. Improved adherence from copayment reductions for medications, even to $0, has typically been only in the range of 3–6 percentage points. Even among patients who had recent heart attacks and were given cardiovascular medications for free, average adherence was only ~45%, just a few percentage points higher than with patient engagement. Based on conventional economic thought, it might seem reasonable to assume that decreasing copayments would create effects equal and opposite to those of increasing copayments. However, behavioral economic research reveals that framing matters and that losses (in this case, higher copayments intended to reduce use) have a larger effect than equivalent size gains (lowered copayments). Furthermore, people who would be deterred by higher copayments are different from people who might become adherent with lower copayments, because the first group consists of those who take their medications while the second group consists of those who do not. In general, copayment increases lead to far smaller decreases in medication adherence than copayment decreases lead to increases in medication adherence.

Value-based insurance design is an appealing idea. Its benefits could be increased through the application of behavioral economic concepts, such as simple changes in reward delivery to increase salience (e.g., retaining the copay, but sending a rebate) and communications from insurers to patients to ensure that those who are nonadherent are aware of the benefit. Better designs might also reflect that most medication adherence happens at least daily, and reinforcements to that behavior probably need to occur more frequently than the 30- or 90-day cycles coinciding with prescription refills.

CONCEPTUAL AND PRACTICAL CONSIDERATIONS

The 5000 Hours Problem Indeed, a major challenge is determining how to reach patients and reinforce their behavior each day if we want to significantly improve their health behaviors. Even patients with chronic illnesses may spend only a few hours a year with a doctor or nurse, but they spend ~5000 waking hours a year doing just about everything else. Those 5000 h are when they live their lives and make choices about what to eat and whether to exercise, smoke, take their medications, or visit the doctor.

Although what people do in those hours almost certainly affects their health outcomes, the hours are typically ignored by the U.S. health care system, in part because current approaches to U.S. health care financing support health care during visits to the doctor, not between them, and because "hovering over" people during the hours between visits is personnel-intensive, often requiring nurses or other clinicians to call or visit patients or to staff telemedicine programs. Hovering also requires a fair amount of the very kind of engagement in their own health and health care that is so often missing in the patients these interventions aim to reach. As a result, many of the most promising efforts in telemedicine and home health care have been disappointing.

If some form of hovering is required to engage people who are otherwise hard to engage during the 5000 h, it almost certainly has to become substantially more automated—both because providers must reduce the need for expensive personnel and because patients have in many cases already revealed limits to their willingness to exert themselves to improve their health. Nevertheless, there is reason for optimism based on the increasing use of cell phones and other wireless devices that make it technologically easier to embed reminders and other forms of touch into patients' lives. Indeed, one key lesson from behavioral economics is that rather than trying to change people's behavior patterns to promote health, it is better to restructure their environment and circumstances so that their existing behavior patterns are more likely to lead to better outcomes. Those efforts require a substantial amount of hovering over patients. Cell phones and other wireless devices do not necessarily change behavior on their own, but because they are already part of many patients' everyday lives, they allow previously private behaviors to be witnessed and at times acted upon.

Indeed, an error in early approaches to technology and health behavior overgeneralized from the technologies that support the "quantified self" movement. Apps and wearables that track your diet, physical activity, and biometrics were largely designed for people passionate about

measuring themselves. Such individuals do not need a lot of encouragement to wear devices or enter data. The same approaches are far less likely to be useful for patients with difficult-to-manage chronic illness. Many of the internal and external challenges that make their chronic illness hard to manage also make such monitoring hard to manage. A patient who is nonadherent to medication is likely also to be nonadherent to using a new electronic device, but devices like cell phones that are already in use or other devices that require much less active involvement (like wireless pill bottles) offer more conceptual appeal.

Changing Clinician Behavior Versus Bypassing Behavior Before the introduction of electronic health record (EHR) systems, clinician decisions might be observable by reviewing charts or insurance claims, but those reviews were labor-intensive and possible only in retrospect, offering no opportunity to intercept decisions and redirect them in real time. Now, reminders and alerts are commonly programmed into EHRs, aimed at reducing errors and promoting best practices in testing and treatment—in real time, as those decisions are made. Although these alerts open up a vast array of new opportunities for changing clinical practice, they have been criticized for recreating "alert fatigue." Perhaps in part for this reason, research has yielded mixed results regarding their effectiveness. For example, while one study found that automated alerts increased hepatitis C antibody screening in a primary practice from 3.2% to 22.7%, another study found that cardiologists largely did not change practices in response to alerts that notified them of patients meeting criteria for statins.

These approaches aim to *inform* clinicians of best practices with just-in-time information, but they continue to rely on conventional pathways of clinician cognition and behavior. A potentially more efficacious approach is to change the "choice architecture" faced by clinicians. Given that those recommended for a statin or hepatitis C screening can often be identified by information already present in the EHR, and given that ordering an antibody test or prescribing a statin are also accomplished through the EHR and the benefits are generally considered much greater than the risks, consideration should be given to systems that identify patients who would benefit from the drugs or tests and automatically order them.

Given ethical reservations, or regulatory limitations, on bypassing physicians, less heavy-handed approaches are possible that make the best practice the easier choice of clinicians. For example, rather than identifying patients meeting criteria for hepatitis C screening and then reminding clinicians to order the test, EHRs could automatically create the order and execute it *unless* the clinician decides against it. A stepped-wedge randomized controlled trial demonstrated a 31.8 percentage point increase in hepatitis C virus antibody screening among hospital patients when eligible patients were defaulted to screening (unless the clinician opted *out*), as compared with a condition in which clinicians received an interruptive prompt to order the test.

These designs are potentially less likely to induce fatigue than alerts that, if attended to, interrupt the physician's train of thought. The increasing number of algorithmic guidelines combined with the increasingly digital ecosystem of clinical care offer opportunities to advance care less through reminders that aim to travel through conventional pathways of clinician cognition and behavior and more through nudges that bypass those pathways.

Enhancing External Validity Through Pragmatic Trials We would never think of introducing a new drug that touched 1000 patients without trials examining its safety and effectiveness. The same types of methodologies often are used to test behavioral interventions. Nevertheless, the evaluation of investigational drugs differs, or should differ, from the evaluation of behavioral interventions when it comes to patient consent.

Informed consent is a central element of human subject protection, and in the case of testing pharmaceuticals, devices, or surgical procedures, we generally expect consent procedures to have little or no impact on the generalizability or external validity of a study. By and large, if 300 of 1000 people approached agree to participate in a trial comparing two drugs, we have little reason to believe that the physiologic effects observed in the 300 people who consent will be much different from what would have happened had the other 700 people participated instead. The 300 people who consent can be relied upon to provide evidence generalizable to the 700 who do not, and the external validity or generalizability of the trial is not threatened by a consent process that results in the drug being tested on only a subset of the possible pool.

Trials in behavioral science, however, may be substantially biased by consent procedures. Imagine that out of 1000 potentially eligible patients with heart failure, 300 agree to participate in a trial of a behavioral intervention to improve medication adherence and 700 decline. If the intervention works among those 300, we may reasonably question whether it will also work among the other 700. It is likely that the 300 patients who consented were, in general, more motivated to improve their medication adherence and that motivation may have increased the likelihood that the intervention would succeed.

Most behavioral interventions will fall under the category of minimal risk, and contemporary human subject projections codified in the common rule permit the waiver of consent under such circumstances when the research could not practicably be carried out without a such a waiver. For these reasons, many behavioral interventions may be appropriate for waivers of informed consent, making these trials more pragmatic and therefore generalizable.

The I-Frame and the S-Frame The vast majority of research applying behavioral economics to health has focused on changing the behavior of individuals (i-frame), mostly patients but also, in some cases, physicians. A major theme of the research has been that individuals are prone to systematic mistakes when it comes to health behaviors such as medication adherence, diet and exercise, and choice between health insurance options, and that modifying these behaviors can lead to improvements in health and health care utilization. Arguably, however, many of the most severe health problems that plague the United States and other nations stem from structural or systemic (s-frame) problems rather than from individual deficiencies. The complicated nature of health care financing in the United States, for example, including fee-for-service arrangements that encourage overprovision of tests and procedures, and the atomized health insurance sector that leaves many individuals without coverage and even insured individuals struggling to pay for needed care do not stem from individual-level behavioral deficiencies but from flaws in the overall system. Likewise, while individual-level factors such as self-control clearly play a role in obesity, systemic factors, such as the subsidization of corn, dairy, and meat and the huge lobbying power of concentrated agribusinesses, help to explain why obesity rates went from 14% to >40% in the United States over the past 40 years.

Although these problems arise at a systemic rather than individual level, the solution is not to focus on s-frame to exclusion of i-frame interventions, but to recognize that both are important and that behavioral economics still has an essential role to play. First, behavioral economics research can, and has, sought to understand the underlying cause of problems such as rising levels of obesity and "deaths of despair" (e.g., suicide, drug overdoses, and liver disease). An understanding of the causes of these problems is essential for determining what types of systemic changes, presumably enacted through regulation and legislation, could successfully mitigate them. Behavioral economics can also play a major role in informing people about the systemic causes of health-related problems and in building public support for needed reforms. In addition, while structural changes might change the preconditions for success or failure, optimizing individual behavior given those structural constraints remains imperative.

Residual Challenges Behavioral economics typically takes its cue from an understanding of universal or near universal patterns of thinking. One might hope, therefore, that harnessing these patterns would have near universal effects and perhaps profound ones. For all the conceptual appeal of behavioral economics in health and medicine, however, few studies have demonstrated the kind of widespread effect we have seen with vaccination for smallpox or polio. As noted previously, switching a default toward generic prescription moved generic prescribing to nearly 100%, which is an example of a profound effect,

but most other studies show modest effects, and many show no effect at all. What are we to make of the frequently disappointing outcomes?

One possibility is that we should simply recognize that human behavior is complex and that interventions traveling along a single pathway coexist with forces along other pathways in cascades that better resemble the complexity of inflammation than a single inborn error of metabolism. We should not be surprised when clever and conceptually well-grounded designs have less effect than we had hoped.

A second possibility is that we have the right pathways but not the right dose or the optimal combination of therapies. If we could think of ways to intensify the treatments of behavioral economics, perhaps a positive dose-response effect would reward us with more success.

A third possibility is that the premise of universality is false—that some individuals are more likely to respond to interventions focused on regret aversion, others on loss aversion, and so on. In this model, if we could just characterize people into their behavioral phenotypes, we might more precisely target behavioral interventions to them just as we aim to target our cancer care to the often unique molecular signatures of tumors. No coherent and consistent way to segment people into behavioral phenotypes has been developed, in part because initial studies have been large enough only to test main effects and not subgroups and in part because we have not yet identified or developed measures that effectively segment personalities for this purpose.

A fourth possibility, aligned with the first, is that some important decisions are no longer just the product of our reasoning, but also a product of our ideology and societal context. These are challenging to change if not aligned with health improvement. The COVID-19 pandemic introduced enormous interest among clinicians and public health experts in interventions that would increase health by promoting behaviors such as mask wearing or vaccination. Efforts to increase the latter, including through the use of financial incentives, were generally ineffective, perhaps because at the time they were introduced those remaining unvaccinated had strong beliefs that had driven the decision not to get vaccinated. Context and ideological or political pathways can create countercurrents stronger than the mechanistic pathways on which behavioral economics is based.

REFLECTIONS ON SARS-CoV-2 Since SARS-CoV-2 began spreading early in 2020, it has become increasingly clear that behavioral decisions among both policymakers and individuals play a major role in spread. Within countries that exercised strict control over individual behavior through measures like mandated testing, isolation, quarantine, use of contact-tracing apps, and fines for noncompliance, containment was achieved and the number of new cases dropped nearly to zero. Within countries like the United States in which there was no comparable national policy and policy decisions were left to the states, the rate of spread and degree of containment varied enormously. Leaders of many states relied on the rational-world bias, assuming individual decisions would be deliberative and rational. Individual decisions about whether to maintain social distance, wear masks, and otherwise modify routines to reduce risk reflect many of the behavioral challenges described earlier in this chapter—present bias, overoptimism, anticipated regret, narrow bracketing, status quo bias, and the peanuts effect all contributed to people either taking more or less precautions depending on their personal decision-making proclivities. The rollout of the vaccine was similarly hampered by s-level factors, most notably the absence of a centralized registry of citizens (a symptom of the atomized health insurance system in the United States), which rendered delivery of vaccines uneven and a somewhat chaotic process. Vaccination acceptance posed similar challenges; governments largely left it up to individuals to decide and did not use strong incentives or mandates. Significant variability in behavior ensued, with corresponding consequences for the populations they govern.

CONCLUSION

Human health derives from the interaction of basic biologic processes, environmental exposures, social structures, government policies, and behavior. The field of behavioral economics has greatly contributed to our understanding of behavior and has made significant contributions to the science of public policy. Given that understanding, we have the opportunity to replace older policies based on unrealistic normative models of rational decision-making with newer policies reflecting our most up-to-date understanding of how humans actually make decisions. Individual and population health outcomes would be very different if people were able to weigh the present and future costs of their actions carefully and dispassionately and had the necessary information and self-control to implement behavioral plans and overcome decision errors that contribute to unhealthy behaviors. Because few people can meet any of those challenges, we should not structure our behavior change interventions and public health policies around such models of behavior.

There is broad potential for improving private and public approaches to health behavior by drawing upon a more realistic understanding of human motivation rooted in behavioral economics. One major question is whether developed economies will continue to invest the majority of their health care dollars in treatment (typically ~97% of health care dollars) rather than shifting it toward innovations that seek to keep people healthy. This will be particularly important in settings where treatment options are limited and highly effective methods of prevention exist. For example, it has been estimated that a combination of low-cost cardiovascular drugs could reduce cardiovascular events by 62–88% with perfect adherence, revealing that reducing atherosclerotic cardiovascular disease risk is largely a *behavioral* challenge, given that adherence to medications remains low despite effective pharmacologic solutions. Shifts in health care financing away from fee-for-service toward various forms of payment that require health delivery systems to take on financial risk for populations of patients may drive greater interest in addressing these behavioral and social determinants of health. Research expenditures, which in many developed countries are also roughly allocated ~97% to new treatments and ~3% to prevention, similarly could be shifted to focus more on testing of innovative approaches to improve population health.

The same errors that misdirect patients and providers also misdirect policymakers. In part because of present bias, preventive services often are covered by insurance only if they show a positive return on investment, yet treatments of existing disease are not held to the same standard. An employer wondering whether to introduce a smoking cessation program for employees wonders about the return on that investment in terms of reduced illness and its cost. The same employer would likely never question the return on investment of treating lung cancer in the same employee pool, despite what would almost certainly be a negative return on investment. These asymmetries are so embedded in policy making as to be nearly invisible or at least unchallengeable. For example, the cost of treatments is not even allowed to be considered in Medicare coverage decisions. This naturally leads to overinvestment in treatments of low value and underinvestment in prevention. The same standard for assessing the impact of health programs, with the goal of achieving the most health possible with the available resources, should be used for both preventive and therapeutic services.

Despite the promise of behavioral economics in structuring policy solutions to social goals, plenty of existing policies that have nothing to do with behavioral economics are effective. For example, raising taxes on cigarettes or sugar-sweetened beverages or other unhealthy goods where it is in the public interest to consume less is a powerful policy tool derived from classical economics. Indeed, tobacco taxes represent one of the most effective ways to curb the use of tobacco and its initiation among youth. Behavioral economics can help make such policies more effective but should not be seen as a substitute for them.

For private-sector entities, the implications of choosing defaults wisely are recognized by many organizations that aim to shift the "path of least resistance" toward healthier choices. Setting up defaults in benefit program design to favor health plans that provide better coverage of preventive services, changing the environment in workplaces to make it easier to take the stairs, and serving more healthful food in cafeterias represent approaches to gently lead people toward individual and population goals.

While medical research continues to generate new tests, interventions, and drugs, all of which successfully target conditions recently

seen as intractable, even the most effective drugs will not work if physicians fail to prescribe them and if patients fail to take them. Although the dominant forms of investigation in medicine seek cellular or molecular therapeutic targets to modify disease, behavioral sciences have revealed cognitive pathways that operate nearly as predictably as the genetic code. The opportunity for behavioral economics to improve health and health care delivery derives from its recognition of these behavioral pathways and the growing empirical evidence about how to best make use of them.

495 Complementary and Integrative Therapies and Practices

Helene M. Langevin

The search for health and improved well-being includes many treatments, practices, and systems of care that may have originated outside conventional medicine but are gradually being folded into mainstream health care. The current health care system is fragmented, often emphasizing the pharmacologic treatment of disease alone, while often neglecting the promotion, support, and, importantly, restoration of health. Though the disease-focused model is dominant in our research and health care ecosystem, there has been a longstanding awareness that many chronic diseases, including pain conditions, can be prevented or better managed by incorporating nonpharmacologic interventions such as nutrition, exercise, and stress management into care, with an emphasis on understanding the person as a whole. Many complementary practices follow this model, and there is preliminary evidence indicating that these approaches lead to improved self-care, a better personal sense of well-being, and a greater commitment to a healthy lifestyle. Integrative health emphasizes not only the integration of complementary and conventional care but also an integrative approach to treatment of the whole person. This includes expanding our understanding of how physiologic systems interact with one another and of the connections between physical, psychological, and social aspects of health. Integrative health also includes striving for a better understanding of "salutogenesis" or pathogenesis in reverse, meaning the process by which health is restored when recovering from an injury, acute illness, or the exacerbation of a chronic disease, or when a "predisease" condition such as prediabetes or prehypertension is reversed through changes in behavior rather than pharmacologic treatment.

DEFINITIONS AND SCOPE

Complementary health therapies and practices include a broad range of practices, interventions, and natural products that are not typically part of conventional medical care **(Table 495-1)**. The term *complementary* refers to the use of these practices together with conventional therapies and is increasingly preferred to the term *alternative*, which denotes usage as a substitute for standard care.

The term *integrative health care* refers to conventional and complementary therapies and practices used together in a coordinated way. Integrative health also emphasizes care of the whole person that aims to improve health in multiple interconnected domains: social, psychological, and physical, including multiple organs and systems.

The term *whole person health* involves looking at the whole person—not just separate organs or body systems—and considering multiple factors that promote either health or disease. It means helping and empowering individuals, families, communities, and populations to improve their health in multiple interconnected biological, behavioral, social, and environmental areas. Instead of treating a specific disease, whole person health focuses on restoring health, promoting resilience, and preventing diseases across a lifespan.

The use of integrative approaches to health and well-being has grown within care settings across the United States. Researchers are currently exploring the potential benefits of integrative health in a variety of situations, including pain management for military personnel and veterans, relief of symptoms in cancer patients and survivors, and programs to promote healthy behaviors.

Although complementary therapies and practices vary widely, it is useful to classify them by their primary therapeutic input, which may be dietary (e.g., diet, herbs), psychological (e.g., meditation), physical (e.g., massage, acupuncture), or the combination of psychological and physical (e.g., yoga, tai chi). Although some complementary health practices are recommended or provided by a physician or a complementary health care provider such as a chiropractor, acupuncturist, or naturopathic practitioner, many of these practices are undertaken as "self-care." Although some are reimbursed, most are paid for out of pocket.

PATTERNS OF USE

The first large survey of use of complementary health practices was performed by David Eisenberg and associates in 1993. It surprised the medical community by showing that >30% of Americans use complementary health products and practices. Many surveys since that time have extended those conclusions. The National Health Interview Survey (NHIS), a large, national household survey in which thousands of Americans are interviewed about their health- and illness-related experiences, is conducted annually by the National Center for Health Statistics, a component of the Centers for Disease Control and Prevention. This survey, which addressed the use of complementary health practices in 2002, 2007, 2012, 2017, and 2022 uses methods that create a nationally representative sample and has a sample size large enough to permit valid estimates about some subgroups.

An analysis of data from 27,651 adults in the most recent survey, which was conducted in 2022, evaluated changes in the U.S. adult use of seven complementary health therapies and practices over a 20-year period (from 2002 to 2022): yoga, meditation, massage therapy, chiropractic care, acupuncture, naturopathy, and guided imagery/progressive muscle relaxation. Over 20 years, U.S. adults not only increased their overall use of complementary health approaches but were also more likely to use them specifically for managing pain. In 2022, 36.7% of people used at least one of the seven approaches, compared to 19.2% in 2002. Use of yoga, meditation, and massage therapy increased the most from 2002 to 2022. Use of yoga increased from 5% in 2002 to 15.8% in 2022, rising from the fifth to the second most-used practice. Meditation increased from 7.5% in 2002 to 17.3% in 2022, and it remained the most-used complementary health practice over the 20 years. The 2012 survey, for which there are data about use of natural products, yielded the estimate that nonvitamin, nonmineral dietary supplements are used by ~18% of adults and 5% of children.

Americans often pay out-of-pocket for complementary health products and practices; the estimated out-of-pocket expenditure for complementary health practices in 2012 was $30.2 billion ($28.3 billion for adults and $1.9 billion for children), representing 1.1% of total health expenditures and 9.2% of out-of-pocket costs. On visits to complementary practitioners, Americans spent $14.7 billion out of pocket,

TABLE 495-1 Glossary of Complementary and Integrative Health Therapies and Practices	
Acupuncture	A family of procedures involving stimulation of defined anatomic points, a component of the major Asian medical traditions; most common application involves penetrating the skin with thin, solid, metallic needles that are manipulated by the hands or by electrical stimulation
Ayurvedic medicine	The major East Indian traditional medicine system; treatment combines products (mainly derived from plants, but may also include animal, metal, and mineral), diet, exercise, and lifestyle
Biofeedback	The use of electronic devices to help people learn to consciously control body functions such as breathing or heart rate
Chiropractic	Chiropractic care involves the adjustment of the spine and joints to influence the body's nervous system and natural defense mechanisms to alleviate pain and improve general health; primarily used to treat back problems, headaches, nerve inflammation, muscle spasms, and other injuries and traumas
Dietary supplement	A product that is intended to supplement the diet, is taken by mouth, contains one or more dietary ingredients (including vitamins, minerals, herbs, amino acids, or certain other substances), and is labeled as being a dietary supplement
Homeopathy	A medical system with origins in Germany that is based on a core belief in the theory of "like cures like"—compounds that produce certain syndromes, if administered in very diluted solutions, will be curative
Hypnosis	The induction of an altered state of consciousness characterized by increased responsiveness to suggestion
Massage	Manual therapies that manipulate muscle and connective tissues to enhance the function of those tissues and promote muscle relaxation and well-being
Meditation	A group of practices, largely based in Eastern spiritual traditions, intended to focus or control attention and obtain greater awareness of the present moment, or mindfulness
Mind and body practices	A large and diverse group of procedures or techniques that are administered or taught by a trained practitioner or teacher; examples include acupuncture, massage therapy, meditation, relaxation techniques, spinal manipulation, tai chi, and yoga
Natural products	A variety of products such as herbs (also known as botanicals), vitamins and minerals, and probiotics, which are widely marketed, readily available to consumers, and often sold as dietary supplements
Naturopathy	A clinical discipline that emphasizes a holistic approach to the patient, herbal medications, diet, and exercise; practitioners have degrees as doctors of naturopathy
Osteopathy	A clinical discipline, now incorporated into mainstream medicine, that historically emphasized spinal manipulative techniques to relieve pain, restore function, and promote overall health
Qigong	A mind and body practice originating in China that involves using exercises to optimize energy within the body, mind, and spirit, with the goal of improving and maintaining health and well-being
Relaxation techniques	A number of practices such as progressive relaxation, guided imagery, biofeedback, self-hypnosis, and deep breathing exercises, with the goal of producing the body's natural relaxation response, characterized by slower breathing, lower blood pressure, and a feeling of increased well-being
Spinal manipulation, osteopathic manipulation	A technique where practitioners use their hands or a device to apply a controlled thrust (i.e., a force of a specific magnitude or degree in a specific direction) to a joint of the spine
Tai chi	A mind and body practice originating in China that involves slow, gentle movements and sometimes is described as "moving meditation"
Traditional Chinese medicine	A medical system that uses acupuncture, herbal mixtures, massage, exercise, and diet

which is almost 30% of what they spent out of pocket on services by conventional physicians ($49.6 billion). On natural products, such as dietary supplements, Americans spent $12.8 billion out of pocket, which was about one-quarter (24%) of what they spent out of pocket on prescription drugs ($54.1 billion).

Trends are even more striking for pain conditions. According to the NHIS surveys, painful conditions are the most common reasons why American adults use complementary health products and practices. About 40 million American adults experience severe pain in any given year, and they spend >$14 billion out of pocket on complementary therapies to manage their pain. A recent analysis of NHIS data showed a notable rise in the proportion of U.S. adults using complementary health approaches specifically for pain management. Among participants using any of the complementary health approaches, the percentage reporting use for pain management increased from 42.3% in 2002 to 49.2% in 2022.

Some patients seek out complementary health practitioners because they offer greater personal attention. For others, therapies and practices perceived as outside the mainstream reflect a "self-help" approach to health and well-being or satisfy a search for "natural" or less invasive alternatives. Since dietary supplements are labeled as "natural," they are often believed, incorrectly, to be inherently healthy.

CATEGORIES OF COMPLEMENTARY AND INTEGRATIVE HEALTH THERAPIES AND PRACTICES BASED ON PRIMARY THERAPEUTIC INPUT

PRIMARY DIETARY INPUT

Natural products, including plant and animal products, have a long and impressive history as sources of medicine and as important resources for biologic research. Whether as herbal supplements or as part of a diet, natural products are frequently consumed as a complex mixture of substances. This complexity can be further amplified by potential interactions with endogenous metabolic pathways, including those associated with the microbiome. The result is a collection of natural products and their metabolites that, individually and/or collectively, are associated with a network of biologic activity. Importantly, in addition to direct action on biologic targets, the activity of natural products can be influenced by an individual's diet, health, and metagenomic background. Although much remains to be understood about mechanisms of action, results of research on some natural products for a few conditions appear promising. In addition, in the 2012 NHIS, users of natural product supplements were twice as likely to report taking the natural product for a general well-being reason than for treatment of a specific health condition (88.9 vs 44.9%, respectively). Although to date, research on natural products has focused on their use for specific diseases as outlined below, a better understanding is needed about how natural products, including food, can be used most effectively to support health.

Cannabinoids An increasing amount of attention has been given recently to the nonpsychogenic effects of cannabinoids, such as cannabidiol (CBD), and terpenes found in the cannabis plant on chronic pain, particularly neuropathic pain; studies have found some limited evidence that these medicines produced better pain relief than placebos. Cannabinoids (cannabis extract, synthetic tetrahydrocannabinol [THC]) have been studied for therapeutic effects in multiple sclerosis (MS) and may relieve spasticity as well as pain in people with MS; however, no marijuana-derived medications are approved by the U.S. Food and Drug Administration (FDA) to treat MS. Sativex, an oral mucosal spray containing a mixture of THC and CBD, has received regulatory

approval in >25 countries outside the United States for the treatment of spasticity (muscle stiffness/spasm) due to MS. Sativex is currently licensed in the United Kingdom for use as an add-on treatment for MS-related spasticity when people have shown inadequate response to other symptomatic treatments. Importantly, the psychoactive properties and other potential adverse effects of preparations containing cannabinoids need to be considered, including interactions with other medications and natural products; more research is needed in this area.

Melatonin Melatonin has been shown to help reduce anxiety in patients who are about to have surgery and may be as effective as standard treatment with midazolam in reducing preoperative anxiety. Findings from clinical trials support the use of melatonin supplements for sleep problems caused by shift work or jet lag and for improving sleep-onset latency and daytime sleepiness in people with insomnia. However, there are safety concerns about the use of melatonin by children and teenagers. U.S. sales of melatonin increased by about 150% during the COVID-19 pandemic, and the number of reports to U.S. poison control centers about pediatric melatonin ingestion increased from 8337 in 2012 to 52,563 in 2021. Further, according to a study published in *JAMA*, a majority of melatonin "gummy" products were inaccurately labeled, with most products exceeding the declared amount of melatonin and CBD.

Omega-3 Fatty Acids Clinical trials on rheumatoid arthritis (RA) have found that fish oil supplements can help alleviate tender joints and morning stiffness and reduce the daily nonsteroidal anti-inflammatory drug (NSAID) requirement of RA patients; however, data are not as definitive for other pain conditions. Gamma-linolenic acid (GLA) is an omega-6 fatty acid found in the oils from some plants, including evening primrose (*Oenothera biennis*), borage (*Borago officinalis*), and black currant (*Ribes nigrum*). Although oils containing GLA may have some benefit in relieving RA symptoms, only a few studies have been conducted on each of the oils. At present, it is uncertain whether omega-3 fatty acid supplementation is useful for depression. Some studies have shown small effects in adjunctive therapy in patients with a diagnosis of major depressive disorder (MDD) and in depressive patients without a diagnosis of MDD; however, most trials have been adjunctive studies. Controlled trials of omega-3 fatty acids as monotherapy are inconclusive compared to standard antidepressant medicines, and it remains unclear whether a mechanism is present to suggest that a pharmacologic or biologic antidepressant effect exists. Furthermore, there is evidence that a high dosage of fish oil supplementation is associated with a significant increased risk of atrial fibrillation (AF) compared with placebo.

Antioxidants Findings from the Age-Related Eye Disease Studies (AREDS and AREDS2) suggest that dietary supplementation with antioxidant vitamins may slow the progression of age-related macular degeneration (AMD). Compared to the original AREDS formulation, the AREDS2 formulation replaced beta-carotene with lutein and zeaxanthin due to increased risk of cancer in smokers taking high dose beta-carotene. Of note, in AREDS2, supplementation with lutein/zeaxanthin only appeared to be beneficial in participants with low dietary lutein and zeaxanthin. In a similar vein, a study using baseline data from the AREDS cohort reported that individuals eating healthier diets, characterized by higher intake of vegetables, whole grains, and seafoods, compared to those eating less healthy "Western" diets, were less likely to show signs of early AMD. It is therefore unclear at present whether the AREDS formula should be recommended for the general population regardless of diet.

Challenges of Research on Natural Products One challenge in this area is the extremely varied doses of natural products that are sold over the counter and used without much guidance or evidence of efficacy. We also know from research on vitamins that "more is not necessarily better" and that taking a "natural" substance such as a vitamin in quantities that greatly exceed what is found in food can be harmful.

Additional challenges in the assessment of plant products include their complexity and variability, including possible instability of active components or the presence of impurities, conflicting or unreliable conclusions in the literature, and low statistical power of studies. Further, there is a paucity of data on the safety of many products, including the safety of their use in a twenty-first-century context (e.g., if taken with modern prescription drugs) and their appropriate use in the context of traditional or indigenous practices.

Regulation There is an important distinction between natural products sold as dietary supplements and drugs developed from natural sources that are used to treat specific diseases. The Dietary Supplement Health and Education Act (DSHEA), passed in 1994, gives authority to the FDA to regulate dietary supplements, but with expectations that differ in many respects from the regulation of drugs or food additives. Purveyors of dietary supplements cannot claim that they prevent or treat any disease. They can, however, claim that they maintain "normal structure and function" of body systems. For example, a product cannot claim to treat arthritis, but it can claim to maintain "normal joint health."

Homeopathic products predate FDA drug regulations and are sold with no requirement that they be proved effective. Although homeopathic products are widely believed to be safe because they are highly dilute, one product, a nasal spray called Zicam, was withdrawn from the market when it was found to produce anosmia, probably because of significant zinc content. In January 2017, the FDA warned consumers about homeopathic teething tablets containing belladonna that pose a serious risk to infants and children.

Regulation of advertising and marketing claims is the purview of the Federal Trade Commission (FTC). The FTC does take legal action against promoters or websites that advertise or sell dietary supplements with false or deceptive statements. Misleading marketing of dietary supplements, homeopathic products, and indeed other complementary health products and practices contributes to the very significant risk that individuals will use them instead of effective conventional modalities. For example, in April 2020, the FTC sent warning letters to several companies allegedly selling unapproved products—some of which included high-dose dietary supplements—that may violate federal law by making deceptive or scientifically unsupported claims about their ability to treat or cure COVID-19.

Inherent Toxicity Although the public may believe that "natural" equates with "safe," it is abundantly clear that natural products can be toxic. Misidentification of medicinal mushrooms has led to liver failure. Contamination of tryptophan supplements caused the eosinophilia-myalgia syndrome. Herbal products containing particular species of *Aristolochia* were associated with genitourinary malignancies and interstitial nephritis. In 2013, dietary supplements containing 1,3-dimethylamylamine (DMAA), often touted as a "natural" stimulant, led to cardiovascular problems, including heart attacks. Among the most controversial dietary supplements is *Ephedra sinica*, or ma huang, a product used in traditional Chinese medicine for short-term treatment of asthma and bronchial congestion. The scientific basis for these indications was revealed when ephedra was shown to contain ephedrine alkaloids, especially ephedrine and pseudoephedrine. With the promulgation of the DSHEA regulations, supplements containing ephedra and herbs rich in caffeine sold widely in the U.S. marketplace because of their claims to promote weight loss and enhance athletic performance. Reports of severe and fatal adverse events associated with use of ephedra-containing products led to an evidence-based review of the data surrounding them, and in 2004, the FDA banned their sale in the United States.

A major current concern with dietary supplements is adulteration with pharmacologically active compounds. Multi-ingredient products marketed for weight loss, bodybuilding, "sexual health," and athletic performance are of particular concern. Recent FDA recalls have involved contamination with steroids, diuretics, stimulants, and phosphodiesterase type 5 inhibitors.

Herb-Drug Interactions A number of natural products have potential impacts on the metabolism of drugs. This effect was illustrated most compellingly with the demonstration in 2000 that consumption

of St. John's wort interferes with the bioavailability of the HIV protease inhibitor indinavir. Later studies showed its similar interference with metabolism of topoisomerase inhibitors such as irinotecan and with cyclosporine and many other drugs. The breadth of interference stems from the ability of hyperforin in St. John's wort to upregulate expression of the pregnane X receptor, a promiscuous nuclear regulatory factor that promotes the expression of many hepatic oxidative, conjugative, and efflux enzymes involved in drug and food metabolism.

Because of the large number of compounds that alter drug metabolism and the large number of agents some patients are taking, identification of all potential interactions can be a daunting task. Several useful Web resources are available as information sources **(Table 495-2)**. Clearly, attention to this problem is particularly important with drugs with a narrow therapeutic index, such as anticoagulants, antiseizure medications, antibiotics, immunosuppressants, and cancer chemotherapeutic agents. Although there are many examples of substances of natural origin successfully used as pharmaceutical drugs, in general, natural products ingested as food or herbal teas, rather than concentrated extracts, are less likely to cause harm.

PRIMARY PSYCHOLOGICAL INPUT

Therapies and practices whose primary therapeutic input is predominantly mental include conventional types of psychotherapy, such as cognitive behavioral therapy (CBT), and complementary practices, such as meditation and mindfulness-based stress reduction (MBSR). Relaxation techniques, including biofeedback-assisted relaxation, also fall into this category. The boundary between conventional and complementary can be blurred, as CBT programs, for example, frequently incorporate elements of MBSR and relaxation techniques. These therapies and practices are being gradually integrated into aspects of conventional care, such as cardiac rehabilitation programs, and are playing an increasingly recognized role in the management of pain, as well as stress and sleep disturbances.

Cognitive Behavioral Therapy (CBT) The American College of Physicians practice guidelines (2016) strongly recommend the use of CBT for insomnia (also called CBT-I) as the initial treatment for chronic insomnia. Although CBT-I often includes relaxation techniques, it is not clear whether relaxation alone is beneficial. Various online applications are increasing the accessibility of these techniques at low cost.

Mindfulness-Based Stress Reduction (MBSR) Mindfulness meditation has been found to significantly reduce pain in experimental and clinical settings and to improve a wide spectrum of clinically relevant cognitive and health outcomes, including low-back pain and fibromyalgia. Recent findings from neuroimaging and randomized controlled trials confirm that mindfulness meditation reduces pain by engaging multiple, unique, nonopioidergic mechanisms that are distinct from placebo and that vary across meditative training level. There is some growing evidence that mindfulness meditation can have a beneficial effect on anxiety and help people recover from substance use disorders.

Hypnosis Findings from a few studies have demonstrated that training patients in the use of self-hypnosis significantly reduced their need for sedatives and analgesia when undergoing interventional radiologic procedures. Some studies also have suggested that hypnosis may be helpful for anxiety and health-related quality of life in people with irritable bowel syndrome (IBS). There is some evidence to suggest that hypnotherapy may improve smoking cessation, but data are not definitive.

Relaxation Techniques Relaxation techniques, including biofeedback and progressive muscle relaxation, may be helpful in managing a variety of stress-related health conditions, including anxiety associated with ongoing health problems and in those who are having medical procedures. Diaphragmatic breathing exercises may modestly lower blood pressure, reduce levels of cortisol, and reduce glycemia in people with type 2 diabetes. The efficacy of biofeedback has been evaluated in numerous studies for tension headaches, with positive results. Several studies have shown that biofeedback decreased the frequency of both pediatric and adult migraines, with some showing an effect lasting over an average follow-up phase of 17 months. Evidence suggests that relaxation techniques may also provide some benefit for symptoms of posttraumatic stress disorder and help reduce occupational stress in health care workers. Clinical practice guidelines issued by the American Cancer Society on the evidence-based use of integrative therapies during and after breast cancer treatment recommend yoga for anxiety and stress reduction. For some of these conditions, relaxation techniques are used as an adjunct to other forms of treatment.

PRIMARY PHYSICAL INPUT

A physical therapeutic input can be delivered manually (e.g., massage) or using a device (e.g., acupuncture) or can be generated by the patient (e.g., exercise).

Acupuncture The role of acupuncture in pain management has been controversial for decades, with critics pointing out its "prescientific" theoretical basis, and indeed, the rationale for the use of specific "acupuncture points" remains to be established. However, recent large-scale meta-analyses have demonstrated acupuncture to be superior to both usual care and sham acupuncture for chronic musculoskeletal pain, headache, and osteoarthritis (OA), with beneficial treatment effects persisting for up to 12 months. Clinical practice guidelines issued by the American College of Rheumatology and the Arthritis Foundation conditionally recommend acupuncture for knee, hip, and/or hand OA. The most recent (2017) American College of Physicians clinical guidelines recommend acupuncture as one of the initial treatment options for patients with acute, subacute, and chronic low-back pain. Acupuncture may provide a modest reduction in symptoms of depression, particularly when compared with no treatment or a control. Acupuncture or electroacupuncture may be an appropriate addition to drug treatment for managing chemotherapy-induced nausea and vomiting in patients with cancer. Clinical guidelines issued by the Society for Integrative Oncology and the American Society of Clinical Oncology in 2022 found intermediate level of evidence (with moderate strength) to recommend that acupuncture, reflexology, acupressure, or massage may help relieve pain in people with cancer. Acupuncture may relieve symptoms of allergic rhinitis. Clinical practice guidelines from the American Academy of Otolaryngology–Head and Neck Surgery include acupuncture among the options that health care providers may offer to interested patients with allergic rhinitis.

Spinal Manipulation The role of both osteopathic and chiropractic spinal manipulative therapies (SMTs) in management of low-back pain also has been the subject of a number of carefully performed trials and many systematic reviews. Conclusions are not consistent, but the American College of Physicians guidelines conclude that spinal manipulation has a small effect on improving function and pain compared with control—either a sham manipulation or an inert treatment.

Although evidence for spinal manipulation for chronic low-back pain is graded as low quality, the recommendation for consideration of nonpharmacologic treatment including spinal manipulation is graded as a strong recommendation, reflecting increasing concern with the impact of chronic opioid use for low-back pain. The evidence of benefit of spinal manipulation for neck pain is not as extensive, and continued concern that cervical manipulation may occasionally precipitate vascular injury clouds a contentious debate.

Massage Low- to moderate-quality evidence suggests that massage therapy is superior to nonactive therapies in reducing arthritis pain and improving functional outcomes. Massage may provide short-term relief from low-back pain, but the evidence is not of high quality. There is some evidence that massage has a positive effect on migraine, tension headaches, and neck pain.

COMBINED PSYCHOLOGICAL AND PHYSICAL INPUT

The primary therapeutic input for other mind and body practices is a combination of physical and psychological. Examples of practices in this category include yoga and tai chi, which combine movement, physical postures, and meditation.

Yoga Yoga can be beneficial for patients with fibromyalgia or chronic low-back pain, and yoga compared to nonexercise controls results in small to moderate improvements in back-related function at 3 and 6 months. There is overall evidence that yoga benefits people's general well-being by relieving stress, supporting good health habits, and improving mental/emotional health and sleep. Yoga can also help with quitting smoking, anxiety or depressive symptoms associated with difficult life situations, and quality of life for people with chronic diseases.

Tai Chi Clinical practice guidelines issued by the American College of Rheumatology and the Arthritis Foundation strongly recommend tai chi, along with other nondrug approaches such as self-management programs, for managing knee and/or hip OA. Tai chi has been shown to improve overall motor function, including balance and stability in older adults. Tai chi may help improve sleep quality in individuals with mild insomnia. Tai chi also has been shown to improve quality of life in people with heart disease, cancer, and other chronic illnesses.

MULTICOMPONENT THERAPIES AND SYSTEMS

Multicomponent approaches to health comprise two or more interventions such as lifestyle changes, physical rehabilitation, psychotherapy complementary health practices, and conventional medicine in various combinations, with an emphasis on whole person health. Complementary health therapies and practices are often multicomponent in nature, both in traditional health systems (e.g., traditional Chinese medicine, naturopathy) and in modern integrative practice. The U.S. Veterans Health Administration uses a multicomponent model of pain care that emphasizes nonpharmacologic methods, both conventional (e.g., physical therapy, CBT) and complementary (e.g., yoga, acupuncture), and may also include nutrition consultations. Several medical systems, such as chiropractic, osteopathy, naturopathy, and homeopathy, that arose in the late nineteenth century continue to be practiced today. Osteopathic medicine is mostly integrated into conventional medicine, with the addition of specific osteopathic musculoskeletal manipulation techniques. While homeopathy and naturopathy have remained largely separate from mainstream medicine, chiropractic care is increasingly available in some conventional care settings. A number of multicomponent systems, often called "whole health" systems, such as traditional Chinese medicine, Ayurveda, and homeopathy, use a diagnostic and therapeutic framework that is different from that of conventional medicine, which has posed additional challenges to their rigorous investigation.

Naturopathy Naturopathy, or naturopathic medicine, is a multicomponent therapeutic system based on philosophical principles that guide practice. Naturopaths prescribe conventional and unconventional diagnostic tests and medications, with an emphasis on relatively low doses of drugs, herbal medicines, healthy diet, and exercise.

Chiropractic The practice of chiropractic care, founded by David Palmer in 1895, is the most widespread practitioner-based complementary health practice in the United States. Although the scope of practice varies widely, chiropractic practice emphasizes manual therapies for treatment of musculoskeletal complaints.

Osteopathic Medicine Founded in 1892 by the physician Andrew Taylor Still, osteopathic medicine was originally based on the belief that manipulation of soft tissue and bone can correct a wide range of diseases of the musculoskeletal and other organ systems. Over the ensuing century, the osteopathic profession has welcomed increasing integration with conventional medicine. Today, the postgraduate training, practice, credentialing, and licensure of osteopathic physicians are virtually indistinguishable from those of allopathic physicians. Osteopathic medical schools, however, include training in manual therapies, particularly spinal manipulation, as well as diagnostic methods based on palpation of musculoskeletal tissues that are not part of conventional medical education.

Homeopathy The theoretical framework of homeopathy is based on two unconventional principles: "like cures like," the notion that a disease can be cured by a substance that produces similar symptoms in healthy people; and the "law of minimum dose," the notion that the lower the dose of the medication, the greater its effectiveness. Although the current lack of biologic underpinning for these principles has seriously limited the rationale for their use, the diagnostic framework of homeopathy could be the source of new insights that could be explored. As previously discussed, the regulatory framework for homeopathic remedies differs from that for dietary supplements, in that homeopathic products are regulated as drugs under the Federal Food, Drug, and Cosmetic Act and are subject to the same requirements related to approval, adulteration, and misbranding as other drug products. There are currently no homeopathic products approved by the FDA. Homeopathic remedies are widely available and commonly recommended by naturopathic physicians, chiropractors, and other licensed and unlicensed practitioners.

Challenges of Clinical Research on Multicomponent Therapies and Systems Classic randomized controlled trial (RCT) designs may not be well suited for research on multicomponent complementary interventions and systems such as naturopathy and Ayurvedic medicine. The dynamic relationships among an array of factors that affect health and well-being is inherent to the philosophy of these systems of care and poses methodologic challenges to the effective application of conventional RCT design. Pragmatic comparative effectiveness designs with "usual care" comparators are widely used to study these types of interventions, and trials may need to take into account the individualization of interventions and the underlying theories of these multicomponent systems. Thus, a key component of research on multicomponent therapeutic systems is the development of validated and reproducible "manualized" treatment protocols allowing for some flexibility and individual patient care. Pragmatic studies that compare multicomponent treatments with usual care cannot determine which treatment components are responsible for benefits, but other kinds of translational studies can address this issue.

THERAPEUTIC OUTPUT—SYSTEMS IMPACTED AND CHALLENGES OF MECHANISTIC RESEARCH

Complementary and integrative interventions whose therapeutic input is dietary, psychological, and/or physical may exert their effects, or therapeutic output, through a variety of mechanisms and physiologic systems. For example, peppermint oil may relieve pain associated with IBS by directly relaxing gastrointestinal smooth muscle, probiotics may have effects on the nervous system as well as the gut, and some components of traditional Chinese medicine, as well as omega-3 fatty acids and their derivatives, have immune-mediated anti-inflammatory effects. Multicomponent interventions with psychological and/or physical therapeutic input such as meditation and acupuncture can have effects on the nervous system and may also target other body systems

affected by the pain condition; for example, tai chi may improve balance and stability by increasing flexibility and core strength, and the stretching involved in yoga may improve low-back pain by reducing connective tissue inflammation. For all types of therapeutic input, biopsychosocial interactions also may be important; for example, participation in an integrative group therapy pain management program may provide tools to help relieve symptoms of anxiety and depression as well as pain.

Deepening the scientific understanding of the connections that exist across domains of human health is important to better understand how conditions interrelate, identify multicomponent interventions that address these problems, and increase the support of patients through the full continuum of their health experience, including the return to health. Studies of multicomponent interventions often require multidisciplinary expertise and use state-of-the-art techniques in areas such as neuroscience, immunology, pharmacognosy, proteomics, genetics, and epigenomics. Further, there are limited preclinical models for some complementary health interventions (e.g., no relevant animal model for meditative movement practices such as yoga or tai chi). Objective, validated measurement tools are essential, as are processes and procedures to ensure quality control, whether the intervention is a mind and body practice or a natural product.

PATIENT AND PROVIDER RESOURCES

Physicians regularly face difficult challenges in providing patients with advice and education about complementary health therapies and practices. Of particular concern to all physicians are practices of uncertain safety and practices that raise inappropriate hopes. Cancer therapies, antiaging regimens, weight-loss programs, and products that claim to improve sexual function or athletic performance are frequently targeted for excessive claims and irresponsible marketing. A number of Internet resources provide critical tools for patient education **(Table 495-3)**.

Because many complementary health products and practices are used as self-care and because many patients research these interventions extensively on the Internet, directing patients to responsible websites can often be very helpful.

The scientific evidence regarding complementary therapies is fragmentary and incomplete. Nonetheless, in some areas, particularly pain management, it is increasingly possible to perform the kind of rigorous systematic reviews of complementary health therapies and practices that are the cornerstone of evidence-based medicine. A particularly valuable resource in this respect is the Cochrane Collaboration, which has performed >800 systematic reviews of complementary health practices. Practitioners will find this a valuable resource to answer patient questions. Practice guidelines, particularly for pain management, are also available from several professional organizations. Links to these resources are provided in Table 495-3.

SUMMARY

The frequent use of complementary and integrative health therapies and practices reflects an active interest among the public in improving health and well-being of the whole person. The current health care system is fragmented, with diseases and comorbid conditions mostly treated separately, sometimes with drugs that interact with one another. An important step in whole person health care is considering health and disease not as separate states but as a bidirectional continuum and understanding how complementary and integrative therapies and practices, which are often multicomponent in nature, consider a patient's long-term recovery and overall health.

496 Placebo and Nocebo Effects

Kathryn T. Hall, Alia J. Crum

Placebos are sham versions of drugs, devices, or surgeries that lack the active compound, function, or procedure they are designed to simulate (Table 496-1). Administration of these "inactive" treatments can have significant therapeutic benefits called placebo effects, which accounts for their use as controls in clinical trials as comparators for active drugs, devices, or surgical interventions. Key drivers of placebo effects include the patient's expectation and conscious or subconscious conditioning. Psychological studies demonstrated that expectations are shaped by factors intrinsic to the patient, including their past experiences and core beliefs or mindsets, and extrinsic factors including environmental cues (e.g., white coat), clinical practice (e.g., physical examination), and information received about a treatment (e.g., expected benefits or side effects). Neuroimaging studies have identified consistent changes in the brain in response to placebo treatment that suggest that placebo effects work by integrating incoming information about extrinsic factors with prior experience and mindsets to update expectations of treatment benefit. When expectations are negative, they can result in negative outcomes, termed, "nocebo effects." For many years, placebo effects were viewed as superfluous nuisance variables to be ignored, marginalized, and simply "controlled for" in clinical trials. With advances in psychology and neuroscience studies of placebo effects, the value of understanding their mechanism of action and harnessing these effects in clinical care and clinical trials has become increasingly apparent.

INTRODUCTION TO PLACEBO EFFECTS: A BRIEF HISTORY

The word "placebo," derived from the Latin *placere*, "to please," first appeared in medical literature in clinical lectures of William Cullen, a leading physician in the eighteenth century. In 1792 he wrote, "I prescribed therefore in pure placebo, but I make it a rule even in employing placebos to give what would have a tendency to be of use to the patient." Cullen was describing placebos being used to please, rather than treat; however, use of placebos was commonplace at that time, especially when effective therapies were exhausted or unavailable.

From the late eighteenth through the early twentieth centuries, sham treatments were also used to expose some unorthodox treatments as frauds—or, at least, as no better than placebos. In his highly publicized 1784 study of "animal magnetism," a therapy developed by Austrian physician Anton Mesmer, Benjamin Franklin and a team of leading scientists in France simulated Mesmer's elaborate rituals using fake practitioners and sham magnetism. This early placebo-controlled trial

TABLE 496-1 Glossary of Terms commonly used in Placebo Studies

TERM	DEFINITION
Additivity in clinical trials	The assumption that placebo and drug treatment responses are additive is a fundamental assumption in clinical trials. However, there are notable exceptions to this assumption in pharmacogenomic and brain imaging studies where subsets of the population have been reported to have differential effects in placebo and drug treatment arms of a trial.
Development and culture	Our caregivers and social environment influence the psychological processes that underlie the placebo effect. These processes are continuously shaped throughout life by the ideas, institutions, and interactions that constitute the culture in which we live.
Expectation	A specific belief about the future based on a prediction of what is most likely to happen. Examples: "This drug will relieve my pain"; "I will experience side effects."
Gene-(drug/placebo) interaction	Pharmacogenomic analysis has identified clinical trials in asthma, depression, pain, chronic fatigue, and cognitive function in which there are subpopulations based on genotype that have differential associations in the drug and placebo treatment arms. These differential effects often result in significant gene-(drug/placebo) interaction effects.
Implicit learning	The nonconscious acquisition of knowledge. Classical conditioning, a form of implicit learning, is implicated in certain instances of the placebo effect (e.g., implicit association of sleepiness with the administration of blue pills).
Mindset	Core belief about a domain or category that orients an individual to a particular set of beliefs, associations, and expectations, and functions to guide attentional and motivational processes (e.g., "cancer is a catastrophe"; "symptoms are signs of efficacy").
Neurobiological mechanisms	Dopamine, endogenous opioids, and endocannabinoids are three of the major neurotransmitter systems implicated in moderating the placebo effect. Placebo effects also work by activating biological properties of the body that facilitate healing, including homeostatic mechanisms and immune and inflammatory responses. These contribute to the natural history of a disease but can also be targets of placebo effects.
Nocebo effect	Sides effect or negative change in clinical outcome observed after exposure to negative information, interactions, or cues that can induce negative expectations.
Open-label placebos (OLPs)	OLPs are placebos administered to patients with their full knowledge that the treatment lacks the active pharmaceutical agent. OLP clinical trials have been conducted in irritable bowel syndrome, chronic back pain, allergic rhinitis, cancer-related fatigue, attention deficit hyperactivity disorder, major depression, and menopausal hot flushes. Meta-analysis of OLP trials found a significant overall effect.
Patient-clinician relationship	The patient-clinician relationship shapes the mindsets and expectations a patient holds about health, illness, and treatments, and affects the quality of care a patient receives. This relationship is influenced by the warmth and competence of the provider and is further shaped by characteristics like empathy and trust.
Placebo	Placebos are sham versions of drugs, devices, or surgeries that lack the active compound, function, or procedure they are designed to simulate. Placebos are often used in clinical trials as controls for placebo effects, natural history, regression to the mean, spontaneous remission, and Hawthorne effects (the tendency for people to change their behaviors when being observed).
Placebo effect	Positive change in clinical outcome observed after a placebo treatment; an exclusively attributed expectation mediated by psychological, neurological, or physiological placebo mechanisms.
Placebo response	Improvement observed among patients assigned to placebo treatment in a clinical trial.
Placebome	The genome-related products that modify placebo response. Several genes in neurotransmitter and other pathways have been implicated in modifying response to placebo treatment in clinical trials. The most well-studied of these is in the gene encoding catechol-*O*-methyltransferase (COMT).
Social and observational learning	Learning through direct observation of others undergoing treatment (i.e., other patients) and interactions with individuals who weild influence over the patient (i.e., physicians and nurses) both may powerfully drive placebo effects.
Treatment characteristics	The specific characteristics include factors like the shape, color, and labeling of the treatment; the method of administration; and the physical environment in which the treatment is administered.

demonstrated that the hugely popular and remarkably effective treatment was no better than a placebo. Early trialists attributed the positive benefits of these therapies to the power of the "imagination," reinforcing the belief that placebo treatments were the product of wayward physicians, or "quacks," who tricked gullible patients.

After World War II, advances in metabolism, physiology, and clinical pharmacology created a growing need for clinical trials to evaluate novel compounds for their ability to kill pathogens and alter disease processes. By the 1960s, the Declaration of Helsinki and Kefauver-Harris Amendments, introduced to protect patient safety by requiring informed consent, rendered use of placebos and the deception historically thought to promote placebo effects unethical, institutionalizing the transformation of placebos from salve to epistemic tool. Together, placebo controls, double-blinding, and randomization are considered the gold standard for acquiring the strongest evidence of efficacy or lack of efficacy for novel treatments. Notably, placebos are rarely used in trials of serious illnesses like cancer or when an effective treatment already exists. Then their use is limited to comparing novel treatments to standard of care plus placebo.

In randomized placebo-controlled clinical trials, the effect of the drug is calculated by simply subtracting outcomes in the placebo treatment arm or placebo response from the drug response **(Fig. 496-1*A*)**. Hence, in addition to controlling for placebo effects, placebos control for changes in the outcome of interest due to natural history (the tendency for a common cold to resolve on its own in 7–10 days), regression to the mean (a statistical phenomenon where extreme baseline measures tend to move toward the group mean), and the Hawthorne effect (the tendency for people to change behaviors when being observed). These variables, together with placebo effects, make up the placebo response. If the active treatment being tested significantly outperforms the placebo response, it is deemed efficacious and can progress through the U.S. Food and Drug Administration (FDA) approval process. However, if response to the drug is not statistically significantly greater than the placebo response, the active treatment is deemed lacking in efficacy.

Clinical trials' limited view of placebos obscures the reality that the effects associated with placebos are not, in practice, superfluous. Indeed, the effects of patient psychology (e.g., expectations, mindsets) and the social and cultural context (e.g., a clinician's demeanor and drug label and advertising information) have a meaningful impact on health outcomes that warrant a more complete understanding. In addition, the effects of these factors are difficult to isolate. In fact, the total response to drug is the product of both the drug and the social and psychological context interacting with patient biology to bring about change **(Fig. 496-1*B*)**. This perspective propels us into a new era of understanding placebo effects: not as treatment alternatives or as something to subtract, but as psychological, social, and biological mechanisms that can be considered an integral component of the overall treatment effect in medicine. By understanding placebo effects in this manner, we can optimize their benefits to improving drug discovery, maximizing existing treatments, and minimizing nocebo consequences to reduce harm.

PLACEBO RESPONSE IN CLINICAL TRIALS

Placebo effects, although often thought of in the context of a placebo pill, extend to many other treatment modalities, including sham surgeries, placebo acupuncture, and placebo diets. They have been documented in numerous conditions and diseases, including pain, depression, Parkinson's disease, anxiety disorders, cardiovascular disorders, cancer-related fatigue, asthma, and gastrointestinal disorders. Not limited to patient-reported outcomes, placebo effects can affect objective physiologic outcomes, including blood pressure measurements, immune biomarker levels, exercise endurance, and cognitive test scores.

Recently, clinical trial sponsors have invested considerable resources in reducing the impact of placebo response by adjusting patient-level variables, such as reducing patient-clinician interactions and reducing patient expectations by providing neutral information about expected benefits and side effects. In conditions like Alzheimer's disease, trialists have modeled placebo response over time and set the optimal treatment duration length to the time period beyond the 8-week period when placebo response is maximal. The placebo run-in design attempts to eliminate the influence of placebo responders by assigning all enrolled blinded patients to a placebo at the beginning of a study; patients who respond to placebo are subsequently excluded. Other more complex models, such as the sequential parallel comparison design (SPCD), randomize patients to placebo or drug at a ratio of 2:1. After a brief treatment period, placebo nonresponders are rerandomized to placebo or drug. Unlike placebo run-ins, SPCD uses all patients and, thus, should have greater power to find an effect. Still, despite these and other considerable investments, no approach reliably reduces the impact of placebo response on clinical trial failure.

MECHANISMS OF PLACEBO EFFECTS

PSYCHOLOGICAL MECHANISMS

Expectations Expectations, or beliefs about the likelihood of future events, are thought to be the key driver of placebo effects. Expectations can be conscious; for example, many patients expect nonsteroidal anti-inflammatory drugs (NSAIDs) will relieve pain, melatonin will improve sleep, and beta blockers will reduce anxiety. Expectations can also be consciously or subconsciously conditioned. Repeated use of blue sleeping pills can induce sleepiness by taking a blue placebo pill. Multiple sclerosis patients who received the immunosuppressant cyclophosphamide paired with flavored syrup later displayed drug-consistent immune responses to the flavored syrup alone. Observational learning can also play a role in eliciting placebo effects by altering expectations. Watching another person experience pain relief in response to a particular treatment can lead the observer to expect to experience similar relief, even if the stimulus is a placebo in both cases.

Mindsets Mindsets are core beliefs about a broader domain or category, such as the meaning of side effects or the nature of a disease or treatment. Mindsets orient individuals to a set of associations, expectations, and goals. A mindset such as "cancer is a catastrophe," "statins are harmful," or "my body is permanently damaged" can shape a patient's experience of pain or other side effects. While mindsets and expectations are related, they are not identical. For example, a patient in pain may have the specific expectation that a treatment will relieve their pain. But they also could have broader mindsets in which those expectations are operating, such as "injections don't work," "my condition is hopeless," or "I am in good hands."

While specific expectations can be measured and assumed to influence placebo effects in studies, mindsets may be particularly powerful in the real-world practice of medicine where individual expectations do not exist in isolation. Mindsets may also be advantageous when considering how to harness placebo and minimize nocebo effects ethically.

SOCIAL AND CULTURAL MECHANISMS

Language and Information Patients' implicit or explicit preexisting mindsets, shaped by the broader culture in which they were raised and/or reside, can be updated and informed through verbal instructions. In "open-hidden design" studies, medication administered openly by a health care professional who informs the patient that they will experience benefit (e.g., "I'm going to administer a dose of morphine, a powerful painkiller that will alleviate your pain") has a significantly greater analgesic effect compared to administering the same dose from a hidden pump without the patient's knowledge. Thus, even potent opioid analgesics lose as much as 30% of their efficacy if the patient is unaware that they received the treatment. Effects of open-hidden paradigms are also seen with objective outcomes, such as heart rate. Information is conveyed not just by a clinician's words but also through information in the health care context more broadly, such as advertising and media related to drugs and health.

Clinician Characteristics Beyond what the patient is told, trust in the source of information can also influence clinical outcomes. Social-psychological research has shown that two qualities are key: patients' perceptions of *competence*, or whether a physician "gets it" (i.e.,

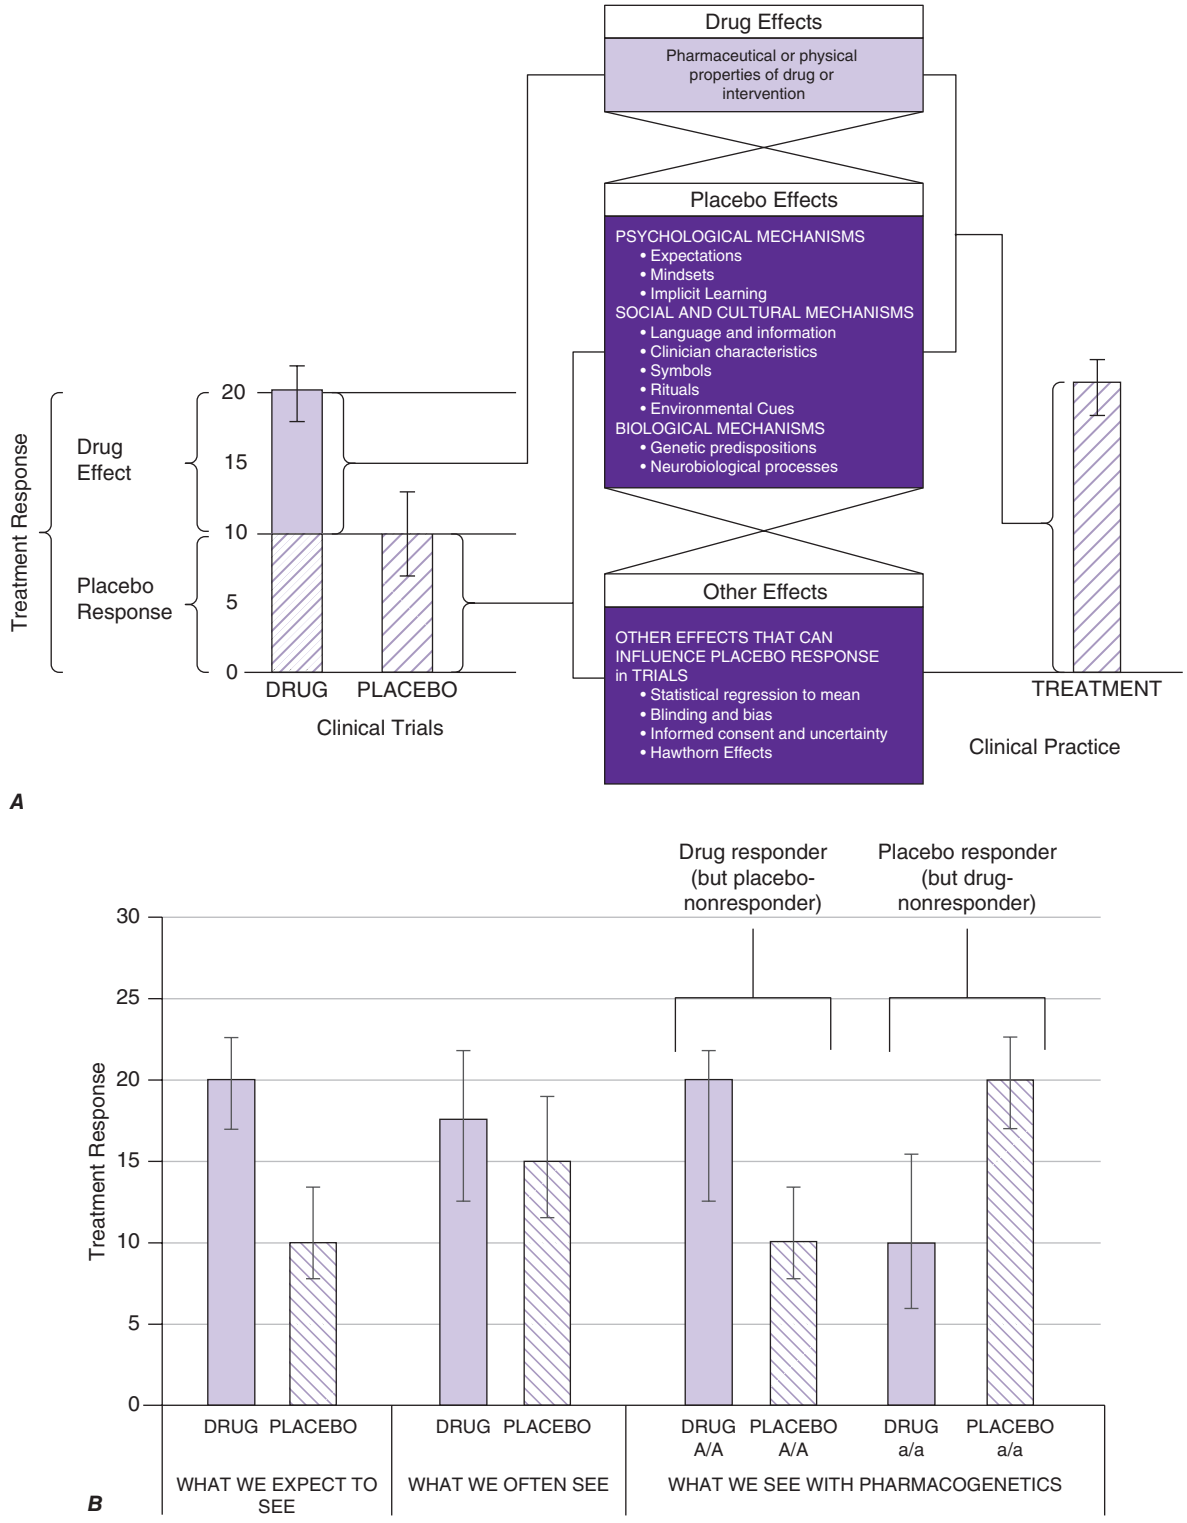

FIGURE 496-1 ***A.*** Additivity of drug and placebo response in a clinical trial. ***B.*** (1) What we expect to see: Expected outcomes from the classic view of clinical trials in which the effect of the drug exceeds placebo response. (2) What we often see: Typical results from a clinical trial in which there is no significant difference between the drug and placebo responses. (3) What we can see with pharmacogenomics: Pharmacogenomic analysis demonstrating differential effects of a genetic locus in the drug and placebo arms of a trial such that the drug effect and placebo response of one version of a variant (patients who are homozygous for the "A" allele, A/A) are opposite that of homozygotes of the alternate allele at that locus (patients who homozygous for the "a" allele, a/a). The average effects of outcomes of the two subpopulations cancel each other to give the results we often see.

displays of efficiency, knowledge, and skill), and patients' perceptions of *warmth*, or whether a physician "gets me" (i.e., displays of personal engagement, connection, and care for the patient).

Patients' assessments of clinician warmth and competence shape their treatment expectations and impact their mindsets about illness and, therefore, can influence placebo effects. In one study, an allergic reaction was induced in participants via a histamine skin prick followed by the administration of a placebo cream. The information about the cream was varied to create either positive expectations ("this cream will reduce your rash and irritation") or negative expectations ("this cream may worsen your symptoms"). When the ensuing wheal was measured 10 min later, the difference in information alone produced

differences in the size of the allergic reaction. Interestingly, the effect of the information differed depending on perceived clinician warmth and competence. When the physician exhibited cues of both competence (e.g., wearing a white coat with a badge that read "Fellow at the Stanford Allergy Center") and warmth (e.g., making eye contact with the patient), the effect of the spoken message was significantly enhanced. However, when social cues were changed to induce questions about the level of competence (e.g., badge read "Student Doctor") and warmth (e.g., staring at a computer screen or making a personal connection), the information about the cream no longer mattered: both placebo and nocebo effects were minimized.

There is no one right way to signal warmth and competence, but there are many ways to fail to convey these qualities and, therefore, lose patients' trust. Indications of warmth and competence are important for building patients' trust not only with their medical providers but also with the broader clinic, hospital, or health care system. Trust in the social context can magnify placebo effects or minimize nocebo effects; it can also have a direct effect on patient care, influencing a wide array of outcomes, such as metabolic complications, immune response, symptoms, and adherence to medication.

Symbols, Rituals, and Environmental Cues Medical treatment occurs within a rich context of environmental cues, symbols, and rituals. Many patients, for example, exhibit a transient (albeit substantial) rise in blood pressure when in a medical setting, a phenomenon known as the "white coat" hypertension. Seemingly inconsequential characteristics of a drug, such as color, drug brand name, and cost, have been found to impact treatment efficacy. Patients tend to perceive capsules as stronger and more effective than tablets and tend to have a reduced response to placebos referred to as discounted or generic. In a within-subjects, repeated-measures study to examine drug labeling in migraine, patients were given either placebo or 10-mg rizatriptan labeled to create three information conditions ranging from negative ("placebo"), to neutral ("Maxalt or placebo") to positive ("Maxalt"). While patients had significantly greater relief from Maxalt labeled as Maxalt compared to placebo labeled as placebo, there was no difference in the effect of Maxalt labeled as placebo compared to placebo labeled as Maxalt. These findings demonstrate the ability of labeling and brand names to influence the effect of a drug. Interestingly, drug companies have increased their use of the letters X and Z in drug names as studies show these visually distinct letters have fewer negative associations with other medications. Furthermore, marketing research has found Z is associated with efficacy, whereas T and S are associated with greater tolerability.

BIOLOGICAL MECHANISMS

Pharmacologic evidence from the 1970s showing that naloxone, an opioid antagonist, could abrogate placebo effects in the experience of pain after molar tooth extraction laid the groundwork for demonstrating that psychological forces could affect patient physiology. Early neuroimaging studies revealed the release of endogenous opioids and dopamine signaling proportionate to the expectation and perception of how well a given placebo intervention worked. Using models of placebo analgesia, neuroscientists imaged the brains of healthy subjects exposed to various forms of thermal or mechanical pain-producing stimuli in the presence or absence of placebo treatments (e.g., inert creams or inactive transcutaneous electrical nerve stimulation devices) to induce placebo effects using conditioning or suggestion. These studies revealed activation of regions in the spinal cord and descending pain-control regions in the brainstem and reduced signaling in the spinothalamic tract. Later meta-analyses of 20 of these studies confirmed reduced signaling proportionate to reported placebo analgesia in pain-related activity in the thalamus, insula, and habenula, while increased signaling was observed in frontal-parietal regions.

Today, placebo treatments are hypothesized to influence brain systems involved in "meaning-making" by constructing internal models that guide our understanding of incoming signals and their source, as well as implications for anticipatory events. These internal models provide predictive signals that are incorporated with incoming sensory signals to produce the sensations and symptoms experienced. In turn, these models inform our perceptions (mindsets) and shape our reactions, amplifying or attenuating perceptual and affective circuits. Thus, contextual information around placebo treatments, including the suggestion of benefit, the visual and behavioral cues provided via the ritual of treatment, and prior experiences of benefit, can modify the neural construction of the experience and, in turn, downstream physiologic consequences in the nervous, immune, endocrine, and cardiovascular systems.

THE CHALLENGE OF IDENTIFYING "PLACEBO RESPONDERS"

In drug development, identifying and excluding placebo responders could lead to more precise, and potentially smaller and less expensive, clinical trials. Predicting which patients are likely to respond to placebos could allow clinicians to optimize patient interactions and even support gradual replacement of drugs with side effects with placebo by dosage titration.

Research into psychological predictors of placebo responders found several personality traits and constructs to be associated with placebo responders, including optimism, habitual desire for control, fun and sensation seeking, neuroticism, self-efficacy, and internal locus of control. Functional magnetic resonance imaging (fMRI) has also been used to create brain-signaling profiles that are predictive of placebo responders. In a study of patients with chronic osteoarthritis pain, right midfrontal gyrus connectivity effectively identified placebo pill responders. Interestingly, in some subjects, the active drug in this study, duloxetine, appeared to enhance the placebo response, but in others, duloxetine reduced it. This finding suggests that while drug and placebo were additive for some patients, the interaction with placebo response diminished the drug effect for others.

The observation that placebo effects are influenced by opioid and dopaminergic signaling suggested that genetic variation in the synthesis, function, or metabolism of these neurotransmitters might influence the magnitude of placebo effects. This observation gave rise to the term "placebome" to describe the group of genome-related products that potentially influence individual response to placebo treatments. Members of the placebome were identified in candidate and genome-wide association studies (GWAS) of the placebo control arms of clinical trials. For example, there is evidence of differential effects associated with the genes *COMT* and *MAO-A*, which encode enzymes that metabolize dopamine; *OPRM1*, which encodes the opioid receptor; and *TPH2* and *HTR2A*, which encode proteins involved in serotonin signaling. Of these genes, *COMT* has the strongest evidence for association with placebo response in clinical trials of irritable bowel syndrome (IBS) and pain. To date, there are 29 genes associated with response to placebo in the GWAS catalog.

Although numerous psychological, neuroimaging, and genetic profiles of placebo responders have been proposed, these biomarkers were mostly derived from small studies and have not yielded consistent results in prospective studies. This is in large part due to the broad heterogeneity in variables intrinsic to patients, including their conditions and disease severity and duration, and extrinsic study variables, including treatment duration, inclusion criteria, study location, number of study visits, outcome measures, and information about the study drug (e.g., possible side effects).

ADDITIVITY IN CLINICAL TRIALS

The study of placebo responders has also led to important evidence of nonadditivity in clinical trials. Additivity between drug and placebo outcomes has been a universal and fundamental, but unproven, assumption in clinical trials. Based on additivity, the drug effect is determined by subtracting the outcome in the placebo arm from the outcome in the drug treatment arm (Fig. 496-1*A*). As reported in the study investigating brain connectivity of patients with depression described above, in some patients, duloxetine enhanced brain connectivity seen in the brain region associated with placebo response. However, in other patients, this connectivity was reduced with duloxetine. Similarly, in clinical trials of chronic pain, chronic fatigue syndrome,

cardiovascular disease, and asthma, significant genetic associations observed in placebo arms were null or found to be in the opposite direction in drug treatment arms. These unexpected gene-by-(drug/placebo) interaction effects suggest that, in some clinical trials, there are subsets of patients for whom the drug and placebo response is not additive (Fig. 496-1*B*). Thus, the potential for differential outcomes in the drug and placebo arms could confound outcomes in clinical trials, warranting further investigation.

NOCEBO EFFECTS

In part, because informed consent in clinical trials requires disclosure of all potential drug side effects, the side effects reported by patients randomized to placebo are often the same as those expected with randomization to drug. When this phenomenon was first documented in 1961, the word nocebo, coined from the Latin *nocere*, "to harm," was used to describe production of negative effects from negative verbal suggestions, contextual cues, or associative learning.

Although the term *nocebo* was originally defined as an adverse effect from an inert treatment, nocebo effects, like placebo effects, are the product of underlying aspects of the patients' psychology (in this case, negative expectations and mindsets) and the social context. In clinical trials, on average, 25% of participants randomized to placebo report side effects, and some studies (such as those of statins) show that the rates of side effects do not significantly differ between the active drug and placebo. Because they did not receive the active drug, we can assume the side effects arose, in part, due to expectation and not due to any active ingredients in the treatment.

Nocebo effects are not limited to clinical trials. While statins are effective cholesterol-lowering agents, the belief that they cause muscle pain is widespread, and treatment is often discontinued because of this reported side effect. This phenomenon has been extensively investigated. In one study, a "within-subjects" design was used in which each patient served as their own control. In this study, patients who reported side effects were blinded and randomized to take a placebo, statin, or no treatment on a monthly basis over a 1-year period. At the end of the study, there was no discernable difference between symptoms reported on placebo versus statin, and 50% of the patients in the trial were able to reinitiate statin therapy successfully. Negative expectations surrounding technology (e.g., wi-fi or cell phone signals), environmental agents (e.g., infrasound generated by wind turbines), or food (e.g., gluten) can also enhance the likelihood of negative symptoms related to their presence.

Ethically, it is hard to test nocebo effects deliberately, but randomized studies in laboratory contexts show that people who are told to expect side effects are more likely to experience those side effects than those who are not told to expect side effects. Expectations and mindsets can deepen negative effects through physiologic activation or by heightening awareness of symptoms that may have already been present, resulting in misattribution of their cause. Nocebo responses can also occur because of conditioned learning. For example, patients receiving chemotherapy can develop nausea when they see or smell a stimulus associated with their treatment, such as the treatment room or even a staff member.

Key drivers of placebo and nocebo effects overlap with factors that create barriers to quality clinical care for black patients and other patients of color. Poor communication, perceived discrimination, and medical mistrust are all factors demonstrated to reduce the quality of care in racially discordant dyads. Prior experiences of discrimination in the health care setting may result in expectations of discrimination and suboptimal clinician communication, enhancing nocebo and reducing placebo effects during treatment encounters. Consequently, the presence of nocebogenic and absence of placebogenic influences associated with racially discordant dyads has the potential to generate and exacerbate racial and ethnic inequities in clinical outcomes and care.

ETHICALLY AND DELIBERATELY HARNESSING PLACEBO EFFECTS

If placebo effects are understood as an integral component of the overall treatment effect, mediated by neurobiological processes and social and environmental factors, they can be personalized and maximized in the practice of medicine. Administering placebos without full knowledge of the patient is no longer acceptable for important ethical reasons. Moreover, administering "impure placebos"—pharmacologically active treatments that are prescribed at too low a dose to be effective or are known to be ineffective for the condition being treated—is reportedly common practice but still controversial and ethically problematic. The use of impure placebos varies by country. In the United States, a survey of 1200 internists and rheumatologists indicated that 62% of participants believed the practice of utilizing impure placebos—over-the-counter analgesics and vitamins—was ethically permissible. Notably, <5% reported using saline or sugar pills. The numbers are higher in Canada and the United Kingdom, where 80 and 77% respectively, of physicians surveyed reported prescribing impure placebos or treatments without proven or expected benefit. In Denmark, 86% of internists, 54% of hospitalists, and 41% of specialists in private practice report that they used placebo interventions at least one time within the previous year. Finally, the German Medical Association, after assessing placebos in medicine, published a report in 2011 acknowledging the complexity of the strong effects that placebos can have, supporting their limited use when no other therapies were available. In addition to using impure placebos, there are several other alternatives that deliberately leverage benefits of placebo effects.

OPEN-LABEL PLACEBOS

One way that researchers have addressed the ethical and legal limitations on placebos is to simply tell patients the facts about placebos. In honest or open-label placebo (OLP) studies, patients are fully informed about the absence of the active agent in the placebo, but are also told that placebo treatments can sometimes result in clinical improvement. The patients are also informed that trying a placebo might yield some benefit; even if they do not believe this to be the case, they could consider suspending their belief. To date, the findings on the effects of OLP are promising. Improvements have been observed in IBS, cancer-related pain and fatigue, depression, posttraumatic memory intrusions, allergic rhinitis, attention deficits, and hyperactivity; however, OLP has yielded no benefit in wound healing and did not enhance the cognitive abilities of healthy volunteers.

DELIBERATELY LEVERAGING PATIENT EXPECTATIONS AND MINDSETS

When understood as being driven by the psychological and social context, placebo effects can be evoked without the use of sham pills or procedures by deliberately shaping patient expectations and mindsets. At their best, doctors and patients alike already harness the forces behind placebo effects through interactions, branding, and language that inspire patients' trust, as well as useful mindsets and expectations about their condition. Once aware of this fact, health care practitioners can work ethically to leverage these forces to improve health outcomes.

In the PsyHEART trial, 124 patients undergoing coronary artery bypass surgery were randomized to standard care, supportive therapy, or an expectation of manipulation in which they were encouraged to develop clear expectations about how their life would improve after surgery (i.e., what activities they would be able to perform). Six months after surgery, patients who were randomized to the expectation manipulation showed significantly greater improvements in quality of life and reductions in disability. In the EMBRACE study, patients diagnosed with cancer were exposed to documentary-style films featuring experts in psychology and oncology and to cancer survivors who spoke about how their mindsets changed throughout and after their treatment, as well as challenges they faced along the way. Participants exposed to the films increased their health-related quality of life, such as their emotional well-being, physical health, and general functioning, by 10%, as measured by changes in industry-standard scales, compared to patients receiving treatment as usual. While these interventions were delivered directly to patients, trainings to help physicians and care teams more deliberately and effectively shape patients' expectations and mindsets in the context of their care are being developed, evaluated, and disseminated.

ETHICAL CONSIDERATIONS

In all of these applications, ethical considerations are of utmost importance; it is never acceptable to deceive or provide false information to the patient. Within these bounds, however, there is much we can do to improve patients' mindsets and expectations. Consider the nocebo effects resulting from informing patients about side effects. While it is not ethical to withhold this information from patients, providers could either provide more realistic expectations about the likelihood of side effects and set more adaptive mindsets about their meaning. In one study of children undergoing oral immunotherapy treatment (OIT) for peanut allergies, half were randomized to receive a typical warning message: side effects are negative outcomes, unrelated to treatment efficacy, that need to be managed and endured. The other half were given messages aimed to instill the mindset that some mild symptoms are often a sign that the treatment is working and signal desensitization. Compared with families informed that symptoms are negative side effects, families informed that "symptoms are positive signs of treatment efficacy" experienced significantly less anxiety, fewer symptoms during the highest doses, and improved levels of IgG4, an immune marker of allergic tolerance. Similar effects of this messaging have proven to reduce anxiety and side effects for those receiving the COVID-19 vaccine.

THE FUTURE OF PLACEBO EFFECTS

We are entering a new era of understanding about placebo effects, one in which they are not viewed as treatment alternatives or as something to subtract, but as psychological, social, and biological mechanisms that can be considered an integral component of the overall treatment effect in medicine. Work in this field is proliferating, and translation of the findings to clinical trials and clinical care is important for optimizing placebo effects to improve existing treatments while minimizing nocebo effects to reduce harm.

497 The Role of Epigenetics in Disease and Treatment

Brian C. Capell, Shelley L. Berger

The term *epigenetics* was coined by Conrad Waddington in 1942, as he sought to explain how changes in phenotype could occur throughout development independent of any changes to genotype. Appending the prefix *epi-* (Greek, meaning "over, outside of, around") to genetics aptly describes the numerous mechanisms by which gene expression and phenotypes are influenced—and sometimes even inherited through cell division—independent of any changes to the underlying DNA sequence. Today, epigenetics occupies one of the most exciting topics in biology and medicine, offering profound opportunities for discovery, as well as promise for the development of new therapies for disease. Interdisciplinary by nature, the field crosses virtually all areas of science and medicine: chemistry and genetics, development and differentiation, immunology, cancer, aging, and neuroscience.

The continuous introduction of ever more powerful technologies for interrogating the epigenome has led epigenetics to become one of the most innovative fields within the biomedical sciences. Given the vast expanse of the topic and limitations of space, in this chapter, we provide a broad but brief overview of the field and then highlight key areas across the landscape of biomedicine where epigenetics has been revealed to play critical roles in physiology and disease, and importantly, where epigenetics-based therapies have demonstrated success in clinical medicine.

THE BIOCHEMICAL BASES OF EPIGENETICS

Fundamental to epigenetic regulation is the intricate organization into chromatin of each cell's genome **(Chap. 479)**. The fundamental unit of the packaging into chromatin is the nucleosome, consisting of 147 base pairs of DNA wrapped around an octamer of 8 histone proteins (two copies of each of the four core histone proteins: H2A, H2B, H3, and H4), and nucleosome assembly into a regular repeating spaced array along the DNA polymer. The presence of nucleosomes and level of compaction of this basic chromatin array determine the accessibility of the DNA strand to transcription factors, to DNA repair machinery, and to other DNA-binding entities. Thus, compaction has a profound influence on gene expression levels and on local DNA mutation rates. Open regions of chromatin (euchromatin) tend to be transcriptionally active, whereas compacted chromatin (heterochromatin) tends to be transcriptionally repressed. Higher order three-dimensional chromatin architecture such as folding and looping further contribute to epigenetic gene regulation and cellular phenotypes.

Histones include the four core histones, which are the most abundant and most frequently found throughout the genome, and the variant histones of H2A, H2B, and H3. The individual protein structures of both core and variant histones include amino- and carboxyl-terminal "tails," which are extended and unstructured, and highly conserved globular domains. The x-ray crystal structure of the nucleosome particle has illuminated the dynamic alterations of chromatin by an astonishing range of regulatory mechanisms, summarized below.

The three main processes that regulate chromatin compaction, and thus access to the DNA template, include direct methylation modifications (and oxidized derivatives of methylation) of the DNA strand itself, posttranslational modifications of histones, and remodeling of nucleosomes to alter their location and composition with variant histones **(Fig. 497-1)**. The major modification of DNA is cytosine methylation of CpG dinucleotides (5-mC), associated with gene repression and catalyzed by the DNMT1, DNMT3A, and DNMT3B enzymes. DNMT3A and 3B catalyze the addition of methyl groups on unmethylated DNA de novo at CpG dinucleotides that are typically located throughout transcribed genes and in intergenic regions, but lacking at promoters, while DNMT1 is critical for the maintenance of the methylation state after DNA replication and after transcription during the

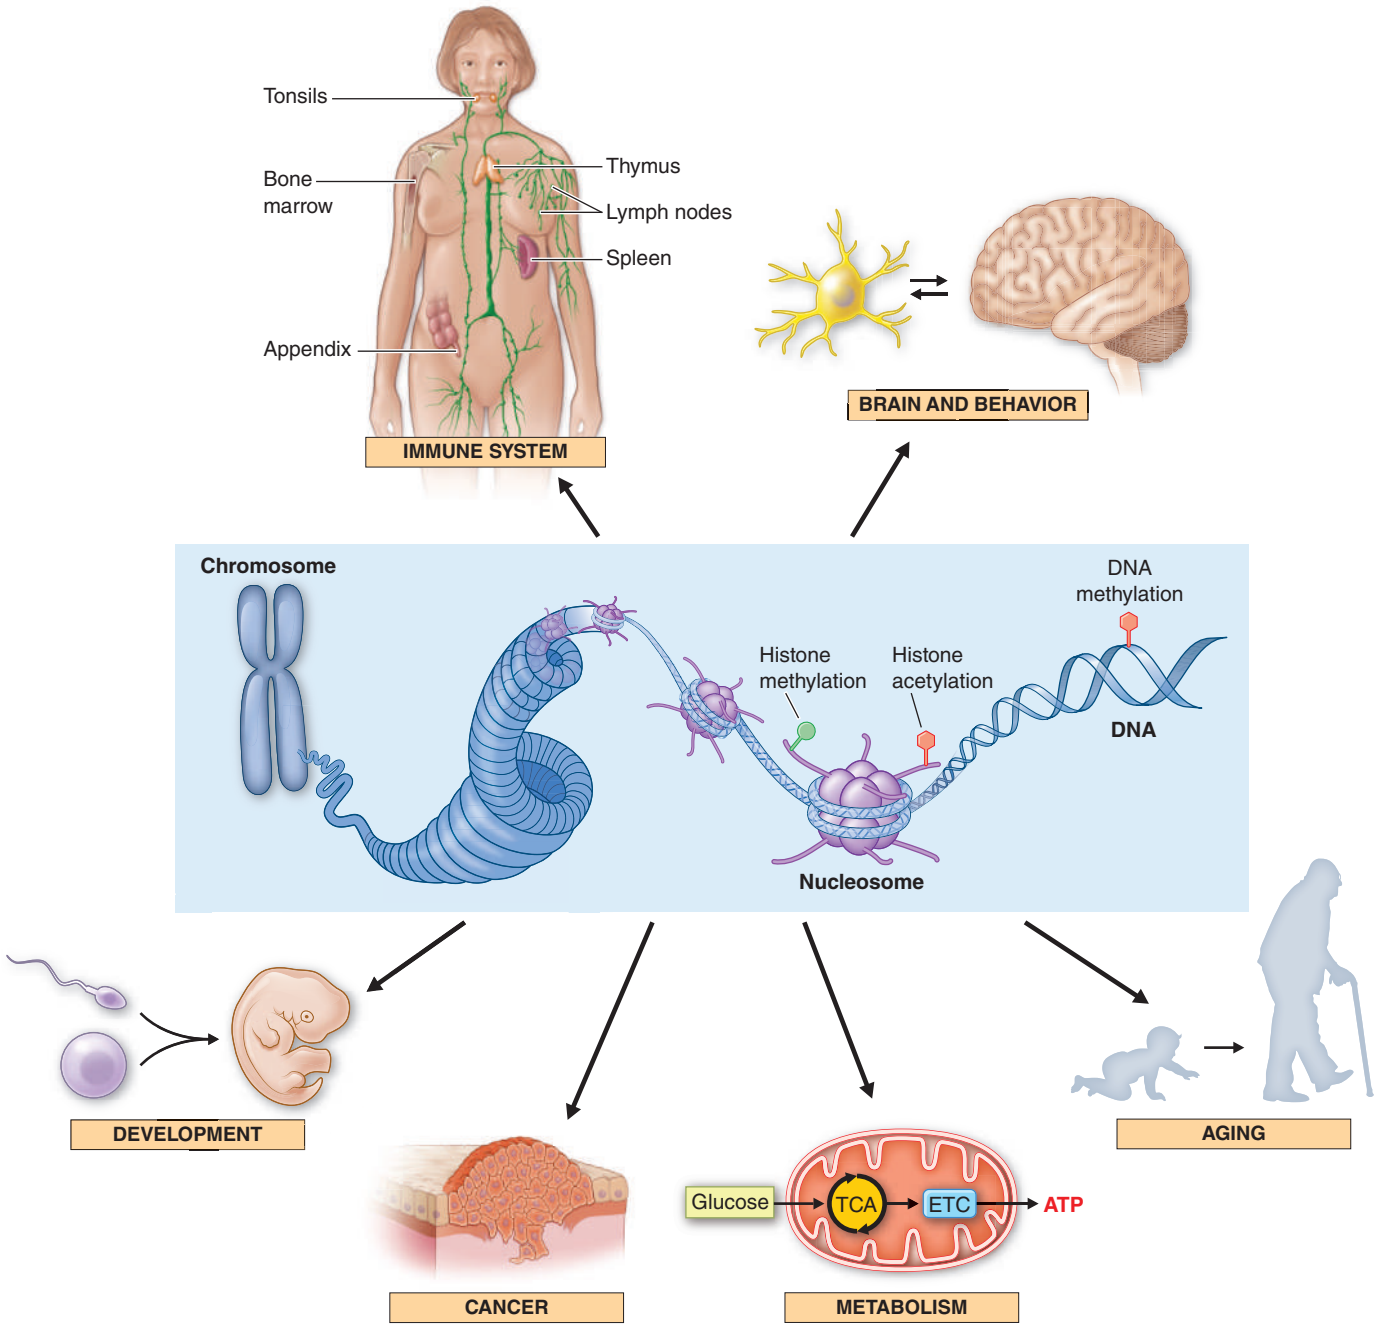

FIGURE 497-1 Epigenetic pathways influence multiple physiologic and disease pathways. As depicted in the center of the illustration, epigenetics refers to the chemical modifications of DNA and histones, which influence chromatin structure, gene expression, and susceptibility to mutations. These molecular pathways, in turn, play important roles in development, cancer, metabolism, aging, neural function, and behavior, and in the immune system. ETC, electron transport chain; TCA, tricarboxylic acid.

S phase of the cell cycle. To further alter and to remove methylation, the TET enzymes (TET1–3) progressively oxidize 5-methylcytosine (5-mC) to 5-hydroxymethylcytosine (5-hmC), to 5-formylcytosine (5-fC), and to 5-carboxylcytosine (5-caC), which are unable to be recognized by DNMT1 but can be removed by additional enzymes. Hence, these are mechanisms to passively lose 5-mC following DNA replication or to actively remove 5-mC, both potentially returning to unmethylated cytosine.

Histone posttranslational modifications (hPTMs) are rich sources of diverse signaling to, and marking of, the chromatin template, including at least 60 different covalent chemical modifications on the histone N- and C-terminal tails and within the globular domains. The hPTMs are added (written) and removed (erased) by enzymes and also serve as sequence- and PTM-specific binding surfaces for effector proteins and complexes (readers) to carry out a wide range of downstream actions including transcription, replication, DNA repair, and recombination. One key point is that the staggering numbers of writers, erasers, and readers provide unlimited potential for diagnostic and therapeutic pharmacologic discovery.

Throughout this chapter, we focus on histone acetylation and methylation, the most abundant and the most well-studied hPTMs (Fig. 497-1), although a wealth of additional modifications, such as serine/threonine/tyrosine phosphorylation, lysine ubiquitination, lysine SUMOylation, and lysine ADP-ribosylation, among others, play important roles in transcriptional and chromatin regulation. For instance, histone phosphorylation targets histone H2A at Ser139 (γH2A.X), which marks DNA double-strand breaks immediately following DNA damage and is critical for the recruitment of the DNA repair machinery. Histone mono-ubiquitination functions similarly to other hPTMs, in signaling and marking the chromatin template, in particular serving to mark the initiation region or elongation of transcribed genes for future rounds of transcription, whereas histone

SUMOylation plays a role in transcriptional repression. Polyubiquitination serves to tag proteins for degradation by the proteasome, and dysfunction in this system may play a role in the pathogenesis of neurodegenerative diseases, including Alzheimer's, Parkinson's, and Huntington's. ADP-ribosylation involves a class of enzymes, the poly-ADP-ribose polymerases (PARPs), which transfer ADP-ribose units from NAD^+ to a variety of nuclear proteins. This PARylation alters the chromatin environment through the recruitment and modification of chromatin-associated proteins. In general, future studies of the profuse types and functions of hPTMs will enhance our understanding of these chromatin-based mechanisms and processes and will illuminate new opportunities and targets for therapies.

In contrast, there is extensive understanding of histone lysine acetyltransferases (KATs) and methyltransferases (KMTs). KATs, previously known as HATs, were among the first identified histone modification enzymes. They attach acetyl groups on the lysine residues of histone tails and other proteins, resulting in both a novel side chain (acetyl-lysine) and an increase in negative charge (from positive charged lysine to neutral acetyl-lysine). This alteration results in loosening of chromatin structure to become more permissive to the binding of transcription factors, and acetylation also creates a novel binding surface for the association of reader proteins. Acetylation on core histones, such as lysine 9 on histone H3 (H3K9ac) or lysine 27 (H3K27ac), is typically associated with transcriptional activation. Acetylation is very dynamic and can be rapidly removed by histone deacetylases (HDACs), of which there are multiple classes, including HDACs and sirtuins (NAD-dependent deacetylases), acting to return the lysine to unmodified ground state.

Methylation of histone tails by KMTs provides more nuanced regulation, in that particular methylated lysines are associated with transcriptional activation (e.g., H3K4me3, H3K36me3, H3K79me3), transcriptional repression (e.g., H3K27me3), or DNA repeat and centromeric silencing (e.g., H3K9me3). The output is strictly determined by effector protein binding, as methylation of lysine does not alter side chain electrostatic charge. Lysine methylation is also a more stable chemical modification than is acetylation and turns over more slowly. Lysine demethylases have been identified for several of the specific methylated sites (H3K4, H3K9, H3K36, H3K27, H3K79).

In addition to their impacts upon local chromatin structure through electrostatic alterations and through recruitment of reader effector proteins, some histone modifications can influence other epigenetic processes. For example, H3K36me3 is involved in a variety of transcriptional processes including elongation and splicing. However, through its recruitment and interaction with other methyltransferases, such as DNMT3B and METTL14, H3K36me3 impacts both DNA and RNA methylation, respectively.

Frequently coordinating with histone modification enzymes are nucleosome remodeling enzymes, which use the energy derived from the hydrolysis of ATP to reposition and remove nucleosomes along the DNA template and to exchange core histones and variant histones (including variants that are located at the transcriptional initiation sites [H2AZ] and over the transcribed genes [H3.3]). The nucleosome remodeling complexes can activate or repress transcription. The SWI/SNF family creates nucleosome-free regions for transcriptional activation, the ISWI family evenly spaces nucleosomes to repress transcription, and the INO80 family exchanges H2A with H2AZ at transcription start sites to poise transcriptional activation. Other remodeling complexes play key roles in the DNA damage response and apoptosis, among additional genomic processes.

As alluded to above, RNA can also be methylated, and "RNA epigenetics" is now an emerging area of gene regulation beyond the direct methylation of DNA and hPTMs. Methylation of RNA, such as messenger RNAs (mRNAs), has been known to exist for over half a century. However, in the last decade, the discovery of enzymes that perform reversible methylation of RNAs led to an explosion of this new field, called *epitranscriptomics*. Indeed, RNA methylation leads to mRNA degradation or facilitates translation. However, mRNA methylation itself occurs co-transcriptionally. Notably, the writer methyltransferase enzymes (METTL3, METTL14) and the demethylases (ALKBH5, FTO) have important roles in a variety of disease pathologies, and drugs targeting their clinical activities are currently in human clinical trials.

Because multiple enzymes redundantly and synergistically write, erase, and recognize these modifications on DNA, RNA, and histones, there is great complexity and the potential for fine-tuning of gene regulation. While extensive knowledge gaps remain to fully explicate these mechanisms of gene regulation, epigenetics has become a fully established discipline within biomedical research. In the coming years, it is likely that the basic understanding of these processes will be further harnessed for further betterment of human health.

TOOLS FOR THE STUDY OF EPIGENETICS

Central to the rapid pace of epigenetic discovery has been the continual development of new cutting-edge epigenetic technologies. Chromatin immunoprecipitation (ChIP), developed over three decades ago, has been a mainstay across epigenetics and molecular biology research more broadly **(Fig. 497-2)**. ChIP involves using formaldehyde to crosslink proteins to DNA and then fragmenting the DNA and reversing of the crosslinks in order to analyze the DNA. The linking of ChIP to next-generation sequencing (ChIP-seq) provided a major leap forward in allowing researchers to probe the entire genome-wide landscape of histone modifications and DNA-binding transcription factors and chromatin-modifying enzymes. This has led to fundamental discoveries regarding the role of the epigenome in the regulation of gene expression and cellular phenotypes in development and disease.

More recent refinements in these methods have expanded the applicability of these methods. Studying chromatin accessibility has become possible through the assay for transposase-accessible chromatin using sequencing (ATAC-seq) (Fig. 497-2). Through ATAC-seq, a Tn5 transposase can be utilized to insert sequencing adapters into open regions of chromatin, allowing for the identification of DNA regulatory elements such as promoters and enhancers even at the single-cell level. Building upon both ChIP-seq and ATAC-seq, the tethering of an antibody of interest to micrococcal nuclease (MNase) allows for the cleavage of the DNA on either side of the target, sidestepping the need for any formaldehyde fixation step, significantly scaling down the signal-to-noise ratio, and reducing the number of cells and DNA required in comparison to standard ChIP-seq. This method, referred to as CUT&RUN (cleavage under targets and release using nuclease), offers the ability to obtain histone and chromatin-binding information in systems and models where cell numbers were previously rate limiting. A further modification of the CUT&RUN protocol replaces the MNase with a Tn5 transposase fused to sequencing adapters (CUT&Tag), offering the ability to profile histone modifications at the single-cell level.

While ATAC- and ChIP-seq and their derivatives have provided tremendous insights into how chromatin accessibility and histone modifications play a role in gene regulation, they did not provide information on how the physical organization and folding of the genome might contribute to gene expression. This was only able to begin to be understood by techniques that could elucidate the three-dimensional architecture and structure of chromatin. Here, techniques such as HiC (Hi-C is a high-throughput form of 3C (chromosome conformation capture) technology to study 3D genome organization) and Hi-ChIP (Hi-ChIP combines Hi-C with ChIP-sequencing to study the relationship of DNA-binding proteins to 3D genome organization) have emerged to reveal nuclear architecture and how it can either inhibit or facilitate gene expression. Collectively, these studies have revealed a model whereby enhancer state drives gene regulation. Once enhancer-promoter loops have formed, these topologically associated domains (TADs) are reinforced and can ultimately help to constrain motion of the genome and in turn increase the likelihood of further promoter-enhancer connections forming to facilitate transcription.

More recently, the latest frontier in biomedical research is spatial technologies that allow the capture of molecular data at subcellular resolution within their native tissue context. While techniques such as spatial CUT&Tag are still in development, as they continue to advance in resolution, throughput, and accessibility, they are certain to offer unprecedented insights into how tissue and disease pathology correlates with alterations in the transcriptome, epigenome, and proteome.

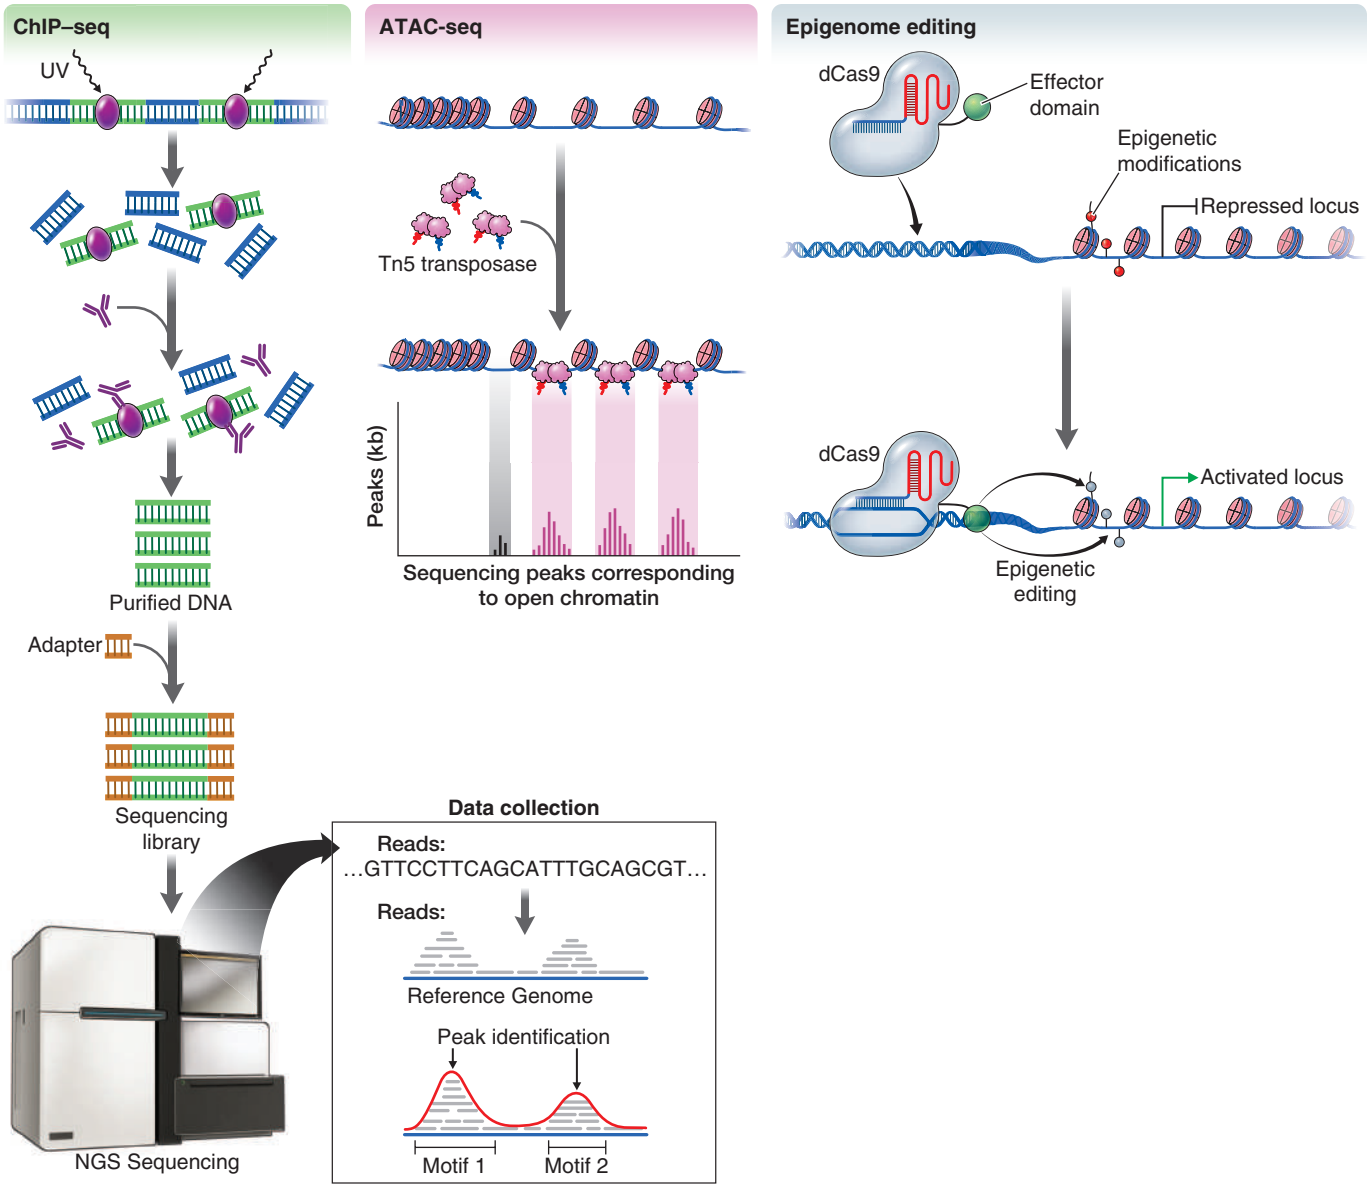

FIGURE 497-2 Core experimental techniques for the study of epigenetics. The explosion of interest and research in the past few decades has been fueled by fundamental advances in the experimental approaches and ability to profile the epigenome. Chromatin immunoprecipitation–next-generation sequencing (ChIP-seq) allows for the ability determine the genome-wide binding of a histone modification or DNA-binding protein of interest. In contrast, assay for transposase-accessible chromatin using sequencing (ATAC-seq) provides a method for determining chromatin accessibility genome-wide even down to the single-cell level. More recently, the development of CRISPR-based epigenome-editing technologies has offered a way to directly deposit histone modification in order to activate or repress specific genes. NGS, next-generation sequencing.

Finally, another major technological breakthrough, and one with tremendous therapeutic potential, is development of CRISPR-based epigenome editing approaches (Fig. 497-2). By fusing a nuclease-deactivated Cas protein to an epigenetic modifying enzyme, one can use guide RNAs to precisely target gene regulatory effectors to turn on and turn off specific genes by changing the gene's histone acetylation or methylation levels. For example, using CRISPR to guide the mRNA of an epigenetic repressor to the oncogene MYC is one strategy currently being tested for cancer treatment. These advances promise to not only elucidate new knowledge regarding principles of gene regulation but also to offer new therapeutic opportunities for disease.

EPIGENETICS IN DEVELOPMENT AND DIFFERENTIATION

Epigenetic processes are critical to organismal development and to cellular differentiation and reprogramming of cell fate (Fig. 497-1). Transcription factors establish the epigenomic landscape that enables and stabilizes cell-type-specific gene expression while simultaneously ensuring stable repression of alternative cell fates. This results in chromatin profiles that display remarkable cell-type specificity in differentiated cells, particularly at the key regulatory nodes of gene enhancers, which are gene-distal DNA elements that control transcription. In fact, epigenome profiling of the chromatin landscape in tumors of unknown cell origin can provide a better index of the origin tissue than does DNA sequencing of gene mutations within the tumor.

The cell-type-specific epigenetic program is first derived from the template of embryonic stem cells, where numerous genes required for differentiation exist in a "bivalent" state, marked by both the activating histone modification, H3K4me3, and the repressive modification, H3K27me3. Due to this unstable epigenetic state, the genes are "poised" for activation or for repression, depending on their subsequent cell fate. Critical genes directing toward a specific cell fate will be turned on, with maintained H3K4me3 and erased H3K27me3, whereas genes leading toward alternative fates will be repressed, with maintained H3K27me3 and removed H3K4me3. Once differentiated, an epigenetic barrier will prevent the cells from returning to the stem cell state. For example, constitutive heterochromatin in the form of H3K9me3 can serve as a barrier to cellular reprogramming when attempting to create induced pluripotent stem cells, and inhibiting the enzymes that catalyze H3K9me3, such as SUV39H1, can enhance reprogramming efficiency.

DNA methylation contributes to the specification of cell fate and to other developmental pathways. DNA methylation alterations are involved in critical processes ranging from sex chromosome dosage compensation to coordinating expression of imprinted genes. Disruption of this latter process can lead to imprinting disorders including Prader-Willi syndrome, Angelman syndrome, and Beckwith-Wiedemann syndrome. Recent discoveries have served to highlight the tremendous amount of interplay between epigenetic modifications and, in particular, between DNA methylation and various histone modifications.

Beyond embryonic development, epigenetics can provide the necessary coordination and balance between adult stem cell self-renewal compared to cell differentiation. This epigenetic control is critical, as impaired self-renewal can lead to stem cell exhaustion and premature aging, while excessive self-renewal may promote cancer. Key epigenetic regulators tend to play conserved roles across diverse tissue types. For instance, BMI1, a component of the polycomb repressive complex 1 (PRC1), is required for stem cell proliferation and self-renewal, and its ablation leads to stem cell depletion in hematopoietic, epidermal, muscle, intestinal, and mammary stem cells. Similarly, the DNA methyltransferase DNMT1 is required for stem cell self-renewal in hematopoietic, epidermal, and mammary stem cells. HDACs 1 and 2 possess some overlapping functions and are required for normal epidermal differentiation. Likewise, a loss of these HDAC enzymes in hematopoietic stem cells can lead to failure of differentiation and severe anemia. In a similar fashion, inhibition or loss of histone lysine demethylase 1 (LSD1), a repressor of transcription, is known to promote differentiation across multiple cellular contexts. These factors represent repressive chromatin regulation, leading to the general concept that restraining specific transcription pathways related to differentiation is crucial to maintaining undifferentiated self-renewing stem cell pools.

The epigenetic regulation of the tumor suppressor p16 (*CDKN2A*) locus during differentiation provides a prime example of this finely tuned system. For example, as mentioned above, DNMT1 is necessary for self-renewal in human epidermal stem cells. Levels of DNMT1 are high in the basal undifferentiated layer of the epidermis, decreasing progressively with epidermal stratification, leading to de-repression of the tumor suppressors p16 and p15, thereby promoting cell cycle arrest and full differentiation. BMI1 displays a similar phenotype in both hematopoietic and epidermal stem cells, repressing key genes that promote differentiation, such as *p16* and *p19ARF*. Consistently, a loss of BMI1 leads to premature differentiation and defective self-renewal. In addition to the repression provided by DNMT1 and BMI1, the p16 locus is highly decorated with the repressive H3K27me3 catalyzed by EZH2 in epidermal stem cells. Then, during epidermal differentiation, H3K27me3 is removed by the KDM6B (JMJD3) histone demethylase. Loss of this control over programmed p16 expression occurs in epithelial cancers, such as squamous cell carcinoma (SCC), where EZH2 is overexpressed and KDM6B expression is lost. Breast cancer is another example where progesterone can increase levels of EZH2 to promote mammary epithelial cell proliferation, and excessive EZH2 expression can occur in cancer. This exemplifies how epigenetics can integrate environmental signals and have a profound influence on the fine balance between stem cell maintenance and overt carcinogenesis. In general, a recurrent theme in cancer is loss of key chromatin regulation that promotes cell differentiation, combined with gain of activities that promote stemness.

Chromatin-modifying enzymes also play a major role in influencing cell-type specificity. High levels of EZH2 that modify H3K27me3 promote adipogenesis while simultaneously inhibiting osteogenesis. In contrast, the H3K27me3 demethylases, KDM6A (UTX) and KDM6B, derepress those same genes, driving stem cells toward osteogenesis. Through interactions with tissue-specific master regulators, epigenetic modifiers also shape cell-type specificity. In the epidermis, p63, the p53 family member that is a master regulator of the epidermal compartment, interacts with several chromatin regulators including HDAC1 and HDAC2, SATB1, MLL4 (KMT2D), and BRG1 to orchestrate epidermal differentiation. Similarly, the gene-activating H3K4 histone methyltransferases, MLL3 (KMT2C) and MLL4, are required for adipogenesis by forming a complex with the transcriptional activator ASC2 and the transcription factor PPARγ to induce adipogenic genes. Overall, loss of epigenetic regulation can reduce cell differentiation and increase stem cell specification to drive diseases encompassing development, cancer, and, broadly, diseases associated with aging.

EPIGENETICS OF METABOLISM

One of the fascinating aspects of epigenetics is that it represents a mechanism for direct connection between the environment and gene expression. Numerous studies in the field of metabolism have identified a complex interplay between diet, metabolism, and the epigenome (Fig. 497-1). Seminal findings in *Drosophila* and mice have shown that changes in diet, particularly the paternal diet, and other environmental factors, can influence the metabolism of offspring, ultimately promoting obesity in later generations. Epidemiologic studies in humans have supported these results, as the nutritional status of grandparents has been correlated with phenotypic effects in grandchildren. In fact, diet can directly affect the levels and activity of chromatin modifiers.

For instance, high-fat diets reduce histone acetylation through their ability to inhibit the enzymes ACLY and ACSS2, which produce acetyl-CoA. Levels of acetyl-CoA, in comparison to all measured metabolites, are indeed the best predictor of histone acetylation levels. Consistent with this, increased acetyl-CoA correlates with rising levels of total histone acetylation, including at the promoters of growth-associated genes. This increase in nuclear acetylation is associated with cell cycle progression and proliferation, and it can have clinically relevant downstream effects. For example, high levels of acetyl-CoA can delay stem cell differentiation and suppress autophagy. The oncogenes MYC and AKT can both hijack metabolic networks to enhance nutrient uptake by cancer cells, thus promoting acetyl-CoA production and resulting in both the initiation and progression of tumorigenesis. Additional evidence suggests that dietary intake of alcohol can directly contribute to acetate levels and therefore histone acetylation in the brain, with effects on the transcription of genes involved in learning and memory.

Contrary to convention that metabolic enzymes are strictly mitochondrial or cytosolic, certain metabolic enzymes can be present in the nucleus and can thereby directly regulate histone acetylation enzymes. This is the case for several enzymes that generate acetyl-CoA, including ACLY, PDH, and ACSS2, which generate acetyl-CoA from citrate, pyruvate, and acetate, respectively. Further, ACSS2 can be chromatin-bound to regulate gene expression, leading to physiologic responses such as autophagy in the liver and mammalian hippocampal function in learning. This direct metabolic-epigenetic enzyme cross-talk illuminates a crucial local role of the acetyl-CoA metabolite to effect rapid gene transcription and represents a fertile intersection for future therapeutics.

Methylation is also altered by metabolism. *S*-Adenosylmethionine (SAM) is the key metabolic cofactor for histone and DNA methylation. Dietary factors are estimated to explain 30% of the variation in human serum methionine concentration and hence can alter SAM levels and histone methylation. For example, dietary methionine availability and intracellular production of SAM affect the levels of histone H3K4me3 associated with transcriptional activation. Furthermore, these fluctuations can have critical physiologic consequences: DNA methylation levels in rectal mucosa and colonic polyps are increased by higher levels of dietary folate, and a diet low in methyl donors reduces the formation of gastrointestinal cancers in mice predisposed to these tumors. Methionine metabolism and the availability of SAM regulate stem cell differentiation and contribute to carcinogenesis. For instance, cancers with mutations in metabolic regulatory genes such as *IDH1/2*, *FH*, and *SDH* lead to the accumulation of by-products (2-hydroxyglutarate, fumarate, and succinate, respectively), which all inhibit α-ketoglutarate (α-KG)–dependent histone demethylases and thus promote hypermethylation and lead to impaired cellular differentiation. Notably, some of the α-KG–dependent demethylases, which are highly mutated in numerous cancers (i.e., KDM5A, KDM6A), also serve as cellular oxygen sensors, thus linking environmental oxygen levels to epigenetic control of methylation levels. In contrast to hypermethylated states, loss of the *MTAP* gene, which is part of the 9p21 locus

containing p16 and one of the most frequent events in human cancer, disrupts normal methionine metabolism. This both lowers methylation levels, and, interestingly, also sensitizes cancer cells to inhibitors of the PRMT5 methyltransferase, therefore opening a therapeutic opportunity. These observations illustrate how connections between epigenetics and metabolism can generate unanticipated advances in medicine. Furthermore, these data highlight the tight interconnections between environmental inputs, metabolism, and epigenetics.

CANCER EPIGENETICS

Cancer is now understood to be a mixed genetic and epigenetic disease, as epigenetic dysregulation is pervasive in human cancers (Fig. 497-1). Beyond simple activation of oncogenes or reduced expression of tumor suppressors, epigenetic mechanisms can contribute to chemotherapy resistance and to failure of antitumor immunity. Accordingly, the development of drugs targeting epigenetic pathways is one of the most active areas of clinical and pharmaceutical development, with several compounds already approved for human use and shown to be effective in a variety of cancers. Epigenetic perturbations in cancer largely affect chromatin-regulating enzymes, which represent robust targets for development of novel small-molecule inhibitors, especially as compared with canonical oncogenic transcription factors (e.g., MYC) and tumor suppressors (e.g., p53).

Epigenetics can contribute to carcinogenesis in a variety of ways. First, on a global scale, chromatin organization is the single most influential factor in determining local mutation rate across the genome. Analysis of abundant tumor sequencing data has demonstrated that heterochromatic regions of the genome contain a higher frequency of mutations compared with more open euchromatic regions. This difference is due to the improved accessibility of the DNA repair machinery to less compact, more open regions of chromatin.

The first discovery of an epigenetic mutation was found in 1998 when the chromatin remodeler *SMARCB1* was shown to drive the formation of malignant rhabdoid tumors. Extensive sequencing of human tumors from the majority of cancer types has been performed by The Cancer Genome Atlas (TCGA) consortium, and remarkably, 25–30% of identified cancer driver mutations occur in chromatin regulatory proteins. Similar to *SMARCB1*, numerous other chromatin modifiers (e.g., methyltransferases *MLL3* and *MLL4*, and acetyltransferases *EP300* and *CBP*) and nucleosome remodeling enzymes and associated complex components (e.g., *SMARCA4*, *SMARCA2*, *ARID1A*) are heavily mutated and inactivated in many cancers. The majority of these mutations are loss-of-function mutations, and indeed, enzymes like MLL4 and demethylase KDM6A possess tumor-suppressive activity across a variety of tissues and cellular contexts. In contrast, the H3K27me3 histone methyltransferase *EZH2* is an oncogene, and accordingly, it is overexpressed in many advanced-stage or metastatic solid tumors such as breast cancer, prostate cancer, and melanoma. Mechanistically, EZH2 represses the *p16* tumor suppressor and other cell cycle genes required for cell cycle exit via H3K27me3 deposition. Consistent with a broad growth regulatory role, EZH2 inhibitors are therapeutically successful for a number of cancers in preclinical models and are being actively studied for B-cell lymphoma, melanoma, and other solid tumors.

In addition, provocative evidence has emerged for a direct tumorigenic role of histones based on the discovery of causative mutations, such as histone H3 mutations identified in pediatric high-grade gliomas. Specifically, the majority of these mutations are in the H3 variant H3.3, where lysine 27 is replaced by methionine (K27M). Similarly, >90% of chondroblastomas replace lysine 36 with methionine (K36M) in histone H3.3. These effects appear to be dominant negative because (1) in H3.3, these are heterozygous mutations, and (2) the mutations also occur in the canonical H3, which exists in ~30 orthologous genes in the human genome. Thus, a minority of H3/H3.3 mutant protein leads to global defects in the associated histone modifications (K27 or K36 methylation), possibly via irreversible inhibition of the cognate enzymes by the mutant histones. These "oncohistone" mutations promote resistance to apoptosis and failure of normal differentiation in a number of pediatric and adult cancers.

Beyond mutations, genetic translocations involving chromatin modifiers also implicate chromatin pathways as direct drivers in cancer. MLL1 (KMT2A), the H3K4 histone methyltransferase, is a frequent translocation partner occurring in adult and pediatric acute myeloid leukemia (AML) and in ~80% of infant acute lymphoid leukemia (ALL) cases. MLL1 can fuse with >70 translocation partners, and these mutant proteins prevent normal hematopoietic differentiation. Consistent with a causative role of MLL1 in these gene fusions, drugs inhibiting the catalytic activity of MLL1 are effective in preclinical models of AML and are currently being evaluated in human clinical trials.

Given the abundance of epigenetic abnormalities in cancer combined with the inherent reversibility of epigenetic changes, extensive efforts are underway to develop epigenetic drugs. The first epigenetic therapeutic involved the use of DNA methylation inhibitors (DNMTi) to reactivate tumor-suppressor genes. Interestingly, the mechanism of traditional chemotherapeutics, such as azacitidine and decitabine, is to inhibit DNMT1, thereby promoting global hypomethylation; these are currently in clinical use for myelodysplastic syndrome (MDS) and AML. In a second broad mechanism, loss of acetylation occurs in many cancers, and thus, HDAC inhibitors (HDACi) are under intensive development. HDACi are effective and approved for treatment in cutaneous T-cell lymphoma and multiple myeloma. Bromodomain (BRD)-containing proteins bind to lysine acetylated target proteins, including histones, and rationally designed BET inhibitors (BETi) block their binding. BETi reduce the amplified expression of oncogenes such as *MYC* in hematologic cancers. Current studies are now focused on optimizing combinatorial epigenetic therapies with conventional chemotherapies and immunotherapies, particularly given the ability of epigenetic therapeutics to promote re-expression of tumor antigens and interferon (IFN)-mediated antitumor immunity. Indeed, the development of a new generation of more specific epigenome-targeted inhibitors, combined with our increased knowledge of the underlying epigenetic mechanisms contributing to tumorigenesis, has enabled a precision medicine–based approach to harnessing the potential of these drugs. This may be particularly valuable in the context of improving patient responses to a variety of therapies beyond chemotherapies and immunotherapies, such as radiation and hormone therapies.

There are several hundred chromatin enzymes and binding proteins in the human genome, and the current focus is to identify more specific inhibitors. Indeed, targeted inhibitors of numerous mutated chromatin regulators have been developed, with >30 compounds currently in various stages of development and preclinical trials. Some notable examples showing early clinical success include EZH2 inhibitors for lymphomas, sarcomas, and melanoma; IDH inhibitors for AML and gliomas carrying mutant *IDH1* or *IDH2* genes; LSD1 inhibitors for AML and small-cell lung cancer; and DOT1L and MLL1 inhibitors for leukemias with activated MLL1. Given the broad potential effects of epigenetic regulators, it is perhaps not surprising that there have been some dose-limiting toxicities, particularly among those that are less target-specific. Collectively, the emerging picture is that the most effective and robust use of epigenetic drugs in cancer will be fine-tuning and potentiating the effects of other therapies that are either incompletely effective or marked by widespread resistance.

EPIGENETICS OF AGING

Like many diseases of aging, human aging itself results from the complex interplay between genes and the environment. Evidence that the epigenome may be the key link between these processes derives from observations that numerous environmental stimuli and stressors—ranging from diet and exercise to hormones and circadian rhythms—contribute to both aging and epigenetic alterations (Fig. 497-1). Thus, a lifetime of exposures progressively disrupts the chromatin landscape. These age-dependent changes in chromatin organization increase the susceptibility of the genome to mutations and also reduce transcriptional fidelity. Further, provocative findings in model systems demonstrate that stress-induced epigenetic changes can be transmitted over several generations and can even affect the life span of later generations. Among these global epigenetic alterations, there

is dysregulation of histone modifications and a general loss of histone proteins with aging across taxa. Amazingly, experimental increases in histone levels, particularly histones H3 and H4, but not H2A or H2B, can reverse these age-related changes in mammalian cells and in the yeast *Saccharomyces cerevisiae* model.

Thus, the sum of current evidence suggests a model of aging via a general increase in activating epigenetic modifications along with a loss of repressive modifications. Together these changes create a state of transcriptional instability and "noise" that inhibits accurate transcription. Cells from patients with Hutchinson-Gilford progeria syndrome (HGPS), the most severe form of human premature aging, display reduced levels of both H3K9me3 and H3K27me3 repressive chromatin. In another premature aging disease, Werner syndrome, DNA damage induces global loss of H3K9me3 and H3K27me3 due to the inherent absence of the Werner syndrome ATP-dependent DNA helicase, which is critical for DNA repair. Such heterochromatin loss is not limited to premature aging conditions, as aged cells derived from healthy older humans display age-dependent loss of H3K9me3 leading to aberrant expression of normally repressed transposable elements. Activation of these mobile elements correlates with neurodegenerative disorders and may also promote other aging-related phenotypes such as cancer. Human fibroblasts undergoing cellular senescence (exit from cell cycle due to replicative or other stress) undergo destabilization of compact heterochromatin adjacent to the nuclear periphery, in so-called lamin-associated domains (LADs). At LADs, in addition to a reduction of repressive histone modifications as discussed above, there are broad new regions of the euchromatic histone modification H3K4me3. This general loss of heterochromatin can promote the activation of cytosolic DNA and RNA sensing pathways that promote innate immune signaling and "inflammaging."

In addition to age-associated alterations of histone modifications, direct manipulation of chromatin-modifying enzymes that control these marks affects the balance between heterochromatic and euchromatic regions, and it alters the lifespan of model organisms. Inhibiting the H3K27me3 histone demethylase KDM6A results in increased repressive H3K27me3 and extended lifespan in *Caenorhabditis elegans*. Consistent with this, genetic reduction of enzymes (*ash-2*, *set-2*, *wdr-5*) that add the activating H3K4me3 histone modification also extends lifespan in *C. elegans*. The consequences of these genetic manipulations nicely correspond to the observed changes in histone modifications as described above. Beyond histone-modifying enzymes, dysregulation of the levels or function of chromatin remodelers can also affect lifespan in model organisms. This dysregulation occurs in humans as well, as in the nucleosome remodeling deacetylase complex (NuRD), which is reduced in HGPS fibroblasts and in aged healthy donors.

In addition to age-related changes in histone methylation, histone acetylation also contributes to aging phenotypes. Dysregulation of histone acetyltransferases (HATs) and HDACs is associated with reduced longevity across model organisms. Further, sirtuin deacetylases (class III NAD^+-dependent HDACs) promote health span and lifespan across species as key mediators of pro-longevity effects of caloric restriction. Indeed, loss of Sirt6 results in premature aging in mice, while caloric restriction–induced increases of Sirt1 and Sirt6 expression can delay aging. As discussed previously, metabolism and acetylation are intricately linked, and the sirtuins, via NAD^+ levels, and other HDACs may play key roles connecting the environment, gene expression, and physiologic output. For instance, exercise in humans reduces activity of HDACs 4 and 5, leading to increased H3K36ac in skeletal muscle, which likely promotes beneficial gene expression.

Epigenetic alterations with aging are not limited to histone modifications and extend to DNA methylation. Consistent with the histone patterns, DNA methylation data support the model described above—that is, general decompaction of the epigenome with aging. Specifically, levels of 5-mC are reduced in senescent human cells, and global DNA hypomethylation occurs across the human genome with aging. Concurrent with this overall hypomethylated state, there are local regions of hypermethylation focused near CpGs at gene promoters, particularly at genes that maintain cellular differentiation and cell identity. This epigenetic disruption during aging thus leads to profound changes in transcription. For example, in hematopoietic stem cells, DNA hypermethylation blocks proper binding of transcription factors, resulting in dysregulation of normal gene expression with aging. Importantly, these patterns are not merely stochastic alterations in response to environmental stressors throughout aging. Indeed, the methylation status of a defined number of CpG sites is a highly accurate predictor of chronologic age in human tissues. This work reveals that DNA methylation status with aging outperforms previous standard biomarkers of aging, such as p16 expression levels and telomere length, and will be highly valuable in the near future to gauge effects of treatment aiming to ameliorate diseases of aging.

EPIGENETICS OF THE BRAIN AND BEHAVIOR

Brain disorders are among the greatest clinical challenges to understand and to treat. Most neurologic and psychiatric disorders result from complex dysregulation of numerous genes and pathways. In this interplay between underlying genetic predisposition and external environmental factors, aberrant epigenetic regulation is increasingly recognized as a potentially key modulator (Fig. 497-1).

More directly, however, several progressive neurodevelopmental disorders are caused by germline mutations in chromatin regulators. Mutations in methyl CpG binding protein 2 (*MECP2*), a protein important for binding to methylated DNA and contributing to gene repression, are the major cause of Rett syndrome. MeCP2 loss leads to overactive gene transcription in neurons and impaired presynaptic excitatory functions. Similarly, Kabuki syndrome, another progressive neurodevelopmental disorder, is caused by germline mutations in either the H3K4me1 histone methyltransferase, *MLL4* (*KMT2D*), or the H3K27me3 demethylase, *UTX* (*KDM6A*). This disorder may derive from dysregulation of transcriptional enhancers, a major class of gene regulatory elements, as both *MLL4* and *UTX* play a key role in activation of enhancers. Finally, the acetyltransferase CBP (*CREBBP*) also is important for gene enhancer function and, when mutated, can lead to Rubinstein-Taybi syndrome, a cause of intellectual disability.

Beyond germline mutations, altered methylation dynamics can drive disorders of neural development and of neurodegeneration. Fragile X syndrome, characterized by learning disabilities and cognitive impairment, is caused by mutations in the *FMR1* or *FMR2* gene or by hypermethylation of the transcriptional promoters regulating *FMR1* or *FMR2*. Similarly, Prader-Willi syndrome and Angelman syndrome, neurodevelopmental conditions caused by abnormal imprinting of the paternal or maternal chromosomal region (15q11-13), respectively, are frequently caused by aberrant DNA methylation. Further, DNA hypomethylation is implicated in some neurodegenerative conditions. For instance, in Parkinson's disease, several genes involved in pathogenesis are hypomethylated due to DNMT1 depletion, including the α-synuclein gene (*SCNA*). In Alzheimer's disease (AD), DNA hypomethylation occurs at promoters of key pathogenic genes such as amyloid precursor protein (*APP*). Indeed, APP promoter methylation is responsive to environmental factors, including aging, a major risk factor for AD. Likewise, presenilin-1 (*PSEN1*) is implicated in AD and displays altered DNA methylation in response to variations in metabolic stimuli. Recent evidence from human AD brains demonstrated significant enrichment of H3K9 and H3K27 acetylation and provided evidence that this dysregulation of the epigenome promotes gene transcription pathways involved in AD pathogenesis. Studies of Huntington's disease (HD) have demonstrated DNA hypomethylation and decreased histone acetylation, in part due to altered function of the acetyl transferase CBP, leading to transcriptional dysregulation. Together, these observations underscore altered epigenetic regulation as a crucial feature of neurodegeneration.

Additional gene regulatory proteins in the nervous system interact with and are regulated by chromatin modifiers. REST (repressor element 1–silencing transcription factor) is important in neuronal homeostasis through its ability to recruit chromatin regulatory enzymes, such as histone deacetylases and histone methyltransferases, and via its control over gene expression. REST levels increase with aging and serve a protective function in neurons against age-associated stressors and loss of cognitive function associated with AD. Similar to REST,

brain-derived neurotrophic factor (BDNF), another important mediator of neural development and homeostasis, is implicated in a variety of neurologic and psychiatric disorders including HD, depression, schizophrenia, bipolar disorder, and autism. Knockdown of BDNF in the dentate gyrus leads to depression-like behavior in mouse models, and BDNF mediates effects of antidepressant therapies. Chromatin pathways, including DNA methylation/MeCP2 and H3K27me3, play a key role in BDNF regulation as observed in brains from patients with schizophrenia.

Finally, addiction medicine is another frontier where epigenetics holds great promise to reveal connections between environmental exposure and phenotypes. Although still in its early stages in terms of mechanistic understanding, emerging evidence demonstrates disruption of epigenetic homeostasis as a consequence of addictive substances ranging from alcohol to cocaine. For example, the acetylation of regulatory elements in the *FOSB* gene by the histone acetyltransferase CBP is associated with behavioral effects of cocaine. Opioid exposure appears to promote a generally more open and permissive state of chromatin marked by increases in histone acetylation and reductions in histone methylation, which may allow for a more hyperresponsive state and reinforce reward-seeking behaviors. Ethanol also induces histone acetylation and a decompacted chromatin structure with direct effects on learning and memory function.

EPIGENETIC INFLUENCES ON INFECTION, IMMUNITY, AND INFLAMMATION

Alterations in gene expression patterns are important determinants of immune-mediated disease, and in turn, epigenetics regulates infection, immunity, and inflammation (Fig. 497-1). Treatment with immune-stimulating agents such as lipopolysaccharide (LPS) and tumor necrosis factor α activates expression of numerous inflammatory genes within hours, with precise gene pathways and activation kinetics determined by the cellular epigenetic state. HATs and HDACs are critical components of this response, coordinating with proinflammatory transcription factors, such as AP-1 and NF-κB, to either activate (in the case of HATs) or repress (in the case of HDACs) inflammatory genes. For example, corticosteroids recruit HDAC2 to promoters of NF-κB–stimulated inflammatory genes to prevent activation during asthma treatment.

Type 1 IFN responses are exceptional examples of regulatory complexity governed by epigenetic control. In an unstimulated state, the H3K9 methyltransferases G9a (*EHMT2*) and EHMT1 suppress expression of IFN and IFN-induced genes. Upon induction of IFN-stimulated genes, STAT transcription factors recruit chromatin remodeling complexes, such as BAF (*SMARCA4*), and recruit HATs including p300, CBP, and GCN5 (*KAT2A*). In turn, chromatin remodeling and acetylation recruit chromatin binding proteins including the bromodomain protein, BRD4, which promotes transcriptional elongation and full activation. Beyond the DNA level, METTL3-mediated m^6A methylation on mRNAs also is a critical regulator of IFN signaling in a variety of distinct cellular contexts.

Major regulators of adaptive immunity pathways are similarly epigenetically regulated. CD4+ and CD8+ T cells undergo extensive changes in histone modification profiles during differentiation to distinct subsets of effector T cells. For example, genes associated with effector T-cell functions in CD8+ memory T cells (e.g., *PRDM1*, *KLRG1*, *IFNG*) display enrichment of H3K4me3 and low levels of H3K27me3 compared with those genes in naïve T cells. DNA methylation also plays an important regulatory role and may contribute to disease. For example, CD4+ T cells from individuals with rheumatoid arthritis (RA), systemic scleroderma, and latent autoimmune diabetes in adults display hypermethylation of the *FOXP3* gene, which activates regulatory T cells that dampen immune responses. In addition, hypermethylation of the *CTLA4* locus occurs in regulatory T cells from RA patients, impairing their immunosuppressive abilities.

During infection, epigenetic processes can play critical roles in both the immune response and defense against pathogens, as well strategies exploited by microorganisms to co-opt the host cellular machinery to advantage of the pathogen. Respiratory syncytial virus (RSV) infection promotes the expression of the histone demethylase KDM5B, which removes H3K4 methyl groups from antiviral genes such as type 1 IFNs, driving a switch from T helper 1– to T helper 2–type immune responses, thereby contributing to chronic infection. Similarly, influenza upregulates the repressive H3K9me3 methyltransferase SETDB2 to block expression of CXCL1 and a variety of NF-κB target genes involved in attracting neutrophils and host defense, both serving to lengthen the infection and contributing to bacterial superinfection. Regarding the host response to infection, studies have revealed that differences in host tissue-, age-, and sex-biased epigenetic profiles might shape susceptibility and responses to infection. For example, differential DNA methylation at the *ACE2* gene may impact expression levels of this key cellular receptor and ultimately the ability of SARS-CoV-2 to infect hosts, while alterations in antiviral IFN signaling may lead to more severe COVID-19 infection and disease. These findings are all supported by new discoveries demonstrating that epigenetics is a key component for the inflammatory memory that has been observed now across a wide variety of contexts. Numerous perturbations ranging from infections and vaccination to skin wounding and Western diets have now been shown to elicit an epigenetic memory that is maintained and propagated. This epigenetic memory extends beyond just the immune system to the involved tissues.

These findings have suggested a potential for epigenome-modifying drugs for the treatment of inflammatory and immune-related conditions. For example, the DNA methylation inhibitors azacitidine and decitabine have immunosuppressive effects possibly mediated by enhanced expression of *FOXP3*, which generally suppresses immune responses. HDACi upregulate and downregulate immune genes, and they inhibit cytokine production in macrophages from patients with RA. Further, the HDACi vorinostat and panobinostat inhibit primary B-cell responses and antibody production in vitro and in vivo. Given these broad effects, it is not surprising that the HDACi trichostatin A (TSA) has efficacy in various model systems for treatment of RA, systemic lupus erythematosus (SLE), asthma, acute kidney injury, sepsis-induced lung and cardiac damage, and acute pancreatitis. Similarly, BETi also display broad effects in blocking antigen presentation and T- and B-cell activation and thus beneficial protective effects in a variety of inflammatory settings including autoimmunity, sepsis, atherosclerosis, psoriasis, periodontitis, and arthritis. Beyond these "broad-spectrum" epigenetic inhibitors, GSK-J4, which is a specific inhibitor of the H3K27me3 demethylases KDM6A and KDM6B, has anti-inflammatory activity, presumably by preventing loss of H3K27me3 repression over inflammatory genes. Similarly, inhibition of the H3K4me3 histone methyltransferase MLL1 blocks the induction of proinflammatory cytokine gene expression in a variety of contexts.

CONCLUSION

Due to the enormity and complexity of the chromatin and epigenetics fields and their reach into all areas of biology and medicine, it is not possible to cover such a broad scope in a single chapter. Thus, here we provide a concise snapshot highlighting key areas of development in medicine. We hope to have conveyed the tremendous excitement and promise that pervades the discipline. Indeed, given the exponential growth in uncovering the interface between the epigenome and epigenetic therapies with the environment and disease, there is little doubt that the coming years will bring important additions to this field.

498 The Role of Circadian Biology in Health and Disease

Jonathan Cedernaes, Kathryn Moynihan Ramsey, Joseph Bass

Circadian rhythms are anticipatory, circa 24-h, autonomous cycles of physiology and behavior. These evolutionarily conserved rhythms have evolved at both the cell and tissue level to synchronize organismal function in anticipation of the 24-h rotation of the Earth. A common feature of modern "24/7" life is the routine disruption of these endogenous circadian cycles due to the rise in shift work, jet travel across time zones, exposure to blue light–emitting devices at night, and disrupted sleep-wake behavior. In-depth characterization of the molecular basis of circadian disorders has generated novel avenues for research on how sleep-wake disruption has been associated with aging, metabolic disease, inflammation, and cancer. This chapter provides an overview of (1) the basic biology of the circadian system; (2) primary circadian rhythm and interrelated sleep disorders; and (3) the role of the circadian system in both normal human physiology and disease states. We also include an overview of how the emerging field of chronobiology may impact drug action. A glossary of terms used in circadian biology is summarized in **Table 498-1**.

BASIC EVOLUTION AND STRUCTURE OF THE CIRCADIAN SYSTEM

Long before the emergence of multicellular life, the Earth's constant rotation around its axis gave rise to a daily cycle of light and darkness. At the emergence of the first prototypal gene involved in biological clock regulation—3.4 billion years ago in photosynthetic cyanobacteria—the period of Earth's rotation along its own axis was only 8 h. The co-occurrence in molecular evolution of the biological clock and photosynthesis hints at an interrelated and selective advantage of the clock in the regulation of energetic processes. Indeed, biological clocks coordinate oxygenic reactions with periods of sunlight each day, and perturbation of clock cycles reduces fitness, reproduction, and survival. Additionally, clocks protect photosynthetic organisms from the DNA-damaging effects of sunlight by timing the production of DNA repair processes, such as photolyase-mediated repair, to the nighttime. Across billions of years of evolution, as day length has gradually extended to today's circa 24 h, highly conserved circadian clocks (from *circa diem*, meaning "about a day") have been found in all photosensitive organisms, governing a wide range of biochemical, physiologic, and behavioral processes. A defining property of the circadian clock system is that it enables organisms to anticipate, rather than simply react to, daily changes in the external environment that are tied to the day-night cycle. In mammals, circadian systems are organized hierarchically with a light-responsive "master" circadian pacemaker located within the suprachiasmatic nucleus (SCN) of the anterior hypothalamus, which in turn presides over a network of both extra-SCN and peripheral clocks (see "Anatomic Organization of the Circadian Clock Network" below). Daily light exposure signals to the SCN and entrains the circadian system to the 24-h day (see "Entrainment and Measurement of the Circadian System," below). In turn, the SCN maintains synchrony of a diverse network of both central and peripheral clocks via a variety of signals that have as of yet to be fully identified. These signals involve direct physiologic rhythms (core body temperature), the autonomic nervous system, and neuroendocrine signals, such as cortisol, which is part of the hypothalamic-pituitary-adrenal (HPA) axis.

MOLECULAR ORGANIZATION OF THE MAMMALIAN CIRCADIAN CLOCK

At the molecular level, mammalian circadian rhythms are generated by a transcription-translation autoregulatory feedback loop. The forward limb of the clock is composed of the basic helix-loop-helix transcription factors (TFs) CLOCK (or its paralogue, NPAS2) and BMAL1. These drive expression of their own repressors (PERs and CRYs) in the negative limb in a cycle that repeats itself every 24 h **(Fig. 498-1)**. A second short feedback loop involves CLOCK/BMAL1-mediated transcription of the retinoic acid–related orphan nuclear receptor families ROR and REV-ERB, which activate and repress *Bmal1* transcription, respectively. Rhythmic posttranslational regulation of the stability and degradation of core clock TFs occurs via events such as phosphorylation by casein kinase 1 epsilon (CK1ε) and casein kinase 1 delta (CK1δ) and ubiquitination by FBXL3 and FBXL21. In addition to the circa 24-h oscillation of core clock genes, a wide array of downstream clock-controlled genes (CCGs) exhibit broad rhythmic amplitude in expression, ultimately giving rise to rhythmic physiologic processes.

The importance of localized clock gene expression has been demonstrated by genetic animal studies, such as with targeted ablation of *Bmal1*, the only clock gene that lacks a known functional paralog. Deletion of *Bmal1* either in the whole brain or in regions that span the brain region that coordinates circadian rhythms—the SCN—causes behavioral arrhythmicity, even when genetic ablation occurs in adult life. Conversely, restoring *Bmal1* expression specifically in brain in global adult *Bmal1* mutant mice rescues behavioral locomotor rhythms. Of note, whereas the protein CLOCK normally heterodimerizes with BMAL1, the paralogous protein NPAS2 can functionally substitute for CLOCK within the pacemaker neurons. Thus, while mice lacking either *Clock* or *Npas2* genes maintain rhythmicity, mutants lacking both CLOCK and NPAS2 lack circadian rhythms in locomotor activity. Further, mutations in many of the clock genes are associated with impaired circadian rhythms and physiology in both experimental animal models and humans (see "Primary Pathologies of the Circadian System" below).

A major transformation in our understanding of circadian biology came with the discovery that the molecular clock network is present not only in the SCN but also within most peripheral tissues, as well as in extra-SCN neurons in the brain. In primates, ~82% of all protein-coding transcripts exhibit daily 24-h rhythms in some tissue or other. In rodents studied under constant conditions, ~3–16% of the transcriptome in each tissue exhibits 24-h rhythms in mRNA expression levels, even though the repertoire of such genes varies substantially between tissues, in accordance with tissue-specific functions. The core clock feedback loop and the induction of transcriptional CCG rhythms also involves epigenetic mechanisms such as conformational chromatin dynamics, histone acetylation, and DNA methylation. Conversely, posttranscriptional events such as RNA polyadenylation, nucleocytoplasmic shuttling, alternative splicing, and mRNA translation also exhibit circadian variation, further increasing the repertoire of rhythmic regulation at a cellular level.

ANATOMIC ORGANIZATION OF THE CIRCADIAN CLOCK NETWORK

The molecular circadian feedback loop is synchronized with sunrise each day by photosensitive melanopsin-expressing neurons within the retina. These neurons provide input to the SCN via the retinohypothalamic tract (RHT), allowing mammals to maintain coherent

TABLE 498-1 Glossary of Terms Used in Discussion of the Circadian System

TERM	DESCRIPTION
ASPD	Advanced sleep phase disorder (see text for description).
CBT	Core body temperature. Often used as an indicator of the circadian rhythm but can be masked by sleep and exercise.
CCGs	Clock-controlled genes; output of the molecular clock.
Chronotype	Internal circadian rhythm of an individual determined by phase of entrainment, determining sleep propensity and timing of maximum alertness over a 24-h period.
Circadian period	Time required for one complete cycle or oscillation. Calculated by the time distance between two consecutive peaks or troughs of a circadian variable.
Circadian phase	Timing of the circadian rhythm. Defined by comparing, e.g., the peak (acrophase) or trough (bathyphase) to a fixed event, e.g., to a point in time. Synonymous with phase angle.
Circadian rhythm	A biological process that exhibits an endogenous, entrainable oscillation of ~24 h.
Circadian rhythm sleep disorders	Disorders of multiple etiology that have in common that they result in maladjustment of the biological clock with respect to the environment.
Constant routine	An experimental paradigm designed to study endogenous circadian rhythms in humans, by keeping behavioral and environmental factors constant. These paradigms thereby typically entail a combination of constant dim lighting, evenly distributed isocaloric energy intake, semirecumbent posture, and forced extended wakefulness.
Desynchrony	Loss of synchrony occurring either between a rhythm and its zeitgeber (external, "time giver" signal) or between two or more rhythms within an organism (internal).
Diurnal rhythm	An oscillation synchronized with the day/night cycle that repeats itself with a 24-h period. The rhythm does not have to persist when time cues (e.g., light) are absent.
DLMO	Dim-light melatonin onset; a marker of melatonin rhythm.
DSPD	Delayed sleep phase disorder (see text for description).
Entrainment	Synchronization of a circadian rhythm or other self-sustaining oscillation by a factor—zeitgeber—that enforces the oscillator. Constant entrainment between the zeitgeber and the oscillator results in a stable phase relationship between these entities.
Infradian rhythm	A recurrent cycle or period with a period length significantly greater than 24 h.
Melatonin	Hormone produced primarily by the pineal gland (chemical name *N*-acetyl-5-methoxytryptamine); derived from L-tryptophan. Various forms of melatonin can be prescribed for circadian rhythm sleep disorders or sleep disorders.
Non-24-h rhythm disorder	A syndrome in which there typically are chronic 1- to 2-h daily delays in sleep onset and wake times in an individual living in society, e.g., due to complete blindness.
Peripheral clocks	Clocks presiding outside of the suprachiasmatic nucleus, the circadian system's master pacemaker.
PRC	Phase response curve; visual representation of how a particular manipulation (e.g., light) produces phase shifts as a function of the phase (i.e., circadian time) at which the manipulation occurs. Defining the PRC to light has enabled researchers to understand and predict how entrainment to light cycles is accomplished.
SCN	The suprachiasmatic nucleus or nuclei, also known as the master pacemaker in mammalian species. A bilateral set of nuclei positioned in the anterior ventral hypothalamus. Essential for entraining extra-SCN central and peripheral oscillators to the prevailing light-dark cycle via photic input from the retina.
Shift work	Work scheduled so that it occurs outside of the traditional work schedule of 9:00 A.M. to 5:00 P.M., or 7:00 A.M. to 6:00 P.M., depending on definition. Various forms of shift work exist, such as early morning, evening, or night shifts, as well as rotating shifts.
Ultradian rhythm	A recurrent cycle or period with a period significantly shorter than 24 h—e.g., a 2-h rhythm would exhibit 12 cycles within a circadian (24-h) rhythm.

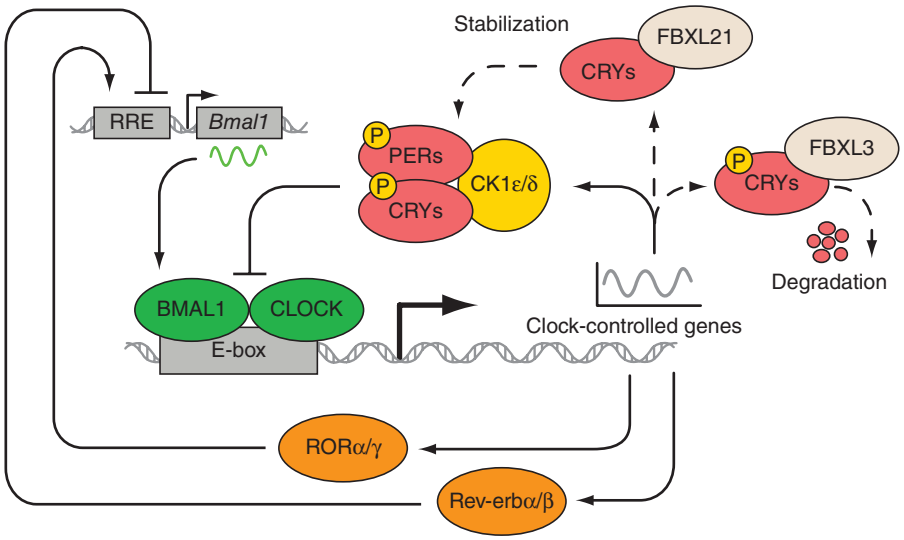

FIGURE 498-1 Central clock molecular mechanism. The core molecular clock machinery in mammals is encoded by interlocking transcription-translation feedback loops that oscillate with ~24-h periodicity. The transcription factors CLOCK and BMAL1 heterodimerize to drive transcription of downstream clock-controlled target genes containing E-box enhancer elements. Among these, the PER and CRY proteins multimerize and inhibit CLOCK/BMAL1, while RORs and REV-ERBs activate and inhibit, respectively, *Bmal1* transcription, resulting in rhythmic oscillations of clock-controlled and downstream target genes.

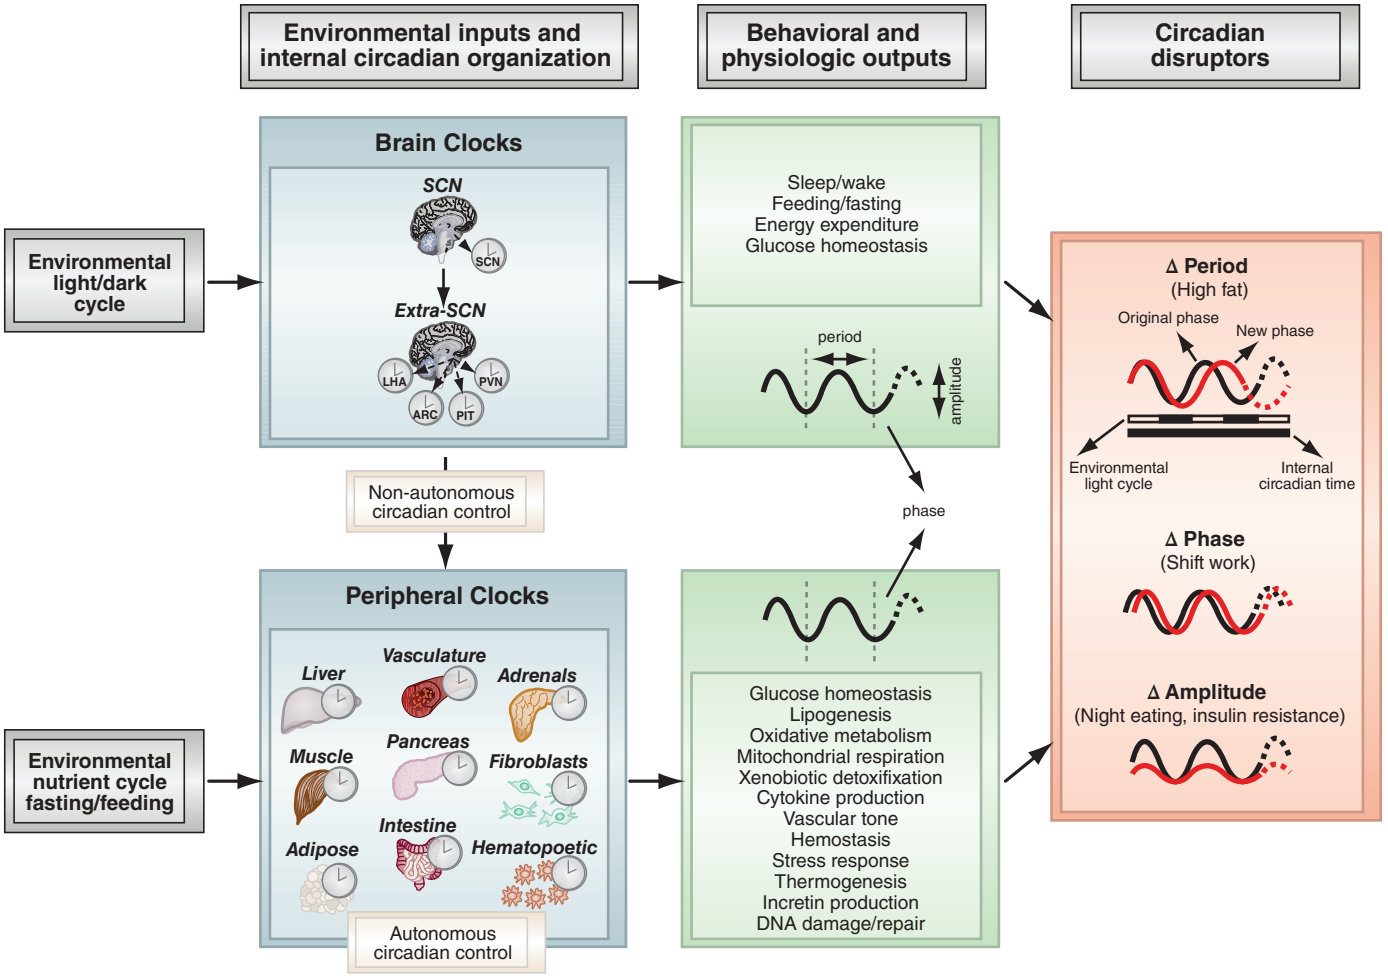

FIGURE 498-2 Central and peripheral clocks coordinate environmental cues with behavior and physiologic outputs. Light entrains the master pacemaker neurons in the suprachiasmatic nucleus (SCN), which subsequently synchronizes extra-SCN and peripheral clocks. Brain clock output includes sleep-wake, fasting-feeding, and energy expenditure cycles, while peripheral clock output includes a wide range of physiologic processes, including glucose homeostasis, oxidative metabolism, cytokine production, and stress response. The right column indicates different ways that circadian disruptors, such as diet, shift work, or other circadian rhythm sleep disorders, may impact the clock—i.e., by changing circadian period, phase, or amplitude.

organismal rhythms in line with the external light/dark cycle. Understanding the circuit organization of the circadian clock within the brain is increasingly relevant in understanding how the master circadian pacemaker center within the SCN regulates feeding, sleep-wake activity, endocrine processes, energy expenditure, and metabolism (Fig. 498-2). Identification of the SCN as the master pacemaker was first established by the observation that SCN lesioning induced complete loss of rhythms of locomotor activity, drinking behavior, and endocrine hormone secretion. The ventral "core" region of the SCN, which is composed of neurons producing vasoactive intestinal polypeptide (VIP), receives photic information directly from the retina through the RHT. At the molecular level, circadian gene transcription is induced within the SCN through the initial activation of immediate early genes, such as *Per1*, *Per2*, *c-fos*, and *jun*. Cells within the "core" region of the SCN then signal primarily via γ-aminobutyric acid (GABA)-ergic neurotransmitter release to synchronize the cells within the "shell" region of the SCN, which produce arginine vasopressin (AVP), the most important neuropeptide for maintaining intra-SCN synchronicity.

The SCN communicates to extra-SCN and peripheral clocks through both secreted factors and neuronal projections. The former was elegantly proven by the ability of SCN grafts to partially restore locomotor rhythms in SCN-lesioned animals. Efferent nerve outputs arise both from the AVP-producing shell region of the SCN and the VIP-predominated core. The SCN projects to several hypothalamic and thalamic regions, including the median preoptic nucleus (MPO), the subparaventricular zone (SPZ), the dorsomedial hypothalamus (DMH), the paraventricular nucleus of the hypothalamus (PVH), and the paraventricular nucleus of the thalamus (PVT). Some of these regions, in turn, regulate output to both sleep- and wake-promoting regions, as well as to regions involved in regulation of autonomic, body temperature, and hormonal rhythms, as well as feeding. The SCN is thereby thought to promote sleep in part through the transmission of neural signals that terminate in the sleep-promoting ventrolateral preoptic nucleus (VLPO), i.e., one of the brain regions that is active during sleep. In contrast, the SCN promotes wakefulness during the active phase by transmission of neural signals that—by passing through regions such as the SPZ and the DMH—terminate in wake-promoting regions, including the locus coeruleus, lateral hypothalamic nucleus, ventral tegmental area, and dorsal raphe nucleus.

The SCN also signals via noradrenergic fibers to the pineal gland to regulate the circadian production of the hormone melatonin. SCN control of the nighttime rise in pineal melatonin release (in both diurnal and nocturnal animals) is mediated through a pathway involving the PVH. Of note, artificial light at night delays the secretion of melatonin, ultimately affecting sleep (see "Endocrine Systems Regulated by the Circadian Clock" below). Melatonin plays a complex role in the circadian system since the MT1 and MT2 melatonin receptors are expressed in the SCN itself; thus, melatonin feeds back to modulate circadian outputs to other cells in the brain and body.

Neuronal output from the SCN also reaches peripheral tissues such as the adrenal glands, liver, and pancreas. The SCN produces rhythmic variation in multiple neuroendocrine axes, producing daily rhythms of gonadotropin, thyrotropin, and somatotropin. Prominent HPA axis rhythms ultimately give rise to daily variation in diverse pathways essential for hemodynamic stability, metabolism, and inflammation. These rhythms originate with SCN control of corticotropin-releasing

hormone (CRH)–producing cells in the PVH, which may regulate sleep as well as induce daily oscillations of both pituitary adrenocorticotropic hormone (ACTH) and adrenal cortisol. Highlighting the importance of SCN output for peripheral rhythms, there is a dramatic reduction in the number of transcripts that exhibit circadian rhythms in the liver following SCN ablation in mice. Nonetheless, when the autonomous clock in the liver is ablated in mice, some key clock transcripts such as *Per2* still cycle provided the core body temperature rhythm persists. Whereas the SCN is exclusively entrained by light, meal timing can signal circadian time directly to peripheral tissues such as the liver. Thus, shifted meal timing as occurs during shift work or jetlag can uncouple peripheral clocks from the central pacemaker. Temperature can also phase shift peripheral tissue clocks, but not the SCN clock. This is an important phenomenon because, at the organismal level, the SCN generates the core body temperature rhythm as one of the major mechanisms to signal circadian time to peripheral clocks.

ENTRAINMENT AND MEASUREMENT OF THE CIRCADIAN SYSTEM

Under normal light-dark cycles, the circadian system is corrected or "entrained" on a daily basis, producing diurnal rhythms of 24 h. Such signals of entrainment are called zeitgebers (German for "time-giver" signals) and include light exposure, meal timing, and activity patterns. Light serves as the dominant zeitgeber for the circadian system, and a breakthrough in understanding photoentrainment in mammals came with the discovery of the melanopsin system, which is composed of a specialized class of photosensitive retinal ganglion cells that expresses the blue light–sensitive photopigment melanopsin in the inner retina, separate from the photoreceptive rods and cones. Blue light around this wavelength (~480 nm) suppresses melatonin, such that melatonin levels are normally low during the day, promoting subjective and objective (electroencephalography assessed) wakefulness.

The ability of light to entrain the circadian system functions according to a so-called phase response curve (PRC). When light exposure occurs prior to the critical phase of the core body temperature (CBT), defined by the CBT's minimum, light produces a phase delay in the circadian rhythm. Conversely, light exposure after this critical period causes phase advances. The circadian system can respond even to small changes in light intensity (e.g., dim light at ~100 lux can produce half of the phase delay compared with an almost 100-fold greater light exposure). This responsiveness has been found to be highly individual and varies widely. This is in part due to genetic variation, as variants in clock genes can modulate the responsiveness of the human circadian system to light.

When an organism is placed in an environment without zeitgebers, the circadian rhythm is said to free-run, as it relies on the endogenous rhythm of the circadian system. In humans, the study of endogenous circadian rhythms can be achieved by using a so-called constant routine that eliminates the risk of masking by factors such as sleep. In these paradigms, subjects are kept awake in a constant semi-recumbent posture, meals are provided on an hourly basis, and light is constantly kept below the level that can phase shift the SCN. Concurrently, circadian rhythms are assessed by frequently measuring CBT, melatonin, or peptidergic hormone rhythms over the course of more than 24 h. In animals, endogenous circadian rhythms are instead studied by examining behavior, physiologic responses, and voluntary locomotor activity following 30–36 h of complete darkness. From these measurements, key properties of the circadian system can be ascertained, such as period length (peak-to-peak or trough-to-trough time), amplitude (peak-to-trough difference), and phase (timing of peak or trough in relation to a reference point) (Fig. 498-2).

These studies have revealed that the endogenous human circadian clock runs with a period length of ~24.2 h, while that of mice runs at ~23.5 h, with some variability across strains. In humans, evidence further indicates that females may have a slightly shorter circadian clock than males (24.1 vs 24.2 h), and many circadian parameters have been found to exhibit differences that are dependent on biological sex. Notably, interindividual variability in the endogenous circadian period length is further diversified by the existence of genetic polymorphisms in clock genes (see below). These gene variants can confer extremes in the endogenous circadian period as well as phase; the latter can be advanced or delayed by ~3–4 h in each direction. This is due both to altered circadian rhythms at the cellular level and to altered SCN responsiveness to entrainment by light. For instance, *PER3* gene contains a variable-number, tandem-repeat polymorphism. Individuals homozygous for a *PER3 5/5* genotype have been reported to be more responsive than *PER3 4/4* homozygous individuals to the melatonin-suppressing effect of evening blue light exposure. By analyzing genetic variation across ~700,000 individuals, the number of genetic loci that have been identified that contribute to variability in chronotype is in the hundreds.

Using specifically developed questionnaires to establish preferred sleep-wake timing, individuals can be categorized into so-called morningness-eveningness types or chronotypes. The most commonly used questionnaires are the Horne-Östberg Morningness-Eveningness Questionnaire (MEQ) and the Munich ChronoType Questionnaire (MCTQ). A composite MEQ score allows grouping into five categories that range from definite morning-type to evening-type individuals based on preferred waking time. In contrast, the MCTQ centers on the midpoint of sleep as a circadian marker, queries age and sex across a range of geographical locations, and can be used to ascertain differences between socially imposed sleep patterns (e.g., on working days) and sleep patterns on free days (the difference constituting so-called social jetlag). According to MCTQs obtained from primarily European populations, ~1% of the general population goes to bed before 10:00 P.M. and ~8% after 3:00 A.M. Differences in chronotype are linked to altered circadian timing, including peak levels of melatonin, which can vary by up to 4 h between extreme morning and evening types. Extreme chronotypes have also been shown to be linked to various traits; i.e., low morningness scores have been associated with greater tolerance to night shift work.

Melatonin is one of the most commonly used peripheral markers of an individual's circadian rhythm, reflecting the rhythmic function of the SCN. Circadian rhythms of melatonin can be measured in saliva or plasma, whereas 6-sulphatoxymelatonin (aMT6S), a metabolite generated from the breakdown of melatonin, can also be measured in urine. Accurate estimations of melatonin rhythms are often obtained by analyzing the dim light melatonin onset (DLMO). As the name implies, this involves evening/nighttime sampling of melatonin as opposed to 24-h sampling. This makes DLMO quantification useful in both the clinical and research settings. In normally entrained individuals, the DLMO can be used to ascertain whether an individual's circadian rhythm is phase advanced or delayed, and this onset typically occurs ~2 h before the onset of sleep. The midpoint of sleep—the main marker used by the MCTQ—correlates more strongly with melatonin onset than the MEQ score. In the morning hours, the offset of melatonin ("DLMoff") can be used as a marker of circadian alignment or misalignment with the light-dark cycle. When individuals are exposed only to the natural light-dark cycle dictated by the sun, such as in an outdoor natural lighting environment, DLMO and DLMoff occur earlier. In contrast, exposure to artificial light has the overall effect of delaying the biological night and contributes to widening differences between chronotypes in modern society.

The CBT is also often utilized as an indicator of the circadian rhythm. Even though CBT is more variable than DLMO, it usually correlates well with the phase obtained using the melatonin rhythm. The CBT, however, can be masked by factors such as sleep, food intake, and activity. CBT can be recorded and registered wirelessly with relative ease. In humans, CBT can be recorded via rectal thermometers or probes that are swallowed to pass through the gastrointestinal tract. When humans are studied under normal conditions with normal lighting and sleep duration from 2300 to 0700 h, the CBT reaches around 37.2°C by 0900 h, and from there, it continues to rise slowly until it reaches 37.4°C around 11 h later. The CBT then drops to the daily low of 36.5°C in the early morning (0400 h). The minimum in body temperature also corresponds to the trough in the 24-h rhythm in resting energy expenditure.

Given the interrelationship between the circadian system and sleep-wake systems, researchers have developed paradigms that uncouple

the circadian system from sleep-wake states, enabling the study of the contribution of the circadian system to investigated parameters across the entire sleep-wake cycle. These paradigms are known as "forced desynchrony" protocols and involve enforcing a significantly shortened (e.g., 20 h) or prolonged (e.g., 28 h) day length upon individuals. These protocols thus attempt to approximate what occurs during rotating shift work or "jetlag," e.g., when travel across several time zones suddenly shifts the light-dark and behavioral cycles drastically away from the entrained 24-h rhythm. As described below, forced desynchrony protocols have contributed to uncovering how the circadian system regulates parameters such as cognitive performance, subjective alertness, and metabolic and cardiovascular health.

TABLE 498-2 Criteria for Circadian Rhythm Sleep Disorders

CRITERIA	DESCRIPTION
A	A persistent or recurrent pattern of sleep disturbance due primarily to one of the following: • Alterations of the internal circadian timekeeping system. • Misalignment between endogenous circadian rhythms and exogenous factors that affect the timing or duration of sleep.
B	A circadian-related sleep disruption that leads to insomnia, excessive daytime sleepiness, or both.
C	A sleep disturbance that is associated with impairment of social, occupational, or other areas of functioning.

PRIMARY PATHOLOGIES OF THE CIRCADIAN SYSTEM

An overarching term for disorders of the circadian system is circadian rhythm sleep disorders (CRSDs), where there is a mismatch between subjective behavioral and physiologic rhythms with the environmental light-dark or social activity-rest cycles (i.e., the body clock is out of sync with the external light-dark cycle). CRSDs can arise either due to misalignment of an exogenous environmental factor, such as light, or misalignment of the activity-rest cycle, such as occurs with shift work or jetlag, in relation to endogenous circadian timing. Mutations in the core clock genes themselves can also alter intrinsic circadian timing in relation to the external environment, which makes it difficult for these individuals to properly realign themselves. These disorders often result in adverse effects such as excessive sleepiness or depressed mood, often causing individuals to be unable to maintain a job or attend school at regular hours. The criteria for CRSDs based on the International Classification of Sleep Disorders (ICSD) are shown in Table 498-2.

Animal models have greatly advanced our understanding of how core molecular clock components contribute to maintaining normal sleep-wake/rest-activity cycles (Table 498-3). For example, *Clock*$^{\Delta 19/\Delta 19}$ mice have reduced total sleep duration and less induction of rapid eye movement (REM) sleep in response to sleep deprivation. Further, mice that lack *Bmal1* have increased total sleep time, but it is more fragmented and lacks clear 24-h sleep-wake rhythms, and mice lacking the repressors *Cry1* and *Cry2* are arrhythmic and spend more time in non-REM sleep. Finally, while ablation of the circadian gene *Dbp* does not alter the specific duration of sleep stages, it does lead to an altered circadian sleep-wake distribution, with more sleep during the normal wake period and vice versa. Consistent with a key role of clock genes in regulating sleep-wake behavior, human genetic studies of twins have found that up to half of the variation in diurnal preference is heritable. Established genetic variants associated with diurnal preference and circadian sleep disorders are listed in Table 498-4. The following briefly mentions the most common CRSDs, but readers should refer to the chapter on sleep disorders (Chap. 33) for a more detailed description.

Delayed Sleep Phase Disorder Delayed sleep phase disorder (DSPD; or delayed sleep-wake phase disorder [DSWPD]) is one of the more common circadian rhythm sleep disorders, ranging from 0.2–16% of the population depending on definition used, and is most common in adolescence and early adulthood. DSPD is characterized by chronic and significant delays in both sleep onset and wake times compared to "socially acceptable" sleep-wake hours (i.e., "extreme night owls"). Rhythms of CBT and melatonin levels are also often

TABLE 498-3 Animal Models of Genetic Circadian Disruption

GENE	AVERAGE CIRCADIAN TIME OF PEAK TRANSCRIPT LEVEL		ALLELE	MUTANT PHENOTYPE
	SCN	PERIPHERY		
Bmal1 (Arntl)	15–21	22–2	*Bmal1*$^{-/-}$	Arrhythmic
CK1δ (Csnk1δ)	No rhythm	No rhythm	*Csnk1δ*$^{+/-}$	0 to 0.5-h shorter period
CK1ε (Csnk1ε)	No rhythm	No rhythm	*CK1ε*^{tau}	4-h shorter period
CK1ε	—	—	*CK1ε*$^{-/-}$	0.2- to 0.4-h longer period
Clock	No rhythm	21–3	*Clock*$^{-/-}$	0.5-h shorter period
—	—	—	*Clock*$^{\Delta 19/\Delta 19}$	4-h longer period/arrhythmic
Clock/Npas2	—	—	*Clock*$^{-/-}$*/NPAS2*$^{-/-}$	Arrhythmic
Cry1	8–14	14–18	*Cry1*$^{-/-}$	1-h shorter period
Cry2	8–14	8–12	*Cry2*$^{-/-}$	1-h longer period
—	—	—	*Cry2*^{A260T}	0.2-h shorter period
Dbp	—	—	*Dbp*$^{-/-}$	0.5-h shorter period
Npas2	N/A	0–4	*Npas2*$^{-/-}$	0.2-h shorter period
Per1	4–8	10–16	*Per1*$^{-/-}$	0.7-h shorter period
—	—	—	*Per1*^{brdm1}	1-h shorter period
—	—	—	*Per1*^{ldc}	0.5-h shorter period/arrhythmic
Per2	6–12	14–18	*Per2*^{brdm1}	1.5-h shorter period/arrhythmic
—	—	—	*Per2*^{ldc}	Arrhythmic
Per3	4–9	10–14	*Per3*$^{-/-}$	0 to 0.5-h shorter period
Rev-erbα (Nr1d1)	2–6	4–10	*Rev-erbα*$^{-/-}$	0.5-h shorter period/disrupted photic entrainment
Rorα	6–10	Arrhythmic/various	*staggerer*	0.5-h shorter period/disrupted photic entrainment
Rorβ	4–8	18–22	*Rorβ*$^{-/-}$	0.5-h longer period
Rorγ	N/A	16–20/various	*Rorγ*$^{-/-}$	Normal behavior

Note: Normal circadian rhythms of circadian clock and related genes, with description of circadian phenotype in mutant mice.

TABLE 498-4 Mutations and Gene Variants Linked to Sleep-Wake Disorders and Diurnal Preference

GENE	POSITION	POPULATION	SYNDROME/SLEEP PREFERENCE
h*CKIε*	S408N	Japanese	Protection against DSPS
h*CKIγ*	T44A	Pedigree	FASPS
h*CKIΔ*	H46R	Pedigree	FASPS
h*CLOCK*	T3111C (3′-UTR)	European	Eveningness
h*CRY2*	A260T	Pedigree	FASPS
h*PER2*	S662G (missense mutations in CKIε binding region)	Pedigree	FASPS
h*PER2*	C111G (5′-UTR)	British	Extreme morningness
h*PER3*	P415A/H417R	Pedigree	FASPS and seasonal affective disorder
h*PER3*	G647	Swedish/Finish/Austrian/German	Morningness
h*PER3*	G647, P864, 4-repeat, T1037, R1158	Japanese	DSPS
h*PER3*	Increased repeats (exon 18, 54 bp)	Brazilian	DSPS
h*VIP*	rs9479402 (gene variant 54 kb upstream of VIP)	European (>97% European ancestry)	Morningness

Abbreviations: DSPS, delayed sleep phase syndrome; FASPS, familial advanced sleep phase syndrome.

delayed. DSPD is associated with polymorphisms within the circadian clock genes *CLOCK, PER3,* and *CRY1*, and the circadian period (tau) of these individuals may be longer. The most effective treatment includes bright-light therapy after waking in the morning (and/or dark-room therapy in the evening) in combination with melatonin administration in the evening several hours prior to the onset of sleep. These approaches attempt to realign endogenous circadian rhythms with the desired sleep-wake schedule, though often face challenges because individuals suffering from DSPD also phase delay more rapidly.

Advanced Sleep Phase Disorder Another CRSD whereby one gets the correct amount and quality of sleep but at a shifted time is advanced sleep phase disorder (ASPD; or advanced sleep-wake phase disorder [ASWPD]). The prevalence of this disorder may be <1%, but the condition may be underreported, given that it may cause fewer conflicts with societal demands (i.e., 9-to-5 schedules) compared with DSPD. Individuals with ASPD experience an advance in their major sleep episode in relation to the desired sleep-wake times. Thus, this disorder typically results both in very early evening bedtimes and morning awakenings (e.g., "extreme early birds"), resulting in reduced quality of life due to excessive sleepiness during the early evening, even in social situations. Individuals with ASPD also have phase-advanced temperature and melatonin rhythms. ASPD occurs more often in older individuals, although early-onset autosomal dominant familial variants (familial advanced sleep phase syndrome [FASPS]) have also been associated with mutations in either the *PER2* or the casein kinase 1δ (*CK1δ*) gene. *PER2* is critical for SCN resetting by light, and these *PER2* mutations have been found to shorten the endogenous circadian period to ~23.3 h compared with the normal 24.2-h period length. Treatment includes bright light or blue-enriched phototherapy in the evening hours to delay the phase of the circadian clock to a later hour.

Shift Work Sleep Disorder Given the increased prevalence of shift work in today's 24/7 society and the accumulating evidence for increased incidence of sleep and metabolic disorders, including obesity, type 2 diabetes, cardiovascular disease, and cancer, in shift workers, the need to develop effective treatments for shift work sleep disorder (SWSD) is increasingly important. SWSD is at its core defined by the primary symptom of either insomnia or excessive sleepiness arising due to work scheduled during regular sleeping hours or at irregular times. The symptoms may arise because recovery sleep consumes a large proportion of the individual's free time, potentially leading to negative social consequences such as difficulties maintaining social relationships. Older individuals are typically at an increased risk of SWSD due to the age-associated decline in the ability to maintain sleep during the time of day that would normally constitute the wake period. Therapeutic approaches include optimizing the sleep environment at home to minimize disruptions, melatonin prior to sleeping, and timed bright-light therapy. For example, for night workers, intermittent bright-light exposure during the night and avoidance of bright light during the morning, even on days off, have been shown to improve sleep and feelings of alertness. Genetic screening combined with chronotype questionnaires may become useful tools for determining whether a given individual is suited for shiftwork. For instance, a twin study indicated that a genetic variant of the circadian gene *DEC2* was associated with reduced sleep duration and shorter recovery sleep following extended sleep deprivation. More studies may reveal additional genetic variants that confer an advantage to repeated phase advances and phase delays as typically occurs in shift work.

Irregular Sleep-Wake Rhythm Damage to the SCN can produce arrhythmicity in animals and is thought to be one of the possible underlying reasons for the temporally disorganized sleep-wake pattern that characterizes the disorder known as irregular sleep-wake rhythm (ISWR). Other contributing factors may be reduced responsiveness to entraining signals such as light and physical activity, as well as decreased exposure to such signals, as often occurs with increasing age. Despite normal total sleep time, there is a relative absence of a circadian pattern to the sleep-wake cycle such that sleep occurs in several distinct randomly distributed bouts. ISWR is often associated with neurologic impairment, foremost Alzheimer's disease in older age; however, ISWR can also occur in individuals with poor sleep hygiene. Treatments involve multimodal interventions such as increased light exposure, improved sleep hygiene, and promotion of social and physical activities.

Non-24-h Sleep-Wake Rhythm Disorder Individuals with non-24-h sleep-wake rhythm disorder ("non-24"), otherwise known as free-running disorder (FRD), have endogenous circadian rhythms that are not synchronized with the external 24-h day-night cycle due to an inability to readjust the circadian clock to the 24-h day on a daily basis. This most commonly occurs in individuals who are completely blind (i.e., lacking all photoreceptors) since they are unable to respond to daily light cues that normally would reset the endogenous circadian clock (although the condition has also been reported in sighted individuals). Instead, the sleep-wake period length corresponds to the individual's endogenous circadian rhythms, which are typically slightly longer than 24 h, thereby shifting sleep and wake cycles over time in relation to the light-dark cycle. Instead of sleeping at the same time each day, their sleep time would gradually be delayed each day until their sleep period literally goes "around the clock." Depending on the individual's endogenous rhythm, the individual will take a given number of days to realign their endogenous phase (in a 360° phase plot) with the zero time point in the exogenous 24-h light-dark cycle. Because of this chronic cycling, prominent symptoms of non-24 include sleep-wake cycle disruption (insomnia and daytime sleepiness), impaired alertness and mood levels, and severe difficulties partaking in normally scheduled work, school, or social activities. Non-24 can be diagnosed following diurnal analysis of an individual's melatonin or cortisol rhythms, in combination with analyses of sleep diaries

where the sleep onset and offset can be visualized over time to identify the free-running period. Treatments for sighted non-24-h patients include a combination of bright-light therapy with appropriately timed melatonin administration, whereas melatonin and dual melatonin (MT1 and MT2) receptor agonist administration in completely blind non-24-h patients has been shown to entrain free-running rhythms and improve symptoms.

Jetlag Most have experienced symptoms associated with jetlag, including insomnia, daytime sleepiness, and fatigue, when traveling from one time zone to another, as one's endogenous circadian rhythms are not yet aligned, or entrained, to the new external light-dark cycle. This is due to the slowness of the circadian system to adapt to the new time zone. Typically, the human circadian system can shift up to ~1.5 h a day in the westward direction (i.e., a phase delay), whereas it shifts more slowly (up to ~1 h daily) with eastward direction of travel (i.e., achieving a phase advance). Usually, symptoms of jetlag abate within the first couple of days after traveling and may present themselves after a first night of good sleep (which is more dependent on a high buildup of homeostatic sleep pressure). Older individuals (age >50) appear to be more at risk. While symptoms are transient, therapeutic approaches aim to hasten the synchronization of internal and external circadian cycles. Behavioral treatments include appropriately timed bright-light exposure and avoidance of bright light during the nighttime in the new destination, while pharmacologic approaches include timed melatonin administration before bedtime both prior to and following travel, resulting in improved sleep quality and decreased night waking.

Social Jetlag Individuals with a late chronotype are prone to suffer from "social jetlag," a phenomenon in which individuals are forced to awaken at a point at which their bodies are entrained to be asleep due to discrepancy between alignment of social and biological time. Social jetlag can be estimated using questionnaires, such as the MCTQ, to compare sleep timing on working or school days compared with free days. This has established that a large proportion of the European population suffers from 2 or more hours of social jetlag. Chronic social jetlag is associated with an increased risk of developing obesity and metabolic syndrome, as well as with greater alcohol consumption, smoking, and poorer academic performance in students.

The aforementioned categories of defined clinical circadian disorders have been traditionally established based on consideration of the endogenous behavioral and physiologic cycles (primarily of melatonin and temperature) with the external 24-h light-dark cycle. In the following sections, we build on the concepts of circadian behavioral disorders to consider new and emerging insight into the role of circadian disruption in organismal homeostasis **(Figs. 498-3 and 498-4)** and the availability of genetic strategies to dissect the interrelationship between clock function, health, and disease.

ROLE OF THE CLOCK SYSTEM IN PHYSIOLOGY

Endocrine Systems Regulated by the Circadian Clock In addition to regulation of behavioral rhythms such as sleep-wake and fasting-feeding cycles, the circadian clock also regulates rhythms of the endocrine system. Cortisol rhythms are regulated through a feedback loop known as the HPA axis. Hypothalamic secretion of CRH and AVP promotes secretion of pituitary ACTH, which in turn regulates rhythmic cortisol secretion from the adrenal cortex. Cortisol release increases toward the morning, and this increase is believed to prepare the brain and peripheral tissues for daytime activity and food intake. AVP secretion in mice occurs prior to sleep to promote water intake, thereby preventing dehydration during the sleep period. Several hormones, such as growth hormone (GH), cortisol, and melatonin, are influenced not only via circadian regulation, but also by sleep. For

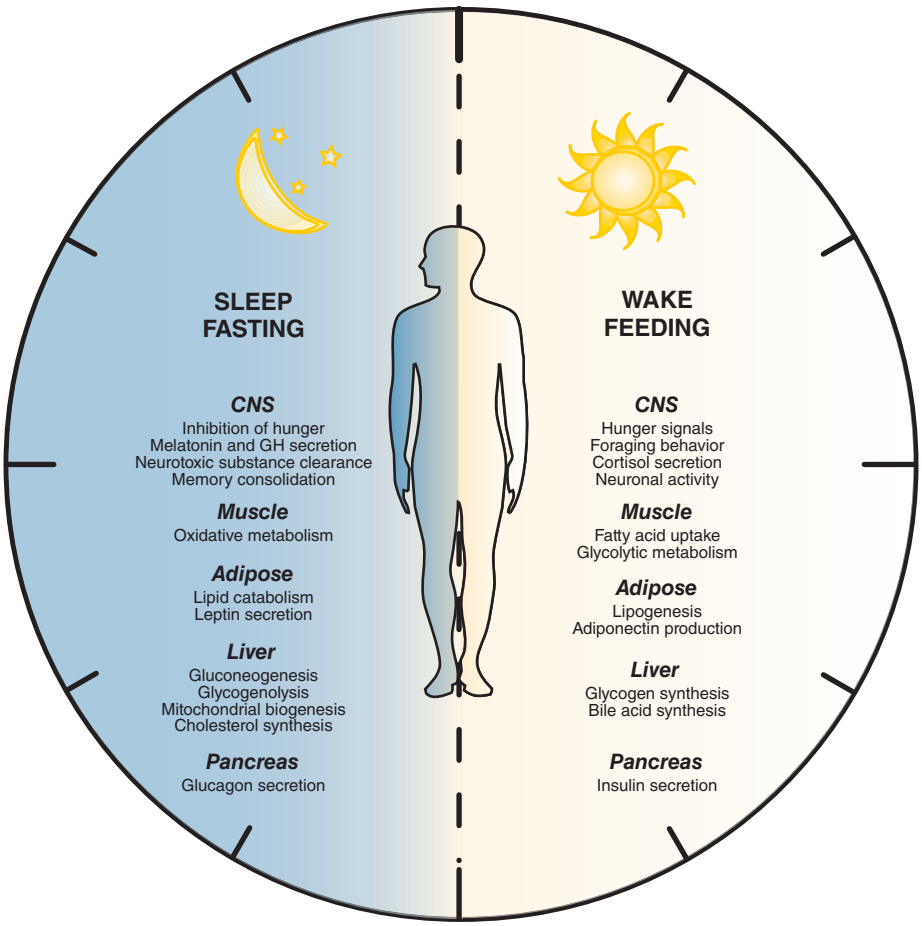

FIGURE 498-3 The circadian clock partitions behavioral, physiologic, and metabolic processes according to time of day. The partitioning of metabolic processes to appropriate times of day is critical for the maintenance of health from cellular to mammalian organisms. This figure highlights which processes peak within the central nervous system (CNS), muscle, adipose, liver, and pancreas during either the sleep/fasting or wake/feeding cycle in humans. GH, growth hormone.

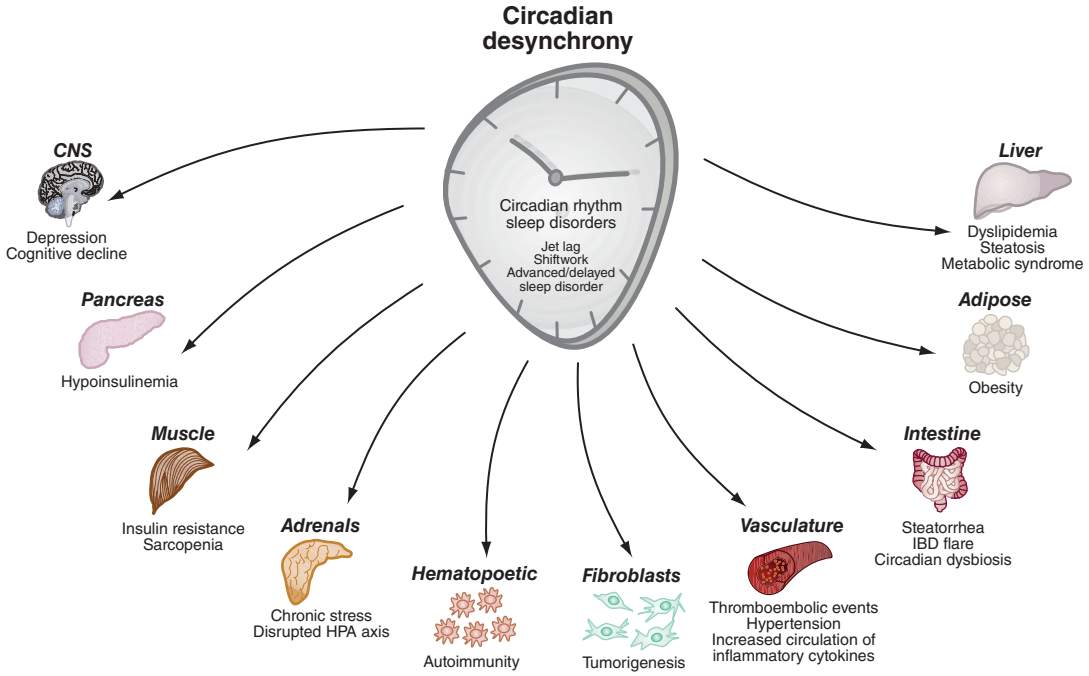

FIGURE 498-4 Pathologies resulting from circadian desynchrony. Circadian rhythm sleep disorders, including advanced/delayed sleep phase disorder, jet lag, social jet lag, and shift work, result in a desynchrony between the environmental light-dark cycle "time" and the endogenous clock "time." Pathologies can thus arise through misalignment imposed by exogenous (e.g., altered light cycle and/or feeding rhythm) and endogenous factors (e.g., mutations in core clock genes). Such desynchrony results in a host of wide-ranging pathologies across multiple tissues, including hypoinsulinemia (pancreas), disrupted hypothalamic-pituitary-adrenal (HPA) axis, autoimmunity, hypertension, obesity, and metabolic syndrome. CNS, central nervous system; IBD, inflammatory bowel disease.

instance, both GH secretion and the cortisol awakening response (CAR, i.e., the peak in cortisol soon after waking) are profoundly blunted by acute overnight wakefulness. GH secretion is primarily dependent on the occurrence of slow-wave sleep, which is a homeostatically driven sleep stage that occurs primarily in the first part of the sleep period. Both the CAR and daytime cortisol levels are also modulated by light exposure levels. Sleep also influences melatonin amplitude, such that sleep deprivation can increase melatonin levels. As sleep deprivation is often accompanied by artificial nighttime light exposure, the effect on melatonin can be combinatorial. In working environments, the effects of curtailed sleep are often confounded by mistimed exposure to light. The sensitivity to light levels that suppress melatonin can vary by an order of magnitude or more in individuals. This partly explains how even low levels of light can potently suppress melatonin secretion. Together with altered timing in light exposure, perturbed hormonal levels likely represent a mechanism through which altered timing and duration of sleep can impact central and peripheral circadian oscillators.

Centrally controlled rhythms of melatonin and cortisol are considered key regulators of extra-SCN and peripheral oscillators. Glucocorticoid receptors exist in both the central nervous system and in peripheral tissues such as skeletal muscle, liver, and adipose tissue. Upon acute shifts in light-dark or feeding cycles, rhythmic levels in cortisol appear to modulate the rate at which behavioral and physiological rhythms phase shift. Indeed, glucocorticoids regulate clock gene expression in muscle, kidney, and lung, and the powerful synthetic glucocorticoid dexamethasone is often employed in vitro for its ability to synchronize (e.g., reset) circadian rhythms of cells, including liver cells. Consistent with a role for glucocorticoid regulation of the clock, both adrenalectomy, which results in a lack of cortisol, and exogenous corticosteroid supplementation significantly disrupt the circadian clock system.

Several peripherally produced hormones and peptides are not only produced rhythmically but can also feed back to central clocks, including within the SCN. For instance, both cortisol and thyroid hormones regulate their own rhythmic synthesis by feedback to central brain regions, i.e., the hypothalamus (for cortisol) and pituitary (for both hormones). Several other peripherally produced factors have been proposed to influence the central clock, including fatty acids produced by the adipose tissue and fibroblast growth factor 21, a hormone primarily produced by the liver. Peripheral hormones that signal energy state and hunger also exhibit circadian rhythms that are regulated by local tissue clocks. The most extensively studied of these hormones are leptin, which is released from white adipose tissue cells, and ghrelin, which is released from specific endocrine cells in the upper fundus region of the stomach. Ghrelin also exhibits significant peaks related to anticipated meal timing, which persist for several days of fasting in humans. Circulating rhythms of leptin and ghrelin are disrupted in circadian mutant mice and in humans experiencing circadian misalignment, with evidence for sex-specific effects. *Per* and *Cry* mutant mice exhibit severely blunted leptin rhythms, and wild-type mice exposed to jetlag (through repeatedly altered light-dark cycles) show a reduced wake-associated decrease in leptin. Similarly, humans forced to live 28-h days exhibit increased 24-h profiles of ghrelin and decreased levels of leptin. Ghrelin and leptin signal to several regions of the brain, including integrative appetitive regions of the hypothalamus such as the arcuate and paraventricular region. The response to these hormones is rhythmically regulated by the molecular clock within several such central sites, effectively gating how these hormones influence rhythms of food intake and energy homeostasis in a time-of-day– and nutrient-dependent manner.

Role for the Clock in Metabolic Homeostasis Circadian control of glucose homeostasis has long been recognized, as early studies demonstrated variation in glucose tolerance and insulin action across the day. For example, due to a combination of circadian control of both peripheral insulin sensitivity and pancreatic β-cell insulin secretion, oral glucose tolerance is lower in the evening and afternoon compared with the morning. Another example is the "dawn phenomenon," whereby glucose levels peak prior to the onset of activity. Further, destruction of the SCN has been shown to abolish circadian regulation of glucose metabolism in rats, and daily cycles of insulin secretion and glucose tolerance are often perturbed in patients with type 2 diabetes, who also exhibit changes in gene expression rhythms in peripheral tissues such as adipose tissue. Changes in rhythmic parameters such as insulin secretion have also been observed in first-degree relatives

of patients with type 2 diabetes, possibly highlighting a key hereditary role for the circadian clock in the pathogenesis of metabolic disease.

Ablating clock genes in mice has revealed a key function for both central and peripheral clocks in regulating energy homeostasis. The circadian system has been shown to regulate rhythmic insulin secretion from the pancreas via both neural signals and hormonal levels (e.g., cortisol and norepinephrine), as well as via cell-autonomous clock regulation within the pancreatic β cell itself. An early observation was that whole-body *Clock*$^{\Delta 19/\Delta 19}$ mutant mice developed obesity without displaying hyperinsulinemia, a phenomenon that indicated concurrent β-cell failure. This was later confirmed using pancreas- and β-cell–specific *Bmal1*-deficient mice, which exhibited glucose intolerance, hypoinsulinemia, and impaired glucose-stimulated insulin secretion. The molecular clock within other peripheral tissues such as liver, adipose tissue, and skeletal muscle also regulates circadian fluctuations in insulin sensitivity and glucose disposal, which are highest in the morning and decline toward the evening in humans. Liver-specific ablation of *Bmal1* in mice has revealed that the liver clock promotes gluconeogenesis, glycogenolysis, and mitochondrial oxidative metabolism in the sleep/fasting period, while promoting glycogen synthesis in the wake/feeding period. Muscle-specific *Bmal1*-deficient mice display reduced glucose tolerance, concomitant with lower levels of proteins involved in glucose uptake by muscle cells (e.g., the glucose transporter GLUT4). Ablation of the *Cry1* and *Cry2* repressors in the negative limb of the clock alters glucagon and glucocorticoid signaling in the liver, contributing to hyperglycemia and impaired glucose tolerance in these mutant mice. Together, these genetic studies in mice suggest a role for tissue-specific clocks in the partitioning of energy utilization across the sleep-wake cycle.

Importantly, peripheral clocks also interact with other environmental factors such as diet and time of feeding. For example, high-fat feeding leads not only to obesity and metabolic syndrome in mice, but also to perturbed clock gene expression across multiple peripheral tissues and a disrupted sleep-wake/fasting-feeding cycle, as revealed by increased activity and feeding during the daytime, the normal rest period in mice. Furthermore, mice that are fed a high-fat diet exclusively during their (inactive) light phase gain significantly more weight than mice that are fed the same diet during the dark period—the active period for mice. Additionally, the metabolic phenotypes arising from ad lib high-fat feeding can be significantly ameliorated by restricting the time of high-fat feeding exclusively to the dark period. Animals with disrupted clock throughout the hypothalamus and SCN exhibit mistimed eating and adverse metabolic rhythms that can be restored by dark-only feeding. Time-restricted feeding can also increase the activity of brown adipose tissue in mice and reduce hepatic glucose production to instead promote beta oxidation of fatty acids. The potential clinical utility of time-restricted eating (TRE) has been corroborated in human interventional studies. These have demonstrated that dietary interventions modulate transcriptional rhythms across tissues and that TRE can improve metabolic homeostasis as well as promote weight loss. Compared with calorie restriction, TRE has repeatedly been shown to promote weight loss by reducing calorie intake without the need to actively count calories. Time-restricted eating may also modulate the central regulation of sleep and hunger, as studies have found that humans who restrict their food intake to a shorter than ad lib period also consume fewer daily calories and report both lower hunger and improved sleep. In the setting of critical illness, nutrition is often provided at the incorrect phase of the light-dark cycle, and interventions to align feeding with environmental zeitgeibers may improve metabolic health. There is also some evidence that consuming a greater proportion of daily calories early compared with later in the day confers metabolic advantages, including weight loss. One contributing mechanism may be that diet-induced thermogenesis (energy expenditure elicited by food intake) is higher in the morning compared with evening and that daytime hunger ratings are lower when calories are preferentially consumed earlier versus later in the day.

Finally, animal studies have further shown that when the light-dark cycle is disrupted or when animals are subjected to conditions mimicking "jetlag" by artificially advancing or delaying the daily light period, there is desynchronization among circadian clocks and subsequent weight gain. Accumulating evidence in humans also finds that circadian misalignment both disrupts and desynchronizes circadian clocks across tissues. Clinical studies that have sampled tissues such as blood, skeletal muscle, and adipose tissue at regular intervals have observed disruptions in the day-night rhythms in clock and metabolic genes following sleep-wake interventions. Prolonged circadian misalignment using forced desynchrony protocols reduces insulin sensitivity in the pre- and postprandial states. Under such conditions, insulin secretion fails to suppress glucose levels, suggesting inadequate β-cell compensation. Moreover, resting metabolic rate declines significantly both in the awake and sleeping state, altogether providing potential explanations why shift work can increase the risk of obesity, type 2 diabetes, and the metabolic syndrome.

Human genetic association studies also support a role for clock genes in metabolic homeostasis and β-cell function. Carriers of a certain *BMAL1* polymorphism have a greater risk of developing type 2 diabetes, while *CLOCK* variants have been found to interact with diet, such that variants can have a protective effect on insulin sensitivity in individuals with high monounsaturated fat intake or in individuals provided a low-fat diet. In contrast, the minor allele of another *CLOCK* gene variant has been associated with increased waist circumference, but only in those with high saturated fat intake. Similarly, *NPAS2* and *BMAL1* variants have been associated with a greater risk of hypertension. Melatonin receptor *MTNR1B* gene variants that result in increased expression of MTNR1B have been associated with elevated fasting blood glucose levels and reduced insulin secretion irrespective of their level of glycemic control, although how melatonin regulates glucose homeostasis remains incompletely understood. These association studies highlight the role of the circadian system in metabolism, as well as the potential for interactions of external perturbations—such as circadian misalignment—with a protective or adverse genetic profile.

A large proportion of society recurrently shifts sleep-wake and eating times between working/nonfree days and free days. This social jetlag has been increasingly tied to metabolic disruptions, including a greater risk of obesity and type 2 diabetes. As this involves recurrent phase advances and phase delays—like shift work but often of smaller magnitude—it is possible that social jetlag, and often interlinked eating jetlag, also results in perturbed rhythms of energy expenditure in combination with disruptions to the circadian hunger drive, further increasing the risk of obesity. Repeated shifts in the food- and SCN-driven rhythm of insulin release may similarly over time increase the risk of type 2 diabetes. Shifted feeding rhythms in relation to the sleep-wake cycle and the timing of SCN activity may be causally involved in this pathogenesis. This is exemplified by the disorders known as night-eating syndrome and sleep-related eating disorder. In the former syndrome, a large part of daily calorie consumption occurs in the evening and nighttime hours, and this shifted meal pattern has been associated with a delayed timing of the internal clock. Some evidence exists that these syndromes are associated with obesity. Individuals who report sleeping fewer hours or who are subjected to restricted sleep for a few consecutive days have also been found to consume more calories, especially later in the evening, a period during which prolonged fasting favors oxidative fuel utilization. As such, this may explain why sleep restriction increases the risk of obesity. These associations have also been observed in individuals with later onset of sleep, i.e., evening chronotypes. Night-eating syndrome and later chronotypes have also been linked to type 2 diabetes and may be more common than other eating disorders such as binge-eating disorder. Both conditions have also been found to be associated with impaired glycemic control—such as a greater likelihood of hemoglobin A_{1c} values exceeding 7%—in patients already suffering from type 2 diabetes. This emphasizes how proper alignment of internal circadian rhythms with external factors are key contributing factors for long-term metabolic homeostasis.

Circadian Clocks in Relation to Brain Health and Cognition Molecular circadian clocks are present not only within the extra-SCN regions of the brain, but also in neurons, astrocytes, microglia, and cells of the blood-brain barrier. Emphasizing the functional

significance of properly aligned clocks for brain health, shift workers have been found to have decreased gray matter in brain regions involved in memory and executive functions, with more notable effects in individuals who had shorter recovery periods between the onset of each shift work cycle. Adults performing rotating shift work for many years have also been shown to exhibit signs of accelerated cognitive aging. Notably, evidence suggests that these effects may be reversible, as those who stopped carrying out shift work exhibited normal cognitive performance 5 or more years later.

Studies have also uncovered an important role for perturbed circadian and sleep-wake rhythms in neurodegenerative conditions such as Alzheimer's disease (AD), Huntington's disease (HD), and Parkinson's disease (PD). Amyloid beta (Aβ), a key pathognomonic component of AD, normally exhibits circadian fluctuations in the extracellular space in the brain, as well as in the cerebrospinal fluid and plasma in humans, peaking during the active period and falling during sleep. Of note, these daily rhythms of Aβ accumulation are dampened in mice that are prone to develop AD; reduced plasma Aβ fluctuations have also been noted in older compared with younger individuals. Animal studies indicate that removal of Aβ (and other neurotoxic substances) during the nighttime sleep period is facilitated by a lymphatic-like system that relies on glial cells (the "glymphatic" system). Relevance of this system to humans is suggested by the observation that non–rapid eye movement (NREM) sleep is accompanied by hemodynamic fluctuations that alter the flow of cerebrospinal fluid, which can remove toxins such as Aβ. Consistent with a role for circadian rhythms in the pathogenesis of AD, ablation of core clock genes throughout the brain, within subregions of the brain or within glia, leads to pathology such as oxidative stress, neuronal cell death, and scarring of brain tissue (astrogliosis). Furthermore, perturbed light-dark cycles increased pathology associated with oxidative stress, and single nucleotide polymorphisms in *CLOCK* and *BMAL1* have been associated with increased risk of developing AD.

Evidence also indicates that the relationship between the circadian/sleep-wake system and AD is bidirectional. For example, patients suffering from AD exhibit several signs of perturbed circadian rhythms, the most prominent of such phenomena being "sundowning," whereby AD patients become more agitated and exhibit delirium-like symptoms in the afternoon or evening. Studies have furthermore indicated that in severe forms of AD, the circadian rhythm is phase delayed. Aged AD-prone mice also display perturbed sleep-wake patterns, which can be corrected by immunization against Aβ or by an orexin antagonist. Further research will help uncover the primary role of the circadian system in disease pathology, independent of the contribution from perturbed sleep, in conditions like AD. Notably, evidence suggests that interventions that increase daytime light exposure and that include melatonin supplementation ameliorate symptoms of AD, presumably by counteracting disrupted circadian rhythms.

Meta-analyses of cohort and longitudinal studies support an association between shift work and the risk of depression, with greater risk in women. This relationship is bidirectional, as disruption of sleep and circadian rhythms is a key feature of depression and multiple other neuropsychiatric conditions. Two important factors for why misaligned sleep increases the risk of neuropsychiatric conditions may be mistimed light exposure and disrupted 24-h rest-activity rhythms. In cross-sectional and longitudinal analyses, greater time spent outdoors during the day has been associated with fewer symptoms of insomnia, lower risk of developing depression, and less need for antidepressive medication. Similarly, decreased rest-activity rhythms are associated with lower subjective happiness and reaction time and a greater lifetime risk of major depressive or bipolar disorder. This may be partly due to genetic variation, as clock genes have been implicated in depression and mood both in human and genetic animal studies. Polymorphisms in genes that regulate sleep and circadian rhythms—for instance, a long gene variant of *PER3*—have also been linked to bipolar disorder and schizophrenia, while *CRY2* and *CLOCK* gene polymorphisms are associated with seasonal affective disorder, a type of depression arising in the fall and winter months when the levels of sunlight are lowest. Bipolar disorder is furthermore often triggered by circadian disruptions or curtailed sleep. Both bipolar disorder and schizophrenia have been linked to various forms of circadian disruption following disease onset, and a critical component of disease treatment often involves normalizing sleep and sleep-wake rhythms.

Sleep deprivation by itself is known to reduce alertness, impair decision-making, and increase risk for accidents—after 18–24 h of continuous wakefulness, several skills exhibit the same degree of decline as following mild alcohol intoxication. However, cognitive abilities may suffer even further when sleep restriction is combined with circadian misalignment as in shift work. In one study, participants were subjected to ~43-h long days in parallel with reduced sleep (equivalent to 5.6 h of sleep in a 24-h period), yielding a forced desynchrony protocol coupled with sleep loss. When subjects were tested at the nadir of their circadian period, the subjects' reaction speed dropped almost by an order of magnitude compared with controls. In another study, researchers noted almost a 36% greater incidence of serious medical errors in resident interns who regularly worked 24-h or longer shifts compared with those who were randomly assigned to work up to 16-h-long shifts. Furthermore, errors that resulted in patient death were three times more likely to occur in residents working extended hours compared with those who only worked up to 16-h-long shifts.

Circadian Regulation of Gastrointestinal Homeostasis and the Microbiota Physiologic aspects of the gastrointestinal (GI) tract exhibit day-night variations that anticipate and prepare for food intake and digestion during the active period. Gastric emptying and colonic motility are considerably greater during the active phase, as the phasic motor program supporting movement of digested material along the intestine is approximately twice as fast during the day compared with night. Bile acid secretion also exhibits circadian rhythmicity in the intestine, as do absorption and the expression of many nutrient uptake transporters in the intestinal wall, including the main glucose transporter protein SGLT1. The permeability of the intestinal wall also varies throughout the sleep-wake cycle, and mice exposed to chronic sleep fragmentation exhibit increased intestinal permeability, which may enable inflammatory molecules from bacteria to reach the systemic circulation.

The composition and function of the fecal microbiome (i.e., the gut microbiota) also display circadian rhythmicity, orchestrated by both host circadian clock gene expression and food intake rhythms. Accordingly, circadian disruption, either by environmental or genetic means, perturbs these microbial rhythms, disrupting both bacterial levels and the metabolic functions of the gut microbiota. For example, alterations in the expression and functions of the gut microbiota have been noted in humans exposed to acute jetlag, and evidence suggests that curtailing sleep, which often accompanies shift work and jetlag, can alter the gut microbiota. Corroborating the importance of the daily timing of food intake, interventions with meals scheduled earlier versus later in the day, or that involve time-restricted eating, have been found to alter the composition of the gut microbiome in humans, although the causal relevance of this remains to be ascertained.

By increasing local and systemic inflammation, circadian disruption of the gut microbiota may be causally involved in increased risk of inflammatory bowel disease (Crohn's disease and ulcerative colitis) and colon cancer in shift workers. Biological sex differences have also been reported, as female mice display more pronounced microbial rhythms. Interestingly, the gut microbiome has also been shown to influence the rhythms of host tissues, such as the intestine and liver, that also appear sex-specific. This relationship indicates that a bidirectional interaction exists between tissues that regulate metabolic processes and the gut microbiome across the sleep-wake cycle. These findings may furthermore have clinical implications, given that the gut microbiome may both directly (in the gut lumen) and indirectly (through host-microbiota interactions such as through signaling molecules) impact metabolic responses and pharmacokinetic and pharmacodynamic properties of therapeutic drugs across the 24-h day-night cycle.

Cardiovascular Health and the Circadian Clock An early epidemiologic observation was a greater incidence of myocardial infarction in the morning hours, with the lowest risk during the

period preceding sleep. Other cardiovascular outcomes such as sudden cardiac death and syncope also exhibit a daily peak in the morning. Blood pressure (BP) typically peaks around 2100 h and decreases later during sleep. The postexercise recovery response of BP is faster in the late afternoon compared with the morning, and the daily timing of physical activity has been found to modulate the risk of all-cause and cardiovascular disease mortality. The lowering of BP during sleep is partially due to a circadian nighttime dip of around 3–6 mmHg in systolic BP (SBP) and 2–3 mmHg in diastolic BP (DBP). A dip in BP of either <10% or >20% during normal sleep has been associated with worse cardiovascular prognosis and risk of dementia. Nighttime BP dipping is also often disrupted in sleep-wake disorders and correlates with increased cardiovascular disease risk in conditions such as insomnia and narcolepsy. Conversely, specifically lowering nighttime BP has been found to confer a lower prospective risk of cardiovascular disease.

In addition to BP, heart rate also typically decreases during sleep, while mistimed sleep leads to higher heart rate during the sleep period. Studies also suggest that heart muscle may be more tolerant to hypoxia and thus fare better under surgery scheduled for the afternoon due to timing of cellular programs driven by the cell autonomous clock in cardiomyocytes. Thus, a combination of factors—which may also involve altered glucocorticoid levels and increased platelet aggregation—may contribute to a greater risk of cardiovascular disease in the morning. Subsequent epidemiologic studies also have demonstrated that shift work increases the risk of dyslipidemia and hypertension, as well as the risk of coronary heart disease, including myocardial infarction. These findings are in line with interventional findings in which circadian misalignment has been induced either by inverting the sleep-wake cycle or by imposing days that are far outside what the endogenous circadian clock can adapt to (i.e., either too short [e.g., 20-h] or too long [e.g., 28-h]). These studies in healthy human subjects have found that circadian misalignment elevates 24-h BP, particularly during sleep. These changes may be causally related to how the autonomic system is regulated during sleep, as evidenced by reduced vagal cardiac control when the sleep-wake cycle is inverted.

Circadian Disruption and Cancer In 2007, the International Agency for Research on Cancer (part of the World Health Organization) declared that shift work that involves circadian disruption is likely carcinogenic to humans. While evidence for an association between shift work and general cancer incidence is mixed, accruing evidence supports a link between shift work and increased risk of developing colon and breast cancer, as well as having a poorer cancer prognosis. Telomere shortening, a phenomenon in aging that destabilizes the genome, has also been observed in shift workers as well as in individuals suffering from short sleep. Such changes may reduce the ability of damaged or senescent cells to undergo apoptosis and, instead, lead to uninhibited cell growth and cancer. An indirect role for the circadian clock has also come from retrospective studies on how cancer risk is related to food timing and duration of the nighttime fast in humans. In combination with interventional studies on time-restricted feeding, these findings suggest that limiting food intake to a restricted period of the day, optimizes circadian processes thereby reducing the risk of potentially carcinogenic cell damage. Studies of recurring fasting have also shown that it lowers the risk and delays the onset of cancer.

Experimental genetic evidence has also implicated clock disruption as a factor in tumorigenesis. Genetic loss of *Per2* or *Bmal1* has been shown to promote lung tumorigenesis, while studies in *Per2* mutant mice have also revealed increased radiation-induced lymphoma associated with dysregulation of the cell cycle. However, disruption of the *Cry* gene in mice has also been implicated in tumor protection due to increased susceptibility to cell death. In contrast, pharmacologic overactivation of REV-ERB may impair growth of glioblastomas. While epidemiologic, experimental, and chronotherapeutic evidence (see section "Chronotherapy and Future Directions") suggests a link between circadian disruption and cancer, the precise role of circadian systems in tumorigenesis remains to be determined.

Circadian Regulation of the Immune System Circadian misalignment and sleep restriction both alter population levels of immune cells and decrease the ability of immune cells to produce reactive radicals, in part likely through disruption of cytokine rhythms. Chronic circadian disruption may thereby impair the immune system's ability to conduct immunosurveillance at the proper time of day. This may reduce the ability to mount an appropriate pathogen-induced effector (cytotoxic T-cell) response during the active period, as well as impair the more long-term adaptive immune response, which is favored by the cytokine milieu (e.g., surges in prolactin and GH) that accompanies the recovery/sleep phase. Instead, circadian misalignment increases a range of clinically used inflammatory markers (e.g., C-reactive protein, tumor necrosis factor α, and interleukin 6), and such changes have been noted even when the sleep-wake cycle is only prolonged to a slightly longer than normal 24.6-h day. While similar effects are also observed following acute total sleep deprivation or recurrent partial sleep restriction, circadian misalignment has been found to promote an even more pronounced elevation of such markers. Genetic clock disruption in peritoneal macrophages has also revealed clock control of Toll-like receptor 9, which is responsible for identifying molecules from foreign pathogens. *Clock* knockout mice also have reduced T-cell antigen response, and mice immunized during the day had a stronger T-cell response than mice immunized at night, supporting regulation of the immune system by the clock. Similar mechanisms likely take place in humans, as clinical studies have noted an impaired vaccine response following sleep disruption, and several studies show improved immunogenic response to various antigens when vaccinated in the morning compared with afternoon.

Aging and the Circadian Clock Instability in the clock system is an often-overlooked hallmark of aging. Aging is associated with a decline in the robustness of intrinsic rhythmic processes at the behavioral, physiologic, and molecular levels in both human and animal models. At the behavioral level, aging leads to reduced and fragmented sleep, dampened locomotor activity and feeding rhythms, and a reduced ability to entrain to light, as old rodents are 20 times less sensitive to the entraining effects of light relative to young animals. Even middle-aged individuals exposed to jetlag exhibit more symptoms of circadian misalignment, such as increased time awake and reduced alertness, compared with young individuals. On a physiologic level, some of the hallmarks of aging are a reduction in amplitude (e.g., flattening of circadian pattern) of circadian processes, which can also be seen at the cellular level in peripheral cells isolated from older compared with younger individuals. This dampening of rhythms also impacts the circadian signal during the evening period (the wake maintenance zone). Epidemiologic evidence indicates that a dampened rest-activity amplitude is associated with an increased prospective risk of a range of common health conditions, such as dementia, CVD, cancer, and all-cause mortality.

Aging also results in a phase advance (e.g., a shift in the timing of the peak or nadir) in rhythms of the endocrine and neuroendocrine systems, including sleep onset and offset. For example, cortisol, dehydroepiandrosterone (DHEA), and melatonin all have dampened rhythms and are phase advanced in aging; the combination of such changes may, for instance, contribute to more fragmented sleep and lower levels of restorative slow-wave sleep in aged individuals. Relatedly, aging results in reduced peptide expression in the SCN (VIP and AVP), cell loss in sleep-wake regions (including the SCN), and reduced amplitude of rhythms of SCN electrical activity. Further, while the SCN-dependent body temperature rhythm—a generally accepted marker for the integrity of circadian rhythms—peaks in the evening and is lowest in the early morning in young individuals, aged healthy subjects display a phase advance and a decrease in circadian amplitude in body temperature rhythms. Indeed, evidence suggests that internal desynchrony between core body temperature rhythms and the sleep-wake cycle may contribute to age-associated circadian alterations.

On a molecular level, aging is associated with decreased expression and altered diurnal profiles of several of the core clock genes, including *Clock* and *Bmal1*, within both SCN and peripheral tissues such as heart and liver. The acute induction of *Per1* in response to light was markedly reduced in the SCN of aged mice compared with young mice,

potentially contributing to their delayed response to light entrainment. Mice lacking *Bmal1* die prematurely compared with control mice, consistent with premature accumulation of reactive oxygen species. These mice have an accelerated onset of numerous age-related pathologies, including cataracts, sarcopenia, reduced organ size, and decreased hair growth. Instead, deficiency of cryptochrome, a repressor of the core clock repressor, has been associated with alterations in liver regeneration, while BMAL1 and PER2 may be important for proper neurogenesis in the hippocampus, a brain region in which adult mammals normally exhibit continuous cell division. Altogether, this suggests that the highly conserved circadian clock is important for regulating a wide range of homeostatic processes, including cell-cycle pathways, which when properly phased to each other promote organismal fitness.

Shift workers have been found to exhibit molecular signs of accelerated aging, as measured by an accelerated DNA methylation clock. Measurements of altered circadian rhythms with age may serve as a useful biomarker for aging. An intriguing question is whether the decline in amplitude of rhythms correlates with a decline in function and, importantly, whether restoration of these rhythms with age, through either behavioral or pharmacologic intervention, would delay the aging process. Studies in mice indicate that behavioral and pharmacologic interventions (including exercise) can restore circadian oscillations in aging. Restoration of levels of the metabolite NAD^+, which are reduced with aging, in old mice by supplementation with the NAD^+ precursor nicotinamide riboside (NR) markedly restores rhythms of metabolic and stress response pathways, as well as late evening activity rhythms, that decline with aging through inhibition of the clock repressor PER2. Similarly, transplantation of the SCN from a young rat into an old rat "rescued" the rhythms of both locomotor activity and corticotropin hormone (CRH), suggesting that the SCN is an important target for age-related changes in clocks. Physical activity or targeted therapeutics may therefore ameliorate some of the circadian deterioration in aged humans.

CHRONOTHERAPY AND FUTURE DIRECTIONS

Chronopharmacology, also known as chronotherapy or circadian medicine, is a rapidly emerging field that studies how the timing of drug administration may impact its effectiveness. Since physiologic processes vary across the day, the timing of administration of medication may help optimize patient care. For example, since endogenous cholesterol synthesis is rhythmic in liver and peaks during the early morning hours, administration of statins (HMG-CoA reductase inhibitors) in the evening prior to bedtime has proven to be more effective than daytime administration at reducing low-density lipoprotein cholesterol (LDL-C) levels because the highest concentration of medication coincides with the peak in rhythmic endogenous cholesterol production. Given that BP exhibits a 24-h rhythm—being lowest during sleep—angiotensin-converting enzyme (ACE) inhibitors have been shown to be most effective at night to normalize the BP rhythms, restoring the nighttime dip in BP that is foremost tied to the occurrence of sleep. Numerous studies have also demonstrated that administration of cancer treatments at specific times of the day can increase chemotherapy effectiveness while also decreasing toxicity for a wide range of drugs. For example, 5-fluorouracil works best to treat colorectal cancer when administered at night, a time when the cancerous cells are more vulnerable while normal cells are quiescent and therefore less sensitive. Doxorubicin administration early in the morning to treat ovarian cancer has also been shown to be less toxic, as white blood cells recover faster than if the drug is given in the evening. Finally, the more severe morning symptoms of rheumatoid arthritis are linked to increased inflammation toward the evening; therefore, prevention of the nighttime upregulation of the immune/inflammatory reaction is more effective when glucocorticoids are administered with a nighttime release formulation.

Recognition of circadian rhythms is also critical for diagnoses and treatment of endocrine disorders. The diagnosis of Cushing's syndrome, which is characterized by hypercortisolemia, might be missed if the patient's cortisol levels are measured in the morning, when endogenous cortisol production peaks. Therefore, clinical diagnosis requires cortisol to be measured in the late evening when the levels of this hormone should typically be low. On the other hand, adrenal insufficiency is diagnosed by measuring cortisol in the morning when at its physiologic peak, and glucocorticoid therapy for these patients aims to mimic the endogenous rhythms of cortisol, as short-acting synthetic glucocorticoids are usually given several times a day in tapering doses, such that the largest amount is taken in the morning and the smallest in the evening.

Diabetes is another endocrine disorder intimately tied to circadian rhythms. Oral glucose tolerance, which is commonly used to diagnose diabetes, is worse in the afternoon and evening compared with the morning. This likely stems from greater daytime insulin sensitivity within peripheral tissues and reduced insulin secretion during the night. Similarly, due to a surge in hormone levels in the morning, diabetes patients may suffer from the dawn phenomenon (or dawn effect), an abnormally high morning increase in blood glucose due to impaired response in insulin secretion. A related phenomenon that can be tied to evening timing of insulin doses is the "rebound" or Somogyi effect. In this scenario, the initially noted clinical sign in the form of elevated glucose levels may be noted in the morning. However, the underlying cause is hypoglycemia occurring during the night, which produces a counterregulatory hormonal response that subsequently results in morning hyperglycemia. As patients with type 2 diabetes often have grossly impaired daily cycles of insulin secretion and glucose tolerance, this further highlights that time of day is an important consideration for the diagnosis and treatment of metabolic disorders such as type 2 diabetes. Another example of potential clinical relevance is how the pharmacokinetics of metformin—the most common treatment for type 2 diabetes—is significantly impacted by time of day due to rhythmicity in glomerular filtration rate and renal plasma flow. Notably, large interindividual variability in the pharmacokinetics seems to stem mostly from differences in chronotype, highlighting the need for patient-specific treatments dictated by circadian gene-environment interactions.

Continuous measurements of 24-h glucose have provided insight into sleep-wake regulation of glucose metabolism. Compared with daytime glucose levels, nighttime blood glucose levels have been found to more accurately predict a range of glucoregulatory parameters. Emerging evidence has also indicated that the daily timing of exercise may be an important determinant for more efficacious improvements in blood triglyceride and glucose levels. Furthermore, consideration of meal timing, particularly in the hospital setting, may impact patient health or responsiveness to treatments, as food in hospitals is often provided either continuously or just during the dark (rest) phase, with the latter being common in neonatal intensive care.

As our knowledge of the complexity of how circadian processes modulate physiology deepens, further advances to rationally develop new strategies for treatments of disorders affected by circadian misalignment are essential. For example, novel compounds have begun to emerge from unbiased drug discovery screens that in cell- and animal-based assays impact circadian clock components, either shortening or lengthening the period. These compounds include CRY stabilizers and various inhibitors of CKIδ, CKIε, and GSK-3. Pharmacologic control of the circadian cycle may be useful in the treatment of circadian disorders and metabolic disturbances with a circadian component. Understanding how the circadian clock controls biological functions will shed new light onto the pathogenesis of metabolic disorders with a circadian component, such as type 2 diabetes and metabolic syndrome, and will yield insight into how timing of drug delivery will impact patient care.

499 Network Medicine and Multiomic Approaches to Health and Disease

Joseph Loscalzo

The field of human biology has progressed over the past three centuries largely as a result of the reductionist approach to the scientific problems that challenge the discipline. Biologists study the experimental response of a variable of interest in a cell or organism while holding all other variables constant. In this way, it is possible to dissect the individual components of a biologic system and assume that a thorough understanding of a specific component (e.g., an enzyme or a transcription factor) will provide sufficient insight to explain the global behavior of that system (e.g., a metabolic pathway or a gene network, respectively). Biologic systems are, however, much more complex than this approach assumes and manifest behaviors that frequently (if not invariably) cannot be predicted from knowledge of their component parts characterized in isolation. Growing recognition of this shortcoming of conventional biologic research has led to the development of the discipline of *systems biology*, which is defined as the holistic study of living organisms or their cellular or molecular network components to predict their response to perturbations. Concepts of systems biology can be applied readily to human disease and therapy and define the field of *systems pathobiology*, in which genetic or environmental perturbations produce disease and drug perturbations restore normal system behavior.

Systems biology evolved from the field of systems engineering in which a linked collection of component parts constitutes a network whose output the engineer wishes to predict. The simple example of an electronic circuit can be used to illustrate some basic systems engineering concepts. All the individual elements of the circuit—resistors, capacitors, transistors—have well-defined properties that can be characterized precisely. However, they can be linked (wired or configured) in a variety of ways, each of which yields a circuit whose response to a voltage applied across it is different from the response of every other configuration. To predict the circuit's (i.e., system's) behavior, the engineer must study its response to perturbation (e.g., voltage applied across it) holistically rather than its individual components' responses to that perturbation. Viewed another way, the resulting behavior of the system is greater than (or different from) the simple sum of its parts, and systems engineering utilizes rigorous mathematical approaches to predict these complex, often nonlinear, responses. By analogy to biological systems, one can reason that detailed knowledge of a single enzyme in a metabolic pathway or of a single transcription factor in a gene network will not provide sufficient detail in context to predict the output of that metabolic pathway or transcriptional network, respectively. Only a systems-based approach will suffice.

It has taken biologists a long time to appreciate the importance of systems approaches to biomedical problems. Reductionism has reigned supreme for many decades, largely because it is experimentally and analytically simpler than holism and because it has provided insights into biological mechanisms and disease pathogenesis that have led to successful therapies. However, reductionism cannot solve all biomedical problems. For example, the so-called off-target effects of new drugs that frequently limit their adoption likely reflect the failure of a drug to be studied in integrated context, that is, the failure to explore all possible actions aside from the principal target action for which it was developed. Other approaches to understanding biology are, therefore, clearly needed. With the growing body of genomic, proteomic, and metabolomic data sets in which dynamic changes in the expression of many genes and many metabolites are recorded after a perturbation and with the growth of rigorous mathematical approaches to analyzing those changes, the stage has been set for applying systems engineering principles to modern biology.

Physiologists historically have had more of a (bio)engineering perspective on the conduct of their studies and have been among the first systems biologists. Yet, with few exceptions, they, too, have focused on comparatively simple physiological systems that are tractable using conventional reductionist approaches. Efforts at integrative modeling of human physiological systems, as first attempted by Guyton for blood pressure regulation, represent one application of systems engineering to human biology. These dynamic physiological models often focus on the acute response of a measurable physiological parameter to a system perturbation, and do so from a classic analytical perspective in which all the conventional physiological determinants of the output parameter are known and can be modeled quantitatively.

Until recently, molecular systems analysis has been limited owing to inadequate knowledge of the molecular determinants of a biological system of interest. Although biochemists have approached metabolic pathways from a systems perspective for more than 50 years, their efforts have been limited by the inadequacy of key information for each enzyme (K_m, k_{cat}, and concentration) and substrate (concentration) in the pathway. With increasingly rich molecular data sets available for systems-based analyses, including genomic, transcriptomic, proteomic, metabolomic data, and enzymatic (kinetic), molecular biologists and biochemists are now poised to use systems biology approaches to explore biological and pathobiological phenomena.

PROPERTIES OF COMPLEX BIOLOGIC SYSTEMS

To understand how best to apply the principles of systems biology to human biomedicine, it is necessary to review briefly the building blocks of any biological system and the determinants of system complexity. All systems can be analyzed by defining their static topology (architecture) and their dynamic (i.e., time-dependent) response to perturbation. In the discussion that follows, system properties are described that derive from the consequences of topology (form) or dynamic response (function). Any system of interacting elements can be represented schematically as a *network* in which the individual elements are depicted as nodes and their connections are depicted as links. The nature of the links among nodes reflects the degree of complexity of the system. *Simple systems* are those in which the nodes are linearly linked with occasional feedback or feedforward loops modulating system throughput in highly predictable ways. By contrast, *complex systems* are nodes that are linked in more complicated, nonlinear networks; the behavior of these systems by definition is inherently more difficult to predict owing to the nature of the interacting links, the dependence of the system's behavior on its complex set of initial conditions, and the inability to measure the overall state of the system at any specific time with great precision. Complex systems can be depicted as a network of lower-complexity interacting components or modules, each of which can be reduced further to simpler analyzable

canonical motifs (such as feedback and feedforward loops or negative and positive autoregulation); however, a central property of complex systems is that simplifying their structures by identifying and characterizing the individual nodes and links or even simpler substructures does not necessarily yield a predictable understanding of a system's behavior. Thus, the functioning system is greater than (or different from) the sum of its individual, tractable parts.

Defined in this way, most biological systems are complex systems that can be represented as networks whose behaviors are not readily predictable from simple reductionist principles. The nodes, for example, can be metabolites that are linked by the enzymes that cause their transformations, transcription factors that are linked by the genes whose expression they influence, or proteins in an interaction network that are linked by cofactors that facilitate interactions or by thermodynamic forces that facilitate their physical association. Biologic systems typically (but not invariably) are organized as *scale-free*, rather than stochastic, networks of nodes. Scale-free networks are those in which a few nodes have many links to other nodes (highly linked nodes, or hubs), but most nodes have only a few links (weakly linked nodes). The term *scale-free* refers to the fact that the connectivity of nodes in the network is invariant with respect to the size of the network. This is quite different from two other common network architectures: random (Poisson) and exponential distributions. Scale-free networks can be mathematically described by a power law that defines the probability of the number of links per node, $P(k) = k^{-\gamma}$, where k is the number of links per node and γ is the slope of the log P(k) versus log(k) plot; this unique property of most biologic networks is a reflection of their self-similarity or fractal nature **(Fig. 499-1)**.

There are unique properties of scale-free biological systems that reflect their evolution and promote their adaptability and survival. Biological networks likely evolved one node at a time in a process in which new nodes are more likely to link to a highly connected node than to a sparsely connected node. Furthermore, scale-free networks can become sparsely linked to one another, yielding more complex, *modular scale-free topologies*. This evolutionary growth of biologic networks has three important properties that affect system function and survival. First, this scale-free addition of new nodes promotes *system redundancy*, which minimizes the consequences of errors and accommodates adverse perturbations to the system robustly with minimal effects on critical functions (unless the highly connected nodes are the focus of the perturbation). Second, this resulting network redundancy provides a survival advantage to the system. In complex gene networks, for example, mutations or polymorphisms in weakly linked genes account for biodiversity and biologic variability without disrupting the critical functions of the system; only mutations in highly linked (*essential*) genes (hubs) can shut down the system and cause embryonic lethality. Third, scale-free biological systems facilitate the flow of information (e.g., metabolite flux) across the system compared with randomly organized biological systems; this so-called "small-world" property of the system (in which the clustered nature of the highly linked hubs defines a local neighborhood within the network that communicates through weaker, less frequent links to other clusters) minimizes the energy cost for the dynamic action of the system (e.g., minimizes the transition time between states in a metabolic network).

These basic organizing principles of complex biologic systems lead to three unique properties that require emphasis. First, biological systems are *robust*, which means that they are quite stable in response to most changes in external conditions or internal modification. Second, a corollary to the property of robustness is that complex biologic systems are *sloppy*, which means that they are insensitive to changes in external conditions or internal modification except under certain uncommon circumstances (i.e., when a hub is involved in the change). Third, complex biological systems exhibit *emergent properties*, which means that they manifest behaviors that cannot be predicted from the reductionist principles used to characterize their component parts. Examples of emergent behavior in biological systems include spontaneous, self-sustained oscillations in glycolysis; spiral and scroll waves of depolarization in cardiac tissue that cause reentrant arrhythmias; and self-organizing patterns in biochemical systems governed by diffusion and chemical reaction.

APPLICATIONS OF SYSTEMS BIOLOGY TO PATHOBIOLOGY

The principles of systems biology have been applied to complex pathologic processes with growing successes. The key to these applications is the identification of emergent properties of the system under study in

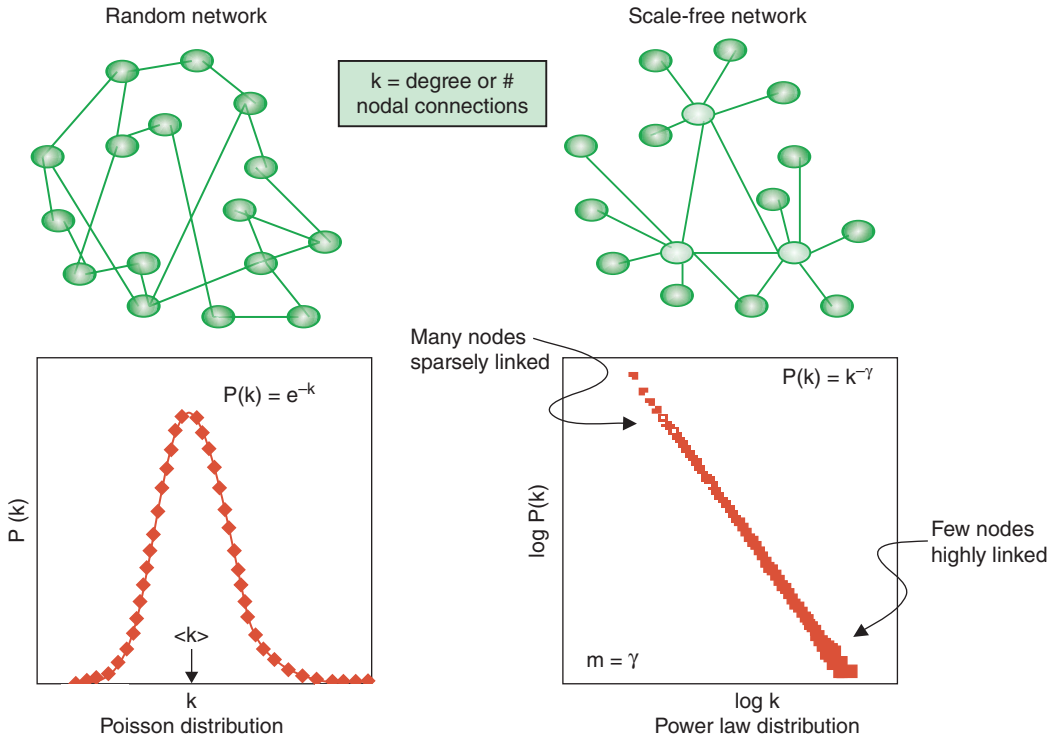

FIGURE 499-1 Network representations and their distributions. A random network is depicted on the left, and its Poisson distribution of the number of nodal connections (k) is shown in the graph below it. A scale-free network is depicted on the right, and its power law distribution of the number of nodal connections (k) is shown in the graph below it. Highly connected nodes (hubs) are lightly shaded.

order to define novel, otherwise unpredictable (i.e., from the reductionist perspective) methods for regulating the system's response. Systems biology approaches have been used to characterize epidemics and ways to control them, taking advantage of the scale-free properties of the network of infected individuals that constitute the epidemic. Through the use of a systems analysis of a neural protein-protein interaction network, unique disease-modifying proteins have been identified that are common to a wide range of cerebellar neurodegenerative disorders causing inherited ataxias. Systems analysis and disease network construction of a pulmonary arterial hypertension network led to the identification of a unique disease module involving a pathway governed by microRNA 21 and, more recently, to a novel profibrotic pathway that promotes vascular disease progression. Systems biology models have been used to dissect the dynamics of the inflammatory response using oscillatory changes in the transcription factor nuclear factor (NF)-κB as the system output. Systems biology principles also have been used to predict the development of an idiotypy–anti-idiotypy antibody network, describe the dynamics of species growth in microbial biofilms, and analyze the innate immune response. In each of these examples, a systems (patho)biology approach provided insights into the behavior of these complex systems that could not have been recognized with conventional scientific reductionism.

A unique application of systems biology to biomedicine is in the area of drug development. Conventional drug development involves identifying a potential target protein and then designing or screening compounds to identify those that inhibit (or activate) the function of that target. This reductionist analysis has identified many potential drug targets and drugs, yet only when a drug is tested in animal models or humans are the systems consequences of the drug's action revealed; not uncommonly, so-called off-target effects may become apparent and be sufficiently adverse for researchers to cease development of the agent. In addition to these types of unexpected outcomes exerted through pathways that were not considered *ab initio*, conventional approaches to drug development typically do not take into consideration the possibility of emergent behaviors of the organism or the metabolic pathway or the transcriptional network of interest that may be influenced by the drug. Thus, a systems-based analysis of potential drugs (drug-target network analysis) can benefit the development paradigm both by enhancing the likelihood that a compound of interest will not manifest unforeseen adverse effects and by promoting novel analytical methods for identifying unique control points or pathways in metabolic or genetic networks that would benefit from drug-based modulation, including the use of drug combinations. In addition and importantly, unbiased knowledge about the systems behavior of a drug can lead to rational approaches to drug repurposing.

SYSTEMS PATHOBIOLOGY AND HUMAN DISEASE CLASSIFICATION: NETWORK MEDICINE

Perhaps most important, systems pathobiology can be used to revise and refine the definition of human disease. The classification of human disease used in this and all medical textbooks derives from the correlation between pathological analysis and clinical syndromes that began in the nineteenth century. Although this approach has been very successful, serving as the basis for the development of many effective therapies, it has major shortcomings. Those shortcomings include a lack of sensitivity in defining preclinical disease, a primary focus on overtly manifest disease, failure to recognize different and potentially differentiable causes of common late-stage pathophenotypes (convergent pathophenotypes), failure to recognize common causes of different pathophenotypes (divergent pathophenotypes), and a limited ability to incorporate the growing body of molecular and genetic determinants of pathophenotype into the conventional classification scheme.

Two examples will illustrate the weakness of simple correlation analyses grounded in the reductionist principle of simplification (Occam's razor) used to define human disease. Sickle cell anemia, the "classic" Mendelian disorder, is caused by a Val6Gln substitution in the β chain of hemoglobin. If conventional genetic teaching holds, this single mutation should lead to a single phenotype in patients who harbor it (genotype-phenotype correlation). This assumption is, however, false, as patients with sickle cell disease manifest a variety of pathophenotypes (divergent pathophenotypes), including hemolytic anemia, stroke, acute chest syndrome, bony infarction, and painful crisis, as well as an overtly normal phenotype. The reasons for these different phenotypic presentations include the presence of disease-modifying genes or gene products (e.g., hemoglobin F, hemoglobin C, glucose-6-phosphate dehydrogenase), (stochastic) exposure to adverse environmental factors (e.g., hypoxia, dehydration), and the genetic and environmental determinants of common intermediate pathophenotypes or endophenotypes (i.e., variations in those generic pathological mechanisms underlying all human disease—inflammation, thrombosis/hemorrhage, fibrosis, cell proliferation, apoptosis/necrosis, immune response, etc.).

A second example of note is familial pulmonary arterial hypertension. This disorder is associated with well over 300 different mutations in three members of the transforming growth factor β (TGF-β) superfamily alone—bone morphogenetic protein receptor-2 (BMPR-2), activin receptor-like kinase-1 (Alk-1), and endoglin—as well as 16 other genes. All of these different genotypes are associated with a common pathophenotype, and each leads to that pathophenotype by molecular mechanisms that range from haploinsufficiency to dominant negative effects. As only approximately one-fourth of individuals in families that harbor these mutations manifest the pathophenotype, other disease-modifying genes (e.g., the serotonin receptor 5-HT2B, the serotonin transporter 5-HTT), genomic and environmental determinants of common intermediate pathophenotypes, and environmental exposures (e.g., hypoxia, infective agents [HIV], anorexigens) probably account for the incomplete penetrance of the disorder.

On the basis of these and many other related examples, one can approach human disease from a systems pathobiology perspective in which each "disease" can be depicted as a network that includes the following modules: the primary disease-determining elements of the genome (or proteome, if posttranslationally modified), the disease-modifying elements of the genome or proteome, environmental determinants, and genomic and environmental determinants of the generic intermediate pathophenotypes (endophenotypes). **Figure 499-2** graphically depicts these genotype-phenotype relationships as modules for the six common disease types with specific examples for each type. **Figure 499-3** shows a network-based depiction of sickle cell disease using this type of modular approach.

Goh and colleagues developed the concept of a human disease network **(Fig. 499-4)** in which they used a systems approach to characterize the disease-gene associations listed in the Online Mendelian Inheritance in Man database. Their analysis showed that genes linked to similar disorders are more likely to have products that physically associate and greater similarity between their transcription profiles than do genes not associated with similar disorders. In addition, proteins associated with the same pathophenotype are significantly more likely to interact with one another than with other proteins not associated with the pathophenotype. Finally, these authors showed that the great majority of disease-associated genes are not highly connected genes (i.e., not hubs) and are typically weakly linked nodes within the functional periphery of the network in which they operate. This set of observations led to a rigorous analysis by Menche and colleagues of 299 diseases whose associated proteins were found to cluster in discrete subnetworks or disease molecules within the global protein-protein interaction network.

This type of analysis validates the potential importance of defining disease on the basis of its systems pathobiological determinants. Clearly, doing so will require a more careful dissection of the molecular elements in the relevant pathways (i.e., more precise molecular pathophenotyping), less reliance on overt (common) manifestations of disease for their classification, and an understanding of the dynamics (not just the static architecture) of the pathobiological networks that underlie pathophenotypes defined in this way. **Figure 499-5** illustrates the elements of a molecular network within which a disease module is contained. This network is first identified by determining

the interactions (physical or regulatory) among the proteins or genes that comprise it (the "interactome"). These interactions then define a topologic module within which exists functional modules (pathways) and disease modules. One approach to constructing this module is illustrated in **Fig. 499-6**. Examples of the use of this approach in defining novel determinants of disease are given in **Table 499-1**, and follow from four key organizing principles that tie the interactions to human disease **(Table 499-2)**.

Interaction network complexity is itself becoming increasingly complex as multiple omic layers can now be ascertained, including the transcriptome, the proteome, the epigenome, and the metabolome. This integrative analysis leads to the formulation of a network of networks, the primary consequence of which from an evolutionary perspective is to enhance the robustness of the system to perturbations. Single-cell omic analysis adds further nuance to organ-based network analysis, which offers even greater promise for understanding individual differences in disease drivers and manifestations. **Figure 499-7** illustrates these points schematically.

Principles of network and systems biology can also be applied to clinical phenotyping. Rather than continuing to approach disease from an inclusive perspective, precision systems analysis of the molecular basis for disease must be linked to nuanced, deep phenotyping. This strategy will lead to the identification of subgroups of patients with a disease, each of which can be studied for differences in their disease modules that account for their phenotypic differences.

As yet another potential consideration, one can argue that disease reflects the later-stage consequences of the predilection of an organ system to manifest a particular intermediate pathophenotype (endophenotype) in response to injury. This paradigm reflects a reverse causality view in which a disease is defined as a tendency to heightened inflammation, thrombosis, or fibrosis, for example, after an injurious perturbation. Where the process is manifest (i.e., the organ in which it

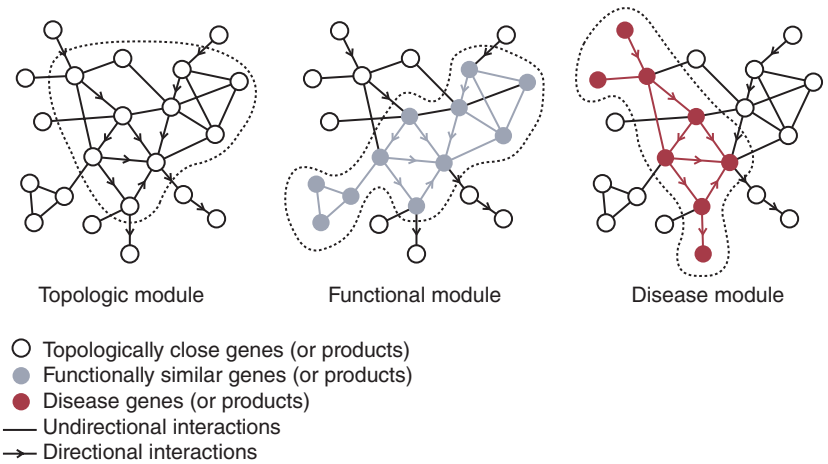

FIGURE 499-5 The elements of the interactome. The interactome includes topologic modules (genes or gene products that are closely associated with one another through direct interactions), functional modules (genes or gene products that work together to define a pathway), and disease modules (genes or gene products that interact to yield a pathophenotype). *(Reproduced with permission from AL Barabási et al: Network medicine: A network-based approach to human disease. Nat Rev Genet 12:56, 2011.)*

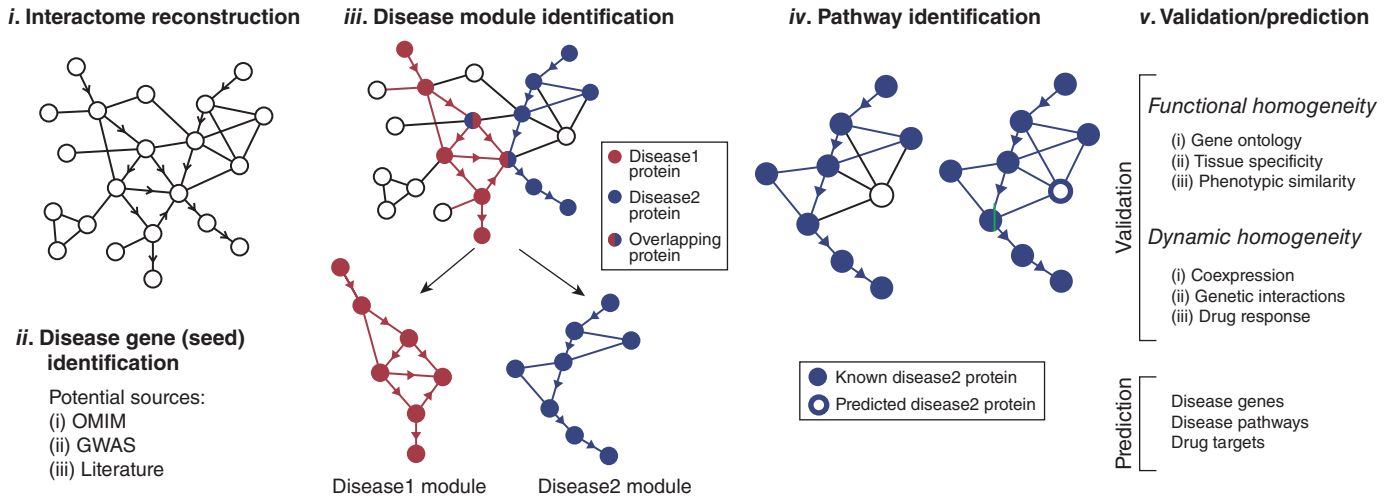

FIGURE 499-6 Approaches to identifying disease modules in molecular networks. A strategy for defining disease modules involves (i) reconstructing the interactome; (ii) ascertaining potential seed (disease) genes from the curated literature, the Online Mendelian Inheritance in Man (OMIM) database, or genomic analyses (genome-wide association studies [GWAS], transcriptional profiling), or proteomic profiling; (iii) identifying the disease module using different modeling or statistical approaches; (iv) identifying pathways and the role of disease genes or modules in those pathways; and (v) disease module validation and prediction. *(Reproduced with permission from AL Barabási et al: Network medicine: A network-based approach to human disease. FIGURE 499-7 Network integration of multiomics data across a wide spectrum from the patient level to the single-cell level. Patient-level omics data, tissue-specific omics data, and cell-specific omics data can be mapped to the human interactome to derive patient-specific networks, tissue-specific networks, and cell-specific networks, respectively. Such integrated networks are quite powerful for resolving the phenotypic heterogeneity in human diseases and guiding precise drug treatments.

occurs) is less important than that it occurs (with the exception of the organ-specific pathophysiological consequences that may require acute attention). For example, from this perspective, acute myocardial infarction (AMI) and its consequences are a reflection of thrombosis (in the coronary artery), inflammation (in the acutely injured myocardium), and fibrosis (at the site or sites of cardiomyocyte death). In effect, the major therapies for AMI address these intermediate pathophenotypes (e.g., antithrombotics, statins) rather than any organ-specific disease-determining process. This paradigm would argue for a systems-based analysis that would first identify the intermediate pathophenotypes to which a person is predisposed, then determine how and when to intervene to attenuate that adverse predisposition, and finally limit the likelihood that a major organ-specific event will occur. Evidence for the validity of this approach is found in the work of Rzhetsky and colleagues, who reviewed 1.5 million patient records and 161 diseases and found that these disease phenotypes form a network of strong pairwise correlations. This result is consistent with the notion that underlying genetic predispositions to intermediate pathophenotypes form the predicate basis for conventionally defined end-organ diseases.

Regardless of the specific nature of the systems pathobiological approach used, these analyses will lead to a drastic revision of the way human disease is defined and treated, continuing to validate the discipline of *network medicine, which reflects a fusion of the fields of systems biology and network science in the study of disease*. This will be a lengthy and complicated process, will be computationally intense and benefit from artificial intelligence and deep learning approaches, but ultimately will lead to better disease prevention and therapy and likely do so from an increasingly personalized, molecularly precise perspective **(Fig. 499-8)**. The analysis of pathobiology from a systems-based perspective is likely to help define specific subsets of patients more likely to respond to particular interventions based on shared disease mechanisms. Although it is unlikely that the extreme of "individualized medicine" will ever be practical (or even desirable), complex diseases can be mechanistically subclassified and interventions may be tailored to those settings in which they are more likely to work. This approach serves as a basis for the development of precision medicine.

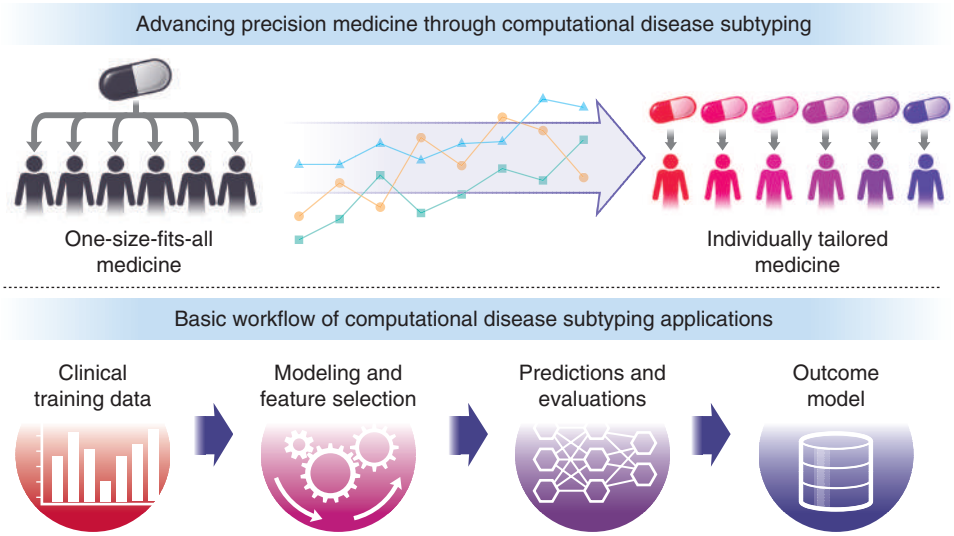

FIGURE 499-8 Advancing precision network medicine through computationally assisted molecular and phenotypic subtyping. ***Top:*** The path toward precision medicine moves from one-size-fits-all medicine to individually tailored medicine. ***Bottom:*** Basic workflow of computational disease subtyping applications.

500 Emerging Neurotherapeutic Technologies

Jyoti Mishra, Karunesh Ganguly

Neurotherapeutic technologies represent a diverse group of very promising treatment approaches with a common purpose of improving neurologic function. Decades of basic science research have paved the path for these novel technologies that have the potential to transform the lives of patients with neurologic diseases. A key goal is to minimize the consequences of lost abilities, whether they are motor, sensory, or cognitive. A common objective is to also harness the inherent plasticity of the nervous system, regardless of age, and even in the face of a degenerative process.

The technologies described below are the culmination of both an increased understanding of neural plasticity mechanisms in both the intact and the injured nervous system as well as advances in technology and computational power. While it is also clear that there may be fundamental limits on plasticity and repair mechanisms (the closing of developmental windows and/or loss of the ability of a network to compensate), the brain remains highly plastic regardless of age and even in the face of ongoing injury and/or degenerative processes. Collectively, there is now growing evidence to support neurologic restorative efforts for both "static" (e.g., stroke) and progressive neurologic disorders.

These technologies may not appear, at first glance, directly relevant to traditional medical care, but it is worth noting that clinicians have the most knowledge and experience about specific disease processes, available treatments, and the expected course of illnesses affecting the nervous system. It is thus critical that neurologic specialists and other clinicians play an important role in the future adoption of these technologies for neurologic rehabilitation. The sections below outline emerging diagnostic and therapeutic approaches that have the potential to transform the lives of patients with neurologic disorders. These include technologies to harness plasticity, neuroimaging, neurostimulation, and brain–machine interfaces.

NONINVASIVE TECHNOLOGIES TO HARNESS PLASTICITY

Neurologic rehabilitation aims to harness activity-dependent plasticity mechanisms to maximize functional restoration. This principle can be applied to a diverse range of functional domains such as movement control, sensory processing, language, pain, and cognition. For example, recent randomized controlled clinical trials for motor recovery after stroke have suggested that intensity of training may be particularly important for sustained long-term improvements. Moreover, studies of the effects of such training in rodent and nonhuman primate models further suggest that plasticity of cortical "motor maps" as well as the coordinated firing of neurons in remaining networks underlie observed functional improvements with rehabilitation. The incorporation of technology for neurologic rehabilitation has the great potential to revolutionize the delivery of care by significantly increasing access, reducing the burden for adherence to high-intensity regimens, and maximizing engagement. Below are three examples of how emerging technology can be used to harness neural plasticity and maximize functional restoration.

ROBOTICS

Rehabilitation robotics for both the upper and the lower limb have the potential to improve motor outcomes after stroke or other forms of brain injury. There is a growing recognition that focused training involving a range of tasks might be important for improved functional outcomes. While there is a growing recognition of "sensitive periods" that might represent optimal windows for rehabilitation after injury (e.g., perhaps the first several months after a stroke), such training likely has a role in the chronic period as well (e.g., maintenance therapy may also guard against known declines in function over time). Notably, the delivery of intensive training is a great challenge from both the perspective of the health care system and each patient. Outside of clinical trials, such a training program can be quite difficult to implement and maintain. It can also be costly and require significant effort.

Motor rehabilitation protocols using robotics have been developed and tested for both the upper limb and the lower limb. Such robotic therapies have often focused on the delivery of high-intensity movement practice that can surpass what is possible via existing standards of care. Moreover, robotic systems are capable of precisely measuring movement parameters (e.g., the kinematics of the movements) and providing quantitative feedback regarding the changes in performance during the training period. A particular focus has been on maximizing patient engagement and recruitment of attentional and reward pathways, both of which are increasingly recognized to drive neural plasticity. Ongoing advances in design and the user interface will continue to improve comfort and support sustained effort. For example, via close monitoring of performance and movement parameters, the system can aid at key points in order to minimize fatigue and ensure maximal engagement. Moreover, antigravity support of the upper limb can allow practice and task engagement even in the presence of severe weakness; this would be extremely challenging and labor intensive under current standards of care. Recent analysis also suggests that robotic devices may at least match outcomes realized with existing standards of care. However, rehabilitation robotics may also provide more precise feedback and permit novel quantitative rehabilitation approaches.

Figure 500-1 shows one example of an upper-limb robotic exoskeleton device that is currently being evaluated for training after stroke. A randomized, multicenter trial compared treatment with this exoskeleton system against conventional therapy provided by physical and occupational therapists. Participants were enrolled in the chronic phase and all had moderate-to-severe deficits; the groups underwent three sessions per week over an 8-week period. For robotic training, subjects trained with games to improve mobilization and to practice activities of daily living. This study provided evidence that both conventional and

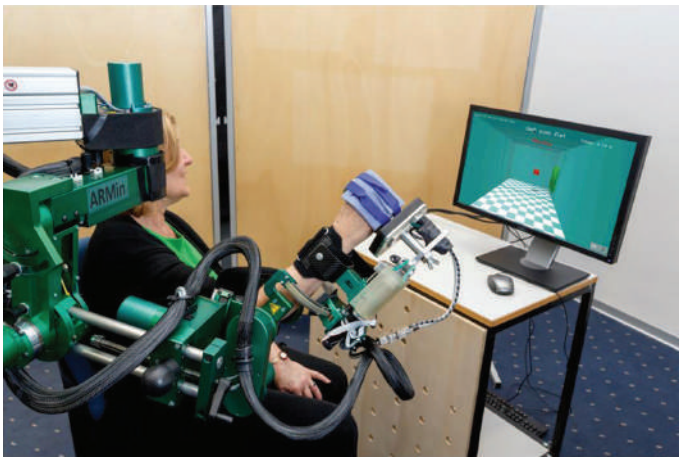

FIGURE 500-1 Photograph of a subject interacting with a complex upper-limb exoskeleton and a virtual reality system. *(From U Keller et al: Robot-assisted arm assessments in spinal cord injured patients: A consideration of concept study. PLoS One 10:e0126948, 2015.)*

robotic therapy could improve function in patients with chronic stroke. Multiple studies have also found similar gains when using either conventional or traditional approaches. Thus, a growing body of research supports the idea that such devices might complement conventional approaches to rehabilitation. Future work will need to define how rehabilitation robotics can optimally use adaptive and quantitative methods to further augment the recovery process.

VIRTUAL AND AUGMENTED REALITY

Therapeutic approaches using virtual reality (VR) and augmented reality (AR) aim to treat neurologic illnesses by specifically and quantitatively altering a patient's subjective experiences and interactions with the environment. Core components of both are advanced hardware and computational methods to generate simulated, yet realistic, perceptions. While some applications permit users to dynamically change the viewed perspective, other applications are designed to allow interactions among multiple users. Visual feedback is often a key component; this can include simple computer monitors or more immersive "head-mounted" viewers that modify the simulation based on changes in perspective. Tracking of movements (e.g., hand and head position) is often included. Multiple methods are used to allow a user to interact with the environment; interactions can be guided by straightforward means such as a keyboard, mouse, or even a joystick. More immersive methods are also frequently used. For example, gloves with embedded sensors and haptic inputs can allow the user's hand to be represented in real time in the simulated environment. Moreover, haptic interfaces can provide sensory feedback, allowing patients to interact with and "feel" virtual objects through multiple sensory modalities. A particular strength of these approaches is that therapeutic interventions can be studied in very controlled environments.

VR enables a user to interact with a simulated reality that can be precisely and quantitatively controlled. In addition to allowing patients to dynamically experience an altered reality, it can simultaneously monitor a subject's behaviors and responses. Such monitoring can allow precise measurements of clinically relevant parameters (e.g., motor actions, perception, cognitive processing) and can also be applied in specific rehabilitation training to achieve functionally meaningful goals. A growing body of literature indicates that VR environments can be tailored to individual needs and preferences, thereby maximizing engagement, motivation, and adaptation to ensure sufficient difficulty of tasks. VR environments can be designed to create powerful "gaming" platforms that are actually targeting clinically relevant parameters. For example, the upper-limb robotic systems described previously are frequently combined with VR environments that allow interaction with virtual objects.

In contrast to VR, AR overlays an artificial filter over a subject's view of the actual physical world, thus providing an "augmented" or enhanced view of the world around. AR is being tested in a diverse group of patients with neurologic impairments in the motor, sensory, or cognitive domains. AR may offer a particularly unique rehabilitation intervention for stroke patients. It is widely known that brain injuries limit patients' physical interaction with their environments. Furthermore, physical and cognitive impairments may limit social interactions. Such impoverished experiences are likely to be present during both the acute and the chronic phases. Importantly, there is clear basic scientific evidence that environmental enrichment can be a key component of rehabilitation; such enrichment may offer additive benefits to the often-limited formal rehabilitation sessions per week. Consistent with this are clinical studies suggesting that motor and cognitive outcomes may suffer when interactions with the environment are reduced; AR may be capable of increasing enrichment. For example, in the case of spatial neglect after stroke, the impaired modality may be accounted for using AR methods. Similarly, physical impairments that limit walking speeds can also limit visual feedback; both AR and VR can be used to enhance visual feedback during gait training.

Figure 500-2 shows an innovative application of AR for the treatment of "phantom limb" pain. A subset of both upper-limb and lower-limb amputees experience painful sensations that appear to originate from the missing limb. Past research has suggested that mirror therapy can be an effective treatment for phantom limb pain. During mirror therapy treatments, patients move their healthy arm in front of a mirror to produce a perception of movements of the missing limb. Previous studies have suggested that maladaptive plasticity of affected sensory cortices may be treated with mirror therapy. Importantly, in comparison to mirror therapy, AR-based therapy for phantom limb pain can be based on movements of the affected limb, i.e., using the remaining portion of the limb as opposed to the unaffected contralateral limb. This study demonstrated a novel treatment in which "phantom motor execution" is enabled using sophisticated machine-learning algorithms. More specifically, the study "decoded" phantom limb movements by measuring electromyogram (EMG) activity at the stump. Importantly, while the distal muscles responsible for movements were lost as a result of amputation, the remaining EMG activity could be used to predict presumed distal limb movements. As shown in Fig. 500-2, these inferred movements were projected onto an AR screen to create the perception of limb movements. The study showed that a subset of patients with long-term refractory phantom limb pain could experience a significant reduction in pain levels after using the AR system.

NEUROGAMING

Computerized programs that harness the power of video games have shown some evidence for ameliorating deficits in visual perception, age-related degeneration, and neuropsychiatric disorders. An essential feature of effective video game training is the progressive adjustment of the level of difficulty in line with the cognitive improvement of the patient. Important areas of active research include ways to enhance sustainability of neurogame training over long time periods and improving training *transfer*, i.e., the generalizability of task-specific training in one cognitive domain to more broad-based functional improvements. By leveraging video game technology, neurogames allow for dynamic user interaction and maintain user engagement across multiple sessions over several days of training. Important game mechanics include repetitive practice, performance-adaptive challenges, and several layers of reward feedback—from moment-to-moment point rewards to reward milestones over multiple sessions.

Notably, neurogames have therapeutic potential as they can be targeted to specific neurocognitive deficits. For instance, games have shown significant benefits in aging, by targeting speed of processing and training the abilities to multitask and suppress distractions. In each case, selective targeting is achieved by focusing the adaptive challenges to the neurocognitive domain of interest. Duration of response time windows available to the user or the level of interference are selectively targeted in the case of speed of processing training and interference training, respectively. More recent research demonstrated that it is possible to engender focused circuit neuroplasticity using such

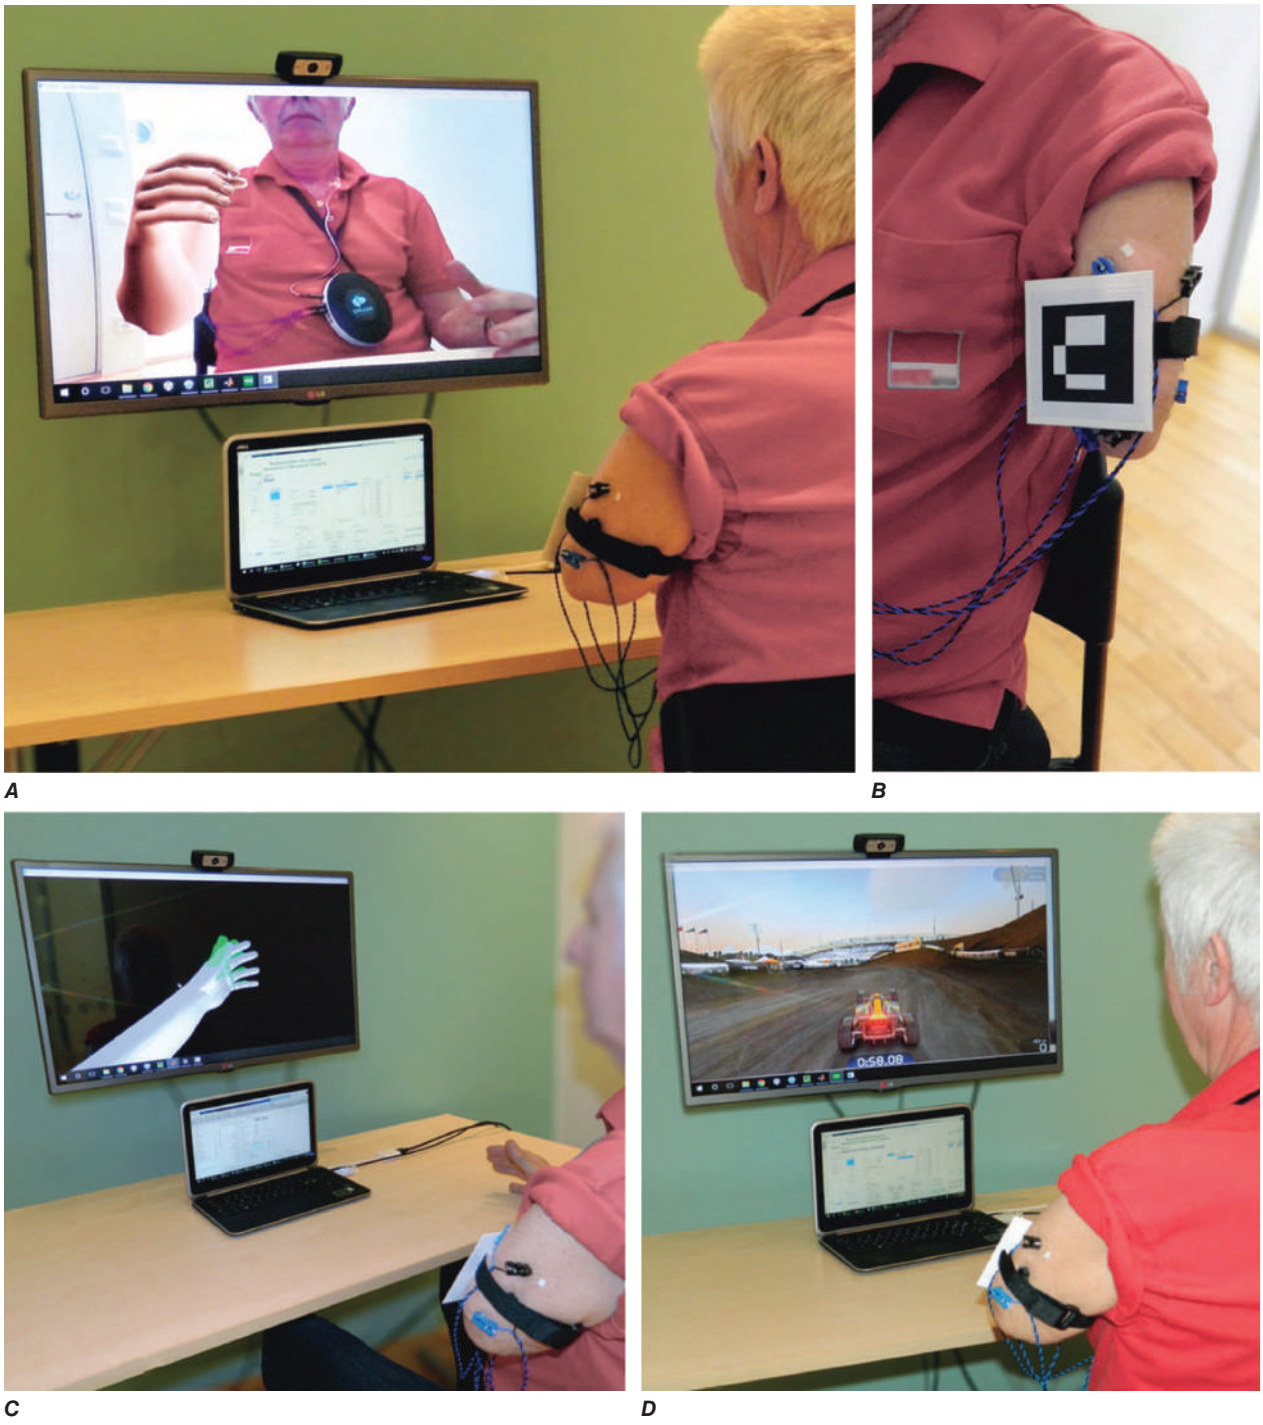

FIGURE 500-2 Augmented reality (AR) for phantom limb pain. ***A.*** A patient is shown a live AR video. ***B.*** Electromyography electrodes placed over the stump record muscle activation during training. ***C.*** The patient matches target postures during rehabilitation. ***D.*** Patient playing a game in which a car is controlled by "phantom movements." *(M Ortiz-Catalan et al: Phantom motor execution facilitated by machine learning and augmented reality as treatment for phantom limb pain: A single group, clinical trial in patients with chronic intractable phantom limb pain. Lancet 388:2885, 2016.)*

selective targeting in neurogaming. For example, older adults learned to adaptively perform within progressively more challenging distractor environments. Neuroplasticity selective to distractor processing was evidenced in this study at both the microscale, i.e., at the resolution of single neuron spiking in sensory cortex, as well as macroscale, i.e., electroencephalography (EEG)-based event-related potential recordings.

Video games have also shown promise in the treatment of visual deficits such as amblyopia, and in cognitive remediation in neuropsychiatric disorders such as schizophrenia. However, while the evidence base has been encouraging in small-sample randomized controlled trials (RCTs), larger RCTs are needed to demonstrate definitive therapeutic benefit. This is especially necessary as the commercial *brain training* industry continues to make unsubstantiated claims of the benefits of neurogaming; such claims have been formally dismissed by the scientific community. Like any other pharmacologic or device-based therapy, neurogames need to be systematically validated in multiphase RCTs establishing neural target engagement and documenting cognitive and behavioral outcomes in specific disorder populations.

Generalizability of training benefits from task-specific cognitive outcomes to more broad-based functional improvements remains the holy grail of neurogaming. Next-generation neurogames will aim to integrate physiologic measures such as heart rate variability (an index of physical exertion), galvanic skin responses, and respiration rate (indices of stress response), and even EEG-based neural measures. The objectives of such multimodal biosensor integration are to enhance the "closed-loop mechanics" that drive game adaptation and

hence improve therapeutic outcomes and perhaps result in greater generalizability. These complex, yet potentially more effective, neurogames of the future will need rigorous clinical study for demonstration of validity and efficacy.

NEUROIMAGING

NEUROIMAGING OF CONNECTIVITY

Multimodal neuroimaging methods including functional magnetic resonance imaging (fMRI), EEG, and magnetoencephalography (MEG) are now being investigated as tools to study functional connectivity between brain regions, i.e., extent of correlated activity between brain regions of interest. Snapshots of functional connectivity can be analyzed while an individual is engaged in specific cognitive tasks or during rest. Resting-state functional connectivity (rsFC) is especially attractive as a robust, task-independent measure of brain function that can be evaluated in diverse neurologic and neuropsychiatric disorders. In fact, methodologic research has shown that rs-fMRI can provide more reliable brain signals of energy consumption than specific task-based fMRI approaches.

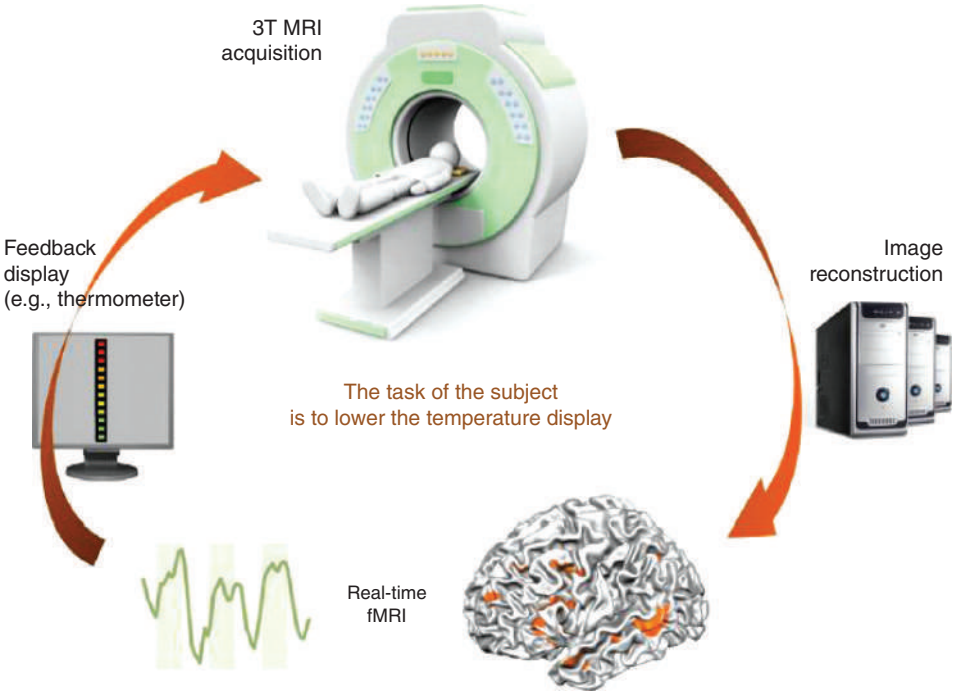

FIGURE 500-3 Neurofeedback using functional magnetic resonance imaging (fMRI). *(From T Fovet et al: Translating neurocognitive models of auditory-visual hallucinations into therapy. Front Psychiatry 7:103, 2016.)*

In recent years, there has been a surge of research to identify robust rsFC-based biomarkers for specific neurologic and neuropsychiatric disorders and thereby inform diagnoses and even predict specific treatment outcomes. For many such disorders, the network-level neurobiologic substrates that correspond to the clinical symptoms are not known. Furthermore, many are not unitary diseases, but rather heterogeneous syndromes composed of varied co-occurring symptoms. Hence, the quest for robust network biomarkers corresponding to complex neuropsychologic disorders is challenging and still in its infancy; yet some studies have made significant headway in this domain. For example, in a large multisite cohort of ~1000 depressed patients, Drysdale et al. (2017) showed that rsFC measures can subdivide patients into four neurophysiologic "biotypes" with distinct patterns of dysfunctional connectivity in limbic and frontostriatal networks. These biotypes were associated with different clinical-symptom profiles (combinations of anhedonia, anxiety, insomnia, anergia, etc.) and had high (>80%) diagnostic sensitivity and specificity. Moreover, these biotypes could also predict responsiveness to transcranial magnetic stimulation (TMS) therapy. Another recent study demonstrated utility of rsFC measures to predict diagnosis of mild traumatic brain injury (mTBI), which is clinically challenging by conventional means.

Apart from fMRI-based measures of rsFC, EEG- and MEG-based rsFC measures are also being actively investigated, as these provide a relatively lower-cost alternative to fMRI. While EEG is of lowest cost, it compromises on spatial resolution. The major strength of MEG is its ability to provide more accurate source-space estimates of functional oscillatory coupling than EEG, as well as provide measures at various physiologically relevant frequencies (up to 50 Hz shown to be clinically useful). In this regard, EEG and MEG are complementary to fMRI, which can only be used to study slow activity fluctuations (i.e., <0.1 Hz); the potential for EEG/MEG modalities to provide valid diagnostic biomarkers is currently underexploited and requires further study.

CLOSED-LOOP NEUROIMAGING

Neuroscientific studies to date are predominantly designed as "open-loop experiments," interpreting the neurobiologic substrates of human behavior via correlation with simultaneously occurring neural activity. In recent years, advances in real-time signal processing have paved the way for "closed-loop neuroimaging," wherein humans can directly manipulate experiment parameters in real-time based on specific brain signals **(Fig. 500-3)**. Closed-loop imaging methods can not only advance our understanding of dynamic brain function but also have therapeutic potential. Humans can learn to modulate their neural dynamics in specific ways when they are able to perceive (i.e., see/hear) their brain signals in real-time using closed-loop neuroimaging-based neurofeedback. Early studies showed that such neurofeedback learning and resulting neuromodulation could be applied as therapy for patients suffering from chronic pain, motor rehabilitation in Parkinson's and stroke patients, modulation of aberrant oscillatory activity in epilepsy, and improvement of cognitive abilities such as sustained attention in healthy individuals and patients with attention-deficit hyperactivity disorder (ADHD). These approaches have also shown potential for deciphering state-of-consciousness in comatose patients, wherein a proportion of vegetative/minimally conscious patients can communicate awareness via neuroimaging-based mental imagery.

Closed-loop neuroimaging therapeutic studies have utilized real-time fMRI, EEG, and MEG methods. It is common for neural signals to be extracted from specific target brain regions for neuromodulation. However, given that distributed neural networks underlie behavioral deficits, new studies have also explored neurofeedback on combinatorial brain signals from multiple brain regions extracted using multivariate pattern analysis (MVPA). While early studies indicate therapeutic potential, clinical RCTs of closed-loop neuroimaging neurofeedback have shown mixed results. This may largely be because of the individual heterogeneity in neuropsychiatric disorders such that there is no one-size-fits-all therapy. Closed-loop neuroimaging-based therapies need to be more personalized to the preintervention cognitive and neurophysiologic states of the individual, and a better understanding developed regarding learning principles and mechanisms of self-regulation underlying neurofeedback. Clinical practitioners applying these methods also need to be well-educated on the hardware/software capabilities of these brain–computer interfaces to maximize patient outcomes.

NONINVASIVE BRAIN STIMULATION

Noninvasive brain stimulation (NIBS) is widely recognized as having great potential to modulate brain networks in a range of neurologic and psychiatric diseases; it is currently approved by the U.S. Food and Drug

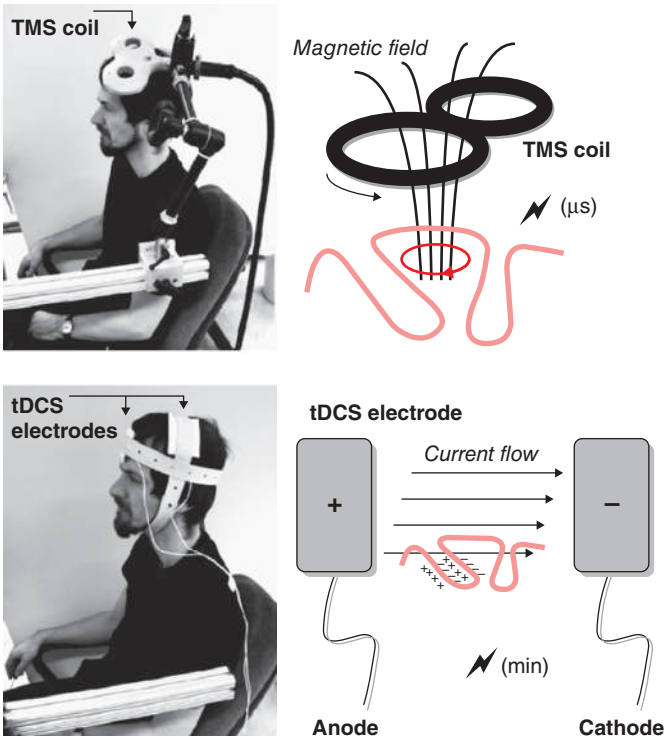

FIGURE 500-4 Illustration of transcranial magnetic stimulation (TMS) and transcranial direct current stimulation (tDCS) setups. The upper panels show a TMS setup. Coils generate magnetic fields that can in turn generate electrical fields in the cortical tissue. The lower panels show a tDCS setup. The electrical current is believed to flow from the anode (+) to the cathode (–) through the superficial cortical areas leading to polarization. *(Reproduced with permission from R Sparing, FM Mottaghy: Noninvasive brain stimulation with transcranial magnetic or direct current stimulation [TMS/tDCS]—From insights into human memory to therapy of its dysfunction. Methods 44:329, 2008.)*

Administration (FDA) as a treatment for depression. Importantly, there is a very large body of basic research indicating that neuromodulation of the nervous system with electrical stimulation can have both short-term and long-term effects. While TMS uses magnetic fields to generate electrical currents, transcranial direct current stimulation (tDCS), in contrast, is based on direct stimulation using electrical currents applied at the scalp **(Fig. 500-4)**. TMS induces small electrical currents in the brain by magnetic fields that pass through the skull; it is known to be painless and therefore widely used for NIBS. Animal research suggests that anodal tDCS causes a generalized reduction in resting membrane potential over large cortical areas, whereas cathodal stimulation causes hyperpolarization. Prolonged stimulation with tDCS can cause an enduring change in cortical excitability under the stimulated regions. Further, changes in resting-state fMRI-based activity and functional connectivity have also been observed after tDCS. Notably, there is uncertainty regarding precisely how much electrical current is able to penetrate through the skull and modulate neural networks. Indeed, recent work has found that typical stimulation paradigms may not generate sufficient electrical fields to modulate neural activity; an alternate possibility is that peripheral nerves may be modulated and thus affect neural activity.

Neuromodulation via stimulation techniques such as tDCS and TMS have shown promise as methods to improve motor function after stroke; there are a growing number of studies demonstrating functional benefits of combining physical therapy with brain stimulation. Two commonly utilized TMS paradigms include low-frequency "inhibitory" stimulation of the healthy cortex or high-frequency "excitatory" stimulation of the injured hemisphere. Each aims to modify the balance of reciprocal inhibition between the two hemispheres after stroke. A meta-analysis of RCTs published over the past decade found a significant beneficial effect on motor outcomes. Unfortunately, a recent large multicenter trial to assess the long-term benefits of TMS on motor recovery after stroke (NICHE trial) did not find a benefit at the population level. Ongoing research aims to better understand how stimulation can directly affect neural patterns and thus allow more customization of stimulation—past trials did not record the neural responses to stimulation.

TMS and tDCS interventions are also being applied in psychiatric disorders. A substantial body of evidence supports the use of TMS as an antidepressant in major depressive disorder (MDD). TMS is also being investigated for its potential efficacy in posttraumatic stress disorder (PTSD), obsessive compulsive disorder (OCD), and treatment of auditory hallucinations in schizophrenia. Various repetitive TMS (rTMS) protocols have shown efficacy in major depression. These include both low-frequency (≤1 Hz) and high-frequency (10–20 Hz) rTMS stimulation over the dorsolateral prefrontal cortex (DLPFC). Mechanistically, low-frequency rTMS is associated with decreased regional cerebral blood flow while high-frequency rTMS elicits increased blood flow, not only over the prefrontal region where the TMS is applied but also in associated basal ganglia and amygdala circuits. Notably, the differential mechanisms of low- versus high-frequency rTMS protocols are associated with mood improvements in different sets of MDD patients, and patients showing benefits with one protocol may even show worsening with the other, again pointing to individual heterogeneity in network function. EEG-guided TMS is also being investigated in psychiatric disorders, for instance, the individual resting alpha-band (8–12 Hz) peak frequency to determine TMS stimulation rates. With respect to transcranial electrical stimulation in psychiatry, tDCS is the most commonly used protocol. In major depression, there is a documented imbalance in left versus right DLPFC activity; hence, differential anodal versus cathodal tDCS in the left versus right prefrontal cortex may be a potentially efficacious approach. Interestingly while meta-analysis shows promise for NIBS methods in psychiatric illness, large RCTs have failed to generate benefits compared to placebo treatment. Future success may require careful personalized targeting based on network dynamics and refinement of protocols to accommodate combinatorial treatments.

IMPLANTABLE NEURAL INTERFACES

Fully implantable neural interfaces that can improve clinical function already exist. Cochlear implants, for example, are sensory prostheses that can restore hearing in deaf patients. Environmental sounds are processed in real-time and then converted into patterned stimulation delivered to the cochlear nerve. Importantly, even while the patterned stimulation remains the same, there are gradual improvements in the perception of speech and other complex sounds over a period of several months after device implantation. Activity-dependent sculpting of neural circuits is hypothesized to underlie the observed perceptual improvements. Similarly, the development of deep-brain stimulation (DBS) was based on decades of work showing that surgical lesions to specific nuclei could alleviate tremor and bradykinesia in animal models. DBS involves chronic implantation of a stimulating electrode that targets specific neural structures (e.g., subthalamic nuclei or the globus pallidus in Parkinson's disease). At least for movement disorders, it is commonly thought that targeted areas are functionally inhibited by the chronic electrical stimulation.

IMPLANTABLE DEVICES FOR NEUROMODULATION

There has been recent progress in the development of implantable neural interfaces to treat neurologic and psychiatric illnesses. For example, for patients with refractory focal epilepsy and clearly identified seizure foci, invasive "responsive stimulation" is FDA approved. Responsive stimulation is grounded on principles of closed-loop stimulation based on real-time monitoring of brain oscillations; specifically, the device aims to detect the earliest signatures of the onset of a seizure, usually at a stage that is not symptomatic, and then deliver focused electrical stimulation to prevent further progression and generalization. A large RCT of this device was performed in patients with intractable focal epilepsy; they were assigned to either sham or active stimulation in response to seizure detection. There was a significant reduction in

seizure frequency in the stimulation group, but it was rare for patients to become seizure-free. There were also modest improvements in quality of life. Notably, there was a small increased risk of hemorrhage associated with the device. In addition to providing clinicians with another treatment option, this device has offered important avenues for research and further optimization. For example, it is now possible to monitor subclinical and clinical seizures and intracranial EEG in patients with chronic epilepsy. This has resulted in new knowledge about the association of seizures with circadian rhythms and sleep. It is also anticipated that a better understanding of the triggers of seizures and the development of better stimulation algorithms, based on real-world data, can ultimately lead to more effective treatments.

There is also great interest in the development of treatments for refractory depression. One area of focus has been on the development of DBS to treat depression. While early smaller studies were promising, a larger study failed to find benefits at the population level. Subsequent analysis has suggested the possibility that more precise tailoring of stimulation parameters to each individual is warranted, both at the level of specific pathways identified through neuroimaging as well as network activity biomarkers. Recent studies have, in fact, supported the notion that individualized patterns of network activity are predictive of a patient's symptoms and how the patient might respond to stimulation. There are now planned studies that aim to tailor stimulation to each individual with severe depression.

VAGUS NERVE STIMULATION TO IMPROVE RECOVERY AFTER STROKE

Vagal nerve stimulation (VNS) has recently been approved by the FDA as a therapy to enhance motor recovery after stroke. Animal studies first provided clear evidence that VNS is safe and can enhance plasticity in both intact animals as well as in models of injury. Importantly, these studies indicated that precise timing of movements is important for efficacy. For example, in animal models of stroke, stimulation of the vagus nerve was timed to the end of successful movement repetitions; these studies further indicated that the precise timing of VNS during rehabilitation is essential. VNS appears to result in rapid activation of cholinergic and noradrenergic systems; the activation of these neuromodulators may enhance attentional effects and improve "signal to noise," thus facilitating the encoding of relevant task features. This basic research culminated in smaller clinical trials and a subsequent pivotal randomized trial of VNS in stroke. In this trial, after 6 weeks of therapy paired with VNS, participants randomized to the VNS group (n = 53) had a significant increase in forelimb function compared to the control group. In addition, 90 days after the study was completed, a higher percentage of patients in the VNS group maintained clinically meaningful responses. Together, this indicates that VNS is a promising new therapy to augment rehabilitation after stroke. However, given the variability of effects for single patients, additional research is required to determine which stroke patients are the most likely to benefit. Future advances that allow VNS to be delivered in the home setting should also lead to greater use of this approach.

BRAIN–COMPUTER INTERFACES FOR PARALYSIS

Brain–computer interfaces (BCIs) represent a more advanced neural interface that aims to restore motor function. Multiple neurologic disorders (e.g., traumatic and nontraumatic spinal cord injury, motor neuron disease, neuromuscular disorders, stroke) can result in severe and devastating paralysis. Patients cannot perform simple activities, and they remain fully dependent for care. In patients with high cervical injuries, advanced amyotrophic lateral sclerosis (ALS), or brainstem strokes, the effects are especially devastating and often leave patients unable to communicate. While there has been extensive research into each disorder, clinically effective approaches for rehabilitation of long-term disability are lacking. BCIs offer a promising means to restore function. In the patient groups described above, while the pathways for transmission of signals to muscles are disrupted, the brain itself is largely functional. Thus, BCIs can restore function by communicating directly with the brain. For example, in a "motor" BCI, a subject's intention to move is translated in real time to control a device. As illustrated in **Fig. 500-5**, the components of a motor BCI include the following: (1) recordings of neural activity, (2) algorithms to transform the neural activity into control signals, (3) an external device driven by these control signals, and (4) feedback regarding the current state of the device.

Many sources of neural signals can be used in a BCI. While EEG signals can be obtained noninvasively, other neural signals require invasive placement of electrodes. Three invasive sources of neural signals include electrocorticography (ECoG), action potentials or spikes, and local field potentials (LFPs). Spikes and LFPs are recorded with electrodes that penetrate the cortex. "Spikes" represent high-bandwidth signals (300–25,000 Hz) that are recorded from either single neurons or multiple neurons ("multiunit"). LFPs are the low-frequency (~0.1–300 Hz) components. In contrast, ECoG is recorded from electrodes that are placed on the cortical surface. ECoG signals may be viewed as an intermediate-resolution signal in comparison with spikes/LFPs and EEG. While it is worth noting that there is still considerable ongoing research into the specific neural underpinning of each signal source, there has been great progress in the ability to decode a user's intention.

A central goal of the field of BCIs is to improve function in patients with severe disability. This can consist of a range of communication and assistive devices such as a computer cursor, keyboard control, wheelchair, or robotic limb. In the ideal scenario, the least invasive method of recording neural signals would allow the most complex level of control. Decades of research in nonhuman primates and early-phase clinical trials have demonstrated the feasibility of direct neural control of assistive technology based on recording of neural signals at multiple resolutions. There have been numerous examples of human subjects with a range of neurologic illnesses (e.g., brainstem stroke, ALS, spinal cord injury) who have demonstrated the actual use of implantable neural interfaces. This includes demonstrations of both the control of communication interfaces as well as robotic limbs. Early pilot clinical trials of BCIs based on invasive recordings of neural signals showed that relatively high rates of brain-controlled typing are possible (e.g., >30 characters per minute). A past case study additionally demonstrated that a fully implantable BCI system could allow communication in a locked-in ALS patient **(Fig. 500-6)**. At the time of the study, the patient required mechanical ventilation and could only communicate using eye movements. She was implanted with multiple subdural cortical electrodes; the neural signals were then processed and sent wirelessly to an external augmentative alternative communication (AAC) device.

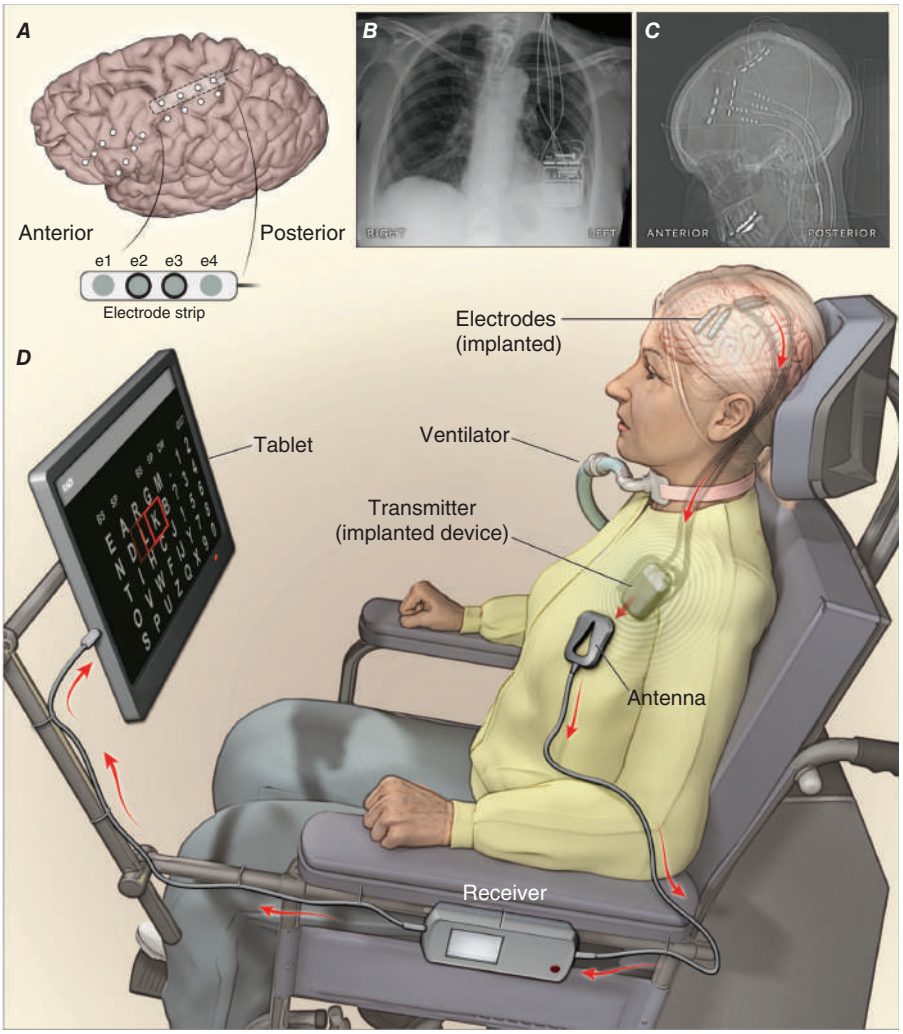

FIGURE 500-6 Illustration of an amyotrophic lateral sclerosis (ALS) patient with a fully implanted communication interface. ***A.*** Illustration of the location of electrodes on the brain. ***B.*** X-ray of chest showing the wireless module. ***C.*** X-ray of leads and wire routing. ***D.*** Schematic of the subject performing a typing task. *(From MJ Vansteensel et al: Fully implanted brain–computer interface in a locked-in patient with ALS. N Engl J Med 375:2060, 2016. Copyright © 2016 Massachusetts Medical Society. Reprinted with permission from Massachusetts Medical Society.)*

Importantly, she could use the interface with no supervision from research staff, albeit with a relatively low communication rate.

Over the past 5 years, there has been tremendous progress toward the goal of restoring much higher rates of communication in participants with severe impairments. These studies have used either ECoG or spike-based decoding. One of the first studies indicated that a participant with a brainstem stroke and anarthria could communicate using a set of 50 words. Two subsequent studies showed that decoding a significantly larger set of words is possible, using either spiking or ECoG. For example, one study, using spike-based recordings, indicated that decoding of a large vocabulary was possible using phoneme-based decoding; that is, an arbitrary and a remarkably large set of words could be decoded by decomposing into its set of phonemes. Together, these studies indicate the real possibility of a clinically viable speech neuroprosthetic to restore fast communication in those with anarthria or severe dysarthria.

Overall, there has been tremendous progress recently in the translation of BCIs. There are now also multiple commercial efforts to take these findings from pilot studies and to scale them to a commercially viable device. In fact, there is already a single participant with tetraplegia implanted with a first-in-class commercial device that can record spiking activity. While there are still challenges with long-term stability, this participant appears to be using this implanted device to control a computer (e.g., to control a cursor and to play video games) in the home setting. Additional work will be required to fully quantify how stable neural interfaces are and the level of performance that can be reliably achieved. As these characteristics become increasingly clear, it should allow targeted clinical translational efforts that are geared toward specific patient needs and preferences (e.g., extent of disability, medical condition, noninvasive vs invasive). For example, patients with high cervical injuries (i.e., above C4, where the arm and the hand are affected) have rehabilitation needs different from patients with lower cervical injuries (i.e., below C5–C6, where the primary deficits are the hand and fingers). Moreover, interfaces to restore communication may be different from those aimed toward movement control. We fully anticipate that over the next decade there will be larger scale clinical studies to demonstrate how BCIs allow participants with severe impairments to experience the ability to communicate and to control assistive technology.

501 Machine Learning and Augmented Intelligence in Clinical Medicine

Arjun K. Manrai, Isaac S. Kohane

Machine learning has reshaped our consumer lives, with self-driving vehicles, conversant chatbots, and machine translation services so ubiquitous that they are at risk of not being considered particularly intelligent for much longer. Will the algorithms underlying these technologies similarly transform the art and practice of medicine? There is hope that modern machine learning techniques—especially the resurgence of artificial neural networks in deep learning—will foster a sea change in clinical practice that augments both the sensory and diagnostic powers of physicians while, perhaps paradoxically, freeing physicians to spend more time with their patients by performing time-consuming laborious tasks for them.

From the birth of artificial intelligence at the Dartmouth Summer Research Project on Artificial Intelligence in 1956 to powerful large language models (LLMs) ubiquitous today, machine learning methods and theory have developed in symbiosis with growing datasets and computational power. In this chapter, we discuss the foundations of modern machine learning algorithms and their emerging applications in clinical practice. Modern machine learning techniques are sufficiently capacious as to learn flexible and rich representations of clinical data and are remarkably adept at exploiting spatial and temporal structure in raw data. Recent machine learning models perform on par with expert physicians or prior state-of-the art models on tasks ranging from those involving the interpretation of images (e.g., grading retinal fundus photographs for diabetic retinopathy), to analysis of unstructured text (e.g., predicting hospital readmission from electronic health record notes or providing a differential diagnosis for a challenging clinical case), and processing of speech (e.g., detecting depression from patient speech). Over the past few years, LLMs, including the generative pretrained transformer (GPT) class of models underlying ChatGPT, have demonstrated the ability not only to excel at medical professional competency examinations but even to engage in general diagnostic reasoning abilities that many would have likely considered science fiction even a few years ago. However, many evaluations of machine learning models occur on tasks that are narrow and unrealistic and further lack the clinical context that a physician would incorporate in actual practice. The models themselves are also often divorced from considerations of actionable recommendations useful in patient care.

To help ensure these models benefit patients, this chapter aims to bring more physicians into the design and evaluation of machine learning models by providing an understanding of how modern machine learning models are developed and how they relate to more familiar methods from the epidemiologic literature.

The terms *machine learning* and *artificial intelligence* evoke distinct images today from those conjured up by the same terms in the 1950s and the 1980s, and they likely will mean something different in a decade. Computer scientist John McCarthy originally defined artificial intelligence in 1956 as "the broad science and engineering of creating intelligent machines," most often embodied today as computer software. Machine learning can be viewed as the subfield of artificial intelligence encompassing algorithms that extract generalizable patterns from data. This approach stands in contrast to approaches to create intelligence from human-engineered and explicitly programmed rules that characterized many early applications of artificial intelligence to medicine during the 1970s and 1980s (e.g., expert systems such as INTERNIST-I and MYCIN).

This chapter covers machine learning methods and applications that may augment physician expertise at the point of care. Many applications of machine learning in health care are therefore not reviewed here, such as algorithms to improve hospital planning, detect insurance fraud, and monitor new drugs for adverse events. Throughout this chapter, we discuss how new machine learning methods can learn rich representations of both clinical state and patient identity by discovering how to represent raw data. At the same time, models largely reflect the data on which they are trained and, thus, may encode and amplify biased prior practices; they may also be brittle in unfamiliar and evolving settings. If machine learning methods are positioned to tackle problems based on physician and patient needs and continuously reassessed, we envisage a future with clinics instrumented with machine learning tools that augment the ability of physicians to reason precisely and probabilistically at the point of care.

CONCEPTS OF MACHINE LEARNING

TYPES OF MACHINE LEARNING

Many physicians will be familiar with the major types of machine learning methods from methodologic counterparts discussed in the context of "traditional" statistical and epidemiologic modeling. In the current machine learning and epidemiology literature, much confusion arises over whether a method "belongs" in one camp or the other. More is gained by focusing on the computational and statistical connections, particularly in understanding how new machine learning methods compare to familiar clinical risk stratification approaches.

Broadly, there are four major types of machine learning with applications to clinical medicine: (1) supervised learning, (2) unsupervised learning, (3) semi-supervised learning, and (4) reinforcement learning. The four subfields of machine learning differ from one another in both their objectives and the degree to which algorithms have access to labeled examples from which to learn **(Fig. 501-1)**. All four subfields have roots tracing back decades with classical examples and modern counterparts **(Table 501-1)**.

Until recently, supervised machine learning approaches have dominated the medical literature. In supervised learning, paired input and labeled output examples are provided together to a machine learning algorithm that learns what combination of (potentially millions) of parameters optimizes a function that predicts output from input. The goal is to learn robust functions that work well with unseen data. If this setting is familiar, it is because clinical researchers often use well-known traditional statistical approaches like linear and logistic regression to achieve the same goal. For example, clinical risk scores, such as the American College of Cardiology (ACC)/American Heart Association (AHA) Atherosclerotic Cardiovascular Disease (ASCVD) Pooled Cohort Risk Equations or the Framingham Risk Score, are based on fitting models with paired input data (e.g., age, sex, total cholesterol, smoking status) and labeled output data (e.g., first occurrence of nonfatal myocardial infarction, coronary heart disease death, or fatal or nonfatal stroke). Contemporary deep learning methods can learn flexible representations of raw input data as opposed to relying on expert-identified features (Table 501-1). A contemporary clinical example of supervised machine learning with convolutional neural networks is the histopathologic detection of lymph node metastases in breast cancer patients (Table 501-1).

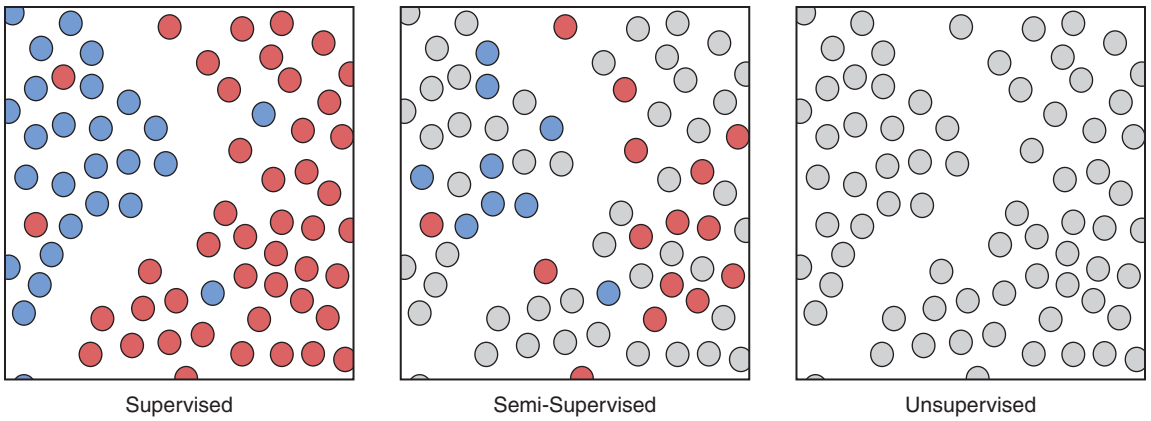

FIGURE 501-1. The subfields of machine learning differ in their access to labeled examples. In supervised learning (*left*), the learning algorithm uses labeled output examples (*red, blue*) to learn a classifier for determining whether a new unlabeled data point is red or blue. Unsupervised learning methods (*right*) do not use labels but, rather, identify structure present in the data. Semi-supervised learning methods (*center*) have access to both unlabeled and labeled examples; the unlabeled data help learn a classifier with fewer labeled examples. *(Reproduced with permission from Luke Melas-Kyriazi.)*

The three remaining types of machine learning have not been as widely applied to clinical problems, but this has started to shift in recent years. These methods include unsupervised learning, semi-supervised learning, and reinforcement learning. Unsupervised learning, in contrast to supervised learning, encompasses methods that use unlabeled input data, where the goal is to discover the "structure" present in the data. A researcher may use unsupervised methods to determine whether or not their data lie on a low-dimensional "manifold" that is "embedded" in a higher-dimensional space (where dimensions here refer to the number or size of the collected elements or features of a sample or system). For example, a researcher may obtain gene expression measurements from >20,000 protein-coding genes for a large group of asthma patients and then "project" (and thereby reduce the dimensionality of) each patient into a lower-dimensional space to visualize and understand structure present in the dataset or may group asthma patients by similarity across all gene expression values. Classical linear methods include principal components analysis (PCA) and contemporary nonlinear approaches include uniform manifold approximation and projection (UMAP) (Table 501-1). Another example of unsupervised learning (or more precisely, self-supervised learning) is the pretraining process for LLMs such as ChatGPT, where massive text corpora are used to teach the model to predict the next word (Table 501-1), a task that is simple to describe but, when coupled with downstream processes to fine-tune model outputs, leads to powerful emergent behavior of these models. Semi-supervised learning is a hybrid between supervised and unsupervised learning, with methods that use both labeled data and unlabeled data. These algorithms exploit the (often low-dimensional) structure of unlabeled data to learn better models than may be possible in a purely supervised setting where labeled data may be scarce. Finally, reinforcement learning is a distinct subfield of machine learning that focuses on optimizing the iterative decision-making of an "agent" that is equipped with a cumulative "reward" function and, thus, must navigate a trade-off between exploration and exploitation of its environment. This is distinct from the other three subfields of machine learning where the entire learning signal (i.e., dataset) is presented at once. This approach to learning has been successful in teaching computers to play games at world-expert levels (e.g., Google's AlphaGo Zero).

MODERN MEDICAL MACHINE LEARNING

The modern machine learning toolkit includes methods that differ substantially in their complexity and ability to learn directly from raw data (Table 501-2). "Traditional" statistical methods such a linear and logistic regression remain vital and often serve at minimum as useful and interpretable baselines, but often provide much more. Generalizations of these approaches as well as many other methods have been developed to learn complicated functions including highly nonlinear relationships. For example, models such as gradient boosted trees (Table 501-2) often achieve excellent performance with tabular data that lack the spatial or temporal structure that newer deep learning methods can exploit.

Modern deep learning models can learn rich and flexible representations of raw clinical data. The building blocks of these models are simple artificial "neurons," often arranged into layers (Fig. 501-2). Each neuron accepts input from neurons in a preceding layer, computes a weighted sum of these inputs, and applies a nonlinear function to the weighted sum (Fig. 501-2).

TABLE 501-1 Types of Machine Learning and Clinical Examples

SUBFIELD OF MACHINE LEARNING	DEFINITION	CLASSIC EXAMPLE	CONTEMPORARY EXAMPLE	CLINICAL EXAMPLE
Supervised learning	Methods that use paired input and *labeled* output examples to learn a generalizable function that predicts output labels from input	Logistic regression	Convolutional neural network (CNN)	Histopathologic detection of lymph node metastases in breast cancer patients
Unsupervised learning	Methods that use *unlabeled* input data to discover data structure and learn efficient representations for data (e.g., clustering, dimensionality reduction)	Principle components analysis (PCA)	Pre-training of large language models (LLMs)	Visualizing structure in gene expression levels and grouping asthma patients into distinct molecular clusters; learning medical knowledge from large-scale text corpora
Semi-supervised learning	Methods that use *both* unlabeled and labeled examples to learn better functions than possible in supervised setting alone	Self-training	Consistency regularization	Use of unlabeled cardiac magnetic resonance images alongside small dataset of labeled examples to detect hypertrophic cardiomyopathy
Reinforcement learning	Methods to teach an "agent" that iteratively interacts with its environment *how* to optimize a numerical reward	Optimal control	Deep reinforcement learning (e.g., AlphaGo Zero)	Selecting fluids and vasopressor dosing iteratively to manage sepsis for patients in the intensive care unit

TABLE 501-2 Select Tools in the Modern Medical Machine Learning Toolkit

METHOD	DEFINITION	NOTES
Linear and logistic regression	Models a linear relationship between predictors and either a continuous or binary outcome variable; "traditional" statistical modeling	Necessary baseline. In small carefully curated clinical datasets, these methods often perform on par with more sophisticated methods
Gradient-boosted trees	Ensemble of "decision trees" with parameters optimized to efficiently learn accurate nonlinear functions in supervised setting	Efficient to train and often performs well on machine learning tasks with tabular data
Convolutional neural network (CNN)	Specialized deep learning architecture with groups of neurons ("convolutional filters") that exploit structure	Widely-used deep learning model for medical imaging tasks (e.g., U-Net architecture for biomedical image segmentation)
Transformer models	Deep learning architecture designed for mapping input sequences to output sequences (e.g., text, speech)	Generative Pre-trained Transformer (GPT-4) and ChatGPT; state of of the art for tasks in natural language processing and machine translation
Latent diffusion models	A generative deep learning model that can create realistic synthetic data across multiple modalities	Can generate realistic, even award-winning art; popular tools include DALL-E2 and Stable Diffusion
Transfer learning	Family of approaches to adapt models trained for one task and apply to another task (across domains)	Useful for "jump-starting" a model for a new problem, e.g., many medical computer-vision models start with a network trained for a separate (often nonmedical) task such as ImageNet and may "fine-tune" for a particular medical application

The values of the adjustable weights between neurons are learned during the training process. Neurons may be arranged into hierarchical layers that build an increasingly rich representation of input data. For example, convolutional neural networks are specialized architectures that combine groups of neurons with the mathematical operation of convolution ("convolutional filters")—to exploit spatial structure (Table 501-2). Initial layers learn low-level features (e.g., edges) and then build to higher layers that learn motifs and objects, creating a powerful representation for discriminating between inputs using output labels **(Fig. 501-3)**.

Modern neural networks may have many millions and even hundreds of billions of weight parameters. For example, the VGG-16 network by Simonyan and Zisserman, a path-breaking architecture and one of the top models in the ImageNet Large Scale Visual Recognition Challenge in 2014, had about 140 million parameters. These models would be considered small by contemporary standards; the GPT-3 model created by the company OpenAI has 175 billion parameters. The U-Net architecture by Ronneberger and colleagues, a convolutional neural network, is used frequently for biomedical image segmentation and other medical imaging tasks. Other deep learning models have architectures tailored for distinct tasks and data types including sequence to sequence and "transformer" models (the "T" in GPT-3/GPT-4), designed for sequential data, including unstructured text notes from electronic health records or patient queries (Table 501-2). In many deep learning applications, it is important to note that practitioners often do not train networks as a tabula rasa but instead benefit substantively from transfer learning (Table 501-2), where the weights may be initialized or "pretrained" from another task.

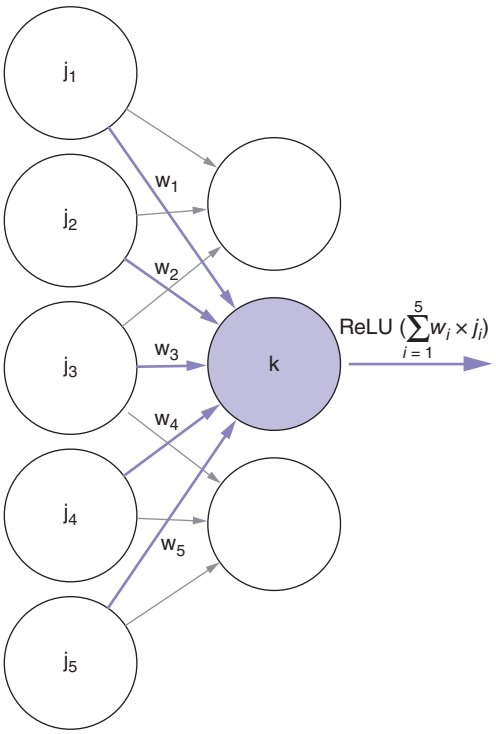

FIGURE 501-2 The artificial neuron, the building block of deep learning models. Neuron k accepts weighted input from neurons in the preceding layer and applies a function [e.g., ReLU(x) = max(0,x), the rectified linear function] to the weighted sum of inputs (often with a bias term, not shown). During training, the weights are iteratively refined to improve data fitting.

PRACTICAL CONCEPTS IN TRAINING A MODERN MACHINE LEARNING MODEL

In this section, we provide a brief overview of practical concepts that emerge when training a modern machine learning model to help readers understand the constraints and choices that confront machine learning practitioners.

Often the first task is to define what a "good" prediction is by specifying a "loss function," which quantifies the error between a model's prediction and the true label **(Table 501-3)**. There are many choices for this function. Linear regression uses quadratic loss; other examples include the cross-entropy and 0-1 loss. Given a loss function, the stochastic gradient descent method coupled with the backpropagation algorithm quantifies how to alter the adjustable weights in the network to optimize the loss function iteratively as labeled examples are provided to the network, either one by one or in batches. The weights themselves are often initialized carefully and frequently transferred over from another task. Most machine learning practitioners use specialized hardware called graphics processing units (GPUs) to perform these calculations. As with most computer hardware, GPUs range dramatically in performance and cost. Software frameworks like PyTorch and TensorFlow automate much of the otherwise cumbersome training process, abstracting away in a dozen lines what might have previously taken a team of machine learning engineers months to build. The machine learning community places great emphasis on generalization through near universal practices like widely available benchmark datasets and splitting training and testing data, with performance measures such as the area under the receiver operating curve (AUC) computed in held-out test data to improve estimates (Table 501-3).

APPLICATIONS OF MODERN MACHINE LEARNING TO CLINICAL MEDICINE

Two major classes of applications have dominated recent machine learning applications in medicine: computer vision and natural language processing. We review some of the recent applications below, highlighting the breadth of problems across clinical specialties being tackled and some emerging new directions.

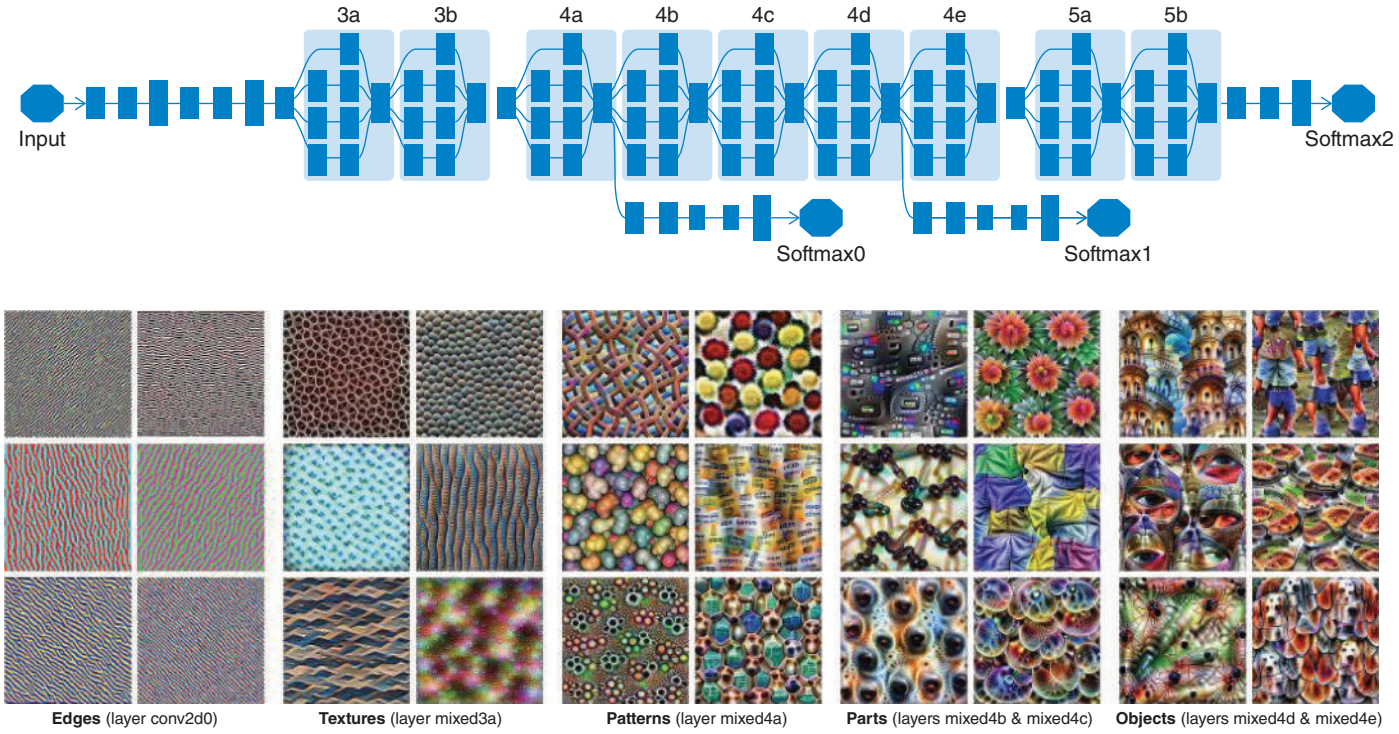

FIGURE 501-3 Deep learning models learn rich hierarchical representations. Visualization of what a convolutional neural network "sees" as it is processing images of common objects from the ImageNet dataset. The initial layers learn low-level features like edges, and the higher layers learn patterns and objects. *(Reproduced from distill.pub by C Olah et al: Feature visualization. Distill, 2017. https://distill.pub/2017/feature-visualization/.)*

COMPUTER VISION

Medical computer vision applications have been dominant in the medical machine learning literature over the past decade. Convolutional neural networks and newer vision transformer (ViT) models are well-suited to exploit the spatial structure in medical imaging data and are able to learn detailed representations of input images, yielding systems that often perform on par with or better than expert physicians at select tasks. A well-known application of convolutional neural networks for medical imaging was published by Gulshan and colleagues in the journal *JAMA* in 2016. The authors trained a convolutional neural network using 128,175 ophthalmologist-labeled retinal fundus photographs to develop an automated diabetic retinopathy detection system, achieving performance on par with expert ophthalmologists, with an AUC of 0.99 in two separate validation datasets. In a separate study by De Fauw and colleagues, 14,884 three-dimensional retinal optical coherence tomography scans were used to train a deep learning model that could make referral suggestions and performed with an accuracy at or superior to eight clinical experts who graded the same scans, with an AUC in test data >0.99 for urgent referral versus other referrals. Some machine learning applications in ophthalmology have already received approval from the U.S. Food and Drug Administration including the IDx-DR "device" to classify more than mild diabetic retinopathy.

Outside of ophthalmology, computer vision applications have been numerous across the many other specialties that rely on imaging data. For example, dermatologist-level classification of skin cancer was achieved in a study by Esteva and colleagues published in *Nature* in 2017. The authors trained a convolutional neural network to distinguish between keratinocyte carcinomas and benign seborrheic keratoses as well as between malignant melanomas and benign nevi. The authors concluded that the model performed at the level of the 21 board-certified dermatologists against which it was tested.

The uses of machine learning models in radiology are numerous as well, with applications including the detection of pneumonia from chest x-rays, identification of pancreatic cancer from computed tomography scans, and fast, automated segmentation of cardiac structures from cardiac magnetic resonance imaging as well as echocardiography.

Specialized deep learning architectures such as the U-Net architecture by Ronneberger and colleagues have become especially popular in the medical computer vision community. Architectures are often designed for specific imaging tasks (e.g., image segmentation) or specialized data types (e.g., three-dimensional images or videos). New frontiers of computer vision research in medicine include semi-supervised learning approaches to take advantage of extensive unlabeled data available at hospitals, particularly given the practical difficulty and cost for an individual researcher to obtain large expert-labeled datasets, and multimodal learning, where machine learning algorithms learn to reason simultaneously over different types of data (e.g., images and text).

TABLE 501-3 Practical Concepts for Training a Deep Learning Model

CONCEPT	DEFINITION	EXAMPLES
Loss function	Mathematical function that quantifies discrepancy between predicted label and true label	Cross-entropy, quadratic, 0–1
Back-propagation	Algorithm to compute the direction of the loss function with respect to changes in the adjustable weights ("gradient")	—
Graphics processing unit (GPU)	Specialized computer hardware to speed up the many matrix calculations involved in training a neural network	NVIDIA Tesla H100
Train-test split	How data are divided to ensure fair estimates of model performance after training	70% training, 30% test
Area under the receiver operating characteristic curve (AUC)	Common performance metric for evaluating binary classification models; 0.5 = random, 1.0 = perfect	—
Deep learning framework	Computational framework for efficiently performing matrix (tensor) calculations for training deep learning models	TensorFlow, PyTorch, Keras

NATURAL LANGUAGE PROCESSING

Like computer vision, natural language processing has been transformed by modern machine learning approaches, particularly the subfield of deep learning. Traditional deep learning approaches for natural

language processing relied on a specialized architecture called recurrent neural networks. Contemporary deep learning methods often leverage the transformer model (Table 501-2), which is well-suited to exploit the structure of natural language and other text. Text-processing machine learning models have been successfully applied to analyze physician notes in the electronic health record, detect depression symptom severity from spoken language, and scribe patient-physician visits. For example, a study by Rajkomar and colleagues analyzed electronic health record data from 216,221 adult patients to predict in-hospital mortality, 30-day unplanned readmission, and discharge diagnoses, among other outcomes, performing at high accuracy, with an AUC of 0.93–0.94 for predicting in-hospital mortality. Importantly, much of the progress in medical natural language processing has stemmed from the widespread availability of datasets, including, for example, the Medical Information Mart for Intensive Care (MIMIC) dataset.

Many specialized deep learning architectures have been developed for natural language processing applications, including the analysis of electronic health record data, using both supervised (e.g., recurrent neural network) and unsupervised (e.g., variational autoencoder) approaches. Domain-specific language representation models have been developed for the purpose of biomedical text mining, serving as a substrate for many downstream natural language processing tasks.

Since ChatGPT was introduced in 2022, large language models including GPT-4 have rapidly been applied to diagnostic reasoning, health care documentation, and many other text-based tasks across medical specialties. The wide-ranging linguistic abilities and performance of these models across myriad tasks have surprised many physicians and machine learning practitioners alike. In a study by Kanjee and colleagues published in *JAMA* in 2023, the authors evaluated the general diagnostic reasoning abilities of GPT-4 on challenging medical cases published as part of the *New England Journal of Medicine* Clinicopathological Conferences (CPCs), also known as the Case Records of the Massachusetts General Hospital. On these challenging cases, GPT-4, which was not trained specifically for medical diagnostic reasoning tasks, included the correct diagnosis as part of its differential diagnosis in 64% of the 70 cases assessed, a surprisingly high accuracy.

OTHER APPLICATIONS

While medical computer vision and natural language processing tasks have been the focus of newer deep learning models due to the extensive structure of imaging and text data, many other application classes exist. For example, cardiologist-level performance has been achieved in deep learning approaches for detecting arrhythmias from ambulatory electrocardiograms, standing in contrast to the rule-based algorithms used traditionally to interpret electrocardiographic signals. In genomics, investigators have analyzed tumor genomes with machine learning methods to predict better survival using both deep learning and other machine learning approaches. Machine learning methods have also been used to characterize the deleteriousness of single nucleotide variants in DNA. Many other applications of machine learning to new patient data streams are emerging, for example, machine learning applied to wearables (e.g., smartwatches).

CONCLUSION

Modern machine learning offers a powerful set of techniques to learn feature representations directly from data, already performing on par with expert physicians on select tasks. If carefully trained and judiciously applied to key areas of clinician workflow, the representational power of new machine learning methods makes them likely to touch every area of clinical practice.

502 Metabolomics

Jared R. Mayers, Mathew G. Vander Heiden

Metabolism, loosely defined, represents the sum of all biochemical reactions involving small molecules with a molecular mass of ≤1000 Da within a given tissue, cell, or fluid. These small molecules are collectively referred to as *metabolites* and are involved in the biochemical processes used to create macromolecules and fulfill the energy needs of a cell or organism. *Metabolomics*, then, represents the measurement of metabolites, either qualitatively or quantitatively, often as a way to gain insight into the metabolism of a cell, tissue, or organism. No one experimental approach can characterize metabolism in its entirety; metabolomics instead strives to measure a portion of the *metabolome*, which consists of all metabolites in a given biological sample at a given time.

A link to a time-specific context is common to all "-omics" techniques, but is particularly important in metabolomics. As metabolic processes are highly connected and interdependent, with individual metabolites often being involved in multiple pathways, levels of a specific metabolite can vary in response to an alteration in either the production or the consumption of that metabolite. Because significant changes in metabolite levels can occur over a very short time frame, the levels measured can be sensitive to perturbations either upstream or downstream of the measured metabolite in a pathway. This sensitivity can make measurement challenging, but it also makes metabolomics a powerful tool with which to assess either acute or chronic changes in cells or tissues. Indeed, the metabolome can be quite dynamic and reflective of the current condition of the material being assessed, as it ultimately represents an integration of outputs from the genome, epigenome, transcriptome, and proteome **(Fig. 502-1)**.

APPROACHES AND SAMPLING CONSIDERATIONS

UNTARGETED AND TARGETED METABOLOMICS

There are two distinct approaches to measuring metabolites in biological materials: untargeted and targeted metabolomics. These strategies differ in whether a predetermined subset of metabolites is intentionally sought in a sample, with the choice of approach dictated by the question under investigation. Regardless of the method utilized, it is important to recognize that no single metabolomics technique is comprehensive. Technical considerations heavily influence metabolite measurement, even with untargeted metabolomics, and no one method is able to capture the entire metabolome. In this respect, metabolomics contrasts with some other -omics techniques, like genomics or transcriptomics—i.e., in metabolomics, if something is not measured, its absence cannot necessarily be assumed.

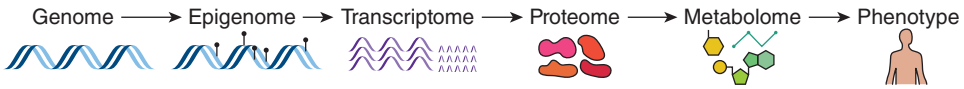

FIGURE 502-1 The metabolome is downstream of the outputs measured by other "-omics" technologies. Thus, the state of the metabolome can more closely reflect clinical and experimental phenotypes.

Untargeted Metabolomics Untargeted metabolomics is the comprehensive analysis of as many measurable analytes in a sample as possible, irrespective of their identity **(Fig. 502-2)**. Among the benefits of this approach is that it is agnostic in its measurement of the metabolome. Thus, it allows for the discovery of novel or unexpected molecules for further study. Coverage of the metabolome in an untargeted approach is influenced by the techniques used for sample preparation, metabolite separation prior to detection, and the inherent sensitivity and specificity of the analytical technique(s) employed (see "Metabolomics Technologies," below).

A major drawback of untargeted metabolomics is that molecules of interest can be measured with less confidence or missed entirely because this approach carries an inherent bias toward the detection of high-abundance molecules. Handling and interpretation of data also represent a major challenge, as each sample run generates large amounts of data whose analysis can be both complicated and time consuming. Identifying each metabolite measured requires database searching, and further experimental investigation is often needed to confirm the exact identity of a signal of interest. Finally, in most cases, this technique yields only relative metabolite quantification, thereby rendering it most useful for comparisons between biological samples.

Targeted Metabolomics Targeted metabolomics involves the measurement of a predefined group of chemically characterized metabolites—typically dictated by a hypothesis or predetermined platform—with the aim of covering a select portion of the metabolome. The metabolites measured represent only a subset of those that would be measured by an untargeted approach; thus, a targeted approach generates a much smaller data set in which individual metabolites are detected with higher confidence (Fig. 502-2). Because the identity of each signal is known in advance, standards can be added to provide absolute quantification of each metabolite measured in the sample, although the use of targeted metabolomics to compare relative metabolite levels across samples is common. In addition, sample preparation and chromatographic separation before measurement can be optimized to improve detection of specific metabolites, enabling assessment of less abundant molecules.

The key downside of targeted metabolomics is that information is gained about only those metabolites targeted by the analytical method.

SAMPLING CONSIDERATIONS

Regardless of the approach used, it is important to consider potential sources of error that can influence the conclusions drawn from a metabolomic analysis. Because of the dynamic nature of the metabolome, numerous biological confounders inherent to the samples themselves can affect levels of the metabolites measured. For this reason, the inclusion of controls or reference populations to account for these confounders can be critical for data interpretation. Established biological confounders for patient-derived material include age, sex, body mass index, time of day collected, fasting status and/or dietary differences, and comorbid conditions such as diabetes or smoking. For example, metabolites commonly altered with respect to aging are those in antioxidant and redox pathways as well as breakdown products of macromolecules. Sex differences influence a number of different metabolites, most prominently those involved in steroid and lipid metabolism. Perhaps it is not surprising that diet can also affect the metabolome, and fasting has been shown to impact almost every category of metabolite frequently measured in biological fluids.

Differences in sample handling and processing also influence metabolite measurements. Work using metabolomics to analyze material from large prospective cohort studies has shown that changes in metabolite levels introduced by sample handling can lead to falsely positive associations between specific metabolite changes and disease risk. Specific considerations include the large geographic area of distribution from which patients are drawn—e.g., a sample, such as blood, is collected locally and then exposed to variable conditions before being sent to a central lab for further processing. Moreover, because of the costs associated with obtaining and storing samples, often only one sample is available for each individual.

Time is a key variable in metabolite measurements, and efforts to assess the impact of sample handling and processing have led to improved analysis pipelines. For example, comparison of metabolites measured in samples undergoing immediate versus delayed processing can provide insight into those metabolites most affected by pre-processing storage under varying conditions. More specifically, because metabolism occurs on a very rapid time scale, some metabolite levels will continue to change after sample collection even if the sample is stored on ice. Therefore, metabolism is ideally halted or "quenched"

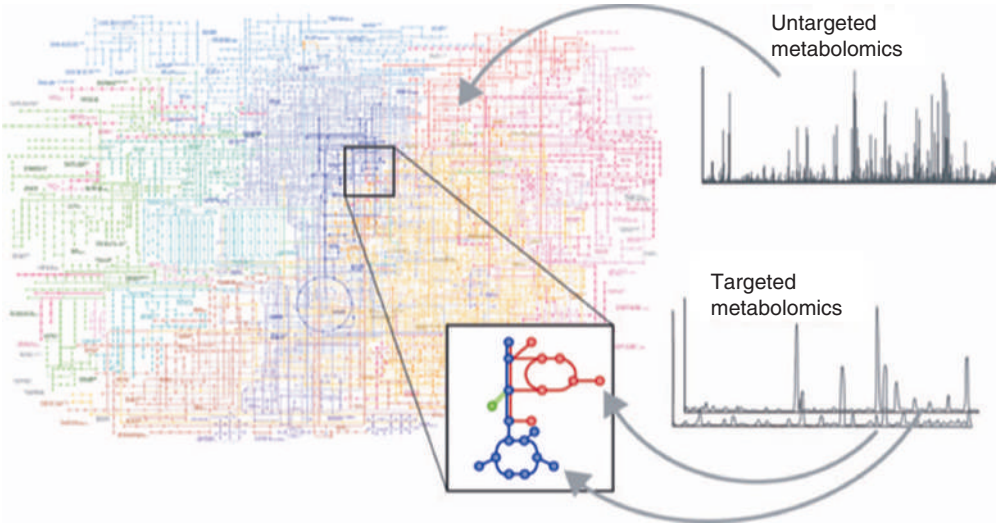

FIGURE 502-2 ***Untargeted*** **metabolomics strives to measure as much of the metabolome as possible within a given biological sample, whereas** ***targeted*** **metabolomics focuses on measuring a predetermined subset of the metabolome.** In untargeted metabolomics, a large number of signals corresponding to metabolites is generated, and further investigation is often necessary to assign a particular signal to a specific metabolite. Targeted metabolomics allows investigators to definitively measure signals that correspond to specific metabolites of interest.

immediately via rapid freezing or chemical extraction, but practical considerations involved in the collection of material from patients can sometimes make rapid quenching impossible. Therefore, focusing analysis on only those metabolites that are less sensitive to change due to delays in processing time may be important to gain biological insight.

Sequential metabolomic analyses of the same type of biological material from a patient can explore how metabolite levels vary over time. It is interesting that, when measured, many metabolites are found to be relatively stable. However, the extensive variability exhibited by some metabolites indicates that findings involving those metabolites should be interpreted with caution.

Finally, the method of sample processing can affect which metabolites are extracted from the material and thus influence what is measured.

METABOLOMICS TECHNOLOGIES

Metabolomics relies heavily on the intersection of instrumentation, software, and statistical and computational approaches for measurement of metabolite levels and downstream data analysis. While the development of new and emerging techniques to assess the metabolome is ongoing, the current, clinically applicable approaches can be separated into two broad categories: nuclear magnetic resonance (NMR)–based approaches and chromatography/mass spectrometry (MS)–based approaches. Each of these two approaches has its own set of advantages and disadvantages.

NUCLEAR MAGNETIC RESONANCE

NMR is a technique that, at its core, exploits intrinsic magnetic properties of atomic nuclei to generate data. Nuclei with an odd total number of protons and neutrons (such as ^{1}H, ^{13}C, ^{15}N, and ^{31}P) have a non-zero spin, and this spin generates a magnetic field that can interact with externally applied electromagnetic fields. NMR places compounds into a magnetic field that induces the smaller magnetic fields to align with the larger one. Samples are then exposed to a perpendicular electromagnetic field; the frequency of electromagnetic radiation needed to flip the spin of a nucleus in the exact opposite direction represents the frequency at which an atom "resonates" and can be measured. The resonance frequency of a given atom is affected by adjacent atoms and is ultimately unique for a given arrangement of atoms (i.e., each metabolite). This distribution or "spectrum" of signals is measured and recorded in an NMR experiment.

With respect to clinical applications, the primary benefits of NMR-based approaches are that they are nondestructive and can be performed on living samples, such as patients, cells, or tissues. They are also highly reproducible and require minimal sample preparation. Measurements are necessarily quantitative as the signal measured directly reflects concentration. These features ensure that multiple, comparable measurements can be made in a given sample either at a single point in time or across time. In addition, given that spins of different elements require sufficiently disparate resonance-inducing radiofrequencies in order to be entirely distinguishable, multiple elements can be assessed in a sample; this feature allows multidimensional cross-referencing of signals such as hydrogen and carbon. In an untargeted analysis, these multidimensional data can then be used for definitive metabolite identification, with comparison of results to known databases in which spectra for many metabolites in the human metabolome have been systematically recorded.

Despite all these benefits, the primary challenge of NMR-based approaches is a lack of sensitivity. Because the time required to detect a signal is proportional to concentration, assessment of less abundant species is impossible or impractical. For example, while a typical NMR-based metabolomics analysis will return data on up to a couple of hundred metabolites at concentrations of >1 μM, the MS-based approaches discussed below can distinguish more than 1000 metabolites at concentrations one to two orders of magnitude lower **(Table 502-1)**.

TABLE 502-1 Comparison of Nuclear Magnetic Resonance (NMR)-Based and Mass Spectrometry (MS)-Based Approaches to Metabolomic Analyses

FEATURE	NMR	MS
Reproducibility	High	Lower
Sensitivity	Low (low μM)	High (low nM)
Selectivity	Untargeted	Targeted >> untargeted
Sample preparation	Minimal	Complex
Sample measurement	Simple: single prep	Multiple preps
Metabolites per sample	50–200	>1000
Identification	Easy, using one- or two-dimensional databases	Complex; need standards and additional analyses
Quantitation	Inherently quantitative; intensity proportional to concentration	Requires standards because of varying ionization efficiency
Sample recovery	Easy, nondestructive	No
Living samples	Yes	No

CHROMATOGRAPHY/MASS SPECTROMETRY

A distinguishing feature of chromatography/MS–based approaches is that a multistep process that destroys the material is necessary to generate a sample for analysis. In addition, each step of the sample preparation process involves decisions that influence the metabolites measured at the time of analysis. In general, once a sample to be analyzed is prepared, that material is subjected to a combined chemical and temporal separation of compounds via chromatography, with the output delivered to a device for performance of mass-based detection (technically, measurement of a mass-to-charge [m/z] ratio)—i.e., mass spectrometry. Finally, data collected by the mass spectrometer are analyzed **(Fig. 502-3)**.

Sample Preparation Although occasionally a part of NMR-based metabolite detection protocols, MS-based approaches almost uniformly require an initial sample-preparation phase called *extraction*. This technique destroys the original sample by partitioning metabolites into distinct immiscible phases, such as polar and nonpolar. These

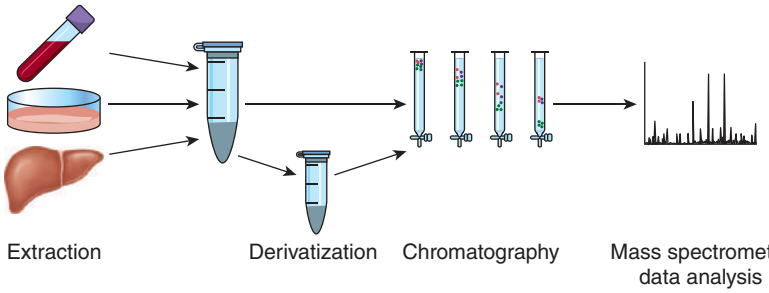

FIGURE 502-3 Metabolite measurement by chromatography/mass spectrometry–based approaches involves multiple steps, and decisions made at each step influence what is measured. First, metabolites are extracted from a biological sample in a manner that is destructive of the original sample. This process stops biochemical activity and creates metabolite samples that can be analyzed, sometimes after a chemical derivatization step that alters a subset of metabolites in a manner that facilitates their downstream analysis. Second, metabolites in the sample are separated via chromatography. Finally, the chromatographically separated compounds are analyzed by mass spectrometry. Each signal detected corresponds to a metabolite's characteristic mass per unit charge while the amplitude of that signal reflects the abundance.

phases are then mechanically separated and processed further for analysis. Given the nature of this extraction process, it is critical to determine in advance the general class of metabolites to be measured. This information will help to determine the optimal extraction protocol for specific types of metabolites of interest and to shape further downstream decisions regarding the chromatography/MS technique that also influences metabolite detection. In addition, depending on the metabolites to be analyzed and the method of separation and/or analysis used, extracted samples sometimes are processed further in a preparative step called *derivatization*: extracted metabolites are chemically modified by the addition or substitution of distinct, known chemical moieties that facilitate separation or detection of types of metabolites. By changing the chemical properties of metabolites, derivatization may improve stability, solubility, or volatility or facilitate separation from closely related compounds, enhancing measurement of specific metabolites.

Chromatography Chromatography is a ubiquitous approach used in chemistry for the separation of complex mixtures. The mixture of interest in a mobile phase is passed over a stationary phase such that compounds in the mixture interact with the stationary phase and transit through that stationary phase at different speeds, allowing their consequent separation. Two general types of chromatography are typically used in metabolomics.

LIQUID CHROMATOGRAPHY Liquid chromatography–mass spectrometry (LC-MS) is the most commonly used approach in MS-based metabolomics. In this case, chromatography is characterized by a mobile phase that is a liquid and a stationary phase that is a solid. In liquid chromatography in particular, the choice of the solid and liquid phases can dramatically influence the types of compounds separated for input into the mass spectrometer. In general, LC-MS metabolomics is highly sensitive and versatile in allowing detection of a broad range of metabolites. A downside, however, is variability in exact separation timing, especially between different instruments; which metabolites are measured is impacted by the chromatography used and how well molecules are separated.

GAS CHROMATOGRAPHY Gas chromatography–mass spectrometry (GC-MS) involves chromatography in which the mobile phase is a gas. In contrast to LC-MS, GC-based approaches have a narrower range of applications because only volatile metabolites that enter a gaseous phase are separated. When combined with appropriate derivatization, GC-MS is a robust way to detect many organic acids, including amino acids, and molecules of low polarity, such as lipids. GC-MS is more reproducible than LC-MS across platforms and requires less expensive instrumentation and less specialized training, but it also typically measures a much more restricted range of metabolites in a sample than does LC-MS.

Mass Spectrometry Once the metabolites in a sample have been separated by chromatography, they are sent into the mass spectrometer for analysis and measurement. The first step in this stage of the process is to generate charged ions, as mass spectrometers measure compounds on the basis of their m/z ratio. Charge can be imparted through various techniques, although most commonly it is attained by either applying a high voltage to a sample or striking it with a laser.

A number of different types of mass spectrometer can be employed for metabolomics. Three of the most commonly available types are discussed below.

TANDEM MASS SPECTROMETRY Tandem MS relies on three sets of quadrupole magnets arranged in series. The power of this arrangement lies in its specificity through two sequential mass analyses of the same starting compound. In the first quadrupole, the "parent" or full ion is measured before being bombarded by an inert gas in the second quadrupole; this process fragments the compound into characteristic smaller "daughter" ions. The third quadrupole then measures these daughter ions.

TIME-OF-FLIGHT MASS SPECTROMETRY While there are multiple types of time-of-flight (TOF) mass spectrometers, they all operate on similar principles. Most simply, lighter metabolites travel faster and heavier metabolites travel more slowly. TOF machines have high mass accuracy and sensitivity while also acquiring data quickly.

ION TRAP MASS SPECTROMETRY Ion trap mass spectrometers, of which the orbital trap is a subtype, offer perhaps the highest degree of flexibility when it comes to MS-based metabolomics. In general, these machines can select for a specific mass range of metabolites at multiple levels, first by filtering with a single quadrupole and then by trapping and accumulating metabolites of a particular mass or range of masses. This accumulation can be applied to low-abundance compounds, allowing increased sensitivity. It also allows repeated fragmentation of metabolites (called MS^n) to produce characteristic "daughter" ions, increasing the specificity of the analysis. Given this versatility coupled with high mass accuracy, the development of these machines is advancing rapidly; however, access to the latest versions can often be limited by cost.

CURRENT CLINICAL APPLICATIONS

Tests to assess small molecules are ubiquitous and well established throughout medicine. These include assays to measure select metabolites of known clinical relevance, such as glucose, lactate, and ammonia. Of note, many standard tests assess these metabolites one at a time; however, metabolomics can allow the assessment of many metabolites in a sample and provide more information on metabolic state at a given point in time. In some cases, metabolomics is used to detect molecules for which there is not a robust single analyte test or when multiple species measured in a sample might provide new information. Here we will focus specifically on some applications of metabolomics techniques in current clinical practice.

MAGNETIC RESONANCE SPECTROSCOPY

Magnetic resonance spectroscopy (MRS) is an adaptation of magnetic resonance imaging (MRI), a widely used technology in clinical practice. MRI, at its core, is essentially proton (^{1}H) NMR with the resulting data rendered spatially to generate an image. Recall that NMR is nondestructive and can be applied to living samples. MRS, then, is a capability built into almost every MRI machine. In practice, radiologists can focus on specific volumes of interest within a patient's imaging and perform additional sequences to obtain an NMR spectrum in that space that can allow for the identification and quantification of specific metabolites in that space. With this approach, several different metabolites across diverse classes, including lipids, sugars, and amino acids, can be measured at a given time.

Extensive work has correlated different biological processes with altered levels and/or ratios of metabolites measured via MRS. One well-established application is in the diagnosis of brain masses. More specifically, *N*-acetylaspartate (NAA) is an amino acid derivative that is abundant in neurons, whereas choline is a metabolite whose level, as measured by MRS, correlates with cellularity and/or proliferation. Thus, an increase in the ratio of choline to NAA (and even loss of NAA signal entirely) correlates with cancer; tumors biologically are associated with the properties of increased cellularity from proliferation and the concurrent exclusion of normal neurons. A different process—for example, a brain abscess—does not result in increased choline levels (which instead may actually decrease), but does exclude neurons, resulting in an isolated NAA decrease. Metabolites such as lactate can also be helpful, depending on the clinical context, in providing insight into the metabolism of a tumor or identifying areas of early hypoxic brain injury after a stroke. Finally, among the several amino acids that can be measured, high levels of glutamine/glutamate can be helpful in a patient with altered mental status as changes in these amino acids are associated with hyperammonemia. (Glutamate serves as the central nervous system sink for ammonia, generating glutamine in the process.)

NEWBORN SCREENING PROGRAMS

Newborn screening programs are used to identify diseases within the first few days of life such that they can be treated or managed with early intervention. Among the classes of disease targeted by newborn screening programs are many inborn errors of metabolism, which often lead to changes in the levels of specific metabolites in blood or urine. One

of the first newborn screening programs tested for phenylketonuria, which results from the inability to metabolize phenylalanine resulting in high blood and urine levels of particular metabolites. Since that time, the panel used by programs throughout the United States and around the world has expanded dramatically. The general protocol is to collect a blood sample from infants in the first few days of life (often by heel prick on a piece of paper). These samples are sent to a central lab for analysis, which typically includes metabolomics measurements with targeted LC–tandem MS. Specific inborn errors of metabolism are suggested by abnormal levels of a given metabolite or set of metabolites.

METABOLITE MEASUREMENTS IN CHILDREN AND ADULTS

Outside the window of newborn screening, direct clinical measurement of metabolite levels is also used in pediatric and adult patients. In these cases, clinical samples such as serum, cerebrospinal fluid, or urine are typically subjected to targeted LC–tandem MS to measure metabolites such as amino acids, acylcarnitines, and fatty acids. These measurements can help diagnose milder cases of inborn errors of metabolism that may have been missed by newborn screening. They can also help identify secondary metabolic defects, such as those that are related to nutritional deficiencies or are acquired in the setting of additional pathology. For example, these measurements are useful in determining the etiology of noncirrhotic hyperammonemia exposed by a catabolic stressor such as sepsis in a patient with a previously unknown subclinical or acquired urea-cycle defect.

MS-based metabolomics is used by various athletic organizations for detection of metabolites associated with banned substances and by the pharmaceutical industry for assessment of levels of pharmaceuticals and their metabolites in both blood and tissues. Such analyses can provide key pharmacokinetic information to guide drug dosing and illuminate toxicology. These approaches can also be useful in clinical practice. For example, chronic pain and its management remain a challenge, and the sequelae of opiate/opioid use and abuse are of concern to many providers, their patients, and their patients' families. Therefore, many electronic medical records systems strive to ensure appropriate and consistent patient access to pain medications, while providers may need a means to ensure that patients are adhering to their prescribed regimens. One way to monitor drug use is to perform targeted LC–tandem MS for detection of specific drug metabolites in patients' urine. This approach is more sensitive than first-generation immunoassays and can detect a range of metabolites associated with other drugs beyond the one prescribed. Given that the first-generation immunoassays also often rely on confirmatory MS testing, upfront metabolomics reduces lab turnaround time and may also reduce costs by limiting multiple tests on the same sample.

EMERGING AND EXPERIMENTAL CLINICAL APPLICATIONS

The current clinical applications of metabolomics are largely limited to the indications described above. However, ongoing efforts are aimed at expanding the use of metabolomics for detection of biomarkers that can help with disease diagnosis or prognostication.

METABOLITES AS BIOMARKERS OF DISEASE

There has been increasing work in prospective human cohort studies on the use of metabolomics, primarily MS-based approaches, to empirically identify small groups of metabolites whose altered levels are associated with the development or progression of disease. Efforts to characterize these "metabolic signatures" have been focused primarily on common, multifactorial diseases such as diabetes, cardiovascular disease, and various cancers that are well represented in large prospective cohort studies. These studies have, for example, identified altered levels of amino acids that are associated with a future diagnosis of diabetes or pancreatic cancer. Similar efforts have proliferated across conditions ranging from chronic lung diseases to neurologic/developmental disorders.

Additional efforts have been made to assess the metabolome in patient samples at the time of an acute presentation. Because altered metabolite levels can be associated with a specific clinical diagnosis and/or outcome, the idea is to identify a metabolite signature that facilitates diagnosis or provides prognostic information. This approach has been studied, for example, in the context of sepsis and septic shock, in which blood lactate levels are assessed in combination with the use of clinical tools such as the Acute Physiology and Chronic Health Evaluation (APACHE II) or the Sequential Organ Failure Assessment Score (SOFA). More recent efforts have identified a strong association between mortality and certain modified amino acids linked to mitochondrial dysfunction, highlighting a potential mechanistic link between sepsis pathogenesis and metabolic alterations.

One key limitation in all of these studies is that researchers are primarily assessing correlations between blood plasma metabolite levels and complex, multisystem diseases. It remains difficult to obtain a biological understanding of the mechanisms driving these changes or, even more simply, the primary tissue source(s) of these alterations from human data alone, without further experimentation in model systems.

REFINING DIAGNOSIS AND PREDICTION OF DRUG SUSCEPTIBILITY

In contrast to the above-described use of metabolomics-based approaches in multifactorial diseases, the application of these approaches in some specific contexts can yield an immediate diagnosis and suggest actionable therapeutic interventions. One specific example in oncology involves an understanding of the pathogenesis of oncogenic mutations in the metabolic enzyme isocitrate dehydrogenase (IDH) isoforms 1 and 2. The normal function of these enzymes is to interconvert isocitrate and α-ketoglutarate; however, cancer-specific point mutations in these enzymes alter the enzymes' function in a manner conferring neomorphic activity that converts isocitrate into 2-hydroxyglutarate (2-HG). 2-HG is a metabolite that is typically present only at very low levels in cells, but when mutant IDH protein is present, 2-HG is produced and accumulates to high levels. Elevation of 2-HG can promote changes that directly contribute to malignancy; IDH mutations and 2-HG accumulation are found in several human cancers, including specific clinical subsets of acute myeloid leukemia and glioma. Given the unique and specific accumulation of 2-HG in these mutant tumors, detection of this metabolite by LC-MS and NMR-based approaches has been studied both for diagnostic purposes and as a means of assessing drug response. For example, researchers have applied MRS-based approaches to assess the accumulation of 2-HG in gliomas, as this finding can noninvasively identify patients with an IDH-mutant subset of this cancer **(Fig. 502-4)**. This diagnosis provides prognostic information and determines if a patient could benefit from drugs targeting mutant IDH that have been shown to benefit patients with IDH-mutant gliomas. In principle, metabolomics may identify other disease biomarkers to aid with diagnosis or therapy assessments in similar ways.

PHARMACOMETABOLOMICS

The previous example positions metabolomics as a possible mechanism for achieving a more personalized approach to medicine. The emerging field of pharmacometabolomics aims to take personalization further by making this approach more widely applicable across drugs and disease states. The general idea is to link pharmacokinetics (PK) and pharmacodynamics (PD) data with baseline metabolomic profiling, with the goal of generating a predictive model for individual PK and PD responses based on a naïve patient's metabolomic profile. Ideally, this approach would allow clinicians to take a baseline set of measurements and then—a priori—choose a specific dose of a specific drug to produce the desired effect in that specific patient. If successful, this method could limit both prolonged titration of medications and medication switching, dramatically shortening and simplifying the current approach to medical therapy.

EMERGING TECHNIQUES

While efforts to improve the existing capabilities discussed above are ongoing, innovations in instrumentation and computation are allowing collection and analysis of metabolite information that previously was not possible.

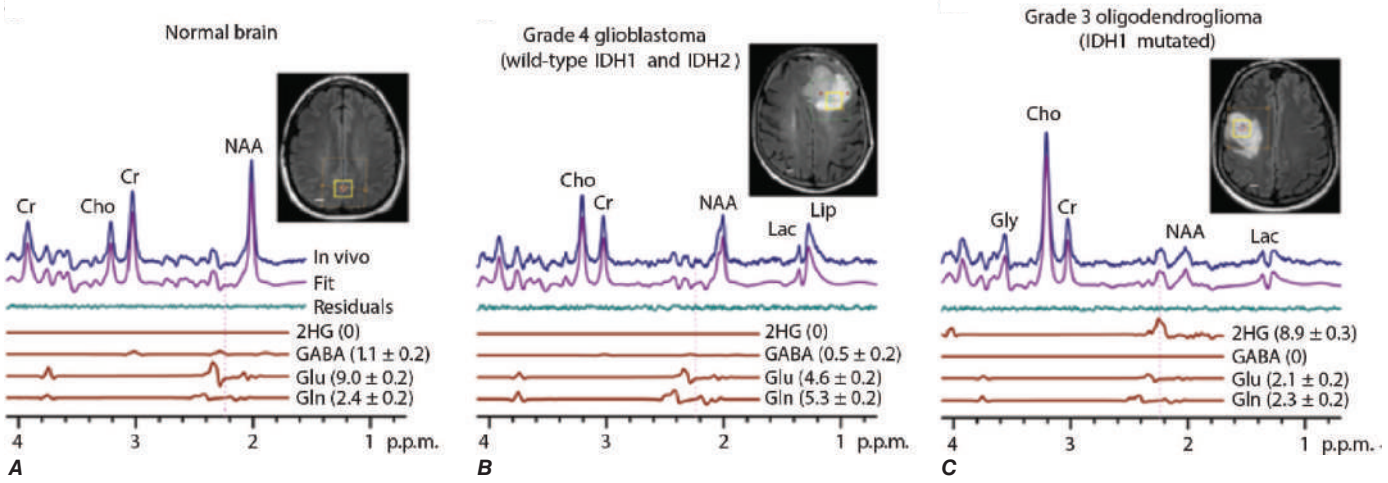

FIGURE 502-4 In vivo ^{1}H spectra and analysis demonstrating 2-hydroxyglutarate (2-HG) detection in isocitrate dehydrogenase (IDH)-mutant brain tumors. ***A–C.*** In vivo spectra from normal brain (***A***) and tumors (***B–C***) are shown. Components of 2-HG, γ-aminobutyric acid (GABA), glutamate, and glutamine are displayed. Measurement location is indicated by *yellow box* (voxel). 2-HG is seen only in mutant IDH brain tumors, but not normal brain or wild-type tumors. Shown in brackets is the estimated metabolite concentration (mM) ± standard deviation (s.d.). Cho, choline; Cr, creatine; Glu, glutamate; Gln, glutamine; Gly, glycine; Lac, lactate; Lip, lipids. Scale bars, 1 cm. *(Reproduced with permission from C Choi et al: 2012.)*

MASS SPECTROMETRY IMAGING

Most clinical metabolomics relies on analysis of bulk material, but in an individual patient, there are areas of normal and diseased tissue, and understanding the differences in metabolism in these areas requires both spatially sensitive resolution (imaging) and interrogation (metabolomics). While MRS can perform some of these functions, it is limited to macroscopic imaging (MRI) and relatively insensitive metabolomics approaches (NMR). In contrast, MS-based approaches, while more sensitive, by their nature rely on specimen destruction and homogenization. The premise of mass spectrometry imaging (MSI) is to overcome these limitations of MRS and mass spectrometry. MSI combines histologic evaluation of tissue with MS-based approaches to assess spatial differences in metabolites. MSI as a technique has been most highly refined in the neurosciences and can provide subcellular resolution. In general, thin slices of tissue are mounted on a slide, and metabolomics is performed at defined points across the slide, yielding spatial information on where in the tissue section metabolites are measured. One specific approach utilizes matrix-assisted laser desorption/ionization (MALDI) coupled to MS. In MALDI, tissues are coated with a special matrix and the MALDI laser scans point-by-point across a tissue slice, ionizing the metabolites at each location for analysis by a mass spectrometer. These data can then be referenced back to an image of the original tissue slice **(Fig. 502-5)**. This approach is being tested for defining tumor margins in real time during resection and thereby providing insight into boundaries between normal and abnormal tissues.

INTEGRATION WITH ADDITIONAL "-OMICS" TECHNIQUES

There is increasing interest in integrating metabolomics data with data derived from other "-omics" techniques evaluating, for example, the transcriptome or proteome (Fig. 502-1), an approach referred to as "multi-omics analysis." Integrated multi-omics may provide a more complete understanding of the biological mechanisms underpinning observed phenotypes and is being used to study heterogeneity across cell populations determined via spatial and single-cell approaches. Additionally, when applied to complex communities like the gut microbiome, these approaches can aid in the discovery of previously uncharacterized metabolic pathways that impact human health.

IMPROVING UNTARGETED METABOLOMICS

Identifying unknown signals in an untargeted metabolomics analysis remains one of the central challenges in the field. As discussed above, NMR can definitively identify unknown signals but is inferior to MS-based approaches in its sensitivity and therefore in the number of signals it can detect in a given sample. To leverage the sensitivity of MS-based detection and overcome the challenge of metabolite identification, researchers are applying computational techniques, using network-style analyses and machine learning based approaches to streamline the process. The general approach is to combine information from known biological perturbations (e.g., changes in experimental conditions or disease states), empirical mass and structural information from MS analysis, and correlations with known metabolites/pathways to place unknown metabolites within existing metabolic networks.

The growing interest in machine learning (a subset of artificial intelligence), which focuses on the training of algorithms to analyze large amounts of data, has led to it being applied to facilitate analysis and interpretation of metabolomics data. These algorithms can be used to identify unknowns in untargeted metabolomics datasets and find patterns of linked metabolites, or between metabolites and other data, that might otherwise be missed by traditional approaches.

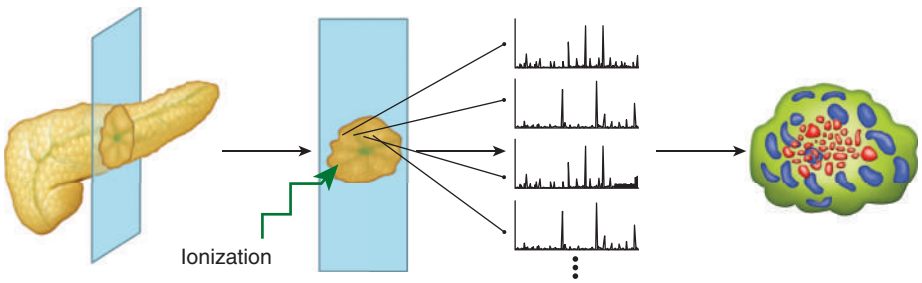

FIGURE 502-5 Mass spectrometry imaging provides spatial information around metabolites in tissues. Tissue is mounted onto a slide, and a laser or another method is used to ionize metabolites in a discreet section of the tissue for detection by mass spectrometry. The process is repeated as the laser scans across the tissue, generating an "image" based on the levels of a metabolite detected at each point in the tissue section.

SUMMARY

Metabolomics is part of a growing list of "-omics" techniques that have a growing role in both research and clinical medicine. Despite its immaturity relative to genomics, the power of metabolomics comes from being directly connected to phenotype and being very sensitive in measuring perturbations within a system or a patient. While the clinical applications of metabolomics are currently limited to specific indications, these technologies have the potential to be used more broadly in medicine. However, if these methods are to be used appropriately, clinicians need to be aware of established biological and practical confounders. Similarly, a basic knowledge of the technologies in use and their inherent limitations is critical. Nevertheless, metabolomics is becoming a part of the clinical armamentarium for diagnosis, monitoring, and treatment of disease.

503 Circulating Nucleic Acids as Liquid Biopsies and Noninvasive Disease Biomarkers

Ash A. Alizadeh, Kiran K. Khush, Yair J. Blumenfeld

While this chapter is focused on the modern use of liquid biopsies and their applications in the context of malignancies, transplantation, and noninvasive prenatal testing, it is worth considering that the history of liquid biopsies dates back many centuries. Indeed, as early as the fourth century B.C., Hippocrates is noted to have studied body fluids and humors to diagnose various maladies in his patients. By the mid-seventeenth century, the analysis of bodily fluids (especially urine) increasingly became a cornerstone of European medicine. However, arguably, the most important use of bodily fluids as liquid biopsies currently involves key clinical applications in oncology, solid organ transplantation, and prenatal diagnosis **(Fig. 503-1)**. Below, we discuss these applications of liquid biopsies in the context of modern medical management of patients with risk of cancer and tumor progression, posttransplantation outcomes, and obstetric management.

CELL-FREE DNA IN ONCOLOGY

Major advances in the twenty-first century in cancer biology have helped transform oncology, particularly with the advent of personalized cancer therapies, which are typically selected using molecular biomarkers to identify tumor-specific vulnerabilities. However, because tumor heterogeneity remains a major obstacle to cancer monitoring and treatment, better approaches are needed to define clinically actionable targets and to facilitate the individualized therapies that embody precision medicine. While much can be learned from studying tumor biopsies directly, such as molecular profiling that informs diagnosis and monitoring of pathologic response, these are invasive clinical procedures. In addition, tumor biopsies may not yield enough material for analysis and can be risky to the patient. Therefore, an approach to analyze cancer less invasively, such as from a blood sample, serves as a potentially attractive alternative in the clinical evaluation of patients with cancer.

Tumors are well known to release analytes into body fluids, including the peripheral blood circulation, and the diagnostic use of such analytes has often been referred to as liquid biopsies **(Fig. 503-2)**. For hematologic malignancies such as leukemias, the direct examination of circulating hematopoietic elements is a cornerstone for diagnosis, response, assessment, and disease monitoring. Indeed, molecular tools allowed the specific detection of lymphoma B cells in the blood circulation using in situ hybridization in the mid-1980s, even before the advent of polymerase chain reaction for more sensitive detection. However, even when considering hematologic neoplasms such as lymphomas, many do not circulate in large numbers in the blood. Indeed, the dominant anatomic distribution of most human cancers results in the absence of detectable circulating tumor cells as evidence for minimal residual disease (MRD) in the cellular compartment of the blood.

Aside from extravasated tumor cells circulating in the bloodstream as circulating tumor cells (CTCs), liquid biopsy methods using peripheral blood also include membrane-bound vesicles released by tumor cells called exosomes, as well as non–membrane-bound derivatives such as cell-free DNA (cfDNA) and cell-free RNA (cfRNA), which are released by apoptotic or necrotic tumor cells. Although the most common source of liquid biopsy is the peripheral blood, various bodily fluids have been used for specific liquid biopsy applications to interrogate proximally associated anatomic compartments, whether using urine, feces, pleural fluid, peritoneal fluid, bronchoalveolar lavage fluid, saliva, or cerebrospinal fluid. For example, urinary cfDNA has shown promise for noninvasive detection of genitourinary tumors including bladder carcinomas, and colorectal cancer screening can be done using multianalyte assays leveraging fecal DNA.

Among the most intensively studied tumor-derived biomarkers is circulating tumor DNA in the blood plasma, as a subset of cfDNA. cfDNA in the blood was first described in 1948 by Mandel and Metais, but it was not for another four decades that tumor-derived DNA was first observed in the plasma of cancer patients. Interestingly, cfDNA is naturally fragmented with lengths that correlate with DNA wrapped around individual nucleosomes. Since both healthy cells and cancer cells release their DNA into the circulation, a major challenge is attaining enough sensitivity to identify and quantify tumor-derived circulating DNA (circulating tumor DNA [ctDNA]) against a potentially large background of normal constitutional or germline DNA, the majority of which derives from hematopoietic sources. Methods based on next-generation sequencing offer a way to achieve this. Over the past two decades, ctDNA has been established as an important biomarker for studying tumor biology and for detection of cancers. Here, we summarize key applications of ctDNA in the context of early cancer detection,

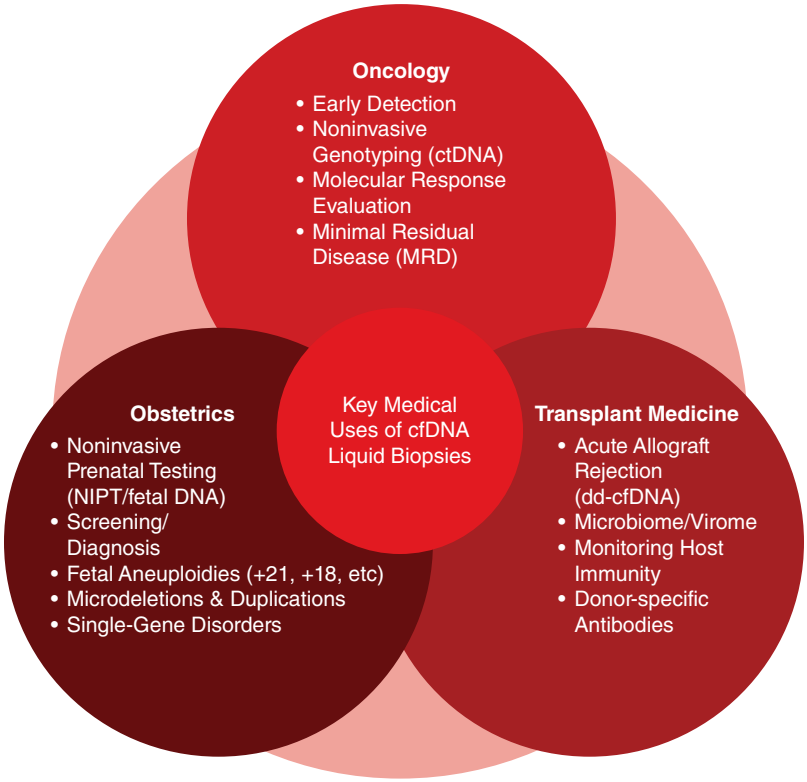

FIGURE 503-1 Key medical applications of liquid biopsies employing cell-free DNA (cfDNA), with specific focus on oncology, transplantation, and obstetrics. ctDNA, circulating tumor DNA; dd-cfDNA, donor-derived cfDNA; NIPT, noninvasive prenatal testing.

noninvasive tumor genotyping and classification, molecular response during therapy, and MRD after definitive therapy **(Fig. 503-3)**.

EARLY CANCER DETECTION

For several common cancer types including carcinomas of the lung, colorectal tract, and breast, early cancer detection via screening can improve outcomes for adults with established risk factors. However, such screening can pose significant risks and associated expenses that limit broad adoption. For example, while annual radiologic screening by low-dose computed tomography is recommended to screen for lung cancers in high-risk populations, implementation has been complicated by a high false discovery rate (~90%) and low compliance. Separately, distinct tumor types currently require unique corresponding screening tests. Finally, most existing cancer screening modalities have not fully integrated some of the key insights gained through molecular profiling of cancer genomes. Therefore, there is an unmet need for new methods for the early detection of cancers. Analysis of ctDNA is a promising approach that could facilitate blood-based screening. In this context, several efforts to leverage ctDNA for early detection are emerging, including approaches focused on individual cancer types, multianalyte testing combining ctDNA with other biomarkers including proteins, and broader multicancer early detection (MCED) assays leveraging mutations, tissue-specific methylation, cfDNA fragmentation profiles, and other features.

Despite much excitement about their promise, most such cancer detection efforts are relatively early in their development. As of 2021, no screening studies have prospectively applied liquid biopsies as interventions in randomized studies, with survival outcomes as clinical endpoints. Indeed, no studies performed to date have demonstrated a survival advantage of early detection using liquid biopsies in randomized trials, and this remains a key hurdle limiting widespread clinical adoption of these tests. With these limitations in mind, future prospective studies with substantially longer-term follow-up are needed to better establish the sensitivity and specificity of MCED tests for early cancer detection, when considering the common cancer types most amenable to localized interventions with curative intent. Separately, because early cancer detection may not improve cancer-specific survival, studies will also be required to determine if these tests can yield more true positives than false positives, especially because false-positive results can generate a substantial number of expensive secondary invasive procedures.

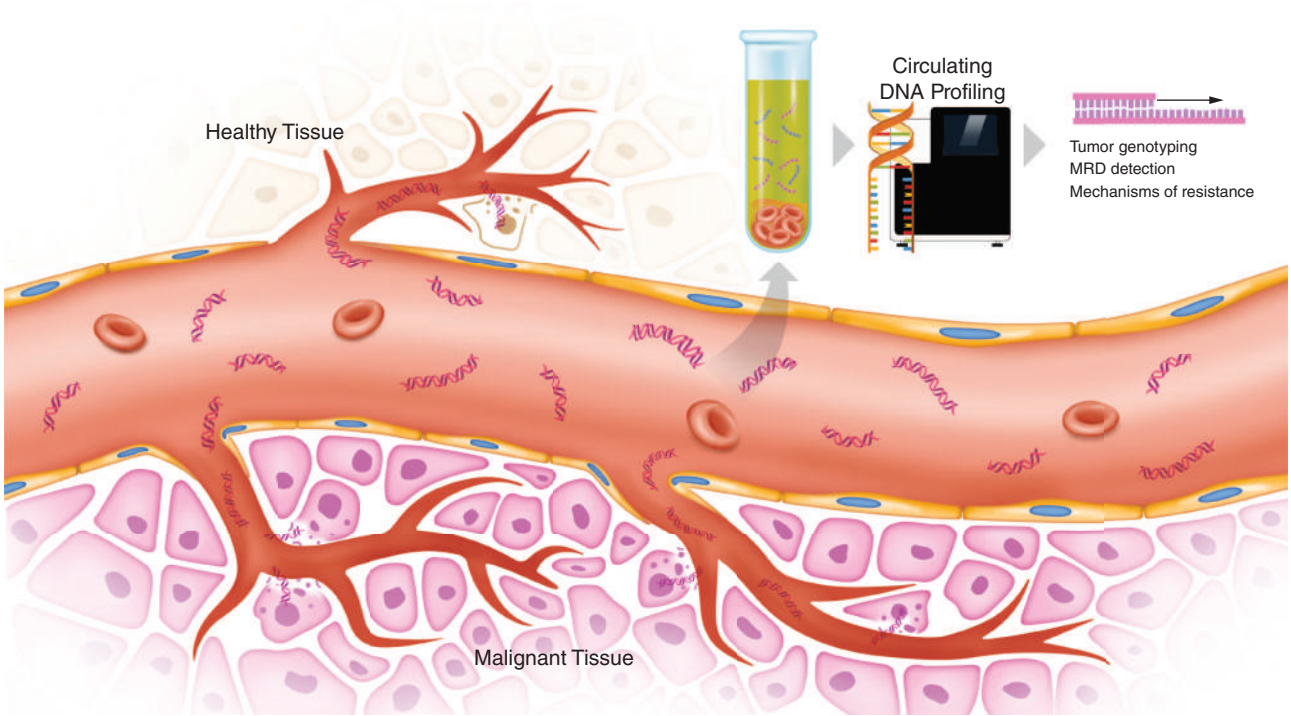

FIGURE 503-2 Cell-free DNA (cfDNA) is released both from healthy and malignant tissues. Tumors shed circulating tumor DNA (ctDNA), a minor fraction of all circulating cfDNA. Molecular profiling of cfDNA enables cancer detection and monitoring applications. MRD, minimal residual disease. *(Source: Adapted from BJ Sworder et al: Hematol Oncol, 39, 2021. https://doi.org/10.1002/hon.6_2879.)*

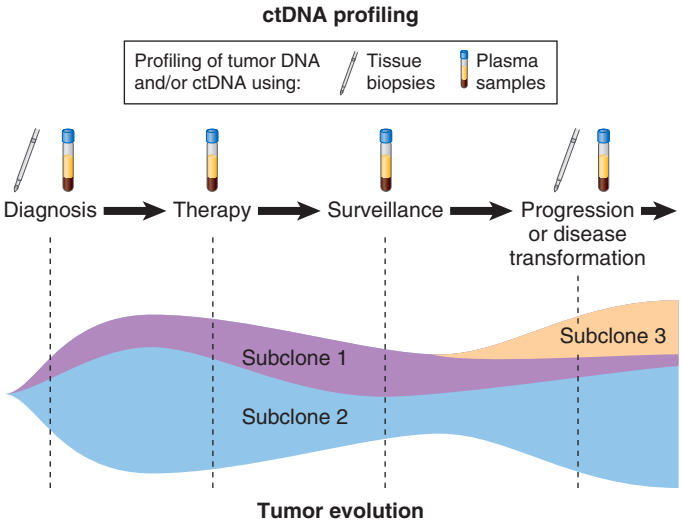

FIGURE 503-3 Framework for noninvasive identification of cancer risk groups. Schematic illustrating the application of ctDNA profiling for the identification of adverse risk at different disease milestones. A cancer patient is imagined as experiencing these disease milestones over time, depicted as an arrow progressing from left to right. During this temporal sequence, ctDNA can inform risk at diagnosis, during therapy, in surveillance of disease, and at progression or disease transformation. At diagnosis, profiling of tumor DNA obtained from either tissue biopsies (indicated by a scalpel) or plasma (depicted as blood collection tubes) allows for the identification of patients with high tumor burden and disease subtypes defined by specific genomic aberrations. Assessment of ctDNA during and after treatment facilitates the detection of both emerging resistance mutations and minimal residual disease (MRD) before progression, with potential for noninvasive prediction of relapse and treatment resistance. Tumor evolution in an anecdotal patient is illustrated, showing tumor response and clonal evolution over the course of the disease (detectable subclones at diagnosis are shown in *blue/gray*; an emergent subclone after therapy is shown in *red*). The profiling of tumor DNA and ctDNA at each milestone is shown by a double-stranded DNA molecule. *(Adapted from F Scherer et al: Distinct biological subtypes and patterns of genome evolution in lymphoma revealed by circulating tumor DNA. Sci Transl Med 8.364:364ra155-364ra155, 2016.)*

NONINVASIVE TUMOR GENOTYPING

Molecular subgroups defined by activating mutations in key oncogenic drivers are the basis for many targeted therapies in oncology across diverse cancers. For example, targetable mutations in the *EGFR* gene are the most common oncogenic driver in non-small-cell lung cancer (NSCLC), and the presence of *EGFR* mutations in NSCLC tumor biopsies is strongly correlated with a positive response to small-molecule epidermal growth factor receptor (EGFR) tyrosine kinase inhibitors (TKIs). While tissue-based determination of tumor genotype is still considered by many to represent the gold standard for diagnostic purposes, liquid biopsies have demonstrated very high positive predictive value for noninvasively determining tumor genotype in the setting of advanced malignancies. Indeed, several liquid biopsy assays have been approved by the U.S. Food and Drug Administration (FDA) for companion diagnostic use to identify mutations associated with response to targeted therapies in diverse tumor types. Currently, several comprehensive genomic profiling liquid biopsy assays targeting >50 frequently mutated genes are currently available as FDA-approved noninvasive tumor genotyping tests for various solid tumors. For example, liquid biopsy testing using the Guardant360 test (Guardant Health, Inc.) in patients with NSCLC can be performed to identify *EGFR* mutations associated with response to osimertinib or amivantamab or to identify *KRAS* mutations associated with sotorasib response. Similarly, liquid biopsy testing using the FoundationOne Liquid CDx test (Foundation Medicine, Inc.) can be performed to identify *BRCA1/2* gene mutations associated with rucaparib response in ovarian cancer, *ALK* rearrangements associated with alectinib response in NSCLC, *PIK3CA* mutations associated with alpelisib response in breast cancer, and *BRCA1*, *BRCA2*, and *ATM* mutations associated with olaparib response in metastatic castration-resistant prostate cancer.

Of note, such assays have largely been developed for noninvasive tumor genotyping in the setting of advanced malignancies and are not well suited in the context of early-stage tumors. Indeed, a recent analysis by the Sequencing Quality Control Phase 2 (SEQC2) Project Working Group led by the FDA found that ctDNA detection was less reliable below a circulating variant allele fraction of 0.5% for mutations of interest. Accordingly, the currently available assays designed for the primary purpose of noninvasive genotyping in advanced disease are generally not optimal for detection of MRD because the residual ctDNA allele fractions after definitive treatment of localized solid cancers are typically much lower than 0.5%. Furthermore, even prior to treatment of advanced cancers and especially in the context of low metastatic tumor burden, the modest sensitivity of such liquid biopsy tests currently requires that if specific lesions of interest are not initially detected in the blood, a tumor biopsy is still needed to determine if the specific mutations and alterations are present, as this could inform therapy selection.

BIOLOGIC CONSIDERATIONS

In addition to the somatic mutations found in cfDNA that originate from tumor cells, somatic mutations arising in nontumor tissues can pose as a source of biologic "background." Such mutations can confound the use of ctDNA for cancer detection and monitoring. Hematopoietic stem cells can acquire mutations through a process called age-related clonal hematopoiesis (CH), resulting in variants that can be found in both cfDNA and circulating peripheral blood leukocytes. When considering peripheral blood cells in patients who do not otherwise meet criteria for a leukemia diagnosis, identification of mutations in ~20 genes canonically associated with hematologic neoplasms (and exceeding 2% in allelic fraction) is termed *clonal hematopoiesis of indeterminate potential* (CHIP). CHIP has been identified as a risk factor for cardiovascular disease and hematologic neoplasms and is also relevant for liquid biopsies **(Fig. 503-4)**. For example, because most cfDNA derives from hematopoietic sources, CH represents a major contributor to biologic mutational background for various applications of liquid biopsies across cancers. Importantly, the prevalence of CH variants increases with patient age, larger gene panels, and more sensitive testing, with prevalence approaching 100% in adults >60 years old.

Indeed, in liquid biopsy applications for noninvasively identifying somatic alterations using cfDNA, CH represents the dominant biologic source of false-positive findings, even if this can vary as a function of the specific genes or lesions being considered. While CHIP disproportionately affects genes such as *DNMT3A*, *TET2*, *ASXL1*, and *JAK2*, which are associated with myeloid cell fitness, population sequencing studies have shown that many more genes in the genome can be affected by somatic mutations arising during CH in aging adults. For example, independent liquid biopsy studies have identified that 15–41% of cfDNA mutations in the *TP53* gene can be attributable to CH because these same lesions were found in matched blood leukocytes but not in biopsied tumor tissues.

Accordingly, direct genotyping of peripheral blood leukocytes can be very helpful to avoid such cfDNA mutations arising from CH,

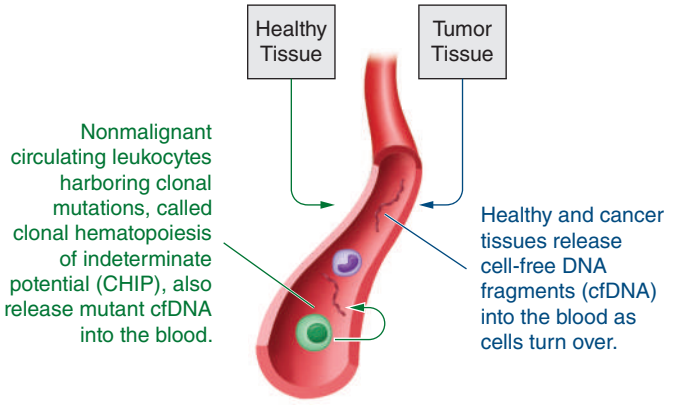

FIGURE 503-4 Contribution of clonal hematopoiesis of indeterminate potential (CHIP) to cell-free DNA, as relevant for tumor genotyping and monitoring using circulating tumor DNA. *(Adapted from J Boegeholz et al: Hematol Oncol 39, 2021. https://doi.org/10.1002/hon.23_2879.)*

which can potentially be false-positive results masquerading as ctDNA. However, studies suggest that ~10% of mutations found in cfDNA of otherwise healthy adults may not be found in matched leukocytes. This suggests other noncirculating sources of such cfDNA mutations, including CH arising in noncirculating hematopoietic precursors in tissues such as the bone marrow or from clonal proliferations of nonmalignant, nonhematopoietic cell types. Indeed, recurrent somatic mutations in genes such as *KRAS*, *MED12*, *BRAF*, and others can be present in diverse nonmalignant cell types. These mutations (and others) can arise in a range of epithelial, endothelial, and stromal constituents of vascular malformations, endometrial leiomyomas, melanocytic nevi, and other nonmalignant proliferations. As detailed below, incorporating sequencing of tumor tissue to initially identify somatic mutations that are later monitored in plasma samples can help to guard against these nonmalignant sources of biologic background.

PRETREATMENT TUMOR BURDEN

In patients with an established cancer diagnosis, liquid biopsies can be useful as a noninvasive means of tumor genotyping using plasma, in a manner that informs therapy selection in such scenarios as described above. Aside from this use, quantitative assessments of tumor burden in the plasma prior to therapy can also provide valuable information via liquid biopsies. For example, pretreatment ctDNA levels have been shown to have significant associations with established measures of tumor burden and disease risk including stage, metabolic tumor volume, and serum protein markers such as lactate dehydrogenase in lymphomas, CA19-9 levels in pancreatic cancers, and carcinoembryonic antigen levels in colorectal cancers, among others. Importantly, in many of these scenarios and in other cancers such as NSCLC where noninvasive tumor biomarkers are not available, pretreatment ctDNA levels have been shown to have strong prognostic value for treatment failure and disease progression, providing an independently prognostic measure of risk. Indeed, such pretreatment ctDNA levels can be used to noninvasively measure tumor burden poorly captured by other indices that can lead to biases in clinical trials, including the diagnosis to treatment interval in lymphomas. Accordingly, pretreatment ctDNA levels may be used to prevent selection bias in prospective clinical trials. However, while such independent prognostic value of liquid biopsies has been validated for several tumors (e.g., using CTC levels in breast cancers), randomized trials demonstrating the clinical utility of these measurements for predicting therapeutic benefit from specific treatments have not yet been performed.

MONITORING RESPONSE TO TREATMENT

Beyond the application of liquid biopsies for early cancer detection and noninvasive tumor genotyping, their use for monitoring therapeutic responses in a quantitative and qualitative fashion deserves discussion. In many cancer types, functional imaging has utility for monitoring systemic response to treatment, when considering relative changes in volumetric and/or metabolic tumor burden to assess complete versus partial responses or stable disease. Similarly, in hematologic malignancies such as chronic myelogenous leukemia, the magnitude of response to systemic therapy with TKIs can be monitored at defined milestones while on continuous treatment, using defined thresholds for reductions in *BCR-ABL1* transcript levels in the blood. Liquid biopsies can be similarly useful for measuring quantitative changes in ctDNA while on therapy. Importantly, as with the use of functional imaging, it is critical to consider several key factors when using quantitative changes in ctDNA levels to monitor response. These include the specific tumor histology and treatment setting (frontline vs relapsed disease), treatment type, the timing of interim ctDNA response assessment, the type of ctDNA assay being used and associated sensitivity and specificity characteristics, and the thresholds for change in ctDNA levels observed as informing early molecular response. For example, liquid biopsy applications for measuring interim responses have been shown to strongly predict survival outcomes in diffuse large B-cell lymphoma and Hodgkin's lymphoma in the frontline setting. Here, 100-fold reductions (2-log) in ctDNA levels after one cycle of induction chemotherapy have been shown to reliably define an early molecular response threshold, and 2.5-log reductions in ctDNA levels after two cycles can be used to define a major molecular response, which are both strongly associated with event-free and overall survival.

MINIMAL RESIDUAL DISEASE

As in the case of several hematologic malignancies, an emerging body of evidence now demonstrates that liquid biopsies including ctDNA can detect MRD following treatment of diverse solid tumor types as a predictor for relapse risk. Indeed, detection of MRD using ctDNA-based techniques has shown strikingly high positive predictive value for predicting relapse risk in many cancer types, including carcinomas of the lung, colon, rectum, bladder, and breast, among others. For example, when considering adjuvant immunotherapy following resection of localized bladder cancers, a retrospective analysis of a randomized clinical trial strongly suggests that clinical utility for the checkpoint inhibitor atezolizumab is likely limited only to patients with ctDNA MRD detectable in the blood plasma after surgery using bespoke assays. Separately, the Centers for Medicare and Medicaid Services recently finalized the first local coverage determination to provide coverage for ctDNA MRD testing for monitoring colorectal cancers after surgery using the Signatera MRD test from Natera, and a broader draft local coverage determination is currently under consideration to enable coverage of ctDNA MRD across tumor types.

Based on these and other similar results, pivotal clinical trials are now underway that select patients for adjuvant therapy integrating liquid biopsies to detect MRD and to measure response to such adjuvant and consolidative treatments. Of note, despite the high positive predictive value of ctDNA MRD for predicting relapse, the clinical sensitivity of several current assays is generally modest, with a substantial fraction of relapses occurring in patients falsely classified as MRD negative after initial maneuvers. As in the case of early detection and noninvasive genotyping described above, for applications of liquid biopsies to MRD, it is critically important to consider the specific therapies administered, the biology of ctDNA release, the timing of MRD measurements, the liquid biopsy assay performance characteristics, and the sources of both technical and biologic background. For instance, the optimal use of liquid biopsies for their negative predictive value (e.g., by withholding unnecessary adjuvant therapy in those without evidence of MRD) is likely to require substantial additional improvements in the analytical and clinical sensitivity of MRD detection for solid tumors. Nevertheless, although the broad clinical utility of ctDNA MRD for treatment personalization has yet to be fully established, liquid biopsies hold substantial promise for guiding adjuvant and consolidative therapies.

TECHNICAL CONSIDERATIONS

Despite generally representing a small fraction of nucleic acids that circulate in the blood plasma, tumor-derived ctDNA molecules can be identified through a range of techniques related to amplification and detection. These methods broadly include assays that target tumor-specific mutations, structural variants, somatic copy number alterations, and epigenetic features and generally involve using polymerase chain reaction (PCR) and high-throughput sequencing. Recently, substantial improvements in the analytical sensitivity of liquid biopsies have been achieved through a combination of refinements in these molecular techniques and the associated computational methods for analyzing the corresponding data.

Currently, liquid biopsy applications for early cancer detection, noninvasive tumor genotyping, response monitoring, and MRD rely mainly either on sequencing-based methods or on amplicon-based techniques that do not require sequencing, such as digital droplet PCR (ddPCR) or allele-specific PCR (AS-PCR). Key factors that distinguish these methods include the cost and turnaround time for the assays (which are generally in favor of amplicon-based methods), as well as the scope of genomic aberrations simultaneously being evaluated and the breadth and depth of the associated molecular profile (which are generally in favor of sequencing-based methods). For MRD applications, the integration of multiple tumor-specific somatic alterations into a single assay can allow multiplexed sequencing-based strategies to

achieve analytical sensitivities in the parts-per-million range, especially in the context of bespoke assays leveraging tumor genotypes.

Among various sequencing-based techniques, liquid biopsy applications have variably profiled the whole human genome or targeted subregions of the genome, depending on the specific applications in oncology. More specifically, selective targeting of portions of the human genome can be achieved either through enrichment by hybridization affinity capture or using locus-specific amplicons, whether focused on the whole coding exome or smaller, more focused genomic regions of interest from tens to hundreds of genes.

The biologic and technical sources of background can limit the sensitivity and specificity of liquid biopsies. Apart from the various strategies described to reduce these sources of error, many liquid biopsy studies monitoring therapeutic response and ctDNA MRD have leveraged tumor genotype–informed analyses to improve performance. Unlike noninvasive genotyping methods that rely entirely on blood plasma, this tumor genotype–informed approach includes the profiling of tumor tissue to identify mutations that are then tracked in posttreatment blood plasma. In reducing the number of mutations under consideration, this approach reduces the risk of false positives due to technical and biologic background sources of error. Separately, the tumor genotype–informed approach can be less demanding for blood sample volumes. However, due to the very low circulating levels of tumor-derived DNA at posttreatment milestones, tracking multiple tumor genotype–informed mutations and minimizing unwanted effects of biologic and technical errors are critical for optimally capturing disease risk in diverse cancers using liquid biopsies to detect ctDNA MRD.

CELL-FREE DNA IN TRANSPLANTATION

cfDNA testing offers very powerful tools for clinical monitoring of organ transplant recipients. After transplantation, cfDNA analyses have been used to assess for development of acute allograft rejection, to study microbial diversity and infection, and to quantify host immunity. This section describes current and potential future clinical applications of cfDNA testing in the transplant arena.

NONINVASIVE DETECTION OF ACUTE ALLOGRAFT REJECTION

In the setting of transplantation, cfDNA is derived from both the recipient tissues and the donated organ or cells. A transplant procedure is essentially a "genome transplant," and methods have been developed to detect and quantify levels of donor-derived cfDNA (dd-cfDNA) after transplant, with elevated levels reflecting graft injury due to acute rejection and other forms of graft damage.

In 1998, Lo and colleagues first reported detection of DNA from the organ donor in the plasma of transplant recipients. By performing PCR amplification using Y chromosome–specific primers, they were able to identify dd-cfDNA in the blood of female kidney and liver transplant recipients. This early work provided proof-of-concept of this unique approach but was limited to female recipients of male donor organs (<25% of transplant procedures).

Subsequently, a universal, sex-independent strategy was developed using whole genome shotgun sequencing to measure single nucleotide polymorphism (SNP) differences between individuals to quantify the donor signal. This approach is applicable to any organ donor and recipient combination, regardless of sex, by first genotyping the donor and recipient to identify sequence differences that can then be used to identify donor cfDNA in the recipient's blood after transplantation. Prospective studies of this approach have demonstrated that dd-cfDNA is present at very high levels during the first few days after the transplant procedure, reflecting cell death within the allograft due to ischemia and reperfusion injury. Within 1–2 weeks after transplantation, however, dd-cfDNA levels fall to a low baseline level and remain constant in the absence of acute rejection.

In the setting of acute rejection, dd-cfDNA levels increase significantly in the transplant recipient's circulation and correlate with severity of rejection. Initial studies in heart transplantation showed that, at a threshold value of 0.25%, dd-cfDNA had an area under the receiver operating characteristic curve (AUC) of 0.60 for distinguishing mild, 0.83 for distinguishing moderate-to-severe, and 0.95 for distinguishing severe rejection events, each compared to the absence of rejection. Notably, this assay can be used for surveillance of both acute cellular and antibody-mediated rejection, as both processes result in graft damage **(Fig. 503-5)**. A subsequent multicenter study confirmed the utility of dd-cfDNA monitoring for acute rejection, showing that, at a threshold of 0.25%, dd-cfDNA had a 99% negative predictive value for acute rejection and would have safely eliminated 81% of routine surveillance biopsy procedures.

Notably, increasing dd-cfDNA levels were detected several weeks to months prior to the rejection event, suggesting that dd-cfDNA is a highly sensitive marker of graft injury and can enable earlier rejection diagnosis. Early detection of graft injury may prompt augmentation of immunosuppressive therapy to halt graft damage in its early stages and to prevent a subsequent rejection event.

Finally, the investigators demonstrated higher dd-cfDNA levels associated with antibody-mediated rejection compared to cellular (T-cell–mediated) rejection, as well as different cfDNA fragment types and lengths during these two rejection processes, suggesting that dd-cfDNA patterns could potentially help differentiate these two rejection subtypes.

Parallel studies in lung, kidney, and liver transplantation have also confirmed the utility of dd-cfDNA as a noninvasive acute rejection biomarker.

A multicenter, prospective study in kidney transplantation (Diagnosing Acute Rejection in Kidney Transplant Recipients [DART]) enrolled 384 patients, on whom 107 biopsies of the transplanted kidney were performed. The dd-cfDNA level discriminated between biopsies showing any acute rejection and controls (no histologic rejection), with an AUC of 0.74, sensitivity of 59%, and specificity of 85% for acute rejection at a dd-cfDNA cutoff of ≥1.0%. A subsequent observational cohort study of 1092 adult kidney transplant recipients showed that elevated dd-cfDNA (≥0.5%) strongly correlated with clinical and subclinical allograft rejection and long-term graft function and graft survival. The study also showed that elevated dd-cfDNA levels were associated with a nearly threefold increase in risk of developing de novo donor-specific antibodies (e.g., antibodies directed against the allograft).

In kidney transplantation, dd-cfDNA could be elevated due to pathologies other than rejection, such as pyelonephritis, and is more likely a marker of severe graft injury rather than rejection alone. Thus, follow-up testing to determine the cause and nature of graft injury or use of dd-cfDNA surveillance primarily in patients at high risk of allograft rejection would be reasonable.

Studies in liver transplantation have consistently demonstrated elevated dd-cfDNA levels during episodes of biopsy-proven acute rejection. As in kidney transplantation, levels appear to rise before development of clinical manifestations of acute rejection, with data demonstrating elevated levels 4–6 days before a rise in transaminase enzyme levels and 8–15 days before biopsy confirmation of rejection. It is important to note that steady-state dd-cfDNA levels vary between transplanted organs, likely relative to the organ's mass, cellularity, or vascularization, with levels of 5–10% seen in stable liver transplant recipients and levels <0.1% seen in heart transplant patients.

Similar patterns of dd-cfDNA have also been seen after lung transplantation, with elevated levels detected weeks prior to and at the time of transbronchial biopsy demonstrating acute rejection. As in heart and kidney transplantation, dd-cfDNA levels correlate with severity of the rejection event, with greater discriminatory power seen for severe rejection and higher levels seen in antibody-mediated rejection compared to cellular (T-cell–mediated) rejection.

Donor-derived cfDNA levels also appear to have prognostic value, even in the absence of acute allograft injury. In a lung transplant cohort, patients with the highest average dd-cfDNA levels within the first 3 months after transplant, in the absence of rejection, were at high risk for subsequent chronic allograft dysfunction and allograft failure. Similarly, in kidney transplantation, donor-derived cfDNA levels at hospital discharge were shown to predict graft dysfunction at 1 year

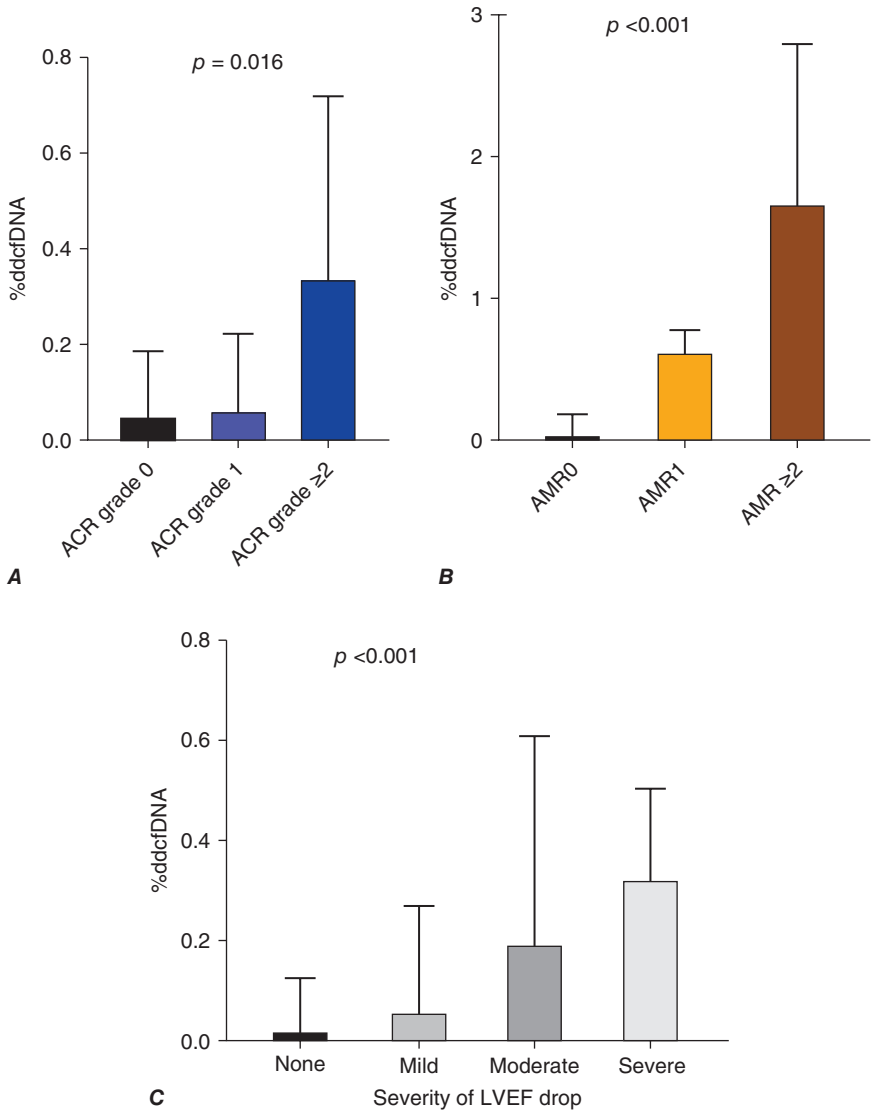

FIGURE 503-5 Correlation of percentage of donor-derived cell-free DNA (%dd-cfDNA) measures with heart transplant biopsy-graded rejection and allograft dysfunction by echocardiography. ***A.*** %dd-cfDNA in relation to severity of acute cellular rejection (ACR) by histopathologic interpretation of endomyocardial biopsy. Grade 0 rejection includes both ACR grade 0 and antibody-mediated rejection (AMR) grade 0. *P* value obtained by generalized estimating equation approach comparing all categories. ***B.*** %dd-cfDNA in relation to severity of AMR by histopathologic interpretation of the endomyocardial biopsy. Grade 0 rejection includes both ACR grades 0 or 1 and AMR grade 0. *P* value obtained by generalized estimating equation approach comparing all categories. ***C.*** %dd-cfDNA in relation to severity of allograft dysfunction measured by echocardiography. Allograft dysfunction was defined as a reduction of left ventricular ejection fraction (LVEF) by ≥5% and was further stratified by severity based on the magnitude of LVEF decline as no (<5%), mild (5% to <10%), moderate (≥10% to <15%), or severe (≥15%) allograft dysfunction. *P* value obtained by generalized estimating equation approach comparing all categories. *(Reproduced with permission from S Agbor-Enoh et al: Cell-free DNA to detect heart allograft acute rejection. Circulation 143:1184, 2021.)*

after transplant. As such, average dd-cfDNA levels over time may reflect cumulative graft injury and related long-term adverse outcomes.

Over the past few years, targeted next-generation sequencing assays (AlloSure [CareDx, Inc.] and Prospera [Natera]) have been developed to quantify dd-cfDNA levels after transplantation. These assays are composed of panels of highly polymorphic SNPs that, when sequenced and quantified, enable differentiation of donor and recipient cfDNA molecules using bioinformatics approaches. Such assays do not require donor or recipient genotyping, are rapid and relatively cost effective (particularly when compared to whole genome sequencing), and are currently available for clinical use.

In summary, dd-cfDNA can be reliably detected in the plasma of transplant recipients. Levels of dd-cfDNA are high immediately after transplantation but rapidly fall to a baseline level within several weeks, after ischemia-reperfusion injury has subsided. These dd-cfDNA levels then remain at stable low levels in the absence of graft injury, with baseline levels varying by organ type, likely related to the mass of the transplanted organ. Most studies performed to date have demonstrated rising levels with development of acute rejection and other forms of allograft injury, with highest discriminatory power for antibody-mediated rejection and severe grades of acute cellular rejection, and have shown that levels rapidly fall after successful rejection treatment.

At this time, dd-cfDNA testing cannot completely replace biopsies of the transplanted organ, which provide immunohistochemical and molecular diagnostic information that helps guide clinical treatment. Rather, this noninvasive assay reduces the need for surveillance biopsies and enables clinicians to selectively perform biopsies on patients for whom they are truly indicated, with attendant improvements in safety, cost, and patient satisfaction. The ultimate goal is to use dd-cfDNA to "personalize" immunosuppressive management by enabling weaning of therapy in stable patients with low dd-cfDNA levels and augmentation of treatment in patients with rising levels suggestive of early graft injury.

MONITORING MICROBIAL DIVERSITY AND INFECTION AFTER TRANSPLANTATION

Immunosuppressive therapies reduce the risk of allograft rejection but increase the transplant recipient's susceptibility to infectious complications. The balance between level of immune system suppression and the competing risks of rejection and infection is delicate, and the desirable "therapeutic window" for patient treatment is narrow. Furthermore, diagnosis of infectious complications after transplantation is challenging, as patients are susceptible to a wide array of pathogens and common diagnostic tests rely on an a priori hypothesis for the source of infection and performance of specific antigen-based or PCR-based molecular tests. Hypothesis-free sequencing of the microbial component of transplant recipients' cfDNA offers a window into the state of the immune response and potential diagnosis of infectious complications.

In 2013, De Vlaminck et al performed shotgun sequencing of heart and lung transplant recipient cfDNA followed by alignment to reference human and microbial databases. This work showed that 2% of cfDNA sequences were microbial in origin, including viral, bacterial, and fungal genomes. They then studied the microbiome composition in plasma at different levels of taxonomic classification and showed that viruses (73%) are more abundant than bacteria (25%) and fungi (2%). Subsequent testing showed quantitative agreement between viral counts as measured by sequencing and quantitative PCR assays for common posttransplant viral pathogens such as herpesviruses.

Available data on clinical drug treatment and dosage, including calcineurin inhibitor use and antiviral prophylaxis, were used to analyze drug-microbiome interactions. The investigators found that the structure of the virome is exquisitely sensitive to drug use and dosage—high doses or levels of immunosuppressive drugs give rise to a virome dominated by *Anelloviridae* or torque teno viruses, which are ubiquitous viruses that have no known pathogenic role in humans but have been shown to replicate in the setting of immune system suppression. Similarly, the relative amount of herpesviruses declines substantially after introduction of the prophylactic antiviral agent valganciclovir **(Fig. 503-6)**. Using this approach, the investigators

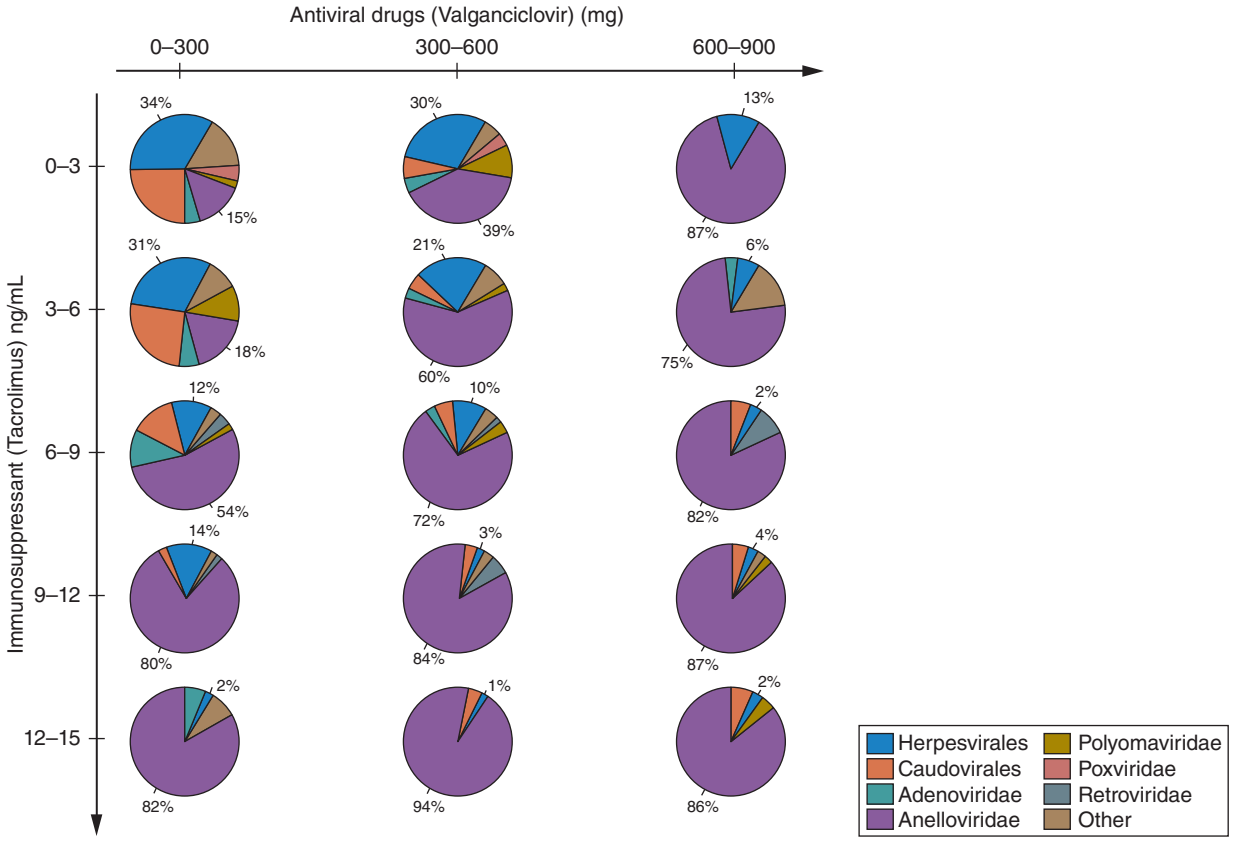

FIGURE 503-6 Relative viral genomic abundance as a function of drug dose in a cohort of heart and lung transplant recipients. Mean virome composition for patients treated with the immunosuppressant tacrolimus (47 patients, 380 samples) as a function of antiviral drug dose (valganciclovir) and concentration of tacrolimus measured in blood. To account for the delayed effect of the virome composition on drug dose, the data on drug doses were window average filtered (window size, 45 days). Herpesvirales and caudovirales dominate the virome when patients receive low doses of immunosuppressants and antiviral drugs. Conversely, anelloviridae dominate the virome when patients receive high doses of these drugs. *(Reproduced with permission from I De Vlaminck et al: Temporal response of the human virome to immunosuppression and antiviral therapy. Cell 155:1178, 2013.)*

demonstrated dramatic changes in the viral composition of the microbiome in response to introduction and weaning of immunosuppressive and antiviral therapies after transplantation.

Using a similar approach, De Vlaminck and colleagues analyzed nonhuman cfDNA as a hypothesis-free approach to test for infectious complications after lung transplantation. They showed that levels of cytomegalovirus-derived sequences in cfDNA correlated well with clinical testing results (AUC 0.91). They also identified adenovirus, polyomavirus, herpesvirus, and microsporidia sequences in patients with clinical infections that had eluded diagnosis, suggesting that cfDNA sequencing can be a powerful approach for nonbiased diagnosis of opportunistic infections after transplantation. However, several obstacles to clinical implementation must first be overcome, including the establishment of pathogen-specific thresholds to discriminate between colonization, infection, and disease.

MONITORING HOST IMMUNITY

As mentioned previously, De Vlamink and colleagues demonstrated that the *Anelloviridae* family of viruses predominated in the virome of lung transplant recipients, as analyzed by plasma cfDNA sequencing, and accounted for 68% of the total viral population. The relative abundance of anellovirus cfDNA is exquisitely sensitive to immunosuppression, ranging from <5% prior to transplant (e.g., in the nonimmunosuppressed state) to 84% during months 4.5–6 after transplantation, when immunosuppression is most profound. Starting at 6 months after transplantation, the relative amount of anellovirus cfDNA declines, corresponding to a reduction in intensity of immunosuppression **(Fig. 503-7)**.

The observation that anellovirus cfDNA levels rise and fall with degree of immune system suppression gave rise to the hypothesis that the abundance of this ubiquitous family of viruses could be used as a marker of the overall strength of the immune response. Indeed, a global marker of the net state of immunosuppression has eluded transplant physicians to date, who currently quantify doses and levels of individual immunosuppressive drugs but cannot reliably assess for their effect or potency in combination. In support of this hypothesis was the subsequent observation that anellovirus load was lower (reflecting less immunosuppression) in lung transplant recipients who developed acute rejection and was relatively high (indicating more profound immunosuppression) in patients who had a rejection-free posttransplant course, suggesting that the anellovirus cfDNA load could be a surrogate marker of immunocompetence.

Subsequent studies have confirmed these observations after different solid organ transplant procedures **(Fig. 503-8)**. A prospective lung transplant study showed a hazard ratio (HR) of 5.05 for infectious complications and an HR of 0.48 for acute rejection with every $\log_{10}$ increase in anellovirus load. Similar results have been shown after liver and kidney transplantation, with higher anellovirus levels associated with opportunistic infections and malignancy (sequelae of chronic immunosuppression) and lower levels associated with acute rejection and chronic allograft dysfunction. Prospective studies that aim to assess the potential of anellovirus levels to predict immune-related adverse events and to guide dosing of immunosuppressive medications in kidney transplant recipients are ongoing.

In summary, cfDNA sequencing has myriad clinical applications after solid organ transplantation. Donor-derived cfDNA assays are currently available for acute rejection monitoring and are being used for noninvasive surveillance after heart, lung, and kidney transplantation. These assays are highly sensitive, provide early detection of allograft injury, and can also be used to monitor response to rejection therapy. cfDNA sequencing can also be used to monitor changes in the microbiome after transplantation, in response to alterations in

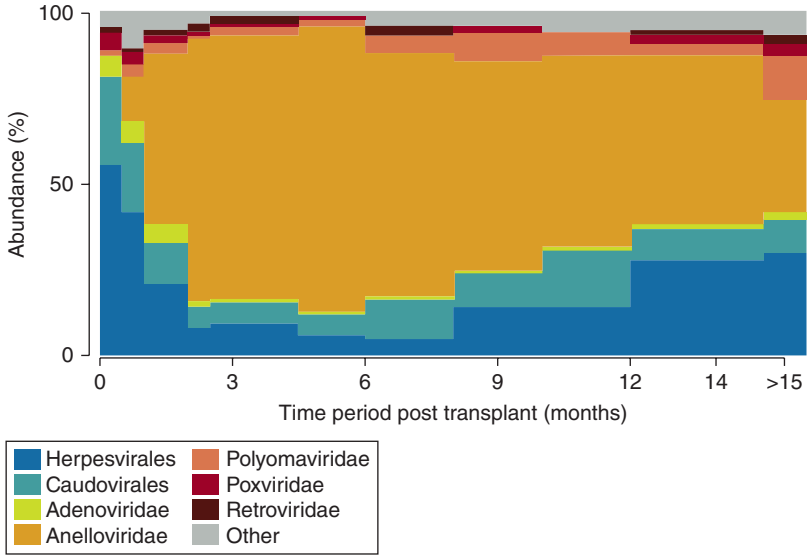

FIGURE 503-7 Viral genome abundance at the family and order level of taxonomic classification for different time periods after heart and lung transplantation. The fraction of anelloviridae expands rapidly in the first several months after transplantation. The fractions of herpesvirales, caudovirales, and adenoviridae decrease in that same time period. After 6 months, the opposite trends are observed. *(Reproduced with permission from I De Vlaminck et al: Temporal response of the human virome to immunosuppression and antiviral therapy. Cell 155:1178, 2013.)*

immunosuppression and antimicrobial therapy, and can potentially be used to diagnose opportunistic infections. Finally, quantification of anellovirus cfDNA load offers the possibility of assessing the overall status of the host immune response, which is a necessary first step for providing individualized immunosuppressive therapy to transplant recipients.

CELL-FREE DNA IN PRENATAL MEDICINE

Fetal genetic disorders are among the leading causes of stillbirth, neonatal death, and long-term developmental delay. Prenatal diagnosis of fetal genetic conditions relies on invasive sampling of fetal tissues via either amniocentesis (sampling of amniotic fluid) or chorionic villus sampling (CVS; sampling of placental tissue). Prenatal diagnostic tests are invasive, ultrasound-guided, needle-based procedures that unfortunately carry a small risk of miscarriage, preterm rupture of the membranes, and preterm birth. Historically, safe noninvasive screening for fetal genetic disorders, particularly aneuploidy (chromosomal copy number abnormalities such as trisomy 21 or Down's syndrome), was performed by combining maternal serum analyte levels (e.g., pregnancy-associated plasma protein A [PAPP-A], β-human chorionic gonadotropin [β-hCG], α-fetoprotein [AFP], inhibin) with first-trimester sonographic assessment of the fetal nuchal translucency (a measurement of the distance between the scalp and skin in the area of the fetal neck). While traditional prenatal screening is safer than invasive diagnostic tests, these modalities suffer from lower detection rates and higher false-positive rates. Advances in cell-free fetal DNA (cfDNA) technology have introduced safe noninvasive prenatal tests with much higher accuracy than traditional screening. Today, cfDNA tests have moved beyond fetal aneuploidy screening, to include fetal microdeletion and duplication syndromes and even single-gene disorders. Moreover, cell-free RNA in maternal serum has recently become a target for technologies aimed at predicting adverse pregnancy outcomes including preterm birth and preeclampsia. This section describes the use of cell-free fetal nucleic acid testing in prenatal medicine.

NONINVASIVE PRENATAL TESTING FOR FETAL ANEUPLOIDY

Passage of fetal cells into the maternal bloodstream was initially described almost 80 years ago. A mismatch between fetal red blood cells and maternal red blood cells was subsequently identified as the cause of isoimmunization and hydrops fetalis, a potentially lethal condition in which maternal antibodies develop against "foreign" fetal red blood cell antigens. With the development of Rho(D) immune globulin (RhoGAM) and its use to prevent RhD isoimmunization in RhD-negative mothers carrying RhD-positive pregnancies, attention then turned toward targeting fetal red blood cells for the detection of fetal aneuploidy. This is because fetal red blood cells contain a nucleus and genomic material, whereas maternal red blood cells do not. Unfortunately, initial research endeavors in the area failed to yield significant results due to several inherent limitations. First, the number of fetal red blood

cells circulating among the more prevalent maternal red blood cell background is quite small. Second, the half-life of the circulating fetal red blood cells in maternal serum was found to be quite long, and circulating cells may actually originate not just from the current pregnancy but even from a prior pregnancy. Finally, the technology available at the time, namely fluorescent-activated cell sorting, was unable to accurately separate the cells to isolate the fetal cells from the maternal background.

In 1990, Lo and colleagues determined that cfDNA, and not just fetal cells, crosses the placenta and could serve as a target for fetal aneuploidy detection. This was subsequently confirmed when the presence of DNA from the Y chromosome was found in the serum of pregnant women carrying a male fetus. Over the next two decades, cfDNA circulating in maternal blood was characterized, and different genetic techniques were employed to delineate differences between fetal DNA and cell-free maternal DNA. Cell-free fetal DNA has several advantages as a diagnostic target over circulating fetal cells. First, the fraction of fetal DNA is much higher (~5–20%) than the fraction of fetal cells in maternal circulation. Second, the level of cfDNA declines within days of delivery, thereby reducing the risk of DNA from previous pregnancies leading to erroneous results.

Unfortunately, in the case of fetal aneuploidy detection, the actual sequence of fetal DNA from the chromosome of interest is identical to the maternal DNA sequence, and the challenge is to distinguish one from the other. In the early 2000s, the most promising technique for distinguishing fetal from maternal DNA was leveraging epigenetic differences between the two, particularly in the chromosomes of interest, namely chromosome 21 and chromosome 18. In 2008, two landmark studies, one by Chiu and colleagues and one by Fan and colleagues, described the utility of massive parallel sequencing technology as a counting method for noninvasive detection of fetal aneuploidy. This sequencing technology allowed for a comparison of the number of sequencing reads from chromosome 21 against an expected reference number of reads. In other words, if more sequences from chromosome 21 were found in maternal serum than what one would expect, the fetus was suspected of having Down's syndrome. While these findings were based on analysis of limited cohorts, subsequent trials in more robust and diverse cohorts confirmed these findings, and cfDNA testing became an approved clinical test in 2011.

While the initial focus of cfDNA testing was on pregnant women at high risk for fetal aneuploidy (e.g., advanced maternal age, high-risk status based on serum analyte screening, presence of fetal structural anomalies), subsequent studies confirmed the utility of cfDNA technology in both high-risk and low-risk cohorts, opening the path for widespread clinical adoption. Over time, it became clear that while the sensitivity for detecting trisomy 21 using cfDNA is high (>99%), the sensitivity for detecting trisomy 18 and 13 is slightly lower, and the positive predictive value of these tests varies by the chromosome of interest, as well as a priori risks including maternal age. Given the variable sensitivity and positive predictive values of these tests, and the fact that most societal guidelines recommend confirmatory diagnostic testing with amniocentesis of CVS in cases of positive testing, these tests are often labeled as "noninvasive prenatal screening" (NIPS) or "noninvasive prenatal testing" (NIPT), rather than "noninvasive prenatal diagnosis" (NIPD). That said, since all three terms are still used, much confusion remains among both patients and providers as to the accuracy of these tests and their inherent limitations. Today, cfDNA testing is offered by private companies, state-wide prenatal testing initiatives, and several public nationwide screening programs around the world.

NONINVASIVE PRENATAL TESTING FOR SEX CHROMOSOME ANEUPLOIDY AND RARE AUTOSOMAL TRISOMY

The accuracy (sensitivity and positive predictive value) of NIPT for the sex chromosome aneuploidies (e.g., 45,X, 47,XXY, 47,XXX, and 47,XYY) is even lower than that for the common autosomal aneuploidies. This is largely because of differences in sex chromosome mosaicism in the fetus, placenta, and even the pregnant mother. Therefore, sex chromosome testing is sometimes offered separately from autosomal aneuploidy testing, and specific pretest counseling regarding the differences in test performance is warranted.

Rare autosomal trisomy (RAT), trisomy in an autosome other than chromosome 21, 18, or 13, occurs in <1% of all pregnancies. Many RATs are usually associated with spontaneous miscarriage, but mosaic RAT has been associated with adverse pregnancy outcomes including fetal growth restriction. Since mosaic RAT can also be associated with normal outcomes, there is no universally accepted recommendation as to whether RAT should be reported by NIPT.

DEPENDENCE ON FETAL FRACTION

As clinical experience with NIPT grew, it became clear that the accuracy of the test depends on the fraction of fetal DNA in maternal serum. While fetal DNA can be found in maternal serum as early as 4–5 weeks' gestation, the fetal fraction increases with gestational age, and most NIPT programs recommend testing after 10 weeks' gestation. Although each NIPT company or national NIPT program uses a different fetal fraction cutoff to accurately report a result, a small percentage of patients will receive a "no call" or uninterpretable result due to low fetal fraction. Factors leading to "no call" also include early gestational age (usually <10 weeks), maternal obesity, underlying maternal autoimmune disease or malignancy, and vanishing twin (twins in which one fetus demises early in gestation). Several studies suggested an association between a no-call result and increased risk for aneuploidy, and the appropriate management of a no-call result remains controversial, with some recommending a repeat NIPT test, while others recommend invasive diagnostic testing given the increased aneuploidy risk.

NIPT IN MULTIPLE GESTATIONS

While initial results questioned the utility of NIPT in multiple gestations, more recent reports from large cohorts have shown that the aneuploidy detection rate in twin gestations mirrors that in singletons. Moreover, many NIPT programs report zygosity in cases of multiple gestations. This is particularly important since one would assume that NIPT results from monozygotic twins (twins originating from a single embryo) would indicate the presence of euploidy or aneuploidy in both twins, and zygosity testing is also important when the number of placentas has not been determined or remains unclear based on sonography. Monochorionic twins (all of whom are monozygotic twins) are considered higher risk than dichorionic twins (most of whom are dizygotic twins but can also be monozygotic twins) and are managed differently. Newer NIPT platforms can also distinguish the presence of aneuploidy in a single fetus in cases of dizygotic twins. The data on the accuracy of NIPT in triplet gestations or multiple gestations in which a single fetal reduction or early fetal loss occurs are more limited.

NIPT FOR FETAL MICRODELETION/ DUPLICATION SYNDROMES

Advanced molecular technologies, particularly chromosomal microarray (CMA), are now the preferred diagnostic method when performing amniocentesis or CVS, particularly in the setting of a known fetal anomaly or fetal growth restriction. Unlike traditional karyotype, which relies on the visual assessment of chromosomes by a cytopathologist with a resolution of ~5–10 MB, CMA is an automated molecular technique that can identify differences as small as a single nucleotide. The main benefit of CMA over traditional karyotype is in its ability to detect copy number variants such as microdeletion/duplication syndromes (e.g., 22q11 microdeletion or DiGeorge's syndrome). Although the focus of NIPT was initially on the prenatal detection of fetal aneuploidies, the potential for NIPT to detect smaller chromosomal rearrangements, including copy number variations (CNVs), was recently evaluated and introduced into clinical care. This is important because CNVs carry a significant neonatal disease burden, and the risk of such variants may be more common than trisomy 21 among young pregnant women. Unfortunately, the detection rates for such conditions by NIPT are not as robust as they are for aneuploidy detection, and the positive predictive values are lower. Moreover, because most cfDNA originates from the placenta (syncytiotrophoblast cells), there is concern that confined placental mosaicism may result in erroneous NIPT results

that target smaller genomic aberrations. High false-positive rates may lead to unnecessary parental anxiety, increased rates of invasive confirmatory testing, and pregnancy termination. Prenatal testing companies and programs offer testing for 22q11 microdeletion syndrome, Prader-Willi syndrome, Angelman syndrome, 1p36 deletion syndrome, and 5p– syndrome (cri du chat syndrome).

WHOLE GENOME NIPT AND SINGLE-GENE DISORDERS

Most NIPT platforms use next-generation sequencing to obtain DNA reads covering the entire genome but only report a fraction of the sequences analyzed. This has led to a debate as to whether whole genome NIPT should be offered and reported. Furthering the debate is the clinical incorporation of whole exome sequencing and even whole genome sequencing into testing of fetal samples obtained by amniocentesis and CVS, particularly in the setting of fetal anomalies, when CMA reports are inconclusive. As with any robust and comprehensive test, questions regarding false-positive rates and abnormalities of unclear significance are being considered. Also, whether to limit the results to known disease-causing mutations remains controversial.

While whole genome NIPT is being considered, NIPT platforms targeting single-gene disorders have been recently developed, and these are slowly becoming clinically available. This is a significant advance because expanded maternal carrier screening of single-gene disorders is becoming more prevalent, with clinically available comprehensive gene panels covering hundreds of potential disease loci. In the absence of NIPT, couples deemed at risk based on maternal and/or paternal carrier screens (e.g., an asymptomatic couple in which both parents are heterozygous for an autosomal recessive gene mutation such as cystic fibrosis) would need to undergo an invasive diagnostic procedure in order to confirm or exclude a significant fetal condition (homozygous for an abnormal cystic fibrosis gene).

NIPT USING CELL-FREE RNA

Cell-free fetal DNA is not the only nucleic acid found in maternal serum. Cell-free fetal RNA is also present, providing a unique snapshot of which genes are being transcribed at any given time in pregnancy. Cell-free fetal RNA can also be linked to tissue-specific genes, offering a unique window into developing fetal organs. Moreover, serial analysis of the pregnancy transcriptome and comprehensive analysis of cfRNA in maternal serum over time have been studied as means of early detection of common third-trimester obstetric complications including preeclampsia, fetal growth restriction, and spontaneous preterm birth. Translational studies have shown that changes in circulating cfRNA may be detected as early as the first trimester, offering an opportunity to identify high-risk pregnancies months before the onset of clinically evident disease.

NIPT DETECTING MATERNAL MALIGNANCY

Maternal malignancy complicates approximately 1 in 1000 to 1 in 1500 pregnancies. Common cancers include hematologic, breast, and gynecologic cancers, including cancers of the cervix and ovary. Because next-generation technologies sequence both maternal and fetal DNA, changes in DNA levels may not only indicate fetal disorders but also maternal disease. While most uninterpretable NIPT tests result from low fetal fraction or other fetal and/or placental conditions, a small subset may be due to undiagnosed maternal malignancy. Presence of multiple aneuploidies or autosomal monosomies has been reported by NIPT with occult maternal malignancies, and cases of maternal lymphoma, leukemia, gastrointestinal malignancy, and neuroendocrine tumors detected incidentally by NIPT have been described in the literature.

BEYOND NEXT-GENERATION SEQUENCING

While most NIPT platforms use next-generation sequencing technology, some studies have analyzed the utility of digital PCR and fetal cell analysis for NIPT. Digital PCR has been described as a useful tool for testing pregnancies at risk of X-linked and autosomal recessive single-gene disorders for both single mutations and compound heterozygous mutations. Although original attempts to isolate circulating fetal cells were abandoned >20 years ago, recent advances have led to new technologies targeting both circulating fetal nucleated red blood cells and trophoblasts. This progress, still in the research phase, suggests that it may be possible to identify and isolate single cells as early as the first trimester and analyze them by whole-gene genome amplification followed by copy number analysis using arrays or next-generation sequencing. Analysis of fetal cells would also allow for fetal gene expression profiling.

SUMMARY

Collectively, the uses described in this chapter summarize some of the myriad clinical applications of liquid biopsy methods including cfDNA profiling in oncology, transplantation medicine, and obstetrics. For each area, several existing assays have enabled transformative approaches to noninvasive diagnosis of disease, assessment of associated risk, and assessment of therapeutic responses. For example, several tumor-derived cfDNA assays are currently available for early cancer detection, noninvasive genotyping, response assessment, and MRD monitoring across diverse cancer types. Liquid biopsy assays for oncology can provide highly sensitive measures of tumor burden and associated risk and can also be used to monitor response to anticancer therapies. Prominent among applications of liquid biopsies is the detection of MRD following definitive therapy for solid cancers as a strongly prognostic biomarker with very high positive predictive value for risk of recurrence. Similarly, cell-free nucleic acids have transformed transplantation medicine. Rising levels of donor-derived cfDNA can indicate acute allograft rejection, and clinical dd-cfDNA assays are now being used for noninvasive rejection surveillance in lieu of invasive biopsy procedures. Microbial cfDNA analysis can potentially be used to screen for opportunistic infections after transplantation and for the hypothesis-free diagnosis of posttransplant infections, and such clinical assays are currently in development. Moreover, quantification of particular microbial cfDNA sequences, such as that of the *Anelloviridae* family, could one day enable transplant physicians to assess the overall status of the alloimmune response—a goal that could enable personalization of immunosuppressive therapy to maximize efficacy and to prevent the long-term toxicities associated with these medications. Finally, detection of cell-free fetal or placental DNA has improved the prenatal detection of fetal aneuploidy and other genomic abnormalities. Accordingly, the potential of these liquid biopsy techniques is rapidly expanding and places us at the cusp of a revolution in personalized management of patients across medical disciplines using innovative noninvasive techniques.

504 Protein Folding Disorders

Richard I. Morimoto, G. Scott Budinger

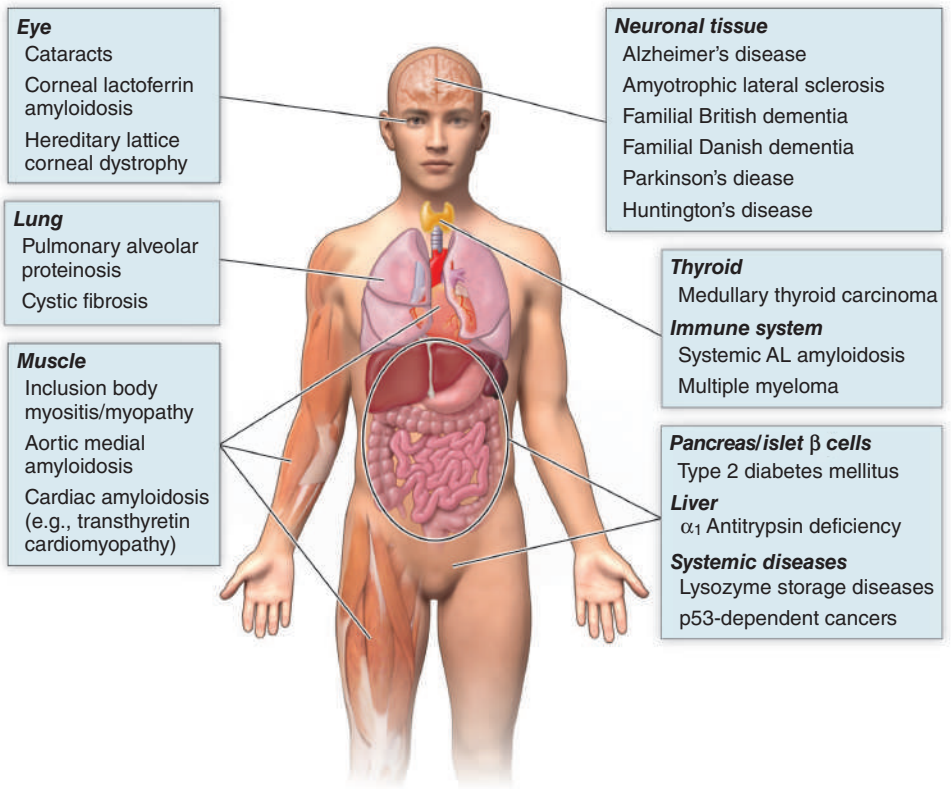
Many hundreds of human diseases, collectively known as protein conformational diseases or protein folding disorders, result from protein misfolding due to intrinsic and extrinsic errors amplified by aging and exposures to environmental and physiologic stress conditions. Such events challenge the functional integrity of the proteome and can lead to dysfunction, enhanced aggregation of proteins, mislocalization, and premature or inhibition of protein clearance, thus affecting cellular robustness, health, and longevity. Mismanagement of the proteome is therefore the basis of a broad class of diseases that includes orphan lysosomal storage diseases, type 2 diabetes mellitus, cystic fibrosis, some fibrotic diseases, metabolic diseases, muscle-wasting diseases, cancer, and neurodegenerative diseases exemplified by Alzheimer's disease, frontal temporal dementia, Parkinson's disease, amyotrophic lateral sclerosis (ALS), and Huntington's disease (Fig. 504-1). For each of these diseases and many others described in this textbook, aging is the major contributing risk factor.

The challenge at the biochemical and molecular level is for the cell to achieve and maintain a stable and functional proteome during development that persists through young adulthood and is maintained throughout aging. For humans, this is essential for the operational health of each of the tens of trillions of cells that comprise our ~80 organs for health span and lifespan. To achieve this, our cells have evolved a remarkably efficient proteostasis network (PN) composed of ~3000 molecular chaperones and other highly conserved components essential for protein synthesis, folding, translocation, and degradation (Fig. 504-2) that balances input with output and ensures that every protein is functional. The PN is, therefore, essential for the robustness of all tissues and for the diverse protein-protein interactions in cell signaling, biosynthetic processes, and the structural demands and mechanical requirements for tissue shape and function. An equal, if not more important, role for the PN is to detect, prevent, and remove misfolded and aggregated proteins that accumulate in stress, aging, and disease and interfere with cellular health. Understanding how proteostasis is achieved and maintained is of fundamental biological interest and essential to prevent age-associated protein folding disorders. Consequently, there is tremendous interest in the detection and treatment of these diseases, in particular as the human population continues to live longer.

All organisms express an evolutionarily conserved set of molecular machines for the synthesis, folding, transport, and removal of unnecessary and damaged proteins. The PN is adapted for the highly specific physiologic requirements of tissues and the expression of abundant and rare proteins with wide-ranging solubilities, folding requirements, stability, and structural demands. Added to this complexity of natural clients for the PN is the additional load generated by genetic mutations carried in natural populations together with diverse environmental stressors that challenge PN capacity. Despite the central role of proteins as the workhorse of the cell, they are also highly susceptible to molecular damage, whether due to intrinsic metastability or to genetically inherited mutation or error-prone synthesis. Hence, dysfunction in the PN may clinically manifest as a gradual decline in homeostatic function in aging as occurs with genetic mutations or a loss of resilience in the face of environmental stressors. Thus, clinicians see the consequences of proteostasis failure and cellular dysfunction in both the myriad disorders that present to physicians as age-associated clinical problems and the increased morbidity and mortality associated with trauma, infection, and other acute illness requiring hospitalization in older individuals.

PROTEIN QUALITY CONTROL MECHANISMS

The PN monitors and controls the flux of protein synthesis to promote functional folding and to minimize the accumulation of off-pathway aggregation-prone intermediates by their selective disaggregation or degradation. However, unlike an automobile assembly plant for which each part is designed and engineered for a specific use and precise assembly, the PN has built-in functional redundancy with properties to tolerate tremendous chemical noise and sequence diversity generated by coding region polymorphisms and biosynthetic errors among its client components. The PN has the ability to recognize and remove kinetically unstable conformational states of proteins that accumulate in aging and that would otherwise compromise assembly and function. Proteins are highly sensitive to fluctuations in their intracellular environment caused by shifts in energetics, pH, and oxidizing and reducing conditions in addition to the myriad small molecules and metabolites that affect folding and function. Added to changes are the effects of external stress conditions caused by elevated temperatures, infection, oxidizing and reducing environments, or osmolytes that can have profound consequences on protein folding thermodynamics, kinetics, and function. These intracellular and extracellular stress conditions, if not properly responded to, are predicted to further amplify protein instability from sequence polymorphisms and biosynthetic errors that contribute to the stress of protein misfolding. The PN is organized at the cellular level into a series of highly coordinated molecular machines that direct the expression, biogenesis, and functional health of essentially all



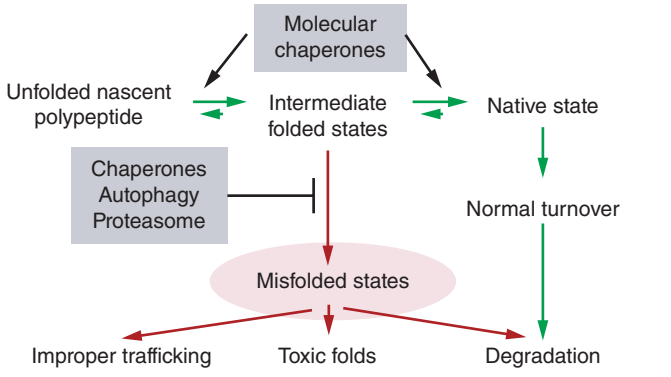


FIGURE 504-1 Diseases of protein folding. A representative list of tissues affected and known folding diseases.

Emphysema	*Amyloidoses*	*Cystic Fibrosis*
α_1 Antitrypsin	Abeta, tau, Huntington, SOD1, α-synuclein	Cystic fibrosis transmembrane conductance regulator

FIGURE 504-2 The proteostasis network (PN) and folding diseases. Protein biogenesis through the action of molecular chaperones ensures the transition of the nascent polypeptide to on-pathway intermediates and the folded functional native state. Such proteins then have a normal turnover mostly through the ubiquitin-proteasome system. Off-pathway species are prevented by the actions of chaperones and the recognition of nonnative misfolded states by the autophagic-lysosomal pathway and the ubiquitin-proteasome system. When misfolded species escape quality control or overwhelm the PN, they can then become improperly trafficked as occurs for α_1 antitrypsin associated with emphysema; for toxic folds as occurs for abeta, tau, Huntington, and SOD1 in amyloidogenic neurodegenerative diseases; and prematurely degraded as occurs for CFTR associated with cystic fibrosis.

proteins (Fig. 504-2). More than to regulate and orchestrate these highly synchronized events, the PN is essential for protein quality control and for the prevention of the appearance of off-pathway conformational states and condensates, with accumulation of aggregates and amyloid species. Proteome health involves the constant exchange between the intrinsic physicochemical properties of polypeptides and the biological milieu of the cellular environment in which protein sequences and function evolved.

Beginning with the synthesis of the nascent polypeptide on the ribosome, ribosome quality control (RQC) together with cytoplasmic chaperones of the HSP70, HSP90, DNAJ/HSP40, chaperonin/HSP60, and small HSPs (sHSPs) family ensure co- and posttranslational folding for the cell. Approximately 60% of the proteome resides in the cytoplasm and nucleus, for which the RQC, HSP70, HSP90, and HSP60 chaperones together with co-chaperones regulate the folded state of client proteins through cycles of ATP binding and hydrolysis. Chaperones of the HSP70 and J-domain family are particularly well studied for their ability to interact transiently with short dispersed hydrophobic regions of nascent polypeptides using the energy from nucleotide hydrolysis to regulate the release of partially folded intermediates that either reenter the chaperone cycle or are released in a folded native state. For other chaperone clients, such as transcription factors, kinases, phosphatases, and signaling molecules, their folding to the functional state is highly regulated and dependent upon interactions with the HSP90 chaperone and other regulatory co-chaperones to form stable heteromeric complexes that hold the client in a partially folded state primed for subsequent regulated release.

Consistent with the recognition that the formation of off-pathway aggregates is a kinetic component of proteostasis are the concerted activities of chaperone machines with disaggregase activity that unravel protein aggregates for refolding. These disaggregases include the AAA^+ protein, ClpB in bacteria, Hsp104 in yeast and plants, and the functionally analogous metazoan disaggregase composed of HSP70, HSP110, and specific J-domain proteins.

The subcellular organelles mitochondria and endoplasmic reticulum (ER) account for ~20% of the proteome. Chaperone interactions are essential for mitochondrial-targeted proteins to maintain the extended polypeptide chain in a recognition-competent state for the organellar receptors for translocation across membranes. Upon import, each translocated polypeptide is met by organellar-specific chaperones of the HSP70 and J-domain family for folding and assembly. While the mitochondrial genome encodes 13 proteins required for electron transport, the great majority of mitochondrial proteins are encoded by the nuclear genome, synthesized in the cytosol, and imported across the outer and inner mitochondrial membrane. Hence, maintenance of the mitochondrial proteome relies on the coordinated efforts of both the cytosolic and mitochondrial PN. For translocation into the lumen of the ER, the extended polypeptide interacts with a set of glycosyltransferases, calnexins, calreticulins, disulphide isomerases, and lumen localized chaperones. Proteins that misfold in the ER are recognized and retro-translocated to the cytoplasm where they are directed to the ubiquitin-proteasome system (UPS) for unfolding, ubiquitination, and degradation.

The PN is balanced by the essential catabolic processes of the UPS and the autophagy-lysosomal pathway (ALP), which recognizes proteins for degradation and recycling. The UPS is generally considered the primary pathway by which most proteins are recognized and tagged for degradation, and the ALP is highly responsive to nutrient deprivation and damage to recognize large aggregates and inclusions and engulf organelles and other subcellular compartments. In addition to their role in the regulated turnover of cellular proteins, these degradation systems are essential for protein quality control and for limiting the accumulation of misfolded and aggregated proteins during stress conditions, aging, and disease. Protein turnover by the UPS involves an enzymatic cascade of E1, E2, and E3 enzymes that utilize ubiquitin and the recognition selectivity of E3s to tag clients, followed by degradation of the polyubiquitinated substrates by the 26S proteasome in the cytoplasm. Client specificity involves the large family of ~750 ubiquitin E3 ligases. In addition to their role of marking proteins for degradation, the ubiquitination machinery has numerous additional functions in cellular processes. For example, the ubiquitin ligase listerin is associated with the ribosome to ubiquitinate nascent chains that stall during protein synthesis to prevent the accumulation of aberrant polypeptides that would subsequently aggregate. Ubiquitination of nonnative aggregated clients by the ubiquitin ligase activity of the cochaperone carboxyl terminus Hsc70 interacting protein (CHIP) is central to the triage decision of the HSP70/HSP90 complex between client folding and proteasome-mediated degradation. ER-targeted clients that are misfolded are retro-translocated to the cytoplasm where they are polyubiquitinated and degraded by cytosolic proteasomes in a process termed ER-associated degradation (ERAD). Ubiquitination also provides crosstalk between the proteasome and autophagy pathways by targeting clients for lysosomal degradation and for endosomal sorting. Chaperones co-label a protein as damaged, recruiting other proteins that place ubiquitin chains on the damaged protein for degradation by the proteasome. Alternatively, chaperones can label proteins or protein aggregates to target them to the lysosome, and in this process, damaged proteins are degraded by the lysosome, an intracellular organelle with an acidic environment enriched in proteases through autophagy.

While there is a comprehensive understanding of the process of in vivo chaperone-dependent protein folding, the details of how these decisions are made for each client, whether and for how long to be maintained in a nonnative folding state through chaperone interactions in a nucleotide-independent state, or how to assemble into a stable chaperone complex for subsequent assembly into a functional state or to interact with chaperones to directly fold to a native state remain to be fully addressed.

CELL STRESS RESPONSES: SENSORS AND REGULATORS OF PROTEIN DAMAGE

Cell stress responses are ancient genetic networks that detect, adapt, and protect all cells against toxic environmental stressors and physiologically relevant changes in their cellular environment, including changes induced during development and tissue repair after injury **(Fig. 504-3)**. At the core of these cell stress responses are molecular switches: (1) the heat shock response (HSR) that protects proteins in the cytoplasm and nucleus regulated by HSF-1; (2) the unfolded protein response (UPR)

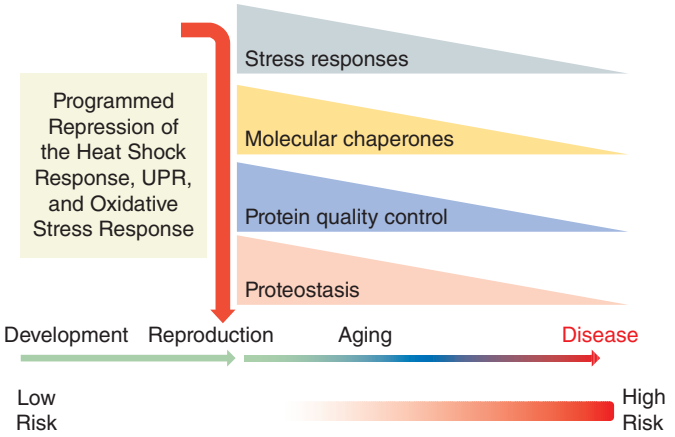

FIGURE 504-3 Aging and protein folding diseases. Aging is the major risk factor for degenerative diseases. Cell stress responses (heat shock response and the unfolded protein responses [UPR] in the endoplasmic reticulum and mitochondria) decline at reproductive maturity in studies from *Caenorhabditis elegans* and prevent adaptive and protective increased expression of molecular chaperones to prevent protein misfolding.

of the ER (UPR^{ER}) controlled by XBP1, ATF6, and ATF4; (3) the UPR of the mitochondria (UPR^{mt}) controlled by ATFS1; (4) the DAF-16/FOX-O stress response pathway associated with insulin signaling; (5) the integrated stress response (ISR) controlled by PERK, PKR, HRI, GCN2, and ATF4; and (6) the antioxidant stress response regulated by NRF-2. Collectively, these cell stress responses and their respective transcription factors (TFs) are essential for all cells and tissues regulated both autonomously and cell nonautonomously across tissues in metazoans to detect proteotoxic stress, to adapt and protect the cell against the toxic consequences of protein damage, and to regulate changes in the proteome necessary for differentiation. While each of these cell stress pathways can be activated independently, they are also induced in different combinations according to the chemical and physiologic properties of the stress signal(s) and provide cross-protective mechanisms.

The HSR is an evolutionarily conserved cellular defense mechanism that protects cells against proteotoxicity associated with misfolding, aggregation, and proteome mismanagement. HSF-1 inducibly regulates the transcription of genes encoding molecular chaperones and components of the PN. In unstressed cells, HSF-1 exists in an inert monomeric state in the cytoplasm or nucleus where it is negatively regulated by the molecular chaperones, HSP70 and HJD-1. Upon exposure to heat shock, HSF-1 undergoes a series of molecular transformations and rapidly trimerizes to acquire DNA-binding activity, undergoes extensive posttranslational modifications by phosphorylation and sumoylation, binds to heat shock elements in promoters of heat shock responsive genes, and associated with these events, forms nuclear stress bodies. Upon dissipation of the stress signal, the HSR attenuates by the active repression of HSF-1 DNA binding by acetylation and loss of HSF-1 transcriptional activity. This is accomplished by binding of HSF-1 with HSP70, HDJ-1, and HSBP1, leading to its dissociation from the trimer to the monomeric state. In addition to HSF-1 being essential for the HSR and cell and organismal stress resilience, HSF-1 is essential during early development in metazoans, functions as a maternal factor for gametogenesis, regulates oocyte maturation by activating genes that function in the meiotic cell cycle, is constitutively activated in cancer, and is necessary to maintain NAD^+ and ATP levels.

In the ER, the UPR^{ER} involves three stress response arms regulated by the transcription factors XBP1, ATF6, and ATF4 that bind to specific cis- elements for these ER-stress-responsive pathways. XBP1 is activated by IRE1, which is a transmembrane protein with kinase and endoribonuclease (RNase) activity that senses misfolding in the ER directly, leading to its autophosphorylation, oligomerization, and acquisition of RNase activity. This allows active IRE1 to cleave *XBP1* mRNA, generating a spliced transcript (*XBP1s*) that encodes XBP1 to induce the transcription of UPR target genes. ER stress also promotes the relocalization of ATF6 from the ER membrane to the Golgi apparatus, where it is cleaved by the proteases SP1 and SP2, generating a cytosolic fragment of ATF6 that translocates to the nucleus to direct transcription of a complementary set of UPR genes. Together, XBP1 and ATF6 induce the expression of genes involved in protein folding, ER-associated protein degradation, and lipid metabolism. A third ER transmembrane protein, PERK, also induced by ER stress, phosphorylates the translation initiation factor eIF2α, linking activation of the UPR^{ER} with the ISR.

In the mitochondria, the UPR^{mt} response involves ATFS1, which contains a mitochondrial targeting sequence and a nuclear localization signal. Under normal cellular conditions, ATFS1 is imported into mitochondria and degraded, but upon mitochondria stress, ATFS1 is directed only to the nucleus to regulate transcription of genes encoding mitochondrial chaperones, mitochondrial import machinery, and glycolysis. In mammals, the UPR^{mt} is regulated by ATF5, which is the orthologue of ATFS1 in *Caenorhabditis elegans*. Inhibitors of mitochondrial electron transport in mammals also activate the ISR through the release of a protease OMA1 that cleaves a cytosolic protein DELE1 to activate HRI.

The ISR is induced by one or more of four kinases: PKR, PERK, HRI, or GCN2. All four of these kinases phosphorylate eIF2a, a key protein in the ternary complex that regulates protein synthesis. The resulting global inhibition of protein synthesis paradoxically promotes translation of mRNA molecules with specific sequences in their upstream open reading frames. These include the transcription factor ATF4, which induces the expression of a gene program that maintains metabolism to preserve stress resilience. Activation of ATF4 also induces its expression and the expression of *Ddit3* (CHOP), lowering the threshold for apoptosis, and *Gadd45a,* a phosphatase that dephosphorylates eIF2a to restore translation. The ISR is linked to ER stress through PERK and to mitochondrial stress through HRI. GCN2 is activated by amino acid deprivation, and PKR is activated during viral infection. Of particular note has been the development of ISRIB, a small molecule that partially inhibits the activity of the ISR with salutary effects across diverse animal models of age-related degenerative diseases. These findings suggest that cell stress pathways that are proteome protective in youth might become pathologic in aging, making them attractive targets for therapeutic intervention. Indeed, activation of the ISR has been shown to impair stem cell differentiation, perhaps linking mitochondrial dysfunction with aging, proteostasis, and stem cell dysfunction.

In metazoans, the integration of stress survival strategies includes the antioxidant factor SKN-1/NRF2, the insulin-signaling factor DAF-16/FOXO, and the tissue identity factor PHA-4/FOXA. Oxidative and xenobiotic stresses activate OxR, which controls the expression of redox-regulatory proteins and components of protein degradative pathways mediated in mammals by NRF1/NFE2L1 and NRF2/NFE2L2, which corresponds to SKN-1 in *C. elegans.* NRF1 is an ER-resident factor that undergoes regulated proteolytic cleavage upon activation to control expression of genes encoding subunits of the proteasome and the UPS. NRF2 in the cytoplasm is negatively regulated by the redox-sensitive ubiquitin ligase KEAP-1; consequently, inactivation of KEAP-1 by oxidative and electrophilic stress leads to stabilization and nuclear translocation of NRF2, which in turn induces the expression of antioxidant proteins and detoxification enzymes.

ORGANISMAL PROTEOSTASIS IN AGING AND DISEASE

Much of our understanding of protein quality control mechanisms has come from in vitro studies with purified molecular chaperones or components of the UPS, complemented with cell extracts and cell-based assays using yeast or mammalian tissue culture cells. A common theme that emerges from these studies is that of hormesis, in which chronic low-level activation of the HSR, UPR^{ER}, and UPR^{mt} is protective against subsequent exposures to extreme and lethal cell stress conditions.

The importance of these pathways is further highlighted by studies in metazoans that indicate that cell stress responses are regulated at the organismal level by neuronal signaling. At the organismal level in

C. elegans, the HSR, UPR^{ER}, and UPR^{mt} are regulated by cell-nonautonomous control by specific sensory neurons. When neuronal signaling is impaired, the HSR reverts to cell-autonomous control. Likewise, neuronal signaling regulates the UPR^{mt} with disruption of mitochondrial function in *C. elegans* neurons activating the UPR^{mt} in nonneuronal tissues, supporting a role for a mitokine signal. Perturbation of the mitochondrial electron transfer chain (ETC) was shown to increase lifespan in both invertebrates and rodents through the activation of the UPR^{mt}. The response to mitochondrial dysfunction in *C. elegans* depends on the severity of mitochondrial impairment, with a mild reduction of ETC or reduction of mitochondrial proteostasis having hormetic effects on organismal stress resilience, proteostasis, and longevity by resetting the cytoplasmic HSR through HSF-1, independent of ATFS-1 and the UPR^{mt}. Mild perturbation of the ETC in *Drosophila* muscle also has systemic benefits on organismal health and lifespan involving the insulin signaling pathway. Communication between neurons also regulates the UPR^{ER} in peripheral tissues of *C. elegans*. During infection of *C. elegans* by pathogens, induction of the UPR^{ER} in nonneuronal tissues is mediated by sensory neurons, suggesting an organismal stress response. Cell-nonautonomous regulation of the UPR^{ER} has also been observed in mice, where overexpression of active XBP1 in pro-opiomelanocortin neurons activates the UPR^{ER} in the liver.

Several other forms of intertissue communication regulate proteostasis with beneficial effects on organismal health in model organisms. For example, muscle cell proteostasis in *C. elegans* is regulated by cholinergic signaling across the synaptic junction through modulation of HSF-1 activity. Transcellular chaperone signaling between somatic tissues, and between somatic tissues and neurons, of *C. elegans* communicate proteotoxic stress signals via the tissue code factor PHA-4/FOXA to control systemic expression of HSP90. In *Drosophila*, overexpression of small HSPs only in the flight motor muscle cells protects neurons and glial cells from elevated temperature-induced death. Enhanced expression of DAF-16/FOXO in the intestine enhances proteostasis in distant muscle cells of *C. elegans*, and likewise, overexpression of dFOXO/4E-BP in *Drosophila* muscle influences proteostasis in retina, brain, and adipose tissues to delay the age-dependent accumulation of protein aggregates.

Cell stress responses and proteostasis decline in aging with insights on the relationships between processes coming primarily from studies using *C. elegans* with support from other invertebrate and vertebrate model systems and human cells. Endogenous metastable proteins that harbor temperature-sensitive properties misfold in *C. elegans* at the permissive temperature in early aging associated with a decline in the HSR. This functional decline of proteostasis in *C. elegans* aging is regulated by cell-nonautonomous control, from the germline stem cells to the somatic tissues for the programmed repression of the organismal HSR, resulting in the loss of stress resilience and proteostasis causing age-associated protein aggregation. This HSR repressive switch is regulated by signaling from the germline stem cells to the somatic tissues, resulting in the timed placement of repressive H3K27me3 chromatin marks at the promoters of heat shock genes, causing chromatin inaccessibility for HSF-1. This age-dependent decline in the HSR can be reversed either by blocking the signal from germline stem cell signal(s) or preventing the epigenetic repressive marks. The relationship between reproduction and inducibility of the HSR observed in animals at reproductive maturity suggests that the age-associated events of cellular failure and loss of tissue robustness during aging are not random processes but rather highly regulated, perhaps to ensure that somatic tissues are programmed to decline after reproduction, consistent with the germline soma theory of aging.

Proteostasis represents one of the primary hallmarks of the biology of aging, which together with genomic instability, telomere attrition, epigenetic alterations, deregulated nutrient sensing, mitochondrial dysfunction, cellular senescence, stem cell exhaustion, and altered intercellular communication provides a mechanistic basis for the aging process. The programmed decline of proteostasis in early adulthood would support the hypothesis that failure in protein quality control would have negative consequences on the other pillars of geroscience. Whether proteostasis collapse is the first to fail or among the earliest events that fail in aging, it is consistent with very large number of human degenerative diseases in aging associated with protein misfolding.

PROPERTIES OF PROTEIN FOLDING DISEASES

The complexity that arises with protein folding diseases is that all tissues are at risk and all proteins are at risk for misfolding and loss-of-function or gain-of-function proteotoxicity. Added to this is the effect of aging and that each protein folding disease exhibits a highly variable age of onset for pathology. There is additional complexity in classification regarding whether to organize folding diseases by tissues (i.e., muscle proteinopathies or neurodegenerative diseases), according to the specific protein that misfolds such as α_1-antitrypsin deficiency, or by the biophysical nature of the misfolded or aggregated species in amyloidoses.

Disorders in which a specific mutation leads to protein misfolding or the formation of a specific insoluble protein aggregate likely represent only the tip of the iceberg of protein folding disorders. Mutations in aggregation-prone proteins coupled with changes in the cellular environment and effects on the capacity of the PN will promote misfolding and aggregation in affected tissues. Chronic stress may cause the aberrant cell stress responses and protein quality control pathways, causing further collateral damage and aggregation of other at-risk proteins. Such a mechanism may only manifest clinically after a seemingly random systemic stress like pneumonia, large bone fracture, or ischemic vascular event, possibly explaining the rapid (1–2 years) accumulation of age-related morbidities in the year following a major biologic stress, marked by a need for hospitalization. As such, the age-related decline in the function of any of the components of the PN could underlie the compounding multiple morbidity that limits health span and lifespan in many elderly individuals. Within this framework, it is useful to discuss some of the better understood mechanisms of proteostasis dysfunction that have been causally linked to diseases in humans.

DISORDERS THAT ENHANCE CLIENT MISFOLDING AND CAUSE PREMATURE DEGRADATION (CYSTIC FIBROSIS)

Cystic fibrosis (CF) is a recessive disorder caused by mutations in both alleles of the cystic fibrosis transmembrane conductance regulator (*CFTR*) gene that encodes a multidomain membrane-spanning chloride ion channel protein. Thousands of mutations in *CFTR* have been identified that affect CFTR biosynthesis, folding, trafficking, and function, leading to chronic obstructive lung disease, intestinal obstruction, liver dysfunction, exocrine and endocrine pancreatic dysfunction, and male infertility. CF is a folding disease due to its recognition by the PN as misfolded protein. The most prominent mutation is deletion of phenylalanine 508 (*F508del*), present in ~90% of CF patients. Mutant ΔF508 retains partial channel function, but because it is recognized as misfolded in the ER and the cytoplasm, it is marked with ubiquitin for degradation by the UPS. Combinations of small molecules that protect the misfolded CFTR protein from degradation and enhance its function have led to substantial improved outcomes in many patients with CF **(Chap. 302)**.

DISORDERS THAT INDUCE TOXIC AGGREGATES AND LOSS OF FUNCTION IN MULTIPLE TISSUES (α_1-ANTITRYPSIN DEFICIENCY)

α_1-Antitrypsin deficiency (AATD) is a co-dominant inherited disease with an increased risk of chronic obstructive pulmonary disease, liver disease, and inflammation of the blood vessels. Pulmonary problems are more frequent in adults, whereas liver and skin problems may occur in adults and children. α_1-Antitrypsin is encoded by the *SERPINA1* gene and secreted into the circulation by the liver and is responsible for inactivating endogenous proteases, particularly those secreted by neutrophils and other inflammatory cells in the lung. Patients with AATD harbor mutations in *SERPINA1* that cause misfolding in the ER. The two major phenotypes resulting from this abnormality highlight

the diverse consequences of misfolding on different cells and organs. In the liver, misfolding of the mutant protein results in the formation of toxic aggregates and hepatocyte death, manifest as liver injury and eventually cirrhosis—a gain-of-function toxicity. In the lung, the failure to secrete sufficient α_1 antitrypsin may lead to unchecked proteolytic damage to the delicate architecture of the alveolus, a process that is markedly worsened when neutrophils are recruited to the lung in response to cigarette smoking. This loss-of-function phenotype manifests pathologically as emphysema and clinically as chronic obstructive pulmonary disease.

INTERACTIONS WITH PN COMPONENTS THAT CHANGE CONFORMATION, STABILITY, OR FUNCTION (CANCER)

Mutations in the tumor suppressor p53 are among the most common mutations observed in patients with cancer. Deletion of p53 combined with overexpression of an oncogene is sufficient to drive metastatic cancer formation in mice, causally linking p53 mutations with cancer. Normally, p53 functions as a transcription factor that suppresses the transcription of genes involved in apoptosis resistance. While myriad mutations in p53 have been described, some result in an alternate conformation that interacts with different HSP70 chaperones within the PN. Binding of the mutant p53 protein to these chaperones affects the DNA binding property necessary for its tumor suppressor function and facilitates binding to other domains, resulting in changes in gene expression that protect malignant cells from apoptosis.

STRONGLY ENHANCED AGGREGATION PROPENSITY AND AMYLOID FORMATION (ALZHEIMER'S DISEASE, PARKINSON'S DISEASE, AMYOTROPHIC LATERAL SCLEROSIS, HUNTINGTON'S DISEASE, TYPE 2 DIABETES MELLITUS)

In some individuals, native or mutant proteins include sequence motifs that promote a highly ordered aggregation state when the cellular environment is altered. The most common of these motifs is the beta sheet, which, when exposed to the solvent environment of the cell, forms intermolecular species that bind in an iterative process that can accommodate many thousands of molecules that form cross-beta sheet amyloids. These intracellular aggregates are described as oligomers (2–24 molecules), protofibrils (rods 4–11 nm wide and 200 nm long), and amyloid fibrils with a similar width to protofibrils but microns in length. While the formation of oligomers is thermodynamically unfavorable, polymerization is favorable, causing aggregates to seed slowly but grow exponentially. In some cases, for example in Huntington's disease and familial forms of Alzheimer's disease and ALS, aggregation is accelerated by mutations or expansion of homopolymers. However, in many cases, the aggregates contain other cellular proteins that share biophysical properties of aggregation propensity or reflect dysfunction in the PN that facilitates their seeding or propagation (see below). While in most instances, damage caused by protein aggregates is localized to the cells in which they form, as occurs with islet amyloid peptide in some patients with type 2 diabetes mellitus, amyloidogenic proteins associated with neurodegenerative diseases have been shown to spread between cells and, in the case of transthyretin amyloidosis, can cause pathology in many tissues. Pathologists use staining of tissues with Congo red, which detects beta sheets, to make this diagnosis. Damage to neurons by aggregates in Alzheimer's disease can elicit a local inflammatory response by resident immune cells in the brain, both of which contribute to pathology. Much effort has been directed toward the detection of aggregates and amyloid and the development of small molecules or antibodies that block further growth or enhancing the cellular activities of the PN to suppress protein misfolding.

SECRETED AGGREGATED AND AMYLOID SPECIES CAUSING SYSTEMIC AMYLOIDOSIS

In patients with systemic amyloidosis, the secretion of large amounts of aggregation-prone proteins results in the deposition of aggregates in many tissues. These proteins can include immunoglobulins secreted from plasma cells in patients with systemic inflammation or multiple myeloma or other aggregation-prone proteins including transthyretin. Similar to other aggregate-induced diseases, mutations in transthyretin that enhance polymerization are associated with an increased risk of developing systemic amyloidosis with advancing age. These aggregates induce cellular toxicity, inflammation, and matrix reorganization, which interfere with function in an organ-specific manner.

NATIVE PROTEINS PRONE TO AGGREGATE WHEN THE CELLULAR ENVIRONMENT IS ALTERED BY STRESS AND AGING

While well-defined genetic abnormalities have been essential in elucidating the molecular mechanisms that underlie the formation of protein aggregates and causally linking them to disease, many if not most clinical diseases associated with the formation of protein aggregates develop in patients without identified mutations. In these patients, a decline in the chaperone and quality control mechanisms of the PN allows exposure of aggregation-prone domains of normal proteins to the solvent environment of the cell. Once seeded, these protein aggregates can expand rapidly to induce local or systemic injury. The decline in function of the PN that allows these aggregates to form might develop gradually with advancing age or might occur suddenly in response to an age-triggered biologic program, as occurs in *C. elegans*.

INFECTIOUS DISEASES AND IMBALANCED CELL STRESS RESPONSES IN AGING

The response to infectious diseases and the disproportionate morbidity and mortality in older individuals exposed to systemic stress are likely associated with the decline in robustness of cell stress responses and proteostasis. While these stressors include infections, surgical or accidental trauma, sepsis, and myocardial infarction, among others, pneumonia, the most common cause of death from an infectious disease in the United States, provides an illustrative example. As was evident during the COVID-19 pandemic, pneumonia morbidity and mortality disproportionately affect the elderly. Viral pneumonias, including those caused by influenza viruses and SAR-CoV-2, are primarily localized to the lung, where they activate a local and systemic inflammatory response and denude the alveolar lining. The resulting hypoxemia and systemic inflammatory response injure distant organs independent of viral injury. Impaired function of the PN during the stress might allow seeding of tissues with toxic aggregates with long-term consequences. Repair of the damaged lung and distant organs represents a major challenge to proteostasis that might be overcome in younger individuals but fails in those who are older with poor stress resilience. This loss of proteostasis resilience necessary to limit damage and allow repair could explain clinical observations in pneumonia survivors who develop persistent lung injury, skeletal muscle dysfunction impairing mobility, chronic kidney disease, cognitive dysfunction, and dementia and an increased risk of ischemic cardiovascular events in the year after hospital discharge.

505 Novel Approaches to Diseases of Unknown Etiology

David R. Adams, Camilo Toro, Joseph Loscalzo

THE UNDIAGNOSED DISEASE STATE

The term *disease*, etymologically meaning "lack of ease" or the presence of discomfort, is defined as an abnormal state that negatively affects the structure or function of all or part of an organism and that is not due to any immediate external injury. When referring to a person experiencing a disease, the word *patient* is used in its original, meaning "the one who endures suffering." These terms are well suited to patients with undiagnosed diseases. A patient with an undiagnosed disease is one for whom a medical diagnosis is not discerned after reasonable efforts utilizing established methods and procedures. Multiple factors may contribute to a failure to reach a diagnosis (Table 505-1). Patients who are affected by an undiagnosed disease for a protracted period exist in an undiagnosed state, which presents characteristic challenges for the patients, their families, and their medical providers.

THE MEANING AND CONTEXT OF A DIAGNOSIS

A diagnosis often entails hierarchical levels of information specificity with varying levels of relevance to the users (consumers) of such information (e.g.) patients and their families, health care providers, government health care agencies, insurers, epidemiologists, genetic counselors, pharmacologists, biologists). As an example, a diagnosis of Parkinson's disease in an adult is based on the progressive emergence of signs and symptoms of bradykinesia, rigidity, asymmetric rest tremor, and postural instability (clinical diagnosis), which are typically responsive to the administration of L-dopa (a therapeutic response biomarker). Together, these are cardinal features of striatonigral degeneration (a mechanistic diagnosis), a process associated with neuronal α-synuclein deposition and Lewy body pathology (histopathologic diagnosis) often based on a genetic susceptibility conferred by mutations in genes such as synuclein (*SYNCA*, a molecular diagnosis) and likely influenced by environmental exposures (e.g., manganese or other neurotoxins).

With ongoing advances in medical science and technology, the standard for what constitutes a reasonable diagnosis continues to evolve toward higher levels of specificity. For example, the utility of an antisense oligonucleotide therapy may be restricted to a specific subset of mutations associated with a given, monogenic, heritable disease. Efforts to adopt the principles of precision medicine include a growing emphasis on the context of disease within the genomic landscape, environment, social factors, medical history, nutrition, and the microbiome of any given individual. Examples include cancer susceptibility, genetically determined idiosyncratic reactions to medications, and unique pathogen susceptibilities in patients with certain immune deficiencies.

UNDIAGNOSED RARE DISEASES

Most chronically undiagnosed diseases are rare. While individual rare diseases have a low prevalence, they are numerous in aggregate. It is estimated that >6000 rare diseases affect millions of people throughout the world. Estimates of aggregate population prevalence range from 6 to 10%. Many rare diseases have a genetic basis and onset in childhood. As the cloud of uncertainty inherent in the undiagnosed disease state is removed, new disease-specific counseling, therapies, resources, community engagement, and advocacy opportunities become possible.

TABLE 505-1 Factors Contributing to the Presence of an Undiagnosed Disease

FACTOR	EXAMPLE
Misleading information	False-negative and false-positive test results
Rare disorder	Many inherited disorders have only been identified in a few individuals. For example, sialuria, a well-understood disorder of sialic acid metabolism, has been reported in 10 individuals (OMIM 269921).
Unusual causes of common diseases, including atypical course of illness	Insulin-dependent diabetes mellitus may be the presenting feature for the relatively rare autoimmune polyendocrinopathy syndrome, type I (OMIM 240300).
Presence of multiple disorders (blended phenotypes)	For an example, see PubMed ID 24863970.
Lack of characteristic symptoms of known disease	Diseases are commonly ascertained via cardinal signs or symptoms leading to incomplete ascertainment of all possible disease presentations. For instance, not all persons with Marfan's syndrome are tall relative to other family members. For progressive diseases, pathognomic signs and symptoms may be missing in early stages of disease.
New disease	No prior knowledge or record of such disease
Incorrect affected status assignments in family history	A heritable disorder may be inappropriately excluded if family history information is incorrect.
Primary disease manifestations obscured by other factors	Maladaptive behavior, medication effects, and secondary disease manifestations may obscure signs and symptoms of a primary disorder.
Disease not expected in region or population	Cystic fibrosis in persons of African ancestry, sickle cell disease in persons of northern European ancestry; infectious agents with marked geographical incidence patterns
Diseases thought to be eradicated	Poliomyelitis
Diseases occurring in unexpected time of life	Parkinson's disease in children, lysosomal storage disease in adults
Malingering	Feigned disease features intended to achieve secondary gain (Munchausen syndrome)
Rare disease mechanisms	Transmitted or sporadic prion disease, unusual zoonotic diseases

Abbreviation: OMIM, Online Mendelian Inheritance in Man.

THE EFFECT OF THE UNDIAGNOSED DISEASE STATE ON THE PATIENT

Patients with an undiagnosed disease are frequently driven to understand the basic nature of their ailment (what, when, where, how, etc.). Individuals, families, physicians, and society, however, might have a wide range of tolerance to the uncertainties associated with the undiagnosed disease state. Being undiagnosed has profound detrimental effects. Patients can go undiagnosed for decades, leading to personal and family uncertainty, high levels of stress, decreased productivity, limited accessibility to disease-specific counseling and resources, decreased quality of life, and excess utilization of medical services.

APPROACH TO CHALLENGING DISEASES OF UNKNOWN ETIOLOGY

Approaches to a patient with an undiagnosed disease can be separated into two categories. The first is a new assessment by a consultant, new provider, or diagnostic referral center. The second is periodic reassessment by an existing provider for a patient who remains undiagnosed.

TABLE 505-2 Essential Records for Undiagnosed Disease Patients

1. Any narrative summaries that detail the course of the illness
2. Copies of original test results with names, dates, testing circumstances, normal ranges, and test facility information
3. Electronic copies of imaging studies
4. Consultation notes
5. Hospitalization intake and discharge summaries
6. Accurate family history accounts and family relations

Optional but potentially useful records include:

1. Photographs and/or videos of disease manifestations
2. Longitudinal data (growth charts, symptom logs, serial lab measurements)
3. Data or specimens that could be reanalyzed, including pathology specimens and genomic sequencing of raw data

COMPREHENSIVE DATA COLLECTION

A potentially time-consuming but critical initial step is the gathering of all available medical data. Essential records are listed in Table 505-2.

The overall goal of data collection is a full understanding of the course of the disease and a verification of critical data elements used for diagnostic decision-making. Incorrect or partial second-hand accounts of prior test results contribute substantively to incorrect or missed diagnoses.

Analysis of the collected data allows for reconstruction of the process by which previous disease presentation, diagnostic thought processes, and test interpretation led to the current understanding of a patient's illness. Unintentional obfuscation of the history and findings can result from missing records, incomplete recall by the patient and fragmentation, and propagation of information (and misinformation) in the medical record. Optimally, the presence and character of key features of the illness will be reinforced by perspectives derived from multiple evaluations.

VALIDATION OF SUBJECTIVE AND OBJECTIVE FINDINGS

Teasing apart the layers of a patient's presentation often uncovers a variety of adaptive (and maladaptive) coping strategies. Some are idiosyncratic to the disease state (e.g., sun avoidance in a patient with xeroderma pigmentosum), whereas others are driven by psychosocial factors and could become primary drivers of the phenotype. It is important to consider, however, that patients believed to have "functional" or "somatoform" disorders may have unrecognized underlying illnesses, e.g., nonepileptic events (pseudo-seizures), frequently have concurrent bona fide epileptic events. Careful consideration of clinical phenomenology and associated findings on physical examination and ancillary investigations may provide clarity, affirmation, and effective redirection. Distinct clinical, radiographic, and laboratory abnormalities provide entry points to the generation of a differential diagnosis and could become effective biomarkers of disease progression and response to interventions.

Testing Strategies and New Technology The historical exclusion of a diagnostic hypothesis may be based on testing that is no longer state of the art. For example, congenital disorders of glycosylation (CDG) were historically diagnosed using transferrin isoelectric focusing. It was subsequently found that the diagnosis of many CDG types required mass spectrometric and molecular approaches. The initial assessment of a patient with an undiagnosed disease should include a reassessment of the diagnostic logic and data used in past decision-making. In the absence of concrete diagnostic leads, the use of broad scope screening tools may prove beneficial in generating meaningful diagnostic hypotheses (Table 505-3). In some cases, newer testing options may be difficult to obtain and/or be costly. Prior probability of disease and available resources will factor in determining whether new diagnostic testing is practical.

Molecular Approaches, Including Genomics The availability and variety of clinical molecular modalities have transformed diagnostic testing in many settings. These advances have arisen from both testing scope, such as exome-wide, genome-wide, and transcriptome (RNA sequencing [RNA-Seq]) sequencing, and new medical knowledge, such as new disease-gene associations and molecular interaction networking (network medicine). Complementary screening tools, such as metabolomics, show diagnostic promise, particularly when combined with sequencing data to generate a fuller picture of disease manifestations. Simultaneous consideration of multiple data types can provide a means of appreciating overlapping and reinforcing evidence, with the potential to inform both hypothesis-driven and agnostic approaches to diagnosis.

HYPOTHESIS-DRIVEN MOLECULAR TESTING Hypothesis-driven testing implies that a defined set of heritable (or potentially heritable) disorders is the principal impetus for testing. Selection of a targeted gene sequencing panel, ideally augmented with structural variant detection, may allow for improved sensitivity, lower cost, and fewer unrelated (secondary) findings relative to full exome or genome sequencing studies. In the setting of an initial undiagnosed disease evaluation, prior sequencing panels may not include recently discovered genes. Testing with an updated panel or targeted sequencing of a newer gene is an option for consideration. In some cases, sequencing panels are generated by selective reporting of relevant genes within an exome dataset. In such cases, it may be possible to expand the analyses to new genes of interest without additional sequencing.

TABLE 505-3 Clinically Available Tests with Notable Utility for Undiagnosed Cases

TEST	TARGET PHENOTYPES	RATIONALE
Single nucleotide polymorphism microarray and/or karyotype	Dysmorphic features, cognitive impairment, neurodevelopmental disorders	Genomic structure abnormalities may be missed by other testing
Exome or genome sequencing	Any undiagnosed disease that is chronic and not clearly acquired	Tests a broad range of potentially unconsidered diagnostic entities
Lysosomal storage diseases (LSDs), molecular or enzymatic tests. urine organic acids, urinary glycosaminoglycans (GAGs), oxysterols	Progressive neurologic disorders, psychiatric disorders	Some LSDs have nonspecific presentations, and adult-onset cases are often missed
Congenital disorders of glycosylation, Apo CIII and N-glycan mass spectrometry	Pediatric-onset disorders, cognitive impairment, neurologic phenotypes	Large group of disorders; phenotypes for many still being characterized
Biochemical disorders, ammonia, serum polyols, urine purines and pyrimidines, plasma amino acids, very-long-chain fatty acids	Neurologic phenotypes, especially with waxing and waning course, selective speech involvement, or patients with unusual self-selected diets	Metabolic disorders may have nonspecific symptoms, and adult-onset cases are often missed
Mitochondrial sequencing and mitochondrial depletion studies; biochemical screening with serum lactate, blood pyruvate, plasma amino acids, and GDF-15	Complex multisystem disorders with neurometabolic, endocrine, and gastrointestinal symptoms, muscle dysfunction, and waxing and waning or progressive course	Large group of disorders with a wide range of presentations; yield is improved by studies in affected tissue (e.g., liver or muscle)
Cerebrospinal fluid (CSF) studies including amino acids (AAs), lactate, pterins, methyltetrahydrofolate (MTHF), or special CSF flow studies	Synthetic neurotransmitter defects in patients with unexplained fluctuating encephalopathy/movement disorders or patients with atypical neuroinflammatory syndromes	Patterns of profiles point to particular enzymatic deficits in neurotransmitter synthesis or characterization of unique immunologic profiles of inflammatory central nervous system diseases

AGNOSTIC MOLECULAR TESTING Agnostic testing typically uses data from a broad testing platform, such as exome or genome sequencing, and considers all detectable diagnoses, even those with a low pretest probability of being present. This approach can also generate hypotheses for potentially new disease-gene associations. Analysis of the sequencing data typically includes an unrestricted search throughout the entire human genome or exome space. DNA sequence variants with potential medical relevance are identified first by bioinformatic characteristics, including known association with disease, predicted importance for protein function, interspecies conservation, population frequency, and an evolving list of other associated or functional factors. The list of candidate variants is then subject to expert review (i.e., curation). The interpretation of test results in this setting is highly influenced by both the adequacy of communication between the clinical and testing teams and the information content of the data sources used to annotate each of the thousands of variants generated in the course of sequencing.

There is a rapid proliferation of new testing platforms and analytical tools with the potential to contribute to solving undiagnosed diseases, but it remains challenging to judge their broad utility. While awaiting systematic validation and practice standards, novel techniques may be considered in special cases where a diagnostic hypothesis is closely aligned with the type of data generated by a specific testing strategy **(Table 505-4)**.

PERIODIC REEVALUATION

The cornerstone for the care of a patient in an undiagnosed disease state is a plan for periodic reevaluation. The Undiagnosed Diseases Network (UDN), a 10-year National Institutes of Health–sponsored national program, was specifically designed to evaluate undiagnosed patients. The overall diagnostic rate of the UDN, including periodic reevaluation of early enrollees, was reported as ~30%. This finding illustrates the fact that many affected individuals remain in an undiagnosed state for a protracted period. For a medical provider, the care of an undiagnosed patient includes a program for symptomatic care, support related to the undiagnosed state itself, and plans for a regular reevaluation strategy seeking new insights into the diagnosis by following its time trajectory. Reevaluation is guided by emerging knowledge in the field, disease progression, and the development of new signs and symptoms. The appearance of a similar disease in a sibling or close relative may provide critical insight. Communication with the patient is an essential component. Many individuals with an undiagnosed disease report feeling abandoned by their providers once initial diagnostic ideas have been exhausted. Providers themselves may feel discouraged in being unable to provide a diagnosis. The institution and discussion of a well-defined plan for periodic reassessment and communication can help reinforce the patient-provider relationship and set reasonable expectations.

TABLE 505-4 Emerging or Special Testing Strategies and Related Diagnostic Questions

TESTING STRATEGY	RELATED DIAGNOSTIC QUESTION	AVAILABLE CLINICALLY[a]
Transcriptomics, RNA-Seq	Relevance of splice, regulatory, and other noncoding variants; correlated changes in gene expression within pathways	Yes
Metabolomics	Hypothesis generation via nontargeted approaches, correlated pathway changes, correlation with molecular findings	Yes
Epigenetics	Diseases known or suspected to be caused by methylation or parent-of-origin effects	Yes
Transcriptional profiling	Search for profile particular to certain disease states, e.g., interferon-inducible gene panels (interferon signature) in certain autoinflammatory disorders	Some
Specialized, disease-specific testing	Prion-related diseases, metabolic diseases, and many other assays	Some
Functional validation	Model organisms, cell biology, and other approaches to validating a hypothesized gene-disease association	No
Metagenomics	Search for molecular fingerprints of other organisms (e.g., infectious agents) within human samples	Yes
Long-read sequencing technology	Accurate resolution of low-complexity regions of the human genome (repeat expansion disorders) and complex genome structural rearrangements	No
Deep sequencing	Accurate resolution of low levels of mosaicism	Some
Optical genome mapping	High-resolution chromosomal structure	Yes

[a]Available clinical tests are often a small subset of approaches available via research collaboration. Clinical testing offerings are evolving rapidly and should be reassessed periodically.

Reevaluation of Differential Diagnosis The key to success for a planned reevaluation visit is preparation. The problem and differential diagnosis lists should be subject to careful, evidence-based review. New or resolved clinical features may add or remove diagnostic considerations. The passage of time may result in the emergence of distinct new phenotypic manifestations that serve as new clues in the formulation of a definitive diagnosis. Special consideration should be given to the effects of reaching maturity and aging. The establishment of a phenotype as being static versus progressive has prognostic value. Careful documentation of the rationale for including or excluding individual disorders will streamline the process for both future reevaluations and the need for consultants. Concurrent development of common diseases should be thoughtfully considered as a possible component of the primary undiagnosed condition. For example, emergence of insulin-dependent diabetes mellitus in an undiagnosed patient with a complex phenotype could be a feature of the rare autoimmune polyendocrinopathy associated with mutations in the autoimmune regulator gene *AIRE*.

New Literature Keeping abreast of current literature is an important and challenging activity for all medical providers as the body of medical knowledge continues to grow exponentially. For undiagnosed diseases, newly reported disorders and disease-gene associations are an important source of diagnostic resolution. Literature search tools such as PubMed can be augmented by online resources that connect clinical signs and symptoms (phenotypes) to disorders. For example, using the search terms "cardiomyopathy arthropathy diabetes hyperpigmentation" in the Online Mendelian Inheritance in Man website (*https://omim.org*) produces a list of disorders that includes hemochromatosis. In the context of an undiagnosed disease, this type of phenotype-driven approach can be used to search for new, relevant publications and disorders. Tools for search automation continue to be developed in both open-source and commercial settings. The success of these approaches is augmented by iterative application, ideally as part of formal, periodic reevaluation of the undiagnosed patient.

GENOMICS

The use of medical testing based on the determination of DNA sequence and structure (sometimes referred to as molecular testing) has proliferated in recent years. A wide variety of approaches are available to the clinician, from single-gene sequencing to exome or genome sequencing. RNA sequencing and optical genome mapping have recently become available as clinical tests. Many reviews of this topic are available (see Marwaha et al., 2022, in "Further Reading"). Consultation with colleagues trained in genetics can be useful when developing an optimal testing approach.

In some cases, genetic testing results may already exist in the medical record during the initial evaluation of an undiagnosed patient. This is increasingly true for younger patients; exome and genome sequencing are being used earlier, and with increasing frequency, for complex diagnostic challenges. Reanalysis of previously obtained exome and genome data should start with consideration of both the age and quality of the study and the reported patient phenotype at the time of the study report. For sequence results generated in a clinical laboratory,

a discussion between the provider and the laboratory director often answers important questions about recommended next steps. The discussion should touch on how technologic advances have affected the utility of the older data and whether the laboratory offers reanalysis of the data. At a minimum, the provider, the testing laboratory, or an identified subspecialist should review previously reported DNA variants of unknown significance considering interval reports about the gene in question. More advanced reanalysis strategies are emerging and may be offered by the testing laboratory.

Some laboratories offer release of raw DNA sequencing data to their patients on request. The utility of raw data varies and depends on the identification of bioinformatics collaborators willing to reanalyze the data. Sequencing data obtained as part of a research study may not be suitable for clinical diagnostic purposes. In practice, raw and research-generated sequencing data are most useful when a collaborating researcher can be identified.

When considering a new sequencing test, the inclusion of the parents and siblings of the proband has the potential to provide enormous value in some situations. Discussion of an optimal approach with an expert colleague or the testing laboratory is encouraged.

EXPOSOME

In many cases, a detailed occupational and environmental exposure history should be obtained. Some rare disease phenotypes are pathognomonic of specific toxicant exposures (e.g., mesothelioma and asbestos exposure, clear cell adenocarcinoma of the vagina and intrauterine diethylstilbestrol [DES] exposure, chloracne and exposure to halogenated aromatic hydrocarbons). For the most part, however, chemical toxicant exposures do not produce unique phenotypes. Rather, chemical exposures operate in conjunction with lifestyle factors (e.g., smoking, alcohol intake, and nutritional status), differential host susceptibility (determined by age, sex, comorbidities, genetics, etc.), and nonchemical stressors (e.g., psychosocial stress) to produce (1) common, readily diagnosed medical diseases (e.g., asthma); (2) unusual or nonspecific phenotypes (e.g., erethism and metallic mercury exposure); or (3) atypical presentations of otherwise well-characterized disease states, initially considered an undiagnosed disease (e.g., manganese-induced parkinsonism). The nonspecificity typical of chemical-induced disease risk is further complicated by lack of exposure biomarkers for many common environmental toxicants (e.g., volatile organics), the short half-life of some contaminants (e.g., arsenic), and the possibility of decades long latency between exposure and disease onset (e.g., chemical carcinogenesis or dietary exposures to specific biochemical risk factors for atherothrombosis). In addition, we live in an era in which new chemicals are introduced into consumer products and the environment at a pace well beyond our capacity to characterize their toxicity. Within this context, one of the most powerful tools for ascertaining chemical-related disease risk is a systematic exposure history. Although there are no standardized instruments for this purpose, there are published guidelines to implement exposure assessments (Goldman and Peters, 1981; see "Further Reading" below). These include a multistep approach to exposure assessment including a job history; a review of exposures at work and at home or via hobbies and recreation; ascertainment of any temporal relationship of symptoms or disease onset to work, home, or recreational activities; and the food frequency questionnaire. If this screening identifies a potential exposure or exposures of concern with respect to patient symptoms and phenotype, a second step of evaluation involves a more detailed history to identify specific suspect agents, options for quantitative environmental exposure assessment (e.g., household tap water sampling, review of workplace Material Safety Data Sheets [MSDSs]) and biomonitoring, and etiologic plausibility for at least some aspects of the patient's phenotype.

The traditional approach to focused external exposure assessment proposed above does not, however, provide an integrated, quantitative measure of all exposures over the life course, an exposure characterization of particular interest for the risk of chronic diseases such as cancer or atherothrombosis. The exposome has been proposed as a promising means for capturing the totality of human exposure over a lifetime (analogous to the totality of genetic exposure assessed via genomic analyses), including not only external chemical or dietary/foodome (Barabasi et al., 2020; see "Further Reading" below) exposures but also internal (e.g., metabolic, hormonal, microbiome) influences and psychosocial factors. However, techniques for measuring the exposome are in relatively early stages of development, are limited by the substantial variability in human exposure experience, and have not yet been designed to capture complex combinations commonly encountered in environmental or occupational exposure settings (Peters et al., 2012; Wild, 2012; Brunekreef 2013; Barabasi et al., 2020; see "Further Reading" below). This important element of assessing patients with undiagnosed disease is, however, evolving rapidly and offers the promise of becoming a more formal part of the evaluation of many patients with undiagnosed disease.

ENGAGEMENT OF RESEARCH APPROACHES

Establishing a research collaboration for a patient with undiagnosed disease can be both challenging and rewarding. Time and effort resources are likely to limit this approach to a subset of patients with particularly compelling clinical presentations and a strong hypothesis about disease causation. The process must include early and detailed communication with the patient. Several approaches may be considered. Undiagnosed disease medicine, as a focus of specialized study, investment, and infrastructure, has proliferated around the world in the last decade, with numerous centers providing support for evaluating qualifying individuals and families.

Leveraging Phenotypic and Genotypic Similarities For a patient with a rare or undiagnosed disease and distinct presenting features, finding similarly affected individuals adds substantial benefits. It can encourage research, provide a community for affected patients, and improve the chances of finding commonalities in pathogenesis and therapeutic strategies. Phenotypic aggregation may also allow the patient to connect with consortia invested in related medical presentations. Examples include organizations dedicated to the study of related diseases such as leukodystrophies, autoinflammatory disorders, and even undiagnosed diseases; NORD, the National Organization for Rare Disorders (*rarediseases.org*), can be a useful starting point. The Office of Rare Disease Research within the National Center for Advancing Translational Science supports consortia under the Rare Disease Clinical Research Network program. Building patient cohorts may also be based on specific biological mechanisms or pathways, for example, the United Mitochondrial Disease Foundation.

Data Sharing The proliferation of DNA sequencing technology and the subsequent generation of many DNA variants of unknown clinical significance have prompted the creation of data-sharing resources specifically designed to match similar cases submitted by clinicians and researchers around the world. For example, a clinical exome report may identify variants in a gene with a potential but unproven relationship to the patient's presenting illness. The clinician could enter the gene name into a gene-matching database, and if the same gene name had been already entered by a different submitter, the database would flag a match and send contact information to both submitters. The matching procedure has the potential to identify additional cases of an ultrarare or newly described condition, while avoiding the sharing of the patient's personal health information. Embellishments of this approach involve inclusion of phenotypic features, data entry by families, and specific details of sequence variants. Example systems include GeneMatcher (the most populated database for single-gene submissions) and DECIPHER (which adds expended utility for larger structural variants). As an illustration of their utilization at the time of this chapter's publication, GeneMatcher has single-gene submissions for almost 70% of all known protein coding genes.

Collaboration Collaborations around undiagnosed disease patients may take many forms. Studies focusing on related medical conditions can sometimes be identified using the *https://clinicaltrials.gov* website, which lists many U.S. and non-U.S. clinical studies. Databases of clinical information (e.g., this textbook, GeneReviews) can be used to identify subject matter experts for related conditions. Such

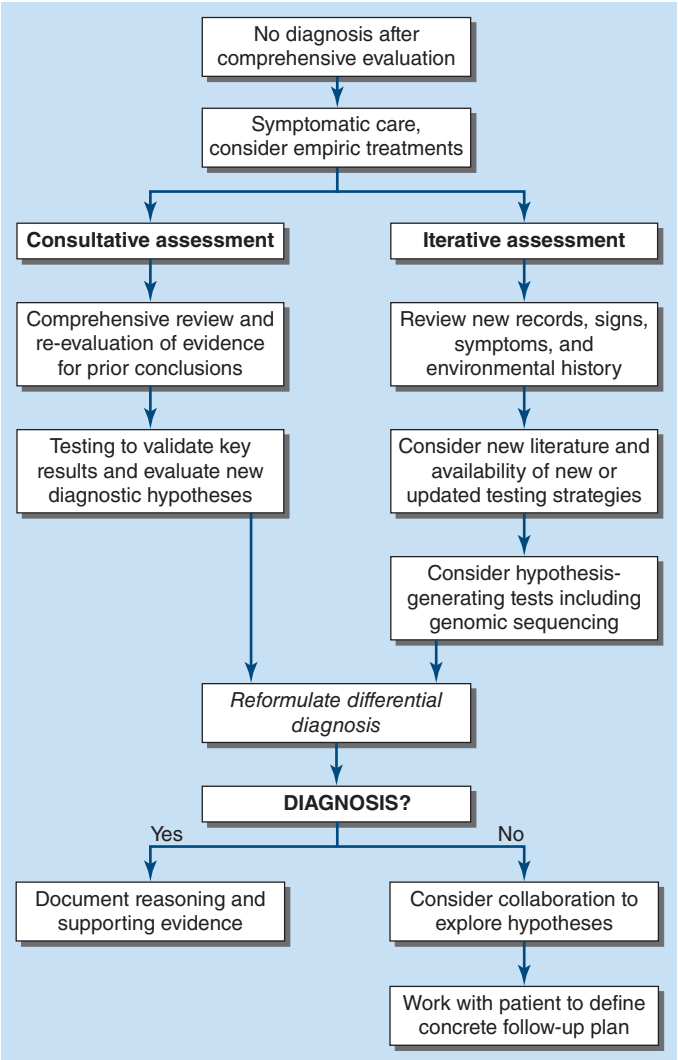

FIGURE 505-1 Approach to the patient with an undiagnosed disease.

experts can be queried about ongoing studies. In some cases, a willingness to work with consenting families to provide biological specimens can open additional avenues for collaboration.

CHALLENGES

Data Portability Obtaining specimens, data, and records for a chronically undiagnosed patient can be time-consuming and challenging. Families may be charged fees for obtaining copies of old studies. Although continuing advances in record access are occurring, families should be encouraged to collect and maintain an updated collection of medical records. These should include copies of consultation notes, original laboratory results, and radiology studies (the latter preferably in electronic form). These record collections are useful for consultation, second opinions, and transitions between primary providers.

Managing Illness Behaviors, Expectations, and Secondary Manifestations Patients with undiagnosed diseases may present in any stage of the grieving process. Coping with uncertainty, loss of abilities, work, relationships, autonomy, and financial security compound the primary manifestation of the disease. Patients may have a wide range of expectations about the possible benefits of achieving a diagnosis, including successful therapy. Patients of reproductive age may find that their greatest uncertainty surrounds the potential heritability of their disorder, its effects on future reproductive decisions, and the potential risk it may represent to their children and living relatives. These factors may be equally or more disabling than the primary illness and require an individualized and multidisciplinary approach.

CONCLUSION

Chronically undiagnosed diseases present a complex challenge to patients, medical providers, and society at large. Development of a comprehensive plan for evaluation, reevaluation, and support requires a substantial investment of time and effort **(Fig. 505-1)**.

Achieving an accurate diagnosis removes at least one level of uncertainty and allows for disease-specific counseling, therapies, resources, community engagement, and advocacy opportunities otherwise not afforded to undiagnosed patients.

in pregnancy and lactation, 1169t
resistance to, 1182t, 1183, 1183f, 1314
for ventilator-associated pneumonia, 1032
Cefixime
for enteritic fever, 1317–1318
for gonococcal infections, 1259t
indications for, 1175
in pregnancy and lactation, 1169t
resistance to, 1100f, 1255, 1259
Cefoperazone, 1175
Cefotaxime
for community-acquired pneumonia, 963t
for enteric fever, 1318
for epiglottitis, 1263
for gonococcal infections, 1259t
indications for, 1175
for infective endocarditis, 1042
for intraabdominal infections, 963t
for leptospirosis, 1444, 1444t
for Lyme disease, 1453, 1453f
for meningitis, 1122, 1122t, 1194, 1263
for meningococcal infections, 1249
for nongonococcal bacterial arthritis, 1057
for peritonitis, 329, 1070
for pneumococcal infections, 1026, 1192
for yersiniosis, 1350
Cefotetan
adverse effects of, 802t
indications for, 1173t, 1175
for pelvic inflammatory disease, 1106, 1106t
prophylactic uses of, 1180t
resistance to, 1173t, 1284, 1379
Cefoxitin
for anaerobic bacterial infections, 1379
for bite-wound infections, 1145t
for gas gangrene, 1054t, 1239t
indications for, 1173t, 1175
for intraabdominal infections, 963t
for NTM infections, 1428
for pelvic inflammatory disease, 1106, 1106t
prophylactic uses of, 1180t
resistance to, 1173t, 1284, 1379
Cefpirome, 1175
Cefpodoxime, 1027t, 1144, 1169t, 1175
Cefprozil, 1175
Ceftaroline
actions of, 1204
adverse effects of, 1175
for community-acquired pneumonia, 1028t
indications for, 1173t, 1175
for infective endocarditis, 1044
for MRSA infections, 1183, 1203t, 1204
resistance to, 1173t, 1183
Ceftazidime
for CAPD peritonitis, 1072
for community-acquired pneumonia, 1028t
for febrile neutropenia, 1309t
for glanders, 1309t
for hospital-acquired pneumonia, 963t
indications for, 1173t, 1175
for intraabdominal infections, 963t

CXCR1, 2769t
CXCR2, 2768t, 2769t
CXCR3-A, 2768t, 2769t
CXCR3-B, 2768t, 2769t
CXCR4 gene mutations, 458, 893, 894, 2795, 2802
CXCR4 receptor
in hematopoietic stem cells, 759, 914
in HIV infection, 1557–1558, 1577, 1578f
ligands, cell types, and disease connection, 2769t
source, target, and biologic activity, 2768t
CXCR5, 2769t
CXCR6, 2769t
CXCR6 gene, 1581t
Cyanide poisoning
in chemical terrorism, S5
clinical features of, 50t, 3713t, S5
complications of, 2346, 2348
differential diagnosis of, S5
mechanisms of, 277, 3713t, S5
prognosis of, S5
treatment of, 3713t, S5
Cyanobacteria, 3752t
