- *What sex were you assigned at birth on your original birth certificate?* Male; female; choose not to disclose.

The physical environment of a hospital or clinic is important, but the majority of clinical spaces do not signal that they are safe spaces for LGBTQIA+ patients. Most health care posters, pamphlets, and materials feature heterosexual individuals or couples; adding LGBTQIA+-friendly images and text can help signal that the hospital or clinic is a safe space for sexual and gender minorities. In addition, easily identifying LGBTQIA+-competent providers by using websites, buttons, and pins can help patients select providers and feel at ease when attending appointments. Lastly, designating all-gender bathrooms is important to creating welcoming spaces, particularly for transgender and gender-nonconforming individuals.

FUTURE DIRECTION IN LGBT HEALTH

While social and cultural acceptance of the LGBTQIA+ community has improved in certain parts of the world, many LGBTQIA+ individuals continue to experience discrimination, stigmatization, and violence. Inequitable health care policies and practices, lack of awareness of LGBTQIA+ health issues, and limited understanding of the unique health needs of LGBTQIA+ individuals contribute to decreased access to care and disparities in health outcomes for LGBTQIA+ individuals. Addressing these barriers will require improved data collection on the LGBTQIA+ population; understanding of the intersectionality of gender identity, sexual orientation, race/ethnicity, and other sociocultural determinants of health; and outcomes-focused research across the life course. In striving to deliver high-quality care experiences for all patients, hospitals, clinics, and providers need to focus on meeting the needs of the LGBTQIA+ community.

Section 3 Obesity, Diabetes Mellitus, and Metabolic Syndrome

413 Pathobiology of Obesity

Stephen O'Rahilly, I. Sadaf Farooqi

Adipose tissue evolved as a solution to the challenge of the intermittent availability of food. At times when food is plentiful, excess calories are converted to triglycerides and efficiently stored in the unilocular lipid droplets that occupy most of the volume of fat cells. When needed, the triglyceride is rapidly broken down to free fatty acids and glycerol, which provide an energy source to other sites throughout the body. However, in environments where food is abundant and when individuals tend to be sedentary, the chronic excess of energy intake over expenditure leads to obesity. The risks of developing obesity under those circumstances and of developing the illnesses associated with obesity vary greatly between individuals, with that variation having a strong genetic basis.

DEFINITION OF OBESITY AND OVERWEIGHT

Obesity is defined as a state of excess adipose tissue mass that adversely affects health. The direct measurement of fat mass is not something that is readily undertaken in routine clinical practice, so a proxy measure, the body mass index (BMI), is generally used. This is calculated as weight/height^2 (in kg/m^2) **(Fig. 413-1)**. BMI-based definitions of obesity and overweight have been established based on associations with certain morbidities and excess mortality. These definitions have been based largely on studies of predominantly white, Western populations, and there is growing evidence that the relationship between BMI and adverse outcomes is different in people from other ethnic groups, usually in the direction of worse health outcomes being seen at lower levels of BMI. The World Health Organization (WHO) defines a BMI of 30 kg/m^2 as the cutoff point for obesity, while individuals with values between 25 and 30 kg/m^2 are classified as overweight. For individuals with a very muscular body habitus, the BMI may overestimate the amount of body fat. For any given BMI, women will generally have a higher percentage of body fat than men.

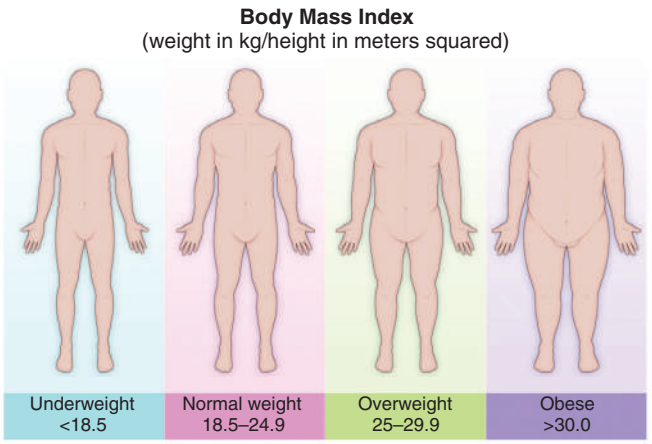

FIGURE 413-1 Definitions of overweight and obesity. The World Health Organization defines obesity based on body mass index (BMI), which is calculated as weight in kilograms divided by the height in meters squared.

The extent to which different adipose depots expand in response to chronic overnutrition varies markedly between people. In general, females store more fat in subcutaneous tissues, especially on buttocks, thighs, and upper arms, whereas men are more prone to store fat in intraabdominal and truncal subcutaneous sites. A simple measure of fat distribution is provided by a measurement of the waist-to-hip ratio. Independent of the degree of obesity, a waist-to-hip ratio >0.9 in women and >1.0 in men is associated with adverse health outcomes such as type 2 diabetes and dyslipidemia.

EPIDEMIOLOGY

The annual National Health and Nutrition Examination Survey (NHANES) provides an ongoing record of the prevalence of obesity in the United States. In 2017–2018, 42.4% of U.S. adults aged ≥20 years old had obesity with no significant differences in prevalence by age group. Non-Hispanic black people had the highest prevalence of obesity at 49.6%, followed by Hispanic (44.8%), non-Hispanic white (42.2%), and non-Hispanic Asian (17.4%) people. In the United States, Asians represent a highly heterogeneous group encompassing both East and South Asia as well as a substantial Filipino community. The risks of obesity and its complications may differ greatly between people from different parts of Asia; in general, the prevalence of obesity is somewhat higher in women than in men, with black women having the highest prevalence at 56.9%. There has been a marked increase in the prevalence of obesity over time. For example, between 1976 and 1980, the NHANES survey reported a prevalence of 14.5%, indicating a near threefold increase over the past 40 years.

This trend is seen globally. According to the WHO, obesity has nearly tripled worldwide since 1975. In 2016, >1.9 billion adults aged ≥18 years old were overweight. Of these, >650 million were obese; 39% of adults aged ≥18 years old were overweight in 2016, and 13% were obese. Most of the world's population lives in countries where overweight and obesity kills more people than underweight.

During this time, one of the most striking changes has been in the prevalence of obesity in children. In children, the relationship between BMI and body fat varies considerably with age and with pubertal maturation; however, when adjusted for age and sex, BMI is a reasonable proxy for fat mass. Using age- and sex-specific BMI cutoffs (overweight ≥91st percentile; obesity ≥99th percentile), in 2019, the WHO estimated that 38 million children under the age of 5 were overweight or obese, and in 2016, they reported that 340 million children and adolescents aged 5–19 were overweight or obese.

PHYSIOLOGIC REGULATION OF ENERGY BALANCE

Discussions about obesity so frequently focus on the issues of personal choice or the obesogenic environment that it can be easy to forget that

the amount of stored energy in our bodies is subject to homeostatic control by fundamental physiologic processes essential to our survival. In the 1940s, it was demonstrated that rodents defend their level of body fat; once returned to ad libitum diets after a short period of enforced caloric restriction or excess, animals either overconsumed or underconsumed calories until they returned to their previous status. Since that time, research has progressively dissected the signals that sense nutrient stores and the contents of our diets and how this information is integrated to control hunger, satiety, and the expenditure of energy. The key locus for the integration of these signals is the hypothalamus, an area of the brain at least partially outside the blood-brain barrier that facilitates its ability to receive hormonal signals and combine these with sensory, cognitive, and other neural inputs.

The hypothalamus receives multiple hormonal signals relevant to energy balance **(Fig. 413-2)**. The circulating concentration of leptin, a peptide hormone produced by fat cells, increases as fat stores increase and declines as fat stores are depleted. Importantly, under conditions of caloric restriction, circulating leptin levels fall faster than the disappearance of fat. Humans born without functional leptin or leptin receptors, although normal weight at birth, develop severe obesity from an early age, largely as a result of an intense drive to eat (hyperphagia). Clearly, a reduction of leptin below normal level is a powerful stimulus to food intake and largely explains the rebound overeating and weight regain that occurs after a period of starvation or dieting. The hypothalamus also receives hormonal signals that are more immediately related to the amount and type of food that has been ingested. Peripheral hormones such as cholecystokinin (CCK) from the stomach, glucagon-like peptide 1 (GLP-1) and gastric inhibitory polypeptide (GIP) from enteroendocrine cells of the small intestine, and peptide YY (PYY) and oxyntomodulin from the large intestine are secreted in response to eating a meal and/or the presence of nutrients in the intestinal lumen. Their release together with neural signals from the vagus nerve and the enteric nervous system contributes to satiety, often indirectly acting on the hypothalamus via projections from the brainstem. Insulin and amylin, produced by the pancreas in response to carbohydrate and protein-rich meals, also have effects on neurons controlling energy balance.

The propeptide pro-opiomelanocortin (POMC) is expressed in a highly restricted population of hypothalamic neurons that project widely throughout the brain **(Fig. 413-3)**. These neurons are responsive to the endocrine signals described above and are critical to the regulation of energy balance. The POMC-derived peptides α- and β-melanocyte-stimulating hormone (MSH) act on the melanocortin 4 receptor (MC4R) to regulate both food intake and aspects of energy expenditure that are influenced by the sympathetic nervous system. γ-MSH, acting mostly through the MC3 receptor, appears to play more of a role in controlling linear growth and the disposition of nutrients into lean versus fat tissues. Signaling through both these melanocortin receptors is also subject to negative control by a different population of neurons, which make and release agouti-related peptide (AGRP), neuropeptide Y (NPY), and the inhibitory neurotransmitter γ-aminobutyric acid (GABA). AGRP actively switches off melanocortin receptors. Leptin, which suppresses food intake, simultaneously stimulates POMC neurons and inhibits NPY/AGRP neurons. Human energy balance is highly sensitive to signaling through this system as people who have a genetic defect in just one of the two copies of the *MC4R* gene are very prone to overeat (hyperphagia) and to gain weight.

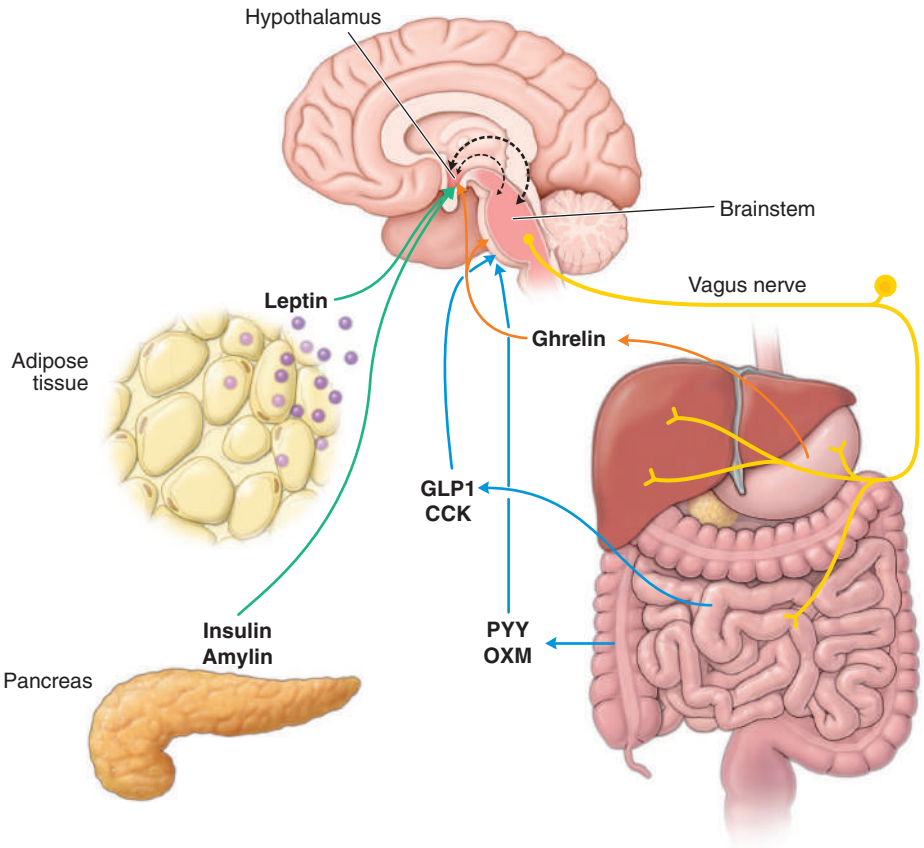

FIGURE 413-2 The homeostatic regulation of body weight. In most people, body weight remains stable over long periods of time despite fluctuations in the amount of food we eat and the amount of activity we undertake. This homeostatic regulation of body weight is controlled by the neurons in the hypothalamus, which receive hormonal signals from adipose tissue such as leptin and neural and hormonal signals from the gut in response to meals. Glucagon-like peptide 1 (GLP1) and cholecystokinin (CCK) from enteroendocrine cells of the small intestine and peptide YY (PYY) and oxyntomodulin (OXM) from the large intestine are secreted in response to eating a meal and/or the presence of nutrients in the intestinal lumen. Their release, together with neural signals from the vagus nerve and the enteric nervous system, contributes to satiety, acting on the hypothalamus via projections from the brainstem. Insulin, produced by the pancreas in response to carbohydrate- and protein-rich meals and potentiated by the action of some of the gut hormones, also has effects on the hypothalamic neurons controlling energy balance, whereas amylin acts predominantly via the brainstem. The release of the hormone ghrelin from the stomach increases in the unfed state and induces appetite by acting on hypothalamic neurons as well as on receptors in the brainstem.

THE PHYSIOLOGY OF NUTRIENT STORAGE IN ADIPOSE TISSUE

When energy intake exceeds energy expenditure, a small amount of that excess energy is stored as glycogen in liver and skeletal muscle. But if the imbalance is greater, then our bodies are designed to store that excess energy in a more efficient way as triacylglycerol (triglyceride). This fat is more efficient because, unlike glycogen, it does not need accompanying water, and when metabolized, it generates more than twice as much energy per gram than does carbohydrate. Adipocytes (fat cells) have evolved to contain a highly specialized organelle, the unilocular fat droplet, which holds the triglyceride within a single-layer of phospholipid that contains all the components needed for enzymes that make and breakdown triglycerides in a manner that is rapidly responsive to metabolic requirements. No other type of cell is specifically designed to store fat safely in this manner, and many of the adverse consequences of obesity are likely caused not by having too much fat in adipocytes but by "nonprofessional" cells being forced to take up and store fat. During weight gain, the amount of lipid in each fat cell increases. Some new fat cells can also be made in adulthood when ~10% of our fat cell population turns over every year.

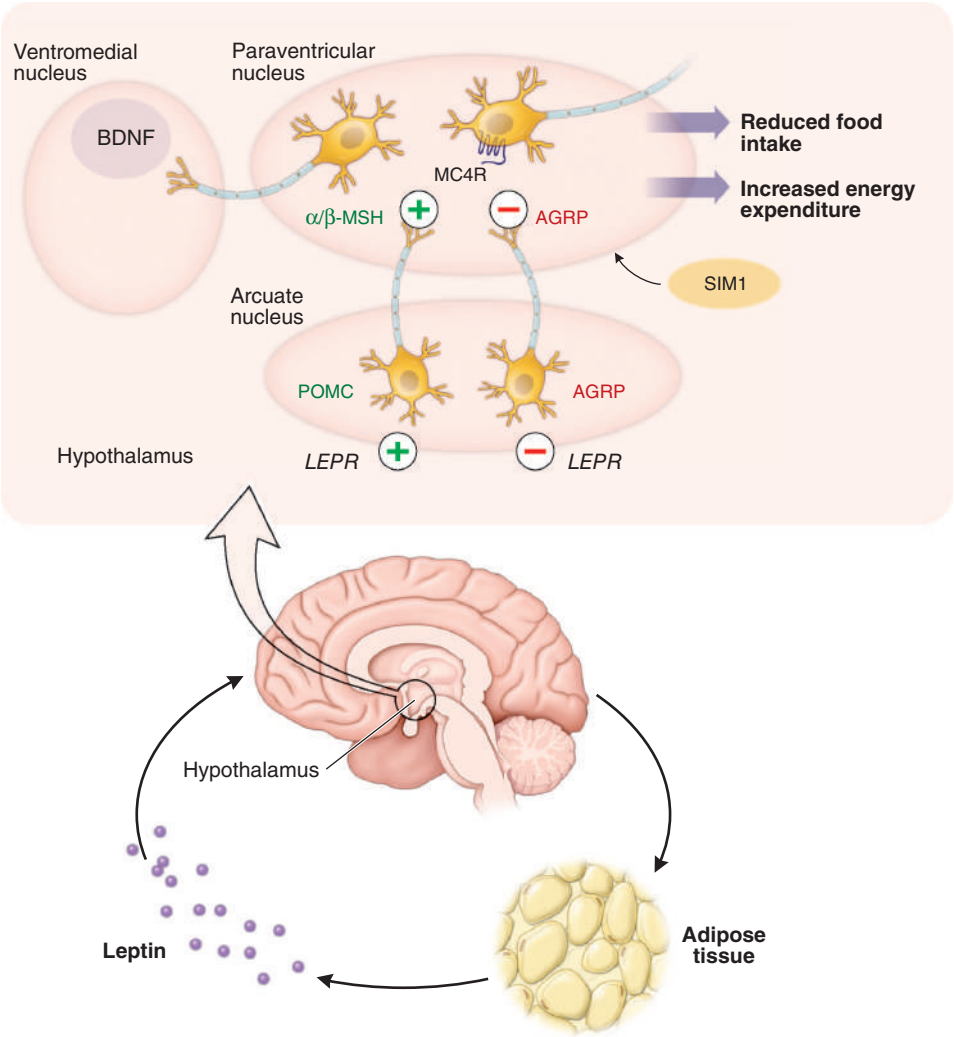

FIGURE 413-3 Hypothalamic pathways regulating body weight. Neurons in the hypothalamus regulate energy intake and expenditure in response to leptin and other hormones. In the fed state, leptin stimulates primary neurons in the arcuate nucleus of the hypothalamus that express pro-opiomelanocortin (POMC). The POMC-derived peptides α- and β-melanocyte-stimulating hormone (MSH) act on the melanocortin 4 receptor (MC4R) expressed on neurons in the paraventricular nucleus to reduce energy intake and increase energy expenditure. At the same time, leptin inhibits neurons expressing agouti-related peptide (AGRP), which switches off melanocortin receptors. When these and other key molecules, such as brain-derived neurotrophic factor (BDNF) and single minded-1 (SIM1), are disrupted by inherited mutations, affected individuals have hyperphagia and severe obesity.

THE CAUSES OF OBESITY: AN INTERACTION OF GENES AND ENVIRONMENT

For a person to develop obesity, energy intake must exceed energy expenditure in a manner that is sufficiently sustained to result in the accumulation of a large excess of triglyceride in adipose tissue. As obesity is a cumulative pathology, if energy intake exceeds energy expenditure by even a small amount (as little as 7 kcal/d), this is sufficient to develop obesity over a matter of years or decades. Even where obesity is common, there are many people who are not overweight. Economic and social factors are likely to play a role as there are more normal-weight people in wealthier and more socially advantaged groups, at least in Western societies. It is also true, however, that because of discrimination, people with obesity may become socially and economically disadvantaged, which complicates interpretation of that data. We can, however, state with considerable certainty that genetic factors play a major role in predisposing people to a range of adiposity. We know this from a large number of studies comparing identical and nonidentical twins. It is particularly telling that the degree of adiposity in adult life of identical twins brought up in different families is very similar between the twins but is not at all correlated with that of the adoptive siblings with whom they were raised.

THE RELATIVE ROLES OF EXCESS INTAKE AND LOWER ENERGY EXPENDITURE IN CONFERRING BIOLOGIC PREDISPOSITION

Do these heritable factors influence energy intake, energy expenditure, or both? It is clear that by the time a person develops obesity the amount of energy they expend in the resting state is more, not less, than a normal weight person. However, if a person with obesity loses weight by dieting, there is some evidence that they tend to be more "energy efficient" than a person who has never been obese, particularly in terms of how many calories they burn during a defined bout of activity. However, the effects are subtle. It seems very likely that there are some individuals who are predominantly predisposed to develop obesity by virtue of a lower metabolic rate, but thus far, apart from severe hypothyroidism, concrete examples are scarce. In contrast, a much more consistent and compelling body of evidence supports the idea that the genetic predisposition to obesity is largely mediated through the brain's control of food intake. When studied in controlled settings, individuals who carry genetic variants that predispose to obesity tend to eat more and be less readily satiated. This is very readily demonstrable when the mutation has a major effect on obesity predisposition, but similar data are now emerging in the case of common genetic variants with smaller effects.

ENVIRONMENTAL FACTORS PREDISPOSING TO OBESITY

Obesity cannot exist in the absence of sufficient food to lay down and maintain excess fat stores. That fact not infrequently leads to the belief that the principal cause of obesity must be either a person's ignorance of the role of excess caloric intake or their conscious choice to prioritize the immediate pleasures of eating over the long-term health harms associated with obesity. Taken to extremes, these views can engender serious social, economic, and medical discrimination against people with obesity. It is clear that genetic factors, however important they are in an individual's predisposition to obesity, cannot explain the marked increase in obesity prevalence that has occurred in the past few decades. We have to look to an environment that has become increasingly obesogenic to explain that phenomenon. In most developed and developing countries, energy-dense and highly palatable food and beverages have been aggressively marketed, made cheaper than ever before, provided in larger portions, and made available ubiquitously and continuously. This has been combined with the reduction in physical activity in work and domestic life due to mechanization and the change in the nature of employment. Even the control of our external temperature by artificial heating and cooling has meant less energy expended on thermoregulation. Taken together, these are likely to be the major factors driving the recent increase in obesity. It is important to remember, however, that a substantial proportion of the population remains normal weight under these circumstances and a large part of that is attributable to their genetic good fortune.

There is much current investigation into other environmental factors that might influence the development of obesity. Heated debates

continue about the optimal balance of macronutrients in the diet to maintain normal weight and good health. Much of this revolves around the potential benefits of reducing the relative proportion of carbohydrates in the diet (Chap. 414). There seems to be reasonable consensus that, in the short term, diets that are rich in protein and fat and lower in carbohydrates more readily result in quick weight loss. This may be because the appetite-suppressing gut hormones discussed above increase more in response to protein than to carbohydrate, thus inducing earlier satiation. However, longer-term studies to date are less compelling, and the long-term increases in protein and fat intake are not without at least theoretical risks. A growing body of evidence suggests that exposures early in life, either in utero or in early postnatal life, might "program" individuals to develop obesity and/or cardiometabolic disease through effects that are often attributed to "epigenetics" (Chap. 497). This is an attractive idea, and if true, it would mean that time-limited and affordable interventions early in life might have lifelong benefits. Inevitably, it will take time to see if the promise of such interventions will be fulfilled. Much excitement has been generated by the increasing recognition of the diversity of our intestinal microbiome, which clearly has relevance to gastrointestinal health (Chap. 484). At present, it is premature to ascribe any significant role to the human microbiome in obesity or its adverse consequences.

WHY DOESN'T LEPTIN PREVENT OBESITY?

Leptin is known to suppress food intake, and its levels rise as fat stores expand. So why does this not prevent us from developing obesity? The most plausible explanation lies in the evolutionary history of leptin and the fact that it appears to defend strongly against the loss of body fat stores, with a fall in circulating leptin below a person's habitual level being a powerful stimulus to food intake, whereas the response to rises in leptin above the normal level is less pronounced. At higher levels of leptin, administering extra amounts of the hormone may have no discernible effect at all—a phenomenon that has come to be called leptin resistance. It is important to remember that even though a person appears to be leptin resistant, some leptin action is occurring; otherwise, the person would become as insatiably hungry and progressively obese as someone with congenital leptin deficiency (see below). It also seems likely that a subgroup of people may have relatively low leptin levels, which plays a role in the etiology of their obesity. There are likely other hormonal signals produced in severe obesity that, unlike leptin, continue to exert a suppressive effect on food intake and help to ensure that the expansion of adipose tissue does not become indefinitely cumulative.

SINGLE-GENE DISORDERS LEADING TO OBESITY

The assessment of severely obese children and, indeed, adults should be directed at screening for potentially treatable endocrine and neurologic conditions and identifying genetic conditions so that appropriate genetic counseling and, in some cases, treatment can be started. Clinically, it remains useful to categorize the genetic obesity syndromes as those with dysmorphism and/or developmental delay and those without these features (Tables 413-1 and 413-2). Although individually these monogenic disorders are rare, cumulatively, up to 20% of children with severe obesity have rare chromosomal abnormalities and/or highly penetrant genetic mutations that drive their obesity. This figure is likely to increase with wider accessibility to genetic testing and as new genes are identified. A genetic diagnosis can inform management (many such patients find it very difficult to lose weight through diet and exercise) and can inform clinical decision-making regarding the use of bariatric surgery (feasible in some; high risk in others) (Chap. 414). There are a number of drugs in clinical trials targeted specifically at patients with genetic obesity syndromes. Specifically, setmelanotide, a MC4R agonist, has been used effectively in phase 2/3 clinical trials in children who are genetically deficient in POMC, PCSK1, and the leptin receptor. It is also being explored for the treatment of other genetic obesity syndromes affecting the melanocortin pathway and in acquired hypothalamic obesity caused by tumors such as craniopharyngiomas.

TABLE 413-1 Classical Genetic Obesity Syndromes

SYNDROME	INHERITANCE	ADDITIONAL CLINICAL FEATURES
Prader-Willi	Autosomal dominant	Hypotonia, failure to thrive in infancy, developmental delay, short stature, hypogonadotropic hypogonadism, sleep disturbance, obsessive behavior
Albright's hereditary osteodystrophy or pseudohypoparathyroidism	Autosomal dominant	Short stature in some, skeletal defects, developmental delay, shortened metacarpals; hormone resistance when mutation on maternally inherited allele
Bardet-Biedl	Autosomal recessive	Syndactyly/brachydactyly/polydactyly, developmental delay, retinal dystrophy or pigmentary retinopathy, hypogonadism, renal abnormalities
Cohen's	Autosomal recessive	Facial dysmorphism, microcephaly, hypotonia, developmental delay, retinopathy
Carpenter's	Autosomal recessive	Acrocephaly, brachydactyly, developmental delay, congenital heart defects; growth retardation, hypogonadism
Alström's	Autosomal recessive	Progressive cone-rod dystrophy, sensorineural hearing loss, hyperinsulinemia, early type 2 diabetes mellitus, dilated cardiomyopathy, pulmonary, hepatic and renal fibrosis
Tubby	Autosomal recessive	Progressive cone-rod dystrophy, hearing loss

CLASSICAL SYNDROMIC DISORDERS

A number of syndromes were identified by clinicians long before their exact genetic cause was known. In these syndromes, obesity is associated with a stereotyped set of other anomalies, often neurodevelopmental in type. The precise genetic basis for the majority of these syndromes is now known. Prader-Willi syndrome (PWS) is the most common syndromic cause of obesity, with an estimated prevalence of ~1 in 25,000. It is an autosomal dominant disorder caused by deletion of an imprinted region on the paternal chromosome 15 (Chap. 479). The characteristic clinical features are hypotonia, feeding difficulties in infancy, developmental delay, hypogonadotropic hypogonadism, hyperphagia (increased food intake), and obesity. Children with PWS are short with reduced lean body mass and increased fat mass, features resembling those seen in growth hormone (GH) deficiency; GH treatment decreases body fat and increases linear growth and muscle mass and is now standard of care in this condition. Low levels of brain expression of the neuropeptide oxytocin and the nerve growth factor brain-derived neurotrophic factor (BDNF) in PWS patients have suggested new therapeutic opportunities for these patients.

Inherited or de novo (not found in either parent) mutations in another imprinted gene, *GNAS1*, which encodes Gsα protein, cause a syndrome known as Albright's hereditary osteodystrophy (AHO) or pseudohypoparathyroidism (PHP) (Chap. 424). Maternal transmission of *GNAS1* mutations leads to short stature, obesity, and skeletal defects plus resistance to several hormones (e.g., parathyroid hormone), whereas paternal transmission leads only to the AHO phenotype. The clinical spectrum is very broad, and some patients may present with obesity alone.

Bardet-Biedl syndrome (BBS) is a rare autosomal recessive disease characterized by obesity, developmental delay, polydactyly, retinal dystrophy or pigmentary retinopathy, hypogonadism, and renal

TABLE 413-2 Obesity Syndromes due to Mutations in Genes Controlling Energy Homeostasis Pathways

GENE AFFECTED	INHERITANCE	ADDITIONAL CLINICAL FEATURES
Leptin	Autosomal recessive	Severe hyperphagia, frequent infections, hypogonadotropic hypogonadism, mild hypothyroidism
Leptin receptor	Autosomal recessive	Severe hyperphagia, frequent infections, hypogonadotropic hypogonadism, mild hypothyroidism
Proopiomelanocortin	Autosomal recessive	Hyperphagia, cholestatic jaundice or adrenal crisis due to ACTH deficiency, pale skin and red hair
Prohormone convertase 1	Autosomal recessive	Small-bowel enteropathy, postprandial hypoglycemia, hypothyroidism, ACTH deficiency, hypogonadism, central diabetes insipidus
Carboxypeptidase E	Autosomal recessive	Severe insulin resistance
Melanocortin 4 receptor	Autosomal dominant	Hyperphagia, accelerated linear growth
Single-minded 1	Autosomal dominant	Hyperphagia, accelerated linear growth, speech and language delay, autistic traits
BDNF	Autosomal dominant	Hyperphagia, developmental delay, hyperactivity, behavioral problems including aggression
TrkB	Autosomal dominant	Hyperphagia, speech and language delay, variable developmental delay, hyperactivity, behavioral problems including aggression
SH2B1	Autosomal dominant	Hyperphagia, disproportionate hyperinsulinemia, early type 2 diabetes mellitus, behavioral problems including aggression

Abbreviations: ACTH, adrenocorticotropic hormone; *BDNF*, brain-derived neurotrophic factor; *SH2B1*, Src-homology-2 (SH2) B-adaptor protein-1 (SH2B1); *TrkB*, tropomyosin receptor kinase B.

abnormalities. The same clinical features can arise from mutations in >26 genes, which disrupt signaling in primary cilia. Melanocortin receptor agonists may be useful in treating hyperphagia and obesity in patients with BBS. Overlapping clinical features are seen in a number of other genetic obesity syndromes (Table 413-1).

DISORDERS OF LEPTIN-MELANOCORTIN SIGNALING

Homozygous mutations that disrupt the production or action of leptin are rare but result in a disorder that is treatable. Children with homozygous loss-of-function leptin mutations have rapid weight gain in the first few months of life, resulting in severe obesity due to an intense drive to eat (hyperphagia) and impaired satiety with food-seeking behavior soon after the end of a meal. Congenital leptin deficiency can be treated with subcutaneous injections of recombinant leptin, which reduce hunger, increase satiety, and lead to weight loss. Similar clinical features are seen in patients with homozygous mutations in the leptin receptor gene, but they are not responsive to leptin treatment (Table 413-2). Normal pubertal development rarely occurs in adults with leptin or leptin receptor deficiency, with biochemical evidence of hypogonadotropic hypogonadism. However, there is some evidence for the delayed but spontaneous onset of menses in a small number of leptin- and leptin receptor–deficient adults. Leptin treatment permits progression of pubertal development, suggesting that leptin is a permissive factor for the development of puberty. An MC4R agonist (setmelanotide) is licensed for chronic weight management in leptin receptor deficiency.

Homozygous or compound heterozygous mutations in POMC lead to hyperphagia and early-onset obesity. As adrenocorticotropic hormone (ACTH) is produced in the pituitary gland by cleavage from POMC, patients also present with isolated ACTH deficiency (neonatal hypoglycemia and cholestatic jaundice). In the skin, POMC-derived melanocortin peptides act on melanocortin 1 receptors to induce pigmentation. For this reason, the lack of POMC-derived peptides in obese patients with POMC deficiency results in hypopigmentation of skin and hair, which is more noticeable in people of Caucasian ancestry who often have red hair. Prohormone convertase 1 (PCSK1) is an enzyme involved in the cleavage of POMC into ACTH, which is then further cleaved to make α-MSH by carboxypeptidase E. Impaired processing of POMC contributes to the hyperphagic severe early-onset obesity and ACTH deficiency in people lacking PCSK1 who also have hypogonadotropic hypogonadism, postprandial hypoglycemia (due to impaired processing of proinsulin to insulin), and a neonatal enteropathy in early childhood. Heterozygous mutations that impair the function of MC4R are found in 5–6% of patients with severe early-onset obesity and at a frequency of ~1 in 300 in the general population, making this the most common gene in which variants contribute to obesity. MC4R mutations are inherited in a co-dominant manner, with variable penetrance and expression in heterozygous carriers; homozygous carriers are severely obese. Patients are often hyperphagic from early childhood and hyperinsulinemic and have increased lean mass and increased linear growth.

GENETIC SUBTYPES OF OBESITY ASSOCIATED WITH NEUROBEHAVIORAL ABNORMALITIES

Both PWS patients and patients with mutations in *SIM1* (a gene that acts downstream of MC4R) exhibit a spectrum of behavioral abnormalities that overlap with autism-like features that could be related to reduced oxytocin signaling (Table 413-2). Mutations affecting BDNF and its receptor tropomyosin receptor kinase B (TrkB) cause speech and language delay, hyperphagia, and severe obesity, as well as hyperactivity, autistic traits, and impaired short-term memory. Interestingly, a common variant in BDNF (V66M), found in heterozygous form in ~20% of the population, is associated with a number of traits and neuropsychiatric disorders including anxiety and depression. Chromosomal deletion and mutations affecting Src-homology-2 (SH2) B-adaptor protein-1 (*SH2B1*) are associated with dominantly inherited, severe, early-onset obesity, disproportionate insulin resistance, early-onset type 2 diabetes, and behavioral problems including aggressive behavior.

OBESITY SECONDARY TO OTHER DISORDERS

Endocrine Disorders Patients with hypothyroidism may gain weight and develop obesity, although it is rarely the sole cause of severe obesity. It is nonetheless prudent always to measure thyroid function in a patient presenting with obesity. Measurement of thyroid-stimulating hormone (TSH) will detect significant primary disease of the thyroid, but for rare secondary hypothyroidism, additional measurement of free thyroxine levels is needed (Chap. 395). Weight gain can also be a presenting feature of Cushing's syndrome. Clinically, the presence of spontaneous bruising, livid striae, myopathy, and marked centripetal distribution of body fat helps to distinguish true endogenous hypercortisolism from common obesity. This condition is usually reasonably straightforward to diagnose based on tests that approximate cortisol production rates (24-h urine free cortisol) or the suppression of serum cortisol by dexamethasone (Chap. 398). Occasionally, in patients with severe obesity, effects of adiposity on glucocorticoid metabolism can make it difficult to interpret results, and more sophisticated tests, including those measuring diurnal rhythm of cortisol, may be necessary to establish or exclude the diagnosis with confidence. Weight gain can also be a presenting feature of patients with insulinoma, driven largely by the need to eat more frequently than normal to avoid hypoglycemia.

Hypothalamic Damage The hypothalamic regions that control energy balance can be disrupted by tumors (such as craniopharyngiomas), inflammatory masses, or after a severe head injury (Chap. 391). In such cases, there is often some accompanying evidence of disruption of the hormonal functions of the anterior or posterior pituitary, although it may be subtle and the history of hyperphagia and weight gain is often short. It is worth noting that in common obesity, GH levels in response

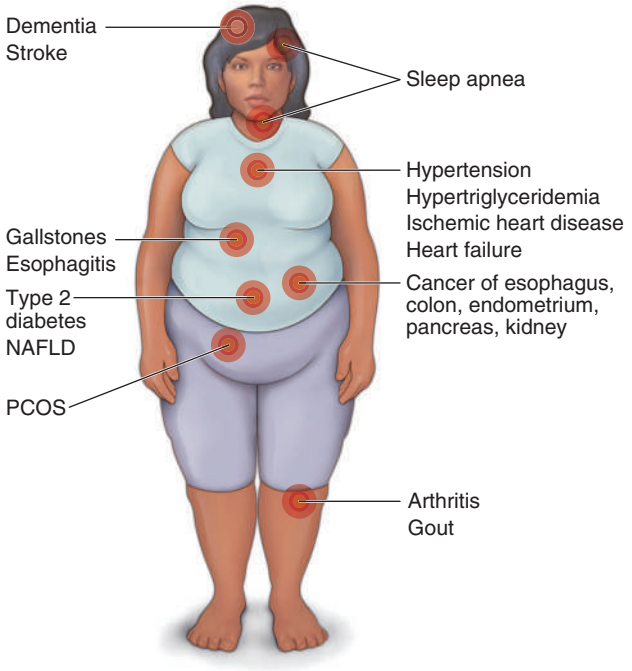

FIGURE 413-4 Obesity-related complications. The expanded fat mass that characterizes obesity predisposes to certain obesity-related complications (e.g., osteoarthritis of knees, reflux esophagitis, and obstructive sleep apnea) directly through its mass and/or volume. However, in the case of the metabolic, endocrine, and cardiovascular complications, the link is less clear. Further research is needed to establish whether some features of the expanded fat mass influence the development of these complications or whether other aspects of the chronically overnourished state, such as excess fat outside the fat depot, are more relevant. NAFLD, nonalcoholic fatty liver disease; PCOS, polycystic ovarian syndrome.

to provocative testing may be somewhat lower than normal, but this does not necessarily suggest the presence of a structural lesion.

ADVERSE CONSEQUENCES OF OBESITY

Mechanistic Considerations Obesity is associated with a wide range of pathologies that can adversely impact morbidity and mortality (Chap. 420). Some of these consequences are related, at least in part, to the direct mechanical or gravitational effects of the expanded fat mass itself (Fig. 413-4). However, the principal mechanisms behind many of the complications of obesity are less likely to be due to the expanded fat mass itself but more closely related to the chronic state of overnutrition itself and its effects on tissues throughout the body.

As people develop obesity, one of the first and most prominent biochemical abnormalities that develops is the need for increased circulating concentrations of insulin to maintain glucose homeostasis. This state of insulin resistance generally worsens with a greater degree of obesity, but there is a high degree of interindividual variability. It is more prominent when fat is distributed more centrally. Insulin resistance/hyperinsulinemia is likely to play a major role in the predisposition to metabolic endocrine and cardiovascular diseases seen more frequently in obesity and may even play a role in the predisposition of people with obesity to develop certain cancers.

The main sites of insulin action in the body are the liver and skeletal muscle. Thus, for insulin resistance to be discernible at the level of the whole body, the action of insulin must be disturbed in one or both of these tissues. It seems unlikely that an expanded fat cell mass would do that directly. How then does obesity lead to a state of insulin resistance? One hypothesis suggests a leading role for the inflammation that occurs in the adipose tissue in obesity (Fig. 413-5). This undoubtedly happens, as there are more macrophages in obese than nonobese adipose tissues, and this is associated with higher levels of inflammatory markers in the circulation of people with obesity. The majority of macrophages in obese adipose tissue are found in clusters around dead or dying adipocytes, so it appears that these cells are clearing debris after cell death. Studies in animal models provide strong support for the notion that this inflammatory state is mechanistically linked to insulin resistance, but evidence from humans for this is not as strong.

An alternative hypothesis is that as individuals develop obesity they become less able to safely store nutrients in their adipose tissue and begin to redirect macronutrients to other tissues that are not designed for fat storage and may be damaged by the nutrient excess. This certainly happens to people who are born with a lack of adipose tissue (lipodystrophy) who, early in life, develop severe versions of all the metabolic complications that are seen in obesity as they have no safe depot in which to store excess nutrients. There are stronger human data from both genetic and pharmacologic studies for the existence of the latter mechanism. How ectopic fat leads to insulin resistance and other damaging effects is still a puzzle, but it is very likely a major driver of pathology associated with obesity.

Metabolic Complications • DYSLIPIDEMIA The insulin resistance of obesity is frequently associated with dyslipidemia characterized by high circulating triglycerides and low high-density lipoprotein cholesterol (Chap. 419). Occasionally, the hypertriglyceridemia may be severe enough to put the patient at risk of pancreatitis. Although there is a relationship between obesity and raised circulating levels of low-density lipoprotein cholesterol (which is the major risk factor for coronary artery disease), genetic factors independent of obesity and the type of dietary fat consumed probably have an even greater impact.

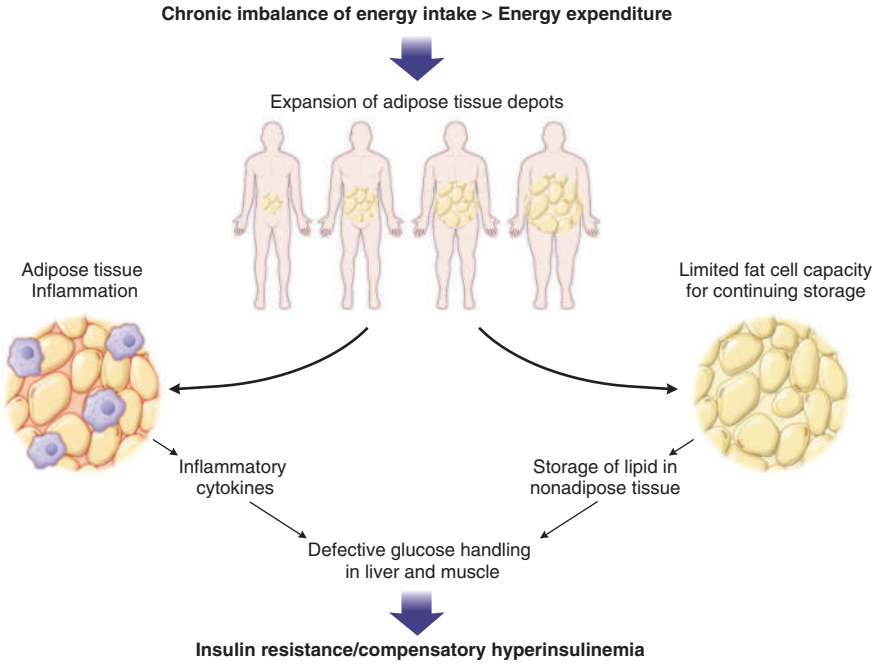

FIGURE 413-5 How does obesity cause metabolic disease? Insulin resistance is one of the earliest complications of obesity and underlies and precedes many of its adverse health consequences. The disposal and production of glucose by the most important tissues, muscle and liver, respectively, become less sensitive to insulin, and this results in a compensatory increase in insulin secretion from the pancreas. There are two main theories for the association of obesity with insulin resistance. In the first, products of macrophages and other inflammatory cells that are more abundant in obese adipose tissue can, through paracrine or endocrine routes, disturb insulin's action in muscle and liver cells. In the second, as adipose storage deposits fill up, they become less able to take on excessive calories, which end up being stored as ectopic lipid in tissues such as muscle and liver, which are not primarily designed to store nutrients of this type. The evidence in humans is stronger for the latter hypothesis.

FATTY LIVER DISEASE Obesity is strongly associated with the presence of ectopic fat in hepatocytes. In a subset of patients, this can progress to nonalcoholic steatohepatitis (NASH), which can progress to fibrosis, which is a precursor to cirrhosis **(Chap. 354)**. The reported incidence of NASH-related cirrhosis and of hepatocellular carcinoma has increased markedly in step with the increase in the prevalence of obesity in adolescents and adults.

TYPE 2 DIABETES The insulin resistance characteristic of the overnourished state strongly predisposes to the development of type 2 diabetes in people who, largely for genetic reasons, are less able to maintain the high levels of insulin secretion over many decades. Impaired glucose tolerance and type 2 diabetes are among the most common complications of obesity **(Chap. 415)**.

Endocrine Complications In females, the insulin resistance/hyperinsulinemia frequently found in obesity strongly predisposes to the development of polycystic ovaries, characterized by irregular menstruation, anovulatory infertility, and hirsutism due to hyperandrogenism. In males, obesity is more often associated with a degree of central hypogonadism, where low circulating testosterone is associated with levels of luteinizing hormone and follicle-stimulating hormone that do not rise appropriately to compensate for the testosterone-deficient state.

Dermatologic Complications Obesity can result in problems with excessive skin folds that can cause discomfort through mechanical irritation and can also become infected with fungi. Insulin resistance/hyperinsulinemia is associated with acanthosis nigricans, where areas such as axilla, groin, and the back of neck develop velvety hyperpigmentation. Hidradenitis suppurativa is a potentially disabling skin condition strongly associated with obesity. It is characterized by recurrent boils often with chronically draining sinus tracts affecting skin areas containing apocrine sweat glands.

Cardiovascular Complications People with obesity, even if they do not have diabetes, have increased morbidity and mortality from atherothrombotic vascular disease, including coronary artery disease and stroke. The factors that result in this are complex and involve increased prevalence of hypertension, dyslipidemia, and insulin resistance/hyperinsulinemia. The rare condition of thrombotic thrombocytopenic purpura, which causes microvascular platelet thrombosis, thrombocytopenia, and hemolytic anemia due to the presence of abnormally large von Willebrand factor multimers, is strongly associated with obesity.

Independent of occlusive arterial disease, people with obesity are also at increased risk of heart failure, particularly characterized primarily by diastolic dysfunction, and of atrial fibrillation, the most common arrhythmia.

Respiratory Complications Exertional dyspnea is common in obesity, contributed to by the increased work required to move a greater mass as well as impacts of pressure on the diaphragm and thoracic cage on chest wall compliance. Enlargement of soft tissue of the mouth and throat and adipose depots around the airways contribute to the high prevalence of sleep apnea, although other factors such as central nocturnal hypoventilation, also contribute in some people.

Gastrointestinal Disorders Reflux esophagitis is the most common gastrointestinal complication of obesity, particularly occurring in those with high intraabdominal pressure. Gallstones are also more common in people with obesity, bringing increased risks of biliary colic, cholecystitis, pancreatitis, and gallbladder cancer.

Rheumatologic Disorders Osteoarthritis of the knee and gout are the two most common rheumatologic conditions clearly associated with obesity. Interestingly, despite obesity being described as a proinflammatory state, there is no evidence for an increase in rheumatoid arthritis or the seronegative arthritides among people with obesity.

Cancers Obesity is a risk factor for a number of common cancers. Indeed, it has recently been calculated that, at least in some countries, obesity has overtaken smoking as the greatest risk factor for developing cancer. Recent research has found that as the BMI increases by 5 kg/m^2, cancer mortality increases by 10%. The largest effects are on colorectal, kidney, and pancreatic cancer, adenocarcinoma of the esophagus, and, in women, endometrial carcinoma. The recent rapid increase in the prevalence of esophageal adenocarcinoma is likely related to the marked recent increase in reflux esophagitis due to the raised intraabdominal pressure (with or without hiatus hernia) characteristic of central obesity.

Response to Infection The fact that obesity can influence the outcome of some infections has become very apparent with the COVID-19 pandemic. Obese patients have a substantially worse outcome if infected by SARS-CoV-2 through mechanisms that are as yet unclear. Obese patients also appear to be more susceptible to bacterial wound infections and postoperative sepsis.

Disorders of the Central Nervous System There is increasing evidence that obesity is a risk factor for dementia in later life, although how that risk is mediated is not clear. Idiopathic intracranial hypertension is a rare disorder that is strongly associated with obesity.

CONCLUSION

Obesity is a medical disorder that has been greatly increasing in prevalence due to environmental factors that are ubiquitous in developed and developing countries. However, it is important to bear in mind that it is a highly heterogeneous condition, which in some people is attributable entirely to genetic causes, and that underlying genetic variation strongly influences the risk of obesity in all people. It is a serious condition leading to multiple adverse health outcomes and considerable human suffering. As our understanding of its pathogenesis increases, our duty to treat obese patients with understanding and compassion and to develop new and better options for its treatment and prevention is worthy of emphasis.

414 Evaluation and Management of Obesity

Robert F. Kushner

More than 70% of U.S. adults are considered to be overweight or have obesity, and the prevalence of obesity is increasing rapidly in most of the industrialized world. Children and adolescents also are developing greater rates of obesity, indicating that the current trends will accelerate

over time. Obesity is associated with an increased risk of multiple health problems, including hypertension, type 2 diabetes, dyslipidemia, obstructive sleep apnea, metabolic dysfunction-associated steatotic liver disease, degenerative joint disease, and some malignancies. Thus, it is important for health care professionals to identify, evaluate, and treat patients for obesity and associated complications and comorbid conditions.

EVALUATION

Health care professionals should screen all adult patients for obesity and offer intensive lifestyle counseling including behavioral interventions to promote sustained weight loss. The four main steps in the evaluation of obesity, as described below, are (1) a focused obesity-related history that includes lifestyle questions about diet, physical activity, sleep, and stress; (2) a physical examination to determine the degree and type of obesity; (3) assessment of complications and comorbid conditions; and (4) assessment of the patient's readiness to engage in weight management.

The Obesity-Focused History The first step in taking an obesity-focused history is to approach the topic in a sensitive manner. The reason for this concern is that the word *obesity* is a highly charged, emotive term. It has a significant pejorative meaning for many patients, leaving them feeling judged and blamed when labeled as such. This is not the case when patients are told that they have other chronic diseases such as diabetes or hypertension. Patients prefer that clinicians use more neutral words or terms such as *weight*, *excess weight*, *body mass index (BMI)*, or *unhealthy weight*, versus more perceived stigmatizing terms such as *obesity*, *morbid obesity*, or *fatness*.

Information from the history should address the following seven questions:

- What factors contribute to the patient's weight gain and obesity?
- How is obesity affecting the patient's health?
- What is the patient's level of risk from obesity?
- What does the patient find difficult about managing weight?
- What are the patient's goals and expectations?
- What is the patient's motivation to begin a weight management program?
- What kind of help does the patient need?

Although the majority of cases of obesity are promoted by biopsychosocial and behavioral factors that affect diet and physical activity patterns, the history may suggest secondary causes that merit further evaluation. Disorders to consider include polycystic ovarian syndrome, hypothyroidism, Cushing's syndrome, and hypothalamic disease. Drug-induced weight gain also should be considered. Common causes include medications for diabetes (insulin, sulfonylureas, thiazolidinediones), steroid hormones, antipsychotic agents (clozapine, olanzapine, risperidone), mood stabilizers (lithium), antidepressants (tricyclics, monoamine oxidase inhibitors, paroxetine, mirtazapine), and antiepileptic drugs (valproate, gabapentin, carbamazepine). Other medications, such as nonsteroidal anti-inflammatory drugs and calcium channel blockers, may cause peripheral edema but do not increase body fat.

The patient's current diet and physical activity patterns may reveal factors that contribute to the development of obesity and may identify behaviors to target for treatment. Physical fitness and sedentary lifestyle, in particular, are important predictors of all-cause mortality rate independent of BMI and body composition, which highlights the importance of taking a physical activity and exercise history during examination as well as emphasizing physical activity as a treatment approach.

Inquiring about sleep health that addresses regularity, duration, efficiency, and satisfaction is also important. Although the mechanisms are uncertain, sleep deprivation is associated with metabolic alterations in appetite regulation, sympathetic nervous system overactivity, insulin sensitivity, and changes in circadian rhythm. Stress may also contribute to obesity, in part due to activation of the adrenal cortical axis and elevated cortisol levels and its impact on emotional health and behaviors. This historic information is best obtained by the combination of a questionnaire and an interview.

TABLE 414-1 Classification of Weight Status and Disease Risk

CLASSIFICATION	BODY MASS INDEX (kg/m^2)	OBESITY CLASS	DISEASE RISK
Underweight	<18.5	—	—
Healthy weight	18.5–24.9	—	—
Overweight	25.0–29.9	—	Increased
Obesity	30.0–34.9	I	High
Obesity	35.0–39.9	II	Very high
Extreme obesity	≥40	III	Extremely high

BMI and Waist Circumference Three key anthropometric measurements are important in evaluating the degree of obesity: weight, height, and waist circumference. The BMI, calculated as weight (kg)/height (m)^2 or as weight (lb)/height (in)^2 × 703, is used to classify weight status and risk of disease **(Table 414-1)**. BMI is correlated with body fat and is related to disease risk. Lower BMI thresholds for overweight and obesity have been proposed for the Asia-Pacific region since this population appears to be at risk for glucose and lipid abnormalities at lower body weights. The problem with BMI is that it only measures the size of an individual. It does *not* measure body composition, distribution of body fat, health, quality of life, or any individual characteristics. BMI has many limitations but is still useful for screening and as a population estimate of increased morbidity and mortality. Currently, direct measurement of excess body fat is not universally practical in the clinical setting.

Excess abdominal fat, assessed by measurement of waist circumference or waist-to-hip ratio, is independently associated with a higher risk for metabolic syndrome, diabetes mellitus, and cardiovascular disease. Measurement of the waist circumference is a surrogate for visceral adipose tissue and should be performed in the horizontal plane above the iliac crest in individuals with a BMI ≤35 kg/m^2 **(Table 414-2)**.

Obesity-Associated Complications and Comorbid Conditions The evaluation of complications and comorbid conditions should be based on presentation of symptoms, risk factors, and index of suspicion. For all patients, a fasting lipid profile (total, low-density lipoprotein, and high-density lipoprotein cholesterol and triglyceride levels), chemistry panel, and glycated hemoglobin should be performed, and blood pressure determined. Symptoms and diseases that are directly or indirectly related to obesity are listed in **Table 414-3**.

TABLE 414-2 Ethnic-Specific Cutpoint Values for Waist Circumference

ETHNIC GROUP	WAIST CIRCUMFERENCE
Europeans	
Men	>94 cm (>37 in)
Women	>80 cm (>31.5 in)
South Asians and Chinese	
Men	>90 cm (>35 in)
Women	>80 cm (>31.5 in)

Stasis pigmentation of legs	
Lymphedema	
Cellulitis	
Intertrigo, carbuncles	
Acanthosis nigricans	
Acrochordons (skin tags)	
Hidradenitis suppurativa	

Although individuals vary, the number and severity of organ-specific complications and comorbid conditions usually rise with increasing levels of obesity.

Identifying the High-Risk Patient Efforts are under way to develop more practical and useful assessments to identify patients who are at high risk in addition to using BMI alone. Analogous to other staging systems commonly used for congestive heart failure or chronic kidney disease, the American Association of Clinical Endocrinology (AACE) and the American College of Endocrinology (ACE) guidelines advocate a simple and clinically useful obesity disease staging system that is based on ethnic-specific BMI cutoffs in conjunction with assessment for adiposity-related complications **(Fig. 414-1)**. Stage 0 is assigned to individuals who are overweight or have obesity by BMI classification but have no complications, whereas stages 1 and 2 are defined as individuals who are overweight or have obesity by BMI classification and have one or more mild-moderate complications (stage 1) or at least one severe complication (stage 2). A different functional staging system for obesity, called the Edmonton Obesity Staging System (EOSS), classifies individuals with obesity into five graded categories (0–4), based on their morbidity and health-risk profile along three domains—medical, functional, and psychological. In this system, staging occurs independent of BMI.

Assessing the Patent's Readiness to Change An attempt to initiate lifestyle changes when the patient is not ready usually leads to frustration and may hamper future weight-loss efforts. Assessment includes patient motivation and support, stressful life events, psychiatric status, time availability and constraints, and appropriateness of goals and expectations. Readiness can be viewed as the balance of two opposing forces: (1) motivation, or the patient's desire to change; and (2) resistance, or the patient's barriers to change.

A helpful method to begin a readiness assessment is to use the motivational interviewing technique of "anchoring" the patient's interest and confidence to change on a numerical scale. With this technique, the patient is asked to rate—on a scale from 0 to 10, with 0 being not so important (or confident) and 10 being very important (or confident)—their level of interest in and confidence about engaging in

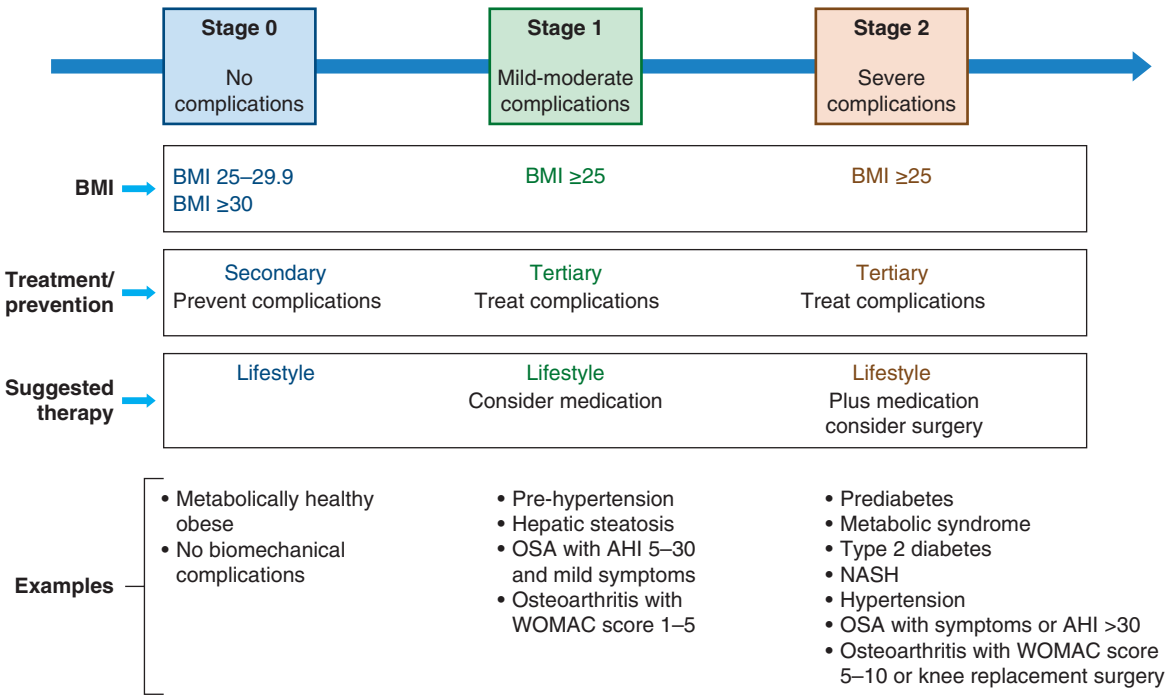

FIGURE 414-1 Staging the severity of obesity using the American Association of Clinical Endocrinology clinical practice guidelines. AHI, apnea-hypopnea index; BMI, body mass index; NASH, nonalcoholic steatohepatitis; OSA, obstructive sleep apnea; WOMAC, Western Ontario and McMaster Universities Osteoarthritis Index (a patient-reported outcome measure for osteoarthritis registering pain, stiffness, and function). *(Data from WT Garvey et al: American Association of Clinical Endocrinologists and American College of Endocrinology comprehensive clinical practice guidelines for medical care of patients with obesity. weight management at this time. This exercise helps establish readiness to change and also serves as a basis for further dialogue.

TREATMENT

Obesity

THE GOAL OF THERAPY

The primary goals of treatment are to improve obesity-related complications and comorbid conditions and quality of life and reduce the risk of developing future obesity-related complications. Information obtained from the history, physical examination, and diagnostic tests is used to determine risk and develop a treatment plan. The decision of how aggressively to treat the patient and which modalities to employ is determined by using shared decision-making that includes the patient's risk status, expectations and personal values, and available resources. Not all patients who are deemed to have obesity by BMI screening need to be treated, since BMI alone is an imperfect measurement of the disease of obesity. However, patients who present with obesity-related complications and comorbidities and who would benefit from weight-loss intervention should be managed proactively. Therapy for obesity always begins with lifestyle management and may include pharmacotherapy or bariatric surgery, depending on BMI risk category **(Table 414-4)**. Setting an initial weight-loss goal of 8–10% over 6 months is a realistic and practical target.

LIFESTYLE MANAGEMENT

Obesity care involves attention to three essential elements of lifestyle: dietary habits, physical activity, and behavior modification. Because obesity is fundamentally a disease of energy imbalance, all patients must learn how and when energy is consumed (diet), how and when energy is expended (physical activity), and how to incorporate this information into their daily lives (behavioral therapy). Lifestyle management has been shown to result in a modest (typically 3–5 kg) weight loss when compared with no treatment or usual care.

Diet Therapy The primary focus of diet therapy is to reduce overall calorie consumption. Guidelines from the American Heart Association/American College of Cardiology/The Obesity Society (AHA/ACC/TOS) recommend initiating treatment with a calorie deficit of 500–750 kcal/d compared with the patient's habitual diet. Alternatively, a diet of 1200–1500 kcal/d for women and 1500–1800 kcal/d for men (adjusted for the individual's body weight) can be prescribed. This reduction is consistent with a goal of losing ~1–2 lb/week. The calorie deficit can be instituted through dietary substitutions or alternatives. Examples include choosing smaller portion sizes, eating more fruits and vegetables, consuming more whole-grain cereals, selecting leaner cuts of meat and skimmed dairy products, reducing consumption of fried foods and other foods with added fats and oils, and drinking water instead of sugar-sweetened beverages. It is important that dietary counseling remains patient centered and that the selected goals are SMART (specific, measurable, agreed upon, realistic, timely).

The macronutrient composition of the diet will vary with the patient's preference and medical condition. The 2020 U.S. Department of Agriculture Dietary Guidelines for Americans **(Chap. 343)**, which focus on health promotion and risk reduction, can be applied to treatment of patients who are overweight or have obesity. The recommendations include maintaining a diet rich in whole grains, fruits, vegetables, and dietary fiber; decreasing sodium intake to <2300 mg/d; consuming fat-free or low-fat dairy products; and keeping added sugars and saturated fat intake to <10% of daily calories. Application of these guidelines to specific calorie goals can be found on the website *www.choosemyplate.gov*. Since portion control is one of the most difficult strategies for patients to manage, the use of preprepared products such as meal replacements is a simple and convenient suggestion. Examples include frozen entrees, protein shakes, and bars. Use of meal replacements in the diet has been shown to result in a 7–8% weight loss.

Numerous randomized trials comparing diets of different macronutrient composition (e.g., low-carbohydrate, low-fat, Mediterranean) have shown that weight loss depends primarily on reduction of total caloric intake and adherence to the prescribed diet, not the specific proportions of carbohydrate, fat, and protein in the diet. The macronutrient composition will ultimately be determined by the patient's taste preferences, cooking style, and culture. However, the patient's underlying medical problems are also important in guiding the recommended dietary composition. The dietary prescription will vary according to the patient's metabolic profile and risk factors. A consultation with a registered nutritionist for medical nutrition therapy is particularly useful in considering patient preference and treatment of comorbid diseases.

Another dietary approach to consider is based on the concept of *energy density*, which refers to the number of calories (i.e., amount of energy) a food contains per unit of weight. People tend to ingest a constant volume of food regardless of caloric or macronutrient content. Adding water or fiber to a food decreases its energy density by increasing weight without affecting caloric content. Examples of foods with low energy density include soups, fruits, vegetables, oatmeal, and lean meats. Dry foods and high-fat foods such as pretzels, cheese, egg yolks, potato chips, and red meat have a high energy density. Diets containing low-energy-dense foods have been shown to control hunger and thus to result in decreased caloric intake and weight loss.

Occasionally, very-low-calorie diets (VLCDs) are prescribed as a form of aggressive dietary therapy. The primary purpose of a VLCD is to promote a rapid and significant (13- to 23-kg) short-term weight loss over a 3- to 6-month period. The proprietary formulas designed for this purpose typically supply ≤800 kcal, 50–80 g of protein, and 100% of the recommended daily intake for vitamins and minerals. Indications for initiating a VLCD include the involvement of well-motivated individuals who have moderate to severe obesity, have failed at more conservative approaches to weight loss, and have a medical condition that would be immediately improved with rapid weight loss. These conditions include poorly controlled type 2 diabetes, hypertriglyceridemia, obstructive sleep apnea, and symptomatic peripheral edema. In the DiRECT trial of patients with type 2 diabetes and obesity, a low-energy formula diet (825–853 kcal/d) was administered for 3 months following by a structured monthly program. At 12 months, almost half of the participants achieved remission to a nondiabetic state off of all antidiabetic drugs. Use of formula diets should be prescribed by trained practitioners in a medical care setting where medical monitoring and high-intensity lifestyle intervention can be provided.

Physical Activity Therapy Although exercise alone is only moderately effective for weight loss, the combination of dietary

TABLE 414-4 A Guide to Opting for Treatment for Obesity

Source: Reproduced from U.S. Department of Health and Human Services Public Health Service. National Institute of Health National Heart, Lung and Blood Institute. The Practical Guide Identification, Evaluation, and Treatment of Overweight and Obesity in Adults. NIH Publication Number 00-4084. October 2000.

modification and exercise is the most effective behavioral approach for the treatment of obesity. The most important role of exercise appears to be in the maintenance of weight loss. The 2018 Physical Activity Guidelines for Americans (*www.health.gov/paguidelines*) recommend that adults should engage in 150 min of moderate-intensity or 75 min a week of vigorous-intensity aerobic physical activity per week, preferably spread throughout the week. Focusing on simple ways to add physical activity into the normal daily routine through leisure activities, travel, and domestic work should be suggested. Examples include brisk walking, using the stairs, doing housework and yard work, and engaging in sports. Additionally, it is important to reduce sedentary behavior, which is associated with all-cause and cardiovascular disease mortality in adults. Asking the patient to use a wearable activity tracker to monitor total accumulation of steps or kcal expended as part of the activities of daily living is a useful strategy. Step counts are highly correlated with activity level. Studies have demonstrated that lifestyle activities are as effective as structured exercise programs for improving cardiorespiratory fitness and weight loss. A high level of physical activity (>300 min of moderate-intensity activity per week) is often needed to lose weight and sustain weight loss. These exercise recommendations are daunting to most patients and need to be implemented gradually. Consultation with an exercise physiologist or personal trainer may be helpful.

Behavioral Therapy Cognitive behavioral therapy is used to help change and reinforce new dietary and physical activity behaviors. Strategies include self-monitoring techniques (e.g., journaling, weighing, and measuring food and activity); stress management; stimulus control (e.g., using smaller plates, not eating in front of the television or in the car); social support; problem solving; and cognitive restructuring to help patients develop more positive and realistic thoughts about themselves. When recommending any behavioral lifestyle change, the patient should be asked to identify what, when, where, and how the behavioral change will be performed. The patient should keep a record of the anticipated behavioral change so that progress can be reviewed at the next office visit. Because these techniques are time consuming to implement, their supervision is often undertaken by ancillary office staff, such as an advanced practice provider or registered nutritionist.

PHARMACOTHERAPY

Adjuvant pharmacologic treatments should be considered for patients with a BMI ≥30 kg/m^2 or a BMI ≥27 kg/m^2 who have concomitant obesity-related diseases and for whom dietary and physical activity therapy has not been successful. When an antiobesity medication is prescribed, patients should be actively engaged in a lifestyle program that provides the strategies and skills needed to use the drug effectively since such support increases total weight loss.

Medications for obesity have traditionally fallen into two major categories: those that affect appetite and those that inhibit gastrointestinal fat absorption. However, since the introduction of more effective nutrient-stimulated hormone-based therapeutics in 2021, an additional designation of first- and second-generation medications has been adopted. Antiobesity medications are approved by the U.S. Food and Drug Administration (FDA) with an indication for chronic weight management, with the exception of phentermine and other sympathomimetics, which are only approved for short-term use. The centrally active medications work biologically to suppress appetite, affecting hunger, satiety, and response to highly rewarding foods, and thus making it easier for patients to follow their dietary intentions to reduce caloric intake. In addition, one capsule that is considered a medical device was marketed in 2020. Characteristics of the currently approved antiobesity medications are shown in **Table 414-5**.

First-Generation Centrally Acting Medications This class of medications directly targets neurotransmitters in the hypothalamus and reward centers in the central nervous system **(Chap. 413)** to affect satiety (feeling of fullness after a meal), hunger (the biologic sensation that prompts eating), and craving (intense desire for a specific food). By controlling appetite, these agents help patients reduce caloric intake without a sense of deprivation. The classic sympathomimetic adrenergic agents (benzphetamine, phendimetrazine, diethylpropion, and phentermine) function by stimulating norepinephrine release or by blocking its reuptake. Among these agents, phentermine is the most commonly prescribed; however, there is limited long-term data on its effectiveness. A 2002 review of six randomized, placebo-controlled trials of phentermine for weight control found that patients lost 0.6–6.0 additional kg of weight over 2–24 weeks of treatment. The most common side effects of the amphetamine-derived agents are restlessness, insomnia, dry mouth, constipation, and increased blood pressure and heart rate.

Phentermine/topiramate (PHEN/TPM) is a combination drug that contains a catecholamine releaser (phentermine) and an anticonvulsant (topiramate). Topiramate is approved by the FDA as an anticonvulsant for the treatment of epilepsy and for the prophylaxis of migraine headaches. Weight loss was identified as an unintended side effect of topiramate during clinical trials for epilepsy. The mechanism responsible for weight loss is uncertain but is thought to be mediated through the drug's modulation of γ-aminobutyric acid receptors, inhibition of carbonic anhydrase, and antagonism of glutamate. PHEN/TPM has undergone two 1-year pivotal randomized, placebo-controlled, double-blind trials of efficacy and safety: EQUIP and CONQUER. In a third study, SEQUEL, 78% of CONQUER participants continued to receive their blinded treatment for an additional year. All participants received diet and exercise counseling. Mean percent weight loss for participants randomized to medication and placebo are displayed in **Fig. 414-2**. Intention-to-treat 1-year placebo-subtracted weight loss for PHEN/TPM was 9.3% (15-mg/92-mg dose) and 6.6% (7.5-mg/46-mg dose), respectively, in the EQUIP and CONQUER trials. Clinical and statistical dose-dependent improvements were seen in selected cardiovascular and metabolic outcome measurements that were related to the weight loss. The most common adverse events experienced by the drug-randomized group were paresthesias, dry mouth, constipation, dysgeusia, and insomnia. Because of an increased risk of congenital fetal oral-cleft formation from topiramate, women of childbearing age should have a negative pregnancy test before treatment and monthly thereafter and use effective contraception consistently during medication therapy.

Naltrexone SR/bupropion SR (NB) is a combination of an opioid antagonist and a dopamine and norepinephrine reuptake inhibitor, respectively. Individually, naltrexone is approved by the FDA for the treatment of alcohol dependence and for the blockade of the effects of exogenously administered opioids, whereas bupropion is approved as an antidepressant and smoking cessation aid. As a combination drug, each component works in consort: bupropion stimulates secretion of α-melanocyte-stimulating hormone (MSH) from proopiomelanocortin (POMC), whereas naltrexone blocks the feedback inhibitory effects of opioid receptors activated by the β-endorphin released in the hypothalamus, thus allowing the inhibitory effects of MSH to reduce food intake.

The medication has undergone three randomized, placebo-controlled, double-blind trials for efficacy and safety. Participants were randomized to receive NB (8 mg/90 mg two tablets bid) or placebo in the three COR studies. Whereas participants received standardized nutritional and exercise counseling in COR-I and COR-II, a more intensive behavior modification program was provided in COR-BMOD (Table 414-5). Intention-to-treat 1-year placebo-subtracted weight loss was 4.8%, 5.1%, and 4.2%, respectively, in the COR-I, COR-II, and COR-BMOD trials. Clinical and statistical dose-dependent improvements were seen in selected cardiovascular and metabolic outcome measurements that were related to the weight loss. However, the medication led to slight increases or smaller decreases in blood pressure and pulse than placebo. The most common adverse events experienced by the drug-randomized groups were nausea, constipation, headache, vomiting, dizziness, diarrhea, insomnia, and dry mouth.

TABLE 414-5 Antiobesity Medications

DRUG CHARACTERISTIC	PHENTERMINE	ORLISTAT	PHEN/TPM	NAL/BUP	LIRAGLUTIDE	SEMAGLUTIDE	TIRZEPATIDE
Mechanism of action	Sympathomimetic, increases norepinephrine release in CNS	Gastrointestinal lipase enzyme inhibitor	Phen: sympathomimetic in CNS; TPM: modulates GABA receptors in the CNS	Nal: blocks opioid-mediated POMC autoinhibition; bup: activates POMC in the hypothalamus	GLP-1 receptor agonist	GLP-1 receptor agonist	GLP-1/GIP dual receptor agonist
Route of administration, frequency, and dose	Oral, once to 3 times daily, doses of 8, 15, 30, and 37.5 mg	Oral, 3 times daily, within 1 h of fat-containing meals	Oral, once daily. Start 3.75/23 mg/d × 2 weeks, then 6.5/46 mg/d; can escalate to max dose of 15/2 mg/d	Oral, 1 tablet (8 mg/90 mg) qAM × 1 week; 1 tablet in morning and evening × 1 week; 2 tablets in morning and 1 tablet in evening × 1 week; then 2 tablets in morning and 2 tablets in evening	Subcutaneous, once daily; initiate at 0.6 mg/d × 1 week; increase by 0.6 mg weekly to 3 mg/d	Subcutaneous, once weekly; 0.25 mg qW × 4 weeks, then 0.5 mg qW × 4 weeks, then 1 mg qW × 4 weeks, then 1.7 mg qW × 4 weeks, then 2.4 mg qW	Subcutaneous, once weekly; 2.5 mg qW × 4 weeks, then 5 mg qW × 4 weeks, then 7.5 mg qW × 4 weeks, then 10 mg qW × 4 weeks, then 12.5 mg qW, then 15 mg qW
Percent weight loss (placebo subtracted)[a]	4.4%	4.1%	8.0%	5.1%	5.4%	12.5%	17.8%
Most common adverse effects	Dry mouth Insomnia Constipation Headache Dizziness	Steatorrhea Increased defecation Oily spotting Liquid stool Fecal urgency	Paresthesia Dry mouth Constipation Headache Insomnia Dizziness	Nausea Constipation Headache Vomiting Dizziness Insomnia	Nausea Diarrhea Constipation Dyspepsia Vomiting	Nausea Diarrhea Constipation Dyspepsia Vomiting	Nausea Diarrhea Constipation Abdominal pain
Contraindications	Uncontrolled hypertension, untreated hyperthyroidism, within 14 d of MAOI use	Chronic malabsorption	Uncontrolled hypertension, untreated hyperthyroidism, history of glaucoma, calcium oxalate nephrolithiasis, within 14 d of MAOI use	Uncontrolled hypertension, history of seizures, bulimia or anorexia nervosa, within 14 d of MAOI use, long-term opioid use	Personal or family history of medullary thyroid cancer, MEN type 2; pancreatitis is a caution	Personal or family history of medullary thyroid cancer; MEN type 2; pancreatitis is a caution	Personal or family history of medullary thyroid cancer, MEN type 2; pancreatitis is a caution

[a]Based on maximal dose.

Abbreviations: CNS, central nervous system; GABA, γ-aminobutyric acid; GIP, gastric inhibitory polypeptide; GLP-1, glucagon-like peptide 1; MAOI, monoamine oxidase inhibitor; MEN, multiple endocrine neoplasia; Nal/Bup, naltrexone/bupropion; Phen/TPM, phentermine/topiramate; POMC, proopiomelanocortin; qW, every week.

Liraglutide was the first glucagon-like peptide 1 receptor agonist (GLP-1 RA) with 97% homology to human GLP-1 that introduces nutrient-stimulated, hormone-based therapy for the treatment of obesity. In addition to its effect as an incretin hormone (glucose-induced insulin secretion), liraglutide inhibits both gastric emptying and glucagon secretion and stimulates GLP-1 receptors in the arcuate nucleus of the hypothalamus, the nucleus tractus solitarius of the brainstem, and projections to other appetite-modulating relay nuclei to reduce appetite. As a result of molecular modifications of the structure, liraglutide has reduced susceptibility to DPP-4 and can be dosed once daily by subcutaneous (SC) administration with a half-life of ~11–15 h. Liraglutide was initially approved for the treatment of type 2 diabetes in the United States in 2010 at doses up to 1.8 mg once daily. It was subsequently approved for obesity treatment at doses up to 3.0 mg once daily in 2014 for adults and, in 2020, for adolescents (aged ≥12 years).

Specifically targeting obesity, liraglutide has undergone five randomized, double-blind, placebo-controlled trials in adults called SCALE (Satiety and Clinical Adiposity–Liraglutide Evidence) involving >5000 adult participants to evaluate its efficacy and safety for weight management. All participants received diet and physical activity counseling and were randomized to receive liraglutide (3.0 mg SC daily) or placebo with the primary outcome of change in body weight. Intention-to-treat 1-year placebo-subtracted weight loss for these trials ranged from 3.4 to 6.1%. Clinical and statistical dose-dependent improvements were seen in selected cardiovascular and metabolic outcome measurements. In SCALE TEENS, which involved adolescents with obesity (average age 14.6 years), the liraglutide-treated group demonstrated a placebo-subtracted weight loss of 5%. The most common adverse events from the SCALE trials were nausea, diarrhea, constipation, and vomiting, which were reported as mild and transient. GLP-1 agonists should not be prescribed in patients with a family or personal history of medullary thyroid cancer or multiple endocrine neoplasia.

Setmelanotide is a melancortin-4 (MC4) receptor agonist that was FDA approved in 2020 for daily SC administration for chronic weight management in adults and pediatric patients 6 years of age and older with monogenic or syndromic obesity due to Bardet-Biedl syndrome (BBS) or POMC, proprotein convertase subtilisin/kexin type 1 (PCSK1), or leptin receptor (LEPR) deficiency. The medication addresses the underlying hyperphagia and specific molecular mechanism of these rare genetic diseases. The most common side effects include injection site reactions, skin hyperpigmentation, nausea, and spontaneous penile erections.

First-Generation Peripherally Acting Medication Orlistat is currently the only medication in this class. It is a synthetic hydrogenated derivative of a naturally occurring lipase inhibitor, lipostatin, that is produced by the mold *Streptomyces toxytricini*. This drug is a potent, slowly reversible inhibitor of pancreatic, gastric, and carboxylester lipases and phospholipase A_2, which are required for the hydrolysis of dietary fat into fatty acids and monoacylglycerols.

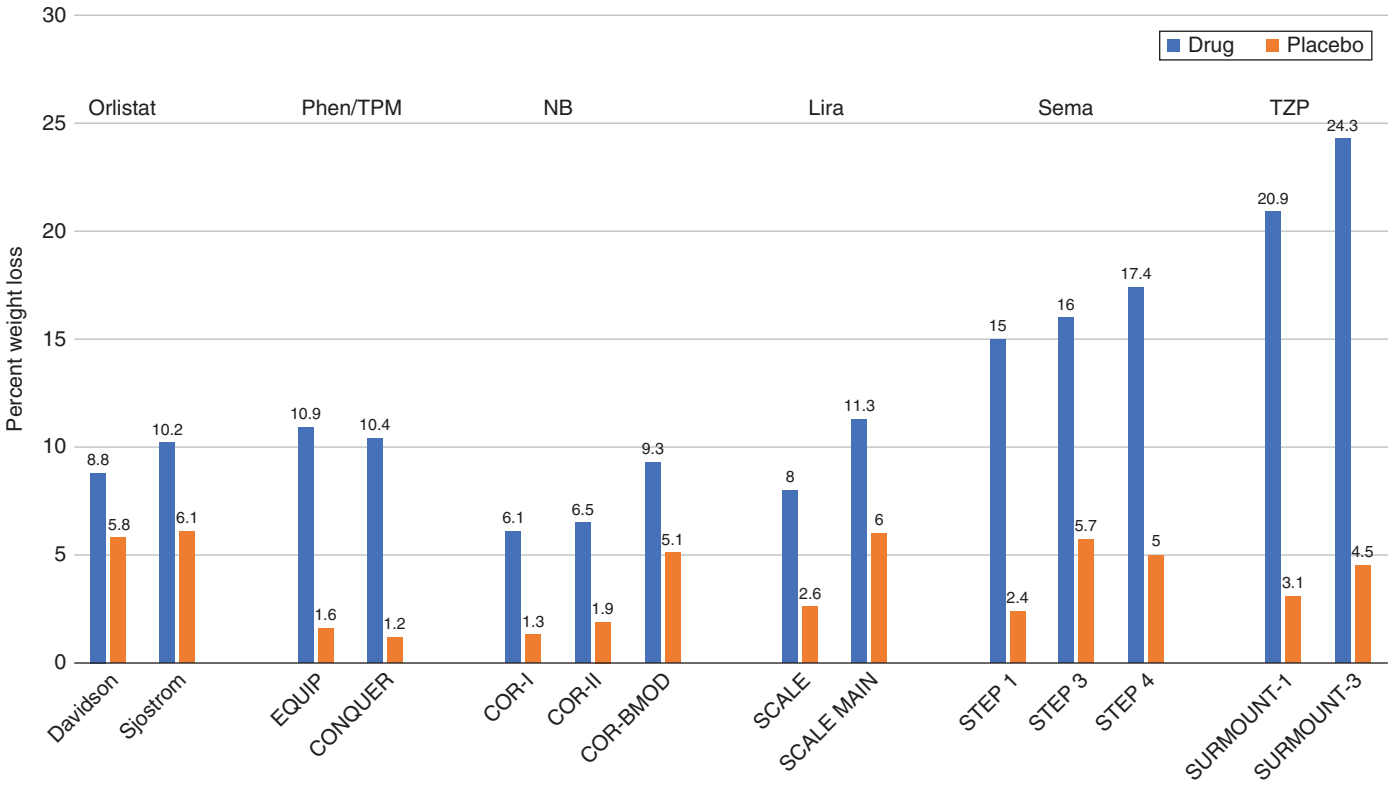

FIGURE 414-2 One-year mean weight loss for antiobesity medications compared to placebo. Lira, liraglutide; NB, naltrexone/bupropion; Phen/TPM, phentermine/topiramate; Sema, semaglutide; TZP, tirzepatide.

Orlistat acts in the lumen of the stomach and small intestine by forming a covalent bond with the active site of these lipases. Taken at a therapeutic dose of 120 mg tid, orlistat blocks the digestion and absorption of ~30% of dietary fat. After discontinuation of the drug, fecal fat content usually returns to normal within 48–72 h.

Multiple randomized, double-blind, placebo-controlled studies have shown an intention-to-treat 1-year placebo-subtracted weight loss of 2.7–4.1%. Because orlistat is minimally (<1%) absorbed from the gastrointestinal tract, it has no systemic side effects. Tolerability is related to the malabsorption of dietary fat, and this is generally diminished as patients control their dietary fat intake. Because serum concentrations of the fat-soluble vitamins D and E and β-carotene may be reduced by orlistat treatment, vitamin supplements are recommended to prevent potential deficiencies. Orlistat was approved for over-the-counter use in 2007.

Second-Generation Medications Semaglutide is generally recognized as the first drug in this category based on its greater weight loss efficacy and further chemical modification that allows for once-weekly SC administration with a longer half-life. Semaglutide was initially approved for the treatment of type 2 diabetes in the United States at doses up to 1.0 mg once weekly in 2017 and at 2.0 mg once weekly in 2022. It was subsequently approved at doses up to 2.4 mg once weekly for chronic weight management for adults in 2021 and for adolescents in 2022.

Semaglutide has undergone multiple prospective, randomized, placebo-controlled trials in the STEP (Semaglutide Treatment Effect in People with Obesity) program that was designed to investigate the effect of semaglutide 2.4 mg SC weekly versus placebo on weight loss, safety, and tolerability in adults with obesity or overweight. Intention-to-treat placebo-subtracted weight loss for the STEP 1 to 4 trials ranged from 6.2 to 14.8% at 68 weeks depending on the population and study design, and loss of 12.6% occurred after 104 weeks for STEP 5. Clinical and statistical dose-dependent improvements were seen in selected cardiovascular and metabolic outcome measurements. The most common adverse effects include nausea, diarrhea, constipation, and vomiting. GLP-1 RAs should not be prescribed in patients with a family or personal history of medullary thyroid cancer or multiple endocrine neoplasia.

In the STEP TEENS trial, adolescents with overweight or obesity randomized to semaglutide 2.4 mg achieved a 16.1% reduction in BMI versus a 0.6% increase for placebo. The recent SELECT (Semaglutide Effects on Cardiovascular Outcomes in People with Overweight or Obesity) trial demonstrated a 20% reduction in major adverse cardiovascular events in patients with preexisting cardiovascular disease and overweight or obesity but without diabetes who were randomized to semaglutide 2.4 mg versus placebo, and the STEP-HFpEF trial observed improved heart failure–related symptoms, physical limitations, and exercise function and reduced body weight and inflammation in patients randomized to semaglutide versus placebo.

Tirzepatide is the first long-acting, weekly, injectable, dual GLP-1/gastric inhibitory polypeptide (GIP) peptide analogue, engineered from the native GIP sequence with agonist activity at both the GLP-1 and GIP receptors with a half-life of ~117 h. Whereas GIP receptor agonism is equal to native GIP, the molecule's GLP-1 receptor affinity is approximately five times weaker than native GLP-1. GIP in the brain appears to act synergistically with GLP-1 receptor activation to allow greater weight loss. Tirzepatide was FDA approved for type 2 diabetes in 2022 and subsequently approved for chronic weight management in adults in 2023, at 5-, 10-, and 15-mg doses.

Tirzepatide has undergone multiple prospective, randomized, placebo-controlled trials in the SURMOUNT clinical development program that was designed to investigate the effect of tirzepatide 5-, 10-, and 15-mg SC weekly doses versus placebo on weight loss, safety, and tolerability in adults with obesity or overweight. Intention-to-treat placebo-subtracted weight loss for SURMOUNT 1 to 4 trials at the 15-mg dose ranged from 11.6 to 21.4% depending on the study population and design. Clinical and statistical dose-dependent improvements were seen in selected cardiovascular and metabolic outcome measurements. Similar to GLP-1 RAs, the most common adverse events are gastrointestinal (nausea, diarrhea,

constipation, and vomiting) and reported as mild and transient; tirzepatide should not be prescribed in patients with a family or personal history of medullary thyroid cancer or multiple endocrine neoplasia.

Oral Device Gelesis100 is a nonsystemic, water-soluble gel that was approved by the FDA in 2019. In the stomach, the capsule releases the cellulose microgel, which absorbs water and forms a matrix with the consistency of food, occupying ~25% of the stomach. In the large intestine, it is broken down by enzymes and the cellulose is excreted. Gelesis100 and placebo were evaluated over 24 weeks in patients with BMI of 27 to ≤40 kg/m^2 and fasting plasma glucose of 90–145 mg/dL. Intention-to-treat, 24-week, placebo-subtracted weight loss was 2.1% (6.4 vs 4.4%). Gelesis100 treatment had no apparent increased safety risks. The capsules are approved for patients with a BMI of ≥25 kg/m^2, with or without comorbidities.

SURGERY

Bariatric surgery **(Fig. 414-3)** can be considered for patients with severe obesity (BMI ≥40 kg/m^2) or for those with moderate obesity (BMI ≥35 kg/m^2) associated with a number of comorbid conditions. The clinical benefits of bariatric surgery in achieving weight loss and alleviating metabolic complications and comorbidities have been attributed largely to changes in the physiologic responses of gut hormones, bile acid metabolism, the microbiota, and adipose tissue metabolism. Metabolic effects resulting from bypassing the foregut include altered responses of ghrelin, GLP-1, peptide YY3-36, and oxyntomodulin. Additional effects on food intake and body weight control may be attributed to changes in vagal signaling. The loss of fat mass, particularly visceral fat, is associated with multiple metabolic, adipokine, and inflammatory changes that include improved insulin sensitivity and glucose disposal; reduced free fatty acid flux; increased adiponectin levels; and decreased interleukin 6, tumor necrosis factor α, and high-sensitivity C-reactive protein levels.

Restrictive surgeries limit the amount of food the stomach can hold and slow the rate of gastric emptying. *Laparoscopic adjustable gastric banding* is the prototype of this category. The first banding device was approved for use in the United States in 2001. In contrast to previous devices, this band has a diameter that is adjustable by way of its connection to a reservoir that is implanted under the skin. Injection of saline into the reservoir and removal of saline from the reservoir tighten and loosen the band's internal diameter, respectively, thus changing the size of the gastric opening. Although the mean percentage of total body weight lost at 5 years is estimated at 20–25%, longer-term follow-up has been more disappointing, leading to near abandonment of the procedure. In the *laparoscopic sleeve gastrectomy*, the stomach is restricted by stapling and dividing it vertically, removing ~80% of the greater curvature and leaving a slim banana-shaped remnant stomach along the lesser curvature. Weight loss after this procedure is superior to that after laparoscopic adjustable gastric banding.

The three restrictive-malabsorptive bypass procedures combine the elements of gastric restriction and selective malabsorption: Roux-en-Y gastric bypass, biliopancreatic diversion, and biliopancreatic diversion with duodenal switch (Fig. 414-3). These procedures are routinely performed by laparoscopy.

These procedures generally produce a 28–33% average total body weight loss at 12–18 months followed by variable weight recurrence. Significant improvement in multiple obesity-related comorbid conditions, including type 2 diabetes, hypertension, dyslipidemia, obstructive sleep apnea, quality of life, and long-term cardiovascular events, has been reported. A meta-analysis of controlled clinical trials comparing bariatric surgery versus no surgery showed that surgery was associated with a reduced odds ratio (OR) risk of global mortality (OR = 0.55), cardiovascular death (OR = 0.58), and all-cause mortality (OR = 0.70).

Among the observed improvements in comorbidities, the prevention and treatment of type 2 diabetes resulting from bariatric

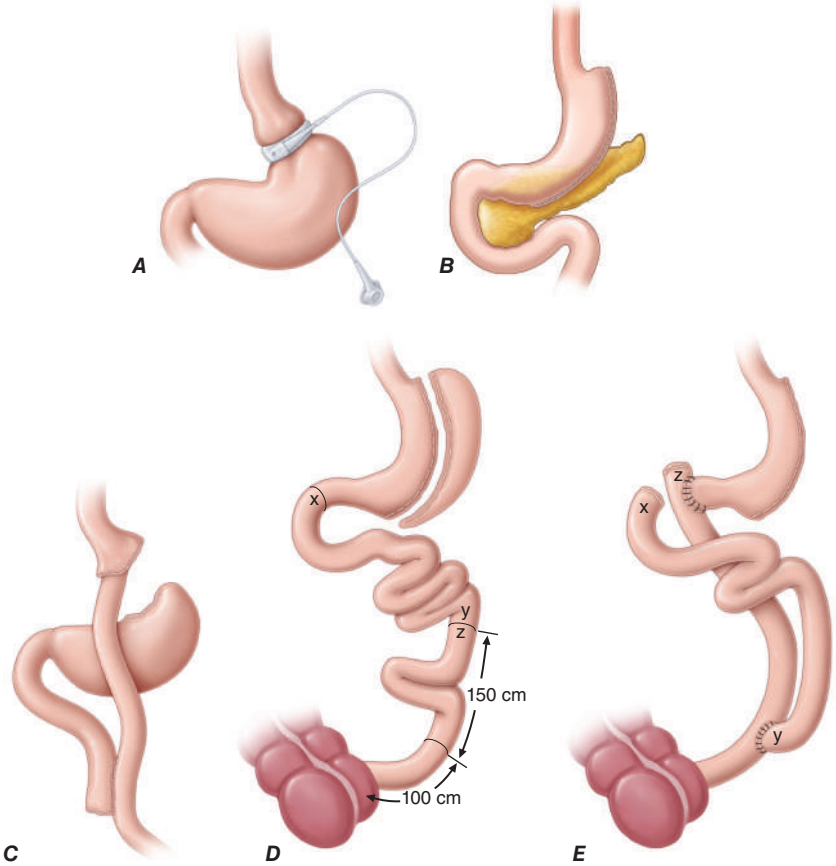

FIGURE 414-3 Bariatric surgical procedures. Examples of operative interventions used for surgical manipulation of the gastrointestinal tract. ***A.*** Laparoscopic adjustable gastric banding. ***B.*** Laparoscopic sleeve gastrectomy. ***C.*** The Roux-en-Y gastric bypass. ***D.*** Biliopancreatic diversion with duodenal switch. ***E.*** Biliopancreatic diversion.

surgery have garnered the most attention. Fifteen-year data from the Swedish Obese Subjects study demonstrated a marked reduction (i.e., by 78%) in the incidence of type 2 diabetes development among patients with obesity who underwent bariatric surgery. Multiple randomized controlled studies have shown greater weight loss and more improved glycemic control from 1 and 12 years among surgical patients than among patients receiving conventional medical therapy. A retrospective cohort study of >4000 adults with diabetes found that, overall, 68.2% of patients experienced an initial complete remission of type 2 diabetes within 5 years after surgery. However, among these patients, one-third redeveloped type 2 diabetes within 5 years. Patients with earlier-stage type 2 diabetes (i.e., those who do not need insulin, with shorter-duration disease, and with lower hemoglobin A_{1c}) appear to have better improvement after bariatric surgery. The rapid improvement seen in diabetes after bariatric surgery is thought to be due to caloric restriction, reduced insulin resistance, and surgery-specific effects on glucose homeostasis brought about by alteration of gut hormones.

The mortality rate from bariatric surgery is generally <1% but varies with the procedure, the patient's age and comorbid conditions, and the experience of the surgical team. The most common surgical complications resulting from the RYGB procedure include stomal stenosis or marginal ulcers (occurring in 5–15% of patients) that present as prolonged nausea and vomiting after eating or inability to advance the diet to solid foods. These complications typically are treated by endoscopic balloon dilation and acid suppression therapy, respectively. For patients who undergo laparoscopic adjustable gastric banding, there are no intestinal absorptive abnormalities other than mechanical reduction in gastric size and outflow. Therefore, selective deficiencies are uncommon unless eating habits become unbalanced. In contrast, the restrictive-malabsorptive procedures carry an increased risk for micronutrient deficiencies of vitamin B_{12}, iron, folate, calcium, and vitamin D. Patients with restrictive-malabsorptive procedures require lifelong supplementation with these micronutrients.

NONSURGICAL ENDOSCOPIC TECHNIQUES

Endoscopic techniques offer potentially reversible and minimally invasive methods for treatment of obesity. These techniques include intraluminal gastric balloons, which are space-occupying devices that limit gastric volume, decrease hunger, and reduce food intake. The balloons generally need to be removed after 6 months, and produce a weight loss of 6–12% at the time of device removal. Adverse effects include nausea, vomiting, and abdominal pain. Gastric remodeling procedures such as the endoscopic sleeve gastroplasty (ESG), which induces early satiety and reduces gastric emptying, has demonstrated a weight loss of 18% at 2 years, comparable to the bariatric sleeve gastrectomy.

415 Diabetes Mellitus: Diagnosis, Classification, and Pathophysiology

Alvin C. Powers, Kevin D. Niswender, Carmella Evans-Molina

Diabetes mellitus (DM) refers to a group of common metabolic disorders that share the phenotype of hyperglycemia. Several distinct types of DM are caused by a complex interaction of genetics and environmental factors. Depending on the etiology of the DM, factors contributing to hyperglycemia include reduced insulin secretion, decreased glucose utilization, and increased glucose production. The metabolic dysregulation associated with DM causes secondary pathophysiologic changes in multiple organ systems that impose a tremendous burden on the individual with diabetes and on the health care system. In the United States, DM is the leading cause of end-stage renal disease (ESRD), nontraumatic lower-extremity amputations, and adult blindness. Persons with diabetes are at increased risk for cardiovascular disease, which is the main cause of morbidity and mortality in this population.

CLASSIFICATION

DM is classified on the basis of the pathogenic process leading to hyperglycemia **(Table 415-1)**. There are two broad categories of DM, designated as either type 1 or type 2 DM. However, there is increasing recognition of other forms of diabetes in which the molecular pathogenesis is better understood and may be associated with a single-gene defect or a combination of genetic loci. These alternative forms, as well as other "atypical" forms, may share features of type 1 and/or type 2 DM. Type 1 DM develops as a result of autoimmunity against the insulin-producing beta cells, resulting in insulin deficiency. Type 2 DM is a heterogeneous group of disorders characterized by variable degrees of insulin resistance, impaired insulin secretion, and increased hepatic glucose production. Defects in insulin action and/or secretion give rise to the common phenotype of hyperglycemia in type 2 DM and have important therapeutic implications now that pharmacologic agents are available to target specific metabolic derangements. Both type 1 and type 2 DM are preceded by a period of progressive worsening of glucose homeostasis, followed by the development of hyperglycemia that exceeds the threshold for clinical diagnosis. In terms of type 2 DM, this phase is referred to as prediabetes and is more specifically classified as impaired fasting glucose (IFG) or impaired glucose tolerance (IGT) **(Fig. 415-1)**. Recently, three distinct stages of type 1 DM have been defined based on the development of autoantibodies against pancreatic beta cell antigens or the development of worsening dysglycemia (discussed below).

OTHER TYPES OF DM

Other etiologies of DM include specific genetic defects in insulin secretion or action, metabolic abnormalities that impair insulin secretion, mitochondrial abnormalities, and a host of conditions that impair glucose tolerance (Table 415-1). *Monogenic diabetes, sometimes referred to as maturity-onset diabetes of the young (MODY),* are types of DM characterized by autosomal dominant inheritance, early onset of hyperglycemia (usually <25 years; sometimes in neonatal period), and impaired insulin secretion (discussed below). Mutations in the insulin receptor cause a group of rare disorders characterized by severe insulin resistance.

DM may also develop as a result of cystic fibrosis or chronic pancreatitis, in which the islets become damaged from a primary pathologic process originating in the pancreatic exocrine tissue. Hormones that antagonize insulin action can lead to DM. Hyperglycemia is often a feature of endocrinopathies such as acromegaly and Cushing's disease. Viral infections have been implicated in pancreatic islet destruction but are an extremely rare cause of DM. A form of acute onset of type 1

TABLE 415-1 Etiologic Classification of Diabetes Mellitus

I. Type 1 DM (immune-mediated beta cell destruction, usually leading to absolute insulin deficiency)

II. Type 2 DM (may range from predominantly insulin resistance with relative insulin deficiency to a predominantly insulin secretory defect with insulin resistance)

III. Other types of diabetes caused by:

- A. Genetic defects of beta cell development or function characterized by mutations such as (e.g., monogenic, MODY):
  1. Hepatocyte nuclear transcription factor (HNF) 4α
  2. Glucokinase
  3. HNF-1α
  4. Insulin promoter factor-1, HNF-1β, NeuroD1, and other pancreatic islet regulators/proteins such as *KLF11, PAX4, BLK, GATA4, GATA6, SLC2A2* (GLUT2), *GLIS3*
  5. Mitochondrial DNA
- B. Neonatal diabetes (onset <6 months of age) due to mutations in subunits of ATP-sensitive potassium channel, *RFX6*, insulin
- C. Transient neonatal diabetes
- D. Diseases of the exocrine pancreas—pancreatitis, pancreatectomy, neoplasia, cystic fibrosis, hemochromatosis, fibrocalculous pancreatopathy, mutations in carboxyl ester lipase
- E. Genetic defects in insulin action, including type A insulin resistance, leprechaunism, Rabson-Mendenhall syndrome, lipodystrophy syndromes
- F. Endocrinopathies—acromegaly, Cushing's syndrome, glucagonoma, pheochromocytoma, hyperthyroidism, somatostatinoma, aldosteronoma
- G. Drug- or chemical-induced—glucocorticoids, calcineurin and mTOR inhibitors (after organ transplantation), pentamidine, nicotinic acid, statins, HIV therapies (antiretroviral, protease inhibitors, nucleoside/nucleotide reverse transcriptase inhibitors), diazoxide, β-adrenergic agonists, thiazides, proprotein convertase subtilisin/kexin type 9 (PCSK9) inhibitors, hydantoins, asparaginase, α-interferon, protease inhibitors, antipsychotics (second-generation atypicals and others), epinephrine, vacor (a rodenticide)
- H. Infections—congenital rubella, cytomegalovirus, coxsackievirus
- I. Uncommon forms of immune-mediated diabetes—"stiff-person" syndrome, anti-insulin receptor antibodies, treatment of malignancy with immune checkpoint inhibitors
- J. Other genetic syndromes sometimes associated with diabetes—Wolfram syndrome, Down's syndrome, Klinefelter's syndrome, Turner's syndrome, Friedreich's ataxia, Huntington's chorea, Laurence-Moon-Biedl syndrome, myotonic dystrophy, porphyria, Prader-Willi syndrome

IV. Gestational diabetes mellitus (GDM)

Abbreviation: MODY, maturity-onset diabetes of the young or monogenic diabetes; see text.

Source: Data from American Diabetes Association: Standards of medical care in diabetes–2014. Diabetes Care 37:S81, 2014 and other sources.

diabetes, termed *fulminant diabetes*, has been noted in Japan and may be related to viral infection of the islets.

GESTATIONAL DM

Glucose intolerance developing during the second or third trimester of pregnancy is classified as gestational diabetes mellitus (GDM). Insulin resistance is related to the metabolic and hormonal changes of pregnancy, during which the increased insulin demands and insulin resistance may lead to IGT or diabetes. The American Diabetes Association (ADA) recommends that diabetes diagnosed within the first trimester be classified as preexisting pregestational diabetes rather than GDM. In 2021, the International Diabetes Federation (IDF) estimated that 16% of pregnancies worldwide were affected by either GDM or preexisting DM. Most women with GDM revert to normal glucose tolerance postpartum but have a substantial risk (35–60%) of developing DM in the next 10–20 years. In addition, children born to a mother with GDM also have an increased risk of developing metabolic syndrome and type 2 DM later in life. Currently, the ADA recommends that women with a history of GDM undergo lifelong screening for the development of diabetes or prediabetes at least every 3 years.

		Hyperglycemia			
		Prediabetes*	Diabetes Mellitus		
	Normal glucose tolerance	Impaired fasting glucose or impaired glucose tolerance	Not insulin requiring	Insulin required for control	Insulin required for survival
			Symptoms of diabetes + random blood glucose concentration ≥11.1 mmol/L (200 mg/dL)[a]		
HbA1C	<5.6% (<41 mmol/mol)	5.7–6.4% (42–47 mmol/mol)	≥6.5%[b] (≥48 mmol/mol)		
FPG	<5.6 mmol/L (100 mg/dL)	5.6–6.9 mmol/L (100–125 mg/dL)	≥7.0 mmol/L (126 mg/dL)[c]		
2-h PG	<7.8 mmol/L (140 mg/dL)	7.8–11.0 mmol/L (140–199 mg/dL)	≥11.1 mmol/L (200 mg/dL)[d]		

FIGURE 415-1 Spectrum of glucose homeostasis and diagnosis of diabetes mellitus (DM). Glucose homeostasis is a spectrum from normal glucose tolerance (*left portion of figure*) to diabetes (*right portion of figure*) including type 1 DM, type 2 DM, specific types of diabetes, and gestational DM. The diagnostic criteria for diabetes are shown in the right portion of the figure and include the hemoglobin A_{1c} (HbA_{1c}), the fasting plasma glucose (FPG), and the 2-h plasma glucose (PG) after a glucose challenge. In most types of DM, the individual traverses from normal glucose tolerance to impaired glucose tolerance to overt diabetes (these should be viewed not as abrupt categories but as a spectrum). Changes in glucose tolerance may be bidirectional in some individuals or types of diabetes. For example, individuals with type 2 DM may return to the impaired glucose tolerance category with weight loss; in gestational DM, diabetes may revert to impaired glucose tolerance or normal glucose tolerance after delivery. [a]Random is defined as without regard to time since the last meal. [b]HbA_{1c} test should be performed in a laboratory using a method approved by the National Glycohemoglobin Standardization Program that can be related to the reference assay of the Diabetes Control and Complications Trial. Some point-of-care HbA_{1c} assays meet these criteria and can be used. [c]Fasting is defined as no caloric intake for at least 8 h. [d]The test should be performed using a glucose load containing the equivalent of 75 g of anhydrous glucose dissolved in water, not recommended for routine clinical use. Assessment of 1-h glucose may be helpful in diabetes risk prediction in individuals with cystic fibrosis or other forms of pancreatic disease. In the absence of unequivocal hyperglycemia and acute metabolic decompensation, the blood glucose criteria should be confirmed by repeat testing on a different day. These values do not apply to the diagnosis of gestational DM. *(Modified from American Diabetes Association Professional Practice Committee. 2. Diagnosis and classification of diabetes: Standards of Care in Diabetes—2024. Diabetes Care 47[Suppl. 1]:S20, 2024.)*

ATYPICAL DIABETES

It is increasingly recognized that some forms of diabetes have features of both type 1 and type 2 DM. These are distinct from monogenic forms (MODY) as they have not been linked to single-gene defects. The development of a type 2 DM phenotype before puberty, a type 2 DM phenotype in very lean individuals, or a type 1 diabetes phenotype in individuals with no autoantibodies are examples of atypical diabetes. An additional example is ketosis-prone diabetes, where individuals present with ketoacidosis but do not require long-term exogenous insulin therapy. Many of these individuals are African American or Asian in heritage. Mechanisms underlying atypical forms of diabetes are being actively studied.

EPIDEMIOLOGY AND GLOBAL CONSIDERATIONS

The worldwide prevalence of DM has risen dramatically over the past four decades, from an estimated 30 million cases in 1985 to 537 million in 2021 (prevalence of 10.5%) **(Fig. 415-2)**. Based on current trends, the IDF projects that 643 million adults aged 20–79 years will have diabetes by the year 2030 (prevalence of 11.3%) and 783 million by 2045 (prevalence of 12.2%) (see *http://www.idf.org/*). Although the prevalence of both type 1 and type 2 DM is increasing worldwide, the prevalence of type 2 DM is rising much more rapidly, presumably because of dietary changes and increasing obesity, reduced activity levels as countries become more industrialized, and aging of the population. The countries with the greatest number of individuals with diabetes in 2021 were China (140.9 million), India (74.2 million),

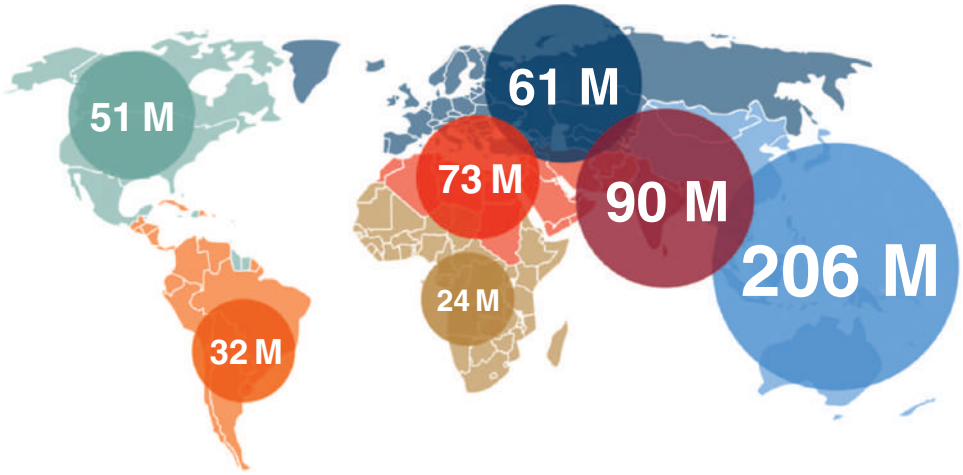

FIGURE 415-2 Worldwide prevalence of diabetes mellitus. Regional estimates of the number of individuals with diabetes (20–79 years of age) are shown (2021). *(Data from the IDF Diabetes Atlas, 10th ed. The International Diabetes Federation; 2021.)*

Pakistan (33.0 million), the United States (32.2 million), Indonesia (19.5 million), Brazil (15.7 million), and Mexico (14.1 million). In the most recent estimate for the United States (2021), the Centers for Disease Control and Prevention (CDC) estimated that 11.6% of the population had diabetes and as many as 38% of U.S. adults had prediabetes. Approximately 22.8% of adults with diabetes in the United States were undiagnosed. Globally, it is estimated that ~50% of those with diabetes who live in middle-income and low-income countries are undiagnosed. The prevalence of DM increases with age. For example, the DM prevalence in the United States was estimated to be 3.0% in individuals aged 18–44 years, 14.5% in persons aged 45–44 years, and 24.4% in those >65 years of age.

There is also considerable geographic variation in the incidence of both type 1 and type 2 DM. Currently, Scandinavia and the Middle East have the highest incidence of type 1 DM, with the lowest incidence in the Pacific Rim. Northern Europe and the United States have an intermediate rate. Much of the risk of type 1 DM is believed to reflect the frequency of high-risk human leukocyte antigen (HLA) alleles among ethnic groups in different geographic locations, but the type 1 DM incidence is increasing in non-European populations and in populations where the presence of the classic high-risk HLA alleles is less. The countries with the greatest number of individuals with type 1 DM, defined as diabetes onset at <19 years of age, are India, the United States, Brazil, and China. Adult-onset type 1 DM is increasingly recognized, but its incidence and prevalence are incompletely defined.

The prevalence of type 2 DM and its harbinger, IGT, is highest in certain Pacific islands and the Middle East and intermediate in countries such as India and the United States. This variability is likely due to genetic, behavioral, and environmental factors. DM prevalence also varies among different ethnic populations within a given country, with indigenous populations usually having a greater prevalence of diabetes than the general population of the country. For example, the CDC estimated that the age-adjusted prevalence of DM in the United States (age >20 years; 2019–2021) was 10.3% in non-Hispanic whites, 9.2% in Asians, 10.3% in Hispanics, 12.5% in non-Hispanic blacks, and 16% in Native American and Alaskan native populations. The onset of type 2 DM occurs, on average, at an earlier age in most non-Hispanic groups. In Asian populations (Southeast Asian and Western Pacific), the prevalence of type 2 DM is increasing rapidly, with onset at a lower body mass index (BMI) and younger age, greater visceral adiposity, and reduced insulin secretory capacity. Approximately 75% of individuals with diabetes live in low- or middle-income countries.

Diabetes is a major cause of mortality. In 2021, diabetes was listed as the eighth leading cause of death in the United States, but several studies indicate that diabetes-related deaths are likely underreported. In 2021, the IDF estimated that diabetes was responsible for nearly 6.7 million deaths worldwide, accounting for 12.2% of global all-cause mortality in adults aged 20–79 years. About one-third of diabetes-related deaths occur in individuals in their working years (<60 years of age). Diabetes also has important economic implications. In 2021, it was estimated that almost $1 trillion of health care expenditures worldwide were spent on individuals with diabetes.

DIAGNOSIS

Glucose tolerance, as assessed using hemoglobin A_{1c} (HbA_{1c}), the fasting plasma glucose (FPG), or the response to oral glucose challenge, is classified into three broad categories: normal glucose homeostasis, impaired glucose homeostasis, or DM (Fig. 415-1). An HbA_{1c} <5.7%, an FPG <5.6 mmol/L (100 mg/dL), and a plasma glucose <7.9 mmol/L (140 mg/dL) following an oral glucose challenge are considered to define normal glucose tolerance. An HbA1c ≥6.5% (> 48 mmol/mol), an FPG ≥7.0 mmol/L (126 mg/dL), or a glucose ≥11.1 mmol/L (200 mg/dL) 2 h after an oral glucose challenge meets the criteria for the diagnosis of DM (Fig. 415-1). A random plasma glucose concentration ≥11.1 mmol/L (200 mg/dL) accompanied by classic symptoms of DM (e.g., polyuria, polydipsia, weight loss) is also sufficient for the diagnosis of DM. DM is defined as the level of glycemia at which a diabetes-specific complication (e.g., retinopathy) occurs rather than a deviation from a population-based mean.

Impaired glucose homeostasis includes an HbA_{1c} of 5.7–6.4%, IFG as defined as an FPG of 5.6–6.9 mmol/L (100–125 mg/dL), or IGT as defined as a plasma glucose level of 7.8–11 mmol/L (140–199 mg/dL) following an oral glucose challenge. The term *prediabetes* refers to those with an HbA_{1c} of 5.7–6.4%, IFG, or IGT. These categories reflect the position of the American Diabetes Association (ADA). The World Health Organization defines IFG as an FPG >6.1 mmol/L (110 mg/dL). Although an HbA_{1c} of 5.7–6.4%, IFG, and IGT do not identify the same individuals (i.e., different biologic mechanisms involved), individuals in all three groups are at greater risk of progressing to type 2 DM, have an increased risk of cardiovascular disease, and should be counseled about ways to decrease these risks. The risk for subsequent diabetes in individuals with prediabetes is related to the HbA_{1c}, with those with a value of 6.0–6.5% (42–48 mmol/mol) having a 25.5% 5-year risk of progressing to type 2 DM. It is important to recognize that HbA_{1c} ≥6.5%, FPG, and the glucose level following an oral glucose challenge are continuous rather than discrete variables, with the risk for comorbidities increasing continuously rather than discretely by diagnostic category.

The current criteria for the diagnosis of DM emphasize the HbA_{1c} and the FPG as the most reliable and convenient tests for identifying DM in asymptomatic individuals (Fig. 415-1). Also, it is important to note that some clinical conditions (e.g., hemoglobinopathies) and ancestry may influence the HbA_{1c} **(Chap. 416)**. An oral glucose tolerance test (OGTT) is not often used in routine clinical care with the exception of pregnancy care and screening for gestational diabetes or cystic fibrosis–related diabetes **(Chap. 302)**. Continuous glucose monitoring (discussed in **Chap. 416**) is being examined as a method to diagnose diabetes, especially type 1 DM in its asymptomatic stages.

The diagnosis of DM has profound implications for an individual from both a medical and a financial standpoint. Thus, abnormalities on screening tests for diabetes should be repeated before making a definitive diagnosis of DM, unless acute metabolic derangements or a markedly elevated plasma glucose are present. These criteria also allow for the diagnosis of DM to be withdrawn in situations when the glucose intolerance reverts to normal.

SCREENING

Widespread use of HbA_{1c} or FPG as a screening test for type 2 DM is recommended because (1) a large number of individuals who meet the

TABLE 415-2 Criteria for Screening for Type 2 DM in Adults

1. Consider testing in adults of any age who are overweight or obese (BMI ≥25 kg/m² or ≥23 kg/m² in Asian Americans) who have one of these risk factors:
   - Family history of diabetes (i.e., parent or sibling with type 2 DM)
   - Race/ethnicity (e.g., African American, Latino, Native American, Asian American, Pacific Islander)
   - Hypertension (blood pressure ≥130/80 mmHg)
   - HDL cholesterol level <35 mg/dL (0.90 mmol/L) and/or a triglyceride level >250 mg/dL (2.82 mmol/L)
   - Polycystic ovary syndrome or acanthosis nigricans
   - History of cardiovascular disease
   - Physical inactivity
   - Other condition associated with insulin resistance (severe obesity, acanthosis nigricans)
2. Individuals with previously identified IFG, IGT, or a hemoglobin A_{1c} of 5.7–6.4% should be screened annually.
3. Women who had GDM should be screened at least every 3 years.
4. For other individuals, initiate testing at 35 years of age and repeat every 3 years.
5. Individuals taking HIV medications or medications associated with diabetes (second-generation antipsychotic, glucocorticoids).
6. History of pancreatitis (screen within 3–6 months of episode of pancreatitis).
7. Cystic fibrosis (beginning at age 10); oral GTT recommended.
8. After organ transplantation; oral GTT recommended.

Abbreviations: BMI, body mass index; GDM, gestational diabetes mellitus; GTT, glucose tolerance test; HDL, high-density lipoprotein; HIV, human immunodeficiency virus; IFG, impaired fasting glucose; IGT, impaired glucose tolerance.

Source: Data from American Diabetes Association: 2. Diagnosis and classification of diabetes: Standards of care in diabetes—2024. Diabetes Care 47:S20, 2024, and other sources.

current criteria for DM are asymptomatic and unaware that they have the disorder, (2) epidemiologic studies suggest that type 2 DM may be present for up to a decade before diagnosis, (3) some individuals with type 2 DM have one or more diabetes-specific complications at the time of their diagnosis, (4) treatment of type 2 DM may favorably alter the natural history of DM or complications related to diabetes, and (5) diagnosis of prediabetes should spur efforts for diabetes prevention (Table 415-2). The ADA recommends screening all individuals aged >35 years every 3 years and screening individuals at an earlier age if they are overweight and have one additional risk factor for diabetes. Screening for cystic fibrosis–related diabetes (beginning at age 10 years) and posttransplantation diabetes should use OGTT rather than HbA_{1c} (Chap. 302). Screening for GDM is not discussed in this chapter. While not discussed here, the rapid increase in type 2 DM incidence and prevalence in children and adolescents, especially in racial and ethnic minority populations, has led to recommendations for screening and therapies.

REGULATION OF GLUCOSE HOMEOSTASIS

OVERALL REGULATION OF GLUCOSE HOMEOSTASIS

Glucose homeostasis reflects a balance between energy intake from ingested food, hepatic glucose production (gluconeogenesis), and peripheral tissue glucose uptake and utilization. Insulin is the most important regulator of this metabolic equilibrium, but neural input, metabolic signals, and other hormones (e.g., glucagon) result in integrated control of glucose supply and utilization (Fig. 415-3). The organs that regulate glucose and lipids communicate by neural and humoral mechanisms with fat and muscle, producing adipokines, myokines, and metabolites that influence liver function. In the fasting state, low insulin levels, together with modest increases in glucagon, increase glucose production by promoting hepatic gluconeogenesis and glycogen breakdown (glycogenolysis). In parallel, glucose uptake in insulin-sensitive tissues (skeletal muscle and fat) is reduced, and there is increased mobilization of gluconeogenic precursors such as amino acids and free fatty acids (lipolysis). Under normal conditions, alpha cells increase glucagon secretion only when blood glucose or insulin levels are low or during exercise, but it is increased in fasting and postprandially in DM and stimulates excess glycogenolysis and gluconeogenesis by the liver and to a small degree by the renal medulla (Chap. 418). Conversely, in healthy people, the postprandial glucose load elicits a rise in insulin and fall in glucagon, leading to optimized glucose disposal. Insulin, an anabolic hormone, promotes the storage of carbohydrate and fat and protein synthesis. The major portion of postprandial glucose is utilized by skeletal muscle, an effect of insulin-stimulated glucose uptake. Other tissues, most notably the brain, utilize glucose in an insulin-independent fashion. Factors secreted by skeletal myocytes, adipocytes (e.g., leptin, resistin, adiponectin), and bone also influence glucose homeostasis.

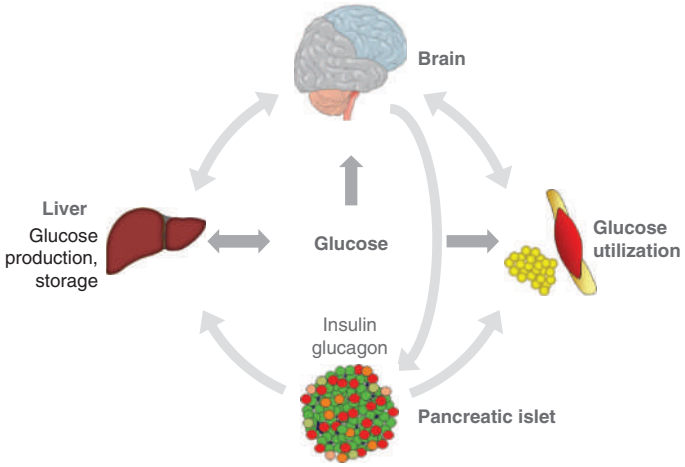

FIGURE 415-3 Regulation of glucose homeostasis. The organs shown contribute to glucose utilization, production, or storage. See text for a description of the communications (*arrows*), which can be neural or humoral. Although not shown, the gastrointestinal tract and bone produce factors that influence glucose homeostasis.

INSULIN BIOSYNTHESIS

Insulin, produced by the beta cells of the pancreatic islets, is initially synthesized as a single-chain 86-amino-acid precursor polypeptide, preproinsulin. Subsequent proteolytic processing removes the amino-terminal signal peptide, giving rise to proinsulin. Proinsulin is structurally related to insulin-like growth factors I and II, which bind weakly to the insulin receptor. Cleavage of an internal 31-residue fragment from proinsulin generates C-peptide with the A (21 amino acids) and B (30 amino acids) chains of insulin being connected by disulfide bonds. The mature insulin molecule and C-peptide are stored together and co-secreted from secretory granules in the beta cells. Because C-peptide is cleared more slowly than insulin, it is a useful marker of insulin secretion and allows discrimination of endogenous and exogenous sources of insulin in the evaluation of hypoglycemia (Chaps. 89 and 418). Elevated levels of serum proinsulin have been observed in both type 1 and 2 DM and are thought to be indicative of beta cell dysfunction. Pancreatic beta cells co-secrete islet amyloid polypeptide (IAPP) or amylin, a 37-amino-acid peptide, along with insulin. The role of IAPP in normal physiology is incompletely defined, but it is the major component of the amyloid fibrils found in the islets of patients with type 2 DM, and an analogue is sometimes used in treating type 1 and type 2 DM (Chap. 416).

INSULIN SECRETION

Glucose is the key regulator of insulin secretion by the pancreatic beta cell, although amino acids, ketones, various nutrients, gastrointestinal peptides, and neurotransmitters also influence insulin secretion. Glucose levels >3.9 mmol/L (70 mg/dL) stimulate insulin synthesis, primarily by enhancing protein translation and processing. Insulin secretion occurs in two phases, a rapid first-phase response, and a more prolonged second phase. Impaired first-phase insulin responses are among the earliest detectable abnormalities during the progression in both type 1 and type diabetes. Glucose stimulation of insulin secretion begins with its transport into the beta cell by a facilitative glucose transporter (Fig. 415-4). Glucose phosphorylation by glucokinase is

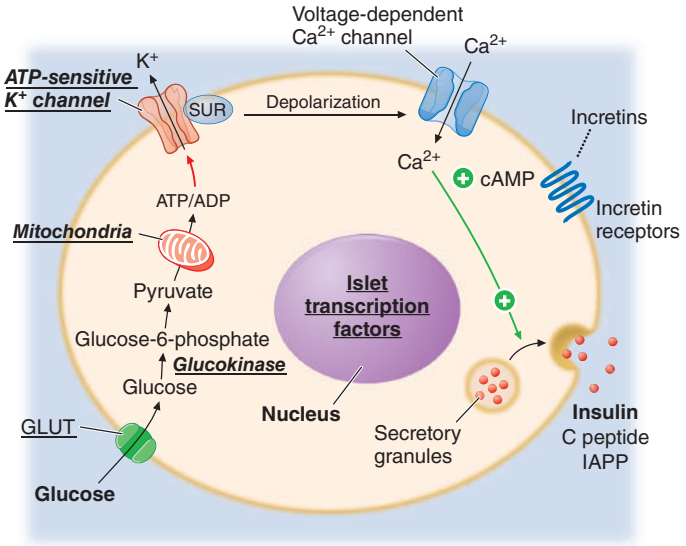

FIGURE 415-4 Mechanisms of glucose-stimulated insulin secretion and abnormalities in diabetes. Glucose and other nutrients regulate insulin secretion by the pancreatic beta cell. Glucose is transported by a glucose transporter (GLUT1 and/or GLUT2 in humans, GLUT2 in rodents); subsequent glucose metabolism by the beta cell alters ion channel activity, leading to insulin secretion. The SUR receptor is the binding site for some drugs that act as insulin secretagogues. Mutations in the events or proteins underlined are a cause of monogenic forms of diabetes. ADP, adenosine diphosphate; ATP, adenosine triphosphate; cAMP, cyclic adenosine monophosphate; IAPP, islet amyloid polypeptide or amylin; SUR, sulfonylurea receptor.

the rate-limiting step that controls glucose-regulated insulin secretion. Further metabolism of glucose-6-phosphate via glycolysis generates ATP, which inhibits the activity of an ATP-sensitive K^+ channel. This channel consists of two separate proteins: one is the binding site for certain oral hypoglycemics (e.g., sulfonylureas, meglitinides); the other is an inwardly rectifying K^+ channel protein (Kir6.2). Inhibition of this K^+ channel induces beta cell membrane depolarization, which opens voltage-dependent calcium channels (leading to an influx of calcium) and stimulates insulin secretion. An alternative model of stimulated insulin secretion does not utilize oxidative phosphorylation, but instead proposes that glycolysis, pyruvate kinase, and spatially confined glucose metabolism impact the K^+ channel protein. A number of metabolic pathways internal to the beta cell as well as external cues amplify glucose-stimulated insulin secretion. For example, calcium release from the endoplasmic reticulum and other internal stores contributes to the rise in cytosolic calcium in response to glucose and contributes to the insulin secretory response. Glucagon-like peptide 1 (GLP-1) and glucose-dependent insulinotropic peptide (GIP) are incretin hormones that bind specific receptors on the beta cell to stimulate insulin secretion through cyclic AMP production, but they have this effect only when the blood glucose is above the fasting level. Incretin hormones also suppress glucagon production and secretion. Incretin analogues or pharmacologic agents that prolong the activity of endogenous GLP-1 are used to treat type 2 DM. Classically, GLP-1 release was thought to occur solely from neuroendocrine L-cells of the gastrointestinal tract following food ingestion. However, recent preclinical studies suggest that intraislet production of GLP-1 from alpha cells may play a role in the regulation of insulin secretion.

INSULIN ACTION

Insulin is secreted into the portal venous system and acts to suppress endogenous hepatic glucose production and increase hepatic glucose uptake. A large portion (50%) of secreted insulin is cleared by the liver in this first pass, yielding a portal-to-peripheral insulin concentration gradient of ~2:1, with important implications for the clinical use of exogenous insulin (Chap. 416). Uncleared insulin enters the systemic circulation where it binds to receptors in peripheral target tissues such as skeletal muscle and adipose. Insulin binding to its receptor stimulates intrinsic tyrosine kinase activity, leading to receptor autophosphorylation and the recruitment of intracellular signaling molecules, including the important insulin receptor substrates (IRS). IRS and other adaptor proteins initiate a complex cascade of phosphorylation and dephosphorylation reactions, resulting in the widespread metabolic and mitogenic effects of insulin. As an example, activation of the phosphatidylinositol-3′-kinase (PI3-kinase) pathway stimulates translocation of a facilitative glucose transporter (e.g., GLUT4) to the cell surface, an event that is crucial for glucose uptake by skeletal muscle and fat. Activation of other insulin receptor signaling pathways induces glycogen synthesis, protein synthesis, lipogenesis, and regulation of various genes in insulin-responsive cells.

PATHOGENESIS OF DM

TYPE 1 DM

Type 1 DM is the result of interactions of genetic, environmental, and immunologic factors that ultimately lead to immune-mediated destruction of the pancreatic beta cells and insulin deficiency. Individuals with type 1 DM, especially children, often have dramatic and acute symptoms of diabetes with marked elevations in the blood glucose, with 25–50% presenting with diabetic ketoacidosis (DKA). Type 1 DM can develop at any age. While classically thought as having its onset in prepuberty and adolescence, recent data estimate that as many as 40% of individuals who develop type 1 DM have onset at over the age of 30. Many individuals with adult-onset type 1 DM are initially misdiagnosed with type 2 DM, highlighting the need for vigilance when classifying the individual's diabetes. Most, but not all, individuals with type 1 DM have evidence of islet-directed autoimmunity, which is detected by the presence of autoantibodies against islet cell antigens in the blood. The presence of two or more autoantibodies is now designated as stage 1 type 1 DM (Fig. 415-5). The temporal decline of beta cell function and mass preceding the development of type 1 DM is shown schematically in Fig. 415-5 as a smooth, gradual reduction in beta cell mass and function. However, natural history studies suggest an initial loss of first-phase insulin response that occurs years in advance of the onset of Stage 3 type 1 DM. This is followed by a gradual reduction in insulin secretion, until ~1-2 years before the onset of Stage 3 type 1 DM, when there is a more accelerated decline in beta cell function,

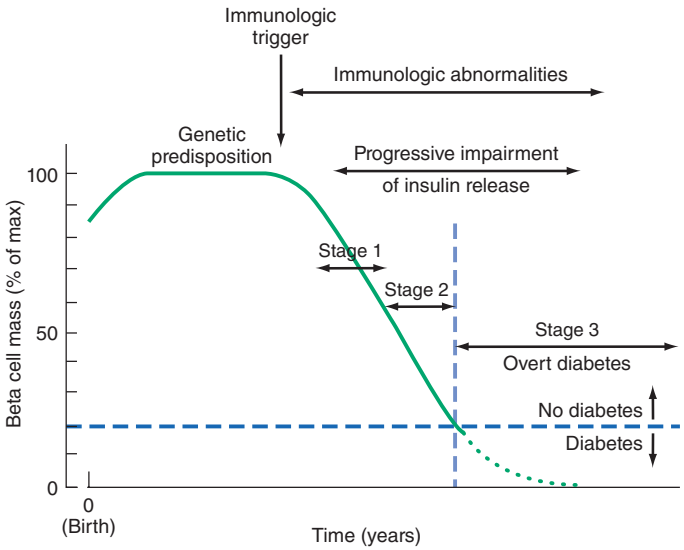

FIGURE 415-5 Temporal model for development of type 1 DM. Individuals with a genetic predisposition are exposed to a trigger that initiates an autoimmune process, resulting in the development of islet autoantibodies and a gradual decline in beta cell function and mass. Stage 1 disease is characterized by the development of two or more islet cell autoantibodies but the maintenance of normoglycemia. Stage 2 disease is defined by continued autoimmunity and the development of dysglycemia. Stage 3 is defined by the development of hyperglycemia that exceeds the diagnostic criteria for the diagnosis of diabetes. The downward slope of the beta cell function varies among individuals and may not be continuous. A "honeymoon" phase may be seen in the first 1 or 2 years after the onset of diabetes and is associated with reduced insulin requirements.

culminating in significant metabolic decompensation at the time of clinical diagnosis. In susceptible individuals, the autoimmune process is thought to be triggered by an infectious or environmental stimulus, but definitive proof is lacking. In the majority of patients, autoantibodies against islet cell antigens appear after this triggering event, followed by a progressive loss of insulin secretion. The time course between this triggering event and the development of Stage 3 type 1 DM varies widely among individuals, with some progressing rapidly to clinical diabetes and others evolving to diabetes more slowly, over a period of several years. Autopsy studies suggest the degree of loss of beta cell mass is variable at the time of disease presentation. At this point, residual functional beta cells exist but are insufficient in number and quality to maintain glucose tolerance. In some individuals, the events that trigger the transition from dysglycemia to frank hyperglycemia are often associated with increased insulin requirements, as might occur during infections or puberty. After the initial clinical presentation of type 1 DM, a "honeymoon" phase may ensue during which time glycemic control is achieved with modest doses of insulin or, rarely, insulin is not needed. However, this fleeting phase of endogenous insulin production from residual beta cells disappears and the individual becomes insulin deficient. Many individuals with long-standing type 1 DM produce a small amount of insulin (as reflected by C-peptide production), and autopsy studies show that beta cells can persist in the pancreas decades after diagnosis.

GENETIC CONSIDERATIONS

Susceptibility to type 1 DM involves multiple genes. The concordance of type 1 DM in identical twins ranges from 30–70%, indicating that additional modifying factors are likely involved in determining whether diabetes develops. The major susceptibility gene for type 1 DM is located in the HLA region on chromosome 6. Polymorphisms in the HLA complex account for ~50% of the genetic risk of developing type 1 DM. This region contains genes that encode the class II major histocompatibility complex (MHC) molecules, which present antigen to helper T cells and thus are involved in initiating the immune response **(Chap. 360)**. The ability of class II MHC molecules to present antigen is dependent on the amino acid composition of their antigen-binding sites. Refinements in genotyping of HLA loci have shown several genetic loci are predisposing (e.g., DRB1*0301-DQB1*0201 [DR3-DQ2] and DRB1*0401-DQB1*0302 [DR4-DQ8]). These haplotypes are present at greater frequency in those with type 1 DM than in the general population, although most individuals with predisposing haplotypes do not develop diabetes. An improved understanding of the genetics of type 1 diabetes has also identified protective HLA haplotypes (e.g., DRB1*1501 and DQA1* 0102-DQB1*).

In addition to MHC class II associations, genome-wide association studies have identified >60 additional genetic loci that contribute susceptibility to type 1 DM (e.g., polymorphisms in the promoter region of the insulin gene, the CTLA-4 gene, interleukin 2 receptor, and PTPN22). Combined assessment of HLA and non-HLA loci using genetic risk scores has been used to improve prediction of type 1 DM risk, with polygenic risk scores being applied in population-based screening studies. Notably, among recent cohorts of individuals with new-onset type 1 DM, there is a decreased representation of the highest-risk HLA alleles and increasing penetrance of disease in genotypes classically associated with lower risk, suggesting environmental factors may have an increasing role in disease pathogenesis.

Although the risk of developing type 1 DM is increased in relatives of individuals with the disease, the risk is relatively low: 1–9% if the parent has type 1 DM and 6–7% in a sibling (depending on which HLA haplotypes are shared). Hence, the majority of individuals with type 1 DM (>80%) do not have a relative with this disorder.

Pathophysiology Pathologically, the pancreatic islets demonstrate a modest infiltration of lymphocytes (a process termed *insulitis*); however, the frequency of insulitis is heterogeneous both within and between individuals. Studies of the autoimmune process have identified the following abnormalities in the innate and adaptive arms of the immune system: (1) islet cell autoantibodies (ICAs); (2) activated lymphocytes in the islets and peripancreatic lymph nodes; (3) T lymphocytes that proliferate when stimulated with islet proteins; and (4) release of cytokines within the insulitis. ICAs are distinct autoantibodies directed at pancreatic islet molecules such as insulin, glutamic acid decarboxylase (GAD), islet antigen 2 (IA-2), or zinc transporter 8 (ZnT8) and serve as a marker of the autoimmune process of type 1 DM. Testing for ICAs is useful in classifying the type of DM as type 1 as they are present in the majority of individuals (>85%) diagnosed with new-onset type 1 DM. ICAs can also identify nondiabetic individuals at risk for developing type 1 DM, although their use for this purpose has been restricted until recently mostly to research studies. In children with high genetic risk followed from birth as part of several cohort studies, the presence of two or more ICAs, which often appeared in the first 3 years of life, was associated with a nearly 70% risk of developing type 1 DM after 10 years of follow-up and a > 80% risk of developing diabetes after 15 years of follow-up. These observations led to a revision in the staging system for type 1 DM (Fig. 415-5), in which the development of multiple autoantibodies is now defined as the onset of stage 1 type 1 DM. While ICAs can be detected in the serum, and their presence is an important biomarker of type 1 DM risk, the antibodies do not have a direct role in beta cell death. Beta cell destruction is mostly likely mediated by direct CD8+ T cell–mediated cytotoxicity. Beta cells may exacerbate this process through the development of modified proteins or "neoantigens" and through increased presentation of these antigens on their cell surface via upregulation of MHC class I molecules. In addition, beta cells may be damaged by the toxic effects of cytokines (i.e., tumor necrosis factor α [TNF-α], interferon γ, and interleukin 1 [IL-1]) as well as reactive oxygen species generated by infiltrating immune cells. Efforts to suppress the autoimmune process at the time of diagnosis of diabetes have partially slowed beta cell destruction as reflected by a slower decline in C-peptide levels. There is now an increased emphasis on identifying high-risk individuals who have multiple ICAs in first-degree relatives of individuals with type 1 DM or in the general population to allow interventions earlier in the disease course (i.e., during stage 1 and 2 disease; Fig. 415-5). An example is a single 14-day course of teplizumab, an Fc receptor–nonbinding anti-CD3 monoclonal antibody, which delayed the onset of stage 3 type 1 DM in high-risk individuals with multiple autoantibodies and dysglycemia (i.e., stage 2 type 1 DM) by a median of 32.5 months. This treatment, recently approved by the U.S. Food and Drug Administration (FDA) for stage 2 type 1 DM, is being used by selected centers in some individuals with stage 2 type 1 DM. Screening for presymptomatic type 1 DM using ICAs is rapidly evolving and is becoming more widely available. If ICAs are detected, referral to a specialized center for testing for dysglycemia and possible treatment to delay clinical diabetes should be considered.

Measurement of ICAs is recommended for adults who have phenotypic features similar to those in classic type 1 DM (e.g., younger age at diagnosis, ketoacidosis, or rapid need for insulin treatment) as these individuals may have adult-onset type 1 DM. See additional discussion below in the section "Classification of DM in an Individual Patient."

Although other islet cell types (alpha cells [glucagon-producing], delta cells [somatostatin-producing], or PP cells [pancreatic polypeptide–producing]) are functionally and embryologically similar to beta cells, they are spared from the autoimmune destruction. However, altered patterns of hormone secretion from these other cell types in type 1 DM likely contribute to metabolic instability. Alpha cell dysfunction is reflected by fasting and postprandial hyperglucagonemia but an impaired glucagon response to hypoglycemia.

Environmental Factors Numerous environmental events have been proposed to trigger the autoimmune process in genetically susceptible individuals; however, none has been conclusively linked to diabetes. Identification of an environmental trigger has been difficult because the event may precede the onset of DM by several years (Fig. 415-5). Putative environmental triggers include viruses (coxsackie, rubella, and enteroviruses most prominently), bovine milk proteins, nitrosourea

compounds, vitamin D deficiency, and environmental toxins. There is increasing interest in the microbiome and type 1 DM **(Chap. 484)**.

TYPE 2 DM

Type 2 DM likely encompasses a range of disorders with the common phenotype of hyperglycemia. Insulin resistance and abnormal insulin secretion are central to the development of type 2 DM. Although the primary defect is controversial, most studies support the view that insulin resistance precedes an insulin secretory defect but that diabetes develops only when insulin secretion becomes inadequate for the degree of insulin resistance. Historically, our understanding of the pathophysiology and genetics is mostly based on studies of individuals of European descent. Studies in more diverse populations are beginning to yield new insights into pathophysiologic differences among ethnic groups. In general, Latinos have greater insulin resistance and East Asians and South Asians have more beta cell dysfunction, but both defects are present in both populations. East and South Asians appear to develop type 2 DM at a younger age and a lower BMI. In some groups, DM that is ketosis prone (often in obese individuals) or ketosis resistant (often lean) is sometimes seen. For example, African Americans can be more prone to nonketotic hyperosmolar presentation of diabetes exacerbations. In many forms of type 2 DM around the world, the social determinants of health play a major role in the rates of type 2 DM.

GENETIC CONSIDERATIONS

Type 2 DM has a strong genetic component. The concordance of type 2 DM in identical twins is between 70 and 90%. Individuals with a parent with type 2 DM have an increased risk of diabetes; if both parents have type 2 DM, the risk approaches 70%. Insulin resistance, as demonstrated by reduced glucose utilization in skeletal muscle, is present in many nondiabetic, first-degree relatives of individuals with type 2 DM. The disease is polygenic and multifactorial, because in addition to genetic susceptibility, environmental factors (e.g., obesity, poor nutrition, reduced physical inactivity, increasing age, and socioeconomic status) modulate the frequency and the phenotype. Shared environmental and lifestyle factors also contribute to the high concordance in families. In addition, the in utero environment contributes, with either increased or reduced birth weight increasing the risk of type 2 DM in adult life. Children of pregnancies complicated by gestational hyperglycemia also exhibit an increased risk of type 2 DM.

The genes that predispose to type 2 DM are incompletely identified, but genome-wide association studies have identified a large number of genetic loci (>600) that convey a relatively small risk for type 2 DM (relative risk of 1.06–1.5). Most prominent is a variant of the transcription factor 7-like 2 gene that has been associated with both type 2 DM and IGT in several populations. The mechanisms by which these genetic loci, which are found mostly in noncoding regions of the genome, increase the susceptibility to type 2 DM are not clear, but most are predicted to alter islet function or development or insulin secretion. Although the genetic susceptibility to type 2 DM is under active investigation (it is estimated that <10% of genetic risk is determined by loci identified thus far), it is currently not possible to use a combination of known genetic loci to reliably predict type 2 DM.

Pathophysiology Type 2 DM is characterized by impaired insulin secretion, insulin resistance, excessive hepatic glucose production, abnormal fat metabolism, and systemic low-grade inflammation. Obesity, particularly visceral or central (as evidenced by the hip-waist ratio), is very common in type 2 DM (≥80% of patients are obese). In the early stages of the disorder, glucose tolerance remains near-normal, despite insulin resistance, because the pancreatic beta cells compensate by increasing insulin output **(Fig. 415-6)**. A number of pathophysiologic mechanisms contribute to type 2 DM, and their relative importance varies from individual to individual. As insulin resistance and compensatory hyperinsulinemia progress, the pancreatic islets in certain individuals are unable to sustain the hyperinsulinemic state,

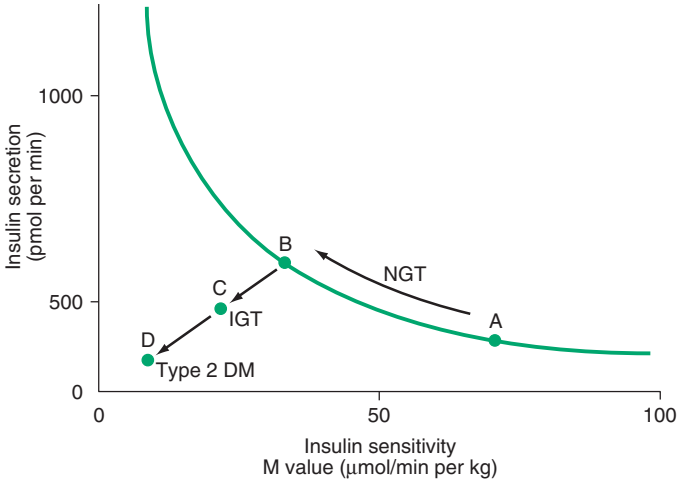

FIGURE 415-6 Metabolic changes during the development of type 2 DM. Insulin secretion and insulin sensitivity are related, and as an individual becomes more insulin resistant (by moving from point A to point B), insulin secretion increases. A failure to compensate by increasing the insulin secretion results initially in impaired glucose tolerance (IGT; point C) and ultimately in type 2 DM (point D). NGT, normal glucose tolerance. *(Data from SE Kahn: Clinical review 135: The importance of beta-cell failure in the development and progression of type 2 diabetes. J Clin Endocrinol Metab 86:4047, 2001 and RN Bergman, M Ader: Free fatty acids and pathogenesis of type 2 diabetes mellitus. Trends Endocrinol Metab 11:351, 2000.)*

manifesting as IGT, defined as elevations in postprandial glucose. A decline in insulin secretion and/or increased glucagon secretion cause an increase in hepatic glucose production leading to fasting hyperglycemia. Ultimately, frank beta cell failure ensues as a combination of these mechanisms leading to the manifestation of type 2 DM.

Metabolic Abnormalities Insulin resistance, the decreased ability of insulin to act effectively on target tissues (especially muscle, liver, and fat), is a prominent feature of type 2 DM and results from a combination of genetic susceptibility, obesity, and metabolic inflammation. Insulin resistance is relative, however, because supranormal levels of circulating insulin will normalize the plasma glucose. In type 2 DM, glucose utilization is 30–60% lower than in nondiabetic individuals. Insulin resistance impairs glucose utilization by insulin-sensitive tissues (skeletal muscle) and, in liver, coupled with elevated glucagon, leads to increased hepatic glucose output. Increased hepatic glucose output predominantly accounts for increased FPG levels, whereas decreased peripheral glucose utilization results in postprandial hyperglycemia.

The precise molecular mechanism leading to insulin resistance in type 2 DM has not been elucidated. Insulin receptor levels and tyrosine kinase activity in skeletal muscle are reduced, but these alterations are most likely secondary to hyperinsulinemia and are not a primary defect. Therefore, "postreceptor" defects in insulin-regulated phosphorylation/dephosphorylation appear to play the predominant role in insulin resistance. Abnormalities include the accumulation of lipid intermediates within skeletal myocytes, which may impair mitochondrial oxidative phosphorylation and reduce insulin-stimulated mitochondrial ATP production. Impaired fatty acid oxidation and lipid accumulation within skeletal myocytes also may generate reactive oxygen species such as lipid peroxides. These and other mechanisms also generate low-grade metabolic inflammation that feeds back and directly worsens insulin resistance. Of note, not all insulin signal transduction pathways are resistant to the effects of insulin (e.g., those controlling cell growth and differentiation using the mitogenic-activated protein kinase pathway). Consequently, hyperinsulinemia may increase the insulin action through these pathways, potentially accelerating diabetes-related conditions such as atherosclerosis.

The obesity accompanying type 2 DM, particularly in a central or visceral location, is thought to be part of the pathogenic process **(Chap. 413)**. In addition to these white fat depots, humans have brown

fat, which has much greater thermogenic capacity. Efforts are underway to increase the activity or quantity of brown fat. The increased adipocyte mass leads to increased levels of circulating free fatty acids and other fat cell products. For example, adipocytes secrete a number of biologic products (nonesterified free fatty acids, retinol-binding protein 4, leptin, TNF-α, resistin, IL-6, and adiponectin). Further, adipose resident macrophages are an important source of metabolic inflammation in diabetes. In addition to regulating body weight, appetite, and energy expenditure, adipokines also modulate insulin sensitivity. The increased production of free fatty acids and some adipokines may cause insulin resistance in skeletal muscle and liver. The venous drainage of the visceral adipose beds is the portal circulation, and this likely contributes to hepatic dysfunction. Free fatty acids also impair glucose utilization in skeletal muscle, promote glucose production by the liver, and impair beta cell function. In contrast, the production by adipocytes of adiponectin, an insulin-sensitizing peptide, is reduced in obesity, and this may contribute to hepatic insulin resistance. Adipocyte products and adipokines also produce an inflammatory state and may explain why markers of inflammation such as IL-6 and C-reactive protein are often elevated in type 2 DM.

IMPAIRED INSULIN SECRETION Insulin secretion and sensitivity are interrelated (Fig. 415-6). In type 2 DM, insulin secretion initially increases in response to insulin resistance to maintain normal glucose tolerance. Initially, the insulin secretory defect is mild and selectively involves glucose-stimulated insulin secretion, including a greatly reduced first secretory phase. The response to other nonglucose secretagogues, such as arginine, is preserved, but overall beta cell function is reduced by as much as 50% at the onset of type 2 DM. Abnormalities in proinsulin processing are reflected by increased secretion of proinsulin in type 2 DM. Eventually, the insulin secretory defect is progressive.

The reason(s) for the decline in insulin secretory capacity in type 2 DM is unclear. The assumption is that a second genetic defect—superimposed upon insulin resistance—leads to defects in beta cell function, mass, and potentially cellular identity and differentiation status. Islet amyloid polypeptide or amylin, co-secreted by the beta cell, forms amyloid fibrillar deposits found in the islets of individuals with long-standing type 2 DM. Whether such islet amyloid deposits are a primary or secondary event is not known. The metabolic environment of diabetes also negatively impacts islet function. For example, chronic hyperglycemia paradoxically impairs islet function ("glucose toxicity") and leads to a worsening of hyperglycemia. Improvement in glycemic control is often associated with improved islet function, an important clinical consideration. In addition, elevated levels of free fatty acids ("lipotoxicity") and systemic and local elevations in proinflammatory cytokines from increased numbers of islet-associated macrophages may also worsen islet function.

INCREASED HEPATIC GLUCOSE AND LIPID PRODUCTION In type 2 DM, insulin resistance in the liver reflects the failure of hyperinsulinemia to suppress gluconeogenesis, which results in fasting hyperglycemia and decreased glycogen storage by the liver in the postprandial state. Increased hepatic glucose production occurs early in the course of diabetes, although likely after the onset of insulin and glucagon secretory abnormalities and insulin resistance in skeletal muscle. As a result of insulin resistance in adipose tissue, lipolysis and free fatty acid flux from adipocytes are increased and efficiently cleared by liver, leading to increased very-low-density lipoprotein (VLDL)-triglyceride synthesis in hepatocytes and secretion from liver. This is also responsible for the dyslipidemia found in type 2 DM (elevated triglycerides, reduced high-density lipoprotein [HDL], and increased small dense low-density lipoprotein [LDL] particles). If this lipid is retained, steatosis in the liver may lead to metabolic dysfunction-associated steatotic liver disease (MASLD) and abnormal liver function tests.

Insulin Resistance Syndromes The insulin resistance condition comprises a spectrum of disorders, with hyperglycemia representing one of the most readily diagnosed features. The *metabolic syndrome* and the *insulin resistance syndrome* are terms used to describe a constellation of metabolic derangements that includes insulin resistance, hypertension, dyslipidemia (decreased HDL and elevated triglycerides), central or visceral obesity, type 2 DM or IGT/IFG, and accelerated cardiovascular disease. This syndrome is discussed in **Chap. 420**.

A number of relatively rare forms of severe insulin resistance include features of type 2 DM or IGT (Table 415-1). Mutations in the insulin receptor that interfere with binding or signal transduction are a rare cause of insulin resistance. Acanthosis nigricans and signs of hyperandrogenism (hirsutism, acne, and oligomenorrhea in women) are also common physical features. Two distinct syndromes of severe insulin resistance have been described in adults: (1) type A, which affects young women more severely and is characterized by severe hyperinsulinemia, obesity, and features of hyperandrogenism; and (2) type B, which affects middle-aged women and is characterized by severe hyperinsulinemia, features of hyperandrogenism, and autoimmune disorders. Individuals with type A insulin resistance syndrome have an undefined defect in the insulin-signaling pathway; individuals with type B insulin resistance syndrome have autoantibodies directed at the insulin receptor. These receptor autoantibodies may block insulin binding or may stimulate the insulin receptor, leading to intermittent hypoglycemia.

Polycystic ovary syndrome (PCOS) is a common disorder that affects premenopausal women and is characterized by chronic anovulation and hyperandrogenism **(Chap. 404)**. Insulin resistance is seen in a significant subset of women with PCOS, and the disorder substantially increases the risk for type 2 DM, independent of the effects of obesity.

Lipodystrophies are a group of heterogeneous disorders characterized by selective loss of adipose tissue, leading to severe insulin resistance and hypertriglyceridemia. Lipodystrophies can be inherited or acquired and associated with variable degrees of adipose tissue loss.

Prevention Type 2 DM is preceded by a period of IGT or IFG, and a number of lifestyle modifications and pharmacologic agents prevent or delay the onset of DM. Individuals with prediabetes or increased risk of diabetes should be referred to a structured program to reduce body weight and increase physical activity and for consideration for treatment with a weight-lowering medication such as a GLP-1 agonist (discussed in **Chap. 416**). In addition, they should be screened for cardiovascular disease. The Diabetes Prevention Program (DPP) demonstrated that intensive changes in lifestyle (diet and exercise for 30 min/d five times/week) in individuals with IGT prevented or delayed the development of type 2 DM by 58% compared to placebo. This effect was seen in individuals regardless of age, sex, or ethnic group. In the same study, metformin prevented or delayed diabetes by 31% compared to placebo. The lifestyle intervention group lost 5–7% of their body weight during the 3 years of the study; the effects of the intervention persisted for at least 15 years. Studies in Finnish and Chinese populations noted similar efficacy of diet and exercise in preventing or delaying type 2 DM. A number of agents, including α-glucosidase inhibitors, metformin, thiazolidinediones, GLP-1 receptor pathway modifiers, SGLT-2 inhibitors, and orlistat, prevent or delay type 2 DM. Individuals with a strong family history of type 2 DM and individuals with IFG or IGT should be strongly encouraged to achieve a normal BMI and engage in regular physical activity. Pharmacologic therapy for individuals with prediabetes is currently undergoing a transformation because of the greater degree of weight loss with GLP-1 receptor agonists and the combined GLP-1 and glucose-dependent insulinotropic peptide (GIP) receptor agonist, tirzepatide. In addition, intensive diet interventions (very-low-calorie intake) have been effective.

OTHER FORMS OF DM

Genetically Defined, Monogenic Forms of DM Several monogenic forms of DM have been identified. Monogenic diabetes, sometimes referred to as MODY, are caused by mutations in genes encoding islet-enriched transcription factors, glucokinase, insulin, and other islet factors (Fig. 415-5; Table 415-1) and present with an autosomal dominant mode of transmission. For example, monogenic diabetes may be caused by mutations in hepatocyte nuclear transcription factor (HNF) 4α, HNF-1α, or HNF-1β. As their names imply, these

transcription factors are expressed in the liver but also in other tissues, including the pancreatic islets and kidney. These factors most likely affect islet development, the expression of genes important in glucose-stimulated insulin secretion, or the maintenance of beta cell mass. For example, individuals with an HNF-1α mutation (MODY 3) have a progressive decline in glycemic control but may respond to sulfonylureas. In fact, some of these patients were initially thought to have type 1 DM but were later shown to respond to a sulfonylurea, and insulin was discontinued. Individuals with an HNF-1β mutation have progressive impairment of insulin secretion and hepatic insulin resistance and require insulin treatment with minimal response to sulfonylureas. These individuals often have other abnormalities such as renal cysts, mild pancreatic exocrine insufficiency, and abnormal liver function tests. Individuals with monogenic diabetes as a result of mutations in the glucokinase gene have mild-to-moderate but stable hyperglycemia that does not respond to oral hypoglycemic agents and otherwise does not require treatment, except possibly during pregnancy. Glucokinase catalyzes the formation of glucose-6-phosphate from glucose, a reaction that is important for glucose sensing by the beta cells (Fig. 415-5) and for glucose utilization by the liver. As a result of glucokinase mutations, higher glucose levels are required to elicit insulin secretory responses, thus altering the set point for insulin secretion. A form of monogenic diabetes is caused by mutations in pancreatic and duodenal homeobox 1, a transcription factor that regulates pancreatic development and insulin gene transcription. Homozygous inactivating mutations cause pancreatic agenesis, whereas heterozygous mutations may result in DM. Studies of populations with type 2 DM suggest that mutations in MODY-associated genes are a relatively uncommon cause of type 2 DM (<5%). Anyone with atypical features of type 1 or type 2 DM should be considered for genetic screening for monogenic diabetes.

Permanent neonatal diabetes (onset <6 months of age) is a heterogeneous group of disorders caused by genetic mutations that impact beta cell function and/or pancreatic development (Fig. 415-5). Affected individuals typically require treatment with insulin and exhibit phenotypic overlap with type 1 DM. Activating mutations in the ATP-sensitive potassium channel subunits (Kir6.2 and ABCC8) impair glucose-stimulated insulin secretion. Importantly, these individuals may respond to sulfonylureas and can be treated with these agents, allowing discontinuation of insulin therapy. Mutations in the transcription factor *GATA6* are the most common cause of pancreatic agenesis. Homozygous glucokinase mutations cause a severe form of neonatal diabetes, whereas mutations in mitochondrial DNA are associated with diabetes and deafness. A number of mutations identified in the coding sequence of the insulin gene have been found to interfere with proinsulin folding, processing, and bioactivity and are designated as mutant *Ins*-gene-induced diabetes of youth (MIDYs). Some of the neonatal diabetes syndromes are associated with a spectrum of neurologic dysfunction and a variety of extrapancreatic manifestations. Any individual who developed diabetes at <6 months of age should have genetic screening.

COVID-19 and DM Early in the COVID-19 pandemic, a marked connection between DM and SARS-CoV-2 infection was noted, with the presence of hyperglycemia being more common in those infected with the virus and the presence of DM worsening clinical outcomes in those with COVID **(Chap. 205)**. Initial studies early in the COVID-19 pandemic suggested an increase in the incidence of type 1 DM. Although data are still accumulating, it is most likely that SARS-CoV-2 infection does not lead directly to beta cell destruction and type 1 DM or cause type 2 DM but rather increases the DM ascertainment and creates clinical conditions that lead to or worsen hyperglycemia as in other serious illnesses in individuals with undiagnosed DM.

Pancreatic Exocrine Disease and DM Several types of pancreatic disease are now recognized to increase the risk of diabetes, sometimes termed type 3 or 3c DM, pancreatic DM, or pancreatogenic DM. The features of this form of DM are distinct from type 1 and type 2 DM, with its pathogenesis likely involving pancreatic islet damage or destruction, leading to insulin and glucagon deficiency. There is an increasing recognition that the pancreatic endocrine and pancreatic exocrine compartments interact, but the exact nature of this communication is still unclear. An episode of pancreatitis should prompt screening for diabetes. Pancreatic cancer and new-onset type 2 DM have an association. As the survival with cystic fibrosis has improved, the prevalence of cystic fibrosis–related diabetes has risen to almost 50%. In most forms of pancreatic diabetes, insulin is the preferred therapy.

Other Forms of DM One rare form of diabetes listed in Table 415-1 is immune checkpoint–related diabetes. This form of insulin-deficient diabetes has a rapid onset of hyperglycemia, often with DKA, and occurs at a variable time after initiation of immune checkpoint therapy, usually anti-programmed cell death 1 (PD-1) or anti-programmed death ligand 1 (PD-L1) alone or in combination with anti-CTLA-4 (<1% of individuals treated). While there are some similarities to type 1 DM in terms of genetics and occasional presence of ICA, it likely has a different, as yet undetermined, pathogenesis. Insulin therapy is required.

APPROACH TO THE PATIENT

Diabetes Mellitus

Once the diagnosis of DM is made, attention should be directed to symptoms related to diabetes (acute and chronic) and classifying the type of diabetes. DM and its complications produce a wide range of symptoms and signs; those secondary to acute hyperglycemia may occur at any stage of the disease, whereas those related to chronic hyperglycemia typically begin to appear during the second decade of hyperglycemia **(Chap. 417)**. Because of long delays in clinical recognition, individuals with previously undetected type 2 DM may present with chronic complications of DM at the time of diagnosis. The history and physical examination should assess for symptoms or signs of acute hyperglycemia and screen for chronic microvascular and macrovascular complications and conditions associated with DM **(Chap. 417)**.

HISTORY

A complete medical history should be obtained with special emphasis on DM-relevant aspects such as current weight as well as any recent changes in weight, family history of DM and its complications, sleep history, risk factors for cardiovascular disease, exercise, smoking status, history of pancreatic disease, and ethanol use. Symptoms of hyperglycemia include polyuria, polydipsia, weight loss, fatigue, weakness, blurry vision, frequent superficial infections (vaginitis, fungal skin infections), and slow healing of skin lesions after minor trauma. Metabolic derangements relate mostly to hyperglycemia (osmotic diuresis) and to the catabolic state of the patient (urinary loss of glucose and calories, muscle breakdown due to protein degradation and decreased protein synthesis). Blurred vision results from changes in the water content of the lens and resolves as hyperglycemia is controlled.

In a patient with established DM, the initial assessment should include a review of symptoms at the time of the initial diabetes diagnosis. This is an essential part of the history that can help define whether the correct type of DM has been diagnosed. Special emphasis should be placed on prior diabetes care, including types of therapies tried, the nature of any intolerance to previous therapies, prior HbA_{1c} levels, self-monitoring glucose results, frequency of hypoglycemia (<3.0 mmol/L, <54 mg/dL), presence of DM-specific complications, and assessment of the patient's knowledge about diabetes, exercise, nutrition, and sleep history. Diabetes-related complications may afflict several organ systems, and an individual patient may exhibit some, all, or none of the symptoms related to the complications of DM **(Chap. 417)**. In addition, the presence of DM-related comorbidities should be established (cardiovascular disease, hypertension, dyslipidemia). Pregnancy plans should be ascertained in women of childbearing age. The ADA recommends that all women of childbearing age be counseled about the importance of tight glycemic control (HbA_{1c} <6.5%) prior to conception.

PHYSICAL EXAMINATION

In addition to a complete physical examination, special attention should be given to DM-relevant aspects such as weight and BMI, retinal examination, orthostatic blood pressure, foot examination, peripheral pulses, and insulin injection sites. Because periodontal disease is more frequent in DM, the teeth and gums should also be examined.

An annual foot examination should (1) assess blood flow (pedal pulses), sensation (vibratory sensation [128-Hz tuning fork at the base of the great toe], the ability to sense touch with a monofilament [5.07, 10-g monofilament]), pinprick sensation, ankle reflexes, and nail care; (2) look for the presence of foot deformities such as hammer or claw toes and Charcot foot; and (3) identify sites of potential ulceration. The ADA recommends annual screening for distal symmetric polyneuropathy beginning with the initial diagnosis of diabetes and annual screening for autonomic neuropathy 5 years after diagnosis of type 1 DM and at the time of diagnosis of type 2 DM. This testing is aimed at detecting loss of protective sensation (LOPS) caused by diabetic neuropathy **(Chap. 417)**.

CLASSIFICATION OF DM IN AN INDIVIDUAL PATIENT

The etiology and classification of diabetes in an individual with new-onset disease is usually assigned based on clinical criteria. DM classification is critical in efforts to provide personalized therapy, but some individuals cannot be neatly classified as having type 1 or type 2 DM at the time of diagnosis. Even if type 1 DM is classified correctly, there is heterogeneity in terms of immune markers, insulin requirements, and the rapidity of beta cell loss. Long-used features such as age of onset, obesity, and the need for insulin treatment are often not helpful in DM classification, especially in adults with new-onset DM. Features such as younger age at diagnosis (<35 years), nonobese BMI, ketoacidosis, markedly elevated plasma glucose at diagnosis, and a family or personal history of other autoimmune disorders such as autoimmune thyroid disease, adrenal insufficiency, pernicious anemia, celiac disease, and vitiligo should prompt consideration of type 1 DM and measurement of ICA. However, these are only broad guidelines and may not be present in every individual with type 1 DM. For example, now many individuals with new-onset type 1 DM are overweight or obese. In contrast, individuals with type 2 DM often exhibit the following features: (1) obesity; 80% are obese, but elderly individuals and those from South and East Asia may be lean; (2) may not require insulin therapy initially; and (3) may have associated conditions such as insulin resistance, hypertension, cardiovascular disease, dyslipidemia, or PCOS. In type 2 DM, insulin resistance is often associated with abdominal obesity (as opposed to hip and thigh obesity) and hypertriglyceridemia. Although most individuals diagnosed with type 2 DM are older, the age of diagnosis is declining, and there is a marked increase among overweight children and adolescents. Some individuals with phenotypic type 2 DM present with DKA but lack autoimmune markers and may be later treated with oral glucose-lowering agents rather than insulin (this clinical picture is sometimes referred to as *ketosis-prone type 2 DM*). On the other hand, some individuals (5–10%) with the phenotypic appearance of type 2 DM do not initially have absolute insulin deficiency but have autoimmune markers (GAD and other ICAs) suggestive of type 1 DM (sometimes termed *autoimmune diabetes of adults*). Such individuals are more likely to require insulin treatment within 5 years of diabetes diagnosis and likely have a form of autoimmune diabetes. Monogenic forms of diabetes should be considered in those with diabetes onset in childhood or early adulthood and especially those diagnosed within the first 6 months of life those with an autosomal pattern of diabetes inheritance, diabetes without typical features of type 1 or 2 DM, and stable mild fasting hyperglycemia. Despite recent advances in the understanding of the pathogenesis of diabetes, it often remains difficult to categorize some patients unequivocally. There is increasing recognition that many forms of diabetes are atypical and do not fit in the type 1 or type 2 DM pattern. Individuals who deviate from the clinical profile of type 1 and type 2 DM, or who have other associated defects such as deafness, pancreatic exocrine disease (type 3c DM), and other endocrine disorders, should be classified accordingly (Table 415-1). While a major goal is personalized or precision medicine in the diagnosis and treatment of diabetes, this is currently an aspirational goal in many individuals with diabetes.

LABORATORY ASSESSMENT

The laboratory assessment should first determine whether the patient meets the diagnostic criteria for DM (Fig. 415-1) and then assess the degree of glycemic control **(Chap. 416)**. In addition to the standard laboratory evaluation, the patient should be screened for DM-associated conditions (e.g., albuminuria, dyslipidemia, thyroid dysfunction).

The classification of the type of DM may be facilitated by laboratory assessments. Serum C-peptide measurements may be useful but should always be interpreted with a concurrent blood glucose level. A low C-peptide in the setting of an elevated blood glucose level may confirm a patient's need for insulin. However, C-peptide levels are unable to completely distinguish type 1 from type 2 DM as many individuals with type 1 DM retain some C-peptide production. Measurement of islet cell antibodies at the time of diabetes onset may be useful if the type of DM is not clear based on the characteristics described above.

416 Diabetes Mellitus: Management and Therapies

Alvin C. Powers, Kevin D. Niswender, Michael R. Rickels

OVERALL GOALS

The goals of therapy for all forms of diabetes mellitus (DM) are to (1) eliminate symptoms related to hyperglycemia, (2) reduce or eliminate the long-term microvascular and macrovascular complications of DM (Chap. 417), and (3) allow the patient to achieve as normal a lifestyle as possible. To reach these goals, the physician and health care team should identify a target level of glycemic control for each patient, provide the patient with the educational and pharmacologic resources necessary to reach this target, avoid hypoglycemia, and monitor/prevent/treat DM-related complications. Symptoms of diabetes usually resolve when the plasma glucose is <11.1 mmol/L (200 mg/dL), and thus most DM treatment focuses on achieving the second and third goals.

The care of an individual with either type 1 or type 2 DM requires a multidisciplinary team. Central to the success of this team are the patient's participation, input, and enthusiasm, all of which are essential for optimal diabetes management. Members of the health care team usually include the primary care provider and/or the endocrinologist or diabetologist, an advanced practice provider (APP), a pharmacist, a certified diabetes educator, a nutritionist, a behavioral health professional, and possibly a social worker. In addition, when the complications of DM arise, subspecialists (including ophthalmologists, neurologists, podiatrists, nephrologists, cardiologists, and cardiovascular and transplant surgeons) with experience in DM-related complications are essential. The American Diabetes Association (ADA) suggests applying the Chronic Care Model to diabetes with an emphasis on these elements: a proactive, team-based delivery and health system design that involves self-management, decision support with evidence-based guidelines for person-specific and population-based approaches, and community resources and policies that support healthy lifestyles. Space limitations do not allow a discussion of all these elements, so this chapter first reviews the ongoing treatment of diabetes in the outpatient setting and then discusses the treatment of severe hyperglycemia, as well as the treatment of diabetes in hospitalized patients.

ONGOING ASPECTS OF COMPREHENSIVE DIABETES CARE

A number of names are sometimes applied to different approaches to diabetes care, such as intensive insulin therapy or intensive glycemic control. The current chapter, and other sources, uses the term *Comprehensive diabetes care* to emphasize the fact that optimal diabetes therapy involves much more than glucose management and medications and that individualized, patient-centered care is essential. Although glycemic control is central to optimal diabetes therapy, comprehensive diabetes care of both type 1 and type 2 DM should also detect and modify risk factors for DM-associated disorders and manage DM-specific complications (Chap. 417). The key elements of comprehensive diabetes care are summarized in Table 416-1. The morbidity and mortality of DM can be greatly reduced by timely and consistent surveillance, including the detection, prevention, and management of DM-related complications (Table 416-1 and Chap. 417). Such approaches are indicated for all individuals with DM, but many individuals with diabetes do not receive these or comprehensive diabetes care. The social determinants of health and family, financial, cultural, and employment-related issues may negatively impact diabetes care. This chapter, while recognizing that resources available for diabetes care vary widely throughout the world, provides guidance for comprehensive diabetes care in health care settings with considerable societal resources.

TABLE 416-1 Guidelines for Ongoing, Comprehensive Medical Care for Individuals with Diabetes

- Individualized glycemic goal and therapeutic plan with an emphasis on shared decision-making
- Blood glucose measurement using continuous glucose monitoring (CGM) or capillary fingerstick device
- HbA_{1c} testing (2–4 times/year)
- Lifestyle management in the care of diabetes, including:
  - Diabetes self-management education and support
  - Nutrition therapy
  - Physical activity
  - Psychosocial care, including evaluation for depression, anxiety, diabetes distress
- Detection, prevention, or management of diabetes-related complications, including:
  - Diabetes-related eye examination (annual or biannual; Chap. 417)
  - Diabetes-related foot examination (1–2 times/year by provider; daily by patient; Chap. 415)
  - Diabetes-related neuropathy examination (annual; Chap. 415)
  - Diabetes-related kidney disease testing (annual; Chap. 417)
  - Screen for other diabetes-related complications (annual; see Table 417-1)
  - Assessment of fracture risk in older adults with diabetes (consider measurement of bone mineral density)
- Manage or treat diabetes-relevant conditions, including:
  - Blood pressure (assess 2–4 times/year; Chap. 417)
  - Lipids (1–2 times/year; Chap. 417)
  - Consider screening individuals with type 2 diabetes or prediabetes for metabolic dysfunction–associated steatotic liver disease if other risk factors are present
  - Consider antiplatelet therapy with low-dose aspirin (Chap. 417)
  - Immunizations, including influenza, pneumococcal, hepatitis B, coronavirus, and respiratory syncytial virus (>60 years of age) (Chap. 6)

Abbreviation: HbA_{1c}, glycated hemoglobin A_{1c}.

Patient-oriented websites also offer important resources for patients and their caregivers. Examples of these resources include: *https://www.tidepool.org/about*; *https://diatribe.org/understanding-diabetes/diabetes-technology*; and *https://pro.diabeteswise.org/en/*.

Lifestyle Management in Diabetes Care The patient with type 1 or type 2 DM should receive education about nutrition, physical activity, psychosocial support, care of diabetes during illness, medications used to control the glucose, methods for glucose monitoring, and strategies to prevent diabetes-related complications. Patient education allows and encourages individuals with DM to assume greater responsibility for their care, leading to improved compliance.

Diabetes Self-Management Education and Support (DSMES) DSMES refers to ways to improve the patient's knowledge, skills, and abilities necessary for diabetes self-care and should also emphasize psychosocial issues and emotional well-being. Patient education is a continuing process with regular visits for reinforcement; it is not a process completed after one or two visits. It should receive special emphasis at the diagnosis of diabetes, annually, or at times when diabetes treatment goals are not attained, and during transitions in life or medical care. DSMES is delivered by a diabetes educator who is a health care professional (nurse, dietician, or pharmacist) with specialized patient-education skills and who is certified in diabetes education (e.g., Association of Diabetes Care and Education Specialists or Certification Board for Diabetes Care and Education). Education topics important for optimal diabetes self-care include continuous glucose monitoring (CGM) or blood glucose monitoring (BGM); urine or blood ketone monitoring (type 1 DM); insulin administration; guidelines for diabetes management during illnesses; prevention and management of hypoglycemia (Chap. 418); foot and skin care; diabetes management before, during, and after exercise; and risk factor–modifying activities. The focus is providing patient-centered, individualized education. More frequent contact between the patient

and the diabetes management team (e.g., electronic, telephone, video) improves glycemic control.

Nutrition Therapy *Medical nutrition therapy* (MNT) is a term used by the ADA to describe the optimal coordination of caloric intake with other aspects of diabetes therapy (e.g., insulin, exercise, and weight loss). Some aspects of MNT are directed at preventing or delaying the onset of type 2 DM in high-risk individuals (obese or with prediabetes) by promoting weight reduction. Other measures of MNT are directed at improving glycemic control through monitoring carbohydrate intake, avoiding simple sugars and fructose, and managing diabetes-related complications (atherosclerotic cardiovascular disease [ASCVD], nephropathy). Medical treatment of obesity, including pharmacologic approaches that facilitate weight loss and metabolic surgery, should be considered in some patients **(Chaps. 413 and 414)**.

In general, the components of optimal MNT are similar for individuals with type 1 or type 2 DM—high-quality, nutrient-dense foods with limits on carbohydrate intake and weight management **(Table 416-2)**. The data are currently inconclusive about various eating patterns (e.g., intermittent fasting). Sleep deprivation and shift work are risk factors for weight gain and insulin resistance. Dietary advice should be individualized, acknowledging personal preferences, cultural, and religious traditions. Use of the *glycemic index*, an estimate of the postprandial rise in the blood glucose when a certain amount of that food is consumed, may reduce postprandial glucose excursions and improve glycemic control.

The goal of MNT in type 1 DM is to coordinate and match the carbohydrate intake, both temporally and quantitatively, with the appropriate amount of insulin. MNT in type 1 DM is informed by CGM and/or BGM that should be integrated to define the optimal insulin regimen. Based on the patient's estimate of the carbohydrate content of a meal, an insulin-to-carbohydrate ratio determines the bolus insulin dose for a meal or snack. MNT must be flexible enough to allow for exercise, and the insulin regimen must allow for variations in caloric intake. An important component of MNT in type 1 DM is to minimize the weight gain often associated with intensive insulin therapy and is best achieved by placing limits on carbohydrate intake.

The goals of MNT in type 2 DM should focus on weight loss and address the greatly increased prevalence of cardiovascular risk factors (hypertension, dyslipidemia, obesity) and disease in this population. The majority of these individuals are obese, and weight loss is strongly encouraged. Very-low-carbohydrate diets that induce weight loss may result in rapid and dramatic glucose lowering in individuals with new-onset type 2 DM. MNT for type 2 DM should emphasize modest caloric reduction, increased physical activity, and weight loss (goal of at least 5–10% loss). Weight loss and exercise each independently improve insulin sensitivity.

Fasting for religious reasons, such as during Ramadan, presents a challenge for individuals with diabetes, especially those taking medications to lower the plasma glucose. Under most guidelines for fasting during Ramadan, individuals are risk-stratified based on a pre-Ramadan risk assessment for people with diabetes as those who can safely fast with medical evaluation and supervision and those in whom fasting is not advised. Thus, patient education and regular glucose monitoring are critical.

TABLE 416-2 Nutritional Recommendations for Adults with Diabetes or Prediabetes[a]

General dietary guidelines

- Vegetables, fruits, whole grains, legumes, low-fat dairy products and food higher in fiber and lower in glycemic content; optimal diet composition and eating pattens are not known.

Fat in diet (optimal percentage of diet is not known; should be individualized)

- Encourage Mediterranean-style diet rich in monounsaturated and polyunsaturated fatty acids.
- Minimal or no trans fat consumption.

Carbohydrate in diet (optimal percentage of diet is not known; should be individualized)

- Monitor carbohydrate intake in regard to calories and set limits for meals to reduce postprandial glycemia.
- Consider limiting overall carbohydrate intake in adults with diabetes as this may improve glycemia.
- Avoid fructose- and sucrose-containing beverages and minimize consumption of foods with added sugar that may displace healthier, more nutrient-dense food choices and elevate postprandial glycemia.
- Estimate grams of carbohydrate in diet for flexible insulin dosing (type 1 diabetes and insulin-dependent type 2 diabetes).
- Consider using glycemic index to predict how consumption of a particular food may affect blood glucose.

Protein in diet (optimal percentage of diet is not known; should be individualized)

Other components

- Reduced-calorie and nonnutritive sweeteners may be useful.
- Routine supplements of vitamins, antioxidants, or trace elements not supported by evidence.
- Vitamin D and calcium supplemental as recommended to promote bone health.
- Sodium intake as advised for general population (<2300 mg/d).
- Minimize disruption to sleep and eating patterns (chrononutrition), and note risk of hypoglycemia associated with religious fasting.

[a]See text for differences for patients with type 1 or type 2 diabetes.

Source: Data from American Diabetes Association: Facilitating positive health behaviors and well-being to improve health outcomes: Standards of care in diabetes—2024. Diabetes Care 47:S77, 2024.

Physical Activity Exercise has multiple positive benefits, including cardiovascular risk reduction, reduced blood pressure, maintenance of muscle mass, reduction in body fat, and weight loss. For individuals with type 1 or type 2 DM, exercise is also useful for lowering plasma glucose (during and following exercise) and increasing insulin sensitivity. In patients with diabetes, the ADA recommends 150 min/week (distributed over at least 3 days) of moderate aerobic physical activity with no gaps longer than 2 days. Resistance exercise, flexibility and balance training, and reduced sedentary behavior throughout the day are also advised.

Despite its benefits, exercise may present challenges for some individuals with DM because they lack the normal glucoregulatory mechanisms (normally, insulin falls and glucagon rises during exercise). Skeletal muscle is a major site for metabolic fuel consumption in the resting state, and the increased muscle activity during vigorous aerobic exercise greatly increases fuel requirements. Individuals with type 1 DM are prone to either hyperglycemia or hypoglycemia during exercise, depending on the pre-exercise plasma glucose, the circulating insulin level, lactate, and the level of exercise-induced catecholamines. If the insulin level is too low, the delivery of lactate to the liver and rise in catecholamines may increase the plasma glucose excessively, promote ketone body formation, and possibly lead to ketoacidosis. Conversely, if the circulating insulin level is excessive, this relative hyperinsulinemia may reduce hepatic glucose production (decreased glycogenolysis, decreased gluconeogenesis) and increase glucose entry into muscle, leading to hypoglycemia.

To avoid exercise-related hyper- or hypoglycemia, individuals with type 1 DM should (1) monitor blood glucose before, during, and after exercise (see below related to CGM and possible blood glucose discordance); (2) delay exercise if blood glucose is >14 mmol/L (250 mg/dL) and ketones are present; (3) if the blood glucose is <5.0 mmol/L (90 mg/dL), ingest carbohydrate before exercising; (4) monitor glucose during exercise and ingest carbohydrate as needed to prevent hypoglycemia; (5) decrease insulin doses (based on previous experience) before and after exercise and inject insulin into a nonexercising area; and (6) learn individual glucose responses to different types of exercise. In individuals with type 2 DM, exercise-related hypoglycemia is less common but can occur in individuals taking either insulin or insulin secretagogues. Untreated proliferative retinopathy is a relative contraindication to vigorous exercise because this may lead to vitreous hemorrhage or retinal detachment **(Chap. 417)**.

Psychosocial Care Because the individual with DM faces challenges that affect many aspects of daily life, psychosocial assessment and support are a critical part of comprehensive diabetes care. The patient should view himself/herself/themself as an essential member of the diabetes care team and not as someone who is cared for by the

diabetes management team. Even with considerable effort, normoglycemia can be an elusive goal, and solutions to worsening glycemic control may not be easily identifiable. Depression, anxiety, or "diabetes distress," defined by the ADA as "negative psychological reactions related to emotional burdens … in having to manage a chronic disease like diabetes," should be recognized and may require the care of a mental health specialist. Emotional stress may provoke a change in behavior so that individuals no longer adhere to a dietary, exercise, or therapeutic regimen. Eating disorders, including binge eating disorders, bulimia, and anorexia nervosa, appear to occur more frequently in individuals with type 1 or type 2 DM.

MONITORING THE LEVEL OF GLYCEMIC CONTROL

Optimal monitoring of glycemic control involves CGM or BGM (blood collected by fingerstick) by the patient and an assessment of long-term control by providers using measurement of hemoglobin A_{1c} (HbA_{1c}). These measurements are complementary: the patient's measurements provide a picture of short-term glycemic control, whereas the HbA_{1c} reflects average glycemic control over the previous 2–3 months. By integrating glycemic measurements with diet and exercise history into comprehensive diabetes care, the diabetes management team and patient can improve glycemic control and reduce diabetes-related complications.

Assessment of Short-Term Glycemic Control All individuals with diabetes should be offered a device to assess their short-term patterns of glycemia. CGM technology utilizes a sensor or electrode to detect interstitial glucose, which is in equilibrium with the blood glucose but may lag when the blood glucose changes rapidly or during exercise. Glucose sensors are placed subcutaneously by the patient and replaced every 10–14 days; a different device can be placed subcutaneously by a minor surgical procedure and replaced every 6–12 months. Some CGMs require calibration by fingerstick blood glucose measurement. CGM provides glucose data every 5 minutes, and the device's output can be provided in an ambulatory glucose profile (AGP) that is a standardized, single page summary that includes the percentage of time in the desired glycemic range (TIR, or time in range), the percentage of time above the target range, the percentage of time below the target range, the glucose management indicator (GMI), which correlates with HbA_{1c} **(Table 416-3)**, and glucose variability. CGM in real time also allows the patient to monitor the trend of glucose change (upward or downward), with this trend being used to avoid predicted hyper- or hypoglycemia.

CGM device technology is rapidly evolving with the number of available CGM devices increasing and features expanding. This chapter uses the term CGM to encompass both real-time CGM and intermittently scanned CGM, with real-time CGM being more effective. Most CGMs require a provider's prescription, but CGM devices are approved for purchase without a provider's prescription. The selection of CGM type should consider the implications for the individual with diabetes (e.g., cost, convenience, insurance coverage), the provider (e.g., access to patient's CGM data), and the health system (e.g., integration of patient CGM data into the electronic medical record). Selection is best optimized by the involvement of a certified diabetes educator knowledgeable about these technologies. Unfortunately, certified diabetes educators are not available in all care settings, so the individual with diabetes and the provider may need to investigate CGM options using online resources and see suggestions in the reference list. Many are vendor specific; some resources provide information on multiple vendors, technologies, and devices. The selection of a CGM device should be individualized based on patient preference and skill level, capability to collect and use the data, and ability to upload data to adjust therapy. CGM may be used in individuals whose diabetes is partially or completely managed by someone else, such as a caregiver (e.g., in a child or an individual with cognitive impairment). After the selection of a CGM device, the individual with diabetes (and/or the caregiver) should receive education and training on a regular basis.

BGM devices use a small drop of blood (<2 μL) and an enzymatic reaction to rapidly measure the capillary blood glucose. It is critical that individuals using CGM also have a capillary (fingerstick) device for times when the CGM technology is malfunctioning, CGM results are questionable, or for CGM calibration (if required or desired). Substances can interfere with the accuracy of measurements by CGM devices (e.g., hydroxyurea, acetaminophen, ascorbic acid, mannitol, and sorbitol) and BGM devices (e.g., uric acid, galactose, xylose, acetaminophen, L-DOPA, or ascorbic acid).

Individuals with type 1 DM or individuals with type 2 DM taking insulin injections each day should monitor their blood glucose by CGM. CGM in type 1 DM, especially in those with hypoglycemia unawareness, can decrease the frequency of serious hypoglycemia (especially nocturnal hypoglycemia). The combination of an insulin-infusion device (discussed below) and a CGM can automate insulin delivery with either predictive suspension of insulin delivery to avoid hypoglycemia or closed-loop control that automatically adjusts insulin delivery by a predictive algorithm **(Fig. 416-1)**. Some CGM/insulin pump manufacturers offer the patient a way to upload glucose data into the manufacturer's server, which can then be securely accessed by the provider's staff. It is critical for the patient's glycemic data to be securely accessible to the provider and uploaded into the electronic health record of the provider and health system, but approaches and systems to accomplish this need further improvement.

Individuals with type 2 DM treated on oral therapy and/or only with diet/lifestyle require less intense glycemic monitoring and can use CGM or BGM to measure the glucose at a lower frequency (e.g., 3–5 times/week). Many individuals with type 1 or type 2 DM report that real-time access to glycemic information via CGM assists in lifestyle choices, diet, and activity in addition to insulin or medication management, thereby improving control.

Assessment of Long-Term Glycemic Control Measurement of glycated hemoglobin (HbA_{1c}) is the standard method for assessing long-term glycemic control. When plasma glucose is consistently elevated, there is an increase in nonenzymatic glycation of hemoglobin; this alteration reflects the glycemic history over the previous 2–3 months, because erythrocytes have an average life span of ~120 days (glycemic level in the preceding month contributes about 50% to the HbA_{1c} value). Laboratory standards for the HbA_{1c} test should be correlated to the reference assay of the Diabetes Control and Complications Trial (DCCT). Measurement of HbA_{1c} at the "point of care" allows for more rapid feedback and may therefore assist in adjustment of therapy.

As the primary predictor of long-term complications of DM, the HbA_{1c} should mirror the short-term measurement by CGM or BGM. HbA_{1c} should be measured in all individuals with DM during their initial evaluation and as part of their comprehensive diabetes care. In patients achieving their glycemic goal, the ADA recommends measurement of the HbA_{1c} at least twice per year. More frequent testing (every 3 months) is warranted when glycemic control is inadequate or when therapy has changed. The HbA_{1c} correlates with the average plasma glucose value or estimated average glucose (eAG) (Table 416-3) but does not detect glycemic variability or recent intercurrent illnesses as CGM or BGM can. There is interindividual variability in the HbA_{1c} to mean glucose relationship, likely genetically determined; there is controversy and some uncertainty about the influence of race or ancestry

TABLE 416-3 Relationship of HbA_{1c} and Estimated Average Glucose (eAG)

HEMOGLOBIN A_{1c} (%)	ESTIMATED AVERAGE GLUCOSE (AVERAGE, RANGE)	
	mmol/L	mg/dL
5	5.4 (4.2–6.7)	97 (76–120)
6	7.0 (5.5–8.5)	126 (100–152)
7	8.6 (6.8–10.3)	154 (123–185)
8	10.2 (8.1–12.1)	183 (147–217)
9	11.8 (9.4–13.9)	212 (170–249)
10	13.4 (10.7–15.7)	240 (193–282)
11	14.9 (12.0–17.5)	269 (217–314)
12	16.5 (13.3–19.3)	298 (240–347)

on HbA_{1c}. For example, the HbA_{1c} in African Americans is slightly higher (~0.3%) than in non-Hispanic white or Hispanic individuals for the same mean glucose. Clinical conditions leading to abnormal red blood cell (RBC) parameters such as hemoglobinopathies, anemias, reticulocytosis, transfusions, uremia, variants in glucose-6-phosphate dehydrogenase, hemodialysis, erythropoietin therapy, and HIV treatment may alter the HbA_{1c} result. Glycemic control can also be assessed by the degree of glycation of other proteins, such as fructosamine or glycated albumin, that reflect glycemia over the prior 2–4 weeks.

PHARMACOLOGIC TREATMENT OF DIABETES

Comprehensive care of type 1 and type 2 DM requires an emphasis on nutrition, exercise, and monitoring of glycemic control in addition to glucose-lowering medication(s). Medications to prevent and manage diabetes-related complications are discussed in **Chap. 417**. This chapter discusses classes of such medications but does not describe all glucose-lowering agents available worldwide. The initial step is to select an individualized glycemic goal for the patient.

ESTABLISHMENT OF TARGET LEVEL OF GLYCEMIC CONTROL

Because the complications of DM are related to glycemic control, normoglycemia or near-normoglycemia is the desired, but often elusive, goal for most patients. Normalization or near-normalization of the plasma glucose for long periods of time had been extremely difficult, as demonstrated by the DCCT and United Kingdom Prospective Diabetes Study (UKPDS), but new technologies and medications are making this goal more feasible. Regardless of the level of hyperglycemia, improvement in glycemic control will lower the risk of diabetes-related complications, most notably the microvascular complications **(Chap. 417)**.

The target for glycemic control (as reflected by the HbA_{1c}) should be individualized, and the goals of therapy should be developed in consultation with the individuals with diabetes after considering a number of medical, social, and lifestyle issues (ADA terms this patient-centered care) such as age, ability to understand and implement a treatment regimen, presence and severity of complications of diabetes such as ASCVD, ability to recognize hypoglycemic symptoms, presence of other medical conditions or treatments that might affect survival or the response to therapy, lifestyle and occupation (e.g., possible consequences of experiencing hypoglycemia on the job), and level of support available from family and friends.

In general, the ADA suggests that the goal is to achieve an HbA_{1c} as close to normal as possible without significant hypoglycemia. In most individuals, the target HbA_{1c} should be <7% **(Table 416-4)** with a more stringent (≤6.5%) target for some patients. With current treatment and devices, the level of HbA_{1c} is no longer inversely related to the frequency and severity of hypoglycemia as seen in the DCCT. A higher HbA_{1c} target of <7.5 or 8% is appropriate for individuals with cognitive impairment, those with reduced ability to sense hypoglycemia, or those with limited life span, realizing that these factors represent a spectrum across individuals (Table 416-4). Approximately one in four individuals over the age of 65 years has diabetes. Thus, the glycemic goal in elderly individuals (>65 years) should be individualized and consider the overall clinical state of the individual. For example, in an elderly individual with robust cognition and few major health issues, the glycemic goal may be the same as in younger individuals (HbA_{1c} target <7.0%), while in an individual with impaired cognition or a resident of a long-term facility, the major goal is avoidance of hypoglycemia and severe hyperglycemia (Table 416-4).

Large clinical trials (UKPDS, Action to Control Cardiovascular Risk in Diabetes [ACCORD], Action in Diabetes and Vascular Disease: Preterax and Diamicron MR Controlled Evaluation [ADVANCE], Veterans Affairs Diabetes Trial [VADT]; DCCT/EDIC study in type 1 DM; see **Chap. 417**) examined glycemic control in type 2 DM in individuals with low risk of ASCVD, a high risk of ASCVD, or established ASCVD. Overall, these studies indicate that (1) improved glycemic control reduces microvascular complications of diabetes; (2) improved glycemic control in individuals early in the course of type 1 DM led to reduction in nonfatal myocardial infarction, stroke, and cardiovascular death almost two decades after the period of improved glycemic control had ended; (3) intense glycemic control is beneficial for ASCVD in

TABLE 416-4 Glycemic Goals for Adults with Diabetes[a]

INDEX OF GLYCEMIC CONTROL	ADULTS (NONPREGNANT)	ELDERLY ADULTS WITH INTACT COGNITION AND FUNCTIONAL STATUS	ELDERLY ADULTS WITH OTHER SERIOUS COMORBIDITIES[b]	ELDERLY ADULTS WITH COMPLEX COMORBIDITIES, POOR HEALTH, OR IMPARIED COGNITION[c]
HbA_{1c}	<7.0% (53 mmol/mol)	<7.0–7.5% (53–57 mmol/mol)	<8.0% (64 mmol/mol)	<8.5% (64 mmol/mol) with avoidance of hypoglycemia
CGM metrics				
% Time within indicated range[c]	>70% within 3.9–10.0 mmol/L (70–180 mg/dL)[c]	>70% within 4.4–10.0 mmol/L (80–180 mg/dL)[c]	>50% within 5.5–10.0 mmol/L (100–200 mg/dL)[c]	>40% within 6.7–12.2 mmol/L (120–220 mg/dL)[c]
Time below 3.9 mmol/L (70 mg/dL) but >54 mg/dL (>3 mmol/L) indicating level 1 or mild hypoglycemia)[c]	<4%	<1%	0%	0%
Time below <54 mg/dL (<3 mmol/L) indicating level 2 or moderate/severe hypoglycemia[c]	<1%	<1%	0%	0%
Glucose variability, % coefficient of variation[d]	≤36%	<33%	N/A	N/A
Preprandial capillary blood glucose	4.4–7.2 mmol/L (80–130 mg/dL)	4.4–7.2 mmol/L (80–130 mg/dL)	5.0–8.3 mmol/L (90–150 mg/dL)	5.6–10.0 mmol/L (100–180 mg/dL)
Postprandial capillary blood glucose[e]	<10.0 mmol/L (<180 mg/dL)	<11.1 mmol/L (200 mg/dL)	<13.9 mmol/L (250 mg/dL)	<13.9 mmol/L (250 mg/dL)

[a]Glycemic goal should be individualized for each patient; elderly >65 years. Some suggest different glycemic targets such as the American Association of Clinical Endocrinology (AACE), which suggests an HbA_{1c} goal <6.5%, and American College of Physicians (ACP), which suggests a goal of 7–8%. [b]Multiple chronic illnesses, impaired activities of daily living, or cognitive impairment. [c]Overall poor health with complex comorbidities, cognitive impairment, or limited life span or resident in skilled nursing facility or a long-term care facility. [d]As determined by CGM. See **Chap. 418** for hypoglycemia definitions. [e]1–2 h after beginning of a meal.

Abbreviations: CGM, continuous glucose monitoring; HbA_{1c}, hemoglobin A_{1c}; N/A, not applicable to glycemia management.

some populations with type 2 DM; and (4) hypoglycemia in high-risk populations with ASCVD should be avoided as it is associated with cardiovascular events and mortality. Thus, near-normal glycemia is not the goal in this population (Table 416-4). As will be discussed later, these studies were conducted before the advent of glucagon-like peptide 1 (GLP-1) receptor agonists (GLP-1RAs) and sodium-glucose cotransporter 2 (SGLT-2) inhibitors, which have greater cardiovascular benefit than agents utilized in these earlier clinical trials.

TYPE 1 DIABETES MELLITUS

General Aspects The goal is to design and implement an insulin regimen that mimics physiologic insulin secretion. Because individuals with type 1 DM partially or completely lack endogenous insulin production, administration of basal insulin is essential for regulating glycogen breakdown, gluconeogenesis, lipolysis, and ketogenesis (e.g., fine-tuning hepatic and adipose metabolism). Likewise, insulin replacement for meals should be appropriate for the carbohydrate intake and insulin sensitivity, promoting normal glucose utilization and storage. The continued increase in insulin costs over the past decade has been a major challenge for individuals with diabetes. Recent federal and state legislative action has begun to address this; however, the cost of insulin continues to be a major issue in diabetes care.

Intensive Management of Glycemia Intensive insulin therapy in type 1 DM seeks to achieve normal or near-normal glycemia. This goal requires the integration of multiple resources and efforts, including thorough and continuing patient education, comprehensive recording of glucose measurements and nutrition intake by the patient, and a variable insulin regimen that matches carbohydrate intake and exercise and insulin dose. Insulin is delivered subcutaneously via multiple daily injections (MDIs), continuous subcutaneous insulin infusion (CSII), a sensor-augmented system, or an automated insulin delivery system (AID). Insulin delivery by CSII requires a manual entry into the pump to alter the basal infusion rate or direct an insulin bolus. A sensor-augmented system has a pump and a CGM device, assisted by an algorithm that suspends the insulin infusion when the glucose is low or predicted to be low in 30 min based on the glucose trajectory. An AID system, using a pump, CGM, and algorithm, increases or decreases the basal insulin infusion rate in real time based on CGM data. Some AID systems deliver a correction insulin bolus, but these

[a]Injectable insulin preparations (with exception of inhaled formulation) available in the United States; others are available in the United Kingdom and Europe. Standard formulations are U-100 (100 units of insulin per mL solution). Insulin detemir, a long-acting insulin, will soon not be available and is not included in this table. [b]Formulation with niacinamide (vitamin B_3) has a slightly more rapid onset and offset. [c]Lispro-aabc formulation has a slightly more rapid onset and offset. Several forms of insulin (e.g., degludec, insulin lispro, Lispro-aabc) are also available in U-200 concentration. [d]Formulation also available in U-500 concentration with delayed onset and offset. [e]Degludec and glargine have minimal peak activity. [f]Duration is dose-dependent. [g]Formulation also available in U-300 concentration, which has longer duration. [h]Other insulin combinations are available. [i]Dual: two peaks—one at 2–3 h and the second one several hours later.

Abbreviations: GLP-1RA, glucagon-like peptide 1 receptor agonist; NPH, neutral protamine Hagedorn.

are not a completely closed-loop system as the patient must input carbohydrate intake data and projected activity or exercise. This is a rapidly evolving area of type 1 DM–related technology, algorithms, and artificial intelligence, with some individuals having considerable success using do-it-yourself (DIY) approaches that are based in the type 1 DM user community and not U.S. Food and Drug Administration (FDA) approved.

The benefits of intensive insulin therapy and improved glycemic control include a reduction in the acute metabolic and chronic microvascular complications of DM. From a psychological standpoint, the patient experiences greater control over their diabetes and often notes an improved sense of well-being, greater flexibility in the timing and content of meals, and the capability to alter insulin dosing with exercise. Intensive insulin therapy prior to and during pregnancy reduces the risk of fetal malformations and morbidity. Intensive insulin therapy is encouraged in newly diagnosed patients with type 1 DM, including the use of CGM. Although intensive management confers impressive benefits, it may not be appropriate at all times for all individuals with T1D (Table 416-4). Some individuals with diabetes prefer subcutaneous, intermittent insulin injections combined with a CGM to being connected continuously to an insulin infusion device, highlighting the need for individualized diabetes care.

Insulin Preparations Insulin preparations are generated by recombinant DNA technology and consist of the amino acid sequence of human insulin or variations thereof. In the United States, most insulin is formulated as U-100 (100 units/mL); short-acting insulin formulated as U-200 (200 units/mL; lispro) and long-acting as U-300 (300 units/mL; glargine) are available in order to limit injection volumes for patients with high insulin requirements. Regular insulin formulated as U-500 (500 units/mL) is sometimes used in patients with severe insulin resistance. Human insulin has been formulated with distinctive pharmacokinetics (regular and neutral protamine Hagedorn [NPH] insulin have the native insulin amino acid sequence) or genetically modified to alter insulin absorption and hence the onset and duration of insulin action. Insulins can be classified as rapid-acting, short-acting, intermediate-acting, long-acting, or ultralong-acting (**Table 416-5;** Fig. 416-1*D*). For example, one rapid-acting insulin formulation, insulin lispro, is an insulin analogue in which the 28th and 29th amino acids (lysine and proline) on the insulin B chain have been reversed. Insulin aspart and insulin glulisine are modified insulin analogues with properties similar to lispro. A biosimilar version of lispro is available. These insulin analogues have full biologic activity but less tendency for self-aggregation, resulting in more rapid absorption and onset of action and a shorter duration of action. These characteristics are particularly advantageous for allowing entrainment of insulin injection and action to the rising plasma glucose levels following meals. The shorter duration of action also appears to be associated with a decreased number of hypoglycemic episodes, primarily because the decay of insulin action corresponds to the decline in plasma glucose after a meal. Thus, insulin aspart, lispro, or glulisine is preferred over regular insulin for prandial coverage. Insulin glargine is a long-acting biosynthetic human insulin that differs from normal insulin in that asparagine is replaced by glycine at amino acid 21, and two arginine residues are added to the C terminus of the B chain, leading to the formation of microprecipitates at physiologic pH in subcutaneous tissue. Compared to NPH insulin, the onset of insulin glargine action is later, the duration of action is longer (~24 h), and there is a less pronounced peak. A lower incidence of hypoglycemia, especially at night, has been reported with insulin glargine when compared to NPH insulin. A biosimilar version is available. Twice-daily injections of glargine are sometimes required to provide optimal 24-h basal insulin coverage. Because of modification and extension of the carboxy-terminus of the B chain, insulin degludec forms multihexamers in subcutaneous tissue and binds albumin, prolonging its duration of action (>42 h); it provides similar glycemic control as glargine but with less frequent nocturnal and severe hypoglycemia. Other modified insulins, such as one with a duration of action of 1 week, are in clinical trials and will likely soon be available.

Basal insulin requirements, largely fine-tuning hepatic glucose metabolism, are provided by long-acting insulin formulations (NPH insulin, insulin glargine, or insulin degludec) (Fig. 416-1*D*; Table 416-5). These are usually prescribed with rapid-acting insulin in an attempt to mimic physiologic insulin release with meals (prandial insulin requirement). In the past, NPH and short-acting insulin formulations were mixed in the same syringe, but this is not common now. The miscibility of some insulins allows for the production of combination insulins that contain 70% NPH and 30% regular (70/30), or equal mixtures of NPH and regular (50/50). By including the insulin analogue mixed with protamine, several additional combinations have a rapid-acting and long-acting profile (Table 416-5; Fig. 416-1*D*). Although more convenient for the patient (only two injections a day), combination insulin formulations do not allow independent adjustment of short-acting and long-acting activity and are not appropriate in type 1 DM management. Most insulin formulations are available as insulin "pens," which are more convenient and accurate than syringes; "smart pens" can assist with insulin dose tracking. Insulin delivery by inhalation to provide mealtime insulin has a more rapid onset of action than insulin injected subcutaneously. Prior to its use, the forced expiratory volume in 1 s (FEV_1) should be measured, and then monitored periodically during treatment. Inhaled insulin can cause bronchospasm and cough and should not be used by individuals with lung disease or those who smoke. Long-acting insulin/GLP-1RA combinations in fixed doses (degludec plus liraglutide or glargine plus lixisenatide) are effective and are associated with less weight gain.

Insulin Regimens There is considerable patient-to-patient variation in the peak and duration. In all regimens, long-acting insulins (NPH, glargine, or degludec) supply basal insulin, whereas regular, insulin aspart, glulisine, or lispro provide prandial insulin (Fig. 416-1*D*; Table 416-5). Rapid-acting insulin analogues should be injected just before (<10 min) and regular insulin 30–45 min prior to a meal. Sometimes rapid-acting insulin analogues are injected just after a meal (gastroparesis, unpredictable food intake). A consensus statement from ADA and the European Association for the Study of Diabetes provides guidance about different insulin regimens used in type 1 DM.

A shortcoming of current insulin regimens is that injected insulin immediately enters the systemic circulation, whereas endogenous insulin is secreted into the portal venous system. Thus, exogenous insulin administration exposes the liver to subphysiologic insulin levels, and requires achieving higher peripheral levels of insulin to restrain hepatic glucose production. No current insulin regimen reproduces the precise insulin secretory pattern of the pancreatic islet. However, the most physiologic regimens entail more frequent insulin injections, greater reliance on rapid-acting insulin, and CGM or more frequent BGM. In general, individuals with type 1 DM require 0.4–1.0 units/kg per day of insulin divided into multiple doses, with 30–50% of daily insulin given as basal insulin with the remainder as prandial insulin. All individuals with type 1 DM should have a filled glucagon prescription **(Chap. 416)**.

MDI regimens refer to the combination of basal insulin and bolus insulin (preprandial rapid-acting insulin). The timing and dose of rapid-acting, preprandial insulin are altered to accommodate the CGM or BGM results, anticipated food intake, and physical activity. Such regimens offer the patient with type 1 DM more flexibility in terms of lifestyle and the best chance for achieving near normoglycemia. Most often, basal insulin with glargine or degludec is used in conjunction with preprandial lispro, glulisine, or insulin aspart. The dose of long-acting insulin is adjusted based on the fasting glucose. The insulin aspart, glulisine, or lispro dose is based on individualized algorithms that integrate the preprandial glucose and the anticipated carbohydrate intake. To determine the meal component of the preprandial insulin dose, the patient uses an insulin-to-carbohydrate ratio (a common ratio for type 1 DM is 1 unit/10–15 g of carbohydrate, but this must be determined for each individual). To this insulin dose is added the supplemental or correcting insulin based on the preprandial blood glucose (one formula uses 1 unit of insulin for every 1.6–3.3 mmol/L [30–60 mg/dL] over the preprandial glucose target; this correction factor can be estimated from 1500/[total daily insulin dose]). Such

TABLE 416-6 Agents Used for Treatment of Type 1 or Type 2 Diabetes

	MECHANISM OF ACTION	EXAMPLES[a]	HBA_{1C} REDUCTION (%)[b]	AGENT-SPECIFIC ADVANTAGES	AGENT-SPECIFIC DISADVANTAGES	CONSIDERATIONS
Oral						
Biguanides[c*]	↓ Hepatic glucose production, ↑ insulin sensitivity, influence gut function	Metformin	1–2	Weight neutral, do not cause hypoglycemia, inexpensive, extensive experience, modest ↓ CV events	Diarrhea, nausea, lactic acidosis, vitamin B_{12} deficiency	Renal insufficiency (see text for GFR <30 mL/min), CHF, radiographic contrast studies, hospitalized patients, acidosis
Sodium-glucose cotransporter 2 (SGLT-2) inhibitors[c***]	↑ Renal glucose excretion	Canagliflozin, dapagliflozin, empagliflozin, ertugliflozin, bexagliflozin, sotagliflozin (SGLT-1/2 inhibitor)	0.5–1.0	Renal protective, ↓ CV events, ↓ heart failure, do not cause hypoglycemia, modest ↓ weight and blood pressure	Increased risk genital mycotic infections and necrotizing fasciitis of perineum; polyuria, dehydration; increased risk of euglycemic DKA[f] (see text); exacerbate tendency to hyperkalemia	Moderate renal insufficiency; discontinue 3–4 days before surgery, during serious illness
Dipeptidyl peptidase-4 inhibitors[c***]	Prolong endogenous GLP-1 action; ↑ insulin, ↓ glucagon	Alogliptin, linagliptin, saxagliptin, sitagliptin, vildagliptin	0.5–0.8	Well tolerated, do not cause hypoglycemia	Angioedema/urticarial and immune-mediated dermatologic effects; rarely associated with pancreatitis	Reduced dose with renal insufficiency
Insulin secretagogues: Sulfonylureas[c*]	↑ Insulin secretion	Glimepiride, glipizide, gliquidone, glyburide	1–2	Short onset of action, lower postprandial glucose, inexpensive	Hypoglycemia, weight gain	Renal/liver insufficiency
Insulin secretagogues: Nonsulfonylureas[c***]	↑ Insulin secretion	Nateglinide, repaglinide	0.5–1.0	Short onset of action, lower postprandial glucose	Hypoglycemia	Renal/liver insufficiency (except repaglinide)
Thiazolidinediones[c****]	↓ Insulin resistance, ↑ glucose utilization	Pioglitazone, rosiglitazone	0.5–1.4	Lower insulin requirements	Peripheral edema, CHF, weight gain, fractures, macular edema	CHF, renal/liver insufficiency
α-Glucosidase inhibitors[c**]	↓ GI glucose absorption	Acarbose, miglitol	0.5–0.8	Reduce postprandial glycemia	GI flatulence, elevated liver function tests	Renal/liver insufficiency
Parenteral/Oral (GLP-1RA-related agents)						
GLP-1RAs[c***]	↑ Insulin, ↓ glucagon, slow gastric emptying, satiety	Dulaglutide, exenatide, liraglutide, lixisenatide, semaglutide (oral formulation available)	0.5–1.0	Weight loss, do not cause hypoglycemia (unless combined with another insulin secretagogue or insulin); ↓ CV events, modest renoprotection	Nausea, GI intolerance; possibly associated with pancreatitis[e], possibly worsen retinopathy	Renal disease, agents that also slow GI motility; medullary carcinoma of thyroid, previous ileus
GLP-1/GIP receptor agonist[c***]	↑ Insulin, ↓ glucagon, slow gastric emptying, satiety	Tirzepatide	1.8-2.4	Weight loss, do not cause hypoglycemia (unless combined with insulin secretagogue or insulin); ↓ CV events	Nausea, GI intolerance, possibly associated pancreatitis[e], possibly worsen retinopathy	Renal disease, agents that also slow GI motility; medullary carcinoma of thyroid, pancreatic disease, history of gastroparesis
Parenteral						
Amylin agonists[c,d***]	Slow gastric emptying, ↓ glucagon	Pramlintide	0.25–0.5	Reduce postprandial glycemia, weight loss	Injection, nausea, ↑ risk of hypoglycemia with insulin	Agents that also slow GI motility
Insulin[c,d****]	↑ Glucose utilization, ↓ hepatic glucose production, and other anabolic actions	See text and Table 416-4	Not limited	Known safety profile	Injection, weight gain, hypoglycemia	Can be combined with most other agents
Medical nutrition therapy and physical activity[c*]	↓ Insulin resistance, ↑ insulin secretion	Low-calorie, carbohydrate-controlled diet, exercise	1–3	Other health benefits	Compliance difficult, long-term success of sustained weight loss low	Other health benefits

[a]Examples are approved for use in the United States; others are available in other countries. Examples may not include all agents in the class. [b]HbA_{1c} reduction (absolute) depends partly on starting HbA_{1c}. [c]Used for treatment of type 2 diabetes. [d]Used in conjunction with insulin for treatment of type 1 diabetes. Cost of agent in the United States: *low, **moderate, ***high, ****variable. [e]Degree of risk uncertain, avoid in individuals with risk factors for pancreatitis. [f]Risk of euglycemic DKA in patients with insulin deficiency.

Note: Some agents used to treat type 2 diabetes are not included in table (see text).

Abbreviations: CHF, congestive heart failure; CV, cardiovascular; DKA, diabetic ketoacidosis; GFR, glomerular filtration rate; GI, gastrointestinal; GIP, gastric inhibitory polypeptide; GLP-1, glucagon-like peptide 1; GLP-1RA, glucagon-like peptide 1 receptor agonist; HbA_{1c}, glycated hemoglobin A_{1c}.

calculations must be adjusted based on each individual's sensitivity to insulin. CGM or BGM is essential for these types of insulin regimens.

AID is the preferred insulin delivery mechanism for most individuals with type 1 DM (Fig. 416-1), but cost and insurance coverage are critical considerations. To the basal insulin infusion, a preprandial insulin ("bolus") is delivered by the insulin infusion device based on instructions from the patient or an algorithm that incorporates the preprandial plasma glucose and anticipated carbohydrate intake. These sophisticated devices can accurately deliver small doses of insulin (microliters per hour) and have several advantages: (1) multiple basal infusion rates can be programmed to accommodate nocturnal versus daytime basal insulin requirement; (2) basal infusion rates can be altered during periods of exercise; (3) different waveforms of insulin infusion with meal-related bolus allow better matching of insulin depending on meal composition; and (4) programmed algorithms consider ongoing action of prior insulin administration and blood glucose values in calculating the insulin dose. As mentioned, the technology, algorithms, and integration of the different components are changing rapidly, indicating the need to match these with patients' desires, for instruction by a health professional with considerable experience with insulin infusion devices, and for frequent patient interactions with the diabetes management team. Insulin infusion devices may present unique challenges, such as infection at the infusion site, unexplained hyperglycemia because the infusion set becomes obstructed, or diabetic ketoacidosis (DKA) if the insulin infusion device becomes disconnected. Because most physicians use lispro, glulisine, or insulin aspart in CSII or AID, the short half-life of these insulins quickly leads to insulin deficiency if the delivery system is interrupted. Essential to the safe use of infusion devices is thorough patient education, CGM or frequent BGM, and a backup plan for injecting long- and/or rapid-acting insulins in the event of insulin infusion device failure. CGM sensor-augmented insulin infusion devices integrate the information from the CGM to inform insulin delivery (Fig. 416-1). Currently, sensor communicating functions can interrupt basal insulin delivery during hypoglycemia (threshold suspension) or when hypoglycemia is anticipated (predictive suspension), which may be particularly useful for preventing nocturnal hypoglycemia. Hybrid closed-loop systems can combine patient-directed preprandial boluses with automated adjustment of between-meal and basal insulin delivery based on CGM. Clinical experience with closed-loop systems is rapidly increasing and expanding. Bihormonal infusion devices that deliver both insulin and glucagon are being tested.

Other Agents That Improve Glucose Control The role of amylin, a 37-amino-acid peptide co-secreted with insulin from pancreatic beta cells in normal glucose homeostasis is uncertain. However, based on the rationale that patients who are insulin deficient are also amylin deficient, an analogue of amylin (pramlintide) was created and found to reduce postprandial glycemic excursions in individuals with type 1 or type 2 DM taking insulin. Pramlintide injected just before a meal slows gastric emptying and suppresses glucagon but does not alter insulin levels. Pramlintide is approved for insulin-treated patients with type 1 or type 2 DM. The addition of pramlintide produces a modest reduction in the HbA_{1c} and seems to dampen meal-related glucose excursions. In type 1 DM, pramlintide is started as a 15-μg SC injection before each meal and titrated up to a maximum of 30–60 μg as tolerated. In type 2 DM, pramlintide is started as a 60-μg SC injection before each meal and may be titrated up to a maximum of 120 μg. The major side effects are nausea and vomiting, and dose escalations should be slow to limit these side effects. Because pramlintide slows gastric emptying, it may influence absorption of other medications and should not be used in combination with other drugs that slow gastrointestinal (GI) motility. The rapid-acting insulin given before the meal should initially be reduced to avoid hypoglycemia and then titrated as the effects of the pramlintide become evident. Because pramlintide suppresses glucagon, it may worsen hypoglycemia recovery and should not be used in patients with hypoglycemia unawareness. GLP-1RAs and SGLT-2 inhibitors modestly improve the HbA_{1c} in type 1 DM, but the SGLT-2 inhibitors increase the risk of DKA and in general should not be used.

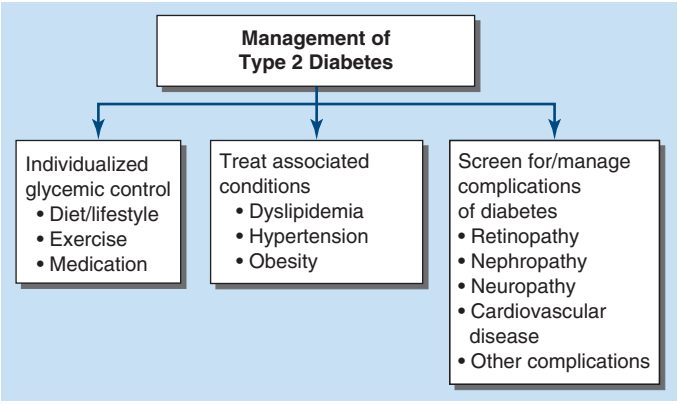

FIGURE 416-2 Essential elements in comprehensive care of type 2 diabetes.

TYPE 2 DIABETES MELLITUS

General Aspects The goals of glucose-directed therapy for type 2 DM are similar to those in type 1 DM and, likewise, should be individualized for each patient. Whereas glycemic control tends to dominate the management of type 1 DM, the care of individuals with type 2 DM must also include even greater attention to the treatment of conditions associated with type 2 DM (e.g., obesity, hypertension, dyslipidemia, ASCVD) and prevention/detection/management of DM-related complications **(Fig. 416-2; Chap. 417)**. Reduction in cardiovascular risk is of paramount importance because this is the leading cause of mortality in these individuals. One approach to pharmacology of glucose-directed therapies in type 2 DM is shown in Fig. 416-3.

Type 2 DM management should begin with MNT (discussed above). An exercise regimen to increase insulin sensitivity and promote weight loss should also be instituted. Pharmacologic approaches to the management of type 2 DM include oral glucose-lowering agents, insulin, and other agents that improve glucose control. Any therapy that improves glycemic control reduces "glucose toxicity" to beta cells and may improve endogenous insulin secretion. However, type 2 DM is a progressive disorder and ultimately requires multiple therapeutic agents and sometimes insulin.

Glucose-Lowering Agents Advances in the therapy of type 2 DM have led to glucose-lowering agents that target different pathophysiologic processes in type 2 DM. Based on their mechanisms of action, glucose-lowering agents are subdivided into agents that increase insulin secretion, reduce glucose production, increase insulin sensitivity, act as a GLP-1 receptor agonist, or promote urinary excretion of glucose (Table 416-6). Insulin is sometimes the initial glucose-lowering agent in type 2 DM if there is severe hyperglycemia or the patient is catabolic.

BIGUANIDES Metformin, representative of this class of agents, reduces hepatic glucose production and improves peripheral glucose utilization slightly (Table 416-6) and is relatively low cost. Metformin acts in multiple tissues, but its mechanism of action remains incompletely defined. Metformin reduces fasting plasma glucose (FPG) and insulin levels, improves the lipid profile, and promotes modest weight loss. An extended-release form is available and may have fewer GI side effects (diarrhea, anorexia, nausea, metallic taste). Because of metformin's relatively slow onset of action and GI symptoms with higher doses, the initial dose should be low and then escalated every 1–2 weeks to a maximally tolerated dose of 2000 mg daily. Metformin is effective as monotherapy and can be used in combination with other glucose lowering agents. The major toxicity of metformin, lactic acidosis, is very rare and can be prevented by careful patient selection. Vitamin B_{12} levels are lower during metformin treatment and should be monitored. Metformin should not be used in patients with moderate renal insufficiency (glomerular filtration rate [GFR] <30 mL/min), any form of acidosis, unstable congestive heart failure (CHF), liver disease, or

severe hypoxemia. Metformin should be discontinued in hospitalized patients, in patients who can take nothing orally, and in those receiving radiographic contrast material. Insulin should be used as needed until metformin can be restarted.

INSULIN SECRETAGOGUES—AGENTS THAT AFFECT THE ATP-SENSITIVE K^+ CHANNEL Insulin secretagogues stimulate insulin secretion by interacting with the ATP-sensitive potassium channel on the beta cell **(Chap. 415)**. These drugs are most effective in individuals with type 2 DM of relatively recent onset (<5 years) who have residual endogenous insulin production. Sulfonylureas reduce both fasting and postprandial glucose and should be initiated at low doses and increased at 1- to 2-week intervals based on CGM or BGM. Glimepiride and glipizide can be given in a single daily dose and are preferred over glyburide, especially in the elderly. Repaglinide and nateglinide are not sulfonylureas but also interact with the ATP-sensitive potassium channel. Because of their short half-life, these glinide agents are given immediately before each meal to reduce meal-related glucose excursions.

Insulin secretagogues, especially the longer-acting ones, have the potential to cause hypoglycemia, especially in elderly individuals. Hypoglycemia is usually related to delayed meals, increased physical activity, alcohol intake, or renal insufficiency. Individuals who ingest an overdose of some agents develop prolonged and serious hypoglycemia and should be monitored closely in the hospital **(Chap. 418)**. Most sulfonylureas are metabolized in the liver to compounds (some of which are active, such as those of glyburide and the glinide nateglinide) that are cleared by the kidney. Thus, their use in individuals with significant hepatic or renal dysfunction is not advisable. For patients with chronic kidney disease the glinide repaglinide may be used with caution. Weight gain, a common side effect of sulfonylurea therapy, results from the increased insulin levels and improvement in glycemic control. Some sulfonylureas have significant drug interactions with alcohol and some medications including warfarin, aspirin, ketoconazole, α-glucosidase inhibitors, and fluconazole. Sulfonylureas interact with some antibiotics such as fluoroquinolones, clarithromycin, sulfamethoxazole-trimethoprim, metronidazole, and fluconazole, so the sulfonylureas should be discontinued when these antimicrobials are added to the patient's medications.

GLP-1RAS ALONE OR IN COMBINATION WITH GIP RECEPTOR AGONIST "Incretins" amplify glucose-stimulated insulin secretion and suppress inappropriate glucagon secretion **(Chap. 415)**. Agents that either act as a GLP-1RA or enhance endogenous GLP-1 activity are approved for the treatment of type 2 DM and obesity (Table 416-6). Agents in this class do not cause hypoglycemia because of the glucose-dependent nature of incretin-stimulated insulin secretion (unless there is concomitant use of an agent that can lead to hypoglycemia—sulfonylureas, etc.). GLP-1RAs increase glucose-stimulated insulin secretion, suppress glucagon, and slow gastric emptying, but the GLP-1 receptor is expressed in several tissues, including the brain. These agents promote weight loss **(see Chaps. 413 and 414)** and reduce cardiovascular events in those with type 2 DM and ASCVD (see **Chap. 417** for additional discussion about the effect on diabetes-related complications). Thus, these agents are particularly advantageous in type 2 DM. Long-acting GLP-1RAs include sustained-release exenatide, dulaglutide, lixisenatide, and semaglutide, all administered weekly, and are the ones most commonly used. Daily oral semaglutide is available that allows gastric absorption to avoid proteolytic degradation in the small intestine. All are modified to avoid enzymatic inactivation by dipeptidyl peptidase IV (DPP-4) in the circulation. Higher doses of liraglutide and semaglutide than used for glucose-lowering effects are effective for weight-loss therapy for obesity. Liraglutide treatment has also been associated with a decrease in cardiovascular disease (CVD) events in patients with type 2 DM and established CVD and with lower rates of diabetic kidney disease. In similar patient populations, semaglutide treatment has been associated with fewer CVD events and reduced diabetic kidney disease, but with an increased rate of retinopathy-related complications. Dulaglutide treatment has been associated with both a reduction in CVD events and a reduction in composite microvascular retinopathy and nephropathy-related complications primarily driven by prevention of renal events. Treatment with GLP-1RAs should start at a low dose to minimize initial side effects (nausea being the limiting one). GLP-1RAs can be used as combination therapy with metformin, sulfonylureas, and thiazolidinediones. Some patients taking insulin or an insulin secretagogue may require a reduction in those agents to prevent hypoglycemia. The major side effects are nausea and vomiting. Some formulations carry a black box warning from the FDA because of an increased risk of thyroid C-cell tumors in rodents and are contraindicated in individuals with medullary carcinoma of the thyroid or multiple endocrine neoplasia. Because GLP-1RAs slow gastric emptying, they may influence the absorption of other drugs. Whether GLP-1RAs enhance beta cell survival or promote beta cell proliferation is not known. It is not clear if these agents alter the natural history of type 2 DM.

Tirzepatide, a once-weekly subcutaneous injectable peptide engineered to have dual agoniism at both the glucose-dependent insulinotropic polypeptide receptor (GIPR) and the GLP-1R, promotes greater weight loss than a GLP-1RA alone. Additional dual-acting and triple-acting molecules are in development and clinical trials.

DPP-4 inhibitors inhibit degradation of native GLP-1 and GIP and thus enhance the incretin effect. DPP-4, which is widely expressed on the cell surface of endothelial cells and some lymphocytes, degrades a wide range of peptides (not incretin specific). DPP-4 inhibitors promote insulin secretion in the absence of hypoglycemia or weight gain and appear to have a preferential effect on postprandial blood glucose. The levels of GLP-1 action in the patient are greater with the GLP-1RAs than with DPP-4 inhibitors. DPP-4 inhibitors are used either alone or in combination with other oral agents in type 2 DM. Reduced doses should be given to patients with renal insufficiency. Allergy, including rash, hypersensitivity reactions (including anaphylaxis, angioedema, and Stevens-Johnson syndrome), and severe joint pain have been reported in association with DPP-4 inhibitors. There is evidence concerning a potentially increased risk for acute pancreatitis with GLP-1RAs and less so with DPP-4 inhibitors. It is prudent to avoid these agents in patients with pancreatic disease or with other significant risk factors for acute pancreatitis (e.g., heavy alcohol use, severely elevated serum triglycerides, hypercalcemia).

SGLT-2 INHIBITORS These agents (Table 416-6) lower the blood glucose by selectively inhibiting this co-transporter, which is expressed almost exclusively in the proximal convoluted tubule in the kidney. This inhibits glucose reabsorption, lowers the renal threshold for glucose excretion, and leads to increased urinary glucose loss. Thus, the glucose-lowering effect is insulin independent and not related to changes in insulin sensitivity or secretion. The loss of urinary glucose may promote modest weight reduction. Since these agents also impair proximal reabsorption of sodium, their use is associated with a diuretic effect and a 3- to 6-mmHg reduction in systolic blood pressure. Due to the increased urinary glucose, urinary and genital mycotic infections are more common in both men and women, and the diuretic effect can lead to reduced intravascular volume and acutely impaired kidney function. Inhibition of SGLT-2 may lead to increased glucagon and, consequently, liver production of glucose and ketones. Euglycemic DKA may occur during illness or when ongoing glucosuria masks stress-induced requirements for insulin. Patients should be educated about this possibility, and providers should be vigilant about detection. These agents should not be prescribed for patients with type 1 DM or pancreatogenic forms of DM associated with insulin deficiency. Empagliflozin or canagliflozin reduces ASCVD events and all-cause cardiovascular mortality in patients with type 2 DM and established ASCVD. SGLT-2 inhibitors may reduce hospitalization for CHF. Empagliflozin, canagliflozin, and dapagliflozin have all been shown to reduce progression of diabetic kidney disease but should not be initiated in patients with stage 3b chronic kidney disease (CKD; estimated GFR [eGFR] <45 mL/min per 1.73 m^2) and should not be used in stage 4 CKD (eGFR <30 mL/min per 1.73 m^2). A possible increased risk of bladder cancer has been seen with dapagliflozin. **The impact of SGLT-2 inhibitors on diabetes-related complications is discussed in Chap. 417 and below.**

THIAZOLIDINEDIONES Thiazolidinediones (Table 416-6) reduce insulin resistance by binding to the peroxisome proliferator-activated receptor γ (PPAR-γ) nuclear receptor (which forms a heterodimer with the retinoid X receptor). The PPAR-γ receptor is found at highest levels in adipocytes but is expressed at lower levels in many other tissues. Agonists of this receptor regulate a large number of genes, promote adipocyte differentiation, reduce hepatic fat accumulation, and promote fatty acid storage. Thiazolidinediones promote a redistribution of fat from central to peripheral locations. Circulating insulin levels decrease with use of the thiazolidinediones, indicating a reduction in insulin resistance.

Rosiglitazone raises low-density lipoprotein (LDL), high-density lipoprotein (HDL), and triglycerides slightly. Pioglitazone raises HDL to a greater degree and LDL to a lesser degree but lowers triglycerides. The clinical significance of the lipid changes with these agents is not known.

Thiazolidinediones are associated with weight gain (2–3 kg), a small reduction in the hematocrit, and a mild increase in plasma volume. Peripheral edema and CHF are more common in individuals treated with these agents. These agents are contraindicated in patients with hepatic insufficiency or CHF (class III or IV). The FDA has issued an alert that rare patients taking these agents may experience a worsening of diabetic macular edema. An increased risk of fractures has been noted in postmenopausal women taking these agents. Thiazolidinediones have been shown to induce ovulation in premenopausal women with polycystic ovary syndrome. Women should be warned about the risk of pregnancy because the safety of thiazolidinediones in pregnancy is not established. According to an FDA review, pioglitazone may be associated with an increased risk of bladder cancer. In one study, pioglitazone lowered the risk for recurrent stroke or myocardial infarction in insulin-resistant individuals without diabetes who had a prior stroke or transient ischemic attack.

α-GLUCOSIDASE INHIBITORS α-Glucosidase inhibitors reduce postprandial hyperglycemia by delaying glucose absorption (Table 416-6). Postprandial hyperglycemia, secondary to impaired hepatic and peripheral glucose disposal, contributes significantly to the hyperglycemic state in type 2 DM. These drugs, taken just before each meal, reduce glucose absorption by inhibiting the enzyme that cleaves oligosaccharides into simple sugars in the intestinal lumen. Therapy should be initiated at a low dose with the evening meal and increased to a maximal dose over weeks to months. The major side effects (diarrhea, flatulence, abdominal distention) are related to increased delivery of oligosaccharides to the large bowel and can be reduced somewhat by gradual upward dose titration. α-Glucosidase inhibitors may increase levels of sulfonylureas and increase the incidence of hypoglycemia. Simultaneous treatment with bile acid resins and antacids should be avoided. These agents should not be used in individuals with inflammatory bowel disease, gastroparesis, or a serum creatinine >177 μmol/L (2 mg/dL). This class of agents is not as potent as other oral agents in lowering the HbA_{1c} but is unique because it reduces the postprandial glucose rise. If hypoglycemia from other diabetes treatments occurs while taking these agents, the patient should consume glucose because the degradation and absorption of complex carbohydrates will be slowed.

OTHER THERAPIES FOR TYPE 2 DM • Bile Acid–Binding Resins Evidence indicates that bile acids, by signaling through nuclear receptors, may have a role in metabolism. Bile acid metabolism is abnormal in type 2 DM. The bile acid–binding resin colesevelam has been approved for the treatment of type 2 DM (already approved for treatment of hypercholesterolemia). The role of this class of drugs in the treatment of type 2 DM is not yet defined.

Bromocriptine A formulation of the dopamine receptor agonist bromocriptine (Cycloset) has been approved by the FDA for the treatment of type 2 DM. However, its role in the treatment of type 2 DM is uncertain.

INSULIN THERAPY IN TYPE 2 DM Insulin should be considered for initial therapy in type 2 DM, particularly in lean individuals or those with severe weight loss, in individuals with underlying renal or hepatic disease that precludes oral glucose-lowering agents, or in individuals who are hospitalized or acutely ill. Insulin therapy is ultimately required by a substantial number of individuals with type 2 DM because of the progressive nature of the disorder and the relative insulin deficiency that develops with long-standing diabetes. Both physician and patient reluctance often delay the initiation of insulin therapy, but glucose control and individual well-being are improved by insulin therapy in patients who have not reached their glycemic target.

Because endogenous insulin secretion is capable of providing some coverage of mealtime caloric intake, insulin is usually initiated in a single dose of long-acting insulin (0.1–0.4 U/kg per day), given in the evening or just before bedtime (NPH, glargine, or degludec). Because fasting hyperglycemia and increased hepatic glucose production are prominent features of type 2 DM, bedtime insulin is more effective in clinical trials than a single dose of morning insulin. Glargine given at bedtime has less nocturnal hypoglycemia than NPH insulin. Some physicians prefer a relatively low, fixed starting dose of long-acting insulin (10–15 units) or a weight-based dose (0.1 units/kg). The insulin dose may then be adjusted in 10–20% increments as dictated by CGM or BGM results. Both morning and bedtime long-acting insulin may be used in combination with oral glucose-lowering agents. Initially, basal insulin may be sufficient, but often prandial insulin coverage with multiple insulin injections is needed as diabetes progresses (see insulin regimens used for type 1 DM). Other insulin formulations that have a combination of rapid-acting and long-acting insulin (Table 416-5) are sometimes used in patients with type 2 DM because of convenience but do not allow independent adjustment of rapid-acting and long-acting insulin dose and often do not achieve the same degree of glycemic control as basal/bolus regimens. AID in selected individuals with type 2 DM should be considered, especially in those who are insulin-deficient. CGM should be used in all individuals taking insulin.

CHOICE OF INITIAL GLUCOSE-LOWERING AGENT The level of hyperglycemia and the patient's individualized goal (see "Establishment of Target Level of Glycemic Control") should influence the initial choice of therapy. Patients with mild hyperglycemia (FPG <7.0–11.0 mmol/L [126–199 mg/dL]) often respond well to a single, oral glucose-lowering agent, while those with moderate hyperglycemia (FPG 11.1–13.9 mmol/L [200–250 mg/dL]) will usually require more than one oral agent or insulin. Patients with more severe hyperglycemia (FPG >13.9 mmol/L [250 mg/dL]) may respond partially but are unlikely to achieve normoglycemia with oral therapy. Insulin can be used as initial therapy in individuals with severe hyperglycemia (FPG <13.9–16.7 mmol/L [250–300 mg/dL]) or in those who are symptomatic from the hyperglycemia. This approach is based on the rationale that more rapid glycemic control will reduce "glucose toxicity" to the islet cells, improve endogenous insulin secretion, and possibly allow oral glucose-lowering agents to be more effective. If this occurs, the insulin may be discontinued. Treatment algorithms by several professional societies (ADA/ European Association for the Study of Diabetes [EASD], International Diabetes Federation, American Association of Clinical Endocrinology) suggest metformin as initial therapy because of its efficacy, known side effect profile, and low cost **(Fig. 416-3)**. Initiation of pharmacologic therapy should be accompanied by an emphasis on lifestyle modification (e.g., MNT, increased physical activity, and weight loss). Metformin's advantages are that it promotes mild weight loss, lowers insulin levels, and improves the lipid profile slightly. Based on CGM or BGM results and the HbA1c, the dose of metformin should be increased until the glycemic target is achieved or the maximum dose is reached. GLP-1RAs and SGLT-2 inhibitors are increasing in use as evidence accumulates for CVD and CKD benefits, in addition to weight loss and glucose-lowering effects.

Insulin secretagogues, biguanides, α-glucosidase inhibitors, thiazolidinediones, GLP-1RAs, DPP-4 inhibitors, SGLT-2 inhibitors, and insulin are approved for monotherapy of type 2 DM. Although each class of oral glucose-lowering agents has advantages and disadvantages (Table 416-6), certain generalizations apply: (1) insulin secretagogues, biguanides, GLP-1RAs, and thiazolidinediones improve glycemic control to a similar degree (1–2% reduction in HbA_{1c}) and are more effective than α-glucosidase inhibitors, DPP-4 inhibitors, and SGLT-2

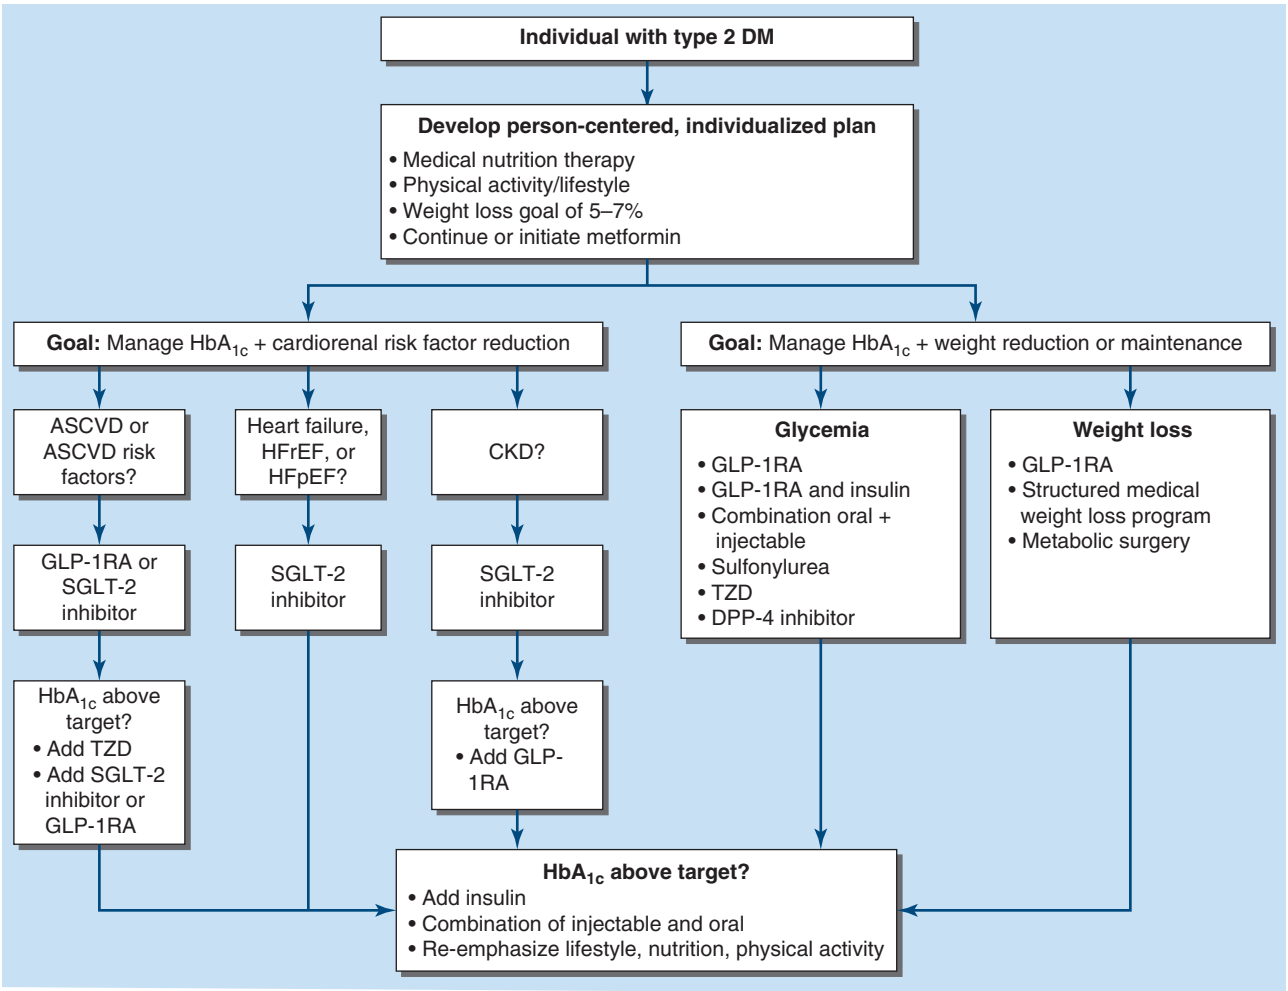

FIGURE 416-3 Glycemic management of type 2 diabetes. See text for discussion of treatment of severe hyperglycemia or symptomatic hyperglycemia. In this Figure, the term glucagon-like peptide-1 receptor agonists (GLP-1RAs) refers to GLP-1 RAs and dual glucose-dependent insulinotropic polypeptide (GIP) and GLP-1 RAs. Agents that can be combined with metformin include insulin, GLP-1RAs, sodium-glucose cotransporter 2 (SGLT-2) inhibitors, insulin secretagogues, thiazolidinediones (TZD), α-glucosidase inhibitors, and dipeptidyl peptidase-4 (DPP-4) inhibitors. Injectable refers to insulin or GLP-RA. In individuals with type 2 DM and metabolic dysfunction–associated steatotic liver disease (see Chap. 354) or metabolic dysfunction–associated steatohepatitis (see Chap. 354), a GLP-1 RA or a dual glucose-dependent insulinotropic polypeptide (GIP) and GLP-1 RA and/or TZD (pioglitazone) should be considered. ASCVD, atherosclerotic cardiovascular disease; CKD, chronic kidney disease; DM, diabetes mellitus; HbA_{1c}, hemoglobin A_{1c}; HFrEF, heart failure with reduced ejection fraction; HFpEF, heart failure with preserved ejection fraction.

inhibitors; (2) insulin secretagogues, GLP-1RAs, DPP-4 inhibitors, α-glucosidase inhibitors, and SGLT-2 inhibitors begin to lower the plasma glucose immediately, whereas the glucose-lowering effects of the biguanides and thiazolidinediones takes several days; (3) not all agents are effective in all individuals with type 2 DM; (4) biguanides, α-glucosidase inhibitors, GLP-1RAs, DPP-4 inhibitors, thiazolidinediones, and SGLT-2 inhibitors do not directly cause hypoglycemia; (5) most individuals will eventually require treatment with more than one class of oral glucose-lowering agents or insulin, reflecting the progressive nature of type 2 DM; and (6) durability of glycemic control is slightly less for sulfonylureas compared to metformin or thiazolidinediones.

COMBINATION THERAPY WITH GLUCOSE-LOWERING AGENTS The approach to type 2 DM has changed dramatically with the demonstration that GLP-1RAs and SGLT-2 inhibitors reduce cardiovascular events and slow the progression of renal disease, indicating that a GLP-1RA or an SGLT-2 inhibitor should be used in most individuals with type 2 DM. Therapy should be dictated by whether ASCVD, heart failure, or CKD is present or whether weight loss is a major goal (Fig. 416-3). A number of combinations of therapeutic agents are useful in type 2 DM: metformin plus SGLT-2 inhibitor, metformin plus GLP-1RA, metformin plus insulin, or combinations of a long-acting insulin and a GLP-1RA. Because the mechanism of action of the first and second agents differs, the effect on glycemic control is usually additive. Recent results from the National Institutes of Health–funded Glycemia Reduction Approaches in Diabetes: A Comparative Effectiveness Study (GRADE) indicated that addition of liraglutide or basal insulin to metformin leads to better glycemic control than glimepiride or sitagliptin (SGLT-2 inhibitors were not studied). Medication costs vary considerably (Table 416-6), and this often factors into medication choice as drugs in some categories are very expensive (e.g., SGLT-2 inhibitors, GLP-1RAs). Several fixed-dose combinations of oral agents are available, but evidence that they are superior to titration of a single agent to a maximum dose and then addition of a second agent is lacking. If adequate control is not achieved with the combination of two agents (based on reassessment of the HbA_{1c} every 3 months), a third oral agent, including basal insulin, should be considered (Fig. 416-3). Treatment approaches vary considerably from country to country. For example, α-glucosidase inhibitors are used commonly in South Asian patients (Indian) but infrequently in the United States or Europe. Whether this reflects an underlying difference in the disease or physician preference is not clear.

Treatment with insulin often becomes necessary as type 2 DM enters the phase of relative insulin deficiency and is signaled by inadequate glycemic control with one or two oral glucose-lowering agents. Insulin alone or in combination should be used in patients who fail to reach glycemic targets. For example, a single dose of long-acting insulin at bedtime is often effective in combination with metformin. As endogenous insulin production falls further, multiple injections of long-acting insulin together with rapid-acting insulin are necessary to control postprandial glucose excursions. These insulin regimens are identical to the long-acting and rapid-acting combination regimens discussed above for type 1 DM, although usually at higher doses given

insulin resistance. Weight gain and hypoglycemia are the major adverse effects of insulin therapy. The addition of a GLP-1RA can limit this and reduce the dose of insulin needed. The daily insulin dose required can become quite large (1–2 units/kg per day) as endogenous insulin production falls and insulin resistance persists, especially in the setting of weight gain. Insulin plus a thiazolidinedione promotes weight gain and may be associated with peripheral edema. Addition of a GLP-1RA or a thiazolidinedione may necessitate a reduction in the insulin dose to avoid hypoglycemia. Patients requiring large doses of insulin (>200 units/day) can be treated with more concentrated forms of insulin to reduce the volume of injectate and improve absorption.

OTHER THERAPIES FOR DIABETES

Metabolic (also referred to as bariatric) surgery for obese individuals with type 2 DM has shown considerable effectiveness, sometimes with dramatic resolution of diabetes or major reductions in the needed dose of glucose-lowering therapies **(Chaps. 413 and 414)**. Several large, nonrandomized clinical trials have demonstrated a much greater efficacy of metabolic surgery compared to medical management in the treatment of type 2 DM, but these trials were conducted before the advent of recently available GLP-1RAs. The ADA clinical guidelines state that metabolic surgery should be considered in individuals with type 2 DM and a body mass index >30 kg/m^2 if hyperglycemia is inadequately controlled despite optimal medical therapy. Metabolic surgery is ideally performed in certified centers with experience with the procedures and associated nutritional support.

Short-term intense caloric restriction (very-low-calorie diet, typically 800–1000 calories/d) can dramatically improve type 2 DM, sometimes leading to resolution of the diabetes. Such an approach is more effective in recent-onset type 2 DM and should be supervised by a provider with expertise and accompanied by a long-term, weight-maintenance program.

Whole-pancreas transplantation can normalize glucose control in type 1 DM and when performed simultaneously with or after kidney transplantation can prolong the life of the kidney transplant by offering protection against recurrent diabetic nephropathy. However, the number of whole-pancreas transplants is declining, likely reflecting the success with CGM and AID. Pancreatic islet transplantation is a less invasive form of beta-cell replacement therapy for type 1 DM; an islet product has received FDA approval. Despite the risks associated with chronic immunosuppression, whole-pancreas and pancreatic islet transplantation may be considered for patients with severe metabolic instability or already requiring immunosuppression in support of a kidney or other organ transplant. Patients with chronic pancreatitis and preserved islet function who require pancreatectomy for pain relief may benefit from autologous islet transplantation as this may prevent or ameliorate postsurgical DM.

EMERGING THERAPIES

Recent clinical trials using transplantation of insulin-producing cells derived from human pluripotent stem cells have shown promise. Cost, durability, long-term safety, and patient selection remain to be determined. Many individuals with long-standing type 1 DM still produce very small amounts of insulin or have insulin-positive cells within the pancreas. This suggests that beta cells may slowly regenerate but are quickly destroyed by the autoimmune process. Efforts to suppress the autoimmune process, for example, with a monoclonal antibody that targets T lymphocytes, may preserve beta cells when given at the time of new-onset hyperglycemia in type 1 DM. This agent, teplizumab, a humanized monoclonal antibody to CD3 on T cells, has been approved by the FDA to delay the onset of clinical type 1 DM (stage 3) in patients 8 years of age or older with preclinical (stage 2) disease. Agents that target thioredoxin-interacting protein (TXNIP), especially Ca^{2+} channel blockers, have shown promise in recent-onset type 1 DM and in rodent models of diabetes.

ADVERSE EFFECTS OF THERAPY FOR DM

The benefits of efforts directed toward glycemic control must be balanced against the risks of treatment (Table 416-6). Side effects of intensive treatment include an increased frequency of serious hypoglycemia, weight gain, and greater demands on the individual with diabetes. The most serious complication of therapy for DM is hypoglycemia, and its prevention and treatment with oral glucose or glucagon administered intra-nasally or by injection are discussed in **Chap. 418**. Severe, recurrent, or unexplained hypoglycemia warrants reassessment of the treatment regimen and glycemic goal for the individual patient and possibly deintensification of insulin therapy (see categories of individuals for this would be appropriate in Table 416-4). Weight gain occurs with most (insulin, insulin secretagogues, thiazolidinediones) but not all (metformin, α-glucosidase inhibitors, GLP-1RAs, SGLT-1 inhibitors, DPP-4 inhibitors) therapies. The weight gain is partially due to the anabolic effects of insulin and the reduction in glucosuria.

ACUTE DISORDERS RELATED TO SEVERE HYPERGLYCEMIA

Individuals with type 1 or type 2 DM and severe hyperglycemia should be assessed for clinical stability, including mentation and hydration. The physician should determine if the individual with diabetes is stable or if DKA or a hyperglycemic hyperosmolar state (HHS) is present. In DKA, the hyperglycemia is accompanied by increased ketone concentration in blood and metabolic acidosis. In HHS, the hyperglycemia is usually greater, leading to hyperosmolality and marked dehydration but without ketosis or acidosis. Ketones bodies, an indicator of DKA, should be measured in individuals with type 1 DM when the plasma glucose is persistently >13.9 mmol/L (250 mg/dL). The possibility of DKA should always be considered in patients with type 1 DM during a concurrent illness or with symptoms such as nausea, vomiting, or abdominal pain. Measurement of β-hydroxybutyrate in the blood is preferred over urine testing with nitroprusside-based assays that measure only acetoacetate and acetone. Worldwide, the number of reported cases of DKA and HHS is increasing for unclear reasons. Both DKA and HHS are associated with potentially serious complications, including greater mortality.

Most cases of DKA are in individuals with type 1 DM, while HHS occurs mostly in individuals with type 2 DM. DKA, formerly considered a hallmark of type 1 DM, can also occur at diabetes diagnosis in obese young adults, often of Hispanic or African descent, whose laboratory values are similar to those seen in DKA associated with type 1 DM. However, after treatment of the DKA, these individuals recover their insulin secretory capacity, can gradually discontinue insulin treatment after a few weeks or months, and remain normoglycemic with only diet or oral medication. The cause of this atypical form of diabetes is unknown; it is often termed ketosis-prone diabetes. DKA can also occur in the setting of treatment of type 2 DM with an SGLT-2 inhibitor. Often the blood glucose is normal or just mildly elevated because of the glucosuria. **Table 416-7** compares the features of DKA, HHS, and euglycemic DKA associated with SGLT-2 inhibitors. DKA and HHS exist along a continuum of hyperglycemia, with up to one-third of patients having features of both.

DIABETIC KETOACIDOSIS

Clinical Features The symptoms and physical signs of DKA are listed in **Table 416-8** and usually develop over 24 h. DKA may be the initial symptom complex that leads to a diagnosis of type 1 DM, but more frequently, it occurs in individuals with established diabetes. Nausea and vomiting are often prominent, and their presence in an individual with diabetes warrants laboratory evaluation for DKA. Abdominal pain may be severe and can resemble acute pancreatitis or ruptured viscus. Hyperglycemia leads to glucosuria, volume depletion, and tachycardia. Hypotension can occur because of volume depletion in combination with peripheral vasodilatation. Kussmaul respirations and a fruity odor on the patient's breath (secondary to metabolic acidosis and increased acetone) are classic signs of the disorder. Lethargy and central nervous system depression may evolve into coma with severe DKA but should also prompt evaluation for other reasons for altered mental status (e.g., infection, hypoxemia). Cerebral edema, an extremely serious complication of DKA, is seen most frequently in children. Signs of infection, which may precipitate DKA, should be sought on physical examination, even in the absence of fever. Failure to augment insulin therapy during physiologic stress often compounds

TABLE 416-7 Laboratory Values in Diabetic Ketoacidosis (DKA), Hyperglycemic Hyperosmolar State (HHS), and Euglycemic DKA [Representative Ranges at Presentation; mmol/L (mg/dL)]

	DKA	HHS	EUGLYCEMIC DKA[c]
Glucose,[a] mmol/L (mg/dL)	11.1–33.3 (250–600)	33.3–66.6 (600–1200)	5.5-13.9 (100–250)[c]
Sodium, meq/L	125–135	135–145	Normal
Potassium[a,b]	Normal to ↑	Normal	Normal to ↑
Magnesium[a]	Normal	Normal	Normal
Chloride[a]	Normal	Normal	Normal
Phosphate[a,b]	Normal	Normal	Normal
Creatinine	Slightly to moderately ↑	Moderately ↑	Slightly ↑
Osmolality (mOsm/mL)	>300	>300	Normal
Serum/urine ketones[a]	>++	+/–	>++
Serum β-hydroxybutyrate, mmol/L	>3.0	<1.0	>3.0
Serum bicarbonate,[a] meq/L	<18	>18	<18
Arterial pH	6.8–7.3	>7.3	<7.3
Arterial Pco_2,[a] mmHg	20–30	Normal	20–30
Anion gap[a] (Na – [Cl + HCO_3])	↑	Normal to slightly ↑	↑

[a]Large changes occur during treatment of DKA; serum level may be normal initially but then require replacement. [b]Although plasma levels may be normal or high at presentation, total-body stores are usually depleted. [c]Sometimes occurs with sodium-glucose cotransporter 2 (SGLT-2) inhibitor treatment; disproportionate glucosuria is consistent with SGLT-2 inhibitor effect.

the problem. Tissue ischemia (heart, brain) can also be a precipitating factor. Omission of insulin because of an infusion pump delivery site occlusion or device malfunction, eating disorder, mental health disorders, or an unstable psychosocial environment may each be a factor precipitating DKA. Complete omission or inadequate administration of insulin by the patient or health care team (in a hospitalized patient with type 1 DM) may precipitate DKA. The rising cost of insulin has been a major challenge and has contributed to individuals with diabetes omitting or rationing their insulin, making them more vulnerable to DKA.

Pathophysiology DKA results from relative or absolute insulin deficiency combined with counterregulatory hormone excess (glucagon, catecholamines, cortisol, and growth hormone). The decreased ratio of insulin to glucagon promotes gluconeogenesis, glycogenolysis, and ketone body formation in the liver, as well as increases in substrate delivery from fat and muscle (free fatty acids, amino acids) to the liver. Ketosis results from a marked increase in free fatty acid release from adipocytes, with a resulting shift toward ketone body synthesis in the liver. Reduced insulin levels, in combination with elevations in catecholamines and growth hormone, also increase lipolysis and the release of free fatty acids. Markers of inflammation (cytokines, C-reactive protein) are elevated in both DKA and HHS.

Laboratory Abnormalities and Diagnosis The timely diagnosis of DKA is crucial and allows for prompt initiation of therapy. DKA is characterized by hyperglycemia (serum glucose >13.9 mmol/L [250 mg/dL], ketosis, and metabolic acidosis [serum bicarbonate <15–18 mmol/L with increased anion gap]) along with a number of secondary metabolic derangements (Table 416-7). Occasionally, the serum glucose is only minimally elevated and may even be normal (euglycemic DKA). This has been noted especially in individuals treated with SGLT-2 inhibitors. Arterial pH usually ranges between 6.8 and 7.3, depending on the severity of the acidosis. Despite a total-body potassium deficit, the serum potassium at presentation may be mildly elevated, secondary to the acidosis and volume depletion. Total-body stores of sodium, chloride, phosphorus, and magnesium are also reduced in DKA but are not accurately reflected by their levels in the serum because of hypovolemia and hyperglycemia. Elevated blood urea nitrogen (BUN) and serum creatinine levels reflect intravascular volume depletion. Leukocytosis, hypertriglyceridemia, and hyperlipoproteinemia are commonly found as well. Hyperamylasemia may suggest a diagnosis of pancreatitis, especially when accompanied by abdominal pain. However, in DKA the amylase is usually of salivary origin and thus is not diagnostic of pancreatitis. Serum lipase should be obtained if pancreatitis is suspected.

The measured serum sodium is reduced as a consequence of the hyperglycemia. An estimated correction is provided by the equation: (1.6-mmol/L [1.6-meq] reduction in serum sodium for each 5.6-mmol/L [100-mg/dL] rise in the serum glucose). A normal serum sodium in the setting of DKA indicates a more profound water deficit.

In DKA, the ketone body, β-hydroxybutyrate, is synthesized at a threefold greater rate than acetoacetate; however, acetoacetate is preferentially detected by a commonly used ketosis detection reagent (nitroprusside). The nitroprusside tablet, or stick, is often used to detect urine ketones; certain medications such as captopril, penicillamine, or valproic acid may cause false-positive reactions. Serum or plasma assays for β-hydroxybutyrate are preferred because they more accurately reflect the true ketone body level.

The degree of acidosis and hyperglycemia do not necessarily correlate closely because a variety of factors determine the level of hyperglycemia (oral intake, urinary glucose loss). Ketonemia is a consistent finding in DKA and distinguishes it from simple hyperglycemia. The differential diagnosis of DKA includes starvation ketosis, alcoholic ketoacidosis (bicarbonate usually >15 meq/L), and other forms of increased anion-gap acidosis (Chap. 55).

TABLE 416-8 Manifestations of Diabetic Ketoacidosis

Symptoms	Physical Findings
Nausea/vomiting	Tachycardia
Thirst/polyuria	Dehydration/hypotension
Abdominal pain	Tachypnea/Kussmaul respirations/ respiratory distress
Shortness of breath	Abdominal tenderness (may resemble acute pancreatitis or surgical abdomen)
Precipitating events	Lethargy/obtundation/cerebral edema/possibly coma
Inadequate insulin administration	
Infection (pneumonia/UTI/ gastroenteritis/sepsis)	
Infarction (cerebral, coronary, mesenteric, peripheral)	
Pancreatitis	
Drugs (cocaine)	
Pregnancy	

Abbreviation: UTI, urinary tract infection.

TREATMENT

Diabetic Ketoacidosis

Based on laboratory values and clinical exam, DKA can be classified as mild (pH 7.25–7.3, serum bicarbonate 15–18 meq/L, mental status normal), moderate (pH 7.0–7.25, serum bicarbonate 10–15 meq/L, mildly reduced mental status), or severe (pH <7.0,

serum bicarbonate <10–15 meq/L, reduced mental status, coma). The management of DKA is outlined in Table 416-9. After initiating IV fluid replacement and insulin therapy, the event that precipitated the episode of DKA should be sought and aggressively treated. If the patient is vomiting or has altered mental status, a nasogastric tube should be inserted to prevent aspiration of gastric contents. Central to successful treatment of DKA is careful monitoring and frequent reassessment to ensure that the patient and the metabolic derangements are improving. A comprehensive flow sheet should record chronologic changes in vital signs, fluid intake and output, and laboratory values as a function of insulin administered.

After the initial bolus of normal saline or lactated Ringer's, replacement of the sodium and free water deficit is carried out over the next 24 h (fluid deficit is often 3–5 L). When hemodynamic stability and adequate urine output are achieved, IV fluids should be switched to 0.45% saline or lactated Ringer's, depending on the calculated volume deficit. Ringer's lactate is associated with more rapid DKA resolution and a reduced trend toward hyperchloremia later in the course of DKA resolution.

A bolus of IV (0.1 units/kg) short-acting regular insulin is usually administered immediately (Table 416-9), and subsequent treatment should provide continuous and adequate levels of circulating insulin. IV administration is usually preferred (0.1 units/kg of regular insulin per h) but uncomplicated DKA can also be treated with SC short-acting insulin analogues. As the acidosis and insulin resistance associated with DKA resolve, the insulin infusion rate can be decreased (to 0.02–0.1 units/kg per h). Long-acting insulin, in combination with SC short-acting insulin, should be administered as soon as the patient resumes eating, because this facilitates transition to an outpatient insulin regimen and reduces length of hospital stay. Hyperglycemia usually improves at a rate of 4.2–5.6 mmol/L (50–100 mg/dL) per h as a result of insulin-mediated glucose disposal, reduced hepatic glucose release, and rehydration. Rehydration reduces catecholamines, increases urinary glucose loss, and expands the intravascular volume. The decline in the plasma glucose within the first 1–2 h may be more rapid and is mostly related to volume expansion. Ketoacidosis begins to resolve as insulin reduces lipolysis, increases peripheral ketone body use, suppresses hepatic ketone body formation, and promotes bicarbonate regeneration. However, the acidosis and ketosis resolve more slowly than hyperglycemia. Depending on the rise of serum chloride, the anion gap (but not bicarbonate) will normalize more quickly. A hyperchloremic acidosis (serum bicarbonate of 15–18 mmol/L [15–18 meq/L]) often follows successful treatment and gradually resolves as the kidneys regenerate bicarbonate and excrete chloride.

Potassium stores are depleted in DKA (estimated deficit 3–5 mmol/kg [3–5 meq/kg]). During treatment with insulin and fluids, various factors contribute to the development of hypokalemia. These include insulin-mediated potassium transport into cells, resolution of the acidosis (which also promotes potassium entry into cells), and urinary loss of potassium salts of organic acids. Thus, potassium repletion should commence as soon as adequate urine output and a normal serum potassium are documented (Table 416-9).

Bicarbonate replacement has not been shown to improve outcomes. However, in the presence of severe acidosis (arterial pH <7.0), sodium bicarbonate (50 mmol [meq/L] in 200 mL of sterile water with 10 meq/L KCl per h) may be administered for the first 2 h until the pH is >7.0. Hypophosphatemia and hypomagnesemia may develop during DKA therapy, and if severe, may also require supplementation.

With appropriate therapy, the mortality rate of DKA is low (<1%) and is related more to the underlying or precipitating event, such as infection ((pneumonia, SARS-Co-V2, etc.) COVID-19), pregnancy, end-stage renal disease, or myocardial infarction. Venous thrombosis, upper GI bleeding, and acute respiratory distress syndrome occasionally complicate DKA. The major nonmetabolic complication of DKA therapy is cerebral edema, which most often develops in children as DKA is resolving. The etiology of and optimal therapy for cerebral edema are not well established.

Following treatment, the physician and patient should review the sequence of events that led to DKA to prevent future recurrences. Even a single episode of DKA is associated with a greatly increased 1-year mortality rate. Foremost is patient education about the symptoms of DKA, its precipitating factors, and the management of diabetes during a concurrent illness. In some individuals, DKA is recurrent and may indicate underlying mental health issues. The structural barriers to accessing care, insulin cost, and the social determinants of health often play a role.

TABLE 416-9 Management of Diabetic Ketoacidosis (DKA)

1. Confirm diagnosis (↑ serum glucose, ↑ serum β-hydroxybutyrate, metabolic acidosis).
2. Admit to hospital; intensive care setting may be necessary for severe DKA (see text). Mild to moderate DKA can be treated in a step-down unit with close nursing and laboratory monitoring.
3. Assess:
   Serum electrolytes (K^+, Na^+, Mg^{2+}, Cl^-, bicarbonate, phosphate)
   Acid-base status—pH, HCO_3^-, PCO_2, β-hydroxybutyrate
   Renal function (creatinine, urine output)
4. Replace fluids: 2–3 L of 0.9% saline or lactated Ringer's over first 1–3 h (10–20 mL/kg per hour); subsequently, 0.45% saline at 250–500 mL/h; change to 5–10% glucose and 0.45% saline or lactated Ringer's at 150–250 mL/h when blood glucose reaches 250 mg/dL (13.9 mmol/L). For treatment of euglycemic DKA, start 5% or 10% dextrose infusion and insulin treatment when 0.9% saline is started; adjust dextrose infusion to prevent hypoglycemia.
5. Administer short-acting regular insulin: IV (0.1 units/kg), then 0.1 units/kg per hour by continuous IV infusion; increase two- to threefold if no response by 2–4 h. In mild to moderate DKA, subcutaneous rapid-acting insulin may be used with close monitoring (0.1 unit/kg rapid-acting insulin analogue subcutaneously and then 0.1 unit/kg every 1 h or 0.2 unit/kg every 2 h). Continue insulin treatment and 5% or 10% dextrose infusion to prevent hypoglycemia. If the initial serum potassium is <3.3 mmol/L (3.3 meq/L), do not administer insulin until the potassium is corrected.
6. Assess patient: What precipitated the episode (noncompliance, infection, trauma, pregnancy, infarction, cocaine)? Initiate appropriate workup for precipitating event (cultures, CXR, ECG, etc.).
7. Measure blood glucose every 1–2 h; measure electrolytes (especially K^+, bicarbonate, phosphate) and anion gap every 4 h for first 24 h.
8. Monitor blood pressure, pulse, respirations, mental status, fluid intake and output every 1–4 h.
9. Replace K^+ if ECG, urine flow, and creatinine are normal. If K^+ <3.5 mmol/L, administer 10–20 mmol/L per hour until K^+ >3.5 mmol/L. If K^+ 3.5–5 mmol/L, administer 10–20 mmol/L in each liter of IV fluid to keep serum K^+ between 4 and 5 mmol/L. If K^+ >5.0 mmol/L, start insulin but hold K^+. Recheck K^+ every 2 h to determine when to start K^+ replacement.
10. Continue above until patient is stable, glucose goal is 8.3–11.1 mmol/L (150–200 mg/dL), normal plasma ketone and pH, and bicarbonate ≥18 mmol/L. Insulin infusion may be decreased to 0.02–0.1 unit/kg per hour. Resolution of euglycemic DKA should be based on bicarbonate, not glucose, correction; see text.
11. Administer long-acting insulin as soon as patient is eating. Allow for a 2- to 4-h overlap in insulin infusion and SC long-acting insulin injection.

Abbreviations: CXR, chest x-ray; ECG, electrocardiogram.

HYPERGLYCEMIC HYPEROSMOLAR STATE

Clinical Features The most common presentation of HHS is an elderly individual with type 2 DM, with a several-week history of polyuria, weight loss, and diminished oral intake that culminates in mental confusion, lethargy, or coma. The physical examination reflects profound dehydration and hyperosmolality and reveals hypotension, tachycardia, and altered mental status. Notably absent are symptoms of nausea, vomiting, and abdominal pain and the Kussmaul respirations characteristic of DKA. HHS is often precipitated by a serious, concurrent illness such as myocardial infarction or stroke. Sepsis, pneumonia,

and other serious infections are frequent precipitants and should be sought. In addition, a debilitating condition (prior stroke or dementia) or social situation that compromises water intake usually contributes to the development of the disorder.

Pathophysiology Relative insulin deficiency and inadequate fluid intake are the underlying causes of HHS. Insulin deficiency increases hepatic glucose production (through glycogenolysis and gluconeogenesis) and impairs glucose utilization in skeletal muscle (see above discussion of DKA). Hyperglycemia induces an osmotic diuresis that leads to intravascular volume depletion, which is exacerbated by inadequate fluid replacement. The absence of ketosis in HHS is not understood. Presumably, the insulin deficiency is only relative and less severe than in DKA. Lower levels of counterregulatory hormones and free fatty acids have been found in HHS than in DKA in some studies. It is also possible that the liver is less capable of ketone body synthesis or that the insulin/glucagon ratio does not favor ketogenesis.

Laboratory Abnormalities and Diagnosis The laboratory features in HHS are summarized in Table 416-7. Most notable are the marked hyperglycemia (plasma glucose may be >55.5 mmol/L [1000 mg/dL]), hyperosmolality (>300 mOsm/L), and prerenal azotemia. The measured serum sodium may be normal or slightly low despite the marked hyperglycemia. The corrected serum sodium is usually increased (add 1.6 meq to measured sodium for each 5.6-mmol/L [100-mg/dL] rise in the serum glucose). In contrast to DKA, acidosis and ketonemia are absent or mild. A small anion-gap metabolic acidosis may be present secondary to increased lactic acid. Moderate ketonuria, if present, is secondary to starvation.

TREATMENT

Hyperglycemic Hyperosmolar State

Volume depletion and hyperglycemia are prominent features of both HHS and DKA. Consequently, the therapy of these disorders shares several elements (Table 416-9). In both disorders, careful monitoring of the patient's fluid status, laboratory values, and insulin infusion rate is crucial. Underlying or precipitating problems should be aggressively sought and treated. In HHS, fluid losses and dehydration are usually more pronounced than in DKA due to the longer duration of the illness. The patient with HHS is usually older, more likely to have mental status changes, and more likely to have a life-threatening precipitating event with accompanying comorbidities. Even with proper treatment, HHS has a substantially higher mortality rate than DKA (up to 15% in some clinical series).

Fluid replacement should initially stabilize the hemodynamic status of the patient (1–3 L of 0.9% normal saline over the first 2–3 h). Because the fluid deficit in HHS is accumulated over a period of days to weeks, the rapidity of reversal of the hyperosmolar state must balance the need for free water repletion with the risk that too rapid a reversal may worsen neurologic function. If the serum sodium is >150 mmol/L (150 meq/L), 0.45% saline should be used. After hemodynamic stability is achieved, the IV fluid administration is directed at reversing the free water deficit using hypotonic fluids (0.45% saline initially, then 5% dextrose in water [D_5W]). The calculated free water deficit (which can be as great as 9–10 L) should be reversed over the next 1–2 days (infusion rates of 200–300 mL/h of hypotonic solution). Potassium repletion is usually necessary and should be dictated by repeated measurements of the serum potassium. In patients taking diuretics, the potassium deficit can be quite large and may be accompanied by magnesium deficiency. Hypophosphatemia may occur during therapy and can be improved by using KPO_4 and beginning nutrition.

As in DKA, rehydration and volume expansion lower the plasma glucose initially, but insulin is also required. A reasonable regimen for HHS begins with an IV insulin bolus of 0.1 unit/kg followed by IV insulin at a constant infusion rate of 0.1 unit/kg per h. If the serum glucose does not fall, increase the insulin infusion rate by twofold. As in DKA, glucose should be added to IV fluid when the plasma glucose falls to 11.1–13.9 mmol/L (200–250 mg/dL), and the insulin infusion rate should be decreased to 0.02–0.1 unit/kg per h. The insulin infusion should be continued until the patient has resumed eating and can be transferred to an SC insulin regimen. The patient should be discharged from the hospital on insulin. Some patients can later switch to oral glucose-lowering agents.

MANAGEMENT OF DIABETES IN A HOSPITAL OR FACILITY

Virtually all medical and surgical subspecialties are involved in the care of hospitalized patients with diabetes or individuals with diabetes in the perioperative setting. Hyperglycemia, whether in a patient with known diabetes or in someone without known diabetes, appears to be a predictor of poor outcome in hospitalized patients. General anesthesia, surgery, infection, or concurrent illness raises the levels of counterregulatory hormones (cortisol, growth hormone, catecholamines, and glucagon) and cytokines that may lead to transient insulin resistance and hyperglycemia. These factors increase insulin requirements by increasing glucose production and impairing glucose utilization and thus may worsen glycemic control. The concurrent illness or surgical procedure may lead to variable insulin absorption and also prevent the patient with DM from eating normally and, thus, may promote hypoglycemia. Glycemic control should be assessed on admission using the HbA_{1c}. Electrolytes, renal function, and intravascular volume status should be assessed as well. The high prevalence of ASCVD in individuals with DM (especially in type 2 DM) may necessitate preoperative cardiovascular evaluation (Chap. 417). CGM in the hospital or intensive care unit (ICU) setting is not FDA approved. Individuals using CGM and/or AID prior to admission should continue to use these devices if the provider, the nursing staff, and the patient agree that this can be safely done within the context of the patient's current reason for hospitalization.

The goals of diabetes management during hospitalization or in the perioperative periods are near-normoglycemia, avoidance of hypoglycemia, and transition back to the outpatient diabetes treatment regimen. Upon hospital admission, frequent glycemic monitoring should begin, as should planning for diabetes management after discharge. Glycemic control appears to improve clinical outcomes in a variety of settings, but optimal glycemic goals for the hospitalized patient are incompletely defined. In a number of cross-sectional studies of patients with diabetes, a greater degree of hyperglycemia was associated with worse cardiac, neurologic, and infectious outcomes. In some studies, patients who do not have preexisting diabetes but who develop modest blood glucose elevations during their hospitalization appear to benefit from achieving near-normoglycemia using insulin treatment. However, a large randomized clinical trial (Normoglycemia in Intensive Care Evaluation Survival Using Glucose Algorithm Regulation [NICE-SUGAR]) of individuals in the ICU (most of whom were receiving mechanical ventilation) found an increased mortality rate and a greater number of episodes of severe hypoglycemia with very strict glycemic control (target blood glucose of 4.5–6 mmol/L or 81–108 mg/dL) compared to individuals with a more moderate glycemic goal (target blood glucose of <10 mmol/L or 180 mg/dL). Currently, most data suggest that very strict blood glucose control in acutely ill patients likely worsens outcomes and increases the frequency of hypoglycemia. The ADA suggests the following glycemic goals for hospitalized patients: (1) in critically or non-critically ill patients, glucose of 7.8–10.0 mmol/L or 140–180 mg/dL; (2) in selected patients, glucose of 6.1–7.8 mmol/L or 110–140 mg/dL with avoidance of hypoglycemia; and (3) the target range in the perioperative period should be 80–180 mg/dL (4.4–10.0 mmol/L).

Critical aspects for optimal diabetes care in the hospital include the following: (1) A hospital-wide system approach to treatment of hyperglycemia and prevention of hypoglycemia is needed. Inpatient diabetes management teams consisting of nurse practitioners and physicians are increasingly common. (2) Diabetes treatment plans should focus on the transition from the ICU and the transition from the inpatient to the outpatient setting. (3) Adjustment of the discharge treatment

regimen of patients whose diabetes was poorly controlled on admission (as reflected by the HbA_{1c}) is important.

The physician caring for an individual with diabetes in the perioperative period, during times of infection or serious physical illness, or simply when the patient is fasting for a diagnostic procedure must monitor the plasma glucose vigilantly, adjust the diabetes treatment regimen, and provide glucose infusion as needed. Hypoglycemia is frequent in hospitalized patients, and many of these episodes are avoidable. Hospital systems should have a diabetes management protocol to avoid inpatient hypoglycemia. Measures to reduce or prevent hypoglycemia include frequent glucose monitoring, but it is also important to prevent hypoglycemia by anticipating drops in insulin requirement by factors such as decreasing renal function, decreasing glucocorticoid doses, or interruption of nutrition (parenteral or enteral or PO).

Depending on the severity of the patient's illness and the hospital setting, the physician can use either an insulin infusion or SC insulin. Insulin infusions are preferred in the ICU or in a clinically unstable setting because the half-life of the infused insulin is quite short (minutes). The absorption of SC insulin may be variable in such situations. Insulin infusions can also effectively control plasma glucose in the perioperative period and when the patient is unable to take anything by mouth, although for relatively short (<4 h) procedures, most patients can remain on SC insulin. Regular insulin is used rather than insulin analogues for IV insulin infusion because it is less expensive and equally effective. The physician must consider carefully the clinical setting in which an insulin infusion will be used, including whether adequate ancillary personnel are available to monitor the blood glucose frequently and whether they can adjust the insulin infusion rate to maintain the blood glucose within the optimal range. Insulin-infusion algorithms should integrate the insulin sensitivity of the patient, frequent blood glucose monitoring, and the trend of changes in the blood glucose to determine the insulin-infusion rate. Insulin-infusion algorithms jointly developed and implemented by nursing and physician staff are advised. Because of the short half-life of IV regular insulin, it is necessary to administer long-acting insulin prior to discontinuation of the insulin infusion (2–4 h before the infusion is stopped) to avoid a period of insulin deficiency.

In patients who are not critically ill or not in the ICU, basal or "scheduled" insulin is provided by SC, long-acting insulin supplemented by prandial and/or "corrective" insulin using a rapid-acting insulin. "Sliding scale," with short-acting or rapid-acting insulin alone, where no insulin is given unless the blood glucose is elevated, is inadequate for inpatient glucose management. The rapid-acting, preprandial insulin dose should include coverage for food consumption (based on anticipated carbohydrate intake) plus corrective insulin based on the patient's insulin sensitivity and the blood glucose. For example, if the patient is thin (and likely insulin-sensitive), an insulin correction factor might be 1 unit for each 2.7 mmol/L (50 mg/dL) over the glucose target. If the patient is obese and likely insulin-resistant, then the insulin correction factor might be 2 units for each 2.7 mmol/L (50 mg/dL) over the glucose target. It is critical to individualize the regimen and adjust the basal and prandial insulin doses frequently based on the corrective insulin required. A consistent carbohydrate-controlled diabetes meal plan for hospitalized patients provides a predictable amount of carbohydrate for a particular meal each day (but not necessarily the same amount for breakfast, lunch, and supper) and avoids concentrated sweets. Individuals with type 1 DM who are undergoing general anesthesia and surgery or who are seriously ill should receive continuous insulin, through an IV insulin infusion, their insulin infusion device, or by SC administration of a reduced dose of long-acting insulin. Rapid-acting insulin alone is insufficient. Prolongation of a surgical procedure or delay in the recovery room is common and may result in periods of insulin deficiency leading to DKA. Insulin infusion is the preferred method for managing patients with type 1 DM over a prolonged (several hours) perioperative period or when serious concurrent illness is present (0.5–1.0 units/h of regular insulin). If the diagnostic or surgical procedure is brief (<4 h), a reduced dose of SC insulin may suffice (20–50% basal reduction, with rapid-acting correctional dose insulin as needed). This approach prevents interruption of insulin infusion device therapy or, for MDI, facilitates the transition back to basal/bolus insulin after the procedure. The blood glucose should be monitored frequently during the illness or in the perioperative period.

Individuals with type 2 DM can be managed with either an insulin infusion or SC long-acting insulin (20–50% reduction depending on clinical setting) plus preprandial, rapid-acting insulin. Oral glucose-lowering agents should be discontinued upon admission (or up to a week prior to planned admission for SGLT-2 inhibitors) and are not useful in regulating the plasma glucose in clinical situations where the insulin requirements and glucose intake are changing rapidly. Moreover, these oral agents may be dangerous if the patient is fasting (e.g., hypoglycemia with sulfonylureas, euglycemic DKA with SGLT-2 inhibitors) or at risk for declining kidney function due to, for example, radiographic contrast media or unstable CHF (lactic acidosis with metformin). Once clinically stable, oral glucose-lowering agents may be resumed in anticipation of discharge. Each patient should receive an individualized, structured discharge plan for diabetes management.

The principles of the care of individuals with diabetes who are in a rehabilitation facility or a long-term care facility are similar to those in a hospitalized patient with the glycemic goals individualized based on the patient's overall clinical status (outlined in Table 416-4). Often the avoidance of hypoglycemia is the major goal with less intense glycemic targets.

SPECIAL CONSIDERATIONS IN DM

TOTAL PARENTERAL NUTRITION (TPN)/TOTAL ENTERAL NUTRITION (TEN)

(See also Chap. 335) TPN or TEN greatly increases insulin requirements. In addition, individuals not previously known to have DM may become hyperglycemic during TPN or TEN and require insulin treatment. For TPN, IV insulin infusion is the preferred treatment for hyperglycemia, and rapid titration to the required insulin dose is done most efficiently using a separate insulin infusion. After the total insulin dose has been determined, a proportion of this insulin may be added directly to the TPN solution to cover the nutritional requirements for insulin and adjusted based on the need for modified dosing of rapid-acting insulin. In TEN, hyperglycemia may be limited by using high-protein formulations but often requires insulin treatment. Individuals receiving enteral bolus feedings should receive SC, rapid-acting insulin prior to each bolus. As a start, 1 unit of insulin is given SC for each 10–15 g of carbohydrate in the bolus. Patients with insulin deficiency (type 1 DM and pancreatogenic DM) should also receive long-acting insulin (0.1–0.2 units/kg per day) to cover basal insulin requirements should the TPN or TEN be interrupted or cycled.

GLUCOCORTICOIDS

Glucocorticoids increase insulin resistance, decrease glucose utilization, increase hepatic glucose production, and impair insulin secretion. These changes lead to a worsening of glycemic control in individuals with DM and may precipitate hyperglycemia in other individuals. If new-onset hyperglycemia remains during chronic treatment with supraphysiologic doses of glucocorticoid (>5 mg of prednisone or equivalent), the DM may be called "steroid-induced diabetes." The effects of glucocorticoids on glucose homeostasis are dose-related, usually reversible, most pronounced in the postprandial period, and dependent on the timing and type of glucocorticoid. If the FPG is near the normal range, oral diabetes agents (e.g., sulfonylureas, metformin) may be sufficient to reduce hyperglycemia. If the FPG is >11.1 mmol/L (200 mg/dL), oral agents are usually not sufficient, and insulin therapy is required. If steroids are administered in the morning, then short-acting insulin and/or NPH in the morning may be sufficient to control postprandial glucose excursions.

DIABETES MANAGEMENT IN OLDER ADULTS

Diabetes is very common in older adults, being present in ~25% of individuals over the age of 65 years. Increasingly, individuals with many years of type 1 DM are part of this patient population. As discussed above (Table 416-4), individualized therapeutic goals and modalities in older adults should consider biologic age, other

comorbidities and risk factors (e.g., hypertension, CVD), neurocognitive and physical functional status, living arrangements, social support, and other medications. For example, the HbA_{1c} goal for a highly functional 80-year-old should be different from that for an individual with diabetes in long-term care (skilled nursing facilities). In the former, the HbA_{1c} goal (<7.0–7.5%) and selected therapies may be similar to younger individuals, whereas in an individual with complex/poor health or cognitive impairment, an HbA_{1c} goal of <8.0–8.5% would be reasonable. Critical to diabetes management in all older individuals is the avoidance of hypoglycemia, which can worsen underlying cognitive impairment or CVD. In choosing medications for diabetes, the adverse effects (Table 416-6) should be considered (especially heart failure, renal insufficiency, propensity for hypoglycemia, etc.). Hypertension and dyslipidemia should be treated in elderly individuals with diabetes because there is clear benefit of blood pressure control, with the benefit for lipid-lowering medications being less clearly demonstrated.

REPRODUCTIVE ISSUES

Reproductive capacity in either men or women with DM appears to be normal. Menstrual cycles may be associated with alterations in glycemic control in women with DM. Pregnancy is associated with marked insulin resistance; the increased insulin requirements often precipitate DM and lead to the diagnosis of gestational diabetes mellitus (GDM). Glucose, which at high levels is a teratogen to the developing fetus, readily crosses the placenta, but insulin does not. Thus, hyperglycemia from the maternal circulation may stimulate insulin secretion in the fetus. The anabolic and growth effects of insulin may result in macrosomia. GDM complicates ~7% (range 1–14%) of pregnancies. The incidence of GDM is greatly increased in certain racial and ethnic groups, including Black and Hispanic, consistent with a similar increased risk of type 2 DM. Current recommendations advise screening for glucose intolerance between weeks 24 and 28 of pregnancy in women not known to have diabetes. Therapy for GDM is similar to that for individuals with pregnancy-associated diabetes and involves MNT and insulin, if hyperglycemia persists. Oral glucose-lowering agents are not approved for use during pregnancy, but studies using metformin or glyburide have shown efficacy and have not found toxicity. With current practices, the morbidity and mortality rates of the mother with GDM and the fetus are not different from those in the nondiabetic population. Individuals who develop GDM are at marked increased risk for developing type 2 DM in the future and should be screened periodically for DM (see screening recommendations in **Chap. 415**). Most individuals with GDM revert to normal glucose tolerance after delivery, but some will continue to have overt diabetes or impairment of glucose tolerance after delivery. In addition, children of women with GDM appear to be at risk for obesity and glucose intolerance and have an increased risk of diabetes beginning in the later stages of adolescence.

Pregnancy in individuals with known DM requires meticulous planning and adherence to strict preconception treatment regimens. Intensive insulin therapy and near-normalization of the HbA_{1c} (<6.5%) are essential for individuals with existing DM who are planning pregnancy. Consideration should be given to insulin infusion (e.g., AID) and CGM devices that may help to improve glycemic control prior to conception since the most crucial period of glycemic control is soon after fertilization. The risk of fetal malformations is increased 4–10 times in individuals with uncontrolled DM at the time of conception, and normal blood glucose during the preconception period and throughout the periods of organ development in the fetus should be the goal, with more frequent monitoring of HbA_{1c} every 2 months throughout gestation. Maintenance of the HbA_{1c} <6.0–6.5% reduces the incidence and severity of fetal macrosomia and neonatal hypoglycemia related to fetal hyperinsulinism driven by elevated maternal glucose.

417 Diabetes Mellitus: Complications

Alvin C. Powers, John M. Stafford, Michael R. Rickels

Diabetes-related complications affect many organ systems and are responsible for most of the morbidity and mortality associated with the disease. For many years in the United States, diabetes has been a leading cause of new blindness in adults, renal failure, and nontraumatic lower extremity amputation and is a leading contributor to coronary heart disease (CHD). Diabetes-associated microvascular complications usually do not appear until the second decade of hyperglycemia. In contrast, diabetes-associated atherosclerotic cardiovascular disease (ASCVD) risk, related in part to insulin resistance and its resultant dyslipidemia, may develop before hyperglycemia is established. Because type 2 diabetes mellitus (DM) often has a long asymptomatic period of hyperglycemia before diagnosis, many

[a]Thickened skin and reduced joint mobility.

individuals with type 2 DM have both glucose-related and insulin resistance–related complications at the time of diagnosis. Fortunately, many of the diabetes-related complications can be prevented or mitigated with aggressive glycemic, lipid, and blood pressure control, as well as efforts at early detection. Diagnosis of type 2 DM at younger age increases diabetes-related complications. One estimate indicated three to four years of reduced life expectancy for every decade of earlier diabetes diagnosis. This is emphasizes the critical role of diabetes prevention or delay.

Diabetes-related complications can be divided into vascular and nonvascular complications and are similar for type 1 and type 2 DM (Table 417-1). The vascular complications of DM are further subdivided into microvascular (retinopathy, neuropathy, and nephropathy) and macrovascular complications (ASCVD, peripheral arterial disease [PAD], cerebrovascular disease, and heart failure). Microvascular complications are diabetes specific, whereas macrovascular complications have additional pathophysiologic features that are shared with the general population. Nonvascular complications include infections, skin changes, cheiroarthropathy, hearing loss, and increased risk of fractures, dementia, and impaired cognitive function.

GLYCEMIC CONTROL AND COMPLICATIONS

The microvascular complications of both type 1 and type 2 DM result from chronic hyperglycemia (Fig. 417-1). Evidence implicating a causative role for chronic hyperglycemia in the development of macrovascular complications is less conclusive with other factors such as dyslipidemia and hypertension playing more important roles. ASCVD events and mortality rate are two to four times greater in patients with type 2 DM, correlate with fasting and postprandial plasma glucose levels as well as the hemoglobin A_{1c} (HbA_{1c}), and can be reduced by intensive diabetes management as demonstrated in patients with type 1 DM.

The Diabetes Control and Complications Trial (DCCT) provided definitive proof that reduction in chronic hyperglycemia can prevent many complications of type 1 DM (Fig. 417-1). This large multicenter clinical trial randomized >1400 individuals with type 1 DM to either intensive or conventional diabetes management and prospectively

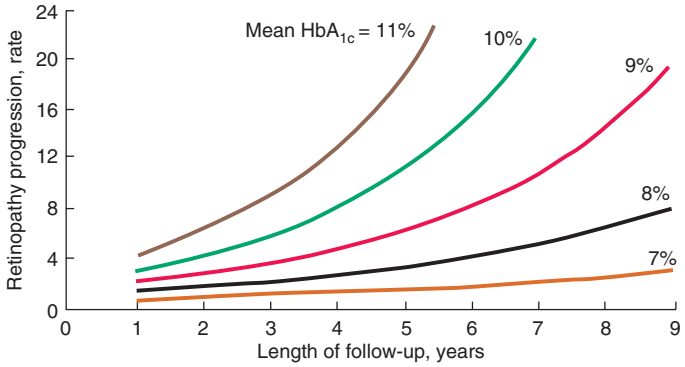

FIGURE 417-1 Relationship of glycemic control and diabetes duration to diabetic retinopathy. The progression of retinopathy in individuals in the Diabetes Control and Complications Trial is graphed as a function of the length of follow-up with different curves for different hemoglobin A_{1c} (HbA_{1c}) values. *(Reproduced with permission from The relationship of glycemic exposure (HbA1c) to the risk of development and progression of retinopathy in the diabetes control and complications trial. Diabetes 44:968, 1995.)*

evaluated the development of diabetes-related complications during a mean follow-up of 6.5 years. Individuals in the intensive diabetes management group received insulin by multiple daily injections or pump delivery along with extensive educational, psychological, and medical support, and achieved a substantially lower HbA_{1c} (7.3%) than individuals in the conventional diabetes management group (9.1%). After the DCCT results were reported in 1993, all study participants were offered intensive therapy and continue to be followed in the Epidemiology of Diabetes Intervention and Complications (EDIC) trial, which has completed >40 years of follow-up (DCCT + EDIC). When the DCCT phase ended at 6.5 years of follow-up, the initial separation in glycemic control disappeared with both arms maintaining a mean HbA_{1c} of 8.0%, allowing assessment of the legacy effect of 6.5 years of near-normoglycemia on the development of long-term complications.

The DCCT phase demonstrated that improvement of glycemic control reduced nonproliferative and proliferative retinopathy (47% reduction), albuminuria (39% reduction), clinical nephropathy (54% reduction), and neuropathy (60% reduction). Improved glycemic control also slowed the progression of early diabetic complications. During the DCCT phase, weight gain (4.6 kg) and severe hypoglycemia (requiring assistance of another person to treat) were more common in the intensive therapy group. The benefits of an improvement in glycemic control occurred over the entire range of elevated HbA_{1c} values (Fig. 417-1). The results of the DCCT predicted that individuals in the intensive diabetes management group would gain 7.7 additional years of vision, 5.8 additional years free from end-stage renal disease, and 5.6 years free from lower extremity amputations. If all complications of DM were combined, individuals in the intensive diabetes management group would experience >15.3 more years of life without significant microvascular complications of DM, compared to individuals who received standard therapy. This translates into an additional 5.1 years of life expectancy for individuals in the intensive diabetes management group. The 30-year follow-up data in the intensively treated group show a continued reduction in retinopathy, nephropathy, and cardiovascular disease. For example, individuals in the intensive therapy group had a 57% reduction in cardiovascular events (nonfatal myocardial infarction [MI], stroke, or death from a cardiovascular event) and a 33% reduction in the mortality rate, even though their subsequent glycemic control was the same as those in the conventional diabetes management group after the DCCT phase ended (year 6.5). During the EDIC phase, fewer in the intensely treated cohort became blind, lost a limb to amputation, or required dialysis. Other complications of diabetes, including autonomic neuropathy, bladder and sexual dysfunction, cardiac autonomic neuropathy, cheiroarthropathy and hearing loss, were reduced in the intensive therapy group. These results are even more impressive when one considers that initial DCCT results were reported in 1993 and diabetes therapy during the trial was quite

different in terms of insulin formulations and delivery systems. Fingerstick blood glucose meters were used for glucose monitoring as this was prior to the advent of continuous glucose monitoring.

The United Kingdom Prospective Diabetes Study (UKPDS) studied the course of >5000 individuals with type 2 DM for >10 years. This study used multiple treatment regimens and monitored the effect of intensive glycemic control and risk factor treatment on the development of diabetes-related complications. Newly diagnosed individuals with type 2 DM were randomized to (1) intensive management using various combinations of insulin, a sulfonylurea, or metformin or (2) conventional therapy using dietary modification and pharmacotherapy with the goal of symptom prevention. In addition, individuals were randomly assigned to different antihypertensive regimens. Individuals in the intensive treatment arm achieved an HbA_{1c} of 7% compared to 7.9% in the standard treatment group. The UKPDS demonstrated that each percentage point reduction in HbA_{1c} was associated with a 35% reduction in microvascular complications. As in the DCCT, there was a continuous relationship between glycemic control and development of complications. Improved glycemic control also reduced the cardiovascular event rate in the follow-up period of >10 years.

One of the major findings of the UKPDS was that strict blood pressure control significantly reduced both macro- and microvascular complications. In fact, the beneficial effects of blood pressure control were greater than the beneficial effects of glycemic control. Lowering blood pressure to moderate goals (144/82 mmHg) reduced the risk of DM-related death, stroke, microvascular endpoints, retinopathy, and heart failure (risk reductions between 32 and 56%). The American Diabetes Association (ADA) recommends blood pressure control <130/80 mmHg. In the UKPDS, improved glycemic control early in the course of diabetes with a sulfonylurea or insulin, or with metformin, subsequently reduced risk of death and MI. Other trials such as the Action to Control Cardiovascular Risk in Diabetes (ACCORD) and Action in Diabetes and Vascular Disease: Preterax and Diamicron MR Controlled Evaluation (ADVANCE) trials also found that improved glycemic control reduced microvascular complications.

Thus, large clinical trials in type 1 and type 2 DM indicate that chronic hyperglycemia plays a causative role in the pathogenesis of diabetic micro- and macrovascular complications. In both the DCCT and the UKPDS, cardiovascular events were reduced at follow-up of >10 years, even though the improved glycemic control was not maintained. This legacy effect for a positive impact of a period of improved glycemic control on later diabetes complications has been termed *metabolic memory*, and this legacy effect was estimated to be 10 years or more. Of note, despite long-standing DM, some individuals never develop retinopathy or nephropathy, suggesting a genetic susceptibility for developing particular complications.

MECHANISMS OF COMPLICATIONS

Chronic hyperglycemia is the important etiologic factor leading to complications of DM, but the mechanism(s) by which it leads to such diverse cellular and organ dysfunction is unknown. The complications are likely multifactorial with an emerging hypothesis that hyperglycemia leads to epigenetic changes **(Chap. 479)** that influence gene expression in affected cells. Chronic hyperglycemia leads to formation of advanced glycosylation end products (AGEs; e.g., pentosidine, glucosepane, and carboxymethyllysine), which bind to specific cell surface receptor and/or the nonenzymatic glycosylation of intra- and extracellular proteins, leading to cross-linking of proteins, glomerular dysfunction, endothelial dysfunction, altered extracellular matrix composition, and accelerated atherosclerosis.

Growth factors may play an important role in some diabetes-related microvascular complications. For example, vascular endothelial growth factor A (VEGF-A) is increased locally in diabetic proliferative retinopathy, decreases after laser photocoagulation, and is the target inhibited by intravitreous injection therapy. A possible unifying mechanism is that hyperglycemia leads to increased production of reactive oxygen species or superoxide in the mitochondria and this may activate several pathways. Although hyperglycemia serves as the initial trigger for complications of diabetes, it is still unknown whether the same pathophysiologic processes are operative in all complications or whether some pathways predominate in certain organs.

The mechanisms of diabetes-related macrovascular complications including MI and stroke also include traditional cardiovascular risk factors (dyslipidemia, hypertension), insulin resistance, and inflammation. In T2DM, insulin resistance is present years prior to diagnosis and is associated with obesity and ectopic accumulation of lipids and fat in liver and muscle. Additionally, insulin fails to appropriately suppress lipolysis from adipose tissue, which results in increased delivery of fatty acids to liver, muscle, endothelial cells, and cardiac tissues, leading to tissue accumulation of triglycerides, diacylglycerol, and ceramides.

OPHTHALMOLOGIC COMPLICATIONS OF DIABETES MELLITUS

DM is the leading cause of new cases of blindness between the ages of 20 and 74 in the United States. Glaucoma and cataracts occur earlier and more frequently in individuals with diabetes. Severe vision loss is primarily the result of progressive diabetic retinopathy, which leads to significant macular edema and new blood vessel formation. Diabetic retinopathy is classified into two stages: nonproliferative and proliferative. Nonproliferative diabetic retinopathy usually appears late in the first decade or early in the second decade of hyperglycemia and is marked by retinal vascular microaneurysms, blot hemorrhages, and cotton-wool spots **(Fig. 417-2)**. Mild nonproliferative retinopathy may progress to more extensive disease, characterized by changes in venous vessel caliber, intraretinal microvascular abnormalities, and more numerous microaneurysms and hemorrhages. The pathophysiologic mechanisms invoked in nonproliferative retinopathy include loss of retinal pericytes, increased retinal vascular permeability, alterations in retinal blood flow, and abnormal retinal microvasculature, all of which can lead to retinal ischemia.

The appearance of neovascularization in response to retinal hypoxemia is the hallmark of proliferative diabetic retinopathy (Fig. 417-2). These newly formed vessels appear near the optic nerve and/or macula and rupture easily, leading to vitreous hemorrhage, fibrosis, and ultimately retinal detachment. Not all individuals with nonproliferative retinopathy go on to develop proliferative retinopathy, but the more severe the nonproliferative disease, the greater is the chance of evolution to proliferative retinopathy within 5 years. This creates an important opportunity for early detection and treatment of diabetic retinopathy. Clinically significant macular edema can occur in the context of nonproliferative or proliferative retinopathy. Fluorescein angiography and optical coherence tomography are useful to detect macular edema, which is associated with an increased chance of moderate visual loss over the next 3 years. Duration of DM and degree of glycemic control are the best predictors of the development of retinopathy; hypertension, nephropathy, and dyslipidemia are also risk factors. Although there is genetic susceptibility for retinopathy, it confers less influence than either the duration of DM or the degree of glycemic control.

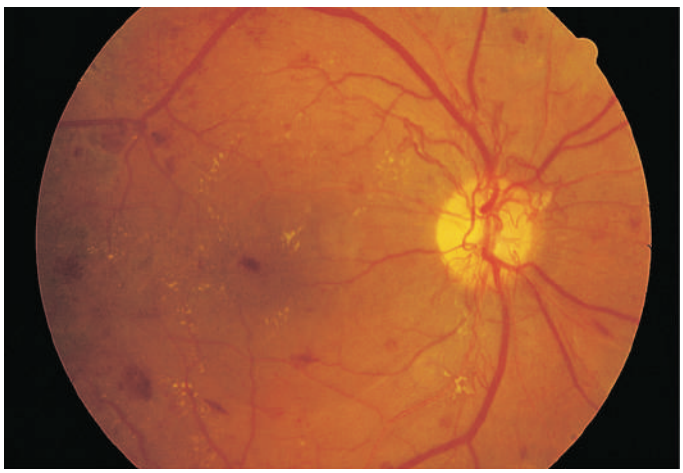

FIGURE 417-2 Diabetic retinopathy results in scattered hemorrhages, yellow exudates, and neovascularization. This patient has neovascular vessels proliferating from the optic disc, requiring urgent panretinal laser photocoagulation.

TREATMENT

Diabetic Retinopathy

The most effective therapy for diabetic retinopathy is prevention. Intensive glycemic and blood pressure control will delay the development and slow the progression of retinopathy in individuals with either type 1 or type 2 DM. Paradoxically, during the first 6–12 months of improved glycemic control, established diabetic retinopathy may transiently worsen. Fortunately, this progression is temporary, and in the long term, improved glycemic control is associated with less diabetic retinopathy. When associated with a marked glycemic improvement, glucagon-like peptide 1 (GLP-1) receptor agonists have been associated with an increased risk of worsening diabetic retinopathy; this should be considered when choosing agents to improve in glycemic control. Individuals with retinopathy may be candidates for prophylactic laser photocoagulation when initiating intensive therapy, and especially prior to pancreas or islet transplantation that can rapidly normalize glycemia. Women with type 1 or type 2 DM who are planning pregnancy should be screened prior to and during pregnancy. Once advanced retinopathy is present, improved glycemic control imparts less benefit. Appropriate ophthalmologic care can prevent most blindness. Lowering elevated levels of triglycerides with fenofibrate may also reduce the progression of retinopathy.

Regular, comprehensive eye examinations are essential for all individuals with DM **(see Table 416-1)**. Most diabetic eye disease can be successfully treated if detected early. Routine, nondilated eye examinations by the primary care provider or diabetes specialist are inadequate to detect diabetic eye disease, which requires a dilated eye exam performed by an optometrist or ophthalmologist or by retinal photography with remote reading. Subsequent management should be by a retinal specialist. Treatment of severe nonproliferative or proliferative retinopathy or macular edema with panretinal laser photocoagulation therapy and/or anti-VEGF therapy (intravitreous injection) usually is successful in preserving vision. Aspirin therapy does not appear to influence the natural history of diabetic retinopathy, and antiplatelet agents and anticoagulation may be continued in patients receiving intravitreal injections of anti-VEGF agents. Patients with severe proliferative retinopathy with vitreous hemorrhage and/or traction involving the macula often require surgical vitrectomy.

RENAL COMPLICATIONS OF DIABETES MELLITUS

Diabetic nephropathy is the leading cause of chronic kidney disease (CKD) and stage 5 CKD (e.g., end-stage renal disease; see **Chap. 322**) requiring renal replacement therapy. CKD in individuals with DM is associated with an increased risk of cardiovascular disease, and the prognosis of individuals with diabetes on dialysis is poor. Individuals with type 1 DM and diabetic nephropathy commonly also have diabetic retinopathy; this association is less pronounced in type 2 DM. The presence of CKD without retinopathy in type 1 DM should prompt investigation for alternative causes of kidney disease. Approximately 20–40% of patients with diabetes develop diabetic nephropathy. Known risk factors include a family history of diabetic nephropathy with additional genetic or environmental susceptibility factors likely contributing. Smoking accelerates the decline in renal function. Diabetic nephropathy and stage 5 CKD (e.g., end-stage renal disease; see **Chap. 322**) secondary to DM develop more commonly in Black, Native American, and Hispanic individuals.

Like other microvascular complications, the pathogenesis of diabetic nephropathy is related to chronic hyperglycemia. The mechanisms by which chronic hyperglycemia leads to diabetic nephropathy are incompletely defined but involve the effects of soluble factors (growth factors, angiotensin II, endothelin, AGEs), epigenetic changes, hemodynamic alterations in the renal microcirculation (glomerular hyperfiltration or hyperperfusion, increased glomerular capillary pressure), structural changes in the glomerulus (increased extracellular matrix, basement membrane thickening, mesangial expansion, fibrosis), and tubular dysfunction (tubulointerstitial damage, fibrosis). **See Chap. 322 for additional discussion.**

The natural history of diabetic nephropathy is characterized by a sequence of events that was initially defined for individuals with type 1 DM but appears similar in type 2 DM **(Fig. 417-3)**. Glomerular hyperperfusion and renal hypertrophy occur in the first years after the onset of DM and are associated with an increase of the estimated glomerular filtration rate (GFR). During the first 5 years of DM, thickening of the glomerular basement membrane, glomerular hypertrophy, and mesangial volume expansion occur as the GFR returns to normal. Once there is marked albuminuria and a reduction in GFR, these pathologic changes are likely irreversible.

As part of comprehensive diabetes care **(Chap. 416)**, diabetic nephropathy should be detected at an early stage when effective therapies can be instituted. Because some individuals with DM may have a decline in GFR in the absence of albuminuria, assessment should include both urinary albumin-to-creatinine ratio (UACR) on a spot specimen and an estimated GFR (eGFR). The urine protein measurement by routine urinalysis does not detect low levels of albumin excretion. Screening for albuminuria should commence 5 years after type 1 DM onset and at the time of diagnosis of type 2 DM and be performed annually. An elevated UACR should be confirmed on two to three occasions over a 3- to 6-month period since it can be falsely elevated by strenuous exercise at a time close to its measurement, infection, fever, congestive heart failure, marked hyperglycemia, marked hypertension, or prostate disease.

The ADA defines albuminuria as a persistently increased UACR >30 mg/g. Albuminuria should be quantified, with a moderate increase defined as 30–299 mg/g creatinine and severely elevated as >300 mg/g creatinine. The UACR is a continuous variable, but the greater the degree of albuminuria the more likely there is a reduced GFR. Elevations in the UACR are associated with an increased risk of cardiovascular disease. Once increased, the UACR should be measured more frequently (2–4 times/year).

Type IV renal tubular acidosis (hyporeninemic hypoaldosteronism) may occur in type 1 or 2 DM. These individuals develop a propensity to hyperkalemia and acidemia, which may be exacerbated by medications (especially angiotensin-converting enzyme [ACE] inhibitors, angiotensin receptor blockers [ARBs], and mineralocorticoid receptor antagonists). Patients with DM are predisposed to radiocontrast-induced nephrotoxicity. Risk factors for radiocontrast-induced nephrotoxicity are preexisting nephropathy and volume depletion. Individuals with DM undergoing radiographic procedures with iodinated contrast dye should be well hydrated before and after dye exposure, and the serum creatinine should be monitored for 24–48 h following the procedure.

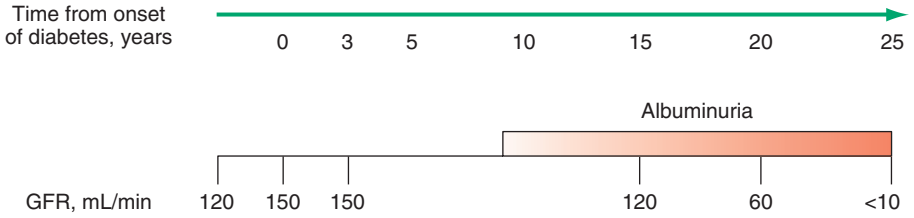

FIGURE 417-3 Time course of development of diabetic nephropathy. The relationship of time from onset of diabetes, albuminuria (urinary albumin-to-creatinine ratio [UACR]), and the glomerular filtration rate (GFR) are shown. This figure is typical for type 1 diabetes; individuals with type 2 diabetes may present with a lower GFR at the time of diagnosis.

Metformin should be held until postintervention confirmation of preserved kidney function.

TREATMENT

Diabetic Nephropathy

The optimal therapy for diabetic nephropathy is prevention by control of glycemia and blood pressure (blood pressure <130/80 mmHg) **(Chap. 416 outlines glycemic goals and approaches)**. Renin-angiotensin-aldosterone system inhibitors do not prevent the development of diabetic kidney disease if hypertension or albuminuria is not present. Interventions effective in slowing progression of albuminuria and the decline in kidney function include (1) improved glycemic control, (2) strict blood pressure control, (3) administration of an ACE inhibitor or ARB, (4) in individuals with type 2 DM, administration of a sodium-glucose cotransporter 2 (SGLT-2) inhibitor and (5) administration of a mineralocorticoid receptor antagonist (especially finerenone). Dyslipidemia should also be treated.

Improved glycemic control reduces the rate at which albuminuria appears and progresses in type 1 and type 2 DM. However, once there is a moderate level of albuminuria, it becomes more difficult for improved glycemic control to slow progression of renal disease, although 10 years of normoglycemia resulting from pancreas transplantation may lead to regression of mesangial glomerular lesions **(Fig. 417-4)**. During the late phase of declining renal function, insulin requirements may fall as the kidney is a site of insulin degradation. As the GFR decreases with progressive nephropathy, the use and dose of glucose-lowering agents should be reevaluated **(see Table 416-6)**. Some glucose-lowering medications (sulfonylureas and metformin) are contraindicated in advanced renal insufficiency, while others may require dose adjustment (glinides and DPP-4 inhibitors). SGLT2 inhibitors are not effective with eGFR < 20 mL/min/1.73 m^2.

HYPERTENSION

Many individuals with type 1 or type 2 DM develop hypertension. Hypertension accelerates complications of DM, particularly ASCVD, nephropathy, and retinopathy. Blood pressure should be measured at every clinic visit; individuals should also be encouraged to monitor their blood pressure at home. The blood pressure goal should be <130/80 mmHg in individuals with diabetes and possibly lower in individuals at increased risk for ASCVD or CKD progression. Because of the high prevalence of ASCVD disease in individuals with type 2 DM, the possibility of renovascular hypertension should be considered when the blood pressure is not readily controlled.

In addition to medications, therapy should include lifestyle modifications, including weight loss, exercise, stress management, sodium restriction, Dietary Approaches to Stop Hypertension (DASH)–style eating, and smoking cessation. In younger individuals or those with increased cardiovascular risk, the provider may recommend a lower target blood pressure. If the blood pressure is >150/90 mmHg, initial treatment should consist of two antihypertensive medications. Multiple agents are often required to control blood pressure. In pregnant individuals with diabetes and chronic hypertension, blood pressure control is associated with better pregnancy outcomes.

In the absence of kidney disease, ACE inhibitors or ARBs are effective antihypertensives but are no more effective than other antihypertensive classes such as thiazide-like diuretics and dihydropyridine calcium channel blockers. There is no benefit of intervention prior to onset of albuminuria or using a combination of an ACE inhibitor and an ARB. If use of either ACE inhibitors or ARBs is not possible or the blood pressure is not controlled, then diuretics, calcium channel blockers (nondihydropyridine class), or beta blockers (with caution in individuals at increased risk for experiencing hypoglycemia) may be used. Mineralocorticoid receptor antagonists can

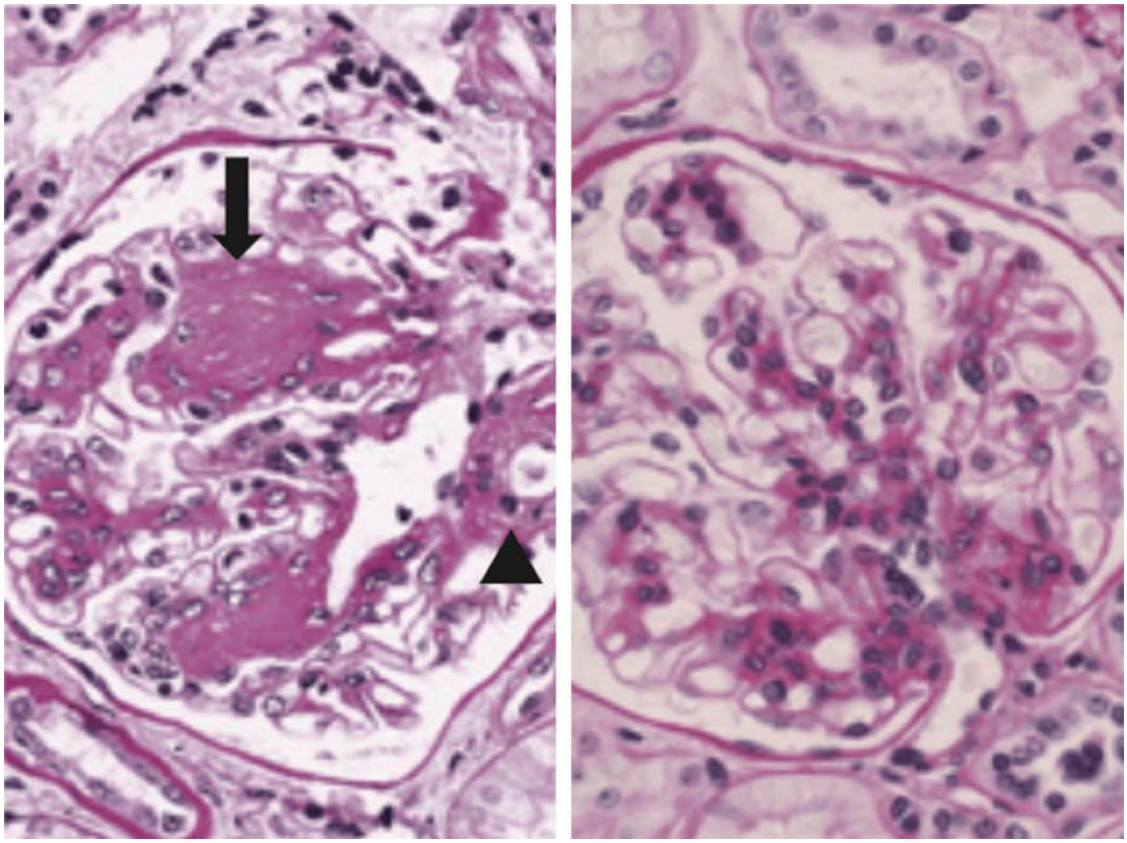

FIGURE 417-4 Diabetic glomerular changes in a patient with type 1 diabetes are reversed by 10 years of normoglycemia as a result of pancreas transplantation. Left panel shows diabetic glomerulosclerosis (*arrow*) and arteriolar hyalinosis (*arrowhead*) on kidney biopsy. Right panel shows a near-normal glomerulus in the same patient after 10 years of normoglycemia from pancreas transplantation. *(Reproduced with permission from P Fioretto et al: Reversal of lesions of diabetic nephropathy after pancreas transplantation. N Engl J Med 339:69, 1998.)*

help reduce blood pressure and albuminuria in refractory cases but require close monitoring of the serum potassium.

ALBUMINURIA OR CKD

Either ACE inhibitors or ARBs should be used to reduce albuminuria and slow the decline in GFR in individuals with type 1 or type 2 DM. Most experts consider the two classes of drugs to be equivalent in patients with diabetes. ARBs can be used as an alternative in patients who develop ACE inhibitor–associated cough or angioedema. After initiation of therapy, one should increase to the maximum tolerated dose while monitoring the serum creatinine and potassium and repeating the UACR one to four times per year. A rise in the serum creatinine up to 30% is acceptable. A goal for individuals with a UACR >300 mg/g creatinine is to reduce the UACR by 30%.

To reduce CKD progression and cardiovascular events in individuals with CKD, type 2 DM, and an eGFR >20 mL/min per 1.73 m^2, the addition of an SGLT-2 inhibitor, while continuing an ACE inhibitor or ARB, is recommended with any level of albuminuria. A GLP-1 agonist or a nonsteroidal mineralocorticoid receptor antagonist like finerenone will also reduce cardiovascular risk in individuals with type 2 DM and CKD. The GLP-1 receptor agonist semaglutide improves kidney outcomes and reduces death from cardiovascular causes in type 2 DM and CKD. SGLT-2 inhibitors are also discussed in **Chap. 265**, especially the use in heart failure treatment or prevention, and in **Chap. 322**, as related to CKD. Because of the elevated risk of euglycemic diabetic ketoacidosis, SGLT-2 inhibitors in individuals with type 1 DM and insulin-deficient type 2 DM should be used with caution and include patient education about ketone monitoring and recognizing diabetic ketoacidosis.

Nephrology consultation is indicated when the estimated GFR is <30 mL/min per 1.743 m^2, albuminuria is >300 mg/g creatinine, or if there are atypical features such as hematuria or rapidly declining renal function. The ADA suggests a protein intake of 0.8 g/kg of body weight per day in individuals with diabetic kidney disease. Complications of ASCVD are the leading cause of death in diabetic individuals with nephropathy; hyperlipidemia should be treated aggressively. Preemptive (before dialysis) kidney transplantation from a living donor should be considered in those nearing stage 5 CKD (e.g., end-stage renal disease; see **Chap. 333**) and for those with type 1 DM or insulin deficient type 2 DM, simultaneous pancreas-kidney transplantation from a deceased donor may be an option. As compared with nondiabetic individuals, hemodialysis in patients with DM is associated with more frequent complications, such as hypotension (due to autonomic neuropathy or loss of reflex tachycardia), more difficult vascular access, accelerated progression of retinopathy, and greater mortality.

NEUROPATHY AND DIABETES MELLITUS

Diabetic neuropathy, which occurs in ~50% of individuals with long-standing type 1 and type 2 DM, manifests as a diffuse neuropathy (distal symmetrical polyneuropathy and/or autonomic neuropathy), a mononeuropathy, and/or a radiculopathy/polyradiculopathy. As with other complications of DM, the development of neuropathy correlates with the duration of diabetes and glycemic control. Additional risk factors are body mass index (BMI) (the greater the BMI, the greater the risk of neuropathy) and smoking. The presence of ASCVD, elevated triglycerides, and hypertension is also associated with diabetic peripheral neuropathy. Both myelinated and unmyelinated nerve fibers are lost. Because the clinical features of diabetic neuropathy are similar to those of other neuropathies, the diagnosis of diabetic neuropathy should be made only after other possible etiologies are excluded **(Chap. 457)**.

Distal Symmetric Polyneuropathy (DSPN) DSPN, the most common form of diabetic neuropathy, most frequently presents with distal sensory loss and pain, but up to 50% of patients do not have symptoms of neuropathy. Symptoms may include a sensation of numbness, tingling, sharpness, or burning that begins in the feet and spreads proximally. Hyperesthesia, paresthesia, and dysesthesia also may occur. Pain typically involves the lower extremities, is usually present at rest, and worsens at night. Both an acute (lasting <12 months) and a chronic form of painful diabetic neuropathy may occur. The acute form is sometimes treatment-related, occurring in the context of improved glycemic control. As diabetic neuropathy progresses, the pain subsides and eventually disappears, but a sensory deficit persists, and motor defects may develop. Physical examination **(Chap. 415)** often reveals sensory loss (to 10-g monofilament and/or vibration), loss of ankle deep-tendon reflexes, abnormal position sense, and muscular atrophy or foot drop. Annual screening for DSPN should begin 5 years after diagnosis of type 1 DM and at the time of diagnosis of type 2 DM and is aimed at detecting loss of protective sensation (LOPS). LOPS and DSPN are major risk factors for foot ulceration and falls due to small and large nerve fiber dysfunction and predispose to lower extremity amputation.

Autonomic Neuropathy Individuals with long-standing type 1 or 2 DM may develop signs of autonomic dysfunction involving the parasympathetic (cholinergic) and sympathetic (adrenergic) systems. DM-related autonomic neuropathy can affect multiple organ systems, including the cardiovascular, gastrointestinal (GI), genitourinary, sudomotor, and metabolic systems. Cardiovascular autonomic neuropathy, reflected by decreased heart rate variability, resting tachycardia, and orthostatic hypotension, is associated with an increase in ASCVD. Orthostatic hypotension, a late and unusual complication of diabetes, is sometimes seen in patients with associated DSPN and severe parasympathetic dysfunction. Reports of sudden death in DM have also been attributed to autonomic neuropathy affecting the cardiovascular system and predisposing to severe hypoglycemia, both of which may prolong the QTc interval. Autonomic neuropathy may reduce counterregulatory hormone release (especially epinephrine), and contribute to an inability to sense hypoglycemia appropriately (hypoglycemia unawareness) **(Chap. 418)** that increases the risk of severe hypoglycemia. Gastroparesis and bladder-emptying abnormalities are often caused by the autonomic neuropathy seen in DM (discussed below). Hyperhidrosis of the upper extremities and anhidrosis of the lower extremities result from sympathetic nervous system dysfunction. Anhidrosis of the feet can promote dry skin with cracking, which increases the risk of foot ulceration.

Mononeuropathy and/or Radiculopathy/Polyradiculopathy Mononeuropathy (dysfunction of isolated cranial or peripheral nerves) is less common than polyneuropathy in DM and presents with pain and motor weakness in the distribution of a single nerve. Mononeuropathies can occur at entrapment sites such as carpal tunnel or be noncompressive. Involvement of the third cranial nerve is most common and is heralded by diplopia. Physical examination reveals ptosis and ophthalmoplegia with normal pupillary constriction to light. Sometimes other cranial nerves, such as IV, VI, or VII (Bell's palsy), are affected. Peripheral mononeuropathies or simultaneous involvement of more than one nerve (mononeuropathy multiplex) may also occur. Diabetic radiculopathy or polyradiculopathy is a syndrome characterized by severe disabling pain in the distribution of one or more nerve roots. It may be accompanied by motor weakness. Intercostal or truncal radiculopathy causes pain over the thorax or abdomen. Involvement of the lumbar plexus or femoral nerve may cause severe pain in the thigh or hip and may be associated with muscle weakness in the hip flexors or extensors (diabetic amyotrophy). Fortunately, diabetic polyradiculopathies are usually self-limited and resolve over 6–12 months.

TREATMENT

Diabetic Neuropathy

Prevention of diabetic neuropathy is critical through improved glycemic control. Treatment of diabetic neuropathy is less than satisfactory. Lifestyle modifications (exercise, diet) have some efficacy

in DSPN in type 2 DM and hypertension and hypertriglyceridemia should be treated. Efforts to improve glycemic control in long-standing diabetes may be limited by hypoglycemia unawareness. Patients should avoid neurotoxins (including alcohol) and smoking and consider supplementation with vitamins for possible deficiencies (B_{12}, folate; **Chap. 344**). Metformin may reduce intestinal absorption of vitamin B_{12} in type 2 DM, and pernicious anemia is more common in type 1 DM where it is associated with anti–parietal cell autoantibodies and may require sublingual or parenteral B_{12} replacement. Patients should be educated that loss of sensation in the foot increases the risk for ulceration and its sequelae and that prevention of such problems is paramount. Patients with symptoms or signs of neuropathy or LOPS should check their feet daily and take precautions (footwear) aimed at preventing calluses or ulcerations. If foot deformities are present, a podiatrist should be involved.

Chronic, painful diabetic neuropathy is difficult to treat with only symptomatic treatment being available; evidence of the effectiveness of improved glycemic control in painful diabetic neuropathy is lacking. Sleep and mood disorders frequently accompany DPSN and should be treated. Symptomatic treatment of the pain using gabapentinoids (pregabalin, gabapentin), serotonin-norepinephrine reuptake inhibitors (duloxetine, venlafaxine, and desvenlafaxine), sodium channel blockers, tricyclic antidepressants, and a capsaicin patch have some efficacy for pain related to DPSN. Tapentadol, a centrally acting opioid, is also approved by the U.S. Food and Drug Administration (FDA) but has only modest efficacy and poses addiction risk, making it and other opioids less desirable and not first-line therapy. No direct comparisons of agents are available, and it is reasonable to switch agents if there is no response or if side effects develop. Referral to a pain management center may be necessary.

Therapy of orthostatic hypotension secondary to autonomic neuropathy is also difficult. Nonpharmacologic maneuvers (adequate salt intake, avoidance of dehydration and diuretics, lower extremity support hose, and physical activity) may offer some benefit. A variety of agents have limited success (midodrine and droxidopa are approved by the FDA for orthostatic hypotension of any etiology). Patients with resting tachycardia may be considered for beta blocker therapy with caution exercised if there is hypoglycemia unawareness. Patients with type 1 DM and orthostatic hypotension should be evaluated for primary adrenal insufficiency (Addison's disease) that may be associated with an autoimmune polyendocrine syndrome **(Chap. 401)**.

GASTROINTESTINAL/GENITOURINARY DYSFUNCTION

Long-standing type 1 and 2 DM may affect the motility and function of the GI and genitourinary systems. The most prominent GI symptoms are delayed gastric emptying (gastroparesis) and altered small- and large-bowel motility (constipation or diarrhea). Gastroparesis may present with symptoms of anorexia, nausea, vomiting, early satiety, and abdominal bloating. Microvascular complications (retinopathy and neuropathy) are usually present. Nuclear medicine scintigraphy after ingestion of a radiolabeled meal or digestible solids may document delayed gastric emptying but may not correlate well with the patient's symptoms. Although parasympathetic dysfunction secondary to chronic hyperglycemia is important in the development of gastroparesis, hyperglycemia itself also impairs gastric emptying. Nocturnal diarrhea, alternating with constipation, may be a feature of DM-related GI autonomic neuropathy. In type 1 DM, these symptoms should also prompt evaluation for celiac disease that is associated with anti-tissue transglutaminase autoantibodies because of its increased frequency.

Diabetic autonomic neuropathy may lead to genitourinary dysfunction, including cystopathy and female sexual dysfunction (reduced sexual desire, dyspareunia, reduced vaginal lubrication). Symptoms of diabetic cystopathy begin with an inability to sense a full bladder and a failure to void completely. As bladder contractility worsens, bladder capacity and the postvoid residual increase, leading to symptoms of urinary hesitancy, decreased voiding frequency, incontinence, and recurrent urinary tract infections.

Erectile dysfunction and retrograde ejaculation are very common in DM and may be one of the earliest signs of diabetic neuropathy **(Chap. 409)**. Erectile dysfunction, which increases in frequency with the age of the patient and the duration of diabetes, may occur in the absence of other signs of diabetic autonomic neuropathy.

TREATMENT

Gastrointestinal/Genitourinary Dysfunction

Current treatments for these complications of DM are inadequate and nonspecific. Improved glycemic control should be a goal but has not clearly shown benefit. Smaller, more frequent meals that are easier to digest (liquid) and low in fat and fiber may minimize symptoms of gastroparesis. Medications that slow gastric emptying (opioids, GLP-1 receptor agonists) should be avoided. Metoclopramide may be used with severe symptoms but is restricted to short-term treatment in both the United States and Europe. Symptoms of gastroesophageal reflux disease may require acid-blocking therapy with a histamine-2 receptor antagonist or proton pump inhibitor. Gastric electrical stimulatory devices are available. Diabetic diarrhea in the absence of bacterial overgrowth is treated symptomatically **(Chap. 336)**.

Diabetic cystopathy should be treated with scheduled voiding or self-catheterization. Drugs that inhibit type 5 phosphodiesterase are effective for erectile dysfunction, but their efficacy in individuals with DM is slightly lower than in the nondiabetic population **(Chap. 409)**.

CARDIOVASCULAR MORBIDITY AND MORTALITY

ASCVD, including PAD, CHD, heart failure, and cerebrovascular disease, occurs more frequently in individuals with type 1 or type 2 DM and is the major cause of mortality for individuals with diabetes. In addition, the prognosis for individuals with diabetes who have CHD is worse than for nondiabetics. CHD is more likely to involve multiple vessels in individuals with DM. The American Heart Association considers DM a controllable risk factor for cardiovascular disease; in some studies, type 2 DM patients without a prior MI have a similar risk for coronary artery-related events as nondiabetic individuals who have had a prior MI. Fortunately, the outcomes related to ASCVD have improved over the last decade for those without diabetes and individuals with diabetes as a result of modification of multiple risk factors.

Heart failure, which has not been recognized until recently as a diabetes-related complication, is twice as common in individuals with diabetes (type 1 or type 2). Heart failure is related to diabetes duration and hypertension and can present as heart failure with preserved ejection fraction (HFpEF), heart failure with mildly reduced ejection fraction (HFmEF), or heart failure with reduced ejection fraction (HFrEF) (see **Chap 276**). Some individuals with DM have reduced left ventricular function without CHD or hypertension, and this is sometimes termed "diabetic cardiomyopathy." The pathogenesis of this and heart failure associated with DM is not clear.

The prevention and management of ASCVD and heart failure in individuals with DM should focus on risk factors, including duration of diabetes, hypertension, dyslipidemia, CKD, albuminuria, obesity, and smoking. Many of these are modifiable and should prompt action by the patient and the provider. The foundation of prevention and management is the concurrent, integrated focus on four targets: glycemia, blood pressure, lipids, and the incorporation of therapies with cardiovascular and kidney outcome benefits. While these results are from observations and studies in type 2 DM, these strategies are also likely relevant to type 1 DM.

Cardiovascular risk assessment in type 2 DM should encompass a nuanced and individualized approach. For example, cardiovascular risk is lower and not equivalent in a younger individual with a brief

duration of type 2 DM compared to an older individual with long-standing type 2 DM. Because of the high prevalence of underlying ASCVD in individuals with diabetes (especially in type 2 DM), evidence of ASCVD (e.g., cardiac stress test) should be sought in an individual with diabetes who has symptoms, even if atypical, suggestive of cardiac ischemia or peripheral or carotid arterial disease. However, the screening of asymptomatic individuals with diabetes for CHD is not recommended or cost-effective. The absence of chest pain ("silent ischemia") is common in individuals with diabetes, and a thorough cardiac evaluation should be considered prior to major surgical procedures.

TREATMENT

Cardiovascular Disease

Treatment of coronary disease in individuals with DM is similar to treatment in individuals without DM **(Chap. 284)**. Revascularization procedures for CHD, including percutaneous coronary interventions (PCIs) and coronary artery bypass grafting (CABG), may be less efficacious in individuals with DM. Initial success rates of PCI in individuals with DM are similar to those in the nondiabetic population, but higher rates of restenosis and lower long-term patency and survival rates have been reported. CABG plus optimal medical management likely has better outcomes than PCI for individuals with diabetes. Very strict glucose control has limited benefit on cardiovascular outcomes in individuals with established cardiovascular disease, indicating the importance of other factors such as insulin resistance, dyslipidemia, and inflammation.

In individuals with type 2 DM and ASCVD, the comprehensive effort to reduce cardiovascular risk (e.g., lifestyle management, blood pressure control, lipid management) should include an SGLT-2 inhibitor or a GLP-1 receptor agonist. If diabetic CKD or heart failure is present or likely, an SGLT-2 inhibitor is preferred. In individuals with type 2 DM and ASCVD or other ASCVD risk factors, a GLP-1 receptor agonist will reduce cardiovascular events. The combination of an SGLT-2 inhibitor and a GLP-1 receptor agonist likely provides additive risk reduction. In individuals with type 2 DM and CKD with albuminuria treated with maximum ACE inhibitor or ARB, addition of either a SGLT2 inhibitor or finerenone reduces CKD progression and improves cardiovascular outcomes. Combining a SGLT2 inhibitor with finerenone reduces the risk of hyperkalemia. Care of individuals with type 2 DM and heart failure or cardiovascular disease should involve a cardiovascular specialist and include treatment with an ACE inhibitor or ARB and a beta blocker. If an individual is already taking metformin and has an eGFR >30 mL/min per 1.73 m^2, reduced-dose metformin can be continued. Because of the elevated risk of euglycemic diabetic ketoacidosis with SGLT-2 inhibitors, patients treated with an SGLT-2 inhibitor should be counseled about the risk and symptoms of diabetic ketoacidosis and educated about the importance of measuring ketones if the clinical scenario suggests this possibility.

Antiplatelet therapy with aspirin (75–162 mg/d) as secondary prevention reduces cardiovascular events in individuals with DM who have ASCVD. Clopidogrel should be used in those with aspirin allergy or intolerance. The ADA recommends considering the use of aspirin for primary prevention of coronary events in individuals with diabetes with an increased cardiovascular risk (>50 years old with at least one risk factor such as hypertension, dyslipidemia, smoking, family history, or albuminuria). Aspirin is not recommended for primary prevention in those with a low cardiovascular risk (<50 years old with no risk factors).

Cardiovascular Risk Factors

DYSLIPIDEMIA Individuals with DM may have several forms of dyslipidemia **(Chap. 419)**. Because of the additive cardiovascular risk of hyperglycemia and hyperlipidemia, lipid abnormalities should be assessed and treated as part of comprehensive diabetes care **(Chap. 416)**. The most common pattern of dyslipidemia is hypertriglyceridemia and reduced high-density lipoprotein (HDL) cholesterol levels. DM itself does not increase levels of low-density lipoprotein (LDL), but the small dense LDL particles found in type 2 DM are more atherogenic because they are more easily glycated and susceptible to oxidation.

Almost all treatment studies of diabetic dyslipidemia have been performed in individuals with type 2 DM because of the greater frequency of dyslipidemia in this form of diabetes. Interventional studies have shown that the beneficial effects of LDL reduction with statins are similar in the diabetic and nondiabetic populations. No prospective studies have addressed similar questions in individuals with type 1 DM. Because the frequency of ASCVD is low in children and young adults with diabetes, assessment of cardiovascular risk should be incorporated into the guidelines discussed below. Statin usage is associated with a mild increase in the risk of developing type 2 DM. However, when appropriately indicated the cardiovascular benefits of statin use outweigh the mildly increased risk of diabetes.

Based on the guidelines provided by the ADA, all individuals with diabetes should be advised about lifestyle modification, including diet, weight loss, and increased physical activity **(Chap. 416)**. If individuals with diabetes have elevated triglyceride levels (>1.7 mmol/L [150 mg/dL]) or low HDL cholesterol (<1 mmol/L [40 mg/dL] in men and <1.3 mmol/L [50 mg/dL] in women), lifestyle modification and improved glycemic control should be further emphasized. If triglycerides are >5.7 mmol/L (500 mg/dL) on a statin, icosapent or fenofibrate can be considered to reduce ASCVD risk. The addition of fenofibrate may require reduction in statin dose to minimize the risk of myopathy.

In terms of pharmacologic therapy directed at LDL, the ADA recommends the following in addition to lifestyle: (1) all patients with diabetes and ASCVD should receive high-intensity statin therapy (atorvastatin 40–80 mg or rosuvastatin 20–40 mg) with a goal of >50% reduction in LDL and a cholesterol goal of <55 mg/dL. Adding ezetimibe or a PCSK9 inhibitor is advised if these goals are not met; (2) in patients aged 40–75 years without ASCVD, moderate-intensity statin therapy (other statins or lower dose of atorvastatin or rosuvastatin) should be used; (3) in patients aged 40–75 years with ASCVD risk factors, use high-intensity statin therapy with a goal to reduce LDL cholesterol by 50% and an LDL target of <70 mg/dL; (4) in patients aged 40–75 years with ASCVD risk factors on maximum statin therapy and a LDL ≥70 mg/dL, consider adding ezetimibe or PCSK9 inhibitor therapy; (5) in patients aged >75 years on a statin, continue statin or, if not on a statin, consider starting moderate-intensity statin therapy after discussion with the patient; and (6) in patients aged 20–39 years with additional risk factors, consider moderate-intensity statin therapy. If a patient with ASCVD cannot tolerate a statin, consider PCSK9 inhibitor therapy (monoclonal antibody or inclisiran, a small interfering RNA), or bempedoic acid. Statin therapy, when combined with fibrate or niacin, for reduction of LDL does not provide additional benefit.

HYPERTENSION Hypertension management is discussed above in the "Renal Complications of Diabetes Mellitus" section.

LOWER EXTREMITY COMPLICATIONS

DM is the leading cause of nontraumatic lower extremity amputation in the United States. Foot ulcers and infections are also a major source of morbidity in individuals with DM. The reasons for the increased incidence of these disorders in DM involve the interaction of several pathogenic factors: neuropathy, abnormal foot biomechanics, PAD, and poor wound healing. The peripheral sensory neuropathy interferes with normal protective mechanisms and allows the patient to sustain major or repeated minor trauma to the foot, often without knowledge of the injury. Disordered proprioception causes abnormal weight bearing while walking and subsequent formation of callus or ulceration. Motor and sensory neuropathy leads to abnormal foot muscle mechanics and to structural changes in the foot (hammer toe, claw toe deformity, prominent metatarsal heads, Charcot joint). Autonomic neuropathy results in anhidrosis and altered superficial blood flow in the foot, which promote drying of the skin and fissure formation. PAD and poor wound healing impede resolution of minor breaks in the skin, allowing them to enlarge and to become infected.

Some individuals with DM will develop a foot ulcer (great toe or metatarsophalangeal areas are most common), and a significant subset may ultimately undergo amputation (14–24% risk with that ulcer or subsequent ulceration). Risk factors for foot ulcers or amputation include male sex, diabetes for >10 years, peripheral neuropathy, abnormal structure of foot (bony abnormalities, callus, thickened nails), PAD, smoking, history of previous ulcer or amputation, visual impairment, poor glycemic control, and diabetic nephropathy, especially dialysis. Large calluses are often precursors to or overlie ulcerations.

TREATMENT

Lower Extremity Complications

The optimal therapy for foot ulcers and amputations is prevention through identification of high-risk patients, education of the patient, and institution of measures to prevent ulceration. High-risk patients should be identified during the routine, annual foot examination performed on all patients with DM (see "Ongoing Aspects of Comprehensive Diabetes Care" in **Chap. 416**). If the monofilament test or one of the other tests is abnormal, the patient is diagnosed with LOPS **(Chap. 415)**. Providers should consider screening for asymptomatic PAD in individuals >50 years of age who have diabetes and other risk factors using ankle-brachial index testing **(Chap. 292)**. Patient education should emphasize (1) careful selection of footwear, (2) daily inspection of the feet to detect early signs of poor-fitting footwear or minor trauma, (3) daily foot hygiene to keep the skin clean and moist, (4) avoidance of self-treatment of foot abnormalities and high-risk behavior (e.g., walking barefoot), and (5) prompt consultation with a health care provider if an abnormality arises. Involvement of a podiatrist is recommended for high-risk individuals (history of foot ulcers or amputation, those on dialysis, those with PAD, and those with foot deformities). Calluses and nail deformities should be treated by a podiatrist. Interventions directed at risk factor modification include orthotic shoes and devices, callus management, nail care, and prophylactic measures to reduce increased skin pressure from abnormal bony architecture. Attention to other risk factors for vascular disease (smoking, dyslipidemia, hypertension) and improved glycemic control are also important, especially LDL management as described above.

Despite preventive measures, foot ulceration and infection are common and represent a serious problem. Due to the multifactorial pathogenesis of lower extremity ulcers, management of these lesions is multidisciplinary and often demands expertise in orthopedics, vascular surgery, endocrinology, podiatry, and infectious diseases. The plantar surface of the foot is the most common site of ulceration. Ulcers may be primarily neuropathic (no accompanying infection) or may have surrounding cellulitis or osteomyelitis. Cellulitis without ulceration should be treated with antibiotics that provide appropriate empiric coverage (see below).

An infected ulcer is a clinical diagnosis, because superficial culture of any ulceration will likely find multiple bacterial species of unknown significance. The infection surrounding the foot ulcer may be due to multiple organisms, with aerobic gram-positive cocci (staphylococci including methicillin-resistant *Staphylococcus aureus* [MRSA], group A and B streptococci) being most common and with aerobic gram-negative bacilli and/or obligate anaerobes as co-pathogens.

Gas gangrene may develop in the absence of clostridial infection. Cultures should be obtained from the debrided ulcer base or from purulent drainage or aspiration of the wound. Wound depth should be determined by inspection and probing with a blunt-tipped sterile instrument. A wound that probes to the bone is highly likely to have underlying osteomyelitis. Plain radiographs of the foot should be performed to assess the possibility of osteomyelitis in chronic ulcers that have not responded to therapy. Magnetic resonance imaging (MRI) is the most specific modality, with nuclear medicine scans (PET, CT/SPECT) and labeled white cell studies as an alternative. Surgical debridement is often necessary.

Osteomyelitis is best treated by a combination of prolonged antibiotics and debridement of infected bone when possible. The possible contribution of vascular insufficiency should be considered in all patients. Peripheral arterial bypass procedures are often effective in promoting wound healing and in decreasing the need for amputation of the ischemic limb **(Chap. 292)**.

Interventions with demonstrated efficacy in diabetic foot ulcers or wounds include the following: (1) off-loading (complete avoidance of weight bearing on the ulcer, which removes the mechanical trauma that retards wound healing), (2) surgical debridement of nonviable tissue, (3) physiologic, topical wound dressings, (4) revascularization, and (5) treatment of infections with appropriate use of antibiotics. Amputation should be limited initially. If a wound fails to show significant improvement after 4 weeks of wound management with these five recommendations, one should consider advanced wound therapy that may include topical growth factors, acellular matrix tissues, bioengineered cellular therapies, negative-pressure wound therapy, electrical stimulation, pulsed radiofrequency, extracorporeal shockwave, hyperbaric oxygen therapy, and topical oxygen therapy. These modalities require interdisciplinary expertise and must be individualized to the patient and clinical setting. Antiseptic agents should be avoided. Topical antibiotics are of limited value. Referral for physical therapy, orthotic evaluation, and rehabilitation should occur once the infection is controlled.

Mild or non-limb-threatening infections can be treated with oral antibiotics directed predominantly at methicillin-susceptible staphylococci and streptococci (e.g., dicloxacillin, early-generation cephalosporins, amoxicillin-clavulanate). However, in patients with a prior history of MRSA or in locations with a high prevalence of MRSA, treatment with trimethoprim-sulfamethoxazole, doxycycline, linezolid, or clindamycin is preferred, depending on local antibiogram data. Surgical debridement of necrotic tissue, local wound care, and avoidance of weight bearing over the ulcer are crucial. Optimization of glycemic control should be a goal. More severe infections may require IV antibiotics as well as offloading and local wound care. IV antibiotics should provide broad-spectrum coverage directed toward *S. aureus*, including MRSA, streptococci, gram-negative aerobes, and anaerobic bacteria. Initial empiric antimicrobial regimens may include vancomycin plus a β-lactam/β-lactamase inhibitor or carbapenem, or vancomycin plus a quinolone with metronidazole. In some cases, daptomycin, ceftaroline, or linezolid may be substituted for vancomycin in consultation with an infectious diseases expert. If the infection surrounding the ulcer is not improving with antibiotics, reassessment of antibiotic coverage and reconsideration of the need for surgical debridement or revascularization are indicated. With clinical improvement, oral antibiotics and local wound care can be continued on an outpatient basis with close follow-up.

INFECTIONS

Individuals with DM have a greater frequency and severity of infection. The reasons for this include incompletely defined abnormalities in cell-mediated immunity and phagocyte function associated with hyperglycemia, as well as diminished vascularization. Hyperglycemia aids the colonization and growth of a variety of organisms (*Candida* and other fungal species). Many common infections are more frequent and severe in the diabetic population, whereas several rare infections are seen almost exclusively in the diabetic population. Examples of this latter category include rhinocerebral mucormycosis, emphysematous infections of the gallbladder and urinary tract, and "malignant" or invasive otitis externa. Invasive otitis externa is usually secondary to *Pseudomonas aeruginosa* infection in the soft tissue surrounding the external auditory canal, typically begins with pain and discharge, and may rapidly progress to osteomyelitis and meningitis. These infections should be considered, in particular, in patients presenting with severe hyperglycemia.

Pneumonia, urinary tract infections, and skin and soft tissue infections are all more common in the diabetic population. In general, the organisms that cause pulmonary infections are similar to those found in the nondiabetic population; however, gram-negative organisms, *S. aureus*, and *Mycobacterium tuberculosis* are more frequent pathogens. Adults with DM should receive vaccination against pneumococcus, respiratory syncytial virus, annually against influenza, and the coronavirus SARS-CoV-2, which causes increased morbidity and mortality in obese individuals and patients with DM **(Chap. 204)**. In addition to early antibiotic therapy for presumed bacterial infections, patients with DM should be considered for early intervention with antiviral agents (e.g., against influenza in flu, varicella-zoster virus in shingles) or SARS-CoV-2 in COVID. Urinary tract infections (either lower tract or pyelonephritis) are the result of common bacterial agents such as *Escherichia coli*, although several yeast species (e.g., *Candida albicans* and *C. glabrata*) are sometimes observed. Complications of urinary tract infections include emphysematous pyelonephritis and emphysematous cystitis. Bacteriuria occurs frequently in individuals with diabetic cystopathy and does not require antibiotic therapy except in specific circumstances such as pregnancy or a planned urologic procedure. Susceptibility to furunculosis, superficial candidal infections, and vulvovaginitis are increased. Poor glycemic control is a common denominator in individuals with these infections. Individuals with diabetes have an increased rate of colonization of *S. aureus* in the skinfolds and nares. Individuals with diabetes also have a greater risk of postoperative wound infections that may be mitigated by perioperative protocols for insulin administration to maintain glycemic control.

DERMATOLOGIC MANIFESTATIONS

The most common skin manifestations of DM are xerosis and pruritus and are usually relieved by skin moisturizers. Protracted wound healing and skin ulcerations are also frequent complications. Diabetic dermopathy, sometimes termed *pigmented pretibial papules*, or "diabetic skin spots," begins as an erythematous macule or papule that evolves into an area of circular hyperpigmentation. These lesions result from minor mechanical trauma in the pretibial region and are more common in elderly men with DM. Bullous diseases, such as bullosa diabeticorum (shallow ulcerations or erosions in the pretibial region), are also seen. *Necrobiosis lipoidica diabeticorum* is an uncommon disorder, accompanying diabetes in predominantly young women. This usually begins in the pretibial region as an erythematous plaque or papules that gradually enlarge, darken, and develop irregular margins, with atrophic centers and central ulceration. They are often painful. Vitiligo and alopecia areata occur at increased frequency in individuals with type 1 DM. *Acanthosis nigricans* (hyperpigmented velvety plaques seen on the neck, axilla, or extensor surfaces) is sometimes a feature of severe insulin resistance and accompanying diabetes. Generalized or localized *granuloma annulare* (erythematous plaques on the extremities or trunk), *lichen planus* (violaceous papules on the cutaneous surface with or without erosions in the mouth and genitalia), and *scleredema* (areas of skin thickening on the back or neck at the site of previous superficial infections) are more common in the diabetic population. *Lipoatrophy* and *lipohypertrophy* can occur at insulin injection sites but are now unusual with the use of human insulin and avoided by rotating injection sites.

418 Hypoglycemia

Stephen N. Davis

Hypoglycemia is most commonly caused by insulin or insulin-producing drugs used to treat diabetes mellitus or by exposure to other drugs, including alcohol. However, a number of other disorders, including critical organ failure, sepsis and inanition, hormone deficiencies, non-β-cell tumors, insulinoma, inborn errors of metabolism, and prior gastric surgery, can cause hypoglycemia **(Table 418-1)**. Hypoglycemia may be documented by *Whipple's triad:* (1) symptoms consistent with hypoglycemia, (2) a low plasma glucose concentration measured with a precise method, and (3) relief of symptoms after the plasma glucose level is raised. The lower limit of the fasting plasma glucose concentration is normally ~70 mg/dL (~3.9 mmol/L), but lower venous glucose levels occur normally, late after a meal, during pregnancy, and during prolonged fasting (>24 h). Severe hypoglycemia can cause serious morbidity and increase the risk for serious cardiovascular events and mortality during and after the initial hypoglycemic episode. It should be considered in any patient with episodes of confusion, an altered level of consciousness, or a seizure.

SYSTEMIC GLUCOSE BALANCE AND GLUCOSE COUNTERREGULATION

Glucose is an obligate metabolic fuel for the brain under physiologic conditions. The brain cannot synthesize glucose or store more than a few minutes' supply as glycogen and therefore requires a continuous supply of glucose from the arterial circulation. As the arterial plasma glucose concentration falls below the physiologic range, blood-to-brain glucose transport becomes insufficient to support brain energy metabolism and function. However, multiple integrated glucose counterregulatory mechanisms normally prevent or rapidly correct hypoglycemia.

Plasma glucose concentrations are normally maintained within a relatively narrow range—roughly 70–110 mg/dL (3.9–6.1 mmol/L) in the fasting state, with transient higher excursions after a meal—despite wide variations in exogenous glucose delivery from meals and in endogenous glucose utilization by, for example, exercising muscle. Between meals and during fasting, plasma glucose levels are maintained

by endogenous glucose production, hepatic glycogenolysis, and hepatic (and renal) gluconeogenesis **(Fig. 418-1)**. Although hepatic glycogen stores are usually sufficient to maintain plasma glucose levels for ~8 h, this period can be shorter if glucose demand is increased by exercise or if glycogen stores are depleted by illness or starvation.

Gluconeogenesis normally requires low insulin levels and the presence of anti-insulin (counterregulatory) hormones together with a coordinated supply of precursors from muscle and adipose tissue to the liver and kidneys. Muscle provides lactate, pyruvate, alanine, glutamine, and other amino acids. Triglycerides in adipose tissue are broken down into fatty acids and glycerol, which is a gluconeogenic precursor. Fatty acids provide an alternative oxidative fuel to tissues other than the brain (which requires glucose).

Systemic glucose balance, maintenance of the normal plasma glucose concentration, is accomplished by a network of hormones, neural signals, and substrate effects that regulate endogenous glucose production and glucose utilization by tissues other than the brain **(Chap. 415)**. Among the regulatory factors, insulin plays a dominant role (**Table 418-2**; Fig. 418-1). As plasma glucose levels decline within the physiologic range, pancreatic β-cell insulin secretion decreases, thereby increasing hepatic glycogenolysis and hepatic (and renal) gluconeogenesis. Low insulin levels also reduce glucose utilization in peripheral tissues, inducing lipolysis and proteolysis and consequently releasing gluconeogenic precursors. Thus, a decrease in insulin secretion is the first defense against hypoglycemia.

As plasma glucose levels decline just below the physiologic range, glucose counterregulatory (plasma glucose–raising) hormones are released (Table 418-2; Fig. 418-1). Among these, pancreatic α-cell glucagon and adrenomedullary epinephrine play a primary role. Glucagon stimulates hepatic glycogenolysis and gluconeogenesis. Adrenomedullary epinephrine also stimulates hepatic glycogenolysis and gluconeogenesis (and renal gluconeogenesis) but limits peripheral uptake of glucose and stimulates lipolysis with production of glycerol and fatty acids. Epinephrine becomes critical when glucagon is deficient. When hypoglycemia is prolonged beyond ~4 h, cortisol and growth hormone also support glucose production and restrict glucose utilization to a limited amount (both mechanisms are reduced by ~80% compared to epinephrine). Thus, cortisol and growth hormone play no role in defense against acute hypoglycemia.

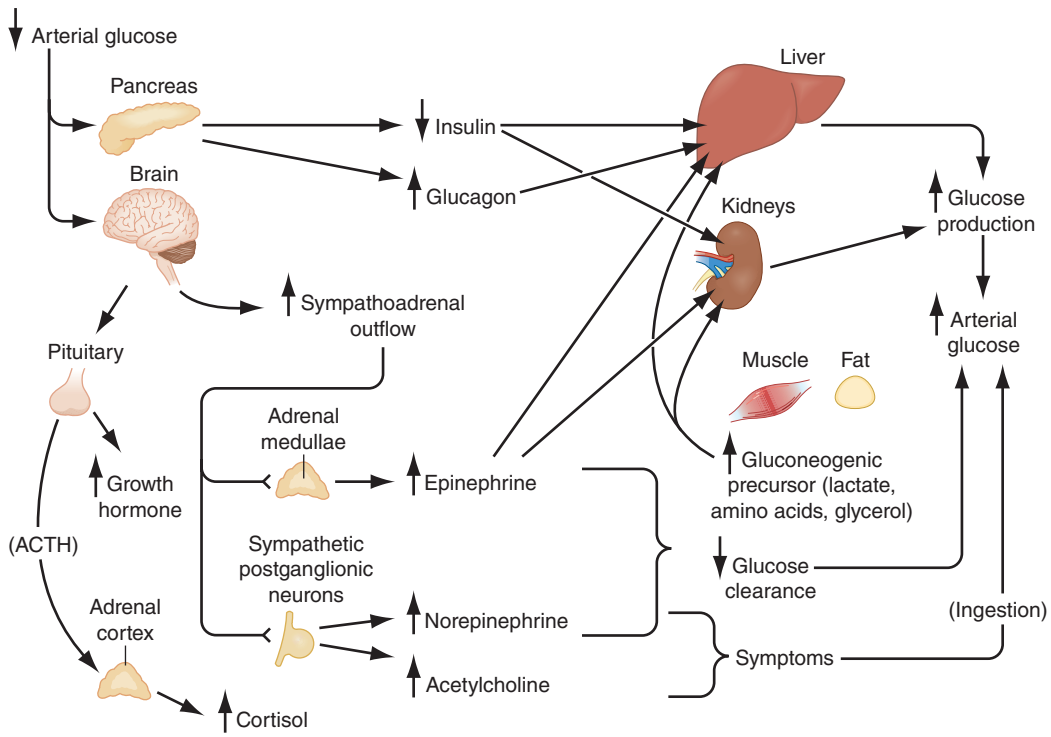

FIGURE 418-1 Physiology of glucose counterregulation: Mechanisms that normally prevent or rapidly correct hypoglycemia. In insulin-deficient diabetes, the key counterregulatory responses—suppression of insulin and increases in glucagon—are lost, and stimulation of sympathoadrenal outflow is attenuated. ACTH, adrenocorticotropic hormone.

TABLE 418-2 Physiologic Responses to Decreasing Plasma Glucose Concentrations

RESPONSE	GLYCEMIC THRESHOLD, mmoL/L (mg/dL)	PHYSIOLOGIC ↓ EFFECTS	ROLE IN PREVENTION OR CORRECTION OF HYPOGLYCEMIA (GLUCOSE COUNTERREGULATION)
↓ Insulin	4.4–4.7 (80–85)	↑ R_a (↓ R_d), increased lipolysis; ↑ FFA ↑ Glycerol	Primary glucose regulatory factor/first defense against hypoglycemia
↑ Glucagon	3.6–3.9 (65–70)	↑ R_a	Primary glucose counterregulatory factor/second defense against hypoglycemia
↑ Epinephrine	3.6–3.9 (65–70)	↑ R_a, ↓ R_d, increased lipolysis; ↑ FFA and glycerol	Third defense against hypoglycemia; critical when glucagon is deficient
↑ Cortisol and growth hormone	3.6–3.9 (65–70)	↑ R_a, ↓ R_d	Involved in defense against prolonged hypoglycemia; not critical
Symptoms	2.8–3.1 (50–55)	Recognition of hypoglycemia	Prompt behavioral defense against hypoglycemia (food ingestion)
↓ Cognition	<2.8 (<50)	—	Compromises behavioral defense against hypoglycemia

Note: R_a, rate of glucose appearance, glucose production by the liver and kidneys; R_d, rate of glucose clearance, glucose utilization relative to the ambient plasma glucose by insulin-sensitive tissues; R_d, rate of glucose disappearance, glucose utilization by insulin-sensitive tissues such as skeletal muscle. R_d by the brain is not altered by insulin, glucagon, epinephrine, cortisol, or growth hormone.

Abbreviation: FFA, free fatty acids.

As plasma glucose levels fall further, symptoms prompt behavioral defense against hypoglycemia, including the ingestion of food (Table 418-2; Fig. 418-1). The normal glycemic thresholds for these responses to decreasing plasma glucose concentrations are shown in Table 418-2. However, these thresholds are dynamic. They shift to higher-than-normal glucose levels in people with poorly controlled diabetes, who can experience symptoms of hypoglycemia when their glucose levels decline toward the normal range. On the other hand, thresholds shift to lower-than-normal glucose levels in people with recurrent hypoglycemia; i.e., patients with intensively treated diabetes or an insulinoma have symptoms at glucose levels lower than those that cause symptoms in healthy individuals.

Clinical Manifestations Neuroglycopenic manifestations of hypoglycemia are the direct result of central nervous system glucose deprivation. These features include behavioral changes, confusion, fatigue, seizure, loss of consciousness, cardiac arrhythmias, and, if hypoglycemia is severe, death. Neurogenic (or autonomic) manifestations of hypoglycemia result from the perception of physiologic changes caused by the central nervous system–mediated sympathoadrenal discharge that is triggered by hypoglycemia. They include *adrenergic* symptoms (mediated largely by norepinephrine released from sympathetic postganglionic neurons but perhaps also by epinephrine released from the adrenal medullae), such as palpitations, tremor, and anxiety, as well as *cholinergic* symptoms (mediated by acetylcholine released from sympathetic postganglionic neurons), such as sweating, hunger, and paresthesias. Clearly, these are nonspecific symptoms. Their attribution to hypoglycemia requires that the corresponding plasma glucose concentration be low and that the symptoms resolve after the glucose level is raised (as delineated by Whipple's triad).

Common signs of hypoglycemia include diaphoresis and pallor. Heart rate and systolic blood pressure are typically increased but may not be raised in an individual who has experienced repeated, recent episodes of hypoglycemia. Neuroglycopenic manifestations are often observable. Transient focal neurologic deficits occur occasionally. Permanent neurologic deficits are rare.

Etiology and Pathophysiology Hypoglycemia activates proinflammatory, procoagulant, and proatherothrombotic responses in type 1 diabetes mellitus (T1DM), type 2 diabetes mellitus (T2DM), and nondiabetic individuals. These responses increase platelet aggregation, reduce fibrinolytic balance (increase plasminogen activator inhibitor-1), and increase intravascular coagulation. Hypoglycemia also reduces protective nitric oxide–mediated arterial vasodilator mechanisms in healthy, T1DM, and T2DM individuals.

HYPOGLYCEMIA IN DIABETES

Impact and Frequency Hypoglycemia is the limiting factor in the glycemic management of diabetes mellitus. First, it causes recurrent morbidity in most people with T1DM and in many with advanced T2DM, and it is sometimes fatal. Second, it precludes maintenance of euglycemia over a lifetime of diabetes and, thus, full realization of the well-established microvascular benefits of glycemic control. Third, it causes a vicious cycle of recurrent hypoglycemia by producing hypoglycemia-associated autonomic failure—i.e., the clinical syndromes of defective glucose counterregulation and of hypoglycemia unawareness.

Hypoglycemia is a fact of life for people with T1DM if treated with insulin, sulfonylurea, or glinides. They suffer an average of two episodes of symptomatic hypoglycemia per week and at least one episode of severe, at least temporarily disabling hypoglycemia each year. An estimated 6–10% of people with T1DM die as a result of hypoglycemia. The incidence of hypoglycemia is lower in T2DM than in T1DM. However, its prevalence in insulin-requiring T2DM is surprisingly high. Recent studies have revealed a hypoglycemia prevalence approaching 70%. In fact, as patients with T2DM outnumber those with T1DM by 10- to 20-fold, the prevalence of hypoglycemia is now greater in T2DM. Hypoglycemia can occur at any hemoglobin A_{1c} (HbA_{1c}) level. Although severe hypoglycemia occurs twice as frequently at lower HbA_{1c} levels in T1DM, it still occurs at HbA_{1c} levels >8%. In insulin-requiring T2DM, severe hypoglycemia can occur at lower HbA_{1c} values but also importantly at values of 8–10%. Severe hypoglycemia in T2DM carries an increased risk of severe cardiovascular and cerebrovascular morbidity and mortality for up to 1 year after the event. The risk of severe hypoglycemia and a subsequent cardiovascular adverse event is, in fact, relatively increased when trying to improve glucose control in some T2DM individuals with persistently raised HbA_{1c} values. Therefore, improvements in glycemic control in these individuals should be performed incrementally and carefully to avoid episodes of hypoglycemia. Insulin, sulfonylureas, or glinides can cause hypoglycemia in T2DM. Metformin, thiazolidinediones, α-glucosidase inhibitors, glucagon-like peptide 1 (GLP-1) receptor agonists, sodium-glucose cotransporter 2 inhibitors, and dipeptidyl peptidase IV (DPP-IV) inhibitors do not cause hypoglycemia. However, they increase the risk when combined with a sulfonylurea, glinide, or insulin. Notably, the frequency of hypoglycemia approaches that in T1DM as persons with T2DM develop absolute insulin deficiency and require more complex treatment with insulin.

Conventional Risk Factors The conventional risk factors for hypoglycemia in diabetes are identified on the basis of relative or absolute insulin excess. This occurs when (1) insulin (or insulin secretagogue) doses are excessive, ill-timed, or of the wrong type; (2) the influx of exogenous glucose is reduced (e.g., during an overnight fast, periods of temporary fasting, or after missed meals or snacks); (3) insulin-independent glucose utilization is increased (e.g., during exercise); (4) sensitivity to insulin is increased (e.g., with improved glycemic control,

in the middle of the night, after exercise, or with increased fitness or weight loss); (5) endogenous glucose production is reduced (e.g., after alcohol ingestion); and (6) insulin clearance is reduced (e.g., in renal failure). However, these conventional risk factors alone explain a minority of episodes; other factors are typically involved.

Hypoglycemia-Associated Autonomic Failure (HAAF) While marked insulin excess alone can cause hypoglycemia, iatrogenic hypoglycemia in diabetes (T1DM and/or T2DM) is typically the result of the interplay of relative or absolute therapeutic insulin excess and compromised physiologic and behavioral defenses against falling plasma glucose concentrations (Table 418-2; **Fig. 418-2**). Defective glucose counterregulation compromises physiologic defense (particularly decrements in insulin and increments in glucagon and epinephrine), and hypoglycemia unawareness compromises behavioral defense (ingestion of carbohydrate).

DEFECTIVE GLUCOSE COUNTERREGULATION In the setting of absolute endogenous insulin deficiency, insulin levels do not decrease as plasma glucose levels fall; thus, the first defense against hypoglycemia is lost. After a few years of disease duration in T1DM, glucagon levels do not increase as plasma glucose levels fall; a second defense against hypoglycemia is lost. Reduced glucagon responses to hypoglycemia also occur in long-duration T2DM. However, pancreatic alpha cells that produce glucagon are present in the same number and size in T1DM as compared to age-matched nondiabetic individuals. Thus, the defect that restricts glucagon release during hypoglycemia in T1DM (and presumably in long-standing T2DM) appears to be a signaling defect, as glucagon responses to other physiologic stress in T1DM (e.g., exercise) are preserved. Finally, the increase in epinephrine levels, the third critical defense against acute hypoglycemia, is typically attenuated. The glycemic threshold for the sympathoadrenal (adrenomedullary epinephrine and sympathetic neural norepinephrine) response is shifted to lower plasma glucose concentrations. That shift is typically the result of recent antecedent iatrogenic hypoglycemia. In the setting of absent decrements in insulin and of absent increments in glucagon, the attenuated increment in epinephrine causes the clinical syndrome of defective glucose counterregulation. Affected patients are at ≥25-fold greater risk of severe iatrogenic hypoglycemia during intensive glycemic therapy for their diabetes than are patients with normal epinephrine responses. This functional—and potentially reversible—disorder is distinct from classic diabetic autonomic neuropathy, which also includes all of the above pathophysiologic defects, and is a structural and irreversible disorder.

HYPOGLYCEMIA UNAWARENESS The attenuated sympathoadrenal response (largely the reduced sympathetic neural response) to hypoglycemia causes the clinical syndrome of *hypoglycemia unawareness*—i.e., loss of the warning adrenergic and cholinergic symptoms that previously allowed the patient to recognize developing hypoglycemia and therefore to abort the episode by ingesting carbohydrates. Affected patients are at a sixfold increased risk of severe iatrogenic hypoglycemia during intensive glycemic therapy of their diabetes.

HAAF IN DIABETES The concept of HAAF in diabetes posits that recent antecedent iatrogenic hypoglycemia (or sleep or prior exercise) causes both defective glucose counterregulation (by reducing the epinephrine response to a given level of subsequent hypoglycemia in the setting of absent insulin and glucagon responses) and hypoglycemia unawareness (by reducing the sympathoadrenal response to a given level of subsequent hypoglycemia). These impaired responses, which can occur in individuals with either T1DM or T2DM, create a vicious cycle of recurrent iatrogenic hypoglycemia (Fig. 418-2). Hypoglycemia unawareness and, to some limited extent, the reduced epinephrine component of defective glucose counterregulation can be reversible by as little as 2–3 weeks of scrupulous avoidance of hypoglycemia in most affected patients.

On the basis of this pathophysiology, additional risk factors for hypoglycemia in diabetes include (1) absolute insulin deficiency, indicating that insulin levels will not decrease and glucagon levels will not increase as plasma glucose levels fall; (2) a history of severe hypoglycemia or of hypoglycemia unawareness, implying recent antecedent hypoglycemia, as well as prior exercise or sleep, indicating that the sympathoadrenal response will be attenuated; (3) impaired renal function resulting in reduced clearance of exogenous and endogenous insulin; (4) classical diabetic autonomic neuropathy; and (5) lower HbA_{1c} or lower glycemic goals even at elevated HbA_{1c} levels (8–10%), as they represent an increased probability of recent antecedent hypoglycemia.

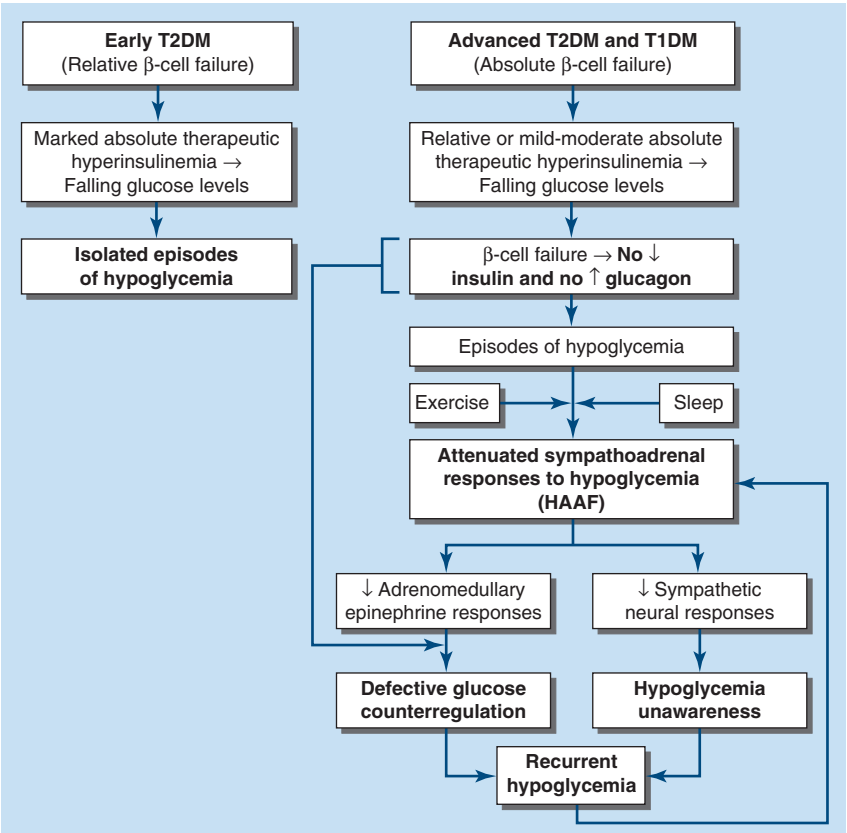

FIGURE 418-2 Hypoglycemia-associated autonomic failure (HAAF) in insulin-deficient diabetes. T1DM, type 1 diabetes mellitus; T2DM, type 2 diabetes mellitus. *(Reprinted with permission from The American Diabetes Association. Copyright 2012 by the American Diabetes Association.)*

Hypoglycemia Risk Factor Reduction Several multicenter, randomized controlled trials investigating the potential benefits of tight glucose control in either inpatient or outpatient settings have reported a high prevalence of severe hypoglycemia. In the NICE-SUGAR study, attempts to control in-hospital plasma glucose values toward physiologic levels resulted in increased mortality risk. The ADVANCE and ACCORD studies and the Veterans Affairs Diabetes Trial (VADT) also found a significant incidence of severe hypoglycemia among T2DM patients. Severe hypoglycemia with accompanying serious cardiovascular morbidity and mortality also occurred in the standard (e.g., not receiving intensified treatment) control group in all of the above studies and in another large study in prediabetic and T2DM individuals (ORIGIN). Thus, as stated above, severe hypoglycemia can and does occur at HbA_{1c} values of 8–10% in both T1DM and T2DM. Somewhat surprisingly, all three studies found little or no benefit of intensive glucose control to reduce macrovascular events in T2DM. In fact, the ACCORD study was ended early because of the increased mortality rate in the intensive glucose control arm. Whether iatrogenic

hypoglycemia was the cause of the increased mortality risk is not known. In light of these findings, some new recommendations and paradigms have been formulated. Whereas there is little debate regarding the need to reduce hyperglycemia in the hospital, the glycemic maintenance goals in critical care settings have been modified to stay between 140 and 180 mg/dL. Similar glycemic targets are also recommended in non–critically ill patients by a number of expert societies, although some recommend even more strict glucose control down to 108 mg/dL. Accordingly, the benefits of insulin therapy and reduced hyperglycemia can be obtained while the prevalence of hypoglycemia is reduced.

Similarly, evidence exists that intensive glucose control can reduce the prevalence of microvascular disease in both T1DM and T2DM. These benefits need to be weighed against the increased prevalence of hypoglycemia. Certainly, the level of glucose control (i.e., the HbA_{1c} value, symptoms of hyper- and hypoglycemia, and home glucose values) should be evaluated for each patient. Multicenter trials have demonstrated that individuals with recently diagnosed T1DM or T2DM can have better glycemic control with less hypoglycemia. In addition, there is still long-term benefit in reducing HbA_{1c} values from higher to lower, albeit still above recommended levels. Perhaps a reasonable therapeutic goal is the lowest HbA_{1c} level that does not cause severe hypoglycemia and that preserves awareness of hypoglycemia.

Recent studies have demonstrated the benefit of second-generation basal and prandial analogue insulins in reducing the risk of both nonsevere and severe hypoglycemia. The reduction of hypoglycemia occurred during both the day and night and was observed in T1DM and T2DM individuals. Addition of longer acting GLP-1 and dual GLP-1/gastric inhibitory polypeptide (GIP) receptor agonists to a basal insulin in the management of insulin-requiring T2DM has also resulted in lower hypoglycemic risk as compared to a basal insulin and a first-generation prandial insulin analogue. Pancreatic transplantation (both whole organ and islet cell) has been used in part as a treatment for severe hypoglycemia. Generally, rates of hypoglycemia are reduced after transplantation. This decrease appears to be due to increased physiologic insulin and glucagon responses during hypoglycemia.

The use of continuous glucose monitors (CGMs), either alone or in combination with continuous subcutaneous infusion via a wearable pump, offers promise as a method of reducing hypoglycemia while improving HbA_{1c}. Specifically, continuous glucose monitoring coupled with temporary discontinuation of subcutaneous insulin infusion when the monitor predicts a low glucose concentration is particularly promising. Studies investigating the use of CGM during inpatient care for both insulin-requiring pediatric and adult patients with diabetes are ongoing. Furthermore, progress utilizing a portable wearable closed-loop automated "artificial pancreas" or sensor-augmented pump therapy incorporating continuous glucose modulation of either insulin alone or bi-hormonal delivery of both insulin and glucagon has been established. Additionally, stem cell–derived β cells also offer promise of novel therapeutic interventions to reduce hypoglycemia.

Nonpharmacologic approaches of hypoglycemia risk reduction utilizing structured patient education have also been proven to be successful in T1DM and T2DM. Outpatient education consisting of adjustment of meal plans, exercise, and medications, combined with early recognition and treatment of hypoglycemia, have all been demonstrated to reduce hypoglycemic risk with even small improvements in HbA_{1c}. Other interventions to stimulate counterregulatory responses, such as selective serotonin reuptake inhibitors, β-adrenergic receptor antagonists, opiate receptor antagonists, and fructose, remain experimental and have not been assessed in large-scale clinical trials.

Thus, intensive glycemic therapy (Chap. 416) needs to be applied along with the patient's education and empowerment, frequent self-monitoring of blood glucose, flexible insulin (and other drug) regimens (including the use of insulin analogues, both short- and longer-acting), individualized glycemic goals, and ongoing professional guidance, support, and consideration of both the conventional risk factors and those indicative of compromised glucose counterregulation. Given a history of hypoglycemia unawareness, a 2- to 3-week period of scrupulous avoidance of hypoglycemia is indicated.

HYPOGLYCEMIA WITHOUT DIABETES

There are many causes of hypoglycemia (Table 418-1). Because hypoglycemia is common in insulin- or insulin secretagogue–treated diabetes, it is often reasonable to assume that a clinically suspicious episode is the result of hypoglycemia. On the other hand, because hypoglycemia is rare in the absence of relevant drug-treated diabetes (pregnancy and during severe episodes of morning sickness), it is reasonable to conclude that a hypoglycemic disorder is present only in patients in whom Whipple's triad can be demonstrated.

Particularly when patients are ill or medicated, the initial diagnostic focus should be on the possibility of drug involvement and then on critical illnesses, hormone deficiency, or non–islet cell tumor hypoglycemia. In the absence of any of these etiologic factors and in a seemingly well individual, the focus should shift to possible endogenous hyperinsulinism or accidental, surreptitious, or even malicious hypoglycemia.

Drugs Insulin and insulin secretagogues suppress glucose production and stimulate glucose utilization. Ethanol blocks gluconeogenesis but not glycogenolysis. Thus, alcohol-induced hypoglycemia typically occurs after a several-day ethanol binge during which the person eats little food, with consequent glycogen depletion. Ethanol is usually measurable in blood at the time of presentation, but its levels correlate poorly with plasma glucose concentrations. Because gluconeogenesis becomes the predominant route of glucose production during prolonged hypoglycemia, alcohol can contribute to the progression of hypoglycemia in patients with insulin-treated diabetes.

Many other drugs have been associated with hypoglycemia. These include commonly used drugs such as angiotensin-converting enzyme inhibitors and angiotensin receptor antagonists, β-adrenergic receptor antagonists, quinolone antibiotics, indomethacin, quinine, and sulfonamides.

Critical Illness Among hospitalized patients, serious illnesses such as renal, hepatic, or cardiac failure; sepsis; and inanition are second only to drugs as causes of hypoglycemia.

Rapid and extensive hepatic destruction (e.g., toxic hepatitis) causes fasting hypoglycemia because the liver is the major site of endogenous glucose production. The mechanism of hypoglycemia in patients with cardiac failure is unknown. Hepatic congestion and hypoxia may be involved. Although the kidneys are a source of glucose production, hypoglycemia in patients with renal failure is also caused by the reduced clearance of insulin (thereby inappropriately increasing insulin relative to the prevailing glucose levels) and the reduced mobilization of gluconeogenic precursors in renal failure.

Sepsis is a relatively common cause of hypoglycemia. Increased glucose utilization is induced by cytokine production in macrophage-rich tissues such as the liver, spleen, and lung. Hypoglycemia develops if glucose production fails to keep pace. Cytokine-induced inhibition of gluconeogenesis in the setting of nutritional glycogen depletion, in combination with hepatic and renal hypoperfusion, may also contribute to hypoglycemia.

Hypoglycemia can be seen with starvation. Due to brain conversion and utilization of alternative substrates, such as lactate, pyruvate, and ketone bodies, there is only a modest counterregulatory neuroendocrine and autonomic nervous system response. During periods of prolonged starvation (fasting), plasma glucose levels are lower in women as compared to men, perhaps because of loss of whole-body fat stores and subsequent depletion of gluconeogenic precursors (e.g., amino acids), necessitating increased glucose utilization.

Hormone Deficiencies Neither cortisol nor growth hormone is critical to the prevention of hypoglycemia, at least in adults. Nonetheless, hypoglycemia can occur with prolonged fasting in patients with primary adrenocortical failure (Addison's disease) or hypopituitarism. Anorexia and weight loss are typical features of chronic cortisol deficiency and likely result in glycogen depletion. Cortisol deficiency is associated with impaired gluconeogenesis and low levels of gluconeogenic precursors; these associations suggest that substrate-limited gluconeogenesis, in the setting of glycogen depletion, is the cause of

hypoglycemia. Growth hormone deficiency can cause hypoglycemia in young children. In addition to extended fasting, high rates of glucose utilization (e.g., during exercise or in pregnancy) or low rates of glucose production (e.g., after alcohol ingestion) can precipitate hypoglycemia in adults with previously unrecognized hypopituitarism.

Hypoglycemia is not a feature of the epinephrine-deficient state that results from bilateral adrenalectomy when glucocorticoid replacement is adequate, nor does it occur during pharmacologic adrenergic blockade when other glucoregulatory systems are intact. Combined deficiencies of glucagon and epinephrine play a key role in the pathogenesis of iatrogenic hypoglycemia in people with insulin-deficient diabetes, as discussed earlier. Otherwise, deficiencies of these hormones are not usually considered in the differential diagnosis of a hypoglycemic disorder.

Non–β-Cell Tumors Fasting hypoglycemia, often termed *non–islet cell tumor hypoglycemia*, occurs occasionally in patients with large mesenchymal or epithelial tumors (e.g., hepatomas, adrenocortical carcinomas, carcinoids). The glucose kinetic patterns resemble those of hyperinsulinism (see next), but insulin secretion is suppressed appropriately during hypoglycemia. In most instances, hypoglycemia is due to overproduction of an incompletely processed form of insulin-like growth factor II ("big IGF-II") that does not complex normally with circulating binding proteins and thus more readily gains access to target tissues. The tumors are usually apparent clinically, plasma ratios of IGF-II to IGF-I are high, and free IGF-II levels (and levels of pro-IGF-II [1–21]) are elevated. Curative surgery is seldom possible, but reduction of tumor bulk may ameliorate hypoglycemia. Therapy with a glucocorticoid, growth hormone, or both has also been reported to alleviate hypoglycemia. Hypoglycemia attributed to ectopic IGF-I production has been reported but is rare.

Endogenous Hyperinsulinism Hypoglycemia due to endogenous hyperinsulinism can be caused by (1) a primary β-cell disorder—typically a β-cell tumor (*insulinoma*), sometimes multiple insulinomas, or a functional β-cell disorder with β-cell hypertrophy or hyperplasia; (2) an antibody to insulin or to the insulin receptor; (3) a β-cell secretagogue such as a sulfonylurea; or perhaps (4) ectopic insulin secretion, among other very rare mechanisms. None of these causes are common.

The fundamental pathophysiologic feature of endogenous hyperinsulinism caused by a primary β-cell disorder or an insulin secretagogue is the failure of insulin secretion to fall to very low levels during hypoglycemia. This feature is assessed by measurement of plasma insulin, C-peptide (the connecting peptide that is cleaved from proinsulin to produce insulin), proinsulin, and glucose concentrations during hypoglycemia. Insulin, C-peptide, and proinsulin levels need not be high relative to normal, euglycemic values; rather, they are inappropriately high in the setting of a low plasma glucose concentration. Critical diagnostic findings are a plasma insulin concentration ≥3 μU/mL (≥18 pmol/L), a plasma C-peptide concentration ≥0.6 ng/mL (≥0.2 nmol/L), and a plasma proinsulin concentration ≥5.0 pmol/L when the plasma glucose concentration is <55 mg/dL (<3.0 mmol/L) with symptoms of hypoglycemia. A low plasma β-hydroxybutyrate concentration (≤2.7 mmol/L) and an increment in plasma glucose level of >25 mg/dL (>1.4 mmol/L) after IV administration of glucagon (1.0 mg) indicate increased insulin (or IGF) actions.

The diagnostic strategy is (1) to measure plasma glucose, insulin, C-peptide, proinsulin, and β-hydroxybutyrate concentrations and to screen for circulating oral hypoglycemic agents during an episode of hypoglycemia and (2) to assess symptoms during the episode and seek their resolution following correction of hypoglycemia by glucose (either oral or parenteral) or by IV injection of glucagon (i.e., to document Whipple's triad). This is straightforward if the patient is hypoglycemic when seen. Since endogenous hyperinsulinemic disorders usually, but not invariably, cause fasting hypoglycemia, a diagnostic episode may develop after a relatively short outpatient fast. Serial sampling during an inpatient diagnostic fast of up to 72 h or after a mixed meal is more problematic. An alternative is to give patients a detailed list of the required measurements and ask them to present to an ambulatory care center or emergency room, with the list, during a symptomatic episode. Obviously, a normal plasma glucose concentration during a symptomatic episode indicates that the symptoms are not the result of hypoglycemia.

An *insulinoma*—an insulin-secreting pancreatic islet β-cell tumor—is the prototypical cause of endogenous hyperinsulinism and therefore should be sought in patients with a compatible clinical syndrome. However, insulinoma is not the only cause of endogenous hyperinsulinism. Some patients with fasting endogenous hyperinsulinemic hypoglycemia have diffuse islet involvement with β-cell hypertrophy and sometimes hyperplasia. This pattern is commonly referred to as *nesidioblastosis*, although β cells budding from ducts are not invariably found. Other patients have a similar islet pattern but with postprandial hypoglycemia, a disorder termed *noninsulinoma pancreatogenous hypoglycemia*. Post–gastric bypass postprandial hypoglycemia, which most often follows Roux-en-Y gastric bypass, is also characterized by diffuse islet involvement and endogenous hyperinsulinism. Multiple pathophysiologic mechanisms have been suggested including exaggerated GLP-1 responses to meals resulting in hyperinsulinemia, hypoglucagonemia, and hypoglycemia. However, other mechanisms may be responsible for the relative hyperinsulinemia, such as reduced insulin clearance and reduced glucagon responses to hypoglycemia. The relevant pathogenesis has not been clearly established. However, if medical treatment with agents such as an α-glucosidase inhibitor, diazoxide, or octreotide fails, partial pancreatectomy may be required. Autoimmune hypoglycemias include those caused by an antibody to insulin that binds postmeal insulin and then gradually disassociates, with consequent late postprandial hypoglycemia. Alternatively, an insulin receptor antibody can function as an agonist. The presence of an insulin secretagogue, such as a sulfonylurea or a glinide, results in a clinical and biochemical pattern similar to that of an insulinoma but can be distinguished by the presence of the circulating secretagogue. Finally, there are reports of very rare phenomena such as ectopic insulin secretion, a gain-of-function insulin receptor mutation, and exercise-induced hyperinsulinemia.

Insulinomas are uncommon, with an estimated yearly incidence of 1 in 250,000. Because >90% of insulinomas are benign, they are a treatable cause of potentially fatal hypoglycemia. The median age at presentation is 50 years in sporadic cases, but the tumor usually presents in the third decade when it is a component of multiple endocrine neoplasia type 1 (Chap. 400). More than 99% of insulinomas are within the substance of the pancreas, and the tumors are usually small (<2.0 cm in diameter in 90% of cases). Therefore, they come to clinical attention because of hypoglycemia rather than mass effects. Computed tomography or magnetic resonance imaging detects ~70–80% of insulinomas. These methods detect metastases in the roughly 10% of patients with a malignant insulinoma. Transabdominal ultrasound often identifies insulinomas, and endoscopic ultrasound has a sensitivity of ~90%. Somatostatin receptor scintigraphy is thought to detect insulinomas in about half of patients. Selective pancreatic arterial calcium injections, with the endpoint of a sharp increase in hepatic venous insulin levels, regionalize insulinomas with high sensitivity, but this invasive procedure is seldom necessary except to confirm endogenous hyperinsulinism in the diffuse islet disorders. Intraoperative pancreatic ultrasonography almost invariably localizes insulinomas that are not readily palpable by the surgeon. Surgical resection of a solitary insulinoma is generally curative. Diazoxide, which inhibits insulin secretion, or the somatostatin analogue octreotide can be used to treat hypoglycemia in patients with unresectable tumors; everolimus, an mTOR (mammalian target of rapamycin) inhibitor, has also been successful in combination with the above approaches.

ACCIDENTAL, SURREPTITIOUS, OR MALICIOUS HYPOGLYCEMIA

Accidental ingestion of an insulin secretagogue (e.g., as the result of a pharmacy or other medical error) or even accidental administration of insulin can occur. Factitious hypoglycemia, caused by surreptitious or even malicious administration of insulin or an insulin secretagogue, shares many clinical and laboratory features with insulinoma. It is most common among health care workers, patients with diabetes or

their relatives, and people with a history of other factitious illnesses. However, it should be considered in all patients being evaluated for hypoglycemia of obscure cause. Ingestion of an insulin secretagogue causes hypoglycemia with increased C-peptide levels, whereas exogenous insulin causes hypoglycemia with low C-peptide levels, reflecting suppression of insulin secretion.

Analytical error in the measurement of plasma glucose concentrations is rare. On the other hand, hand-held and continuous glucose monitors used to guide treatment of diabetes are not quantitative instruments, particularly at low glucose levels, and should not be used for the definitive diagnosis of hypoglycemia. Even with a quantitative method, low measured glucose concentrations can be artifactual—e.g., the result of continued glucose metabolism by the formed elements of the blood ex vivo, particularly in the presence of leukocytosis, erythrocytosis, or thrombocytosis or with delayed separation of the serum from the formed elements (pseudohypoglycemia).

INBORN ERRORS OF METABOLISM CAUSING HYPOGLYCEMIA

Nondiabetic hypoglycemia also results from inborn errors of metabolism. Such hypoglycemia most commonly occurs in infancy but can also occur in adulthood. Cases in adults can be classified into those resulting in fasting hypoglycemia, postprandial hypoglycemia, and exercise-induced hypoglycemia.

Fasting Hypoglycemia Although rare, disorders of glycogenolysis can result in fasting hypoglycemia. These disorders include glycogen storage disease (GSD) of types 0, I, III, and IV and Fanconi-Bickel syndrome **(Chap. 430)**. Patients with GSD types I and III characteristically have high blood lactate levels before and after meals, respectively. Both groups have hypertriglyceridemia, but ketones are high in GSD type III. Defects in fatty acid oxidation also result in fasting hypoglycemia. These defects can include (1) defects in the carnitine cycle; (2) fatty-acid β-oxidation disorders; (3) electron transfer disturbances; and (4) ketogenesis disorders. Finally, defects in gluconeogenesis (fructose-1,6-biphosphatase) have been reported to result in recurrent hypoglycemia and lactic acidosis.

Postprandial Hypoglycemia Inborn errors of metabolism resulting in postprandial hypoglycemia are also rare. These errors include (1) glucokinase, SUR1, and Kir6.2 potassium channel mutations; (2) congenital disorders of glycosylation; and (3) inherited fructose intolerance.

Exercise-Induced Hypoglycemia Exercise-induced hypoglycemia, by definition, follows exercise. It results in hyperinsulinemia caused by increased activity of monocarboxylate transporter 1 in β cells.

APPROACH TO THE PATIENT

Hypoglycemia

In addition to the recognition and documentation of hypoglycemia as well as its treatment (often on an urgent basis), diagnosis of the hypoglycemic mechanism is critical for the selection of therapy that prevents, or at least minimizes, recurrent hypoglycemia.

RECOGNITION AND DOCUMENTATION

Hypoglycemia is suspected in patients with typical symptoms; in the presence of confusion, an altered level of consciousness, or a seizure; or in a clinical setting in which hypoglycemia is known to occur. Blood should be drawn, whenever possible, before the administration of glucose to allow documentation of a low plasma glucose concentration. Convincing documentation of hypoglycemia requires the fulfillment of Whipple's triad. Thus, the ideal time to measure the plasma glucose level is during a symptomatic episode. A normal glucose level excludes hypoglycemia as the cause of the symptoms. A low glucose level confirms that hypoglycemia is the cause of the symptoms, provided the latter resolve after the glucose level is raised. When the cause of the hypoglycemic episode is obscure, additional measurements—made while the glucose level is low and before treatment—should include plasma insulin, C-peptide, proinsulin, and β-hydroxybutyrate levels; also critical are screening for circulating oral hypoglycemic agents and assessment of symptoms before and after the plasma glucose concentration is raised.

When the history suggests prior hypoglycemia and no potential mechanism is apparent, the diagnostic strategy is to evaluate the patient as just described and assess for Whipple's triad during and after an episode of hypoglycemia. On the other hand, while it cannot be ignored, a distinctly low plasma glucose concentration measured in a patient without corresponding symptoms raises the possibility of an artifact (pseudohypoglycemia).

DIAGNOSIS OF THE HYPOGLYCEMIC MECHANISM

In a patient with documented hypoglycemia, a plausible hypoglycemic mechanism can often be deduced from the history, physical examination, and available laboratory data (Table 418-1). Drugs, particularly alcohol or agents used to treat diabetes, should be the first consideration—even in the absence of known use of a relevant drug—given the possibility of surreptitious, accidental, or malicious drug administration. Other considerations include evidence of a relevant critical illness, hormone deficiencies (less commonly), and a non-β-cell tumor that can be pursued diagnostically (rarely). Absent one of these mechanisms in an otherwise seemingly well individual, the care provider should consider endogenous hyperinsulinism and proceed with measurements and assessment of symptoms during spontaneous hypoglycemia or under conditions that might elicit hypoglycemia.

URGENT TREATMENT

If the patient is able and willing, oral treatment with glucose tablets or glucose-containing fluids, candy, or food is appropriate. A reasonable initial dose is 15–20 g of glucose. If the patient is unable or unwilling (because of neuroglycopenia) to take carbohydrates orally, parenteral therapy is necessary. IV administration of glucose (25 g) should be followed by a glucose infusion guided by serial plasma glucose measurements. If IV therapy is not practical, SC or IM glucagon (1.0 mg in adults) can be used, particularly in patients with T1DM. Because it acts by stimulating glycogenolysis, glucagon is ineffective in glycogen-depleted individuals (e.g., those with alcohol-induced hypoglycemia). Glucagon also stimulates insulin secretion and is therefore less useful in T2DM. The somatostatin analogue octreotide can be used to suppress insulin secretion in sulfonylurea-induced hypoglycemia. These treatments raise plasma glucose concentrations only transiently, and patients should therefore be urged to eat as soon as is practical to replete glycogen stores.

PREVENTION OF RECURRENT HYPOGLYCEMIA

Prevention of recurrent hypoglycemia requires an understanding of the hypoglycemic mechanism. Offending drugs should be discontinued or their doses reduced. Hypoglycemia caused by a sulfonylurea can persist for hours or even days. Underlying critical illnesses can often be treated. Cortisol and growth hormone can be replaced if levels are deficient. Surgical, radiotherapeutic, or chemotherapeutic reduction of a non–islet cell tumor can alleviate hypoglycemia even if the tumor cannot be cured; glucocorticoid or growth hormone administration also may reduce hypoglycemic episodes in such patients. Surgical resection of an insulinoma is curative; medical therapy with diazoxide or octreotide can be used if complete resection is not possible and in patients with a nontumor β-cell disorder. Partial pancreatectomy may be necessary in the latter patients. The treatment of autoimmune hypoglycemia (e.g., with glucocorticoid or immunosuppressive drugs) is problematic, but these disorders are sometimes self-limited. Failing these treatments, frequent feedings and avoidance of fasting may be required. Administration of uncooked cornstarch at bedtime or even an overnight intragastric infusion of glucose may be necessary for some patients.

419 Disorders of Lipoprotein Metabolism

Daniel J. Rader

Lipoproteins are complexes of lipids and proteins that are essential for transport of cholesterol, triglycerides (TGs), and fat-soluble vitamins in the blood. Lipoproteins play essential roles in the transport of dietary cholesterol, long-chain fatty acids, and fat-soluble vitamins from the intestine to peripheral tissues and the liver; the transport of TGs, cholesterol, and fat-soluble vitamins from the liver to peripheral tissues; and the transport of cholesterol from peripheral tissues back to the liver and intestine for excretion. Disorders of lipoprotein metabolism can be primary (caused by genetic conditions) or secondary (to other medical conditions or environmental exposures) and involve either a substantial increase or decrease in specific circulating lipids or lipoproteins. Lipoprotein disorders can have a number of clinical consequences, most notably atherosclerotic cardiovascular disease (ASCVD), and are therefore important to appropriately diagnose and treat. This chapter reviews the etiology and pathophysiology of disorders of lipoprotein metabolism and clinical approaches to their diagnosis and management.

LIPOPROTEIN STRUCTURE AND METABOLISM

Lipoproteins contain an "oil droplet" core of hydrophobic lipids (TGs and cholesteryl esters) surrounded by a shell of hydrophilic lipids (phospholipids, unesterified cholesterol) and proteins (called apolipoproteins) that interact with body fluids (Fig. 419-1). The plasma lipoproteins are divided into major classes based on their relative density: chylomicrons, very-low-density lipoproteins (VLDLs), intermediate-density lipoproteins (IDLs), low-density lipoproteins (LDLs), and high-density lipoproteins (HDLs). Each lipoprotein class comprises a family of particles that vary in density, size, and protein composition. Because lipid is less dense than water, the density of a lipoprotein particle is primarily determined by the amount of lipid per particle. Chylomicrons are the most lipid-rich and therefore least dense lipoprotein particles, whereas HDL have the least lipid and are therefore the most dense. Lipoprotein particles vary widely in size, with the largest particles (chylomicrons) being the most lipid-rich and the smallest particles (HDL) being the most dense.

The proteins associated with lipoproteins, called *apolipoproteins* (Table 419-1), are required for the assembly, structure, function, metabolism, and catabolism of lipoproteins. Apolipoproteins provide a structural basis for lipoproteins, activate enzymes important in lipoprotein metabolism, and act as ligands for cell surface receptors. ApoB is the major structural protein of chylomicrons, VLDLs, IDLs, and LDLs (collectively known as apoB-containing lipoproteins). One

TABLE 419-1 Major Apolipoproteins

APOLIPOPROTEIN	PRIMARY SOURCE	LIPOPROTEIN ASSOCIATION	FUNCTION
ApoA-I	Intestine, liver	HDL, chylomicrons	Core structural protein for HDL, promotes cellular lipid efflux via ABCA1, activates LCAT
ApoA-II	Liver	HDL, chylomicrons	Structural protein for HDL
ApoA-V	Liver	VLDL, chylomicrons	Promotes LPL-mediated triglyceride lipolysis
Apo(a)	Liver	Lp(a)	Structural protein for Lp(a)
ApoB-48	Intestine	Chylomicrons, chylomicron remnants	Core structural protein for chylomicrons
ApoB-100	Liver	VLDL, IDL, LDL, Lp(a)	Core structural protein for VLDL, LDL, IDL, Lp(a); ligand for binding to LDL receptor (except for Lp(a))
ApoC-II	Liver	Chylomicrons, VLDL, HDL	Cofactor for LPL
ApoC-III	Liver, intestine	Chylomicrons, VLDL, HDL	Inhibitor of LPL activity and remnant lipoprotein binding to receptors
ApoE	Liver	Chylomicron remnants, IDL, HDL	Ligand for binding to LDL receptor and other receptors

Abbreviations: HDL, high-density lipoprotein; IDL, intermediate-density lipoprotein; LCAT, lecithin-cholesterol acyltransferase; LDL, low-density lipoprotein; Lp(a), lipoprotein(a); LPL, lipoprotein lipase; VLDL, very-low-density lipoprotein.

molecule of apoB, either apoB-48 (chylomicrons) or apoB-100 (VLDL, IDL, or LDL), is present on each lipoprotein particle. The human liver synthesizes the full-length apoB-100 (one of the largest proteins in humans), whereas the intestine makes the shorter apoB-48, which is derived from transcription of the same *APOB* gene after posttranscriptional mRNA editing. HDLs lack apoB and have different apolipoproteins that define this lipoprotein class, most importantly apoA-I, which is synthesized in both the liver and intestine and is found on virtually all HDL particles. ApoA-II is the second most abundant HDL apolipoprotein and is on approximately two-thirds of the HDL particles. ApoC-II, apoC-III, and apoA-V regulate the metabolism of TG-rich lipoproteins. ApoE plays a critical role in the metabolism and clearance of TG-rich particles. Most apolipoproteins, other than apoB, exchange actively among lipoprotein particles in the blood. Apolipoprotein(a) [apo(a)] is a distinctive apolipoprotein that results in the formation of a lipoprotein known as lipoprotein(a) [Lp(a)], which is discussed more below.

TRANSPORT OF INTESTINALLY DERIVED DIETARY LIPIDS BY CHYLOMICRONS

Chylomicrons play a critical role in the efficient transport of absorbed dietary lipids from the intestine to tissues that require fatty acids for energy or storage and then return of cholesterol, lipids, and fat-soluble vitamins to the liver **(Fig. 419-2)**. Dietary lipids are hydrolyzed by lipases within the intestinal lumen and emulsified with bile acids to form micelles. Dietary cholesterol, fatty acids, and fat-soluble vitamins are absorbed in the proximal small intestine. Cholesterol and retinol are esterified (by the addition of a fatty acid) in the enterocyte to form cholesteryl esters and retinyl esters, respectively. Longer-chain fatty acids (>12 carbons) are incorporated into TGs and packaged with apoB-48, phospholipids, cholesteryl esters, retinyl esters, and α-tocopherol (vitamin E) in a process that requires the action of the microsomal TG transfer protein (MTP) to form chylomicrons. Nascent chylomicrons are secreted into the intestinal lymph and delivered via the thoracic duct directly to the systemic circulation, where they are extensively processed by peripheral tissues before reaching the liver. The particles encounter lipoprotein lipase (LPL), which is transported from parenchymal cells and anchored to the luminal surface of the endothelium by the protein GPIHBP1 of capillaries in tissues, particularly adipose, heart, and skeletal muscle (Fig. 419-2). ApoC-II and apoA-V are apolipoproteins that are transferred to circulating chylomicrons from HDL in the postprandial state; apoC-II acts as a required cofactor for LPL activation, and apoA-V serves as a facilitator of LPL activity. The TGs in chylomicrons are hydrolyzed by LPL, and free fatty acids are released and taken up by adjacent myocytes or adipocytes and are either oxidized to generate energy or reesterified and stored as TG. Some of the released free fatty acids bind albumin before entering cells and are transported to other tissues, especially the liver. The chylomicron particle progressively shrinks in size as the hydrophobic TG core is hydrolyzed and the excess hydrophilic lipids (cholesterol and phospholipids) and apolipoproteins on the particle surface are transferred to HDL, ultimately creating chylomicron remnants.

Chylomicron remnants contain apoB-48, which lacks the region in apoB-100 that binds to the LDL receptor. Nevertheless, they are rapidly removed from the circulation by the liver through a process that critically requires apoE as a ligand for receptors in the liver. Few, if any, chylomicrons or chylomicron remnants are generally present in the blood after a 12-h fast, except in patients with certain disorders of lipoprotein metabolism as described below.

TRANSPORT OF HEPATICALLY DERIVED LIPIDS BY VLDL AND LDL

Another key role of lipoproteins is the transport of hepatic lipids from the liver to the periphery (Fig. 419-2) to provide an energy source during fasting and to deliver fat-soluble vitamins to key tissues. During the fasting state, lipolysis of adipose TGs generates fatty acids that are transported to the liver, and the liver is also capable of synthesizing fatty acids through de novo lipogenesis. These fatty acids are esterified by the liver into TGs, which are packaged into VLDL particles along with apoB-100, phospholipids, cholesteryl esters, and vitamin E in a process that also requires MTP. VLDL thus resemble chylomicrons in that they are "triglyceride-rich lipoproteins," but they contain apoB-100 rather than apoB-48, are smaller and less buoyant, and have a higher ratio of cholesterol to TG (~1 mg of cholesterol for every 5 mg of TG, whereas in chylomicrons, this ratio is closer to ~1:8). After secretion by the liver into the plasma, the circulating TGs in VLDL are hydrolyzed by LPL. After the relatively TG-depleted VLDL remnants dissociate from LPL, they are referred to as IDLs, which contain roughly similar amounts of cholesterol and TG by mass. The liver removes ~40–60% of IDL by receptor-mediated endocytosis via binding to apoE, which is acquired through transfer of this protein from HDL. The remainder of IDL is further remodeled by hepatic lipase (HL) to form LDL. During this process, phospholipids and TGs in the particle are hydrolyzed, and most of the remaining apolipoproteins except apoB-100 are transferred to other lipoproteins. LDL is primarily a by-product of fatty acid energy transport by VLDL with little true physiologic role; one exception is that LDL may be partially responsible for delivery of vitamin E to the retina and brain. LDL is ultimately removed from the circulation by receptor-mediated endocytosis (primarily via the LDL receptor) in the liver, with a region of apoB-100 serving as the specific ligand for binding to the LDL receptor. It should be noted that apoB-48 does not contain the LDL receptor-binding ligand region, and therefore, clearance of apoB-48-containing chylomicron remnants is dependent on apoE-mediated clearance as noted above. Some LDL particles are lipolytically processed to small dense LDL particles that are believed to be especially atherogenic.

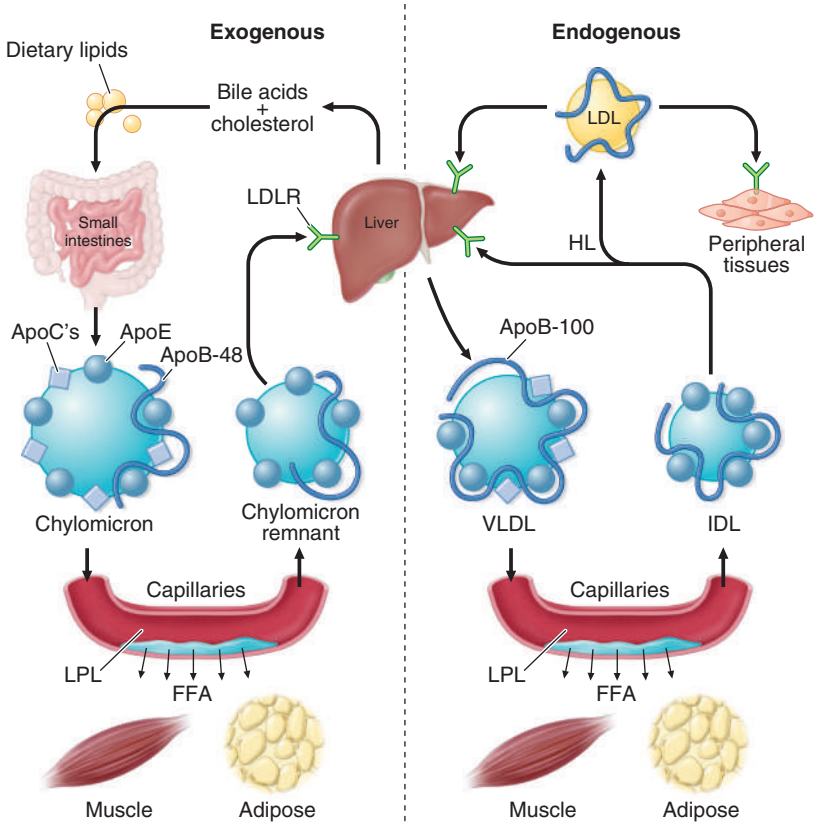

FIGURE 419-2 The exogenous and endogenous lipoprotein metabolic pathways. The exogenous pathway transports dietary lipids to the periphery and the liver. The endogenous pathway transports hepatic lipids to the periphery. FFA, free fatty acid; HL, hepatic lipase; IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; LDLR, low-density lipoprotein receptor; LPL, lipoprotein lipase; VLDL, very-low-density lipoprotein.

Lp(a) is a lipoprotein similar to LDL in lipid and protein composition, but it contains an additional distinctive protein called apo(a). Apo(a) is synthesized in the liver and attached to apoB-100 by a disulfide linkage. The major site of clearance of Lp(a) is the liver, but the uptake pathway is not known. Lp(a) is now established as causal factor for ASCVD and aortic stenosis, and an elevated level of Lp(a) serves as an independent risk factor and merits more aggressive therapy to reduce LDL cholesterol levels (see below).

HDL METABOLISM AND REVERSE CHOLESTEROL TRANSPORT

All nucleated cells synthesize cholesterol, but only hepatocytes and enterocytes can effectively excrete cholesterol from the body, into either the bile or the gut lumen, respectively. In the liver, cholesterol is secreted into the bile, either directly or after conversion to bile acids. Cholesterol in peripheral cells is transported from the plasma membranes of peripheral cells to the liver and intestine by a process termed *reverse cholesterol transport* that is facilitated by HDL **(Fig. 419-3)**.

Nascent HDL particles are synthesized by the intestine and the liver. Newly secreted apoA-I rapidly acquires phospholipids and unesterified cholesterol from its site of synthesis (intestine or liver) via cellular efflux promoted by the membrane protein ATP-binding cassette protein A1 (ABCA1). This process results in the formation of discoidal HDL particles, which then recruit additional unesterified cholesterol from cells or circulating lipoproteins. Within the HDL particle, the cholesterol is esterified to cholesteryl ester (CE) through the addition of a fatty acid by lecithin-cholesterol acyltransferase (LCAT), a plasma enzyme associated with HDL; the hydrophobic CE forms the core of the mature HDL particle. As HDL acquires more CE, it becomes spherical, and additional apolipoproteins and lipids are transferred to the particles from the surfaces of chylomicrons and VLDLs during lipolysis.

HDL cholesterol in the blood is transported to hepatocytes by two major pathways. HDL CE can be "selectively" taken up by hepatocytes via the scavenger receptor class B1 (SR-B1), a cell surface HDL receptor that mediates the selective transfer of CE from HDL with subsequent dissociation and "recycling" of the HDL particle. In addition, HDL CE can be transferred to apoB-containing lipoproteins in exchange for TG by the cholesteryl ester transfer protein (CETP). The CE esters are then removed from the circulation by LDL receptor–mediated endocytosis. HDL-derived CE taken up by the hepatocyte through these pathways is hydrolyzed, and much of the cholesterol is ultimately excreted directly into the bile or converted to bile acids with excretion to bile, providing a biliary route into the intestinal lumen. There is also evidence that, under certain conditions, HDL cholesterol can be transported directly into the intestinal lumen without requiring a transhepatobiliary route, a process known as transintestinal cholesterol excretion.

HDL particles undergo extensive remodeling within the plasma compartment by a variety of lipid transfer proteins and lipases. The phospholipid transfer protein (PLTP) transfers phospholipids from other lipoproteins to HDL or among different classes of HDL particles and is a regulator of HDL metabolism. After CETP- and PLTP-mediated lipid exchange, the TG-enriched HDL becomes a much better substrate for HL, which hydrolyzes the TGs and phospholipids to generate smaller HDL particles. A related enzyme called endothelial lipase (EL) hydrolyzes HDL phospholipids, generating smaller HDL particles that are catabolized faster. Remodeling of HDL influences the metabolism, function, and plasma concentrations of HDL.

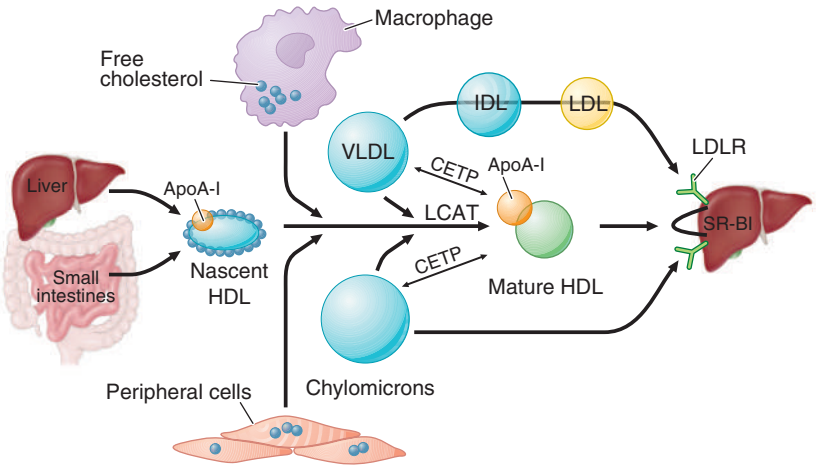

FIGURE 419-3 High-density lipoprotein (HDL) metabolism and reverse cholesterol transport. The HDL pathway transports excess cholesterol from the periphery back to the liver for excretion in the bile. The liver and the intestine produce nascent HDLs. Free cholesterol is acquired from macrophages and other peripheral cells and esterified by lecithin-cholesterol acyltransferase (LCAT), forming mature HDLs. HDL cholesterol can be selectively taken up by the liver via SR-BI (scavenger receptor class BI). Alternatively, HDL cholesteryl ester can be transferred by cholesteryl ester transfer protein (CETP) from HDLs to very-low-density lipoproteins (VLDLs) and chylomicrons, which can then be taken up by the liver. IDL, intermediate-density lipoprotein; LDL, low-density lipoprotein; LDLR, low-density lipoprotein receptor.

SCREENING

Dyslipidemia is an important causal factor in ASCVD, and treatment has been proven to substantially reduce cardiovascular risk. Therefore, all adults (and many children) should be actively screened for plasma lipids. A lipid panel should be measured, preferably after an overnight fast. In most clinical laboratories, the total cholesterol and TGs in the plasma are measured enzymatically, and then after precipitation of apoB-containing lipoproteins, the cholesterol in the supernatant is measured to determine the HDL cholesterol (HDL-C). The LDL cholesterol (LDL-C) is then estimated using the following equation (the Friedewald formula):

$$\text{LDL-C} = \text{total cholesterol} - (\text{TG}/5) - \text{HDL-C}$$

(The VLDL cholesterol content is estimated by dividing the plasma TG by 5, reflecting the ratio of TG to cholesterol in VLDL particles.) This formula is reasonably accurate if test results are obtained on fasting plasma and if the TG level does not exceed ~200 mg/dL; by convention, it cannot be used if the TG level is >400 mg/dL. LDL-C can be directly measured by a number of methods. The non-HDL-C can be easily calculated by subtracting the HDL-C from the total cholesterol. It has the advantage of incorporating the cholesterol contained within VLDL and IDL, which in most cases is also atherogenic and associated with increased ASCVD risk. There is increasing evidence that measurement of plasma apoB levels may provide a better assessment of cardiovascular risk than the LDL-C level, and even the non-HDL-C level, and is recommended by some experts. While this has not yet become standard clinical practice, the data supporting the use of apoB as a risk marker and guide to therapeutic intervention are quite strong. There is also increasing interest in Lp(a), an independent ASCVD risk factor that is highly heritable and may be helpful in risk stratification. In patients with evidence of dyslipidemia, further evaluation and treatment are based on evidence of preexisting ASCVD and clinical assessment of cardiovascular risk using risk calculators such as the American Heart Association (AHA)/American College of Cardiology (ACC) risk calculator as well as, in some cases, based on additional approaches to risk assessment such as apoB and Lp(a) (see "Approach to the Patient" for more detailed discussion).

DISORDERS ASSOCIATED WITH ELEVATED APOB-CONTAINING LIPOPROTEINS

Disorders of lipoprotein metabolism that cause elevated levels of apoB-containing lipoproteins are among the most common and clinically important of the dyslipoproteinemias. They are generally characterized by increased plasma levels of total cholesterol, accompanied by increased TGs, LDL-C, or both. Many patients with hyperlipidemia have some combination of genetic predisposition (often polygenic) and medical

or environmental contribution (medical condition, diet, lifestyle, or drug). Many, but not all, patients with hyperlipidemia are at increased risk for ASCVD, which is the primary reason for making the diagnosis, as intervention can substantially reduce this risk. In addition, patients with severe hypertriglyceridemia may be at risk for acute pancreatitis and require intervention to reduce this risk.

Although hundreds of proteins influence lipoprotein metabolism, and genetic variants in most of the genes that encode them interact with each other and the environment to produce dyslipidemia, there are a limited number of discrete "nodes" or pathways that regulate lipoprotein metabolism and are dysfunctional in specific dyslipidemias. These include (1) lipolysis of TG-rich lipoproteins by LPL; (2) receptor-mediated uptake of apoB-containing lipoproteins by the liver; (3) cellular cholesterol metabolism in the hepatocyte and the enterocyte; (4) assembly and secretion of VLDLs by the liver; and (5) neutral lipid transfer and phospholipid hydrolysis in the plasma. Primary genetic disorders of lipoprotein metabolism caused by single-gene mutations (Table 419-2) have taught us a great deal about the physiologic roles of specific proteins in these pathways in humans and are clinically important to diagnose and treat.

SEVERE HYPERTRIGLYCERIDEMIA

Severe hypertriglyceridemia (HTG) is defined by fasting TG levels >500 mg/dL and is usually accompanied by moderately elevated total cholesterol levels and reduced levels of HDL-C, usually without important elevation in LDL-C or apoB. It is medically important because it is associated with risk of acute pancreatitis and, in some cases, is also associated with increased risk of ASCVD. Severe HTG is usually caused by impaired lipolysis of TGs in TG-rich lipoproteins (TRLs) by the enzyme LPL. LPL is synthesized by adipocytes, skeletal myocytes, and cardiomyocytes, and its posttranslational maturation and folding require the action of lipase maturation factor 1 (LMF1). After secretion, it is transported from the subendothelial to the vascular endothelial surfaces by GPIHPB1, which docks it to the endothelial surface. ApoC-II is a required cofactor for LPL, and apoA-V promotes LPL activity, and both are transported to the bound LPL on the TRLs. Single-gene Mendelian disorders that reduce LPL have been described (Table 419-3) as reviewed below; the majority of patients with severe HTG have a polygenic predisposition to secondary factors like obesity or insulin resistance.

Primary (Genetic) Causes of Severe Hypertriglyceridemia

• **FAMILIAL CHYLOMICRONEMIA SYNDROME (FCS)** LPL is required for the hydrolysis of TGs in chylomicrons and VLDLs. Genetic deficiency or inactivity of LPL results in impaired lipolysis and profound elevations in plasma TGs, mostly in chylomicrons. While chylomicronemia predominates, in fact, these patients often have elevated plasma levels of VLDL as well. The fasting plasma is turbid, and if left undisturbed for several hours, the chylomicrons float to the top and form a creamy supernatant layer. Fasting TG levels are >500 mg/dL and usually >1000 mg/dL. Because chylomicrons contain cholesterol, fasting total cholesterol levels are also elevated. There are five genes in which mutations can result in FCS (Table 419-2). FCS has an estimated frequency of ~1 in 200,000–300,000, although its true prevalence is unknown. The most common molecular cause of FCS involves mutations in the *LPL* gene. *LPL deficiency* has autosomal recessive inheritance (loss-of-function mutations in both alleles). Heterozygotes with *LPL* mutations often have moderate elevations in plasma TG levels and increased risk for coronary heart disease (CHD). FCS can also be caused by mutations in genes that affect LPL processing or activity. For example, apoC-II is a required cofactor for LPL. *APOC2 deficiency* due to loss-of-function mutations in both *APOC2* alleles results in functional lack of LPL activity and severe hyperchylomicronemia that is indistinguishable from LPL deficiency. It is also recessive in inheritance pattern and much rarer than LPL deficiency. Another apolipoprotein, apoA-V, facilitates the association of TRLs with LPL and promotes hydrolysis of the TGs. Individuals harboring loss-of-function mutations in both *APOA5* alleles causing *APOA5 deficiency* develop a form of FCS. GPIHBP1 is required for transport and tethering of LPL to the endothelial luminal surface. Homozygosity for mutations in *GPIHBP1* that interfere with its synthesis or folding causes FCS. Autoantibodies to GPIHBP1 have also been reported to cause severe hyperchylomicronemia. Finally, *LMF1* is required for appropriate processing and folding of LPL, and biallelic loss-of-function mutations can cause FCS.

FCS can present in childhood or adulthood with severe abdominal pain due to acute pancreatitis. In this setting, the diagnosis should be suspected if a fasting TG level is >500 mg/dL. Eruptive xanthomas, which are small, yellowish-white papules, may appear in clusters on the back, buttocks, and extensor surfaces of the arms and legs. On funduscopic examination, the retinal blood vessels may be opalescent (lipemia retinalis). Hepatosplenomegaly is sometimes noted as a result of uptake of circulating chylomicrons by reticuloendothelial cells in the liver and spleen. Premature ASCVD is not generally a feature of FCS.

The diagnosis of FCS is a clinical diagnosis based on persistence and severity of HTG, with a history of acute pancreatitis or eruptive xanthomas increasing the suspicion. While LPL activity can be measured in "postheparin plasma" obtained after an IV heparin injection to release the endothelial-bound LPL, this assay is not widely available. Genetic testing of a panel of candidate FCS genes can be used to confirm the diagnosis but is not required for making the clinical diagnosis.

Because of the risk of pancreatitis, it is important to consider the diagnosis and institute therapeutic interventions in FCS. The goal is to prevent pancreatitis by reducing fasting TG levels to <500 mg/dL. Consultation with a registered dietician familiar with this disorder is essential. Dietary fat intake should be markedly restricted (to as little as 15 g/d), often with fat-soluble vitamin supplementation. Strict adherence to dietary fat restriction can be successful at controlling the chylomicronemia; fish oils or fibrates (such as fenofibrate) may be tried but are unlikely to be effective. Promising therapeutic approaches include the silencing of *APOC3* or ANGPTL3 in the liver. In patients with *APOC2* deficiency, apoC-II can be provided exogenously by infusing fresh-frozen plasma to resolve the chylomicronemia in the setting of severe acute pancreatitis. Management of patients with FCS is particularly challenging during pregnancy when VLDL production is increased.

FAMILIAL PARTIAL LIPODYSTROPHY (FPLD) FPLD is a genetic condition in which the generation of adipose tissue in certain fat depots is impaired and in others is excessive. FPLD is an underrecognized monogenic cause of severe HTG, which is likely due to both increased lipid synthesis and VLDL production, as well as reduced LPL-mediated clearance of TRLs. FPLD is typically a dominantly inherited disorder caused by mutations in several different genes, including lamin A/C (*LMNA*), PPARγ (*PPARG*), perilipin (*PLIN1*), *AKT2*, and *ADRA2A* (Table 419-2). FPLD is characterized by loss of subcutaneous fat in the extremities and buttocks, often accompanied by increased visceral fat. Because of the reduced or absent subcutaneous fat in the arms and legs, patients are often described as having a "muscular" appearance. In addition to severe HTG, FPLD patients usually have insulin resistance, often quite severe, accompanied by type 2 diabetes and hepatosteatosis. Pancreatitis secondary to HTG can be a complication; in addition, ASCVD risk is substantially increased in FPLD patients. The diagnosis of FPLD is a clinical diagnosis based on the constellation of metabolic findings accompanied by the distinctive distribution of adipose tissue. Genetic testing of a panel of candidate FPLD genes can be used to confirm the diagnosis but is not required for making the clinical diagnosis, and a negative result does not rule out the diagnosis. Because FPLD is a dominant disorder, the finding of a causal mutation should lead to family-based screening.

The dyslipidemia of FPLD can be difficult to manage clinically. Patients should be treated aggressively not only to reduce TG levels but also with statins and, if necessary, additional LDL-lowering therapies to reduce atherogenic lipoproteins. The insulin-resistant diabetes often requires aggressive management as well. Some patients have progression of fatty liver disease to metabolic-associated steatohepatitis, fibrosis, and cirrhosis. A different group of very rare patients have congenital generalized lipodystrophy, a recessive disorder caused by mutations in the *AGPAT2* and *BSCL2* genes. These patients have nearly complete absence of subcutaneous fat, accompanied by profound

TABLE 419-2 Primary Dyslipoproteinemias Caused by Known Single-Gene Mutations

GENETIC DISORDER	GENES MUTATED	LIPOPROTEINS AFFECTED	CLINICAL FINDINGS	GENETIC TRANSMISSION	ESTIMATED PREVALENCE
Severe Hypertriglyceridemia					
Familial chylomicronemia syndrome (FCS)	Biallelic LoF mutations in: *LPL, APOC2, APOA5, GPIHBP1, LMF1*	Elevated: Chylomicrons, VLDL Reduced: HDL	Pancreatitis, eruptive xanthomas, hepatosplenomegaly	AR	~1/200,000–300,000
Familial partial lipodystrophy (FPLD)	Heterozygous LoF mutations in: *LMNA, PPARG, PLIN1, AKT2, ADRA2A*	Elevated: Chylomicrons, VLDL, LDL Reduced: HDL	Insulin resistance, fatty liver disease, pancreatitis, central obesity, lack of subcutaneous adipose in extremities	AD	<1/1,000,000
Hypercholesterolemia					
Familial hypercholesterolemia (FH)	Heterozygous LoF mutations in *LDLR*	Elevated: LDL	Tendon xanthomas, premature atherosclerotic cardiovascular disease (ASCVD)	AD	~1/250
Familial defective apoB-100 (FDB)	Heterozygous LoF receptor binding region mutations in *APOB*	Elevated: LDL	Tendon xanthomas, premature ASCVD	AD	~1/1500
Autosomal dominant hypercholesterolemia (ADH), type 3	Heterozygous GoF mutations in *PCSK9*	Elevated: LDL	Tendon xanthomas, premature ASCVD	AD	<1/1,000,000
Autosomal recessive hypercholesterolemia (ARH)	Biallelic LoF mutations in *LDLRAP1*	Elevated: LDL	Tendon xanthomas, premature ASCVD	AR	<1/1,000,000
Sitosterolemia	Biallelic LoF mutations in *ABCG5, ABCG8*	Elevated: LDL	Tendon xanthomas, premature ASCVD	AR	<1/1,000,000
Lysosomal acid lipase deficiency	Biallelic LoF mutations in *LIPA*	Elevated: LDL Reduced: HDL	Fatty liver disease, micronodular cirrhosis	AR	<1/1,000,000
Mixed Dyslipidemia					
Familial dysbetalipoproteinemia (FDBL)	Biallelic carriers of the *APOE2* variant	Elevated: Chylomicron remnants, IDL	Palmar and tuberoeruptive xanthomas, premature ASCVD	AR	~1/10,000
Hepatic lipase deficiency	Biallelic LoF mutations in *LIPC*	Elevated: Chylomicron remnants, IDL, HDL	Premature ASCVD	AR	<1/1,000,000
Familial Hypolipidemia Syndromes					
Abetalipoproteinemia	Biallelic LoF mutations in *MTTP*	Absent: LDL Reduced: TG, HDL	Spinocerebellar degeneration, retinal degeneration	AR	<1/1,000,000
Familial hypobetalipoproteinemia	Heterozygous truncating mutations in *APOB*	Reduced: LDL	Fatty liver, reduced risk of ASCVD	AD	<1/1,000,000
Familial PCSK9 deficiency	Heterozygous LoF mutations in *PCSK9*	Reduced: LDL	Reduced risk of ASCVD	AD	~1/1,000
Familial combined hypolipidemia	Heterozygous LoF mutations in *ANGPTL3*	Reduced: TG, LDL, HDL	Reduced risk of ASCVD	AD	<1/1,000,000
Primary Low HDL Cholesterol Syndromes					
ApoA-I deletions/ mutations	Heterozygous structural mutations in *APOA1*	Reduced: HDL	Variable depending on mutation: premature ASCVD, systemic amyloidosis	AD	<1/1,000,000
Tangier disease	Biallelic LoF mutations in *ABCA1*	Nearly absent: HDL Reduced: LDL Elevated: TG	Peripheral neuropathy, hepatosplenomegaly	AR	<1/1,000,000
Familial LCAT deficiency (FLD); fish eye disease (FED)	Biallelic LoF mutations in *LCAT*	Markedly reduced: HDL	Corneal opacities (both FLD and FED), progressive chronic kidney disease (FLD only)	AR	<1/1,000,000

Abbreviations: AD, autosomal dominant; apo, apolipoprotein; AR, autosomal recessive; ARH, autosomal recessive hypercholesterolemia; CHD, coronary heart disease; GoF, gain of function; HDL, high-density lipoprotein; IDL, intermediate-density lipoprotein; LCAT, lecithin-cholesterol acyltransferase; LDL, low-density lipoprotein; LoF, loss of function; LPL, lipoprotein lipase; PVD, peripheral vascular disease; TG, triglyceride; VLDL, very-low density lipoprotein.

leptin deficiency, insulin resistance, severe HTG, and accumulation of TGs in multiple tissues including the liver. Patients with generalized lipodystrophy can be effectively treated with recombinant leptin administration, which often manages the multiple metabolic issues in these patients.

Multifactorial Severe Hypertriglyceridemia Most patients with severe HTG do not have a single-gene mutation but instead have a multifactorial etiology that includes genetics and environment. The prevalence of this phenotype is ~1 in 1000. HTG often runs in families, and the term *familial HTG* has been employed; however, except for the

TABLE 419-3 Secondary Causes of Altered Lipid and Lipoprotein Levels

	LDL-C		HDL-C		LP(a) ELEVATED
TG ELEVATED	ELEVATED	REDUCED	ELEVATED	REDUCED	
High-carbohydrate diet	Hypothyroidism	Vegan diet	High-fat diet	Hypertriglyceridemia	Chronic kidney disease
Alcohol	Cholestasis	Malabsorption	Alcohol	Vegan diet	Nephrotic syndrome
Obesity	Nephrotic syndrome	Malnutrition	Exercise	Malabsorption	Inflammation
Insulin resistance	Cushing's syndrome	Severe liver disease	Drugs: estrogen, phenytoin	Malnutrition	Menopause
Type 2 diabetes	Acute intermittent porphyria	Gaucher's disease		Sedentary lifestyle	Orchidectomy
Lipodystrophy	Drugs: corticosteroids, cyclosporin, sirolimus, carbamazepine	Chronic infectious disease		Smoking	Hypothyroidism
Chronic kidney disease		Hyperthyroidism		Obesity	Acromegaly
Nephrotic syndrome				Gaucher's disease	Drugs: growth hormone, isotretinoin
Viral hepatitis				LAL deficiency	
Sepsis				Drugs: anabolic steroids, testosterone, beta blockers	
Cushing's syndrome					
Acromegaly					
Glycogen storage disease					
Pregnancy					
Drugs: estrogen, glucocorticoids, isotretinoin, bexarotene, other retinoids, beta blockers, bile acid binding resins					

Abbreviations: HDL-C, high-density lipoprotein cholesterol; LAL, lysosomal acid lipase; LDL-C, low-density lipoprotein cholesterol; Lp(a), lipoprotein(a); TG, triglyceride.

genes in which mutations cause FCS or FPLD, reviewed above, no other classic Mendelian causes of HTG have been identified to date. Instead, extensive human genetic studies have clearly established a polygenic basis to this phenotype that consists of two categories: (1) rare heterozygous variants in the five genes discussed earlier that cause FCS in the homozygous state, and (2) a high burden of common variants that have small individual effects at raising TGs. Patients who inherit some combination of rare and common TG-raising alleles often have environmental factors that exacerbate their HTG. These "secondary" factors are reviewed in detail below, but the quantitatively most important factors promoting HTG include obesity, type 2 diabetes, insulin resistance, high-carbohydrate diet, and alcohol use. Multifactorial HTG is characterized by elevated fasting TGs but average to below average LDL-C levels and low HDL-C levels; apoB levels are not generally elevated. This condition is not generally associated with a significantly increased risk of ASCVD. However, if the HTG is exacerbated by environmental factors, medical conditions, or drugs, the TGs can rise to a level at which acute pancreatitis is a risk. Indeed, management of patients with this condition is mostly focused on reduction of TGs to prevent pancreatitis. It is important to consider and rule out secondary causes of the HTG. Patients who are at high risk for ASCVD due to other risk factors should be treated with statin therapy. In patients who are otherwise not at high risk for ASCVD, lipid-lowering drug therapy can frequently be avoided with appropriate dietary and lifestyle changes. Patients with plasma TG levels >500 mg/dL after a trial of diet and exercise should be considered for drug therapy with a fibrate or fish oil to reduce TGs in order to prevent pancreatitis. These patients should also be carefully evaluated for ASCVD risk and may be candidates for statin therapy to further reduce cholesterol and cardiovascular risk.

HYPERCHOLESTEROLEMIA (ELEVATED LDL-C)

Elevated LDL-C is common and is medically important because it is associated with risk of premature ASCVD. Elevated LDL-C is often caused by impaired uptake of LDL by the liver. As discussed above, the LDL receptor is the major receptor responsible for uptake of LDL, and most causes of elevated LDL-C converge on reduced expression or activity of the LDL receptor in the liver. One major environmental factor that reduces LDL receptor activity is a diet high in saturated and trans fats. Other medical conditions that reduce LDL receptor activity include hypothyroidism and estrogen deficiency. The diagnosis of familial hypercholesterolemia involving several genes that influence LDL clearance should be considered in patients with LDL-C levels >190 mg/dL (Table 419-2). However, the majority of patients with elevated LDL-C have a polygenic predisposition exacerbated by secondary factors like a diet high in saturated and trans fats.

Primary (Genetic) Causes of Elevated LDL-C • **FAMILIAL HYPERCHOLESTEROLEMIA (FH)** FH is an autosomal dominant disorder characterized by elevated plasma levels of LDL-C usually with relatively normal TG levels. FH is caused by mutations that lead to reduced function of the LDL receptor, with the most common being mutations in the *LDLR* gene itself. The reduction in LDL receptor activity in the liver results in a reduced rate of clearance of LDL from the circulation. The plasma level of LDL increases to a level such that the rate of LDL production equals the rate of LDL clearance by residual LDL receptor as well as non-LDL receptor mechanisms. Individuals with two mutated *LDLR* alleles (homozygotes or compound heterozygotes) have much higher LDL-C levels than those with one mutant allele, causing a condition known as *homozygous FH*.

Although mutations in *LDLR* are the most common cause of FH (and originally the term *FH* was used specifically for patients with *LDLR* mutations), mutations in at least two other genes, *APOB* and *PCSK9*, can also cause FH. ApoB-100 is the critical structural protein in LDL and contains a domain that serves as the ligand for binding to the LDL receptor. Mutations in the LDL receptor–binding domain of apoB-100 reduce the affinity of apoB/LDL binding to the LDL receptor, such that LDL is removed from the circulation at a reduced rate. This condition has also been termed *familial defective apoB* (FDB). Of note, truncating mutations in *APOB* cause *low* LDL-C levels (see below). The proprotein convertase subtilisin/kexin type 9 (PCSK9) is a secreted protein that binds to the LDL receptor and targets it for lysosomal degradation. Normally, after LDL binds to the LDL receptor, it is internalized along with the receptor, and in the low pH of the endosome, the LDL receptor dissociates from the LDL and recycles to the cell surface. When circulating PCSK9 binds the receptor, the complex is internalized and the receptor is directed to the lysosome, rather than to the cell surface, reducing the number of active LDL receptors. *Gain-of-function* mutations in *PCSK9* that enhance the activity of PCSK9 cause a form of FH, also known as ADH type 3. Of note, loss-of-function mutations in *PCSK9* reduce LDL-C levels (see below).

The population frequency of heterozygous FH was originally estimated to be 1 in 500 individuals, but recent data suggest it may be as high as ~1 in 250 individuals, making it one of the most common single-gene disorders in humans. FH has a much higher prevalence in certain founder populations, such as South African Afrikaners, Christian Lebanese, French Canadians, and Lancaster County Amish.

Heterozygous FH is characterized by elevated plasma levels of LDL-C (usually >190 mg/dL) and relatively normal levels of TGs. Patients with FH have hypercholesterolemia from birth, and FH diagnosis is often based on detection of hypercholesterolemia on routine lipid screening; this serves as the basis for the recommendation to screen children between the ages of 9 and 11. A family history of hypercholesterolemia or premature ASCVD should prompt targeted screening. Inheritance of FH is dominant, meaning that the condition is inherited from one parent, and ~50% of the patient's siblings and children can be expected to have FH. For this reason, family-based "cascade screening" can be very effective in identifying additional persons with FH. Physical findings in some, but not all, patients with FH may include corneal arcus and/or tendon xanthomas, particularly involving the dorsum of the hands and the Achilles tendons. Untreated heterozygous FH is associated with a markedly increased risk of cardiovascular disease; untreated men with heterozygous FH have an ~50% chance of having a myocardial infarction before age 60 years, and women with heterozygous FH are at substantially increased risk as well. The age of onset of cardiovascular disease is highly variable and depends on the specific molecular defect, the level of LDL-C, and coexisting cardiovascular risk factors.

The diagnosis of FH is generally a clinical diagnosis based on hypercholesterolemia with LDL-C >190 mg/dL in the absence of a secondary etiology and ideally with a family history of hypercholesterolemia and/or premature ASCVD. Secondary causes of significant hypercholesterolemia such as hypothyroidism, nephrotic syndrome, and obstructive liver disease should be excluded. Sequencing of an FH gene panel (*LDLR*, *APOB*, *PCSK9*) to confirm the diagnosis is widely available and worthy of consideration; persons with molecularly confirmed FH are at higher risk of ASCVD and therefore may benefit from more aggressive treatment, and the finding of a specific causal variant has implications for family-based cascade screening.

FH patients should be actively treated to lower plasma levels of LDL-C, preferably starting in childhood. Initiation of a diet low in saturated and trans fats is recommended, but heterozygous FH patients almost always require pharmacologic therapy for effective control of their LDL-C levels. Statins are the initial drug class of choice, and usually "high-intensity" statin therapy is needed. Many FH patients cannot achieve adequate control of their LDL-C levels even with high-intensity statin therapy, and a cholesterol absorption inhibitor (ezetimibe), a PCSK9 inhibitor, an ACL inhibitor (bempedoic acid), and a bile acid sequestrant are other classes of drugs that can be added to statins **(Table 419-4)**. Some patients with severe heterozygous FH cannot be adequately managed using existing therapies and are candidates for LDL apheresis, a physical method of purging the blood of LDL in which the LDL particles are selectively removed from the circulation. Other novel approaches for these patients are under development.

Homozygous FH (HoFH) is caused by loss-of-function mutations in both alleles of the LDL receptor or double heterozygosity for mutations in two FH genes. Patients with HoFH have been classified into those with virtually no detectable LDL receptor activity (*receptor negative*) and patients with markedly reduced but detectable LDL receptor activity (*receptor defective*). Untreated LDL-C levels in patients with HoFH range from ~400 to >1000 mg/dL, with receptor-defective patients at the lower end and receptor-negative patients at the higher end of the range. TGs are usually relatively normal. Some patients with HoFH, particularly receptor-negative patients, present in childhood with cutaneous planar xanthomas on the hands, wrists, elbows, knees, heels, or buttocks. The devastating consequence of HoFH is accelerated ASCVD, which often presents in childhood or early adulthood. Atherosclerosis often develops first in the aortic root, where it can cause aortic valvular or supravalvular stenosis, and typically extends into the coronary ostia, which become stenotic. Symptoms can be atypical, and sudden death is not uncommon. Untreated, receptor-negative patients with HoFH rarely survive beyond the second decade; patients with receptor-defective LDL receptor defects have a better prognosis but almost invariably develop clinically apparent atherosclerotic vascular disease by age 30 and often much sooner.

HoFH should be suspected in a child or young adult with LDL >400 mg/dL without secondary cause. Cutaneous xanthomas, evidence of ASCVD, and/or hypercholesterolemia in both parents all are supportive of the diagnosis. While the diagnosis is usually made on clinical grounds, genetic testing should be performed to identify specific causal variants. Patients with HoFH must be treated aggressively to delay the onset and progression of cardiovascular disease (CVD). Although receptor-negative patients have no response to statins and PCSK9 inhibitors, receptor-defective patients can have modest responses to these medicines, and they should be tried in patients with HoFH. Two drugs that reduce the hepatic production of VLDL and thus LDL, a small-molecule inhibitor of MTP and an antisense oligonucleotide to apoB, and an antibody that inhibits ANGPLT3 are approved for the treatment of patients with HoFH and should be considered in HoFH patients. LDL apheresis should be considered in HoFH patients who have persistently elevated LDL-C levels despite drug therapy. Liver transplantation is effective in decreasing plasma LDL-C levels in this disorder and is sometimes used as a last resort. Liver-directed gene therapy is under development for HoFH, as are other new therapeutic approaches intended to address the remaining unmet medical need.

FH is an autosomal dominant disorder. There are a few rare conditions that cause an FH-like phenotype in an autosomal recessive manner and should be considered in patients with severe hypercholesterolemia who do not report a family history of hypercholesterolemia or premature CHD.

AUTOSOMAL RECESSIVE HYPERCHOLESTEROLEMIA (ARH) ARH is a very rare autosomal recessive disorder that was originally reported in individuals of Sardinian descent. The disease is caused by mutations in the gene *LDLRAP1* encoding the protein LDLR adaptor protein (also called the ARH protein), which is required for LDL receptor–mediated endocytosis in the liver. LDLRAP1 binds to the cytoplasmic domain of the LDL receptor and links the receptor to the endocytic machinery. In the absence of LDLRAP1, LDL binds to the extracellular domain of the LDL receptor, but the lipoprotein-receptor complex fails to be internalized. ARH, like HoFH, is characterized by hypercholesterolemia, tendon xanthomas, and premature coronary artery disease (CAD). The levels of plasma LDL-C tend to be intermediate between the levels present in FH homozygotes and FH heterozygotes, and CAD is not usually symptomatic until the third decade. LDL receptor function in cultured fibroblasts is normal or only modestly reduced in ARH, whereas LDL receptor function in the liver is negligible. Unlike FH homozygotes, the hyperlipidemia responds to treatment with statins, but these patients often require additional therapy to lower plasma LDL-C to acceptable levels.

SITOSTEROLEMIA Sitosterolemia is a rare autosomal recessive disease that is caused by biallelic loss-of-function mutations in either of two members of the ATP-binding cassette (ABC) half transporter family, *ABCG5* and *ABCG8*. These genes are expressed in both enterocytes and hepatocytes. The proteins heterodimerize to form a functional complex that transports plant sterols such as sitosterol and campesterol, and animal sterols, predominantly cholesterol, across the apical biliary membrane of hepatocytes into the bile and across the apical luminal membrane of enterocytes into the gut lumen, thus reducing their (re)absorption and promoting their excretion. In normal individuals, <5% of dietary plant sterols are absorbed by the proximal small intestine. The small amounts of plant sterols that enter the circulation are preferentially excreted into the bile, and thus, levels of plant sterols are kept very low in tissues. In sitosterolemia, the intestinal absorption of sterols is increased and biliary and fecal excretion of the sterols is reduced, resulting in increased plasma and tissue levels of both plant sterols and cholesterol. The increase in hepatic sterol levels results in transcriptional suppression of the expression of the LDL receptor, resulting in reduced uptake of LDL and substantially increased LDL-C levels. In addition to the clinical picture of severe hypercholesterolemia, often accompanied by tendon xanthomas and premature ASCVD, these patients also have anisocytosis and poikilocytosis of erythrocytes and megathrombocytes due to the incorporation of plant sterols into cell membranes. Episodes of hemolysis and splenomegaly are a distinctive clinical feature of this disease compared

TABLE 419-4 Drugs Used to Treat Dyslipidemia

DRUG	MAJOR INDICATIONS	STARTING DOSE	MAXIMAL DOSE	MECHANISM	ADVERSE EFFECTS
LDL-Lowering Drugs					
HMG-CoA reductase inhibitors (statins)	Elevated LDL-C; increased CV risk			↓ Inhibition of cholesterol synthesis → ↑ Hepatic LDL receptors	Myalgias and myopathy, ↑ transaminases, ↑ diabetes risk
Lovastatin		20–40 mg daily	80 mg daily		
Pravastatin		40–80 mg daily	80 mg daily		
Simvastatin		20–40 mg daily	80 mg daily		
Fluvastatin		20–40 mg daily	80 mg daily		
Atorvastatin		20–40 mg daily	80 mg daily		
Rosuvastatin		5–20 mg daily	40 mg daily		
Pitavastatin		1–2 mg daily	4 mg daily		
Cholesterol absorption inhibitor	Elevated LDL-C			↓ Cholesterol absorption→ ↑ LDL receptors	Elevated transaminases
Ezetimibe		10 mg daily	10 mg daily		
Bile acid sequestrants	Elevated LDL-C			↑ Bile acid excretion → ↑ LDL receptors	Bloating, constipation, elevated triglycerides
Cholestyramine		4 g daily	32 g daily		
Colestipol		5 g daily	40 g daily		
Colesevelam		3750 mg daily	4375 mg daily		
PCSK9 inhibitors	Elevated LDL-C	140 mg SC every 2 weeks	420 mg SC every 1 month (HoFH)	↓ PCSK9 activity due to Ab inhibition → ↑ LDL receptors	Injection site reactions
Evolocumab (Ab)		75 mg SC every 2 weeks	150 mg SC every 2 weeks		
Alirocumab (Ab)					
Inclisiran (siRNA)		300 mg SC every 6 months	300 mg SC every 6 months	↓ PCSK9 synthesis due to siRNA silencing → ↑ LDL receptors	Injection site reactions
ATP citrate lyase inhibitor	Elevated LDL-C	180 mg daily	180 mg daily	↓ Inhibition of cholesterol synthesis → ↑ LDL receptors	↑ uric acid and gout ↑ cholelithiasis
Bempedoic acid					
MTP inhibitor	HoFH	5 mg daily	60 mg daily	MTP inhibition → ↓ VLDL assembly and secretion	Nausea, diarrhea, increased hepatic fat
Lomitapide					
ApoB inhibitor (ASO)	HoFH	200 mg SC weekly	200 mg SC weekly	↓ ApoB synthesis due to ASO silencing → ↓ ApoB/VLDL secretion	Injection site reactions, flu-like symptoms, increased hepatic fat
Mipomersen					
ANGPTL3 inhibitor (Ab)	HoFH	15 mg/kg IV q 4 weeks	15 mg/kg IV q 4 weeks	↓ ANGPTL3 activity due to Ab inhibition → ↑ LPL and EL activity, ↑ LDL catabolism	Reduced HDL-C levels
Evinacumab					
TG-Lowering Drugs					
Fibric acid derivatives (fibrates)	Elevated TG	600 mg bid	600 mg bid	↑ LPL, ↓ VLDL synthesis	Dyspepsia, myalgia, cholelithiasis, elevated transaminases
Gemfibrozil		40–160 mg daily depending on product	40–160 mg daily depending on product		
Fenofibrate					
Omega-3 fatty acids	Elevated TG	4 g daily	4 g daily	↑ TG catabolism	Dyspepsia
Acid ethyl esters					
Icosapent ethyl		4 g daily	4 g daily		

Abbreviations: Ab, antibody; GI, gastrointestinal; HDL-C, high-density lipoprotein cholesterol; HoFH, homozygous familial hypercholesterolemia; LDL, low-density lipoprotein; LDL-C, LDL cholesterol; LPL, lipoprotein lipase; TG, triglyceride; VLDL, very-low-density lipoprotein.

to other genetic forms of hypercholesterolemia and can be a clue to the diagnosis. Sitosterolemia should be suspected in a patient with severe hypercholesterolemia without a family history of such or who fails to respond to statin therapy. Sitosterolemia can be diagnosed by a laboratory finding of a substantial increase in plasma sitosterol and/or other plant sterols and should be confirmed by gene sequencing of *ABCG5* and *ABCG8*. It is important to make the diagnosis, because diet, bile acid sequestrants, and cholesterol-absorption inhibitors are the most effective agents to reduce LDL-C and plasma plant sterol levels in these patients. Of note, heterozygosity for mutations in *ABCG5* or *ABCG8* is now recognized to cause a moderate form of hypercholesterolemia.

LYSOSOMAL ACID LIPASE DEFICIENCY (LALD) LALD, also known as *cholesteryl ester storage disease*, is an autosomal recessive disorder caused by loss-of-function variants in both alleles of the gene *LIPA* encoding the enzyme lysosomal acid lipase (LAL). LAL is responsible for hydrolyzing neutral lipids, particularly TGs and CEs, after delivery to the lysosome by cell surface receptors such as the LDL receptor. It is particularly important in the liver, which clears large amounts of lipoproteins from the circulation. LALD is characterized by elevated LDL-C, usually in association with low HDL-C and with variably elevated TG levels, together with progressive fatty liver ultimately leading to hepatic fibrosis. Genetic deficiency of LAL results in accumulation of neutral lipid in the hepatocytes, leading to hepatosplenomegaly, microvesicular steatosis, and ultimately fibrosis and end-stage liver disease. The most severe form of this disorder, Wolman's disease, presents in infancy and is rapidly fatal. The etiology of the elevated LDL-C levels is primarily due to impaired LDL receptor–mediated clearance

of LDL. LALD should be suspected in nonobese patients with elevated LDL-C, low HDL-C, and evidence of fatty liver in the absence of overt insulin resistance. The diagnosis can be made with a dried blood spot assay of LAL activity and confirmed by DNA genotyping for the most common mutation, followed if necessary by sequencing of the gene to find the second mutation. Liver biopsy is required to assess the degree of inflammation and fibrosis. LALD is underdiagnosed; it is critically important to suspect it and make the diagnosis because enzyme replacement therapy with sebelipase alfa is now available and is highly effective in treating this condition.

The above conditions primarily cause elevations in LDL due to impaired catabolism of LDL from the blood. There are a few forms of primary dyslipidemia that impair the catabolism of "remnant" TRLs (after their processing by LPL) and therefore cause elevations in both cholesterol and TGs due to remnant accumulation.

Multifactorial Hypercholesterolemia Most patients with elevated LDL-C do not have a single-gene disorder, as described above, but instead have a multifactorial etiology that includes genetics and environment. Genetic variation contributes substantially to elevated LDL-C levels in the general population. It has been estimated that at least 50% of variation in LDL-C is genetically determined. Many patients with elevated LDL-C have *polygenic hypercholesterolemia* due to multiple common genetic variants exerting modest LDL-raising effects. Individuals at the tail of the highest burden of polygenic risk score for LDL-C often have LDL-C levels that are similar to those with FH. In patients who are genetically predisposed to higher LDL-C levels, diet plays a key exacerbating role; indeed, increased saturated and trans fats in the diet shift the entire distribution of LDL-C levels in the population to the right. As described in more detail below, patients with elevated LDL-C should be carefully assessed for their risk of ASCVD and managed with lifestyle modification and LDL-lowering medications as needed to reduce LDL-C and risk of ASCVD.

MIXED HYPERLIPIDEMIA (ELEVATED TG AND LDL-C)

Mixed hyperlipidemia can be defined as fasting TGs >150 mg/dL and evidence of elevated cholesterol-containing lipoproteins (such as LDL-C >130 mg/dL or non-HDL-C >160 mg/dL). It is one of the most common types of lipid disorders seen in clinical practice, due both to genetic predisposition and influence of medical conditions and environmental factors (see below). It is generally associated with elevated risk of ASCVD, and therefore, patients with mixed hyperlipidemia should be carefully evaluated and managed to reduce this risk.

Primary (Genetic) Causes of Mixed Hyperlipidemia • **FAMILIAL DYSBETALIPOPROTEINEMIA (FDBL)** FDBL (also known as *type III hyperlipoproteinemia*) is a recessive disorder characterized by a mixed hyperlipidemia due to the accumulation of remnant lipoprotein particles (chylomicron remnants and VLDL remnants, or IDL). ApoE is present in multiple copies on chylomicron remnants and IDL and mediates their removal via hepatic lipoprotein receptors (Fig. 419-2). The *APOE* gene is polymorphic in sequence, resulting in the expression of three common isoforms: apoE3, which is the most common (~78% global allele frequency [AF]), apoE4 (~14% global AF), and apoE2 (~8% global AF). The apoE4 allele, which has an arginine instead of a cysteine at position 112, is widely known for being the major genetic risk factor for Alzheimer's disease. It is associated with slightly higher LDL-C levels and increased ASCVD risk but is not associated with FDBL. The apoE2 allele, which has a cysteine at position 158 instead of an arginine, is the cause of FDBL when present on both alleles. ApoE2 has a lower affinity for the LDL receptor; therefore, chylomicron remnants and IDL containing apoE2 are removed from plasma at a slower rate, leading to their accumulation in blood.

Approximately 0.5% of the general population are apoE2/E2 homozygotes, but only a small minority of these individuals actually develop hyperlipidemia characteristic of FDBL (which has a prevalence of ~1 in 10,000). Thus, an additional, sometimes identifiable, factor precipitates the development of overt dysbetalipoproteinemia in apoE2/E2 homozygotes. The most common precipitating factors are a high-fat diet, sedentary lifestyle, obesity, alcohol use, menopause, diabetes mellitus, hypothyroidism, renal disease, HIV infection, or certain drugs. Certain dominant-negative mutations in apoE can cause a dominant form of FDBL where the hyperlipidemia is fully manifest in the heterozygous state, but these mutations are very rare.

Patients with FDBL usually present in adulthood with hyperlipidemia, xanthomas, or premature coronary or peripheral vascular disease. In FDBL, in contrast to other disorders of elevated TGs, the plasma levels of cholesterol and TG are often elevated to a similar degree, and the level of HDL-C is usually normal. Two distinctive types of xanthomas, tuberoeruptive and palmar, are seen in FDBL patients. Tuberoeruptive xanthomas begin as clusters of small papules on the elbows, knees, or buttocks and can grow to the size of small grapes. Palmar xanthomas (alternatively called *xanthomata striata palmaris*) are orange-yellow discolorations of the creases in the palms and wrists. Both of these xanthoma types are virtually pathognomonic for FDBL. Subjects with FDBL have premature ASCVD and tend to have more peripheral vascular disease than is typically seen in FH.

The definitive diagnosis of FDBL can be made either by the documentation of very high levels of remnant lipoproteins or by identification of the apoE2/E2 genotype. A variety of methods are used to identify remnant lipoproteins in the plasma, including "β-quantification" by ultracentrifugation (ratio of directly measured VLDL cholesterol to total plasma TG >0.30), lipoprotein electrophoresis (broad β band), or nuclear magnetic resonance lipoprotein profiling. The Friedewald formula for calculation of LDL-C is not valid in FDBL because the VLDL particles are depleted in TG and enriched in cholesterol. The plasma levels of LDL-C are actually low in this disorder due to defective metabolism of VLDL to LDL. DNA-based apoE genotyping can be performed to confirm homozygosity for apoE2, which is diagnostic for FDBL. However, absence of the apoE2/E2 genotype does not strictly rule out the diagnosis of FDBL, because other mutations in apoE can (rarely) cause this condition.

Because FDBL is associated with increased risk of premature ASCVD, it should be treated aggressively. Other metabolic conditions that can exacerbate the hyperlipidemia (see above) should be managed. Patients with FDBL are typically diet-responsive and can respond favorably to low-cholesterol, low-fat diets and weight reduction. Alcohol intake should be curtailed. Pharmacologic therapy is often required, and statins are the first line in management. In the event of statin intolerance or insufficient control of hyperlipidemia, cholesterol absorption inhibitors, PCSK9 inhibitors, and fibrates are also effective in the treatment of FDBL.

HEPATIC LIPASE DEFICIENCY Hepatic lipase (HL; gene name *LIPC*) is a member of the same gene family as LPL and hydrolyzes TGs and phospholipids in remnant lipoproteins and HDL. Hydrolysis of lipids in remnant particles by HL contributes to their hepatic uptake via an apoE-mediated process. HL deficiency is a very rare autosomal recessive disorder caused by biallelic loss-of-function mutations in *LIPC*. It is characterized by elevated plasma levels of cholesterol and TGs (mixed hyperlipidemia) due to the accumulation of lipoprotein remnants, accompanied by elevated plasma level of HDL-C. The diagnosis is confirmed by confirmation of pathogenic mutations in both alleles of *LIPC*. Due to the small number of patients with HL deficiency, the association of this genetic defect with ASCVD is not entirely clear, although anecdotally, patients with HL deficiency who have premature CVD have been described. As with FDBL, statin therapy is recommended to reduce remnant lipoproteins and cardiovascular risk.

FAMILIAL COMBINED HYPERLIPIDEMIA (FCHL) FCHL is one of the most common familial lipid disorders; it is estimated to occur in ~1 in 100–200 individuals. FCHL is characterized by elevations in plasma levels of TGs (VLDL) and LDL-C (including especially a small dense form of LDL) and reduced plasma levels of HDL-C. This disorder is an important contributor to premature CHD; ~20% of patients who develop CHD under age 60 have FCHL. FCHL can manifest in childhood but is usually not fully expressed until adulthood. The disease clusters in families, and affected family members typically have one of three possible phenotypes: (1) elevated plasma levels of LDL-C, (2)

elevated plasma levels of TGs due to elevation in VLDL, or (3) elevated plasma levels of both LDL-C and TG. The lipoprotein profile can switch among these three phenotypes in the same individual over time and may depend on factors such as diet, exercise, weight, and insulin sensitivity. Patients with FCHL have substantially elevated plasma levels of apoB, often disproportionately high relative to the plasma LDL-C concentration, indicating the presence of small dense LDL particles, which are characteristic of this syndrome.

Individuals with this phenotype generally share the same metabolic defect, namely overproduction of VLDL and apoB by the liver. The molecular etiology of this condition remains poorly understood, and no single gene has been identified in which mutations convincingly cause this disorder in a simple Mendelian fashion. It is likely that defects in a combination of genes can cause the condition, suggesting that a more appropriate term for the disorder might be *polygenic combined hyperlipidemia.*

The presence of a mixed dyslipidemia (plasma TG levels between 150 and 500 mg/dL and total cholesterol levels between 200 and 400 mg/dL, usually with HDL-C levels <40 mg/dL in men and <50 mg/dL in women) and a family history of mixed dyslipidemia and/or premature CHD suggests the diagnosis. Measurement of plasma apoB levels can help support the diagnosis if they are substantially elevated, particularly relative to the LDL-C level. Individuals with this disorder should be treated aggressively due to significantly increased risk of premature CHD, often disproportionate to the LDL-C level. Decreased dietary intake of simple carbohydrates, increased aerobic exercise, and weight loss can all have beneficial effects on the lipid profile. Patients with type 2 diabetes should be aggressively treated to maintain good glucose control. Virtually all patients with FCHL merit lipid-lowering drug therapy to reduce apoB-containing lipoprotein levels and lower the risk of ASCVD. High-intensity statins are first line, but many patients with FCHL require combination therapy that includes ezetimibe, a PCSK9 inhibitor, and/or bempedoic acid.

SECONDARY CONTRIBUTORS TO ELEVATED LEVELS OF APOB-CONTAINING LIPOPROTEINS

There are many "secondary" factors that contribute to dyslipidemia (Table 419-3), often acting in concert with polygenic predisposition as reviewed above. Some primarily affect TGs, some primarily affect LDL-C, and some influence both, with a great deal of variability. Here the major secondary contributors are reviewed.

Secondary Factors That Primarily Elevate TG Levels • **HIGH-CARBOHYDRATE DIET** Dietary carbohydrates are utilized as a substrate for fatty acid synthesis in the liver. Some of the newly synthesized fatty acids are esterified, forming TGs, and secreted in VLDL. Thus, excessive intake of calories as carbohydrates, which is frequent in Western societies, leads to increased hepatic VLDL-TG secretion and elevated TG levels. Reduction in carbohydrate consumption can have a substantial effect in reducing TG levels, although replacing carbohydrates with saturated fat can elevate LDL-C levels.

OBESITY, INSULIN RESISTANCE, AND TYPE 2 DIABETES (See also Chaps. 413–415) Obesity, insulin resistance, and type 2 diabetes mellitus are the most frequent contributors to dyslipidemia, primarily by influencing TGs. The increase in adipocyte mass and accompanying decreased insulin sensitivity associated with obesity have multiple effects on lipid metabolism, with one of the major effects being excessive hepatic VLDL production. More free fatty acids are delivered from the expanded and insulin-resistant adipose tissue to the liver, where they are reesterified in hepatocytes to form TGs, which are packaged into VLDLs for secretion into the circulation. In addition, the increased insulin levels promote increased fatty acid synthesis in the liver. In insulin-resistant patients who progress to type 2 diabetes mellitus, dyslipidemia remains common, even when the patient is under relatively good glycemic control. In addition to increased VLDL production, insulin resistance can also result in decreased LPL activity, resulting in reduced catabolism of chylomicrons and VLDLs and more severe HTG. This may be due in part to the effects of tissue insulin resistance leading to reduced transcription of LPL in skeletal muscle and adipose, as well as to increased production of the LPL inhibitor apoC-III by the liver. This reduction in LPL activity often exacerbates the effects of increased VLDL production and contributes to the dyslipidemia seen in these patients. The dyslipidemia in this setting is almost invariably associated with low HDL-C levels as well. A cluster of metabolic risk factors are often found together, including obesity, insulin resistance, hypertension, high TGs, and low HDL-C (the so-called "metabolic syndrome," Chap. 420).

ALCOHOL CONSUMPTION Excessive alcohol consumption inhibits hepatic oxidation of free fatty acids, thus promoting hepatic TG synthesis and VLDL secretion and leading to increased plasma TG levels. Regular alcohol use also raises plasma levels of HDL-C and should be considered in patients with the relatively unusual combination of elevated TGs and normal or elevated HDL-C. A careful history of alcohol use should be taken in patients with elevated TGs. Reduction in alcohol consumption can often have a substantial effect in reducing TG levels.

CHRONIC KIDNEY DISEASE (See also Chap. 322) Chronic kidney disease (CKD) is often associated with mild HTG (150–400 mg/dL) due to the accumulation of VLDLs and remnant lipoproteins in the circulation. TG lipolysis and remnant clearance are both reduced in patients with renal failure. Because the risk of ASCVD is increased in CKD, patients should usually be treated with lipid-lowering agents, particularly statins.

ESTROGEN AND OTHER DRUGS Many drugs have an impact on lipid metabolism and can result in significant alterations in the lipoprotein profile (Table 419-3). Estrogens often elevate TG levels, and TG levels can also increase during pregnancy. In women with HTG, plasma TG levels should be monitored when birth control pills or postmenopausal estrogen therapy is initiated and during pregnancy. Use of low-dose preparations of estrogen or the estrogen patch can minimize the effect of exogenous estrogen on lipids. Isotretinoin therapy for acne can cause substantial elevations in TGs, and TG levels should be checked at baseline and after initiation of therapy. Bexarotene therapy for cutaneous T-cell lymphoma often causes substantial increases in TGs, and patients should be monitored accordingly.

Secondary Factors That Elevate LDL-C Levels • **DIET HIGH IN SATURATED AND TRANS FATS** Dietary saturated and trans fats act to downregulate LDL receptor expression in the liver, leading to elevation in LDL-C levels and increased ASCVD risk. A careful dietary history should be taken in individuals with elevated LDL-C with a focus on sources of saturated and trans fats. Reduction in consumption of saturated and trans fats can sometimes have a substantial effect in reducing LDL-C levels and is a cornerstone of the initial nonpharmacologic management of hypercholesterolemia.

HYPOTHYROIDISM (See also Chap. 394) Hypothyroidism is the most important medical condition causing elevated LDL-C levels. It causes elevated plasma LDL-C levels due to downregulation of the hepatic LDL receptor, which is normally increased by the action of thyroid hormone. Because hypothyroidism is often subtle and therefore easily overlooked, all patients presenting with elevated plasma levels of LDL-C, especially if there has been an unexplained increase in LDL-C, should be screened for hypothyroidism by measuring thyroid-stimulating hormone (TSH). Thyroid replacement therapy usually reduces LDL-C levels; if not, the patient probably has a primary lipoprotein disorder and may require lipid-lowering drug therapy with a statin.

LIVER DISORDERS (See also Chap. 347) Cholestasis is almost invariably associated with hypercholesterolemia due to elevated LDL-C levels and, if severe, particles called Lp-X. A major pathway by which cholesterol is excreted from the body is via secretion into bile, either directly or after conversion to bile acids, and cholestasis blocks this critical excretory pathway. The increase in hepatocellular cholesterol results in downregulation of the LDL receptor, leading to increased plasma LDL-C levels. In severe cholestasis, excess free cholesterol, coupled with phospholipids, is shed into the plasma as a constituent of a lamellar particle called Lp-X. These unusual particles, which are not lipoproteins, lack apoB, and have an aqueous and not neutral lipid

core, are rich in free cholesterol, and can deposit in the skin, producing xanthomas sometimes seen in patients with cholestasis. Some liver disorders can affect plasma lipid levels in other ways. Viral hepatitis can increase TGs, and liver failure can result in reduction in plasma cholesterol and TGs.

NEPHROTIC SYNDROME (See also Chap. 322) Nephrotic syndrome is a classic cause of excessive VLDL production leading to elevation in both TGs and LDL-C. The molecular mechanism of VLDL overproduction remains poorly understood but has been attributed to the effects of hypoalbuminemia leading to increased hepatic protein synthesis. Effective treatment of the underlying renal disease may normalize the lipid profile, but many patients with chronic nephrotic syndrome require lipid-lowering drug therapy with statins and sometimes additional drugs.

CUSHING'S SYNDROME (See also Chap. 398) Endogenous glucocorticoid excess in Cushing's syndrome is associated with increased VLDL synthesis and secretion leading to dyslipidemia characterized by HTG and elevated LDL-C. Treatment of the underlying cause is often sufficient to manage the dyslipidemia, but sometimes lipid-lowering drug therapy is needed.

IMMUNOSUPPRESSIVE THERAPY AND CORTICOSTEROIDS Several of the immunosuppressants used after solid organ transplantation, including cyclosporin and sirolimus, can cause substantial elevation in LDL-C and TG levels. These patients can present a difficult clinical management problem. Chronic corticosteroid use, whether after transplant or in other inflammatory conditions, can also result in elevations in LDL-C and TG levels, sometimes producing a substantial mixed dyslipidemia. When the immunosuppressant or steroid must be continued, which is often the case, drug therapy with statins may be indicated in certain patients, with careful attention to the potential for untoward muscle-related side effects.

DISORDERS ASSOCIATED WITH REDUCED APOB-CONTAINING LIPOPROTEINS

Plasma concentrations of LDL-C <60 mg/dL are unusual. Although in some cases, LDL-C levels in this range may be reflective of malnutrition or serious chronic illness, LDL-C <60 mg/dL in an otherwise healthy individual suggests an inherited condition. The major inherited causes of low LDL-C are reviewed here and listed in Table 419-2.

Abetalipoproteinemia The synthesis and secretion of apoB-containing lipoproteins in the enterocytes of the proximal small bowel and in the hepatocytes of the liver involve a complex series of events that coordinate the coupling of various lipids with apoB-48 and apoB-100, respectively. Abetalipoproteinemia is a rare autosomal recessive disease caused by loss-of-function mutations in the gene encoding MTP (gene name *MTTP*), a protein that transfers lipids to nascent chylomicrons and VLDLs in the intestine and liver, respectively. Plasma levels of cholesterol and TG are extremely low in this disorder, and chylomicrons, VLDLs, LDLs, and apoB are undetectable in plasma. The parents of patients with abetalipoproteinemia (obligate heterozygotes) have normal plasma lipid and apoB levels. Abetalipoproteinemia usually presents in early childhood with diarrhea and failure to thrive due to fat malabsorption. The initial neurologic manifestations are loss of deep tendon reflexes, followed by decreased distal lower extremity vibratory and proprioceptive sense, dysmetria, ataxia, and the development of a spastic gait, often by the third or fourth decade. Patients with abetalipoproteinemia also develop a progressive pigmented retinopathy presenting with decreased night and color vision, followed by reductions in daytime visual acuity and ultimately progressing to near-blindness. The presence of spinocerebellar degeneration and pigmented retinopathy in this disease has resulted in some patients with abetalipoproteinemia being misdiagnosed as having Friedreich's ataxia.

Most of the clinical manifestations of abetalipoproteinemia result from defects in the absorption and transport of fat-soluble vitamins. Vitamin E and retinyl esters are normally transported from enterocytes to the liver by chylomicrons, and vitamin E is dependent on VLDL for transport out of the liver and into the circulation. As a consequence of the inability of these patients to secrete apoB-containing particles, patients with abetalipoproteinemia are markedly deficient in vitamin E and are also mildly to moderately deficient in vitamins A and K. Patients with abetalipoproteinemia should be referred to specialized centers for confirmation of the diagnosis and appropriate therapy. Treatment consists of a low-fat, high-caloric, vitamin-enriched diet accompanied by large supplemental doses of vitamin E. It is imperative that treatment be initiated as soon as possible to prevent development of neurologic sequelae, which can progress even with high-dose vitamin E therapy. New therapies for this serious, albeit rare, disease are needed. The discovery that genetic loss of MTP causes absent LDL-C led to the development of an MTP inhibitor to treat homozygous FH (see below).

Familial Hypobetalipoproteinemia (FHBL) FHBL generally refers to a condition of low total cholesterol, LDL-C, and apoB due to mutations in the *APOB* gene. Most of the mutations causing FHBL result in a truncated apoB protein, resulting in impaired assembly and secretion of chylomicrons from enterocytes and VLDL from the liver. Any secreted VLDL particles containing a truncated apoB protein are cleared from the circulation at an accelerated rate, which also contributes to the low levels of LDL-C and apoB. Individuals heterozygous for these mutations usually have LDL-C levels <60–80 mg/dL and also tend to have low levels of plasma TG. Many FHBL patients have elevated levels of hepatic fat (due to reduced VLDL export) and sometimes have increased levels of liver transaminases, although it appears that these patients infrequently develop associated hepatic inflammation and fibrosis.

Truncating mutations in both apoB alleles cause homozygous FHBL, an extremely rare disorder resembling abetalipoproteinemia with nearly undetectable LDL-C and apoB. The neurologic defects in homozygous hypobetalipoproteinemia are similar to those seen in abetalipoproteinemia but tend to be less severe. Homozygous hypobetalipoproteinemia can be distinguished from abetalipoproteinemia by examining the inheritance pattern of the plasma LDL-C level. The levels of LDL-C and apoB are normal in the parents of patients with abetalipoproteinemia, a classic recessive condition, and low in those of patients with homozygous hypobetalipoproteinemia, a co-dominant condition. The discovery that truncating mutations in apoB reduce LDL-C led to the development of an antisense oligonucleotide to treat HoFH (see below).

Familial PCSK9 Deficiency Another inherited cause of low LDL-C results from loss-of-function mutations in *PCSK9*. PCSK9 is a secreted protein that binds to the extracellular domain of the LDL receptor in the liver and promotes the degradation of the receptor. Heterozygosity for nonsense mutations in *PCSK9* that interfere with the synthesis of the protein are associated with increased hepatic LDL receptor activity and reduced plasma levels of LDL-C. Such mutations are more frequent in individuals of African descent. Individuals who are heterozygous for a loss-of-function mutation in *PCSK9* have an ~30–40% reduction in plasma levels of LDL-C and have a substantial protection from CHD relative to those without a *PCSK9* mutation, presumably due to having lower plasma cholesterol levels since birth. Homozygotes for these nonsense mutations have been reported and have extremely low LDL-C levels (<20 mg/dL) but appear otherwise healthy. A sequence variation of somewhat higher frequency (R46L) is found predominantly in individuals of European descent. This mutation impairs, but does not completely destroy, PCSK9 function. As a consequence, the plasma levels of LDL-C in individuals carrying this mutation are more modestly reduced (~15–20%); individuals with these mutations have a 45% reduction in CHD risk. The discovery of this condition led to the development of therapies that antagonize or silence PCSK9, thus reducing LDL-C levels and risk of CHD (see below).

Familial Combined Hypolipidemia Nonsense mutations in both alleles of the gene angiopoietin-like 3 (*ANGPTL3*) lead to low plasma levels of all three major lipid fractions—TG, LDL-C, and HDL-C—a phenotype termed *familial combined hypolipidemia*.

ANGPTL3 is a protein synthesized by the liver and secreted into the bloodstream. It inhibits LPL, thus delaying clearance of TRLs from the blood and increasing TRL blood concentrations. Deficiency of ANGPTL3, therefore, raises LPL activity and lowers blood TG; it also lowers LDL-C and raises HDL-C levels apparently related to the effects of ANGPTL3 on endothelial lipase. ANGPTL3 deficiency is associated with a reduced risk for CHD. The discovery of this condition led to the development of therapies that antagonize or silence ANGPTL3 to reduce LDL-C and TG levels (see below).

DISORDERS ASSOCIATED WITH REDUCED HIGH-DENSITY LIPOPROTEINS

Low levels of HDL-C, generally defined as <50 mg/dL in women and <40 mg/dL in men, are very common in clinical practice. Low HDL-C is an important independent predictor of increased cardiovascular risk and has been used regularly in standardized risk calculators. As an independent risk factor, it has clinical value in the assessment of cardiovascular risk, and a patient with low HDL-C should generally be considered at higher risk of ASCVD. However, it is now considered doubtful that low HDL-C is directly *causal* for the development of ASCVD. Thus, while HDL-C remains an important biomarker for assessing cardiovascular risk, it is no longer considered a target for therapeutic intervention to raise HDL-C levels in order to reduce cardiovascular risk.

HDL metabolism is strongly influenced by TG metabolism, insulin resistance, and inflammation, among other environmental and medical factors. Thus, the HDL-C measurement integrates a number of cardiovascular risk factors, potentially explaining its strong inverse association with ASCVD. The majority of patients with low HDL-C have some combination of genetic predisposition and secondary factors. Variants in hundreds of genes have been shown to influence HDL-C levels. Even more important quantitatively, obesity and insulin resistance have strong suppressive effects on HDL-C, and low HDL-C in these conditions is widely observed. Furthermore, the vast majority of patients with elevated TGs have reduced levels of HDL-C due to the substantial interplay between the metabolism of TRLs and HDL (see above). Most patients with low HDL-C who have been studied in detail have accelerated catabolism of HDL and its associated apoA-I protein as the physiologic basis for the low HDL-C. Single-gene Mendelian disorders that reduce HDL-C have been described (Table 419-2) but are rare; the vast majority of patients with low HDL-C have a polygenic predisposition with secondary factors like obesity, insulin resistance, or HTG.

PRIMARY (GENETIC) CAUSES OF LOW HDL-C

Mutations in three key genes encoding proteins that play critical roles in HDL synthesis and catabolism result in hypoalphalipoproteinemia (primary low levels of HDL-C). Unlike the genetic forms of hypercholesterolemia, which are invariably associated with premature coronary atherosclerosis, genetic forms of hypoalphalipoproteinemia are usually not associated with clearly increased risk of ASCVD. Nevertheless, in the clinical setting of an HDL-C level <20 mg/dL without accompanying severe HTG, these rare conditions should be considered.

Gene Deletions and Missense Mutations in *APOA1* Complete genetic deficiency of apoA-I due to a complete deletion of the *APOA1* gene results in the virtual absence of circulating HDL, proving the critical role of apoA-I in HDL biogenesis. The *APOA1* gene is part of a gene cluster on chromosome 11 that includes *APOA5*, *APOC3*, and *APOA4*. Some patients with no apoA-I have large genomic deletions that include other genes in the cluster. The rare patient lacking apoA-I may have cholesterol deposits in the cornea and in the skin, and in contrast to the other genetic disorders of low HDL-C, premature CHD has been reported. Heterozygotes for apoA-I deletions have reduced HDL-C levels but no obvious clinical sequelae.

More common, but still rare, are heterozygous missense mutations in the *APOA1* gene associated with low plasma levels of HDL-C. The first example reported, and still the best known, is an Arg173Cys substitution in apoA-I (so-called apoA-I_{Milano}), found in multiple residents of a town in northern Italy. Heterozygotes for this mutation have very low plasma levels of HDL-C (<25 mg/dL) due to impaired LCAT activation and accelerated clearance of the HDL particles containing the abnormal apoA-I. Despite having very low plasma levels of HDL-C, these individuals do not appear to have an increased risk of premature CHD (neither are they protected against CHD as was initially believed). Multiple other rare *APOA1* missense mutations causing low HDL-C have been reported. A few of these mutations in *APOA1* (as well as some mutations in *APOA2*) promote the formation of amyloid fibrils, causing systemic amyloidosis.

Tangier Disease (*ABCA1* Deficiency) Tangier disease is a rare autosomal co-dominant form of extremely low plasma HDL-C levels that is caused by mutations in the *ABCA1* gene encoding ABCA1, a cellular transporter that facilitates efflux of unesterified cholesterol and phospholipids from cells to apoA-I as an acceptor (Fig. 419-3). Through transporting cellular lipids, ABCA1 in the hepatocytes and intestinal enterocytes promotes the extracellular lipidation of the apoA-I secreted from the basolateral membranes of these tissues. In the genetic absence of ABCA1, the nascent, poorly lipidated apoA-I is rapidly cleared from the circulation. Thus, patients with Tangier disease (both *ABCA1* alleles mutated) have extremely low circulating plasma levels of HDL-C (<5 mg/dL) and apoA-I (<5 mg/dL). Cholesterol accumulates in the reticuloendothelial system of these patients, resulting in hepatosplenomegaly and pathognomonic enlarged, grayish yellow or orange tonsils. An intermittent peripheral neuropathy (mononeuritis multiplex) or a sphingomyelia-like neurologic disorder can also be seen in this disorder. Tangier disease may be associated with some increased risk of ASCVD, although the association is not as robust as might have been anticipated, given the extremely low levels of HDL-C in these patients. Patients with Tangier disease also have low plasma levels of LDL-C, which may attenuate the atherosclerotic risk. Heterozygotes for *ABCA1* mutations have moderately reduced plasma HDL-C levels (~15–40 mg/dL), and the effect on risk of ASCVD remains uncertain.

Familial LCAT Deficiency This rare autosomal recessive disorder is caused by mutations in LCAT, an enzyme synthesized in the liver and secreted into the plasma, where it circulates associated with lipoproteins (Fig. 419-3). As reviewed above, the enzyme is activated by apoA-I and mediates the esterification of cholesterol to form CEs. Consequently, in familial LCAT deficiency, the proportion of free cholesterol in circulating lipoproteins is greatly increased (from ~25% to >70% of total plasma cholesterol). Deficiency in this enzyme interferes with the maturation of HDL particles and results in rapid catabolism of circulating apoA-I.

Two genetic forms of familial LCAT deficiency have been described in humans: complete deficiency (also called *classic LCAT deficiency*) and partial deficiency (also called *fish eye disease*). Progressive corneal opacification due to the deposition of free cholesterol in the cornea, very low plasma levels of HDL-C (usually <10 mg/dL), and variable HTG are characteristic of both disorders. In partial LCAT deficiency, there are no other known clinical sequelae. In contrast, patients with complete LCAT deficiency have hemolytic anemia and progressive renal insufficiency that eventually leads to end-stage renal disease. Remarkably, despite the extremely low plasma levels of HDL-C and apoA-I, premature ASCVD is not a consistent feature of either LCAT deficiency or fish eye disease. The diagnosis can be confirmed in a specialized laboratory by assaying plasma LCAT activity or by sequencing the *LCAT* gene.

Primary Hypoalphalipoproteinemia Primary hypoalphalipoproteinemia is defined as a plasma HDL-C level below the tenth percentile in the setting of relatively normal cholesterol and TG levels, no apparent secondary causes of low plasma HDL-C, and no clinical signs of LCAT deficiency or Tangier disease. A family history of low HDL-C suggests an inherited condition and may trigger an evaluation of one of the Mendelian causes of hypoalphalipoproteinemia. However, most patients with isolated low HDL do not have an identifiable single-gene disorder and likely have a polygenic etiology, possibly exacerbated by a secondary factor. The physiologic defect appears to be accelerated catabolism of HDL and its apolipoproteins. Several kindreds with

primary hypoalphalipoproteinemia and an increased incidence of premature CHD have been described, although it is not clear if the low HDL-C level is the cause of the accelerated atherosclerosis in these families.

SECONDARY FACTORS THAT REDUCE HDL-C LEVELS

Hypertriglyceridemia Low HDL-C is very commonly found in association with elevated TG levels. The lipolysis of TRLs generates lipids that transfer to HDL, and therefore, any impairment of lipolysis (the most common cause of elevated TGs) leads to reduced HDL biosynthesis. In settings of elevated TGs, where the HDL-C is not reduced, alternative explanations (e.g., FDBL, alcohol, estrogens) should be considered. Conversely, an isolated low HDL-C in the presence of normal TGs should prompt consideration of a primary genetic etiology (as above) or specific secondary factors (see below).

Very-Low-Fat Diet Dietary fat is positively associated with HDL-C levels. Individuals who eat very-low-fat vegan diets or who have anorexia or severe fat malabsorption often have low levels of HDL-C that are secondary to low dietary fat. In this setting, LDL-C levels are also usually low as well. There is no known harm to low HDL-C levels in this setting and no indication for liberalizing the diet solely for the purpose of raising the HDL-C.

Sedentary Lifestyle and Obesity Physical activity is known to have a (generally modest) effect in raising HDL-C levels, and conversely, a sedentary lifestyle is often associated with low HDL-C levels. Concordant with that observation, obesity is frequently associated with low HDL-C levels even when overt insulin resistance or HTG is not present. Increased physical activity and weight loss usually have some effect in raising HDL-C, which is not the primary reason for recommending these interventions but can have a motivating influence on the patient.

ANABOLIC STEROIDS AND TESTOSTERONE Anabolic steroids have a well-established effect on lowering HDL-C levels, sometimes quite dramatically. Testosterone supplementation can also reduce HDL-C levels, although not to the degree caused by anabolic steroids. In a young male patient who presents with unexplained very low HDL-C, a careful history of medication and supplement use should be taken.

APPROACH TO THE PATIENT

Lipoprotein Disorders

The major goals in the diagnosis and clinical management of lipoprotein disorders are (1) prevention of CVD and related cardiovascular events and (2) prevention of acute pancreatitis in patients with severe HTG. Given the high prevalence of dyslipidemia and the proven clinical benefits of early diagnosis and initiation of therapy, it is essential that physicians screen lipids systematically, rule out secondary causes of dyslipidemia, suspect inherited disorders of lipoprotein metabolism where appropriate, actively promote family-based screening, carefully assess risk for ASCVD and consider additional risk stratification approaches, and be knowledgeable about the wide range of existing therapeutic options for dyslipidemia. The field of clinical lipidology has matured and is moving toward a more systematic clinical application of genomic medicine. Diagnostic DNA sequencing or genotyping in patients with suspected FCS, FPLD, FH, and FDBL has the potential to enhance molecular diagnosis, facilitate appropriate therapeutic interventions, and promote family-based cascade screening based on genetic diagnosis.

DIAGNOSIS

A critical first step in managing a lipoprotein disorder is to attempt to determine the class or classes of lipoproteins that are increased or decreased in the patient. Once the dyslipidemia is accurately classified, efforts should be directed to identify or rule out any possible secondary causes (Table 419-3). A careful social, medical, and family history should be obtained. In patients with elevated TG levels (>150 mg/dL), a fasting glucose and/or hemoglobin A_{1c} should be obtained to rule out diabetes. In patients with elevated LDL-C levels (>160 mg/dL), a TSH should be obtained to rule out hypothyroidism and consideration should be given to the possibility of liver or kidney disease. Once secondary causes have been ruled out, attempts should be made to diagnose a primary lipid disorder, because the underlying genetic defect can provide important prognostic information regarding the risk of pancreatitis in severe HTG and the risk of ASCVD in other dyslipidemias, as well as impact on the choice of drug therapy and the screening of other family members. Obtaining the correct diagnosis often requires a detailed family history, lipid analyses in family members, and sometimes specialized or genetic testing.

Severe Hypertriglyceridemia If the fasting plasma TG level is >500 mg/dL, the patient has severe HTG and may be at risk for pancreatitis. If the TG levels are persistently severely elevated, especially if they are >1000 mg/dL, and the total cholesterol-to-TG ratio is >8, FCS should be considered, and genetic testing of an FCS gene panel may be indicated (Table 419-2). If central obesity, insulin resistance, and/or fatty liver disease are also present, consideration should be given to the possibility of FPLD, and an FPLD gene panel may be indicated (Table 419-2). However, most individuals with severe HTG do not have a single-gene disorder but have increased polygenic risk for high TGs often exacerbated by secondary factors (e.g., diet, alcohol, obesity, insulin resistance, medications). Such patients are still at risk for acute pancreatitis and should be treated to reduce their TG levels and thus their risk of pancreatitis (see below).

Hypercholesterolemia If the LDL-C levels are >190 mg/dL, the patient has severe hypercholesterolemia and is at risk for premature ASCVD. In absence of secondary causes, FH should be considered, particularly if there is a family history of hypercholesterolemia and/or premature CHD, and genetic testing of an FH gene panel may be indicated (Table 419-2). The Centers for Disease Control and Prevention has identified FH as a Tier 1 condition for implementation of public health genomics. While FH is ultimately a clinical diagnosis, a finding of a causal mutation may appropriately result in earlier and more aggressive therapy to lower LDL-C and should also promote family-based cascade screening. Recessive forms of severe hypercholesterolemia are rare, but if a patient with severe hypercholesterolemia has parents with normal cholesterol levels, ARH, sitosterolemia, and LALD should be considered, and genetic testing may be indicated (Table 419-2). Patients without an identified genetic variant or who have more moderate hypercholesterolemia are likely to have polygenic hypercholesterolemia but should still be considered at risk and eligible for treatment (see below).

Mixed Hyperlipidemia Patients with elevations in fasting plasma levels of both TGs (>150 mg/dL) and LDL-C (>130 mg/dL), often accompanied by reduced levels of HDL-C (<40 mg/dL in men and <50 mg/dL in women), are common and such patients are often diagnosed as having "mixed hyperlipidemia." Most such patients are at increased risk of ASCVD and merit consideration of lifestyle and often pharmacologic interventions. Secondary factors, particularly obesity, insulin resistance, and type 2 diabetes, are common in such patients, who often also have increased polygenic risk for dyslipidemia. The presence of palmar or tuberous xanthomas or an unusual lipid profile of total cholesterol and TG levels in the same range with an HDL-C that is not reduced should prompt consideration of FDBL, or type III hyperlipidemia, and can be diagnosed by advanced lipoprotein testing or genetic testing for the *APOE2* genotype. FDBL patients should be managed aggressively due to substantially increased risk of ASCVD. More commonly, patients with mixed hyperlipidemia, particularly those with family histories of dyslipidemia or premature ASCVD, have familial combined hyperlipidemia (FCHL). ApoB should be measured in such patients, and the finding of substantially elevated apoB levels can help identify patients with FCHL, who are at especially increased risk of ASCVD and require more aggressive treatment.

TREATMENT

Severe Hypertriglyceridemia

There is a well-established observational relationship between severe HTG, particularly chylomicronemia, and acute pancreatitis; however, there has never been a clinical trial designed or powered to definitively prove that intervention to reduce TGs reduces the risk of pancreatitis. Nevertheless, it is generally considered appropriate medical practice to intervene in patients with TGs >500 mg/dL in order to reduce the risk of pancreatitis. It remains uncertain whether chylomicronemia increases risk for ASCVD per se. Importantly, moderate HTG (TG 150–500 mg/dL) is associated with increased ASCVD risk; management of these patients is focused on reducing risk of ASCVD and on reducing LDL-C, non-HDL-C, and apoB.

LIFESTYLE AND MODIFIABLE FACTORS

In patients with severe HTG, lifestyle modification can be associated with a significant reduction in plasma TG level. Importantly, certain medications can exacerbate HTG (Table 419-3). Patients who drink alcohol should be encouraged to decrease or preferably eliminate their intake. Patients with severe HTG often benefit from a formal dietary consultation with a dietician intimately familiar with counseling patients on the dietary management of high TGs. Dietary fat intake should be restricted to reduce the formation of chylomicrons in the intestine. The excessive intake of simple carbohydrates should be discouraged because insulin drives TG production in the liver. Aerobic exercise and even increase in regular physical activity can have a positive effect in reducing TG levels and should be strongly encouraged. For patients who are overweight, weight loss can help to reduce TG levels. In extreme cases, bariatric surgery has been shown to not only produce effective weight loss but also substantially reduce plasma TG levels. Many patients with diabetes have HTG, and better control of diabetes can result in lowering of TGs. GLP-1 agonists prescribed for diabetes or obesity can reduce TG levels.

PHARMACOLOGIC THERAPY

Despite lifestyle interventions, many patients with severe HTG require pharmacologic therapy (Table 419-4). Patients who persist in having fasting TG >500 mg/dL despite active lifestyle management are candidates for pharmacologic therapy. The two major classes of drugs used for management of these patients are fibrates and omega-3 fatty acids (fish oils). In addition, statins can reduce plasma TG levels and also reduce ASCVD risk and should be used in patients with severe HTG who are at increased risk of ASCVD.

Fibrates Fibric acid derivatives, or fibrates, are agonists of PPARα, a nuclear receptor involved in the regulation of lipid metabolism. Fibrates stimulate LPL activity (enhancing TG hydrolysis), reduce apoC-III synthesis (enhancing lipoprotein remnant clearance), promote β-oxidation of fatty acids, and may reduce VLDL TG production. Fibrates reduce TG levels by ~30% in individuals with severe HTG and are often used as first-line therapy. They do not reduce and sometimes modestly raise LDL-C levels. Fibrates are generally well tolerated but can cause myopathy, especially when combined with statins, can raise creatinine, and are associated with an increase in gallstones. Fibrates can potentiate the effect of warfarin and certain oral hypoglycemic agents.

Omega-3 Fatty Acids (Fish Oils) Omega-3 fatty acids, or omega-3 polyunsaturated fatty acids (n-3 PUFAs), commonly known as fish oils, are present in high concentration in fish and in flaxseed. The n-3 PUFAs used for the treatment of HTG are eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA). n-3 PUFAs have been concentrated into capsules and, in doses of 3–4 g/d, are effective at lowering fasting TG levels by ~30%. Fish oils can cause an increase in plasma LDL-C levels in some patients. Icosapent ethyl is an EPA-only product that has been shown to reduce cardiovascular events in patients with HTG. In general, fish oils are well tolerated, with the major side effect being dyspepsia. They appear to be safe, at least at doses up to 3–4 g, but can be associated with a prolongation in the bleeding time. Fish oils can be first-line therapy for the treatment of severe HTG or can be used in combination with fibrates.

APOC3 Silencing ApoC-III inhibits LPL and TRL uptake, and genetic variants in the *APOC3* gene reduce TG levels and risk of ASCVD. Volanesorsen is an antisense oligonucleotide (ASO) targeted to the *APOC3* mRNA in the liver; it significantly reduces plasma apoC-III and TG levels and is approved in Europe for patients with FCS. It has been associated with severe thrombocytopenia. Additional therapeutic approaches to APOC3 and other targets for TG lowering (e.g., ANGPTL3) are in development.

Hypercholesterolemia (Elevated LDL-C with or without Elevated TG)

There are abundant and compelling data that intervention to reduce LDL-C substantially reduces the risk of ASCVD, including myocardial infarction and stroke, as well as total mortality. Thus, it is imperative that patients with hypercholesterolemia be carefully assessed for cardiovascular risk and need for intervention. It is also worth emphasizing that patients with or at high risk for ASCVD who have plasma LDL-C levels in the "normal" or average range also benefit from intervention to reduce LDL-C levels.

LIFESTYLE AND MODIFIABLE FACTORS

In patients with elevated LDL-C, lifestyle modifications can be effective but are often less effective than in HTG. Patients should receive dietary counseling to reduce the content of saturated fats and trans fats in the diet. Obese patients should make an effort to lose weight. Regular aerobic exercise has relatively little impact on reducing plasma LDL-C levels, although it has cardiovascular benefits independent of LDL-C lowering. Patients with hypothyroidism should be optimally controlled. Finally, certain medications can elevate LDL-C levels (Table 419-3).

PHARMACOLOGIC THERAPY

The decision to use LDL-lowering drug therapy (Table 419-4)—with a statin being first-line therapy—depends on the presence of ASCVD or, if absent, the level of LDL-C as well as the level of cardiovascular risk. In patients with established ASCVD, drug therapy to reduce LDL-C is well supported by clinical trial data to reduce LDL-C as long as it remains >70 mg/dL, using combination drug therapy if necessary. In the absence of ASCVD, patients with FH must be treated to reduce the very high lifetime risk of ASCVD, and treatment should be initiated as early as possible, ideally during childhood. Otherwise, the decision to initiate LDL-lowering drug therapy is generally determined by the level of cardiovascular risk. For patients >40 years old without clinical CVD, the ASCVD pooled cohort risk calculator can be used to determine the 10-year absolute risk for CVD, and current guidelines suggest that a 10-year risk >7.5% merits consideration of statin therapy regardless of plasma LDL-C level. For younger patients, the assessment of lifetime risk of CVD may help inform the decision to start a statin, as well as a careful assessment of family history of ASCVD. In patients for whom the decision to start a statin is uncertain due to borderline ASCVD risk and/or borderline LDL-C levels, additional risk stratification might be considered. Blood tests that predict ASCVD risk beyond traditional risk factors include apoB, Lp(a), and high-sensitivity C-reactive protein (hs-CRP). In patients who are of a sufficient age (men >40 years and women >50 years), a coronary artery calcium (CAC) score has been shown to provide independent information about risk of future CAD. Elevated levels of one or more of these biomarkers or an elevated CAC score might be used to justify initiation of statin therapy in primary prevention for patients who are in a borderline zone with regard to treatment. Finally, given the strong polygenic contribution to ASCVD, there is increasing interest in

the concept that a polygenic risk score for CAD might eventually be of clinical utility in lifetime risk assessment and decision-making regarding statin therapy in primary prevention.

HMG-CoA Reductase Inhibitors (Statins) Statins inhibit HMG-CoA reductase, a key enzyme in cholesterol biosynthesis. By inhibiting cholesterol synthesis in the liver, statins lead to a counterregulatory increase in the expression of the LDL receptor and thus accelerated clearance of circulating LDL, resulting in a dose-dependent reduction in plasma levels of LDL-C. The magnitude of LDL-C lowering associated with statin treatment (~30–55%) varies by statin and among individuals, but once a patient is on a statin, the doubling of the statin dose produces a ~6% further reduction in the level of plasma LDL-C. An extensive body of randomized clinical trials has clearly established that statin therapy significantly reduces major cardiovascular events (and in some cases total mortality) in both primary and secondary prevention settings. The seven statins currently available differ in their LDL-C–reducing potency (Table 419-4). Current recommendations are to use high-intensity statin therapy in patients with ASCVD or deemed at high risk of ASCVD. Statins also modestly reduce plasma TGs in a dose-dependent fashion roughly proportional to their LDL-C–lowering effects.

Statins, taken in tablet form once a day, are remarkably safe and well tolerated. The most important side effect associated with statin therapy is muscle pain, or myalgia, which occurs in 3–5% of patients, some of whom are unable to tolerate any statin. Severe myopathy (associated with an increase in plasma creatine kinase [CK]) and even rhabdomyolysis can occur rarely with statin treatment. The risk of statin-associated myalgia or myopathy is increased by the presence of older age, frailty, renal insufficiency, and coadministration of drugs that interfere with the metabolism of certain statins, such as erythromycin and related antibiotics, antifungal agents, immunosuppressive drugs, and fibric acid derivatives (particularly gemfibrozil). In the event of muscle symptoms, a plasma CK level may be obtained to differentiate myopathy from myalgia. Serum CK levels need not be monitored on a routine basis in patients taking statins because an elevated CK in the absence of symptoms does not predict the development of myopathy and does not necessarily suggest the need for discontinuing the drug. Statins can result in elevation in liver transaminases (alanine aminotransferase [ALT] and aspartate aminotransferase [AST]), but it is usually mild and transient and generally does not require discontinuation. Finally, meta-analyses of large randomized controlled clinical trials with statins indicate a slight excess in incident type 2 diabetes, an observation as yet not fully understood. However, the cardiovascular benefits associated with statin therapy far outweigh the slight increase in incident diabetes. Based on their safety and extensively documented benefit with regard to cardiovascular outcomes, statins are the clear drug class of choice for LDL-C reduction and are by far the most widely used class of lipid-lowering drugs.

Cholesterol Absorption Inhibitor Cholesterol within the lumen of the small intestine is derived from the diet (about one-third) and the bile (about two-thirds) and is actively absorbed by the enterocyte through a process that involves the protein NPC1L1. Ezetimibe (Table 419-4) is a cholesterol absorption inhibitor that binds directly to and inhibits NPC1L1 and blocks the intestinal absorption of cholesterol. Ezetimibe (10 mg taken once daily) inhibits cholesterol absorption by almost 60%, resulting in a reduction in delivery of dietary sterols in the liver and a compensatory increase in hepatic LDL receptor expression. The mean reduction in plasma LDL-C on ezetimibe (10 mg) is 18%, and the effect is additive when used in combination with a statin. Effects on TG and HDL-C levels are negligible. Ezetimibe added to a statin has been shown to significantly reduce major cardiovascular events compared with statin alone. It is generally considered the second-line option for adding to a statin in order to achieve further LDL-C reduction. Ezetimibe is very safe and well-tolerated. When used in combination with a statin, monitoring of liver transaminases is recommended. The only roles for ezetimibe in monotherapy are in patients who do not tolerate statins and in some patients with sitosterolemia.

PCSK9 Inhibitors Circulating PCSK9 targets the LDL receptor for lysosomal degradation, thus reducing its recycling and abundance at the surface of the hepatocyte. Genetic loss of function of *PCSK9* results in low levels of LDL-C and protection from CAD. Antibodies to PCSK9 (Table 419-4) sequester it and functionally increase the number of LDL receptors available to remove LDL from the blood. They are highly effective in lowering LDL-C, with an ~60% reduction in LDL-C. They also reduce plasma levels of Lp(a) modestly. Both PCSK9 antibodies have been shown to significantly reduce cardiovascular events when added to a statin in patients with existing CAD. These antibodies are administered subcutaneously every 2 weeks. They are generally well tolerated, with a side effect being injection site reactions. They are generally indicated as second-line (added to statin) or third-line (added to statin plus ezetimibe) therapy in patients with FH or ASCVD in whom LDL-C is not reduced to acceptable levels with a statin (with or without ezetimibe) alone. An alternative approach to silencing *PCSK9*, inclisiran, is a therapeutic siRNA molecule that targets the *PCSK9* mRNA in the liver. In contrast to the antibodies, it is administered subcutaneously every 6 months. It is effective in reducing LDL-C by ~60% and appears to be well tolerated and safe; cardiovascular outcomes trials are ongoing.

ATP Citrate Lyase Inhibitor Bempedoic acid is a first-in-class competitive inhibitor of ATP citrate lyase (ACL), which acts on mitochondrial-derived citrate to generate production of acetyl-CoA, which is subsequently used for cholesterol synthesis. Thus, it reduces cholesterol synthesis through a different mechanism than statins, ultimately upregulating the hepatic LDL receptor. Bempedoic acid is a prodrug that requires activation by very-long-chain acyl-CoA synthetase-1 (ASCVL1), which is not expressed in skeletal muscle, potentially explaining why it has less association with myalgias than statins; indeed, it has been shown to be relatively well tolerated in patients with statin-induced myalgias. In phase 3 trials, bempedoic acid 180 mg daily reduced LDL-C by ~18% when added to a statin and by ~23% as monotherapy. In a large cardiovascular outcomes trial in statin-intolerant patients, bempedoic acid 180 mg daily was shown to significantly reduce (by 13%) a four-component composite of major adverse cardiovascular events. It is also available in a fixed-dose combination with ezetimibe, which reduced LDL-C by ~36%, for patients who are statin intolerant. It can be used in combination with statins but should not be used with simvastatin in a dose >20 mg. Bempedoic acid is associated with increased uric acid levels and gout as well as with increased liver enzymes and cholelithiasis. Unlike statins, it is not associated with increased incidence of diabetes.

Bile Acid Sequestrants (Resins) Bile acid sequestrants (BAS) bind bile acids in the intestine and promote their excretion rather than reabsorption in the ileum. To maintain the bile acid pool size, the liver diverts cholesterol to bile acid synthesis. The decreased hepatic intracellular cholesterol content results in upregulation of the LDL receptor and enhanced LDL clearance from the plasma. BAS, including cholestyramine, colestipol, and colesevelam (Table 419-4), primarily reduce plasma LDL-C levels but can cause an increase in plasma TGs. Therefore, patients with HTG generally should not be treated with bile acid–binding resins. Cholestyramine and colestipol are insoluble resins that must be suspended in liquids. Colesevelam is available as tablets but generally requires up to six to seven tablets per day for effective LDL-C lowering. BAS are effective in combination with statins and in combination with ezetimibe. Side effects of resins are limited to the gastrointestinal tract and include bloating and constipation. Because BAS are not systemically absorbed, they are very safe and are the cholesterol-lowering drug

of choice in children and in women who are pregnant, lactating, or actively trying to conceive. However, they are otherwise fourth- or fifth-line drugs for LDL-C reduction in other settings.

Specialized Drugs for HoFH Three "orphan" drugs are approved specifically for the management of HoFH, a rare condition caused by biallelic mutations in the major genes causing FH in which patients respond poorly to traditional LDL-lowering medications. Lomitapide is a small-molecule inhibitor of MTP that reduces LDL-C by ~50%, and mipomersen is an antisense oligonucleotide against apoB that reduces LDL-C by ~25%. Both of these drugs reduce hepatic VLDL production and thus LDL-C levels; however, due to their mechanism of action, each drug causes an increase in hepatic fat, the long-term consequences of which are unknown. In addition, lomitapide is associated with gastrointestinal-related side effects, and mipomersen is associated with skin reactions and flulike symptoms. Finally, an antibody inhibitor of ANGPTL3, evinacumab, was approved in 2021 for the treatment of HoFH. In a phase 3 trial, an intravenous infusion every 4 weeks reduced LDL-C levels in patients with HoFH by ~50% and was well tolerated. One of these three drugs should be strongly considered in HoFH patients after a trial of a high-intensity statin, and possibly a PCSK9 inhibitor, is shown to be insufficient to reduce LDL-C levels.

LDL Apheresis Patients with severe hypercholesterolemia who cannot reduce their LDL-C to acceptable levels despite optimally tolerated combination drug therapy are candidates for LDL apheresis. In this process, the patient's plasma is passed over a column that selectively removes the LDL, and the LDL-depleted plasma is returned to the patient. LDL apheresis is indicated for patients on maximally tolerated combination drug therapy (including a PCSK9 inhibitor) who have CHD and a plasma LDL-C level >200 mg/dL or no CHD and a plasma LDL-C level >300 mg/dL; LDL apheresis could be considered in high-risk patients who have an LDL-C >160 mg/dL on maximal therapy.

420 The Metabolic Syndrome

Robert H. Eckel

The metabolic syndrome (syndrome X, insulin resistance syndrome) consists of a constellation of metabolic abnormalities that confer increased risk of cardiovascular disease (CVD) and diabetes mellitus. Evolution of the criteria for the metabolic syndrome since the original definition by the World Health Organization in 1998 reflects growing clinical evidence and analysis by a variety of consensus conferences and professional organizations. The major features of metabolic syndrome include central obesity, hypertriglyceridemia, low levels of high-density lipoprotein (HDL) cholesterol, hyperglycemia, and hypertension **(Table 420-1)**.

GLOBAL HEALTH/EPIDEMIOLOGY

The most challenging feature of the metabolic syndrome to define is waist circumference. Intraabdominal circumference (visceral adipose tissue) is most strongly related to insulin resistance and risk of diabetes and CVD, and for any given waist circumference, the distribution of adipose tissue between subcutaneous (SC) and visceral depots varies substantially. Thus, within and between populations, there is a lesser versus greater risk at the same waist circumference. These differences in populations reflect the range of waist circumferences considered to confer risk in different geographic locations (Table 420-1).

The prevalence of the metabolic syndrome varies around the world, in part reflecting the age and ethnicity of the populations studied and the diagnostic criteria applied. In general, the prevalence of metabolic syndrome increases with age. The prevalence of metabolic syndrome in the U.S. adult population meeting the criteria of the National Cholesterol Education Program (NCEP) and Adult Treatment Panel III (ATPIII) is ~35%. Greater global industrialization is associated with rising rates of obesity and related increase in the prevalence of the metabolic syndrome, especially as the population ages.

Using National Health and Nutrition Examination Survey (NHANES) data from 1999–2018, the prevalence of metabolic syndrome in 28,049 adults in the United States was 33.4%. The highest prevalence was age-dependent with reduction by age 80 among all subgroups, i.e., from 19.5% among those aged 20–39 years to 48.6% among those aged ≥60 years. Importantly, the rising prevalence and severity of obesity among children reflect features of the metabolic syndrome in a younger population, now estimated to be 12 and 30% among obese and overweight children, respectively.

The frequency distribution of different components of metabolic syndrome for the U.S. population (NHANES III) and the Guangdong Gut Microbiome Project of China is summarized in **Fig. 420-1**. Note the major differences in the U.S. population compared to Han Chinese. Moreover, within the United States, abdominal obesity appears equally prevalent in all U.S. races, whereas the prevalence of age-dependent other components differs as shown in Fig. 420-1. Increases in hyperglycemia were most evident in the 2017–2018 sample, whereas central obesity, low HDL cholesterol, and hypertension prevalence have been relatively constant, while levels of triglycerides (defined as >150 mg/dL) have progressively decreased.

RISK FACTORS

Overweight/Obesity Metabolic syndrome was first described in the early twentieth century; however, the worldwide overweight/obesity epidemic has recently been the force driving its increasing recognition. Central adiposity is a key feature of the syndrome, and the syndrome's prevalence reflects the strong relationship between waist circumference and increasing adiposity. However, despite the importance of obesity, patients who are of normal weight may also be insulin-resistant and may have metabolic syndrome. This phenotype is particularly evident for populations in India, Southeast Asia, and Central America.

TABLE 420-1 NCEP:ATPIII[a] 2001 and Harmonizing Definition Criteria for the Metabolic Syndrome

NCEP:ATPIII 2001	HARMONIZING DEFINITION[b]
Three or more of the following: • Central obesity: waist circumference >102 cm (males), >88 cm (females) • Hypertriglyceridemia: triglyceride level ≥150 mg/dL or specific medication • Low HDL[c] cholesterol: <40 mg/dL and <50 mg/dL for men and women, respectively, or specific medication • Hypertension: blood pressure ≥130 mmHg systolic or ≥85 mmHg diastolic or specific medication • Fasting plasma glucose level ≥100 mg/dL or specific medication or previously diagnosed type 2 diabetes	**Three of the following:** Waist circumference (cm) **Men** / **Women** / **Ethnicity** ≥94 / ≥80 / Europid, sub-Saharan African, Eastern and Middle Eastern ≥90 / ≥80 / South Asian, Chinese, and ethnic South and Central American ≥85 / ≥90 / Japanese • Fasting triglyceride level >150 mg/dL or specific medication • HDL cholesterol level <40 mg/dL and <50 mg/dL for men and women, respectively, or specific medication • Blood pressure >130 mm systolic or >85 mm diastolic or previous diagnosis or specific medication • Fasting plasma glucose level ≥100 mg/dL (alternative indication: drug treatment of elevated glucose levels)

[a]National Cholesterol Education Program and Adult Treatment Panel III. [b]In this analysis, the following thresholds for waist circumference were used: white men, ≥94 cm; African-American men, ≥94 cm; Mexican-American men, ≥90 cm; white women, ≥80 cm; African-American women, ≥80 cm; Mexican-American women, ≥80 cm. For participants whose designation was "other race—including multiracial," thresholds that were once based on Europid cutoffs (≥94 cm for men and ≥80 cm for women) and on South Asian cutoffs (≥90 cm for men and ≥80 cm for women) were used. For participants who were considered "other Hispanic," the International Diabetes Federation thresholds for ethnic South and Central Americans were used. [c]High-density lipoprotein.

Sedentary Lifestyle Physical inactivity and less cardiorespiratory fitness are predictors of CVD events and the related risk of death. Many components of the metabolic syndrome are associated with a sedentary lifestyle, including increased adipose tissue (predominantly central), reduced HDL cholesterol, and increased triglycerides, blood pressure, and glucose in genetically susceptible persons. Compared with individuals who watch television or videos or use the computer <1 h daily, those who do so for >4 h daily have a twofold increased risk of the metabolic syndrome.

Genetics No single gene explains the complex phenotype called metabolic syndrome. However, using genome-wide association and candidate gene approaches, several genetic variants are associated with metabolic syndrome. Although many of the loci have unknown function, many others relate to body weight and composition, insulin resistance, and unfavorable disturbances in lipid and lipoprotein metabolism. In general, heritability estimates for each of the metabolic traits exceed 50%.

Aging The metabolic syndrome affects nearly 50% of the U.S. population aged >60, and at >60 years of age, women are more often affected. The age dependency of the syndrome's prevalence is seen in most populations around the world.

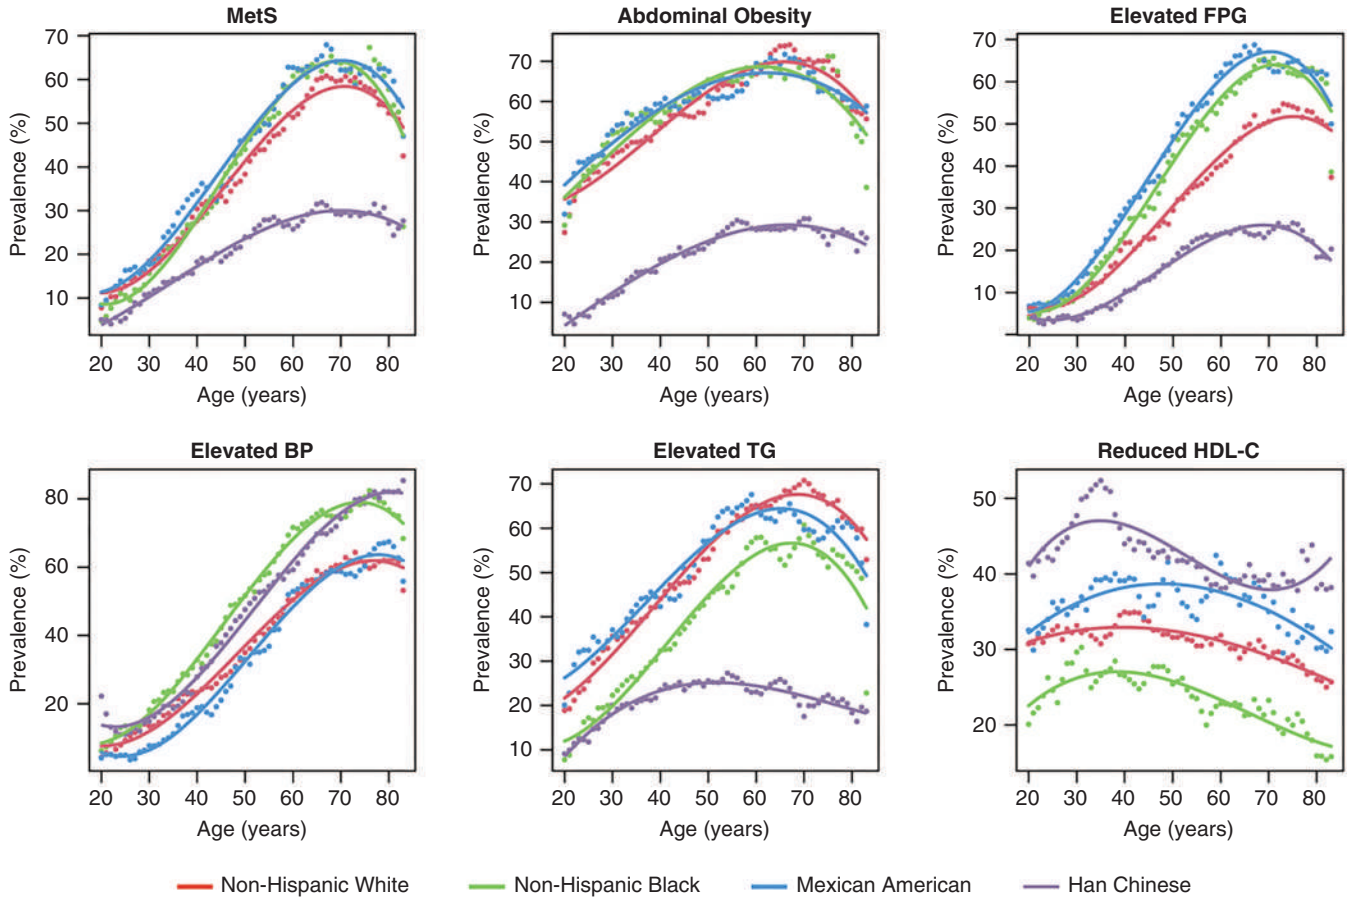

FIGURE 420-1 The frequency distribution of the metabolic syndrome for the U.S. population (National Health and Nutrition Examination Survey [NHANES] III) and the Guangdong Gut Microbiome Project of China. The prevalence of metabolic syndrome (MetS) and its components with age across different races. Prevalence was estimated using a SWAN algorithm (shown as dots). The trajectory of the prevalence of MetS with age was fitted by cubic regressions (shown as lines). BP, blood pressure; FPG, fasting plasma glucose; HDL-C, high-density lipid cholesterol; SWAN, sliding window–based algorithm; TG, triglycerides. *(Reproduced from R Zhang et al: The racial disparities in the epidemic of metabolic syndrome with increased age: A study from 28,049 Chinese and American adults. Front Public Health 9:797183, 2022.)*

Diabetes Mellitus Diabetes mellitus can be included in both the NCEP and the Harmonizing Definitions of metabolic syndrome, but the greatest value of metabolic syndrome, and especially fasting glucose, is predicting type 2 diabetes. The great majority (~75%) of patients with type 2 diabetes or impaired glucose tolerance have metabolic syndrome. The presence of metabolic syndrome in these populations relates to a higher prevalence of CVD than in patients who have type 2 diabetes or impaired glucose tolerance but do not have the syndrome.

Cardiovascular Disease Individuals with metabolic syndrome are twice as likely to die of CVD as those who do not, and their risk of acute myocardial infarction or stroke is threefold higher. The approximate prevalence of metabolic syndrome among patients with coronary heart disease (CHD) is up to 60% in persons >75 years, with a prevalence of ~35% among patients with premature coronary artery disease (age ≤45) and a particularly higher prevalence among women. With appropriate cardiac rehabilitation and changes in lifestyle (e.g., nutrition, physical activity, weight reduction, and—in some cases—pharmacologic therapy), the prevalence of the syndrome can be reduced.

Lipodystrophy Lipodystrophic disorders in general are associated with metabolic syndrome. Moreover, it is quite common for such patients to present with the metabolic syndrome. Both genetic lipodystrophy (e.g., Berardinelli-Seip congenital lipodystrophy, Dunnigan familial partial lipodystrophy) and acquired lipodystrophy (e.g., HIV-related lipodystrophy and in HIV patients receiving certain antiretroviral therapies) may give rise to severe insulin resistance and many of the components of metabolic syndrome.

ETIOLOGY

Insulin Resistance The most accepted and unifying hypothesis to describe the pathophysiology of metabolic syndrome is insulin resistance, caused systemically by an incompletely understood defect in insulin action **(Chap. 415)**. The onset of insulin resistance is heralded by postprandial hyperinsulinemia, which is followed by fasting hyperinsulinemia and ultimately by hyperglycemia.

An early major contributor to the development of insulin resistance is an overabundance of circulating fatty acids **(Fig. 420-2)**. Plasma albumin-bound free fatty acids are derived predominantly from adipose-tissue triglyceride stores released by intracellular lipolytic enzymes. The lipolysis of triglyceride-rich lipoproteins in tissues by lipoprotein lipase also produces free fatty acids. Insulin mediates both anti-lipolysis and the stimulation of lipoprotein lipase in adipose tissue. Of note, the inhibition of lipolysis in adipose tissue is the most sensitive pathway of insulin action. Thus, when insulin resistance develops, increased lipolysis produces more fatty acids, which further decreases the anti-lipolytic effect of insulin. Excessive fatty acids enhance substrate availability and create insulin resistance by modifying downstream signaling. Fatty acids impair insulin-mediated glucose uptake and are associated with accumulation of triglycerides in both skeletal and cardiac muscle, whereas increased fatty acid flux increases endogenous glucose production and triglyceride production, accumulation, and secretion in the liver.

Reductions in leptin action may also be a pathophysiologic mechanism to explain metabolic syndrome. Physiologically, leptin reduces appetite, promotes energy expenditure, and enhances insulin sensitivity. In addition, leptin may regulate cardiac and vascular function through a nitric oxide–dependent mechanism. However, when obesity

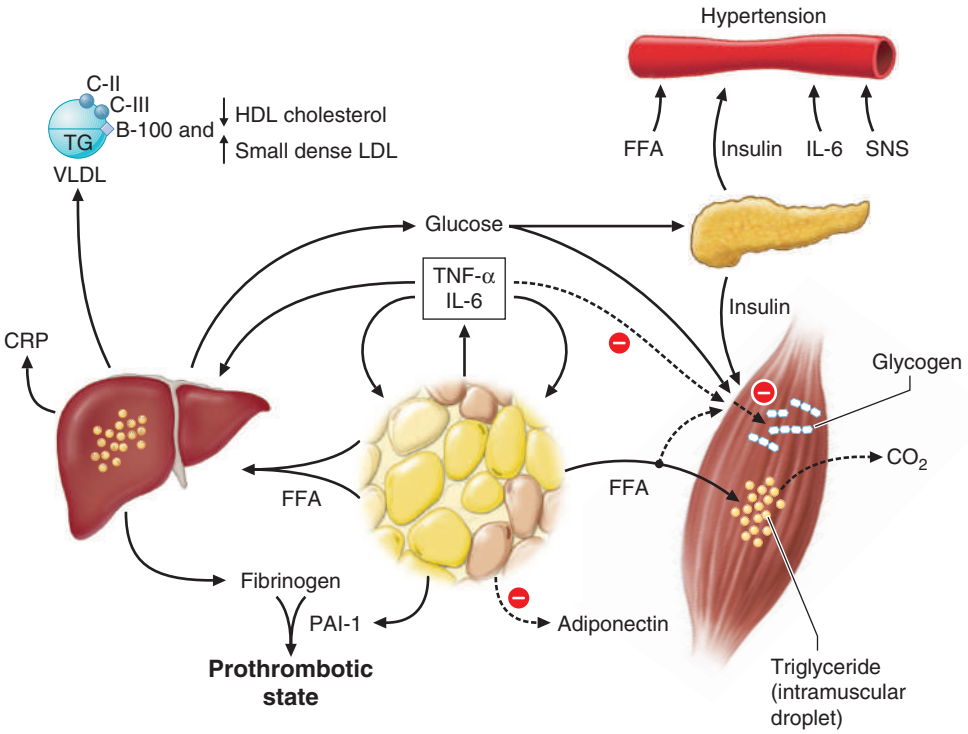

FIGURE 420-2 Pathophysiology of the metabolic syndrome. Free fatty acids (FFAs) are released in abundance from an expanded adipose tissue mass. In the liver, FFAs result in increased production of glucose and triglycerides and secretion of very-low-density lipoproteins (VLDLs). Associated lipid/lipoprotein abnormalities include reductions in high-density lipoprotein (HDL) cholesterol and an increased low-density lipoprotein (LDL) particle number. FFAs also reduce insulin sensitivity in muscle by inhibiting insulin-mediated glucose uptake. Associated defects include a reduction in glucose partitioning to glycogen and increased lipid accumulation in triglyceride (TG). The increase in circulating glucose, and to some extent FFAs, increases pancreatic insulin secretion, resulting in hyperinsulinemia. Hyperinsulinemia may result in enhanced sodium reabsorption and increased sympathetic nervous system (SNS) activity and contribute to hypertension, as might higher levels of circulating FFAs. The proinflammatory state is superimposed and contributory to the insulin resistance produced by excessive FFAs. The enhanced secretion of interleukin 6 (IL-6) and tumor necrosis factor α (TNF-α) produced by adipocytes and monocyte-derived macrophages results in more insulin resistance and lipolysis of adipose tissue triglyceride stores to circulating FFAs. IL-6 and other cytokines also enhance hepatic glucose production, VLDL production by the liver, hypertension, and insulin resistance in muscle. Insulin resistance also contributes to increased triglyceride accumulation in the liver (nonalcoholic fatty liver disease). Cytokines and FFAs also increase hepatic production of fibrinogen and adipocyte production of plasminogen activator inhibitor 1 (PAI-1), resulting in a pro-thrombotic state. Higher levels of circulating cytokines stimulate hepatic production of C-reactive protein (CRP). Reduced production of the anti-inflammatory and insulin-sensitizing cytokine adiponectin is also associated with the metabolic syndrome. *(Reproduced with permission from RH Eckel et al: The metabolic syndrome. Lancet 365:1415, 2005.)*

develops, hyperleptinemia ensues, with evidence of leptin resistance in the brain and other tissues resulting in insulin resistance and associated inflammation, hyperlipidemia, and a plethora of cardiovascular disorders, such as hypertension, atherosclerosis, CHD, and heart failure. Moreover, a series of adipokines relate to metabolic syndrome. Whereas adiponectin improves insulin sensitivity in adipose tissue and skeletal muscle, visfatin, fetuin-A, resistin, asprosin, and plasminogen activator inhibitor-1 contribute to insulin resistance and systemic glucose intolerance.

The oxidative stress hypothesis provides a unifying theory for aging and the predisposition to metabolic syndrome. In studies of insulin-resistant individuals with obesity or type 2 diabetes, the offspring of persons with type 2 diabetes, and the elderly, a defect in mitochondrial oxidative phosphorylation leads to the accumulation of triglycerides and related lipid molecules in muscle, liver, and other tissues, i.e., β-cells.

The gut microbiome has emerged as an important contributor to the development of obesity and related metabolic disorders, including inflammation and components of metabolic syndrome. Although the mechanisms remain uncertain, an increased ratio of Firmicutes/Bacteroidetes species in addition to genetic predisposition, diet, and bile acid metabolism are associated with and may play an etiologic role in metabolic syndrome.

Increased Waist Circumference Waist circumference is an important component of the most recent and frequently applied diagnostic criteria for metabolic syndrome. However, measuring waist circumference does not reliably distinguish increases in SC abdominal adipose tissue from that in intra-abdominal or visceral fat; this distinction requires dual X-ray absorptiometry (DEXA), computed tomography (CT), or magnetic resonance imaging (MRI) to discriminate. With increases in visceral adipose tissue, adipose tissue–derived free fatty acids reach the liver more readily. In contrast, increases in abdominal SC fat release lipolysis products into the systemic circulation and therefore have fewer direct effects on hepatic metabolism. Relative increases in visceral versus SC adipose tissue with increasing waist circumference in Asians and Asian Indians may explain the greater prevalence of metabolic syndrome in those populations than in African Americans, in whom SC fat predominates. It is also possible that visceral fat is a marker for—but not the source of—excess postprandial free fatty acids in obesity.

Dyslipidemia (See also Chap. 419) In general, free fatty acid flux from adipose tissue to the liver results in increased production of apolipoprotein (apo) B–containing, triglyceride-rich, very-low-density lipoproteins (VLDLs). The direct effect of insulin on this process is complex, but *hypertriglyceridemia* is an excellent marker of the insulin-resistant condition. Not only is hypertriglyceridemia a feature of metabolic syndrome, but patients with metabolic syndrome have elevated levels of apoC-III carried on VLDLs and other lipoproteins. This increase in apoC-III is inhibitory to lipoprotein lipase, reducing triglyceride-rich lipoprotein remnant removal, further contributing to hypertriglyceridemia, and confers more risk for atherosclerotic cardiovascular disease (ASCVD).

The other major lipoprotein disturbance in metabolic syndrome is a *reduction in HDL cholesterol*. This reduction is a consequence of changes in HDL composition and metabolism. In the presence of hypertriglyceridemia, a decrease in the cholesterol content of HDL is a consequence of reduced cholesteryl ester content of the lipoprotein core in combination with cholesteryl ester transfer protein–mediated alterations in triglycerides that make the HDL particle small and dense. This change in lipoprotein composition also results in increased clearance of HDL from the circulation. These changes in HDL have a relationship to insulin resistance that is probably indirect, occurring in concert with the changes in triglyceride-rich lipoprotein metabolism.

In addition to HDLs, low-density lipoproteins (LDLs) have alterations in composition in metabolic syndrome. With fasting serum triglycerides at >2.0 mM (~180 mg/dL), there is usually a predominance of small dense LDLs, which are thought to be more atherogenic, although their association with hypertriglyceridemia and low HDLs makes their independent contribution to ASCVD difficult to assess. Individuals with hypertriglyceridemia often have increases in cholesterol content of both VLDL1 and VLDL2 subfractions and in LDL particle number. Both lipoprotein changes may contribute to atherogenic risk in patients with metabolic syndrome.

Glucose Intolerance (See also Chap. 415) Defects in insulin action in metabolic syndrome lead to impaired suppression of endogenous glucose production by the liver (and kidney) and reduced glucose uptake and metabolism in insulin-sensitive tissues—i.e., muscle and adipose tissue. There is a strong relationship between impaired fasting glucose or impaired glucose tolerance and insulin resistance in studies of humans, nonhuman primates, and rodents. To compensate for defects in insulin action, insulin secretion and/or clearance increases or decreases, respectively, so that euglycemia remains. Ultimately, this compensatory mechanism fails because of defects in insulin secretion, resulting in progression from impaired fasting glucose and/or impaired glucose tolerance to type 2 diabetes mellitus.

Hypertension The relationship between insulin resistance and hypertension is well established. Paradoxically, under normal physiologic conditions, insulin-mediated increases in nitric oxide cause vasodilation with secondary effects on sodium reabsorption in the kidney. However, in the setting of insulin resistance, the vasodilatory effect of insulin is lost but the renal effect on sodium reabsorption is preserved. Sodium reabsorption is increased in Caucasians with metabolic syndrome but not in Africans or Asians. Insulin also increases the activity of the sympathetic nervous system, an effect that is preserved in the setting of insulin resistance. Insulin resistance is also associated with pathway-specific impairment in phosphatidylinositol-3-kinase signaling. In the endothelium, this impairment may cause an imbalance between the production of nitric oxide and the secretion of endothelin 1, with a consequent decrease in blood flow. In addition, increases in angiotensinogen gene expression in adipose tissue of obese subjects results in increases in circulating angiotensin II and vasoconstriction. Although these mechanisms are provocative, the inadequate evaluation of insulin action by measurement of fasting insulin levels or by homeostasis model assessment shows that insulin resistance contributes only partially to the increased prevalence of hypertension in metabolic syndrome.

Another possible mechanism underlying hypertension in metabolic syndrome is the vasoactive role of perivascular adipose tissue. Reactive oxygen species released by NADPH oxidase impair endothelial function and result in local vasoconstriction. Other paracrine effects such as leptin or other proinflammatory cytokines released from adipose tissue, such as tumor necrosis factor α (TNF-α), may also be important.

Hyperuricemia is another consequence of insulin resistance in metabolic syndrome. There is growing evidence not only that uric acid is associated with hypertension but also that reduction of uric acid normalizes blood pressure in hyperuricemic adolescents with hypertension. The mechanism appears to be in part related to an adverse effect of uric acid on nitric oxide synthase in the macula densa of the kidney and stimulation of the renin-angiotensin-aldosterone system.

Proinflammatory Cytokines The increases in proinflammatory cytokines—including interleukins 1, 6, and 18; resistin; TNF-α; and the systemic biomarker C-reactive protein—reflect overproduction by the expanded adipose tissue mass (Fig. 420-2). Adipose tissue–derived macrophages may be the primary source of proinflammatory cytokines locally and in the systemic circulation. It remains unclear, however, how much of the insulin resistance is caused by the paracrine effects of these cytokines and how much by the endocrine effects.

Adiponectin Adiponectin is an anti-inflammatory cytokine produced exclusively by adipocytes. Adiponectin enhances insulin sensitivity and inhibits many steps in the inflammatory process. In the liver, adiponectin inhibits the expression of gluconeogenic enzymes and the rate of glucose production. In muscle, adiponectin increases glucose transport and enhances fatty acid oxidation, partially through the activation of AMP kinase. Reductions in adiponectin levels are common in metabolic syndrome. The relative contributions of adiponectin deficiency and overabundance of the proinflammatory cytokines are unclear.

CLINICAL FEATURES

Symptoms and Signs Metabolic syndrome typically is not associated with symptoms. On physical examination, waist circumference and blood pressure are often elevated. The presence of either or both signs should prompt the clinician to search for other biochemical abnormalities that may be associated with metabolic syndrome. Much less frequently, lipoatrophy or acanthosis nigricans is present on examination. Because these physical findings characteristically are associated with severe insulin resistance, other components of metabolic syndrome are much more common.

Associated Diseases • **CARDIOVASCULAR DISEASE** The relative risk for new-onset CVD in patients with metabolic syndrome who do not have diabetes averages 1.5- to 3-fold. However, in INTERHEART, a study of 26,903 subjects from 52 countries, the risk for acute myocardial infarction in subjects with metabolic syndrome (World Health Organization or International Diabetes Federation definition) is comparable to that conferred by some, but not all, of the component risk factors. Diabetes mellitus (odds ratio [OR], 2.72) and hypertension (OR, 2.60) are stronger than other risk factors. Although congestive heart failure and metabolic syndrome can occur together, typically this consequence is secondary to metabolic syndrome–related ASCVD or hypertension. Metabolic syndrome is also associated with increases in the risk for stroke, peripheral vascular disease, and Alzheimer's disease. However, as for myocardial infarction, the risk beyond the additive role of the components of metabolic syndrome remains debatable. In the Reasons for Geographic and Racial Differences in Stroke (REGARDS) cohort, an observational study of black and white adults ≥45 years old across the United States, there were 9741 participants, and 41% had metabolic syndrome. After adjustment for multiple confounders, metabolic syndrome was associated with increases in high-sensitivity C-reactive protein (hsCRP), and this relationship was associated with a 1.34 relative risk for all-cause mortality, but <50% of deaths were from CVD. The population-attributable risk was 9.5% for metabolic syndrome alone and 14.7% for both metabolic syndrome and increased hsCRP. The relationship of metabolic syndrome and hsCRP to mortality was greater for whites than blacks.

TYPE 2 DIABETES Overall, the risk for type 2 diabetes among patients with metabolic syndrome is increased three- to fivefold. In the Framingham Offspring Study's 8-year follow-up of middle-aged participants, the population-attributable risk of metabolic syndrome for developing type 2 diabetes was 62% among men and 47% among women, yet increases in fasting plasma glucose explained most, if not all, of this increased risk.

Other Associated Conditions In addition to the features specifically used to define metabolic syndrome, other metabolic alterations are secondary to or accompany insulin resistance. Those alterations include increases in apoB and apoC-III, uric acid, prothrombotic factors (fibrinogen, plasminogen activator inhibitor 1), serum viscosity, asymmetric dimethylarginine, homocysteine, white blood cell count, proinflammatory cytokines, C-reactive protein, urine albumin/creatinine ratio, metabolic-associated fatty liver disease (MAFLD) and/or nonalcoholic steatohepatitis (NASH), polycystic ovary syndrome, and obstructive sleep apnea.

METABOLIC-ASSOCIATED FATTY LIVER DISEASE MAFLD has become the most common liver disease, in part a consequence of the insulin resistance of metabolic syndrome. The mechanism relates to increases in free fatty acid flux and reductions in intrahepatic fatty acid oxidation with resultant increases in triglyceride biosynthesis and hepatocellular accumulation, with variable inflammation and oxidative stress. The more serious Metabolic dysfunction-associated steatohepatitis (MASH), a consequence of MAFLD in some patients and a precursor of cirrhosis and end-stage liver disease, includes a more substantial proinflammatory contribution. MAFLD affects ~10% of the nonobese population and up to 65% of patients with metabolic syndrome; over half of these patients have metabolic dysfunction-associated steatohepatitis (MASH). As the prevalence of overweight/obesity and metabolic syndrome increases, NASH may become one of the more common causes of end-stage liver disease and hepatocellular carcinoma. Increasingly, studies have shown that MAFLD is related independently to CVD, especially coronary artery disease.

HYPERURICEMIA (See also Chap. 384) Hyperuricemia reflects defects in insulin action on the renal tubular reabsorption of uric acid and may contribute to hypertension through its effect on the endothelium. An increase in asymmetric dimethylarginine, an endogenous inhibitor of nitric oxide synthase, also relates to endothelial dysfunction. In addition, increases in the urine albumin/creatinine ratio may relate to altered endothelial pathophysiology in the insulin-resistant state.

POLYCYSTIC OVARY SYNDROME (See also Chap. 404) Polycystic ovary syndrome is highly associated with insulin resistance (50–80%) and metabolic syndrome, with a prevalence of the syndrome between 12 and 60% based on phenotypes D through A.

OBSTRUCTIVE SLEEP APNEA (See also Chap. 33) Obstructive sleep apnea is commonly associated with obesity, hypertension, increased circulating proinflammatory cytokines, impaired glucose tolerance, and insulin resistance. In fact, obstructive sleep apnea may predict metabolic syndrome, even in the absence of excess adiposity. Moreover, when biomarkers of insulin resistance are compared between patients with obstructive sleep apnea and weight-matched controls, insulin resistance is found to be more severe in those with apnea. Continuous positive airway pressure treatment improves insulin sensitivity in patients with obstructive sleep apnea.

DIAGNOSIS

The diagnosis of metabolic syndrome relies on fulfillment of the criteria listed in Table 420-1, as assessed using tools at the bedside and in the laboratory. The medical history should include evaluation of symptoms for obstructive sleep apnea in all patients and polycystic ovary syndrome in premenopausal women. Family history will help determine the risk for CVD and diabetes mellitus. Blood pressure and waist circumference measurements provide information necessary for the diagnosis.

Laboratory Tests Measurement of fasting lipids and glucose is needed in determining whether metabolic syndrome is present. The measurement of additional biomarkers associated with insulin resistance can be individualized. Such tests might include those for apoB, hsCRP, fibrinogen, uric acid, urinary albumin/creatinine ratio, and liver function. A sleep study should be performed if symptoms of obstructive sleep apnea are present. If polycystic ovary syndrome is suspected based on clinical features and anovulation, testosterone, luteinizing hormone, and follicle-stimulating hormone should be measured. MAFLD can be further assessed by the MAFLD fibrosis score (FIB4) or elastography.

TREATMENT

The Metabolic Syndrome

LIFESTYLE (SEE ALSO CHAP. 414)

Obesity, particularly abdominal, is the driving force behind metabolic syndrome. Thus, weight reduction is the primary approach to the disorder. With at least 5% and more so with 10% weight reduction, improvement in insulin sensitivity results in favorable modifications in many components of metabolic syndrome. In general, recommendations for weight loss include a combination of caloric restriction, increased physical activity, and behavior modification. Caloric restriction is the most important component, whereas increases in physical activity are important for maintenance of weight loss. Some but not all evidence suggests that the addition of exercise to caloric restriction may promote greater weight loss from the visceral depot. The tendency for weight regains after successful weight reduction underscores the need for long-lasting behavioral changes.

Diet Before prescribing a weight-loss diet, it is important to emphasize that it has taken the patient a long time to develop an expanded fat mass; thus, the correction need not occur quickly. Given, in general, that ~3500 kcal = 1 lb of adipose tissue, an ~500-kcal restriction daily equates to weight reduction of 1 lb per week. Diets restricted in carbohydrate typically provide a more rapid initial weight loss. However, after 1 year, the amount of weight reduction is minimally reduced or no different from that with caloric restriction alone. Thus, adherence to the diet is more important than the chosen diet. Moreover, there is concern about low-carbohydrate diets enriched in saturated fat, particularly for patients at risk for ASCVD. Therefore, a high-quality dietary pattern—i.e., a diet enriched in fruits, vegetables, whole grains, lean poultry, and fish—should be encouraged to maximize overall health benefit.

Physical Activity Before prescribing a physical activity program to patients with metabolic syndrome, it is important to ensure that the increased activity does not incur risk. Some high-risk patients should undergo formal cardiovascular evaluation before initiating an exercise program. For an inactive participant, gradual increases in physical activity should be encouraged to enhance adherence and avoid injury. Although increases in physical activity can lead to modest weight reduction, 60–90 min of moderate- to high-intensity daily activity is required to achieve this goal. Even if an overweight or obese adult is unable to undertake this level of activity, a health benefit will follow from at least 30 min of moderate-intensity activity daily. The caloric value of 30 min of a variety of activities can be found at *https://www.health.harvard.edu/diet-and-weight-loss/calories-burned-in-30-minutes-of-leisure-and-routine-activities*. Of note, a variety of routine activities, such as gardening, walking, and housecleaning, require moderate caloric expenditure. Thus, physical activity should not be defined solely in terms of formal exercise such as jogging, swimming, or tennis.

Behavior Modification Behavioral treatment typically includes recommendations for dietary restriction and more physical activity that predicts sufficient weight loss that benefits metabolic health. The subsequent challenge is the duration of the program because weight regain so often follows successful weight reduction. Improved long-term outcomes often follow a variety of methods, such as a personal or group counselor, the Internet, social media, and telephone follow-up to maintain contact between providers and patients.

Obesity **(See also Chap. 414)** In some patients with metabolic syndrome, treatment options need to extend beyond lifestyle intervention. Weight-loss drugs come in two major classes: appetite suppressants and absorption inhibitors. Appetite suppressants approved by the U.S. Food and Drug Administration (FDA) include phentermine (for short-term use [3 months] only) as well as phentermine/topiramate, naltrexone/bupropion, high-dose (3.0 mg) liraglutide (rather than 1.8 mg, the maximum for treatment of type 2 diabetes), and semaglutide (2.4 mg), which are approved without restrictions on the duration of therapy. In clinical trials, the phentermine/topiramate extended-release combination resulted in ~8% weight loss relative to placebo in 50% of patients. Side effects include palpitations, headache, paresthesias, constipation, and insomnia. Naltrexone/bupropion extended release reduces body weight by ≥10% in ~20% of patients; however, the drug combination is contraindicated in patients with seizure disorders or any condition that predisposes to seizures. Naltrexone/bupropion also increases pulse and blood pressure and should not be given to patients with uncontrolled hypertension. High-dose liraglutide, a glucagon-like peptide 1 (GLP-1) receptor agonist, results in ~6% weight loss relative to placebo with ~33% of patients with >10% weight loss. Common side effects are limited to the upper gastrointestinal tract, including nausea and, less frequently, emesis. Semaglutide (2.4 mg weekly) has been shown to produce an average weight loss of 14.9% over 68 weeks. Tirzepatide, a novel glucose-dependent insulinotropic polypeptide (GIP) and GLP-1 receptor agonist, has been tested for 72 weeks in participants with a mean body weight of 104.8 kg and mean body mass index (BMI) of 38.0 kg/m^2, with 94.5% of patients with a BMI of ≥30 kg/m^2. Participants experienced a dose-dependent reduction in weight ranging from −15.0% with 5 mg of tirzepatide weekly to 20.9% with the 15-mg dose. Benefits of GLP-1 receptor agonists on MAFLD are also noteworthy, but not yet FDA approved.

Orlistat inhibits fat absorption by ~30% and is moderately effective compared with placebo (~4% more weight loss). Moreover, orlistat reduced the incidence of type 2 diabetes, an effect that was especially evident among patients with impaired glucose tolerance at baseline. This drug is often difficult to take because of oily leakage per rectum. In general, for all weight-loss drugs, greater weight reduction leads to greater improvement in metabolic syndrome components, including the conversion from prediabetes to type 2 diabetes.

Metabolic or bariatric surgery is an important option for patients with metabolic syndrome who have a BMI >40 kg/m^2 or >35 kg/m^2 with comorbidities. An evolving application for metabolic surgery includes patients with a BMI as low as 30 kg/m^2 and type 2 diabetes. Gastric bypass or vertical sleeve gastrectomy results in dramatic weight reduction and improvement in most features of metabolic syndrome. A survival benefit with gastric bypass has also been realized.

LDL CHOLESTEROL (SEE ALSO CHAP. 419)

The rationale for the development of criteria for metabolic syndrome by NCEP was to go beyond LDL cholesterol in identifying and reducing the risk of ASCVD. The working assumption by the panel was that LDL cholesterol goals had already been achieved and that increasing evidence supports a linear reduction in ASCVD events because of progressive lowering of LDL cholesterol with statins with subsequent benefit using additional LDL cholesterol–lowering agents. The 2019 American College of Cardiology (ACC)/American Health Association (AHA) Cholesterol Guidelines have no specific recommendations for patients with metabolic syndrome; however, they recommend that patients aged 20–75 years with LDL cholesterol levels ≥190 mg/dL should use a high-intensity statin (e.g., atorvastatin 40–80 mg or rosuvastatin 20–40 mg daily) and those with type 2 diabetes aged 40–75 years should use a moderate-intensity statin and, if or when risk estimate is high, a high-intensity statin. For patients with metabolic syndrome but without diabetes, the 10-year ASCVD risk estimator should be employed, and patients with a risk ≥7.5% and ≤20% or persons aged 20–59 with elevated lifetime risk should have a discussion with their provider about initiating statin therapy for primary prevention of ASCVD. A coronary calcium score may help in making this decision.

Diets restricted in saturated fats (<6% of calories) and trans fats (as few as possible) should be applied aggressively. Although evidence is controversial, dietary cholesterol can also be restricted. If LDL cholesterol remains elevated, pharmacologic intervention is needed. Based on substantial evidence, treatment with statins, which lower LDL cholesterol by 15–60%, is the first-choice medication intervention. Of note, for each doubling of the statin dose, LDL cholesterol is further lowered by only ~6%. Hepatotoxicity (more than a threefold increase in hepatic aminotransferases) is rare, but myopathy occurs in ~10–20% of patients. The cholesterol absorption inhibitor ezetimibe is well tolerated and should be the second-choice medication intervention. Ezetimibe typically reduces LDL cholesterol by 15–20%. Bempedoic acid alone or in combination with ezetimibe is another option, with up to a 35% lowering of LDL cholesterol with the combination. Bempedoic acid can increase plasma uric acid. Proprotein convertase subtilisin/kexin type 9 (PCSK9) inhibitors are potent LDL cholesterol–lowering drugs (~45–60%) but are not needed for most patients with metabolic syndrome. Of course, if these patients also have familial hypercholesterolemia or insufficient LDL cholesterol lowering on statins with or without ezetimibe, a PCSK9 inhibitor should be considered. The bile acid sequestrants cholestyramine, colestipol,

and colesevelam may be more effective than ezetimibe alone, but because they can increase triglyceride levels, they must be used with caution in patients with metabolic syndrome when fasting triglycerides are >300 mg/dL. Side effects include gastrointestinal symptoms (palatability, bloating, belching, constipation, anal irritation). Nicotinic acid has similar LDL cholesterol–lowering capabilities (<20%); however, it may be associated with multiple adverse effects. Fibrates are best employed to lower LDL cholesterol when triglycerides are not elevated. Fenofibrate may be more effective than gemfibrozil in this setting.

TRIGLYCERIDES (SEE ALSO CHAP. 419)

The 2019 ACC/AHA Cholesterol Guidelines stated that fasting triglycerides >500 mg/dL should be treated to prevent more serious hypertriglyceridemia and pancreatitis. Although a fasting triglyceride value of >150 mg/dL is a component of metabolic syndrome, post hoc analyses of multiple fibrate trials have not suggested a triglyceride-related reduction in the primary ASCVD outcome in patients (with or without concomitant statin therapy) with fasting triglycerides >200 mg/dL, often in the setting of reduced levels of HDL cholesterol. It remains uncertain whether triglycerides cause ASCVD or if levels are just associated with increased ASCVD risk.

A fibrate (gemfibrozil or fenofibrate) is one drug class of choice to lower fasting triglyceride levels, which are typically reduced by 30–45%. Concomitant administration with drugs metabolized by the 3A4 cytochrome P450 system (including some statins) increases the risk of myopathy. In these cases, fenofibrate may be preferable to gemfibrozil. In the Veterans Affairs HDL Intervention Trial, gemfibrozil was administered to men with known CHD and levels of HDL cholesterol <40 mg/dL. A coronary disease event and mortality rate benefit was experienced predominantly among men with hyperinsulinemia and/or diabetes, many of whom were identified retrospectively as having metabolic syndrome. Of note, the degree of triglyceride lowering in this trial or other fibrate trials did not predict benefit.

Other drugs that lower triglyceride levels include statins, nicotinic acid, and prescription omega-3 fatty acids. For this purpose, an intermediate or high dose of the "more potent" statins (atorvastatin, rosuvastatin) is needed. The effect of nicotinic acid on fasting triglycerides is dose related and ~20–35%, an effect that is less pronounced than that of fibrates. In patients with metabolic syndrome and diabetes, nicotinic acid may increase fasting glucose levels, and clinical trials with nicotinic acid plus a statin have failed to reduce ASCVD events. Prescriptions of omega-3 fatty acid preparations that include high doses of eicosapentaenoic acid (EPA) with or without docosahexaenoic acid (DHA) (~1.5–4.5 g/d) lower fasting triglyceride levels by ~25–40%. The two omega-3 randomized controlled trials associated with ASCVD risk reduction, JELIS and REDUCE-IT, used EPA only, whereas STRENGTH, which was terminated prematurely because of futility, used EPA plus DHA. Here, no drug interactions with fibrates or statins occur, and the main side effect of their use is eructation with a fishy taste. Freezing the nutraceutical can partially block this unpleasant side effect. Importantly, lowering triglycerides with any of the pharmaceuticals has not been proven to be an independent predictor of CVD outcomes.

HDL CHOLESTEROL (SEE ALSO CHAP. 419)

Very few lipid-modifying compounds increase HDL cholesterol levels. Statins, fibrates, and bile acid sequestrants have modest effects (5–10%), whereas ezetimibe and omega-3 fatty acids have no effect. Nicotinic acid is the only currently available drug with predictable HDL cholesterol–raising properties. The response is dose related, and nicotinic acid can increase HDL cholesterol by up to 30% above baseline. After several trials of nicotinic acid versus placebo in statin-treated patients, there is no evidence that raising HDL cholesterol with nicotinic acid beneficially affects ASCVD events in patients with or without metabolic syndrome.

BLOOD PRESSURE (SEE ALSO CHAP. 288)

The direct relationship between blood pressure and all-cause mortality rate has been well established in studies comparing patients with hypertension (>140/90 mmHg), patients with prehypertension (>120/80 mmHg but <140/90 mmHg), and individuals with normal blood pressure (<120/80 mmHg). In patients who have metabolic syndrome without diabetes, the best choice for the initial antihypertensive medication is an angiotensin-converting enzyme (ACE) inhibitor or an angiotensin II receptor blocker, as these two classes of drugs are effective and well tolerated. Additional agents include a diuretic, calcium channel blocker, beta blocker, and mineralocorticoid inhibitor, such as the recent FDA-approved mineralocorticoid receptor antagonist finerenone. In all patients with hypertension, a sodium-restricted dietary pattern enriched in fruits and vegetables, whole grains, and low-fat dairy products should be advocated. Home monitoring of blood pressure may assist in maintaining good blood pressure control.

IMPAIRED FASTING GLUCOSE (SEE ALSO CHAP. 415)

In patients with metabolic syndrome and type 2 diabetes, aggressive glycemic control may favorably modify fasting levels of triglycerides and/or HDL cholesterol. In patients with impaired fasting glucose who do not have diabetes, a lifestyle intervention that includes weight reduction, dietary saturated fat restriction, and increased physical activity has been shown to reduce the incidence of type 2 diabetes. Metformin also reduces the incidence of diabetes, although the effect is less pronounced than that of lifestyle intervention.

INSULIN RESISTANCE (SEE ALSO CHAP. 416)

Several drug classes (biguanides, thiazolidinediones [TZDs]) increase insulin sensitivity. Because insulin resistance is the primary pathophysiologic mechanism for metabolic syndrome, representative drugs in these classes reduce its prevalence. Both metformin and TZDs enhance insulin action in the liver and suppress endogenous glucose production. TZDs, but not metformin, also improve insulin-mediated glucose uptake in muscle and adipose tissue. In a meta-analysis of nine trials involving 12,026 participants, the TZD pioglitazone versus placebo was associated with reduction in ASCVD events in patients with insulin resistance (metabolic syndrome), prediabetes, and type 2 diabetes. However, adverse effects including weight gain, bone fracture, and congestive heart failure with/or without edema were seen. Benefit of TZDs has been seen in patients with MAFLD, and with metformin in women with polycystic ovary syndrome, and both drug classes have been shown to reduce markers of inflammation. GLP-1 receptor agonists also improve insulin sensitivity, which is related to the amount of weight reduction.

421 Bone and Mineral Metabolism in Health and Disease

F. Richard Bringhurst, Henry M. Kronenberg, Eva S. Liu, Marc N. Wein

BONE STRUCTURE AND METABOLISM

Bone is a dynamic tissue that is remodeled constantly throughout life. The arrangement of compact and cancellous bone provides strength and density suitable for both mobility and protection. Compact or cortical bone forms the roughly cylindrical shell of long bones; cancellous or trabecular bone forms the plate-like meshwork that internally supports the cortical shell. In addition, bone provides a reservoir for calcium, magnesium, phosphorus, sodium, and other ions necessary for homeostatic functions. Bone also hosts and regulates hematopoiesis by providing niches for hematopoietic cell proliferation and differentiation. The skeleton is highly vascular and receives ~10% of the cardiac output. Remodeling of bone is accomplished by two distinct cell types: osteoblasts produce bone matrix, and osteoclasts resorb the matrix. The activities of these cells are coordinated by osteocytes, long-lived regulatory cells embedded within bone matrix.

The extracellular components of bone consist of a solid mineral phase in close association with an organic matrix, of which 90–95% is type I collagen **(Chap. 425)**. The noncollagenous portion of the organic matrix is heterogeneous and contains serum proteins such as albumin as well as many locally produced proteins, whose functions are incompletely understood. Those proteins include cell attachment/signaling proteins such as thrombospondin, osteopontin, and fibronectin; calcium-binding proteins such as matrix gla protein and osteocalcin; and proteoglycans such as biglycan and decorin. Some of the proteins organize collagen fibrils; others influence mineralization and binding of the mineral phase to the matrix.

The mineral phase is made up of calcium and phosphate and is best characterized as a poorly crystalline hydroxyapatite. The mineral phase of bone is deposited initially in intimate relation to the collagen fibrils and is laid down in specific locations in the "holes" between the collagen fibrils. This architectural arrangement of mineral and matrix results in a two-phase material well suited to withstand mechanical stresses. The organization of collagen influences the amount and type of mineral phase formed in bone. Although the primary structures of type I collagen in skin and bone tissues are similar, there are differences in posttranslational modifications and distribution of intermolecular cross-links. The holes in the packing structure of the collagen are larger in mineralized collagen of bone and dentin than in unmineralized collagens such as those in tendon. Single amino acid substitutions in the helical portion of either the α1 (*COL1A1*) or α2 (*COL1A2*) chains of type I collagen disrupt the organization of bone in the disease, osteogenesis imperfecta. The severe skeletal fragility associated with this group of disorders highlights the importance of the fibrillar matrix in the structure of bone **(Chap. 425)**.

Osteoblasts synthesize and secrete the organic matrix and regulate its mineralization. They are derived from cells of mesenchymal origin **(Fig. 421-1*A*)**. Osteoblast precursors derive from the periosteum, the bone marrow, or the hypertrophic chondrocytes at the end of the growth plate. Active osteoblasts are found on the surface of newly forming bone. As an osteoblast secretes matrix, which then is mineralized, the cell may become an *osteocyte*, still connected with its nutrient supply through a series of canaliculi. Osteocytes account for the vast majority of the cells in bone. They are thought to be the mechanosensors that communicate signals to surface osteoblasts and osteoclasts and their progenitors through the canalicular network and thereby serve as master regulators of bone formation and resorption. Osteocytes also secrete fibroblast growth factor 23 (FGF23), a major hormonal regulator of phosphate metabolism (see below). Mineralization of the matrix, both in trabecular bone and in osteones of compact cortical bone (*Haversian systems*), begins soon after the matrix is secreted (primary mineralization) but is not completed for several weeks or even longer (secondary mineralization). Although this mineralization takes advantage of the high concentrations of calcium and phosphate, already near saturation in serum, mineralization is a carefully regulated process that is dependent on the activity of osteoblast-derived alkaline phosphatase, which probably works by hydrolyzing inhibitors of mineralization, such as pyrophosphate.

Genetic studies in humans and mice have identified several key genes that control osteoblast development. *Runx2* is a transcription factor expressed specifically in chondrocyte (cartilage cells) and osteoblast progenitors as well as in hypertrophic chondrocytes and mature osteoblasts. *Runx2* regulates the expression of several important osteoblast proteins, including osterix (SP7) (another transcription factor needed for osteoblast maturation), osteopontin, bone sialoprotein, type I collagen, osteocalcin, and receptor-activator of nuclear factor (NF)-κB (RANK) ligand. *Runx2* expression is regulated in part by bone morphogenic proteins (BMPs). *Runx2*-deficient mice are devoid of osteoblasts, whereas mice with a deletion of only one allele (*Runx2* +/–) exhibit a delay in formation of the clavicles and some cranial bones. The latter abnormalities are similar to those in the human disorder *cleidocranial dysplasia*, which is also caused by heterozygous inactivating mutations in *Runx2*.

The paracrine signaling molecule, Indian hedgehog (Ihh), also plays a critical role in osteoblast development, as evidenced by Ihh-deficient mice that lack osteoblasts in the type of bone formed on a cartilage mold (endochondral ossification). Signals originating from members of the wnt family of paracrine factors are also important for osteoblast proliferation and differentiation. Osteocytes regulate osteoblasts partly by secreting a potent inhibitor of wnt signaling called sclerostin. Numerous other growth-regulatory factors affect osteoblast function, including the three closely related transforming growth factor βs, fibroblast growth factors (FGFs) 2 and 18, platelet-derived growth factor, and insulin-like growth factors (IGFs) I and II. Hormones such as parathyroid hormone (PTH) and 1,25-dihydroxyvitamin D [1,25$(OH)_2$D] activate receptors expressed by osteoblasts to assure mineral homeostasis and influence a variety of bone cell functions. Osteoclasts that resorb bone (see below) also regulate osteoblasts by releasing growth factors from bone matrix and by synthesizing proteins that can directly regulate osteoblastogenesis.

Resorption of bone is carried out mainly by *osteoclasts*, multinucleated cells that are formed by fusion of cells derived from the common precursor of macrophages and osteoclasts. Thus, these cells derive from the hematopoietic lineage, quite different from the mesenchymal lineage cells that become osteoblasts. Multiple factors that regulate osteoclast development have been identified **(Fig. 421-1*B*)**. Factors produced by osteocytes, osteoblasts, and marrow stromal cells allow cells of the osteoblast lineage to control osteoclast development and activity. Macrophage colony-stimulating factor (M-CSF) plays a critical role during several steps in the pathway and ultimately leads to fusion of osteoclast progenitor cells to form multinucleated, active osteoclasts. RANK ligand, a member of the tumor necrosis factor (TNF) family, is expressed on the surface of osteocytes, osteoblasts, and stromal fibroblasts. In a process involving cell-cell interactions, RANK ligand binds to the RANK receptor on osteoclast progenitors, stimulating osteoclast differentiation and activation. Alternatively, a soluble decoy receptor, referred to as osteoprotegerin (OPG), can bind RANK ligand and inhibit osteoclast differentiation. Several growth factors and cytokines (including interleukins 1, 6, and 11; TNF; and interferon γ) modulate osteoclast differentiation and function. Most hormones that influence osteoclast function do not target these cells directly but instead target cells of the osteoblast lineage to increase production of M-CSF and RANK. Both PTH and 1,25$(OH)_2$D increase osteoclast number and

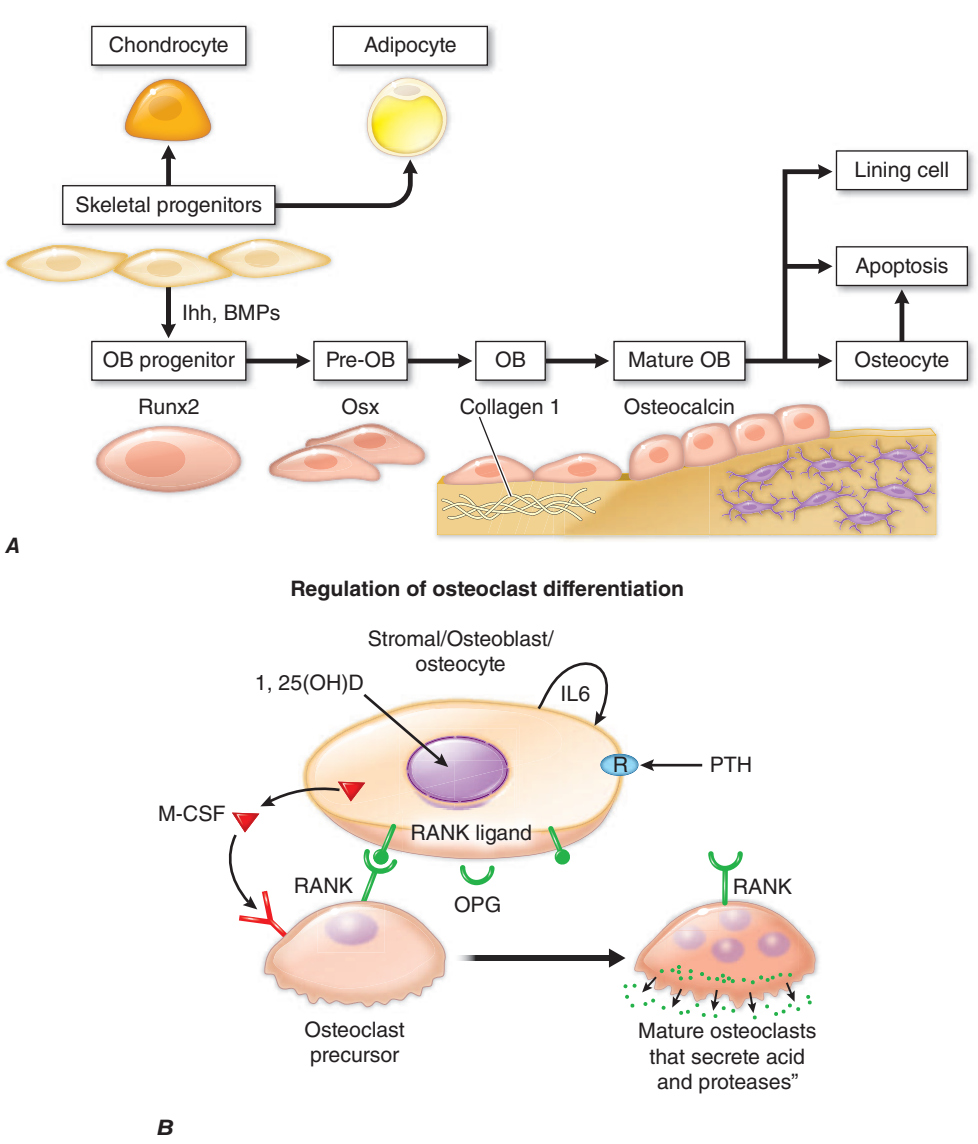

FIGURE 421-1 Pathways regulating development of (*A*) osteoblasts and (*B*) osteoclasts. ***A.*** Osteoblast lineage cells. Osteoblast progenitors are mesenchymal cells that are found in the perichondrium/periosteum, the bone marrow (where they also support hematopoietic stem cells and can become marrow adipocytes), and the growth plate (where late hypertrophic chondrocytes can die or become osteoblast precursors in the marrow). These progenitors can become chondrocytes early in development or in response to fracture postnatally. In response to Indian hedgehog (Ihh) and bone morphogenetic proteins (BMPs), these precursors become committed to osteoblast differentiation and are regulated by a series of transcription factors, with early essential factors, Runx2 and then osterix (SP7), shown here. On the bone surface, these cells express large amounts of collagen I and cell surface alkaline phosphatase, a crucial regulator of mineralization. Osteoblasts are relatively short-lived and subsequently either die or become osteocytes buried in bone matrix or quiescent bone-lining cells. To track the osteoblast (OB) lineage, we use CreERt mice driven by the Osx and collagen1 gene promotors. During OB differentiation, Osx is starting to be expressed early on in pre-OBs, while col1 is expressed later in OB development. It can therefore be expected that Osx- and col1-CreERt mouse lines will mark osteoblastic cells at different stages of differentiation. ***B.*** Regulation of osteoclast production. Osteoclast progenitors, derived from the hematopoietic lineage, respond to signals from cells of the osteoblast lineage to increase their number and activity. IL, interleukin; M-CSF, macrophage colony-stimulating factor; OPG, osteoprotegerin; PTH, parathyroid hormone.

activity by this indirect mechanism. Calcitonin, in contrast, binds to its receptor on the basal surface of osteoclasts and directly inhibits osteoclast function. Estradiol has multiple cellular targets in bone, including osteoclasts, immune cells, and osteoblasts; actions on all these cells serve to decrease osteoclast number and bone resorption.

Osteoclast-mediated resorption of bone takes place in scalloped spaces (*Howship's lacunae*) where the osteoclasts are attached through a specific αvβ3 integrin to components of the bone matrix. The osteoclast forms a tight seal to the underlying matrix and secretes protons, chloride, and proteinases into a confined space that has been likened to an extracellular lysosome. The active osteoclast surface forms a ruffled border that contains a specialized proton pump ATPase that secretes acid that solubilizes the mineral phase. Carbonic anhydrase (type II isoenzyme) within the osteoclast generates the needed protons. The bone matrix is resorbed in the acid environment adjacent to the ruffled border by proteases, such as cathepsin K, that act at low pH.

A distinct process, called osteocytic osteolysis, also causes bone resorption. Using a molecular machinery similar to that in osteoclasts, osteocytes dissolve mineral and matrix from the bone surrounding osteocytes. PTH and its relative, parathyroid hormone–related peptide (PTHrP), stimulate osteocytic osteolysis. The relative contributions of osteoclasts and osteocytes to bone resorption is uncertain.

In the embryo and the growing child, bone develops mostly by replacing previously calcified cartilage (endochondral bone formation) with subsequent remodeling or, in a few bones, is formed without a cartilage matrix (intramembranous bone formation). During endochondral bone formation, chondrocytes proliferate, secrete and mineralize a matrix, enlarge (hypertrophy), and then either die or differentiate into precursors of osteoblasts, lengthening bone and

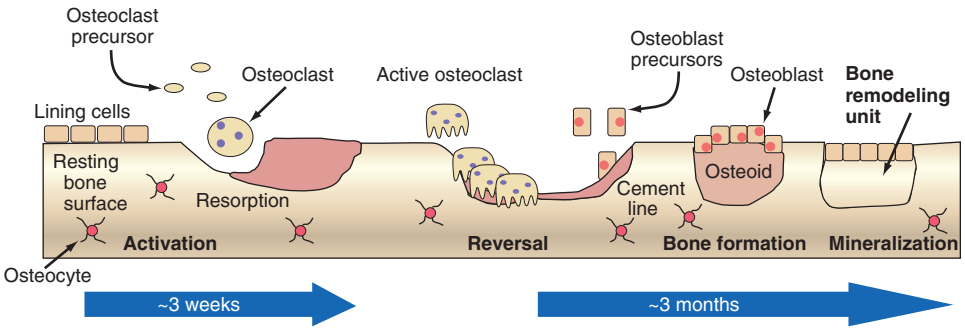

FIGURE 421-2 Schematic representation of bone remodeling. The cycle of bone remodeling is carried out by the basic multicellular unit (BMU), which consists of a group of osteoclasts and osteoblasts. In cortical bone, the BMUs tunnel through the tissue, whereas in cancellous bone, they move across the trabecular surface. The process of bone remodeling is initiated by the recruitment of osteoclast precursors, perhaps to sites of microdamage. These precursors fuse to form multinucleated, active osteoclasts that mediate bone resorption. Osteoclasts adhere to bone and subsequently remove it by acidification and proteolytic digestion. As the BMU advances, osteoclasts leave the resorption site, and osteoblasts, derived from marrow precursors and previously inactive bone lining cells, move in to cover the excavated area and begin the process of new bone formation by secreting osteoid, which eventually is mineralized into new bone. After osteoid mineralization, osteoblasts flatten and form a layer of lining cells over new bone, become osteocytes, or die.

providing the matrix and factors that stimulate endochondral bone formation. This program is regulated by both local factors, such as IGF-I and -II, Ihh, PTHrP, BMPs, and FGFs, and systemic hormones, such as growth hormone, glucocorticoids, and estrogen.

New bone, whether formed in infants or in adults during repair, has a relatively high ratio of cells to matrix and is characterized by coarse fiber bundles of collagen that are interlaced and randomly dispersed (woven bone). In adults, the more mature bone is organized with fiber bundles regularly arranged in parallel or concentric sheets (lamellar bone). In long bones, deposition of lamellar bone in a concentric arrangement around blood vessels forms the Haversian systems. Growth in length of bones is dependent on proliferation of cartilage cells and the endochondral sequence at the growth plate. Growth in width and thickness is accomplished by formation of bone at the periosteal surface and by resorption at the endosteal surface, with the rate of formation exceeding that of resorption. In adults, after the growth plates of cartilage close through the actions of estrogen, growth in length and endochondral bone formation cease. Even in adults, however, remodeling of bone (within Haversian systems as well as along the surfaces of trabecular bone) continues throughout life. In adults, ~4% of the surface of trabecular bone (such as iliac crest) is involved in active resorption, whereas 10–15% of trabecular surfaces are covered with osteoid, unmineralized new bone formed by osteoblasts. Radioisotope studies indicate that as much as 18% of the total skeletal calcium is deposited and removed each year. Thus, bone is an active metabolizing tissue that requires an intact blood supply. The cycle of bone resorption and formation is a highly orchestrated process, directed by osteocytes and carried out by the basic multicellular unit, which is composed of a group of osteoclasts and osteoblasts **(Fig. 421-2)**.

The response of bone to fractures, infection, and interruption of blood supply and to expanding lesions is relatively limited. Dead bone must be resorbed, and new bone must be formed, a process carried out in association with growth of new blood vessels into the involved area. In injuries that disrupt the organization of the tissue, such as a fracture, in which apposition of fragments is poor or when motion exists at the fracture site, progenitor stromal cells recapitulate the endochondral bone formation of early development and form cartilage that is replaced by bone and, variably, fibrous tissue. When there is good apposition with fixation and little motion at the fracture site, repair occurs predominantly by formation of new bone without other mediating tissue.

Remodeling of bone occurs along lines of force generated by mechanical stress. The signals from these mechanical stresses are sensed by osteocytes, which transmit signals to osteoclasts and osteoblasts or their precursors. One such signal made by osteocytes is sclerostin, an inhibitor of wnt signaling. Mechanical forces, as well as parathyroid hormone, suppress sclerostin production and thus increase bone formation by osteoblasts. Expanding lesions in bone such as tumors induce resorption at the surface in contact with the tumor by producing ligands such as PTHrP that stimulate osteoclast differentiation and function. Thus, bone plasticity reflects the interaction of cells with each other and with the environment.

Measurement of the products of osteoblast and osteoclast activity can assist in the diagnosis and management of bone diseases. Osteoblast activity can be assessed by measuring serum bone-specific alkaline phosphatase. Similarly, osteocalcin, a protein secreted from osteoblasts, is made virtually only by osteoblasts. Measurement of an amino-terminal fragment of procollagen I is also an effective index of bone formation. Osteoclast activity can be assessed by measurement of products of collagen degradation. Collagen molecules are covalently linked to each other in the extracellular matrix through the formation of hydroxypyridinium cross-links **(Chap. 425)**. After digestion by osteoclasts, these cross-linked peptides can be measured both in urine and in blood.

CALCIUM METABOLISM

Over 99% of the 1–2 kg of calcium present normally in the adult human body resides in the skeleton, where it provides mechanical stability and serves as a reservoir when needed to maintain extracellular fluid (ECF) calcium concentration **(Fig. 421-3)**. Skeletal calcium accretion first becomes significant during the third trimester of fetal life, accelerates throughout childhood and adolescence, reaches a peak in early adulthood, and gradually declines thereafter at rates that rarely exceed 1–2% per year. These slow changes in total skeletal calcium content contrast with relatively high daily rates of closely matched fluxes of calcium into and out of bone (~250–500 mg each), a process mediated by coupled activity of osteoblasts, osteoclasts, and osteocytes. Another 0.5–1% of skeletal calcium is freely exchangeable (e.g., in chemical equilibrium) with that in the ECF.

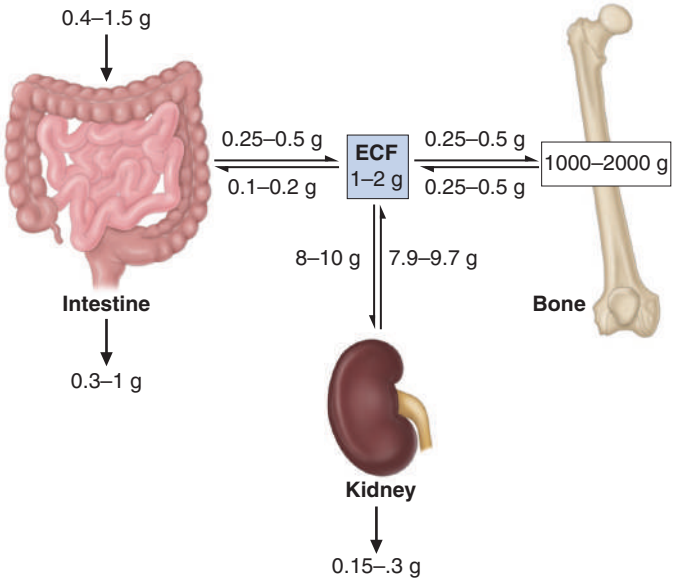

FIGURE 421-3 Calcium homeostasis. Schematic illustration of calcium content of extracellular fluid (ECF) and bone as well as of diet and feces; magnitude of calcium flux per day as calculated by various methods is shown at sites of transport in intestine, kidney, and bone. Ranges of values shown are approximate and were chosen to illustrate certain points discussed in the text. In conditions of calcium balance, rates of calcium release from and uptake into bone are equal.

The concentration of ionized calcium in the ECF must be maintained within a narrow range because of the critical role calcium plays in a wide array of cellular functions, especially those involved in neuromuscular activity, secretion, and signal transduction. Intracellular cytosolic free calcium levels are ~100 nmol/L and are 10,000-fold lower than ionized calcium concentration in the blood and ECF (1.1–1.3 mmol/L). Cytosolic calcium does not play the structural role played by extracellular calcium; instead, it serves a signaling function. The steep chemical gradient of calcium from outside to inside the cell promotes rapid calcium influx through various membrane calcium channels that can be activated by hormones, metabolites, or neurotransmitters, swiftly changing cellular function. In blood, total calcium concentration is normally 2.2–2.6 mM (8.5–10.5 mg/dL), of which ~50% is ionized. The remainder is bound ionically to negatively charged proteins (predominantly albumin and immunoglobulins) or loosely complexed with phosphate, citrate, sulfate, or other anions. Alterations in serum protein concentrations directly affect the total blood calcium concentration even if the ionized calcium concentration remains normal. An algorithm to correct for protein changes adjusts the total serum calcium (in mg/dL) upward by 0.8 times the deficit in serum albumin (g/dL) or by 0.5 times the deficit in serum immunoglobulin (in g/dL). Notably, such corrections provide only rough approximations of actual free calcium concentrations, however, and may be misleading, particularly during acute illness. Acidosis also alters ionized calcium by reducing its association with proteins. Accordingly, the best practice is to measure blood ionized calcium directly by a method that employs calcium-selective electrodes in acute settings during which calcium abnormalities might occur.

Control of the ionized calcium concentration in the ECF ordinarily is accomplished by adjusting the rates of calcium movement across intestinal and renal epithelia and into and out of bone. These adjustments are mediated mainly via changes in blood levels of the hormones PTH and $1,25(OH)_2D$. Acting via binding to calcium-sensing receptors (CaSRs) on the surface of parathyroid cells, blood ionized calcium suppresses PTH secretion by reducing levels of PTH mRNA, promoting the cleavage of PTH to inactive peptides, and suppressing release of PTH-containing granules from parathyroid cells. $1,25(OH)_2D$ inhibits PTH production in the parathyroid by an incompletely understood mechanism of negative feedback (Chap. 422).

Normal dietary calcium intake in the United States varies widely, ranging from 10 to 37 mmol/d (400–1500 mg/d). A National Academy of Medicine (formerly, Institute of Medicine) analysis recommends a daily allowance of 25–30 mmol (1000–1200 mg) for most adults. Intestinal absorption of ingested calcium involves both active (transcellular) and passive (paracellular) mechanisms. Passive calcium absorption is nonsaturable and approximates 5% of daily calcium intake, whereas active absorption involves apical calcium entry via specific ion channels (TRPV5 in the kidney's distal tubule and TRPV6 in the intestine), whose expression is controlled principally by $1,25(OH)_2D$. This active transport mechanism normally accounts for absorption of 20–70% of dietary calcium. Active gastrointestinal calcium transport occurs mainly in the proximal small bowel (duodenum and proximal jejunum), although some active calcium absorption occurs in most segments of the small intestine. Optimal rates of calcium absorption require gastric acid. This is especially true for weakly dissociable calcium supplements such as calcium carbonate. In fact, large boluses of calcium carbonate are poorly absorbed because of their neutralizing effect on gastric acid. In achlorhydric subjects and for those individuals taking drugs that inhibit gastric acid secretion, or with diminished acid secretion following bariatric surgery, supplements should be taken with meals to optimize their absorption. Use of calcium citrate may be preferable in these circumstances. Calcium absorption may also be blunted in disease states such as pancreatic or biliary insufficiency, in which ingested calcium remains bound to unabsorbed fatty acids or other food constituents. At high levels of calcium intake, synthesis of $1,25(OH)_2D$ is reduced; this decreases the rate of active intestinal calcium absorption. The opposite occurs with dietary calcium restriction. Some calcium, ~2.5–5 mmol/d (100–200 mg/d), is excreted as an obligate component of intestinal secretions and is not regulated by calciotropic hormones.

The feedback-controlled hormonal regulation of intestinal absorptive efficiency results in a relatively constant daily net calcium absorption of ~5–10 mmol/d (200–400 mg/d) despite large changes in daily dietary calcium intake. This daily load of absorbed calcium is excreted by the kidneys in a manner that is also tightly regulated by the concentration of ionized calcium in the blood. Approximately 8–10 g/d of calcium is filtered by the glomeruli, of which only 2–3% appears in the urine. Most filtered calcium (65%) is reabsorbed in the proximal tubules via a passive, paracellular route that is coupled to concomitant NaCl reabsorption and not specifically regulated. The cortical thick ascending limb of Henle's loop (cTAL) reabsorbs roughly another 20% of filtered calcium, also via a paracellular mechanism. Calcium reabsorption in the cTAL requires a tight-junctional proteins called paracellin-1 and Claudin14 and is inhibited by increased blood concentrations of calcium or magnesium, acting via the CaSR, which is highly expressed on basolateral membranes in this nephron segment. Operation of the renal CaSR provides a mechanism, independent of those engaged directly by PTH or $1,25(OH)_2D$, by which serum ionized calcium can control renal calcium reabsorption. Finally, ~10% of filtered calcium is reabsorbed in the distal convoluted tubules (DCTs) by a highly regulated transcellular mechanism. Calcium enters the luminal surface of the cell through specific apical calcium channels (TRPV5). It then moves across the cell in association with a specific calcium-binding protein (calbindin-D28k) that buffers cytosolic calcium concentrations from the large mass of transported calcium. Basolateral Ca^{2+}-ATPases and Na^+/Ca^{2+} exchangers actively extrude calcium and thereby maintain the transcellular calcium gradient. All these processes are stimulated directly or indirectly by PTH and $1,25(OH)_2D$. The DCT is also the site of action of thiazide diuretics, which lower urinary calcium excretion by inducing sodium depletion and thereby augmenting proximal calcium reabsorption. Conversely, dietary sodium loads, or increased distal sodium delivery caused by loop diuretics or saline infusion, induce calciuresis.

The homeostatic mechanisms that normally maintain a constant serum ionized calcium concentration may fail at extremes of calcium intake or when the hormonal systems or organs involved are compromised. Thus, even with maximal activity of the vitamin D–dependent intestinal active transport system, sustained calcium intake <5 mmol/d (<200 mg/d) cannot provide enough net calcium absorption to replace obligate losses via the intestine, the kidney, sweat, and other secretions. In this case, increased blood levels of PTH and $1,25(OH)_2D$ activate osteoclastic bone resorption to obtain needed calcium from bone, which leads to progressive bone loss and negative calcium balance. Increased PTH and $1,25(OH)_2D$ also enhance renal calcium reabsorption, and $1,25(OH)_2D$ enhances calcium absorption in the gut. At very high calcium intakes (>100 mmol/d [>4 g/d]), passive intestinal absorption continues to deliver calcium into the ECF despite maximally downregulated intestinal active transport and renal tubular calcium reabsorption. This can cause severe hypercalciuria, nephrocalcinosis, progressive renal failure, and hypercalcemia (e.g., "milk-alkali syndrome"). Deficiency or excess of PTH or vitamin D, intestinal disease, and renal failure represent other commonly encountered challenges to normal calcium homeostasis (Chap. 422).

PHOSPHORUS METABOLISM

Although 85% of the ~600 g of body phosphorus is present in bone mineral, phosphorus is also a major intracellular constituent both as the free anion(s) and as a component of numerous organophosphate compounds, including structural proteins, enzymes, transcription factors, carbohydrate and lipid intermediates, high-energy stores (ATP [adenosine triphosphate], creatine phosphate), and nucleic acids. Unlike calcium, phosphorus exists intracellularly at concentrations close to those present in ECF (e.g., 1–2 mmol/L). In cells and in the ECF, phosphorus exists in several forms, predominantly as $H_2PO_4^-$ or $NaHPO_4^-$, with perhaps 10% as HPO_4^{2-}. This mixture of anions will be referred to here as "phosphate." In serum, ~12% of phosphorus is bound to proteins. Concentrations of phosphates in blood and ECF generally are expressed in terms of elemental phosphorus, with the normal range in adults being 0.75–1.45 mmol/L (2.5–4.5 mg/dL).

Because the volume of the intracellular fluid compartment is twice that of the ECF, measurements of ECF phosphate may not accurately reflect phosphate availability within cells that follows even modest shifts of phosphate from one compartment to the other.

Phosphate is widely available in foods and is absorbed efficiently (65%) by the small intestine even in the absence of vitamin D. However, gut phosphate absorptive efficiency may be enhanced (to 85–90%) via active transport mechanisms that are stimulated by $1,25(OH)_2D$. These mechanisms involve activation of Na^+/PO_4^{2-} co-transporters, such as Npt2b, that move phosphate into intestinal cells against an unfavorable electrochemical gradient. Daily net intestinal phosphate absorption varies widely with the composition of the diet but is generally in the range of 500–1000 mg/d. Phosphate absorption can be inhibited by large doses of calcium salts or by sevelamer hydrochloride (Renagel), strategies commonly used to control levels of serum phosphate in chronic kidney disease. Aluminum hydroxide antacids also reduce phosphate absorption but are used less commonly because of the potential for aluminum toxicity. Low serum phosphate stimulates renal proximal tubular synthesis of $1,25(OH)_2D$, perhaps by suppressing blood levels of FGF23 (see below).

Serum phosphate levels vary by as much as 50% on a normal day. This reflects the effect of food intake but also an underlying circadian rhythm that produces a nadir between 7 and 10 A.M. Carbohydrate administration, especially as IV dextrose solutions in fasting subjects, can decrease serum phosphate by >0.7 mmol/L (2 mg/dL) in common clinical settings including treatment of ketoacidosis or metabolic or respiratory alkalosis. Because of this wide variation in serum phosphate, it is best to perform measurements in the basal, fasting state.

Control of serum phosphate is determined mainly by the rate of renal tubular reabsorption of the filtered load, which is ~4–6 g/d. Because intestinal phosphate absorption is highly efficient, urinary excretion is not constant but varies directly with dietary intake. The fractional excretion of phosphate (ratio of phosphate to creatinine clearance) is generally in the range of 10–15%. The proximal tubule is the principal site at which renal phosphate reabsorption is regulated. This is accomplished by changes in the levels of apical expression and activity of specific Na^+/PO_4^{2-} co-transporters (NaPi-2a and NaPi-2c) in the proximal tubule. Levels of these transporters at the apical surface of these cells are reduced rapidly by PTH, a major hormonal regulator of renal phosphate excretion. In addition, the circulating hormone FGF23 can inhibit phosphate reabsorption by a similar mechanism. FGF23 is synthesized by osteocytes. Activating *FGF23* mutations cause the rare disorder autosomal dominant hypophosphatemic rickets (ADHR). In contrast to PTH, FGF23 reduces synthesis of $1,25(OH)_2D$, which may worsen the resulting hypophosphatemia by lowering intestinal phosphate absorption. Renal reabsorption of phosphate is responsive to changes in dietary intake such that experimental dietary phosphate restriction leads to a dramatic lowering of urinary phosphate within hours, preceding any decline in serum phosphate (e.g., filtered load). This physiologic renal adaptation to changes in dietary phosphate availability occurs independently of PTH and may be mediated in part by changes in levels of serum FGF23. Findings in *FGF23*-deficient mice suggest that FGF23 normally acts to lower blood phosphate and $1,25(OH)_2D$ levels. In turn, elevation of blood phosphate and $1,25(OH)_2D$ increases blood levels of FGF23.

Renal phosphate reabsorption is impaired by hypocalcemia, hypomagnesemia, and severe hypophosphatemia. Phosphate clearance is enhanced by ECF volume expansion and impaired by dehydration. Phosphate retention is an important pathophysiologic feature of renal insufficiency (Chap. 322).

HYPOPHOSPHATEMIA

Causes Hypophosphatemia can occur by one or more of three primary mechanisms: (1) inadequate intestinal phosphate absorption, (2) excessive renal phosphate excretion, and (3) rapid redistribution of phosphate from the ECF into bone or soft tissue (Table 421-1). Because phosphate is so abundant in foods, inadequate intestinal absorption is almost never observed now that aluminum hydroxide antacids, which

bind phosphate in the gut, are no longer widely used. Fasting or starvation, however, may result in depletion of body phosphate and predispose to subsequent hypophosphatemia during refeeding, especially if this is accomplished with IV glucose alone.

Chronic hypophosphatemia usually signifies the presence of a persistent renal tubular phosphate-wasting disorder. Excessive activation of PTH/PTHrP receptors in the proximal tubule, as a result of primary or secondary hyperparathyroidism or because of the PTHrP-mediated hypercalcemia syndrome in malignancy **(Chap. 422)**, is a common cause of renal hypophosphatemia. Familial hypocalciuric hypercalcemia and Jansen's metaphyseal chondrodysplasia are rare examples of genetic disorders in this category **(Chap. 422)**.

Several genetic and acquired diseases cause PTH/PTHrP receptor-independent tubular phosphate wasting with associated rickets and osteomalacia. All these diseases manifest severe hypophosphatemia; renal phosphate wasting, sometimes accompanied by aminoaciduria; inappropriately low blood levels of $1,25(OH)_2D$; low-normal serum levels of calcium; and evidence of impaired cartilage or bone mineralization (osteomalacia). Analysis of these diseases in patients *without* generalized proximal tubular defects (Fanconi syndrome) led to the discovery of the hormone FGF23, which is an important physiologic regulator of phosphate metabolism. FGF23 decreases phosphate reabsorption in the proximal tubule and also suppresses the 1α-hydroxylase responsible for synthesis of $1,25(OH)_2D$. FGF23 is synthesized by cells of the osteoblast lineage, primarily osteocytes. High-phosphate diets increase FGF23 levels, and low-phosphate diets decrease them. ADHR was the first disease linked to abnormalities in FGF23. ADHR results from activating mutations in the gene that encodes FGF23. These mutations alter a cleavage site that ordinarily allows for inactivation of intact FGF23. Several other genetic disorders lead to elevated FGF23, hypophosphatemia, and osteomalacia. The most common of these is X-linked hypophosphatemic rickets (XLH), which results from inactivating mutations in an endopeptidase termed *PHEX* (*p*hosphate-regulating gene with *h*omologies to *e*ndopeptidases on the *X* chromosome) that is expressed most abundantly on the surface of osteocytes and mature osteoblasts. Patients with XLH usually have high FGF23 levels, and ablation of the *FGF23* gene reverses the hypophosphatemia found in the mouse version of XLH. How inactivation of PHEX leads to increased levels of FGF23 has not been determined. Two rare autosomal recessive hypophosphatemic syndromes associated with elevated FGF23 are due to inactivating mutations of dentin matrix protein 1 (DMP1) and ectonucleotide pyrophosphatase/phosphodiesterase 1 (ENPP1), respectively, both of which normally are highly expressed in bone and presumably regulate FGF23 production. An unusual hypophosphatemic disorder, tumor-induced osteomalacia (TIO), is an acquired disorder in which tumors, usually of mesenchymal origin, secrete FGF23. The hypophosphatemic syndrome resolves completely within hours to days after successful resection of the responsible tumor. Such tumors typically express large amounts of FGF23 mRNA, and patients with TIO usually exhibit elevations of FGF23 in their blood. Neutralizing antibodies against FGF23 can be used to treat hypophosphatemia in patients with XLH and TIO.

Dent's disease is an X-linked recessive disorder caused by inactivating mutations in *CLCN5*, a chloride transporter expressed in endosomes of the proximal tubule; features include hypercalciuria, hypophosphatemia, and recurrent kidney stones. Renal phosphate wasting is common among poorly controlled diabetic patients and alcoholics, who therefore are at risk for iatrogenic hypophosphatemia when treated with insulin or IV glucose, respectively. Diuretics and certain other drugs and toxins can cause defective renal tubular phosphate reabsorption (Table 421-1).

In hospitalized patients, hypophosphatemia is often attributable to massive redistribution of phosphate from the ECF into cells. Insulin therapy for diabetic ketoacidosis is a paradigm for this phenomenon, in which the severity of the hypophosphatemia is related to the extent of antecedent depletion of phosphate and other electrolytes **(Chap. 416)**. The hypophosphatemia is usually greatest at a point many hours after initiation of insulin therapy and is difficult to predict from baseline measurements of serum phosphate at the time of presentation, when prerenal azotemia can obscure significant phosphate depletion. Other factors that may contribute to such acute redistributive hypophosphatemia include antecedent starvation or malnutrition, administration of IV glucose without other nutrients, elevated blood catecholamines (endogenous or exogenous), respiratory alkalosis, and recovery from metabolic acidosis.

Hypophosphatemia also can occur transiently (over weeks to months) during the phase of accelerated net bone formation that follows parathyroidectomy for severe primary hyperparathyroidism or during treatment of vitamin D deficiency or lytic Paget's disease. This is referred to as "hungry bone syndrome" and is most prominent in patients who preoperatively have evidence of very high bone turnover (e.g., elevated serum levels of alkaline phosphatase). Osteoblastic metastases can also lead to this syndrome.

Clinical and Laboratory Findings The clinical manifestations of severe hypophosphatemia reflect a generalized defect in cellular energy metabolism because of ATP depletion, a shift from oxidative phosphorylation toward glycolysis, and associated tissue or organ dysfunction. Acute, severe hypophosphatemia occurs mainly or exclusively in hospitalized patients with underlying serious medical or surgical illness and preexisting phosphate depletion due to excessive urinary losses, severe malabsorption, or malnutrition. Chronic hypophosphatemia tends to be less severe, with a clinical presentation dominated by musculoskeletal complaints such as bone pain, osteomalacia, pseudofractures, and proximal muscle weakness or, in children, rickets and short stature.

Neuromuscular manifestations of severe hypophosphatemia are variable but may include muscle weakness, lethargy, confusion, dysarthria, dysphagia, oculomotor palsies, nystagmus, ataxia, hyporeflexia, impaired sphincter control, paresthesia, generalized or Guillain-Barré–like ascending paralysis, seizures, coma, and even death. Serious sequelae such as paralysis and seizures are likely only at phosphate concentrations <0.25 mmol/L (<0.8 mg/dL). Rhabdomyolysis may develop during rapidly progressive hypophosphatemia. The diagnosis of hypophosphatemia-induced rhabdomyolysis may be overlooked, as up to 30% of patients with acute hypophosphatemia (<0.7 m*M*) have creatine phosphokinase elevations that peak 1–2 days after the nadir in serum phosphate, when the release of phosphate from injured myocytes may have led to a near normalization of circulating levels of phosphate.

Respiratory failure and cardiac dysfunction, which are reversible with phosphate treatment, may occur at serum phosphate levels of 0.5–0.8 mmol/L (1.5–2.5 mg/dL). Renal tubular defects, including tubular acidosis, glycosuria, and impaired reabsorption of sodium and calcium, may occur. Hematologic abnormalities correlate with reductions in intracellular ATP and 2,3-diphosphoglycerate and may include erythrocyte microspherocytosis and hemolysis; impaired oxyhemoglobin dissociation; defective leukocyte chemotaxis, phagocytosis, and bacterial killing; and platelet dysfunction.

TREATMENT

Hypophosphatemia

Severe hypophosphatemia (<0.75 mmol/L [<2 mg/dL]), particularly in the setting of underlying phosphate depletion, constitutes a dangerous electrolyte abnormality that should be corrected promptly. Unfortunately, the cumulative deficit in body phosphate cannot be predicted directly from knowledge of the circulating level of phosphate, and therapy must be approached empirically. The threshold for IV phosphate therapy and consequently the dose of phosphate to be administered should reflect consideration of renal function, the likely severity and duration of the underlying phosphate depletion, and the presence and severity of symptoms consistent with those of hypophosphatemia. In adults, phosphate may be safely administered IV as neutral mixtures of sodium or potassium phosphate salts at initial doses of 0.2–0.8 mmol/kg of elemental phosphorus over 6 h (e.g., 10–50 mmol over 6 h), with doses >20 mmol/6 h reserved for those who have serum levels

TABLE 421-2 Intravenous Therapy for Hypophosphatemia

CONSIDER			
Likely severity of underlying phosphate depletion			
Concurrent parenteral glucose administration			
Presence of neuromuscular, cardiopulmonary, or hematologic complications of hypophosphatemia			
Renal function (reduce dose by 50% if serum creatinine >220 μmol/L [>2.5 mg/dL])			
Serum calcium level (correct hypocalcemia first; reduce dose by 50% in hypercalcemia)			
Guidelines			
SERUM PHOSPHORUS, MM (MG/DL)	**RATE OF INFUSION, MMOL/H**	**DURATION, H**	**TOTAL ADMINISTERED, MMOL**
<0.8 (<2.5)	2	6	12
<0.5 (<1.5)	4	6	24
<0.3 (<1)	8	6	48

Note: Rates shown are calculated for a 70-kg person; levels of serum calcium and phosphorus must be measured every 6–12 h during therapy; infusions can be repeated to achieve stable serum phosphorus levels >0.8 mmol/L (>2.5 mg/dL); most formulations available in the United States provide 3 mmol/mL of sodium or potassium phosphate.

<0.5 mmol/L (1.5 mg/dL) and normal renal function. A suggested approach is presented in Table 421-2. Serum levels of phosphate and calcium must be monitored closely (every 6–12 h) throughout treatment. It is important to avoid a serum calcium-phosphorus product >50 mg^2/dL^2 to reduce the risk of heterotopic calcification. Hypocalcemia, if present, should be corrected before administering IV phosphate. Less severe hypophosphatemia, in the range of 0.5–0.8 mmol/L (1.5–2.5 mg/dL), usually can be treated with oral phosphate in divided doses of 750–2000 mg/d as elemental phosphorus; higher doses can cause bloating and diarrhea.

Management of chronic hypophosphatemia requires knowledge of the cause(s) of the disorder. Hypophosphatemia related to the secondary hyperparathyroidism of vitamin D deficiency usually responds to treatment with vitamin D and calcium alone. XLH, ADHR, TIO, and related renal tubular disorders usually are managed with divided oral doses of phosphate, often with calcium and $1,25(OH)_2D$ supplements to bypass the block in renal $1,25(OH)_2D$ synthesis and prevent secondary hyperparathyroidism caused by suppression of ECF calcium levels. Care must be taken to be sure that oral calcium and phosphate are not administered at the same time, to avoid precipitation before absorption. Thiazide diuretics may be used to prevent nephrocalcinosis in patients who are managed this way. Complete normalization of hypophosphatemia is generally not possible in these conditions. Burosumab, a human monoclonal antibody that inhibits FGF23, has been approved for the treatment of XLH and TIO. It corrects hypophosphatemia, improves bone pain, and heals fractures in both adults and children.

Optimal therapy for TIO is surgical removal of the responsible tumor, which may be localized by radiographic skeletal survey or bone scan (many are located in bone) or by radionuclide scanning using sestamibi or labeled octreotide. Successful treatment of TIO-induced hypophosphatemia with octreotide has been reported in a small number of patients. Burosumab treatment can be used to treat hypophosphatemia in patients with TIO in whom tumors cannot be localized or removed.

HYPERPHOSPHATEMIA

Causes When the filtered load of phosphate and glomerular filtration rate (GFR) are normal, control of serum phosphate levels is achieved by adjusting the rate at which phosphate is reabsorbed by the proximal tubular NaPi-2 co-transporters. Hyperphosphatemia, defined in adults as a fasting serum phosphate concentration >1.8 mmol/L (5.5 mg/dL), usually results from impaired glomerular filtration, hypoparathyroidism, excessive delivery of phosphate into the ECF (from bone, gut, or parenteral phosphate therapy), or a combination of these factors (Table 421-3). The upper limit of normal serum phosphate concentrations is higher in children and neonates (2.4 mmol/L [7 mg/dL]). It is useful to distinguish hyperphosphatemia caused by impaired renal phosphate excretion from that which results from excessive delivery of phosphate into the ECF (Table 421-3).

    - 5. Cytotoxic therapy
    - 6. Severe hemolytic anemia
  - C. Transcellular phosphate shifts
    - 1. Metabolic acidosis
    - 2. Respiratory acidosis

In chronic renal insufficiency, reduced GFR leads to phosphate retention. Hyperphosphatemia, and progressive loss of nephron function, in turn further impairs renal synthesis of $1,25(OH)_2D$, increases FGF23 levels, and stimulates PTH secretion and parathyroid gland hypertrophy both directly and indirectly (by lowering blood ionized calcium levels). Thus, hyperphosphatemia is a major cause of the secondary hyperparathyroidism of renal failure (Chaps. 322 and 422).

Hypoparathyroidism leads to hyperphosphatemia via increased expression of NaPi-2 co-transporters in the proximal tubule. Hypoparathyroidism, or parathyroid suppression, has multiple potential causes, including autoimmune disease; developmental, surgical, or radiation-induced absence of functional parathyroid tissue; vitamin D intoxication or other causes of PTH-independent hypercalcemia; cellular PTH resistance (pseudohypoparathyroidism or hypomagnesemia); infiltrative disorders such as Wilson's disease and hemochromatosis; and impaired PTH secretion caused by hypermagnesemia, severe hypomagnesemia, or activating mutations in the CaSR. Hypocalcemia may also contribute directly to impaired phosphate clearance, as calcium infusion can induce phosphaturia in hypoparathyroid subjects. Increased tubular phosphate reabsorption also occurs in acromegaly, during heparin administration, and in tumoral calcinosis. Tumoral calcinosis is caused by a rare group of genetic disorders in which FGF23 is processed in a way that leads to low levels of active FGF23 in the bloodstream. This may result from mutations in the FGF23 sequence or via inactivating mutations in the *GALNT3* gene, which encodes a galactosaminyl transferase that normally adds sugar residues to FGF23 that slow its proteolysis. A similar syndrome results from FGF23 resistance due to inactivating mutations of the FGF23 co-receptor Klotho. These

abnormalities cause elevated serum 1,25(OH)$_2$D, parathyroid suppression, increased intestinal calcium absorption, and focal hyperostosis with large, lobulated periarticular heterotopic ossifications (especially at shoulders or hips) and are accompanied by hyperphosphatemia. In some forms of tumoral calcinosis, serum phosphorus levels are normal.

When large amounts of phosphate are delivered rapidly into the ECF, hyperphosphatemia can occur despite normal renal function. Examples include overzealous IV phosphate therapy, oral or rectal administration of large amounts of phosphate-containing laxatives or enemas (especially in children), extensive soft tissue injury or necrosis (crush injuries, rhabdomyolysis, hyperthermia, fulminant hepatitis, cytotoxic chemotherapy), extensive hemolytic anemia, and transcellular phosphate shifts induced by severe metabolic or respiratory acidosis.

Clinical Findings The clinical consequences of acute, severe hyperphosphatemia are due mainly to the formation of widespread calcium phosphate precipitates and resulting hypocalcemia. Thus, tetany, seizures, accelerated nephrocalcinosis (with renal failure, hyperkalemia, hyperuricemia, and metabolic acidosis), and pulmonary or cardiac calcifications (including development of acute heart block) may occur. The severity of these complications relates to the elevation of serum phosphate levels, which can reach concentrations as high as 7 mmol/L (20 mg/dL) in instances of massive soft tissue injury or tumor lysis syndrome.

TREATMENT

Hyperphosphatemia

Therapeutic options for management of severe hyperphosphatemia are limited. Volume expansion may enhance renal phosphate clearance. Aluminum hydroxide antacids or sevelamer may be helpful in chelating and limiting absorption of offending phosphate salts present in the intestine. Hemodialysis is the most effective therapeutic strategy and should be considered early in the course of severe hyperphosphatemia, especially in the setting of renal failure and symptomatic hypocalcemia.

MAGNESIUM METABOLISM

Magnesium is the major intracellular divalent cation. Normal concentrations of extracellular magnesium and calcium are crucial for normal neuromuscular activity. Intracellular magnesium forms a key complex with ATP and is an important cofactor for a wide range of enzymes, transporters, and nucleic acids required for normal cellular function, replication, and energy metabolism. The concentration of magnesium in serum is closely regulated within the range of 0.7–1 mmol/L (1.5–2 meq/L; 1.7–2.4 mg/dL), of which 30% is protein-bound and another 15% is loosely complexed to phosphate and other anions. One-half of the 25 g (1000 mmol) of total body magnesium is located in bone, only one-half of which is insoluble in the mineral phase. Almost all extraskeletal magnesium is present within cells, where the total concentration is 5 m*M*, 95% of which is bound to proteins and other macromolecules. Because only 1% of body magnesium resides in the ECF, measurements of serum magnesium levels may not accurately reflect the level of total body magnesium stores.

Dietary magnesium content normally ranges from 6 to 15 mmol/d (140–360 mg/d), of which 30–40% is absorbed, mainly in the jejunum and ileum. Intestinal magnesium absorptive efficiency is stimulated by 1,25(OH)$_2$D and can reach 70% during magnesium deprivation. Urinary magnesium excretion normally matches net intestinal absorption and is ~4 mmol/d (100 mg/d). Regulation of serum magnesium concentrations is achieved mainly by control of renal magnesium reabsorption. Only 20% of filtered magnesium is reabsorbed in the proximal tubule, whereas 60% is reclaimed in the cTAL and another 5–10% in the DCT. Magnesium reabsorption in the cTAL occurs via a paracellular route that requires both a lumen-positive potential, created by NaCl reabsorption, and tight-junction proteins encoded by members of the Claudin gene family. Magnesium reabsorption in the cTAL is increased by PTH but inhibited by hypercalcemia or hypermagnesemia, both of which activate the CaSR in this nephron segment.

HYPOMAGNESEMIA

Causes Hypomagnesemia usually signifies substantial depletion of body magnesium stores (0.5–1 mmol/kg). Hypomagnesemia can result from intestinal malabsorption; protracted vomiting, diarrhea, or intestinal drainage; defective renal tubular magnesium reabsorption; or rapid shifts of magnesium from the ECF into cells, bone, or third spaces (Table 421-4). Dietary magnesium deficiency is unlikely except possibly in the setting of alcoholism. Rare genetic disorders that cause selective intestinal magnesium malabsorption have been described (primary infantile hypomagnesemia types 1 and 2). Another rare

inherited disorder (hypomagnesemia with secondary hypocalcemia) is caused by mutations in the gene encoding TRPM6, a protein that, with TRPM7, forms a channel important for both intestinal and distal-tubular renal transcellular magnesium transport. Malabsorptive states, often compounded by vitamin D deficiency, can critically limit magnesium absorption and produce hypomagnesemia despite the compensatory effects of secondary hyperparathyroidism and of hypocalcemia and hypomagnesemia to enhance cTAL magnesium reabsorption. Diarrhea or surgical drainage fluid may contain ≥5 mmol/L of magnesium. Proton pump inhibitors (omeprazole and others) may produce hypomagnesemia by an unknown mechanism that does not involve renal wasting of magnesium.

Several genetic magnesium-wasting syndromes have been described, including inactivating mutations of genes encoding the DCT NaCl co-transporter (Gitelman's syndrome), proteins required for cTAL Na-K-2Cl transport (Bartter's syndrome), claudin 16 or claudin 19 (autosomal recessive renal hypomagnesemia with hypercalciuria), a DCT Na^+,K^+-ATPase γ-subunit (autosomal dominant renal hypomagnesemia with hypocalciuria), DCT K^+ channels (Kv1.1, Kir4.1), and a mitochondrial gene encoding a tRNA. Activating mutations of the CaSR can cause hypomagnesemia as well as hypocalcemia. ECF expansion, hypercalcemia, and severe phosphate depletion may impair magnesium reabsorption, as can various forms of renal injury, including those caused by drugs such as cisplatin, cyclosporine, aminoglycosides, and pentamidine as well as the epidermal growth factor (EGF) receptor inhibitory antibody cetuximab (EGF action is required for normal DCT apical expression of TRPM6) (Table 421-4). A rising blood concentration of ethanol directly impairs tubular magnesium reabsorption, and persistent glycosuria with osmotic diuresis leads to magnesium wasting and probably contributes to the high frequency of hypomagnesemia in poorly controlled diabetic patients. Magnesium depletion is aggravated by metabolic acidosis, which causes intracellular losses as well.

Hypomagnesemia due to rapid shifts of magnesium from ECF into the intracellular compartment can occur during recovery from diabetic ketoacidosis, starvation, or respiratory acidosis. Less acute shifts may be seen during rapid bone formation after parathyroidectomy, with treatment of vitamin D deficiency, or with osteoblastic metastases. Large amounts of magnesium may be lost with acute pancreatitis, extensive burns, or protracted and severe sweating and during pregnancy and lactation.

Clinical and Laboratory Findings Hypomagnesemia may cause generalized alterations in neuromuscular function, including tetany, seizures, muscle weakness, ataxia, nystagmus, vertigo, depression, irritability, and psychosis. Patients are usually asymptomatic when serum magnesium concentrations are >0.5 mmol/L (1 meq/L; 1.2 mg/dL), although the severity of symptoms may not correlate well with serum magnesium levels. Cardiac arrhythmias may occur, including sinus tachycardia, other supraventricular tachycardias, and ventricular arrhythmias. Electrocardiographic abnormalities may include prolonged PR or QT intervals, T-wave flattening or inversion, and ST straightening. Sensitivity to digitalis toxicity may be enhanced.

Other electrolyte abnormalities often seen with hypomagnesemia, including hypocalcemia (with hypocalciuria) and hypokalemia, may not be easily corrected unless magnesium is administered as well. The hypocalcemia may be a result of concurrent vitamin D deficiency, although hypomagnesemia can cause impaired synthesis of $1,25(OH)_2D$, cellular resistance to PTH, and, at very low serum magnesium (<0.4 mmol/L [<0.8 meq/L; <1 mg/dL]), defects in PTH secretion; these abnormalities are reversible with therapy.

TREATMENT

Hypomagnesemia

Mild, asymptomatic hypomagnesemia may be treated with oral magnesium salts ($MgCl_2$, MgO, $Mg[OH]_2$) in divided doses totaling 20–30 mmol/d (40–60 meq/d). Diarrhea may occur with larger doses. More severe hypomagnesemia should be treated parenterally, preferably with IV $MgCl_2$, which can be administered safely as a continuous infusion of 50 mmol/d (100 meq Mg^{2+}/d) if renal function is normal. If GFR is reduced, the infusion rate should be lowered by 50–75%. Use of IM $MgSO_4$ is discouraged; the injections are painful and provide relatively little magnesium (2 mL of 50% $MgSO_4$ supplies only 4 mmol). $MgSO_4$ may be given IV instead of $MgCl_2$, although the sulfate anions may bind calcium in serum and urine and aggravate hypocalcemia. Serum magnesium should be monitored at intervals of 12–24 h during therapy, which may continue for several days because of impaired renal conservation of magnesium (only 50–70% of the daily IV magnesium dose is retained) and delayed repletion of intracellular deficits, which may be as high as 1–1.5 mmol/kg (2–3 meq/kg).

It is important to consider the need for calcium, potassium, and phosphate supplementation in patients with hypomagnesemia. Vitamin D deficiency frequently coexists and should be treated with oral or parenteral vitamin D or 25(OH)D (but not with $1,25(OH)_2D$, which may impair tubular magnesium reabsorption, possibly via PTH suppression). In severely hypomagnesemic patients with concomitant hypocalcemia and hypophosphatemia, administration of IV magnesium alone may worsen hypophosphatemia, provoking neuromuscular symptoms or rhabdomyolysis, due to rapid stimulation of previously suppressed PTH secretion. This is avoided by administering both calcium and magnesium.

HYPERMAGNESEMIA

Causes Hypermagnesemia is rarely seen in the absence of renal insufficiency as normal kidneys can excrete large amounts (250 mmol/d) of magnesium. Mild hypermagnesemia due to excessive reabsorption in the cTAL occurs with CaSR mutations in familial hypocalciuric hypercalcemia and has been described in some patients with adrenal insufficiency, hypothyroidism, or hypothermia. Massive exogenous magnesium exposures, usually via the gastrointestinal tract, can overwhelm renal excretory capacity and cause life-threatening hypermagnesemia (Table 421-5). A notable example of this is prolonged retention of even normal amounts of magnesium-containing cathartics in patients with intestinal ileus, obstruction, or perforation. Extensive soft tissue injury or necrosis also can deliver large amounts of magnesium into the ECF in patients who have suffered trauma, shock, sepsis, cardiac arrest, or severe burns. Further, infusion of magnesium in pregnant women with eclampsia can lead to hypocalcemia.

Clinical and Laboratory Findings The most prominent clinical manifestations of hypermagnesemia are vasodilation and neuromuscular blockade, which may appear at serum magnesium concentrations >2 mmol/L (>4 meq/L; >4.8 mg/dL). Hypotension that is refractory to vasopressors or volume expansion may be an early sign. Nausea, lethargy, and weakness may progress to respiratory failure, paralysis,

	C. Hypothermia

and coma, with hypoactive tendon reflexes, at serum magnesium levels >4 mmol/L. Other findings may include gastrointestinal hypomotility or ileus; facial flushing; pupillary dilation; paradoxical bradycardia; prolongation of PR, QRS, and QT intervals; heart block; and, at serum magnesium levels approaching 10 mmol/L, asystole.

Hypermagnesemia, acting via the CaSR, causes hypocalcemia and hypercalciuria due to both parathyroid suppression and impaired cTAL calcium reabsorption.

TREATMENT

Hypermagnesemia

Successful treatment of hypermagnesemia generally involves identifying and interrupting the source(s) of magnesium and employing measures to increase magnesium clearance from the ECF. Use of magnesium-free cathartics or enemas may be helpful in clearing ingested magnesium from the gastrointestinal tract. Vigorous IV hydration should be attempted, if appropriate. Hemodialysis is effective and may be required in patients with significant renal insufficiency. Calcium, administered IV in doses of 100–200 mg over 1–2 h, has been reported to provide temporary improvement in signs and symptoms of hypermagnesemia.

VITAMIN D

SYNTHESIS AND METABOLISM

1,25-Dihydroxyvitamin D [1,25(OH)$_2$D] is the major steroid hormone involved in regulation of mineral ion homeostasis. Vitamin D and its metabolites are hormones and hormone precursors rather than vitamins, since in the proper biologic setting, they can be synthesized endogenously **(Fig. 421-4)**. In response to ultraviolet radiation of the skin, a photochemical cleavage results in the formation of vitamin D from 7-dehydrocholesterol. Cutaneous production of vitamin D is decreased by melanin and high solar protection factor sunblocks, which effectively impair skin penetration by ultraviolet light. The increased use of sunblocks in North America and Western Europe and a reduction in the magnitude of solar exposure of the general population over the past several decades has led to an increased reliance on dietary sources of vitamin D. In the United States and Canada, these sources largely consist of fortified cereals and dairy products, in addition to fish oils and egg yolks. Vitamin D from plant sources is in the form of vitamin D$_2$, whereas that from animal sources is vitamin D$_3$. These two forms have equivalent biologic activity and are activated equally well by the vitamin D hydroxylases in humans. Vitamin D enters the circulation, whether absorbed from the intestine or synthesized cutaneously, bound to vitamin D–binding protein, an α-globulin synthesized in the liver. Vitamin D is subsequently 25-hydroxylated in the liver by a cytochrome P450 oxidase in the mitochondria and microsomes. The activity of this hydroxylase is not tightly regulated, and the resultant metabolite, 25-hydroxyvitamin D [25(OH)D], is the major circulating and storage form of vitamin D. Approximately 88% of 25(OH)D circulates bound to the vitamin D–binding protein, 0.03% is free, and the rest circulates bound to albumin. The half-life of 25(OH)D is ~2–3 weeks, with that of 25(OH)D$_2$ being shorter than that of 25(OH)D$_3$ due to a lower affinity of vitamin D–binding protein for the former. The half-life of 25(OH)D is also greatly shortened when vitamin D–binding protein levels are reduced, as can occur with increased urinary losses in the nephrotic syndrome.

The second hydroxylation, required for the formation of the mature hormone, occurs in the kidney **(Fig. 421-5)**. The 25-hydroxyvitamin D-1α-hydroxylase (encoded by the *CYP27B1* gene) is a tightly regulated cytochrome P450–like mixed-function oxidase expressed in the proximal convoluted tubule cells of the kidney. PTH and hypophosphatemia are the major inducers of this microsomal enzyme in the kidney, whereas calcium, FGF23, and the enzyme's product, 1,25(OH)$_2$D, repress it. The 25-hydroxyvitamin D-1α-hydroxylase is also present in numerous other cell types, where it is not subject to hormonal regulation. It is expressed in epidermal keratinocytes, but keratinocyte production of 1,25(OH)$_2$D is not thought to contribute to circulating levels of this hormone. In addition to being present in the trophoblastic layer of the placenta, the 1α-hydroxylase is produced by macrophages associated with granulomas and lymphomas. In these latter pathologic states, the activity of the enzyme is induced by interferon γ and TNF-α but is not regulated by calcium or 1,25(OH)$_2$D; therefore, hypercalcemia, associated with elevated levels of 1,25(OH)$_2$D, may be observed. Treatment of sarcoidosis-associated hypercalcemia with glucocorticoids, ketoconazole, or chloroquine reduces 1,25(OH)$_2$D production and effectively lowers serum calcium. In contrast, chloroquine has not been shown to lower the elevated serum 1,25(OH)$_2$D levels in patients with lymphoma.

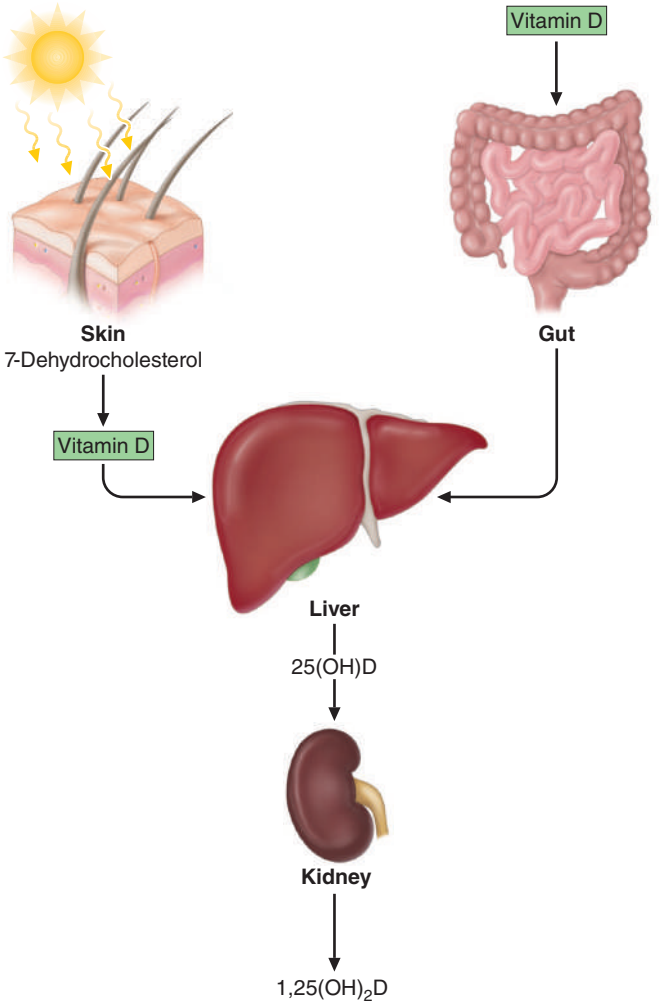

FIGURE 421-4 Vitamin D synthesis and activation. Vitamin D is synthesized in the skin in response to ultraviolet radiation and also is absorbed from the diet. It is then transported to the liver, where it undergoes 25-hydroxylation. This metabolite is the major circulating form of vitamin D. The final step in hormone activation, 1α-hydroxylation, occurs in the kidney.

The major pathway for inactivation of vitamin D metabolites is an additional hydroxylation step by the vitamin D 24-hydroxylase, an enzyme that is expressed in most tissues. 1,25(OH)$_2$D is the major inducer of this enzyme; therefore, this hormone promotes its own inactivation, thereby limiting its biologic effects. FGF23 also induces this hydroxylase, thereby reducing circulating 1,25(OH)$_2$D levels by increasing its inactivation, as well as by impairing its synthesis. Mutations of the gene encoding this enzyme (*CYP24A1*) can lead to infantile hypercalcemia, and in those less severely affected, long-standing hypercalciuria, nephrocalcinosis, and nephrolithiasis can occur.

Polar metabolites of 1,25(OH)$_2$D are secreted into the bile and reabsorbed via the enterohepatic circulation. Impairment of this recirculation, which is seen with diseases of the terminal ileum, leads to accelerated losses of vitamin D metabolites.

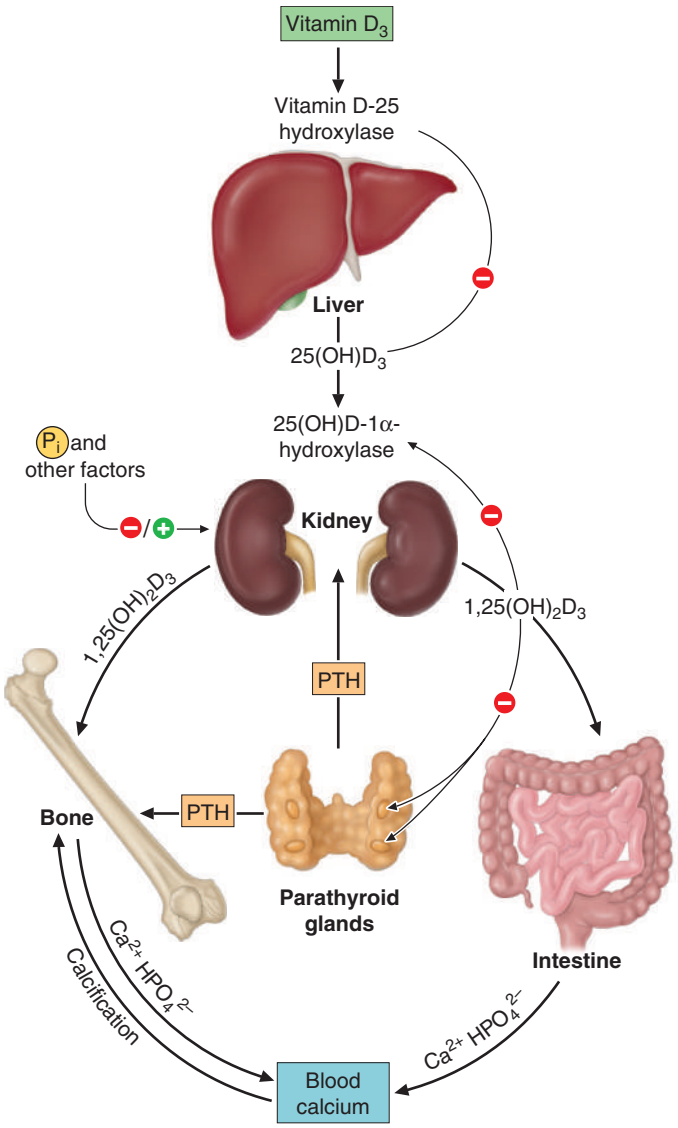

FIGURE 421-5 Schematic representation of the hormonal control loop for vitamin D metabolism and function. A reduction in the serum calcium below ~2.2 mmol/L (8.8 mg/dL) prompts a proportional increase in the secretion of parathyroid hormone (PTH) and so mobilizes additional calcium from the bone. PTH promotes the synthesis of 1,25$(OH)_2$D in the kidney, which in turn stimulates the mobilization of calcium from bone and intestine and regulates the synthesis of PTH by negative feedback.

ACTIONS OF 1,25$(OH)_2$D

1,25$(OH)_2$D mediates its biologic effects by binding to a member of the nuclear receptor superfamily, the vitamin D receptor (VDR). This receptor belongs to the subfamily that includes the thyroid hormone receptors, the retinoid receptors, and the peroxisome proliferator–activated receptors; however, in contrast to the other members of this subfamily, only one VDR isoform has been isolated. The VDR binds to target DNA sequences as a heterodimer with the retinoid X receptor, recruiting a series of coactivators that modify chromatin and approximate the VDR to the basal transcriptional apparatus, resulting in the induction of target gene expression. The mechanism of transcriptional repression by the VDR varies with different target genes but has been shown to involve either interference with the action of activating transcription factors or the recruitment of novel proteins to the VDR complex, resulting in transcriptional repression.

The affinity of the VDR for 1,25$(OH)_2$D is approximately three orders of magnitude higher than that for other vitamin D metabolites. Metabolites resulting from the 24-hydroxylation of vitamin D, including 1,24,25 trihydroxyvitamin D_3 (1,24,35$(OH)_3D_3$) and 24,25 dihydroxyvitamin D_3 (24,25$(OH)D_3$) have biologic effects that mimic 1,25$(OH)_2$D. In normal physiologic circumstances, these other metabolites are not thought to play significant roles in stimulating receptor-dependent actions. However, in states of vitamin D toxicity, the markedly elevated levels of 25(OH)D may lead to hypercalcemia by interacting directly with the VDR and by displacing 1,25$(OH)_2$D from vitamin D–binding protein, resulting in increased bioavailability of the active hormone.

The VDR is expressed in a wide range of cells and tissues. The molecular actions of 1,25$(OH)_2$D have been studied most extensively in tissues involved in the regulation of mineral ion homeostasis. This hormone is a major inducer of calbindin 9K, a calcium-binding protein expressed in the intestine, which is thought to play an important role in the active transport of calcium across the enterocyte. The two major calcium transporters expressed by intestinal epithelia, TRPV5 and TRPV6 (transient receptor potential vanilloid), are also vitamin D responsive. By inducing the expression of these and other genes in the small intestine, 1,25$(OH)_2$D increases the efficiency of intestinal calcium absorption, and it also has been shown to have several important actions in the skeleton. The VDR is expressed in osteoblasts and regulates the expression of several genes in this cell. These genes include the bone matrix proteins osteocalcin and osteopontin, which are upregulated by 1,25$(OH)_2$D, in addition to type I collagen, which is transcriptionally repressed by 1,25$(OH)_2$D. Both 1,25$(OH)_2$D and PTH induce the expression of RANK ligand in osteoblasts, which promotes osteoclast differentiation and increases osteoclast activity, by binding to RANK on osteoclast progenitors and mature osteoclasts. This is the mechanism by which 1,25$(OH)_2$D induces bone resorption. 1,25$(OH)_2$D regulates phosphate homeostasis, primarily by inducing the expression of FGF23 in osteocytes. The skeletal features associated with VDR-knockout mice (rickets, osteomalacia) are largely corrected by increasing calcium and phosphorus intake, underscoring the importance of vitamin D action in the gut.

The VDR is expressed in the parathyroid gland, and 1,25$(OH)_2$D has been shown to have antiproliferative effects on parathyroid cells and to suppress the transcription of the parathyroid hormone gene. These effects of 1,25$(OH)_2$D on the parathyroid gland are an important part of the rationale for current therapies directed at preventing and treating hyperparathyroidism associated with renal insufficiency and complications of chronic oral phosphate therapy.

The VDR is also expressed in tissues and organs that do not play a role in mineral ion homeostasis. Notable in this respect is the observation that 1,25$(OH)_2$D has an antiproliferative effect on several cell types, including keratinocytes, breast cancer cells, and prostate cancer cells. The effects of 1,25$(OH)_2$D and the VDR on keratinocytes are particularly intriguing, since the VDR is primarily a transcriptional repressor in these cells. Alopecia is seen in humans and mice with mutant VDRs but is not a feature of vitamin D deficiency; thus, the effects of the VDR on the hair follicle are ligand-independent. Vitamin D action is also important for regulating the normal maturation of the bone-tendon attachment site, called the enthesis.

VITAMIN D DEFICIENCY

The mounting concern about the relationship between solar exposure and the development of skin cancer has led to increased reliance on dietary sources of vitamin D. Although the prevalence of vitamin D deficiency varies, the third National Health and Nutrition Examination Survey (NHANES III) revealed that vitamin D deficiency is prevalent throughout the United States, with the prevalence being >29% in obese children. The clinical syndrome of vitamin D deficiency can be a result of deficient production of vitamin D in the skin, lack of dietary intake, accelerated losses of vitamin D, impaired vitamin D activation, or resistance to the biologic effects of 1,25$(OH)_2$D (Table 421-6). The elderly and nursing home residents are particularly at risk for vitamin D deficiency, since both the efficiency of vitamin D synthesis in the skin and the absorption of vitamin D from the intestine decline with age. The presence of terminal ileal disease also results in impaired enterohepatic circulation of vitamin D metabolites. While intestinal malabsorption of dietary fats and short bowel syndrome, including that associated with intestinal bypass surgery, lead to vitamin D deficiency, the cause of vitamin D deficiency in obese individuals is poorly understood.

TABLE 421-6 Causes of Impaired Vitamin D Action

Vitamin D deficiency	Impaired 1α-hydroxylation
Impaired cutaneous production	Hypoparathyroidism
Dietary absence	Ketoconazole
Malabsorption (short gut syndrome, gastric bypass)	1α-Hydroxylase mutation
Accelerated loss of vitamin D	FGF23 excess
Increased metabolism (barbiturates, phenytoin, rifampin)	Oncogenic osteomalacia
Impaired enterohepatic circulation	Hypophosphatemic rickets
Nephrotic syndrome	Fibrous dysplasia
CYP3A4 mutation	Chronic kidney disease
Impaired 25-hydroxylation	Target organ resistance
Liver disease, isoniazid	Vitamin D receptor mutation
25-Hydroxylase mutation	Phenytoin
	Other
	Obesity

In addition to intestinal diseases, accelerated inactivation of vitamin D metabolites can be seen with drugs that induce hepatic cytochrome P450 mixed-function oxidases such as barbiturates, phenytoin, and rifampin. Gain-of-function mutations in *CYP3A4* accelerate the oxidation and inactivation of vitamin D metabolites, thus resulting in decreased serum levels of 25OHD and $1,25(OH)_2D$. This form of rickets is autosomal recessive and presents during early childhood and can be treated with high doses of calcitriol or vitamin D Impaired 25-hydroxylation, associated with severe liver disease or isoniazid, is an uncommon cause of vitamin D deficiency. A mutation in the gene responsible for 25-hydroxylation has been identified in a few kindreds. Increased circulating FGF23 levels impair 1α-hydroxylation, preventing the production of $1,25(OH)_2D$. High levels of FGF23 are seen in those with genetic disorders associated with hypophosphatemic rickets, the most common of which is X-linked hypophosphatemia, and are prevalent in populations with profound renal dysfunction. Thus, therapeutic interventions should be considered in patients whose creatinine clearance is <0.5 mL/s (30 mL/min). Mutations in the renal 1α-hydroxylase are the basis for the genetic disorder pseudovitamin D–deficiency rickets (also called vitamin D–dependent rickets type I). This autosomal recessive disorder presents with the syndrome of vitamin D deficiency in the first year of life. Patients present with growth retardation, rickets, and hypocalcemic seizures. Serum $1,25(OH)_2D$ levels are low despite normal 25(OH)D levels and elevated PTH levels. Treatment with vitamin D metabolites that do not require 1α-hydroxylation for activity results in disease remission, although lifelong therapy is required. A second autosomal recessive disorder, hereditary vitamin D–resistant rickets (also called vitamin D-dependent rickets type II), a consequence of vitamin D receptor mutations, is a greater therapeutic challenge. These patients present in a similar fashion during the first year of life, but alopecia often accompanies the disorder, demonstrating a functional role of the VDR in the keratinocyte stem cell population required for hair follicle regeneration. Serum levels of $1,25(OH)_2D$ are dramatically elevated in these individuals both because of increased production due to stimulation of 1α-hydroxylase activity as a consequence of secondary hyperparathyroidism and because of impaired inactivation since induction of the 24-hydroxylase by $1,25(OH)_2D$ requires an intact VDR. Since the receptor mutation results in hormone resistance, daily calcium and phosphate infusions may be required to bypass the defect in intestinal mineral ion absorption.

Regardless of the cause, the clinical manifestations of vitamin D deficiency are largely a consequence of impaired intestinal calcium absorption. Mild to moderate vitamin D deficiency is asymptomatic, whereas long-standing vitamin D deficiency results in hypocalcemia accompanied by secondary hyperparathyroidism, impaired mineralization of the skeleton (osteopenia on x-ray or decreased bone mineral density), and proximal myopathy. Vitamin D deficiency also has been shown to be associated with an increase in overall mortality, including cardiovascular causes. In the absence of an intercurrent illness, the hypocalcemia associated with long-standing vitamin D deficiency rarely presents with acute symptoms of hypocalcemia such as numbness, tingling, and seizures. However, the concurrent development of hypomagnesemia, which impairs parathyroid function, or the administration of potent bisphosphonates, which impair bone resorption, can lead to acute symptomatic hypocalcemia in vitamin D–deficient individuals.

Rickets and Osteomalacia In children, before epiphyseal fusion, vitamin D deficiency results in growth retardation associated with an expansion of the growth plate known as *rickets*. Three layers of chondrocytes are present in the normal growth plate: the reserve zone, the proliferating zone, and the hypertrophic zone. Rickets associated with impaired vitamin D action is characterized by expansion of the hypertrophic chondrocyte layer. The expansion of the growth plate is a consequence of impaired apoptosis of the late hypertrophic chondrocytes, an event that precedes replacement of these cells by osteoblasts during endochondral bone formation. Investigations in murine models demonstrate that hypophosphatemia, which in vitamin D deficiency is a consequence of secondary hyperparathyroidism, is a key etiologic factor in the development of the rachitic growth plate. Impaired actions specific to vitamin D also contribute to the expansion of the hypertrophic layer in the rachitic growth plate.

The hypocalcemia and hypophosphatemia that accompany vitamin D deficiency result in impaired mineralization of bone matrix proteins, a condition known as *osteomalacia*. Osteomalacia is also a feature of long-standing hypophosphatemia, which may result from renal phosphate wasting, or chronic use of etidronate or phosphate-binding antacids. This hypomineralized matrix is biomechanically inferior to normal bone; as a result, patients with osteomalacia are prone to bowing of weight-bearing extremities and skeletal fractures. Vitamin D and calcium supplementation have been shown to decrease the incidence of hip fracture among ambulatory nursing home residents in France, suggesting that undermineralization of bone contributes significantly to morbidity in the elderly. Proximal myopathy is a striking feature of severe vitamin D deficiency both in children and in adults. Rapid resolution of the myopathy is observed upon vitamin D treatment.

Although vitamin D deficiency is the most common cause of rickets and osteomalacia, many disorders lead to inadequate mineralization of the growth plate and bone. Calcium deficiency without vitamin D deficiency, the disorders of vitamin D metabolism previously discussed, and hypophosphatemia can all lead to inefficient mineralization. Even in the presence of normal calcium and phosphate levels, chronic acidosis and drugs such as bisphosphonates can lead to osteomalacia. The inorganic calcium/phosphate mineral phase of bone cannot form at low pH. Bisphosphonates bind to and prevent hydroxyapatite crystal growth. Since alkaline phosphatase is necessary for normal mineral deposition, probably because the enzyme can hydrolyze inhibitors of mineralization such as inorganic pyrophosphate, genetic inactivation of the alkaline phosphatase gene (hereditary hypophosphatasia) also can lead to osteomalacia in the setting of normal calcium and phosphate levels.

Diagnosis of Vitamin D Deficiency, Rickets, and Osteomalacia
The most specific screening test for vitamin D deficiency in otherwise healthy individuals is a serum 25(OH)D level. Although the normal ranges vary, levels of 25(OH)D <37 nmol/L (<15 ng/mL) are associated with increasing PTH levels and lower bone density. The National Academy of Medicine has defined vitamin D sufficiency as a vitamin D level >50 nmol/L (>20 ng/mL), although higher levels may be required to optimize intestinal calcium absorption in the elderly and those with underlying disease states, including obesity. Vitamin D deficiency leads to impaired intestinal absorption of calcium, resulting in decreased serum total and ionized calcium values. This hypocalcemia results in secondary hyperparathyroidism, a homeostatic response that initially maintains serum calcium levels at the expense of the skeleton. Due to the PTH-induced increase in bone turnover, alkaline phosphatase levels are often increased. In addition to increasing bone resorption, PTH decreases urinary calcium excretion while promoting phosphaturia. This results in hypophosphatemia, which exacerbates the mineralization defect in the skeleton. With prolonged vitamin D deficiency resulting in osteomalacia, calcium stores in the skeleton become

relatively inaccessible, since osteoclasts cannot resorb unmineralized osteoid, and frank hypocalcemia ensues. Since PTH is a major stimulus for the renal 25(OH)D 1α-hydroxylase, there is increased synthesis of the active hormone, $1,25(OH)_2D$. Paradoxically, levels of this hormone are often normal in severe vitamin D deficiency. Therefore, measurements of $1,25(OH)_2D$ are not accurate reflections of vitamin D stores and should not be used to diagnose vitamin D deficiency in patients with normal renal function.

Radiologic features of vitamin D deficiency in children include a widened, expanded growth plate that is characteristic of rickets. These findings not only are apparent in the long bones but also are present at the costochondral junction, where the expansion of the growth plate leads to swellings known as the "rachitic rosary." Impairment of intramembranous bone mineralization leads to delayed fusion of the calvarial sutures and a decrease in the radiopacity of cortical bone in the long bones. If vitamin D deficiency occurs after epiphyseal fusion, the main radiologic finding is a decrease in cortical thickness and relative radiolucency of the skeleton. A specific radiologic feature of osteomalacia, whether associated with phosphate wasting or vitamin D deficiency, is pseudofractures, or Looser's zones. These are radiolucent lines that occur where large arteries are in contact with the underlying skeletal elements; it is thought that the arterial pulsations lead to the radiolucencies. As a result, these pseudofractures are usually a few millimeters wide, are several centimeters long, and are seen particularly in the scapula, the pelvis, and the femoral neck.

TREATMENT

Vitamin D Deficiency

Based on the National Academy of Medicine 2010 report, the recommended daily intake of vitamin D is 600 IU from 1 to 70 years of age, and 800 IU for those >70. Based on the observation that 800 IU of vitamin D, with calcium supplementation, decreases the risk of hip fractures in elderly women, this higher dose is thought to be an appropriate daily intake for prevention of vitamin D deficiency in adults. Multiple clinical trials, including the Vitamin D and Omega-3 Trial (VITAL), revealed that supplementation of vitamin D in older community-dwelling adults (>50 years of age) with adequate vitamin D levels, at doses at or above the recommended daily intake, does not further improve bone mineral density. The VITAL trial further showed that supraphysiologic doses of vitamin D in adults with normal vitamin D levels do not improve skeletal microarchitecture and do not prevent falls. Furthermore, treating older adults with daily small doses of vitamin D_3, such as 400 IU, can prevent fractures and falls, as compared with large intermittent bolus doses of vitamin D_3, which can result in increased incidence of fractures and falls. The safety margin for vitamin D is large, and vitamin D toxicity usually is observed only in patients taking doses in the range of 40,000 IU daily. Treatment of vitamin D deficiency should be directed at the underlying disorder, if possible, and also should be tailored to the severity of the condition. Vitamin D should always be repleted in conjunction with calcium supplementation since most of the consequences of vitamin D deficiency are a result of impaired mineral ion homeostasis. In patients in whom 1α-hydroxylation is impaired, metabolites that do not require this activation step are the treatment of choice. They include $1,25(OH)_2D_3$ (calcitriol [Rocaltrol], 0.25–0.5 μg/d) and 1α-hydroxyvitamin D_2 (doxercalciferol [Hectorol], 2.5–5 μg/d). Outside the United States, 1α-hydroxyvitamin D_3 (alfacalcidol [One-Alpha], 0.25–1.0 μg/d) is also used. If the pathway required for activation of vitamin D is intact, severe vitamin D deficiency can be treated with pharmacologic repletion initially (50,000 IU weekly for 3–12 weeks), followed by maintenance therapy (800 IU daily). Pharmacologic doses may be required for maintenance therapy in patients who are taking medications such as barbiturates or phenytoin that accelerate metabolism of or cause resistance to $1,25(OH)_2D$. Polymorphisms in the 25-hydroxylase and the 24-hydroxylase genes can also lead to different responses to the normal recommended daily intake of vitamin D. The hepatic enzyme cytochrome P450 3A4 (CYP3A4) is a strong inducer of the catabolism of vitamin D metabolites. Polymorphisms of the *CYP3A4* gene and certain drugs, such as phenytoin and rifampin, lead to strong induction of this enzyme; thus, those affected may also require higher doses of vitamin D supplementation. Calcium supplementation should include 1.5–2 g/d of elemental calcium. Normocalcemia is usually observed within 1 week of the institution of therapy, although increases in PTH and alkaline phosphatase levels may persist for 3–6 months. The most efficacious methods to monitor treatment and resolution of vitamin D deficiency are serum and urinary calcium measurements. In patients who are vitamin D replete and are taking adequate calcium supplementation, the 24-h urinary calcium excretion should be in the range of 100–250 mg/24 h. Lower levels suggest problems with adherence to the treatment regimen or with absorption of calcium or vitamin D supplements. Levels >250 mg/24 h predispose to nephrolithiasis and should lead to a reduction in vitamin D dosage and/or calcium supplementation.

422 Disorders of the Parathyroid Gland and Calcium Homeostasis

Michael Mannstadt, Harald Jüppner

Four parathyroid glands are located posterior to the thyroid gland. They produce parathyroid hormone (PTH), which is the primary regulator of calcium homeostasis. PTH acts directly on bone, where it induces calcium (and phosphate) release, and on the kidney, where it enhances calcium reabsorption in the distal tubules. In the proximal renal tubules, PTH increases excretion of phosphate and the synthesis of 1,25-dihydroxyvitamin D ($1,25(OH)_2D$), a hormone that increases

gastrointestinal calcium absorption. Serum PTH levels are tightly regulated by a negative feedback loop. Calcium, acting through the calcium-sensing receptor, and vitamin D, acting through its nuclear receptor, reduce PTH release and synthesis. Additional evidence indicates that fibroblast growth factor 23 (FGF23), a phosphaturic hormone, can suppress PTH secretion. Understanding the hormonal pathways that regulate calcium and phosphate levels as well as bone metabolism is essential for effective diagnosis and management of a wide array of hyper- and hypocalcemic disorders.

Primary hyperparathyroidism, characterized by excess production of PTH, is a common cause of hypercalcemia and is usually the result of autonomously functioning adenomas or hyperplasia. Surgery for this disorder is highly effective and has been shown to reverse some of the deleterious effects of long-standing PTH excess on bone density. Humoral hypercalcemia of malignancy (HHM) is also a common cause of hypercalcemia, which is usually due to the overproduction of parathyroid hormone–related peptide (PTHrP) by cancer cells. The similarities in the biochemical characteristics of hyperparathyroidism and HHM, first noted by Albright in 1941, are now known to reflect the actions of PTH and PTHrP through the same G protein–coupled PTH/PTHrP receptor (PH1R). The converse, namely hypocalcemia, can be caused by the lack of functional PTH, i.e., hypoparathyroidism, or by reduced PTH responsiveness of the proximal renal tubules, i.e., pseudohypoparathyroidism (PHP).

The genetic basis of numerous calcium and phosphate disorders, and the molecular characterization of parathyroid cell biology, have provided new insights into the regulation of calcium and phosphate homeostasis. In addition, PTH(1-34) and possibly some of its analogues are promising agents for the treatment of postmenopausal osteoporosis and as replacement therapy for hypoparathyroidism. Calcimimetic agents, which activate the calcium-sensing receptor (CaSR), have provided new approaches for PTH suppression, and calcilytics, which are negative allosteric modulators of the CaSR, show promising results in early clinical trials of patients with autosomal dominant hypocalcemia type 1, a rare dominant disease that is caused by activating CaSR mutations.

PTH

Structure and Physiology PTH is an 84-amino-acid single-chain peptide. The amino-terminal portion, PTH(1–34), is highly conserved and is critical for the biologic actions of the molecule. Modified synthetic fragments of the amino-terminal sequence as small as PTH(1–11) are sufficient to activate the PTH/PTHrP receptor, if provided at high enough concentrations (see below). C-terminal portions of full-length PTH(1–84) were shown to bind to a separate binding protein/receptor; however, the properties and biologic role(s), if any, of this presumed receptor for C-terminal PTH remain undefined.

The primary function of PTH is to maintain ionized calcium concentration in the extracellular fluid (ECF) within a narrow normal range. The hormone acts directly on bone and kidney and indirectly on the intestine through its effects on synthesis of $1,25(OH)_2D$ to increase serum calcium concentrations; in turn, PTH production is closely regulated by the concentration of serum ionized calcium. This feedback system is the critical homeostatic mechanism for maintenance of ECF calcium. Any tendency toward hypocalcemia, as might be induced by calcium- or vitamin D–deficient diets, is counteracted by increased PTH secretion. This in turn (1) increases bone turnover, thereby increasing the flow of calcium (and phosphate) from bone into blood; (2) increases calcium reabsorption in the distal tubules; and (3) indirectly increases the efficiency of calcium absorption in the intestine by stimulating the renal production of $1,25(OH)_2D$. Immediate control of blood calcium is due to PTH effects on bone and, to a lesser extent, on renal calcium clearance. Maintenance of calcium balance over a longer timescale, on the other hand, probably results from the effects of $1,25(OH)_2D$ on intestinal calcium absorption **(Chap. 421)**. The renal actions of PTH are exerted at multiple sites; in the proximal tubules, it increases urinary phosphate excretion, it augments calcium reabsorption in the distal tubules, and it enhances in the proximal tubules expression of CYP27B1, the enzyme that encodes the 25(OH) D-1α-hydroxylase. Every day, up to 12 mmol (500 mg) of calcium is transferred between the ECF and bone, which is a significant amount in relation to the total ECF calcium pool, and PTH plays a crucial role in regulating this transfer.

PTH has multiple actions on bone and integrates its calcemic actions (bone resorption to protect against hypocalcemia) with stimulation of bone formation. PTH-mediated changes in bone calcium release can be seen within minutes. The chronic effects of PTH are to increase the number of bone cells, both osteoblasts and osteoclasts, and to increase the remodeling of bone; these effects are apparent within hours after the hormone is given and persist for hours after PTH is withdrawn. Continuous exposure to elevated PTH (as in primary hyperparathyroidism or long-term PTH infusions in animals) leads to increased osteoclast-mediated bone resorption. However, the intermittent administration of relatively small amounts of PTH that elevate hormone levels minimally for 1–2 h each day lead to a net increase of bone mass rather than bone loss. Striking increases, especially in trabecular bone in the spine and hip, have been reported with the intermittent use of PTH for osteoporosis, and large clinical trials with PTH(1–34) as monotherapy revealed a highly significant increase in bone density and reduction in fracture incidence.

Osteoblasts (or their stromal cell precursors), which have PTH/PTHrP receptors, are crucial to this bone-forming effect of PTH. When PTH activates PTH/PTHrP receptors on osteocytes, release of calcium from the matrix surrounding these cells is enhanced; osteoclasts, which mediate bone breakdown, lack such receptors. PTH-mediated stimulation of osteoclasts is indirect, acting in part through RANKL released from osteoblasts to activate RANK on osteoclasts; in experimental studies of bone resorption in vitro, osteoblasts must be present for PTH to activate osteoclasts to resorb bone **(Chap. 421)**.

Synthesis, Secretion, and Metabolism • **SYNTHESIS** Parathyroid cells have multiple methods of adapting to increased needs for PTH production. Most rapid (within minutes) is secretion of preformed hormone in response to hypocalcemia. Second, within hours, PTH mRNA expression is induced by sustained hypocalcemia. Finally, protracted challenge leads within days to cellular replication to increase parathyroid gland mass.

PTH is initially synthesized as a larger molecule (preproPTH, consisting of 115 amino acids). After a first cleavage step to remove the "pre" sequence of 25 amino acid residues, a second cleavage step removes the "pro" sequence of 6 amino acid residues before secretion of the mature peptide comprising 84 residues. Homozygous or heterozygous mutations in the prepro-region can cause hypoparathyroidism by interfering with hormone synthesis, transport, or secretion. Thus far, only three homozygous mutations have been identified in the secreted PTH(1–84) that reduce its biological activity and are detected in some, but not all, PTH assays (see below).

Transcriptional suppression of the PTH gene by calcium is nearly maximal at physiologic calcium concentrations. Hypocalcemia increases transcriptional activity within hours. $1,25(OH)_2D$ also strongly suppresses PTH gene transcription. In patients with chronic kidney disease (CKD), administration of supraphysiologic doses of $1,25(OH)_2D$ or analogues of this active metabolite can dramatically suppress PTH overproduction and is thus used clinically to control severe secondary hyperparathyroidism. Regulation of proteolytic destruction of preformed PTH (posttranslational regulation of hormone production) is an important mechanism for mediating rapid (within minutes) changes in hormone availability. High calcium increases and low calcium inhibits the proteolytic destruction of stored hormone.

REGULATION OF PTH SECRETION PTH secretion increases steeply to a maximum value of about five times the basal rate of secretion as the calcium concentration falls from normal to 1.9–2.0 mmol/L (7.6–8.0 mg/dL; measured as total calcium). Severe intracellular magnesium deficiency impairs PTH secretion (see below).

ECF calcium controls PTH secretion by interaction with a CaSR, a G protein–coupled receptor (GPCR) for which Ca^{2+} ions act as the primary ligand (see below). This receptor, which also has phosphate

binding sites, is a member of the class C GPCR superfamily and functions as an obligate homodimer. Characterized by a large extracellular domain that effectively clamps the small-molecule ligand, the CaSR is expressed in many tissues and cell types. The CaSR can couple to all four classes of G proteins in a cell-dependent context. In the parathyroids, the CaSR mediates its actions by coupling to two closely related G protein alpha-subunits, namely Gαq and Gα11, as well as Gαi. Activation of the CaSR by high calcium levels negatively regulates PTH secretion in the parathyroids and reduces calcium reabsorption in the distal renal tubules.

Genetic evidence further reinforced the essential role for the CaSR in maintaining calcium balance. Heterozygous loss-of-function CaSR mutations cause familial hypocalciuric hypercalcemia (FHH) type 1, a benign disease in which the blood calcium abnormality resembles that observed in hyperparathyroidism but with hypocalciuria; other more recently defined variants of FHH, namely FHH2 and FHH3, are caused either by heterozygous loss-of-function mutations in Gα11, the alpha-subunit of one of the signaling proteins downstream of the CaSR, or by heterozygous mutations in the adaptor protein AP2S1, which is key in the intracellular trafficking of the CaSR. Homozygous loss-of-function mutations in the CaSR are the cause of severe neonatal hyperparathyroidism, a disorder that is typically lethal if not treated within the first days of life. On the other hand, heterozygous gain-of-function mutations cause a form of hypocalcemia resembling hypoparathyroidism (see below).

METABOLISM PTH undergoes intraglandular proteolysis, which is regulated by extracellular calcium, and further degradation occurs after secretion into the circulation, mainly by liver and kidney. Removal of the critically important amino-terminus (as little as the first amino acid) produces biologically inactive PTH fragments, such as PTH(7–84), which can be detected equally well as PTH(1–84) by several commonly used immunometric PTH assays that employ two antibodies directed against portions of the N- and C-terminus, respectively. Earlier assays, now used only infrequently, measure predominantly middle and carboxyl-terminal fragments that have no or incompletely defined biological activity and are cleared more slowly from blood than the secreted PTH(1–84).

Although the problems inherent in PTH measurements have been largely circumvented by use of double-antibody immunometric assays, some evidence suggests that the PTH(7–84) (and probably related amino-terminally truncated fragments) can act, through yet undefined mechanisms, as an inhibitor of PTH action and may therefore be of clinical significance, particularly in patients with CKD. In this group of patients, efforts to prevent secondary hyperparathyroidism by a variety of measures (vitamin D analogues, higher calcium intake, higher dialysate calcium, phosphate-lowering strategies, and calcimimetic drugs) can lead to oversuppression of the parathyroid glands since some amino-terminally truncated PTH fragments can react in some immunometric PTH assays, thus overestimating the levels of biologically active PTH(1–84). Excessive parathyroid gland suppression in CKD can lead to adynamic bone disease (see below), which has been associated in children with further impaired growth and increased bone fracture rates in adults and can furthermore lead to significant hypercalcemia. The measurement of PTH with newer third-generation immunometric assays, which use detection antibodies directed against extreme amino-terminal PTH epitopes and thus detect only full-length PTH(1–84), has not yet clearly shown to be advantageous in the clinical setting.

PTHRP

Structure and Physiology PTHrP is responsible for most instances of HHM (Chap. 98), a syndrome that resembles primary hyperparathyroidism but without elevated PTH levels. Most cell types normally produce PTHrP, including brain, pancreas, heart, lung, mammary tissue, placenta, endothelial cells, and smooth muscle. In fetal animals, PTHrP directs transplacental calcium transfer, and high concentrations of PTHrP are produced in mammary tissue and secreted into milk, but the biologic significance of this peptide in breast milk is unknown. PTHrP has paracrine and autocrine functions and it plays an essential role in diverse functions such as endochondral bone formation, branching morphogenesis of the breast, and possibly in uterine contraction.

PTH and PTHrP, although products of different genes, exhibit considerable functional and structural homology (Fig. 422-1) and have evolved from a shared ancestral gene. The structure of the gene encoding human PTHrP, however, is more complex than that of PTH, containing multiple additional exons, which can undergo alternate splicing patterns during formation of the mature mRNA. Protein products of 139, 141, and 173 amino acids are produced, and other molecular forms may result from tissue-specific degradation at accessible internal cleavage sites. The biologic roles of these various molecular species and the nature of the circulating forms of PTHrP are unclear. In fact, it is uncertain whether PTHrP circulates at any significant level in healthy children and adults. As a paracrine factor, PTHrP may be produced, act, and be destroyed locally within tissues. In adults, PTHrP appears to have little influence on calcium homeostasis, except in disease states, when large tumors, especially of the squamous cell type as well as renal cell carcinomas, lead to massive overproduction of the hormone and hypercalcemia.

Both PTH and PTHrP bind to and activate the PTH/PTHrP receptor. The PTH/PTHrP receptor (also known as the PTH-1 receptor [PTH1R]) belongs to the class B GPCRs that includes the receptors for calcitonin, glucagon, secretin, vasoactive intestinal peptide, and a few other peptides. Although both ligands activate the PTH1R, the two peptides induce distinct responses by the receptor, which explains how a single receptor without isoforms can serve different biologic roles. The extracellular regions of the receptor are involved in hormone binding, and the intracellular domains, after hormone activation, bind G protein subunits to transduce hormone signaling into cellular responses through the stimulation of second messenger formation. A second receptor that binds PTH, originally termed the PTH-2 receptor (PTH2R), is primarily expressed in brain, pancreas, and testis. Different mammalian PTH1Rs respond equivalently to PTH and PTHrP, at least when tested with traditional assays, whereas the human PTH2R responds efficiently only to PTH, but not to PTHrP. PTH2Rs from other species show little or no stimulation of second-messenger

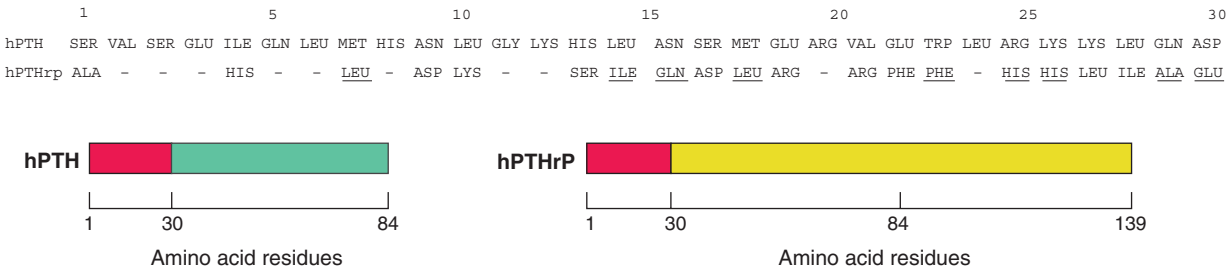

FIGURE 422-1 Schematic diagram to illustrate similarities and differences in structure of human parathyroid hormone (hPTH) and human PTH-related peptide (hPTHrP). Close structural (and functional) homology exists between the first 30 amino acids of hPTH and hPTHrP. The PTHrP sequence may be ≥139 amino acid residues in length. PTH is only 84 residues long; after residue 30, there is little structural homology between the two. Dashed lines in the PTHrP sequence indicate identity; underlined residues, although different from those of PTH, still represent conservative changes (charge or polarity preserved). Ten amino acids are identical, and a total of 20 of 30 are homologues.

formation in response to PTH or PTHrP. In fact, the endogenous ligand of the PTH2R was shown to be a hypothalamic peptide referred to as tubular infundibular peptide of 39 residues, TIP39, that is only distantly related to PTH and PTHrP. The PTH1R and the PTH2R can be traced backward in evolutionary time to fish, which express also a third receptor, the PTH3R, that is more closely related to the fish PTH1R than to the fish PTH2R. The evolutionary conservation of structure and function suggests important biologic roles for these receptors, even in fish, which lack discrete parathyroid glands but produce two molecules that are closely related to mammalian PTH.

Studies using the cloned PTH1R confirm that it can be coupled to more than one G protein and second-messenger pathway, thus contributing to the multiplicity of pathways stimulated by PTH. Activation of protein kinases (A and C) and calcium transport channels is associated with a variety of hormone-specific tissue responses. These responses include inhibition of phosphate and bicarbonate transport, stimulation of calcium transport, and activation of renal 1α-hydroxylase in the kidney. The responses in bone include effects on collagen synthesis, alkaline phosphatase, ornithine decarboxylase, citrate decarboxylase, and glucose-6-phosphate dehydrogenase activities; phospholipid synthesis; and calcium and phosphate transport. Ultimately, these biochemical events lead to an integrated hormonal response in bone turnover and calcium homeostasis. PTH also activates Na^+/Ca^{2+} exchangers at renal distal tubular sites and stimulates translocation of preformed calcium transport channels, moving them from the interior to the apical surface to increase tubular uptake of calcium. PTH-dependent stimulation of phosphate excretion involves reduced expression of two sodium-dependent phosphate co-transporters, NPT2a and NPT2c, at the apical membrane, thereby reducing phosphate reabsorption in the proximal renal tubules. Similar mechanisms may be involved in other renal tubular transporters that are influenced by PTH.

PTHrP exerts important developmental influences on fetal bone development and in adult physiology. Homozygous ablation of the gene encoding PTHrP (or disruption of the PTH1R gene) in mice causes a lethal phenotype in which animals are born with pronounced acceleration of chondrocyte maturation that resembles a human disease, Blomstrand lethal chondrodysplasia (BLC), that is caused by homozygous or compound heterozygous, inactivating PTH1R mutations (Fig. 422-2). Heterozygous inactivating PTH1R mutations in humans furthermore can be a cause of delayed tooth eruption, while heterozygous inactivating PTHrP mutations lead to premature growth plate closure and reduced adult heights. Besides the lethal, biallelic PTH1R mutations that cause BLC, several homozygous mutations in this gene have now been identified in a rare recessive disease referred to as Eiken syndrome. Affected patients typically have normal mineral ion regulation, yet delayed growth plate maturation resulting in some bone deformities, reduced growth, and delayed tooth eruption; recently, a few cases were described with symptomatic hypocalcemia and considerably elevated PTH levels.

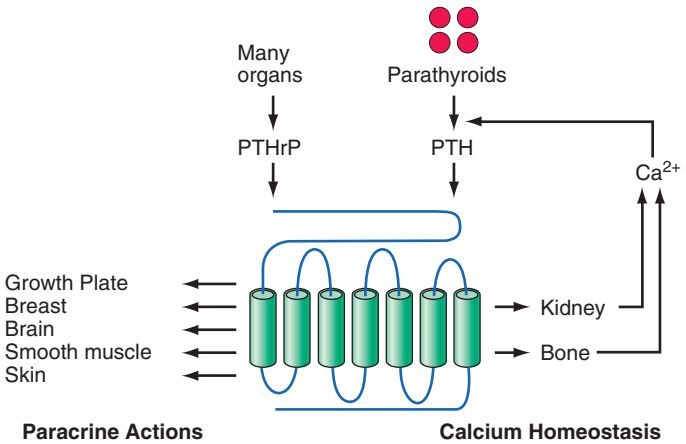

FIGURE 422-2 Dual role for the actions of the PTH/PTHrP receptor (PTH1R). Parathyroid hormone (PTH; endocrine-calcium homeostasis) and PTH-related peptide (PTHrP; paracrine–multiple tissue actions including growth plate cartilage in developing bone) use the single receptor for their disparate functions mediated by the amino-terminal 34 residues of either peptide. Other regions of both ligands interact with other receptors (not shown).

CALCITONIN

(See also Chap. 400) Calcitonin is a peptide hormone with hypocalcemic properties that in several mammalian species acts as an indirect antagonist to the calcemic actions of PTH. Calcitonin seems to be of limited physiologic significance in humans, at least with regard to calcium homeostasis. It is of medical significance because of its role as a tumor marker in sporadic and hereditary cases of medullary thyroid carcinoma and its medical use as an adjunctive treatment in severe hypercalcemia and in Paget's disease of bone at pharmacologic doses. Levels can also be elevated in patients with pseudohypoparathyroidism (PHP); the significance of this observation is unclear.

The hypocalcemic activity of calcitonin is accounted for primarily by inhibition of osteoclast-mediated bone resorption and secondarily by stimulation of renal calcium clearance. These effects are mediated by receptors on osteoclasts and renal tubular cells. Calcitonin exerts additional effects through receptors present in the brain, the gastrointestinal tract, and the immune system. The hormone, for example, exerts analgesic effects directly on cells in the hypothalamus and related structures, possibly by interacting with receptors for related peptide hormones such as calcitonin gene–related peptide (CGRP) or amylin. Both of these ligands have specific high-affinity receptors that share considerable structural similarity with the PH1R and can also bind to and activate calcitonin receptors. The calcitonin receptor shares considerable structural similarity with the PTH1R.

The naturally occurring calcitonins consist of a peptide chain of 32 amino acids. There is considerable sequence variability among species. Calcitonin from salmon, which is used therapeutically, is 10–100 times more potent than mammalian forms in lowering serum calcium.

The circulating level of calcitonin in humans is lower than that in many other species. In humans, even extreme variations in calcitonin production do not change calcium and phosphate metabolism; no definite effects are attributable to calcitonin deficiency (totally thyroidectomized patients receiving only replacement thyroxine) or excess (patients with medullary carcinoma of the thyroid, a calcitonin-secreting tumor) (Chap. 400). Calcitonin has been a useful pharmacologic agent to suppress bone resorption in Paget's disease (Chap. 424) and osteoporosis (Chap. 423) and in the treatment of hypercalcemia of malignancy (see below). However, bisphosphates are usually more effective, and the physiologic role, if any, of calcitonin in humans is uncertain. On the other hand, ablation of the calcitonin gene (combined with ablation of the CGRP gene because both genes are in close proximity) in mice leads to reduced bone mineral density, suggesting that its biologic role in mammals is still not fully understood.

HYPERCALCEMIA

Introduction (See also Chap. 57) Hypercalcemia can be a manifestation of a serious illness such as malignancy or can be detected coincidentally by laboratory testing in a patient with no obvious illness. The number of patients recognized with asymptomatic hypercalcemia, usually primary hyperparathyroidism, increased in the late twentieth century when wider testing became readily available.

Whenever hypercalcemia is confirmed, a definitive diagnosis must be established. Although hyperparathyroidism, a frequent cause of asymptomatic hypercalcemia, is a chronic disorder in which manifestations, if any, may be expressed only after months or years, hypercalcemia can also be the earliest manifestation of malignancy, the second most common cause of hypercalcemia in the adult. The causes of hypercalcemia are numerous (Table 422-1), but hyperparathyroidism and cancer account for 90% of all cases.

Before initiating a diagnostic workup, confirm the presence of true hypercalcemia, not a false-positive laboratory test from factors like hemoconcentration during blood collection or elevation in serum proteins such as albumin. Since hypercalcemia is typically chronic, it is cost-effective to obtain several serum calcium and concomitant albumin measurements, which do not require fasting.

TABLE 422-1 Classification of Causes of Hypercalcemia

I. Parathyroid-Related
- A. Primary hyperparathyroidism
  1. Adenoma(s)
  2. Multiple endocrine neoplasia
  3. Parathyroid carcinoma
  4. Ectopic production of parathyroid hormone (PTH)
  5. Exogenous administration of PTH or analogues
- B. Lithium therapy
- C. Familial hypocalciuric hypercalcemia

II. Malignancy-Related
- A. Tumors with osteolytic metastases (breast, multiple myeloma, lymphoma, etc.)
- B. Solid tumor with humoral mediation of hypercalcemia (squamous cell carcinoma of the lung, kidney, breast, and others)
- C. $1,25(OH)_2D$-mediated hypercalcemia of malignancies (lymphoma, ovarian dysgerminoma, etc.)

III. Vitamin D–Related
- A. Vitamin D intoxication
- B. ↑ $1,25(OH)_2D$; sarcoidosis and other granulomatous diseases, lymphoma
- C. ↑ $1,25(OH)_2D$; impaired $1,25(OH)_2D$ metabolism due to biallelic 24-hydroxylase mutations or increased $1,25(OH)_2D$ synthesis due to inactivating biallelic mutations involving the renal sodium-dependent phosphate co-transporters

IV. Associated with High Bone Turnover
- A. Hyperthyroidism
- B. Immobilization
- C. Thiazides
- D. Vitamin A intoxication
- E. Fat necrosis

V. Associated with Renal Failure
- A. Tertiary hyperparathyroidism
- B. Aluminum intoxication and adynamic bone disease
- C. Milk-alkali syndrome

Clinical features are helpful in differential diagnosis. Hypercalcemia in an adult who is asymptomatic is usually due to primary hyperparathyroidism. In malignancy-associated hypercalcemia, the disease is usually not occult; rather, symptoms of malignancy bring the patient to the physician, and hypercalcemia is discovered during the evaluation. If asymptomatic hypercalcemia can be documented for more than a year, malignancy is unlikely. Nevertheless, differentiating primary hyperparathyroidism from occult malignancy can occasionally be difficult, and careful evaluation is required, particularly when the duration of the hypercalcemia is unknown. Other causes of hypercalcemia may include excessive intake of vitamin D or activated analogues, impaired metabolism of $1,25(OH)_2D$, high bone turnover from any of several causes, or renal failure (Table 422-1). Immunometric PTH assays serve as the principal laboratory test in establishing the diagnosis.

Hypercalcemia from any cause can result in fatigue, depression, mental confusion, anorexia, nausea, vomiting, constipation, reversible renal tubular defects, increased urine output, a short QT interval in the electrocardiogram, and, in some patients, cardiac arrhythmias. Generally, symptoms are more common at calcium levels >2.9–3.0 mmol/L (11.6–12.0 mg/dL), but some patients, even at this level, are asymptomatic. When the calcium level is >3.2 mmol/L (12.8 mg/dL), calcification in kidneys, skin, vessels, lungs, heart, and stomach occurs, and renal insufficiency may develop, particularly if blood phosphate levels are normal or elevated due to impaired renal excretion. Severe hypercalcemia, usually defined as ≥3.7–4.5 mmol/L (14.8–18.0 mg/dL), can be a medical emergency; coma and cardiac arrest can occur.

Acute management of the hypercalcemia is usually successful. The type of treatment is based on the severity of the hypercalcemia and the nature of associated symptoms, as outlined below.

PRIMARY HYPERPARATHYROIDISM

Pathophysiology • **NATURAL HISTORY AND INCIDENCE** Primary hyperparathyroidism, which is typically a disease of postmenopausal women, results from excessive secretion of PTH that is disproportionate to serum calcium levels. This typically causes hypercalcemia and hypophosphatemia. There is great variation in the manifestations. Patients may present with multiple signs and symptoms, including recurrent nephrolithiasis, peptic ulcers, mental changes, and, less frequently, extensive bone resorption. However, with greater awareness of the disease and wider use of multiphasic screening tests, including measurements of blood calcium, the diagnosis is frequently made in patients who have no symptoms and minimal, if any, signs of the disease other than hypercalcemia and elevated levels of PTH. The manifestations may be subtle, and the disease may have a benign course for many years or a lifetime. This milder form of the disease is usually termed *asymptomatic hyperparathyroidism* and can present with or without end-organ involvement. Rarely, hyperparathyroidism develops or worsens abruptly and causes severe complications such as marked dehydration and coma, so-called hypercalcemic parathyroid crisis.

The annual incidence of the disease varies globally and has changed over the decades likely reflecting changes in the usage of laboratory screening panels that include serum calcium. The current incidence in the United States is calculated to be about 50 per 100,000 person-years.

ETIOLOGY Parathyroid tumors are most often encountered as isolated monoclonal adenomas without other endocrinopathy. They may also arise in hereditary syndromes such as multiple endocrine neoplasia (MEN) syndromes. As many as 10% of patients with hyperparathyroidism have a genetic basis for the disease (see below). Parathyroid tumors may also arise as secondary to underlying disease (excessive stimulation in secondary hyperparathyroidism, especially chronic renal failure) or after other forms of excessive stimulation such as lithium therapy. These etiologies are discussed below.

Solitary Adenomas A single abnormal gland is the cause in ~80% of patients; the abnormality in the gland is usually a benign neoplasm or adenoma and extremely rarely a parathyroid carcinoma. More than one adenoma has been reported, and genetic causes of the disease often underlies chief cell hyperplasia of all four glands.

Hereditary Syndromes and Multiple Parathyroid Tumors Hereditary hyperparathyroidism can occur without other endocrine abnormalities but is usually part of a MEN syndrome **(Chap. 400)**. MEN 1 (Wermer's syndrome) consists of hyperparathyroidism and tumors of the pituitary and pancreas, often associated with gastric hypersecretion and peptic ulcer disease (Zollinger-Ellison syndrome). MEN 2A is characterized by pheochromocytoma and medullary carcinoma of the thyroid, as well as hyperparathyroidism; MEN 2B has additional associated features such as multiple neuromas but usually lacks hyperparathyroidism. MEN4, caused by mutations in the p27 cyclin-dependent kinase inhibitor (encoded for by *CDKN1B*), has similar clinical manifestations as MEN 1. Mutations in the *MAX* gene are associated with familial forms of pheochromocytoma/paraganglioma, and a few family members have also been reported to have primary hyperparathyroidism. Each of these MEN syndromes is transmitted in an apparent autosomal dominant manner.

The *hyperparathyroidism jaw tumor* (HPT-JT) syndrome occurs in families with parathyroid tumors (sometimes carcinomas) in association with benign jaw tumors. This disorder is caused by mutations in *CDC73* (*HRPT2*), and mutations in this gene are also observed in sporadic parathyroid cancers. Some kindreds exhibit hereditary hyperparathyroidism without other endocrinopathies, which has been referred to as *nonsyndromic familial isolated hyperparathyroidism* (FIHP). In some of these familial cases, the disease co-segregated with heterozygous mutations in *GCM2*. Inactivating or dominant-negative mutations in this parathyroid-specific transcription factor had initially been identified in familial forms of hypoparathyroidism. However, GCM2 variants that are predicted to cause a gain-of-function of GCM2 have been reported in a subset of patients with FIHP. Because the prevalence of these GCM2 variants is much higher than the prevalence

of primary hyperparathyroidism, they might be a risk factor for developing the disease. Furthermore, there is speculation that some FIHP cases may be examples of variable expression of the other syndromes such as MEN 1, MEN 2, or the HPT-JT syndrome, but they may also have distinctive, still unidentified genetic causes.

Genetic Defects Associated with Hyperparathyroidism As in many other types of neoplasia, two fundamental types of genetic defects have been identified in parathyroid gland tumors: (1) overactivity of protooncogenes and (2) loss of function of tumor-suppressor genes. The former, by definition, can lead to uncontrolled cellular growth and function by activation (gain-of-function mutation) of a single allele of the responsible gene, whereas the latter requires loss of function of both allelic copies. Biallelic loss of function of a tumor-suppressor gene is usually characterized by a germline defect (all cells) of one allele (autosomal-dominant mode of inheritance) and an additional somatic deletion/mutation in the second allele of the tumor **(Fig. 422-3)**.

Mutations in the *MEN1* gene, which encodes the tumor suppressor MENIN, on chromosome 11q13 are responsible for causing MEN 1. Inheritance of one mutated allele in this hereditary syndrome, followed by loss of the other allele via somatic cell mutation, leads to monoclonal expansion and tumor development. Also, in ~15–20% of sporadic parathyroid adenomas, both alleles of the *MEN1* locus on chromosome 11 are somatically deleted, implying that the same defect responsible for MEN 1 can also cause the sporadic disease **(Fig. 422-3*A*)**. Consistent with the Knudson hypothesis for two-step neoplasia in certain inherited cancer syndromes **(Chap. 76)**, the earlier onset of hyperparathyroidism in the hereditary syndromes reflects the need for only one mutational event to trigger the monoclonal outgrowth. In sporadic adenomas, typically occurring later in life, two different somatic events must occur before the *MEN1* gene is silenced.

MEN 2 is an example for a mutation in a protooncogene and is associated with gain-of-function mutations in the *Ret* oncogene.

A more complex pattern, still incompletely resolved, arises with genetic defects and carcinoma of the parathyroids. This appears to be due to biallelic loss of a functioning copy of a gene, *CDC73* (or *HRPT2*), originally identified as the cause of the HPT-JT syndrome. Several inactivating mutations have been identified in *CDC73* (located on chromosome 1q21-31), which encodes a 531-amino-acid protein called parafibromin.

The discovery of the genetic mutations that lead to multiple endocrine neoplasias allows genetic testing of suspected probands and family members. Benefits of genetic testing include the ability to verify the clinical diagnosis, identify affected family members, and rule out the genetic variant in family members, who seem to be unaffected.

An important contribution from studies on the genetic origin of parathyroid carcinoma has been the realization that the mutations involve a different pathway than that involved with the benign gland enlargements. Unlike the pathogenesis of genetic alterations seen in colon cancer, where lesions evolve from benign adenomas to malignant disease by progressive genetic changes, the alterations commonly seen in most parathyroid cancers (*HRPT2* mutations) are infrequently seen in sporadic parathyroid adenomas.

Study of the parathyroid cancers found in some patients with the HPT-JT syndrome has led to identification of a much larger role for *HRPT2* mutations in most parathyroid carcinomas, including those that arise sporadically, without apparent association with the HPT-JT syndrome. Mutations in the coding region have been identified in 75–80% of all parathyroid cancers analyzed, leading to the conclusion that, with addition of presumed mutations in the noncoding regions, this genetic defect may be seen in essentially all parathyroid carcinomas. Of special importance was the discovery that, in some sporadic parathyroid cancers, germline mutations have been found; this, in turn, has led to careful investigation of the families of these patients and a new clinical indication for genetic testing in this setting.

Abnormalities at the *Rb* gene were the first to be noted in parathyroid cancer. The *Rb* gene, a tumor-suppressor gene located on

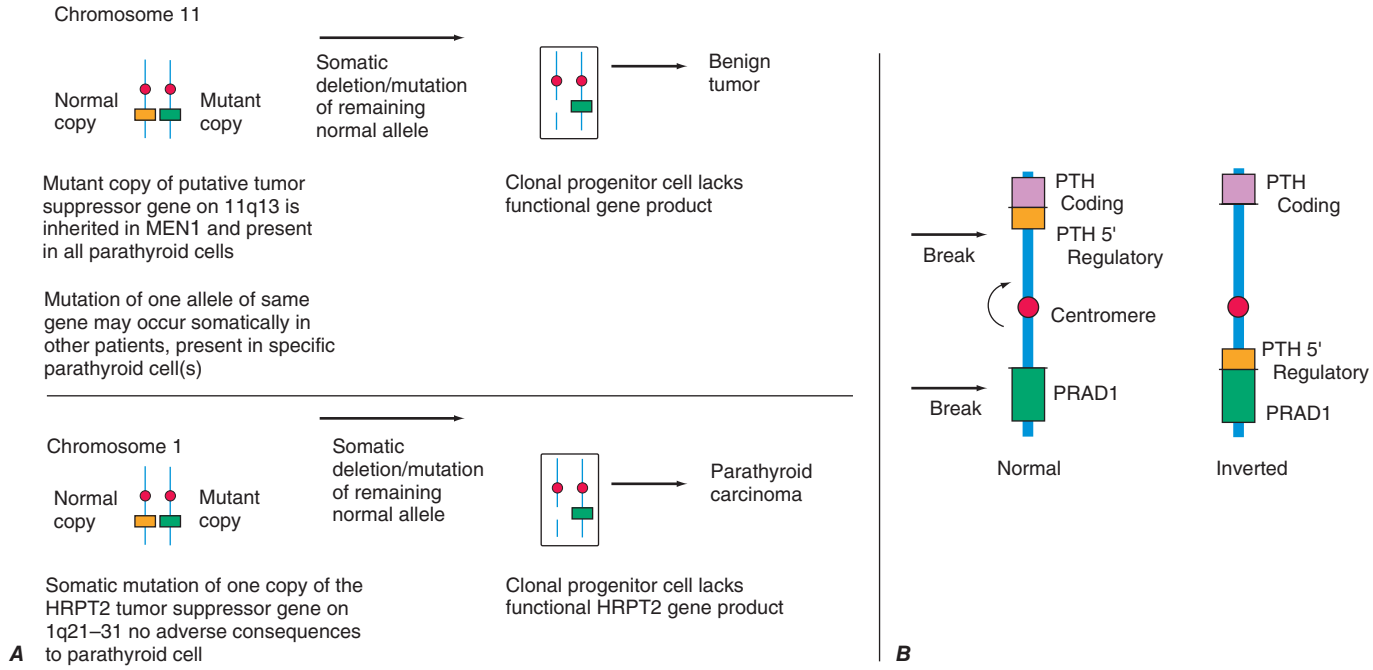

FIGURE 422-3 ***A.*** Schematic diagram indicating molecular events in tumor susceptibility. The patient with the hereditary abnormality (multiple endocrine neoplasia [MEN]) is envisioned as having one defective gene inherited from the affected parent on chromosome 11, but one copy of the normal gene is present from the other parent. In the monoclonal tumor (benign tumor), a somatic event, here partial chromosomal deletion, removes the remaining normal gene from a cell. In nonhereditary tumors, two successive somatic mutations must occur, a process that takes a longer time. By either pathway, the cell, deprived of growth-regulating influence from this gene, has unregulated growth and becomes a tumor. A different genetic locus also involving loss of a tumor-suppressor gene termed *HRPT2* is involved in the pathogenesis of parathyroid carcinoma. *(Reproduced with permission from A Arnold: Genetic basis of endocrine disease 5. Molecular genetics of parathyroid gland neoplasia. J Clin Endocrinol Metab 77:1108, 1993.)* ***B.*** Schematic illustration of the mechanism and consequences of gene rearrangement and overexpression of the *PRAD1* protooncogene (pericentromeric inversion of chromosome 11) in parathyroid adenomas. The excessive expression of PRAD1 (a cell cycle control protein, cyclin D1) by the highly active PTH gene promoter in the parathyroid cell contributes to excess cellular proliferation. *(Reproduced with permission from J Habener, in L DeGroot, JL Jameson (eds): Endocrinology, 4th ed. Philadelphia, PA: Saunders; 2001.)*

chromosome 13q14, was initially associated with retinoblastoma but has since been implicated in other neoplasias, including parathyroid carcinoma. Early studies implicated allelic deletions of the *Rb* gene in many parathyroid carcinomas and decreased or absent expression of the Rb protein. However, because there are often large deletions in chromosome 13 that include many genes in addition to the *Rb* locus (with similar findings in some pituitary carcinomas), it remains possible that other tumor-suppressor genes on chromosome 13 may be playing a role in parathyroid carcinoma.

Overall, it seems there are multiple factors in parathyroid cancer, in addition to the *HRPT2* and *Rb* gene, although the *HRPT2* gene mutation is the most invariant abnormality. *RET* encodes a tyrosine kinase type receptor; specific inherited germline mutations lead to a constitutive activation of the receptor, thereby explaining the autosomal dominant mode of transmission and the relatively early onset of neoplasia. In the MEN 2 syndrome, the *RET* protooncogene may be responsible for the earliest disorder detected, the polyclonal disorder C-cell hyperplasia, which then is transformed into a clonal outgrowth—a medullary carcinoma with the participation of other, still uncharacterized genetic defects.

In some parathyroid adenomas, activation of a protooncogene occurs **(Fig. 422-3*B*)**. A reciprocal translocation involving chromosome 11 was identified as a somatic event that juxtaposes the *PTH* gene promoter upstream of *CCND1*, which encodes a cyclin D protein that plays a key role in normal cell division. This translocation plus other mechanisms that cause an equivalent overexpression of cyclin D1 are found in 20–40% of parathyroid adenomas.

Mouse models have confirmed the role of several of the major identified genetic defects in parathyroid disease and the MEN syndromes. Loss of the *MEN1* gene locus and overexpression of the *CCND1* protooncogene or the mutated *RET* protooncogene have been analyzed by genetic manipulation in mice, with the expected onset of parathyroid tumors or medullary thyroid carcinoma, respectively.

Pathology Adenomas are most often located in the inferior parathyroid glands, but in 6–10% of patients, parathyroid adenomas may be located in the thymus, the thyroid, the pericardium, or behind the esophagus. Adenomas are usually 0.5–5 g in size but may be as large as 10–20 g (normal glands weigh 25 mg on average). Chief cells are predominant in both hyperplasia and adenoma. With chief cell hyperplasia, the enlargement may be so asymmetric that some involved glands appear grossly normal. If generalized hyperplasia is present, however, histologic examination reveals a uniform pattern of chief cells and disappearance of fat even in the absence of an increase in gland weight. Thus, microscopic examination of biopsy specimens of several glands is essential to interpret findings at surgery.

Parathyroid carcinoma is often not aggressive. Long-term survival without recurrence is common if at initial surgery the entire gland is removed without rupture of the capsule. Recurrent parathyroid carcinoma is usually slow growing with local spread in the neck, and surgical correction of recurrent disease may be feasible. Occasionally, however, parathyroid carcinoma is more aggressive, with distant metastases (lung, liver, and bone) found at the time of initial operation. It may be difficult to appreciate initially that a primary tumor is carcinoma; increased numbers of mitotic figures and increased fibrosis of the gland stroma may precede invasion. The diagnosis of carcinoma is often made in retrospect when metastasis occur. Hyperparathyroidism from a parathyroid carcinoma may be indistinguishable from other forms of primary hyperparathyroidism but is usually more severe clinically. A potential clue to the diagnosis is offered by the degree of calcium elevation. Calcium values of 3.5–3.7 mmol/L (14–15 mg/dL) are frequent with carcinoma and may alert the surgeon to remove the abnormal gland with care to avoid capsular rupture. Recent findings concerning the genetic basis of some patients with parathyroid carcinoma (distinct from that of benign adenomas) indicate the need, in these kindreds, for family screening (see below).

Signs and Symptoms Many patients with primary hyperparathyroidism are asymptomatic. Manifestations of hyperparathyroidism involve primarily the kidneys and the skeletal system. Kidney involvement, due either to deposition of calcium in the renal parenchyma or to recurrent nephrolithiasis, was present in 60–70% of patients prior to 1970. With earlier detection, renal complications occur in <20% of patients in many large series. Renal stones are usually composed of either calcium oxalate or calcium phosphate. In occasional patients, repeated episodes of nephrolithiasis or the formation of large calculi may lead to urinary tract obstruction, infection, and loss of renal function. Nephrocalcinosis may also cause decreased renal function and phosphate retention.

The distinctive bone manifestation of hyperparathyroidism is *osteitis fibrosa cystica*, which occurred in 10–25% of patients in series reported 50 years ago. Histologically, the pathognomonic features are an increase in the giant multinucleated osteoclasts in scalloped areas on the surface of the bone (Howship's lacunae) and a replacement of the normal cellular and marrow elements by fibrous tissue. Radiographic changes include resorption of the phalangeal tufts and replacement of the usually sharp cortical outline of the bone in the digits by an irregular outline (subperiosteal resorption). In recent years, osteitis fibrosa cystica is very rare in primary hyperparathyroidism, probably due to the earlier detection and therefore milder form of the disease.

Dual-energy x-ray absorptiometry of the spine provides reproducible quantitative estimates (within a few percent) of spinal bone density. Similarly, bone density in the extremities can be quantified by densitometry of the hip or of the distal radius at a site chosen to be primarily cortical. Computed tomography (CT) is a very sensitive technique for estimating spinal bone density, but reproducibility of standard CT is no better than 5%. Newer CT techniques (spiral, "extreme" CT) are more reproducible but are currently available in a limited number of medical centers and used for research purposes. Cortical bone density is reduced, while cancellous bone density, especially in the spine, is relatively preserved.

In symptomatic patients, dysfunctions of the central nervous system (CNS), peripheral nerve and muscle, gastrointestinal tract, and joints also occur. It has been reported that severe neuropsychiatric manifestations may be reversed by parathyroidectomy. When present in symptomatic patients, neuromuscular manifestations may include proximal muscle weakness, easy fatigability, and atrophy of muscles and may be so striking as to suggest a primary neuromuscular disorder. The distinguishing feature is the complete regression of neuromuscular disease after surgical correction of the hyperparathyroidism.

Gastrointestinal manifestations are sometimes subtle and include vague abdominal complaints and disorders of the stomach and pancreas. Again, cause and effect are unclear. In MEN 1 patients with hyperparathyroidism, duodenal ulcer may be the result of associated pancreatic tumors that secrete excessive quantities of gastrin (Zollinger-Ellison syndrome). Pancreatitis has been reported in association with hyperparathyroidism, but the incidence and the mechanism are not established.

Much attention has been paid in recent years to the manifestations of and optimum management strategies for asymptomatic hyperparathyroidism. This is now the most prevalent form of the disease. *Asymptomatic primary hyperparathyroidism* is defined as biochemically confirmed hyperparathyroidism (elevated or inappropriately normal PTH levels despite hypercalcemia) with the absence of symptoms typically associated with more severe hyperparathyroidism and can occur with or without target organ involvement such as renal or bone disease.

Five conferences on the topic have been held in the United States over the past two decades, with the most recent in 2022. The published proceedings provide guidelines for diagnosis and treatment of primary hyperparathyroidism.

Issues of concern include the potential for cardiovascular deterioration, the presence of subtle neuropsychiatric symptoms, and the longer-term status of skeletal integrity in patients not treated surgically. The current consensus is that medical monitoring rather than surgical correction of hyperparathyroidism may be justified in certain patients. The current recommendation is that patients who show mild disease, as defined by the meeting guidelines **(Table 422-2)**, can be safely followed under management guidelines **(Table 422-3)**. There is, however, growing uncertainty about subtle disease manifestations and whether

TABLE 422-2 Guidelines for Surgery in Asymptomatic Primary Hyperparathyroidism

PARAMETER	GUIDELINE
Serum calcium	>1 mg/dL above normal
Renal	Creatinine clearance <60 mL/min 24-h urine for calcium >300 mg/d in men or >250 mg/d in women and increased stone risk by biochemical stone risk analysis Presence of nephrolithiasis or nephrocalcinosis by x-ray, ultrasound, or other imaging modalities
Skeletal	BMD by DXA: T score <–2.5 at any site Vertebral fracture by x-ray or VFA
Age	<50

Abbreviations: BMD, bone mineral density; DXA, dual-energy x-ray absorptiometry; VFA, vertebral fracture assessment.

surgery is therefore indicated in most patients. Among the issues is the evidence of eventual (>8 years) deterioration in bone mineral density after a decade of relative stability. There is concern that this late-onset deterioration in bone density in nonoperated patients could contribute significantly to the well-known age-dependent fracture risk (osteoporosis). Significant and sustained improvements in bone mineral density are seen after successful parathyroidectomy, and there is some evidence for reduction in fractures.

Cardiovascular disease, including left ventricular hypertrophy, cardiac functional defects, and endothelial dysfunction, has been reported as reversible in European patients with more severe symptomatic disease after surgery, leading to numerous studies of these cardiovascular features in those with milder disease. There are reports of endothelial dysfunction in patients with mild asymptomatic hyperparathyroidism, but the expert panels concluded that more observation is needed, especially regarding whether there is reversibility with surgery.

A topic of considerable interest and some debate is assessment of neuropsychiatric status and health-related quality of life status in hyperparathyroid patients both before surgery and in response to parathyroidectomy. Several observational studies have suggested improvements in symptom score after surgery. Randomized studies of surgery versus observation, however, have yielded inconclusive results, especially regarding benefits of surgery. Many studies report that hyperparathyroidism is associated with increased neuropsychiatric symptoms, but it is not possible at present to determine which patients might improve after surgery.

Diagnosis The diagnosis is typically made by detecting an elevated or inappropriately normal immunoreactive PTH level in a patient with asymptomatic hypercalcemia **(Fig. 422-4)** (see "Differential Diagnosis: Special Tests," below). Serum phosphate is usually low but may be normal, especially if renal failure has developed.

TABLE 422-3 Guidelines for Monitoring in Patients with Primary Hyperparathyroidism Who Do Not Undergo Parathyroidectomy

PARAMETER	GUIDELINE
Serum calcium and 25OHD	Annually
Renal	eGFR, annually; serum creatinine, annually. Abdominal imaging (x-ray, ultrasound, or CT), if clinically indicated. 24-h urine for calcium, if indicated
Creatinine clearance	Annually
Skeletal	DXA every 1–2 years (3 sites) (unless BMD is normal). X-ray or VFA of spine if clinically indicated (e.g., height loss, back pain)

Abbreviations: BMD, bone mineral density; CT, computed tomography; DXA, dual-energy x-ray absorptiometry; eGFR, estimated glomerular filtration rate; VFA, vertebral fracture assessment.

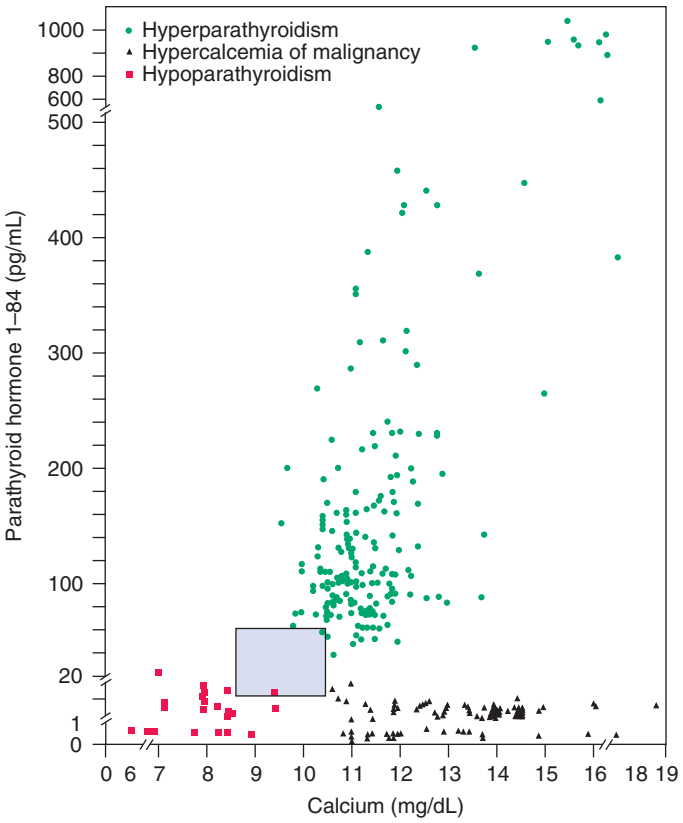

FIGURE 422-4 Levels of immunoreactive parathyroid hormone (PTH) detected in patients with primary hyperparathyroidism, hypercalcemia of malignancy, and hypoparathyroidism. Boxed area represents the upper and normal limits of blood calcium and/or immunoreactive PTH. *(Reproduced with permission from SR Nussbaum et al (eds): Endocrinology, 4th ed. Philadelphia, PA: Saunders; 2001.)*

Several modifications in PTH assays have been introduced in efforts to improve their utility in light of information about metabolism of PTH (as discussed above). First-generation assays were based on displacement of radiolabeled PTH from anti-PTH antibodies that often reacted with PTH fragments. Second-generation, double-antibody, or immunometric assays (one antibody that is usually directed against the carboxyl-terminal portion of intact PTH to capture the hormone and a second enzyme-labeled antibody that is usually directed against the amino-terminal portion of intact PTH) greatly improved the diagnostic discrimination of the tests by eliminating interference from circulating biologically inactive fragments, detected by the original first-generation assays. Third-generation assays, which detect even fewer inactive fragments, may be useful for clinical research studies as in management of chronic renal disease but have not replaced second-generation assays, which reliably help make the diagnosis of hypo- and hyperparathyroidism and differentiate this disease from other conditions of hypo- and hypercalcemia

TREATMENT

Primary Hyperparathyroidism

Surgical excision of the abnormal parathyroid tissue is the definitive therapy for this disease. As noted above, medical surveillance without operation for patients with mild, asymptomatic disease is, however, still preferred by some physicians and patients, particularly when the patients are more elderly. Evidence favoring surgery, if medically feasible, is growing because of concerns about skeletal, cardiovascular, and neuropsychiatric disease, even in mild hyperparathyroidism.

Two surgical approaches are generally practiced. The conventional parathyroidectomy procedure is neck exploration with general anesthesia; however, an outpatient procedure with local anesthesia,

termed *minimally invasive parathyroidectomy,* is gaining traction though it has not yet replaced the traditional surgical approach.

Parathyroid exploration is challenging and should be undertaken by a surgeon experienced in this procedure. Certain features, like multiple abnormal glands in familial cases along with presurgical identification of one enlarged gland using several different imaging methods, can assist in determining the surgical approach. However, some critical decisions regarding management can be made only during the operation.

Preoperative imaging, such as neck ultrasounds, ^{99m}Tc sestamibi scans with single-photon emission CT (SPECT), C(11) choline PET/CT, and four-dimensional (4D) CT are used to predict the location of an abnormal gland. Intraoperative monitoring of PTH levels by rapid PTH immunoassays may be useful in guiding the surgery and a rapid fall (>50%) to normal levels of PTH is used in many centers to predict successful removal of the culprit gland(s).

Multiple-gland hyperplasia, as predicted in familial cases, and reoperation pose more difficult questions of surgical management and increase the risk of developing permanent hypoparathyroidism. Immediate transplantation of a portion of a removed, minced parathyroid gland into the muscles of the forearm is sometimes performed, with the view that surgical excision is easier from the ectopic site in the arm if there is recurrent hyperfunction.

In a minority of cases, if no abnormal parathyroid glands are found in the neck, the issue of further exploration must be decided. There are documented cases of five or six parathyroid glands and of unusual locations for adenomas such as in the mediastinum.

A decline in serum calcium often occurs within 24 h after successful surgery; usually, blood calcium falls to low-normal values for 3–5 days until the remaining parathyroid tissue resumes full hormone secretion. Risk factors for acute postoperative hypocalcemia is undermineralized bone matrix leading to "hungry bone" and vitamin D deficiency. With unexpected hypocalcemia, coexistent hypomagnesemia should be considered, as it interferes with PTH secretion and impairs response to PTH **(Chap. 421)**.

Transient hypoparathyroidism can occur but typically resolves within days; protracted recovery over several months can occur. Patients are unlikely to develop permanent hypoparathyroidism (often defined as hypoparathyroidism that persists 12 months after surgery) if their PTH levels tested within 12–24 h after surgery are >15 pg/mL.

Signs of hypocalcemia include symptoms such as muscle twitching, a general sense of anxiety, and positive Chvostek's and Trousseau's signs coupled with hypocalcemia. Therapy with oral calcium and sometimes low-dose calcitriol is often sufficient. Parenteral calcium therapy should be instituted when severe hypocalcemia is present. The rate and duration of IV therapy are determined by the severity of the symptoms and the response of the serum calcium to treatment. An infusion of 0.5–2 mg/kg per hour or 30–100 mL/h of a 1-mg/mL solution usually suffices to relieve symptoms. Usually, parenteral therapy is required for only a few days. If symptoms worsen or if parenteral calcium is needed for >2–3 days, therapy with a vitamin D analogue and/or oral calcium (2–4 g/d) should be started (see below). It is cost-effective to use calcitriol (doses of 0.5–1 μg/d) because of the rapidity of onset of effect and prompt cessation of action when stopped, in comparison to other forms of vitamin D. A rise in blood calcium after several months of treatment with calcium and calcitriol may indicate restoration of parathyroid function to normal. It is also appropriate to monitor serum PTH serially to estimate gland function in such patients.

If magnesium deficiency is present, it can complicate the postoperative course since significant magnesium deficiency impairs the secretion of PTH. Hypomagnesemia should be corrected whenever detected, typically with oral magnesium replacement, but parenteral repletion may be necessary.

MEDICAL MANAGEMENT

Medical monitoring rather than corrective surgery is still acceptable, but it is clear that surgical intervention is the more frequently recommended option for the reasons noted above. Despite the usefulness of the guidelines, the importance of individual patient and physician judgment and preference is clear in all recommendations.

There is no long-term experience regarding specific clinical outcomes such as fracture prevention, but it has been established that bisphosphonates increase bone mineral density significantly without changing serum calcium. Calcimimetics reduce PTH secretion and thus lower serum calcium but do not affect bone mineral density (BMD). A Scandinavian randomized clinical trial of parathyroidectomy versus observation in patients with mild primary hyperparathyroidism revealed no differences in morbidity or mortality after 10 years.

OTHER PARATHYROID CAUSES OF HYPERCALCEMIA

Lithium Therapy Lithium, used in the management of bipolar depression and other psychiatric disorders, causes hypercalcemia in ~10% of treated patients. The hypercalcemia is dependent on continued lithium treatment, remitting and recurring when lithium is stopped and restarted. The parathyroid adenomas reported in some hypercalcemic patients with lithium therapy may reflect the presence of an independently occurring parathyroid tumor; a permanent effect of lithium on parathyroid gland growth need not be implicated as most patients have complete reversal of hypercalcemia when lithium is stopped. However, long-standing stimulation of parathyroid cell replication by lithium may predispose to development of adenomas (as is documented in secondary hyperparathyroidism and renal failure).

At the levels achieved in blood in treated patients, lithium can be shown in vitro to shift the PTH secretion curve to the right in response to calcium; i.e., higher calcium levels are required to lower PTH secretion, probably acting at the calcium sensor (see below). This effect can cause elevated PTH levels and consequent hypercalcemia in otherwise normal individuals. Cinacalcet has been used successfully in these patients. Fortunately, there are usually alternative medications for the underlying psychiatric illness. Parathyroid surgery should not be recommended unless hypercalcemia and elevated PTH levels persist after lithium is discontinued.

GENETIC DISORDERS CAUSING HYPERPARATHYROIDISM-LIKE SYNDROMES

Familial Hypocalciuric Hypercalcemia FHH (also called *familial benign hypercalcemia*) is inherited as an autosomal dominant trait. Affected individuals are discovered because of asymptomatic hypercalcemia. Most cases of FHH are caused by an inactivating heterozygous CaSR mutations; this disorder, designated as FHH type 1, leads to inappropriately normal or even increased PTH secretion. Other forms of FHH are caused either by heterozygous loss-of-function mutations in *GNA11* (encoding Gα11), one of the signaling proteins at the CaSR (FHH2), or by heterozygous mutations in *AP2S1* (FHH3).

In FHH1, the primary defect is abnormal sensing of the blood calcium by the parathyroid gland and renal tubule, causing inappropriate secretion of PTH and excessive reabsorption of calcium in the distal renal tubules. Many different inactivating CaSR mutations have been identified in patients with FHH1. These mutations lower the capacity of the sensor to bind calcium and the mutant receptors function as though blood calcium levels were low; thus, inappropriate secretion of PTH occurs from an otherwise normal gland. Approximately two-thirds of patients with FHH have mutations within the protein-coding region of the CaSR gene (FHH1). Others have mutations in *GNA11*, the gene encoding the alpha-subunit of G11, a G-protein through which the CaSR signals (FHH2). These loss-of-function mutations have similar consequences to the loss-of-function mutations in the CaSR. FHH3 is caused by heterozygous mutations of the adaptor protein-2δ subunit (AP2S1), which is a component of clathrin-coated vesicles, and critical in clathrin-mediated endocytosis.

Since FHH is a life-long disease that cannot be cured by parathyroidectomy, it is critical to distinguish this rare disease from the more common primary hyperparathyroidism. One striking exception to the

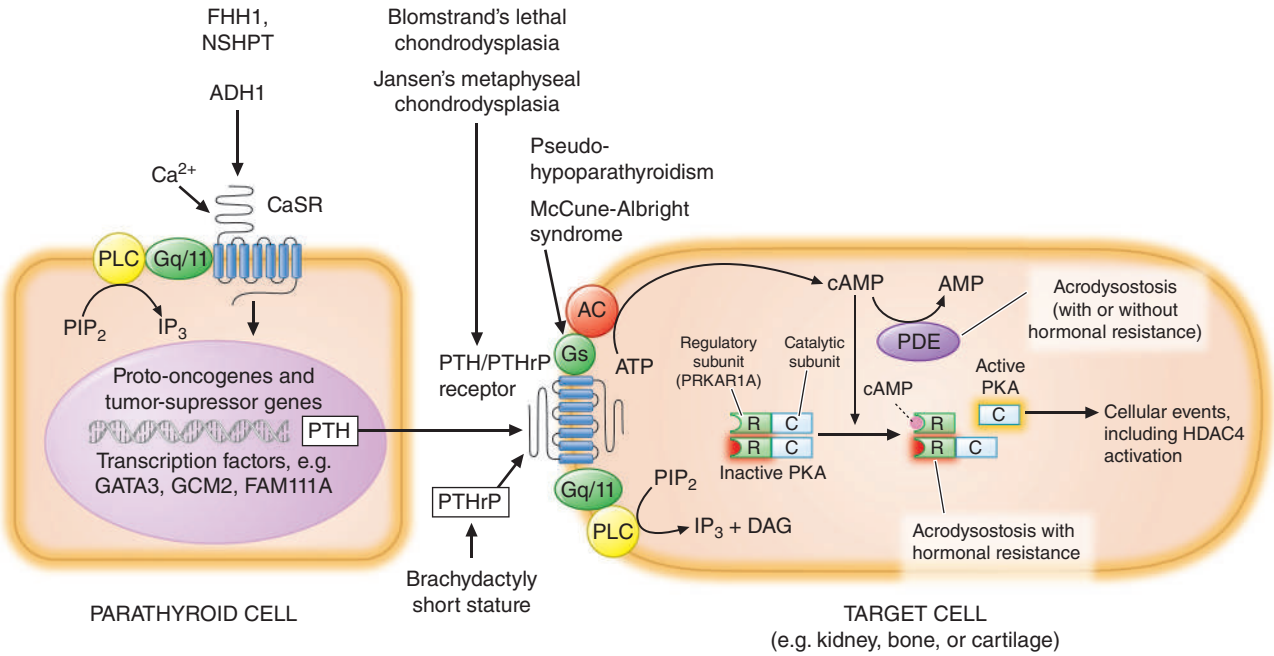

FIGURE 422-5 Illustration of some genetic mutations that alter calcium metabolism by effects on the parathyroid cell or target cells of parathyroid hormone (PTH) action. Alterations in PTH production by the parathyroid cell can be caused by changes in the response to extracellular fluid calcium (Ca^{2+}) that are detected by the calcium-sensing receptor (CaSR). Furthermore, PTH (or PTH-related peptide [PTHrP]) can show altered efficacy in target cells such as in proximal tubular cells, by altered function of its receptor (PTH/PTHrP receptor) or the signal transduction proteins, G proteins such as Gsα that is linked to adenylate cyclase (AC), the enzyme responsible for producing cyclic AMP (cAMP) (also illustrated are Gαq/Gα11, which activate an alternate pathway of receptor signal transmission involving the generation of inositol triphosphate [IP_3] or diacylglycerol [DAG]). Heterozygous loss-of-function mutations in the CaSR cause familial benign hypocalciuric hypercalcemia (FBHH) and homozygous mutations (both alleles mutated) and neonatal severe hyperparathyroidism (NSHPT); heterozygous gain-of-function causes autosomal dominant hypercalciuric hypocalcemia (ADH1). Other defects in parathyroid cell function that occur at the level of gene regulation (oncogenes or tumor-suppressor genes) or transcription factors are discussed in the text. Blomstrand's lethal chondrodysplasia is due to homozygous or compound heterozygous loss-of-function mutations in the PTH/PTHrP receptor, a neonatally lethal disorder, while pseudohypoparathyroidism involves inactivation at the level of the G proteins, specifically mutations that eliminate or reduce Gsα activity in the kidney (see text for details). Acrodysostosis can occur with (mutant regulatory subunit of PKA) or without hormonal resistance (mutant *PDE4D* or *PDE3A*). Jansen's metaphyseal chondrodysplasia and McCune-Albright syndrome represent gain-of-function mutations in the PTH/PTHrP receptor and Gsα protein, respectively.

rule against parathyroid surgery in this syndrome is the occurrence, usually in consanguineous marriages (due to the rarity of the gene mutation), of a homozygous or compound heterozygote state, resulting in severe impairment of CaSR function. In this condition, neonatal severe hypercalcemia, total parathyroidectomy is mandatory, but calcimimetics have been used as a temporary measure.

Patients with FHH have lifelong hypercalcemia, which is typically mild and about 11 mg/dL. PTH values are often within normal laboratory range (which is inappropriate for hypercalcemia) or mildly elevated. Family history is often positive but can be negative because the patient has a de novo mutation or the penetrance of the disease is not 100%. Patients with primary hyperparathyroidism have <99% renal calcium reabsorption, whereas most patients with FHH have >99% reabsorption. The calcium–to–creatine clearance ratio (CCCR), determined on spot or 24-hour urine, can be used to help differentiate the two disorders, with the CCCR typically <0.01 in FHH and >0.02 in primary hyperparathyroidism. This distinction is far from perfect, and genetic testing is helpful in establishing the diagnosis. Panel testing for hypercalcemic disorders allows the simultaneous sequencing of all genes known to be implicated in hypercalcemia, including the genes causing FHH.

Rare but well-documented cases of acquired hypocalciuric hypercalcemia are reported due to antibodies against the CaSR. They appear to be a complication of an underlying autoimmune disorder and respond to therapies directed against the underlying disorder.

Jansen's Disease Activating mutations in the PTH/PTHrP receptor (PTH1R) have been identified as the cause of this rare autosomal dominant syndrome. Because the mutations lead to constitutive activation of receptor function, one abnormal copy of the mutant receptor is sufficient to cause the disease, thereby accounting for its dominant mode of transmission. Besides often severe hypercalcemia, patients affected by Jansen's disease have short-limbed dwarfism due to abnormal regulation of chondrocyte maturation in the growth plates of the bone that are formed through the endochondral process. In adult life, there are numerous abnormalities in bone, including multiple cystic resorptive areas resembling those seen in severe hyperparathyroidism. Hypercalcemia and hypophosphatemia with undetectable or low PTH levels are typically observed. The pathogenesis of the growth plate abnormalities in Jansen's disease has been confirmed by transgenic experiments in which targeted expression of the mutant PTH/PTHrP receptor to the proliferating chondrocyte layer of growth plate emulated several features of the human disorder. Other genetic mutations in the parathyroid gland or PTH target cells that affect Ca^{2+} metabolism are illustrated in Fig. 422-5.

MALIGNANCY-RELATED HYPERCALCEMIA

Clinical Syndromes and Mechanisms of Hypercalcemia

Hypercalcemia due to malignancy is common (occurring in as many as 20% of cancer patients, especially with certain types of tumors such as lung carcinoma), often severe and difficult to manage, and, typically easy to distinguish from primary hyperparathyroidism by a suppressed PTH. Although malignancy is usually clinically obvious or readily detectable by medical history, hypercalcemia can occasionally be due to an occult tumor.

Three main mechanisms of hypercalcemia are operative in cancer hypercalcemia. Humoral hypercalcemia of malignancy (HHM) is caused by tumors producing and secreting PTHrP that causes a clinical picture similar to primary hyperparathyroidism with increased bone resorption and hypercalcemia. However, PTH is suppressed. Patients with HHM may have low to normal levels of $1,25(OH)_2D$, instead of elevated levels as in true hyperparathyroidism probably reflecting subtle differences in the activation of the PTH1R by PTHrP versus PTH. Squamous cell carcinomas and renal, bladder, and colorectal cancer are examples of tumors that can cause HHM. Several different assays (single- or double-antibody, different epitopes) have been developed to detect PTHrP and do not cross-react with PTH. Most data indicate that

circulating PTHrP levels are undetectable or low in normal individuals except in pregnancy (high in human milk) and elevated in most cancer patients with the humoral syndrome.

Alternatively, local osteolysis leading to release of cytokines (e.g., interleukin 1 and tumor necrosis factor) that activate osteoclasts occurs with hematologic malignancies such as leukemia, lymphoma, and multiple myeloma, but also with breast cancer.

A third mechanism leading to malignancy-associated hypercalcemia is an increased production and blood level of $1,25(OH)_2D$, produced by abnormal lymphocytes or adjacent macrophages in lymphoma but also in ovarian dysgerminomas.

The etiologic mechanisms in cancer hypercalcemia may be multiple, even in the same patient. For example, in breast carcinoma (metastatic to bone) and in a distinctive type of T-cell lymphoma/leukemia initiated by human T-cell lymphotropic virus 1, hypercalcemia is caused by direct local lysis of bone as well as by a humoral mechanism involving excess production of PTHrP.

Hyperparathyroidism has been reported to coexist with the humoral cancer syndrome, and rarely, ectopic hyperparathyroidism due to tumor elaboration of true PTH is reported.

TREATMENT

Malignancy-Related Hypercalcemia

Treatment of the hypercalcemia of malignancy is first directed to control of tumor; reduction of tumor mass usually corrects hypercalcemia. If a patient has severe hypercalcemia yet has a good chance for effective tumor therapy, treatment of the hypercalcemia should be vigorous while awaiting the results of definitive therapy (see "General Approach to Hypercalcemic States" below). If hypercalcemia occurs in the late stages of a tumor that is resistant to antitumor therapy, the treatment of the hypercalcemia should be judicious as high calcium levels can have a mild sedating effect. Standard therapies for hypercalcemia (discussed below) are applicable to patients with malignancy.

VITAMIN D–RELATED HYPERCALCEMIA

Vitamin D–mediated hypercalcemia can be due to excessive ingestion of vitamin D analogues or abnormal metabolism of the vitamin. Abnormal metabolism of the vitamin is usually acquired in association with a widespread granulomatous disorder. Vitamin D metabolism is carefully regulated, particularly the activity of renal 1α-hydroxylase, the enzyme responsible for the production of $1,25(OH)_2D$ **(Chap. 421)**. The regulation of 1α-hydroxylase in sites other than the renal tubule differs and lacks the negative feedback regulations; these phenomena may explain the occurrence of hypercalcemia secondary to excessive $1,25(OH)_2D$ production in patients with sarcoidosis or lymphoma.

Vitamin D Intoxication Chronic ingestion of >10 times the normal physiologic requirement of vitamin D (amounts >10,000 U/d) is usually required to produce significant hypercalcemia in otherwise healthy individuals. The stated upper limit of safe dietary intake is 2000 U/d (50 μg/d) in adults because of concerns about potential toxic effects of cumulative supraphysiologic doses. These recommendations are now regarded as too restrictive, since some estimates are that, in elderly individuals in northern latitudes, ≥2000 U/d may be necessary to avoid vitamin D insufficiency.

Hypercalcemia in vitamin D intoxication is due to an excessive biologic action of the vitamin, perhaps the consequence of increased levels of 25(OH)D rather than merely increased levels of the active metabolite $1,25(OH)_2D$ (the latter may not be frankly elevated in vitamin D intoxication). These actions lead to both increased intestinal absorption of calcium and increased release of calcium from bone. 25(OH)D has definite, if low, biologic activity in the intestine and bone. The production of 25(OH)D is less tightly regulated than is the production of $1,25(OH)_2D$. Hence, concentrations of 25(OH)D can be elevated severalfold in patients with excess vitamin D intake.

The diagnosis is substantiated by documenting elevated levels of 25(OH)D >100 ng/mL. Hypercalcemia is usually controlled by restriction of dietary calcium intake and appropriate attention to hydration. These measures, plus discontinuation of vitamin D, usually lead to resolution of hypercalcemia. However, because of the increased bone resorption caused by high levels of vitamin D, simple cessation of calcium intake is often insufficient therapy. Further, 25(OH)D stores in fat may be substantial, and vitamin D intoxication may persist for weeks after vitamin D ingestion is terminated. Such patients are responsive to glucocorticoids, which in doses of 40–100 mg/d of prednisone or its equivalent, usually return serum calcium levels to normal over several days; severe intoxication may require intensive therapy.

Sarcoidosis and Other Granulomatous Diseases In patients with sarcoidosis and other granulomatous diseases, such as tuberculosis and fungal infections, excess $1,25(OH)_2D$ is synthesized in macrophages or other cells in the granulomas. Indeed, increased $1,25(OH)_2D$ levels have been reported in anephric patients with sarcoidosis and hypercalcemia. Macrophages obtained from granulomatous tissue convert 25(OH)D to $1,25(OH)_2D$ at an increased rate. There is a positive correlation in patients with sarcoidosis between 25(OH)D levels (reflecting vitamin D intake) and the circulating concentrations of $1,25(OH)_2D$, whereas normally, there is no increase in $1,25(OH)_2D$ with increasing 25(OH)D levels due to multiple feedback controls on renal 1α-hydroxylase **(Chap. 421)**. The usual regulation of active metabolite production by calcium and phosphate or by PTH does not operate in these patients. Instead, macrophages increase their production of the vitamin D receptor and of the 1α-hydroxylase in response to tumor necrosis factor and other inflammatory stimuli. PTH levels are usually low and $1,25(OH)_2D$ levels are elevated, but primary hyperparathyroidism and sarcoidosis may coexist in some patients.

Management of the hypercalcemia can often be accomplished by avoiding excessive sunlight exposure and limiting vitamin D and calcium intake. Presumably, however, the abnormal sensitivity to vitamin D and abnormal regulation of $1,25(OH)_2D$ synthesis will persist as long as the disease is active. Alternatively, glucocorticoids in the equivalent of 100 mg/d of hydrocortisone or equivalent doses of glucocorticoids may help control hypercalcemia. Glucocorticoids appear to act by blocking excessive production of $1,25(OH)_2D$, as well as the response to it in target organs.

Hypercalcemia of Infancy Several variants of this rare abnormality of calcium homeostasis are now known. For example, *Williams' syndrome* is an autosomal dominant disorder characterized by multiple congenital development defects, including supravalvular aortic stenosis, intellectual disability, and an elfin facies, in association with hypercalcemia due to abnormal sensitivity to vitamin D. The hypercalcemia associated with the syndrome was first recognized in England, where it was thought, incorrectly, to be caused by the fortification of milk with vitamin D. The cardiac and developmental abnormalities were independently described, but the connection between these defects and hypercalcemia was not described until later. Levels of $1,25(OH)_2D$ can be elevated, ranging from 46 to 120 nmol/L (150–500 pg/mL). The mechanism of the abnormal sensitivity to vitamin D and of the increased circulating levels of $1,25(OH)_2D$ is still unclear. Studies suggest that genetic mutations involving microdeletions at the elastin locus and perhaps other genes on chromosome 7 may play a role in the pathogenesis.

Another genetic cause of hypercalcemia that starts in infancy is 24-hydroxylase deficiency that impairs catabolism of $1,25(OH)_2D$ caused by biallelic inactivating mutations in CYP24A1. Another rare cause of hypercalcemia involves mutation in the renal sodium-dependent phosphate transporters that lead to increased production of $1,25(OH)_2D$ leading to hypercalcemia (*NPT2a* mutations lead to more severe hypercalcemia than *NPT2c* mutations).

HIGH-BONE-TURNOVER STATES

Hyperthyroidism As many as 20% of hyperthyroid patients have high-normal or mildly elevated serum calcium concentrations;

hypercalciuria is even more common. The hypercalcemia is due to increased bone turnover, with bone resorption exceeding bone formation. Usually, the diagnosis is obvious, but signs of hyperthyroidism may occasionally be occult, particularly in the elderly (Chap. 396). Hypercalcemia is managed by treatment of the hyperthyroidism.

Immobilization Immobilization is a rare cause of hypercalcemia in adults in the absence of an associated disease but may cause hypercalcemia in children and adolescents, particularly after spinal cord injury and paraplegia or quadriplegia. With resumption of ambulation, the hypercalcemia in children usually returns to normal.

The mechanism appears to involve a disproportion between bone formation and bone resorption; the former decreased and the latter increased. Hypercalciuria and increased mobilization of skeletal calcium can develop in normal volunteers subjected to extensive bed rest, although hypercalcemia is unusual. Immobilization of an adult with a disease associated with high bone turnover, however, such as Paget's disease, may cause hypercalcemia.

Thiazides Administration of thiazides can cause hypercalcemia in patients with high rates of bone turnover. Commonly, thiazides are associated with aggravation of hypercalcemia in primary hyperparathyroidism, but this effect can be seen in other high-bone-turnover states as well. The mechanism of thiazide action is complex. Chronic thiazide administration leads to reduction in urinary calcium; the hypocalciuric effect appears to reflect the enhancement of proximal tubular resorption of sodium and calcium in response to sodium depletion. Some of this renal effect is due to augmentation of PTH action and is more pronounced in individuals with intact PTH secretion. However, thiazides cause hypocalciuria in hypoparathyroid patients if sodium intake is restricted. This finding is the rationale for the use of thiazides as an adjunct to therapy in hypoparathyroid patients, as discussed below. Thiazide administration to normal individuals causes a transient increase in blood calcium (usually within the high-normal range) that reverts to preexisting levels after a week or more of continued administration. If hormonal function and calcium and bone metabolism are normal, homeostatic controls are reset to counteract the mild calcium-elevating effect of the thiazides. In the presence of hyperparathyroidism or increased bone turnover from another cause, homeostatic mechanisms are ineffective. The abnormal effects of the thiazide on calcium metabolism disappear within days of cessation of the drug.

Vitamin A Intoxication Vitamin A intoxication is a rare cause of hypercalcemia and is most commonly a side effect of dietary faddism (Chap. 344). Calcium levels can be elevated into the 3- to 3.5-mmol/L (12–14 mg/dL) range after the ingestion of 50,000–100,000 units of vitamin A daily (10–20 times the minimum daily requirement). Typical features of severe hypercalcemia include fatigue, anorexia, and, in some, severe muscle and bone pain. Excess vitamin A intake is presumed to increase bone resorption.

The diagnosis can be established by history and by measurement of vitamin A levels in serum. Diagnostic challenges may arise in CKD where mildly elevated vitamin A levels are often seen with no association to hypercalcemia. Occasionally, skeletal x-rays reveal periosteal calcifications, particularly in the hands. Withdrawal of the vitamin is usually associated with prompt disappearance of the hypercalcemia and reversal of the skeletal changes. As in vitamin D intoxication, administration of 100 mg/d hydrocortisone or its equivalent leads to a rapid return of the serum calcium to normal.

HYPERCALCEMIA ASSOCIATED WITH CHRONIC KIDNEY DISEASE

The pathogenesis of secondary hyperparathyroidism in CKD is multifactorial and includes resistance to PTH and an increase in FGF23, which, in turn, inhibits the renal 1α-hydroxylase, thus reducing $1,25(OH)_2D$ levels and leading to further increases of PTH.

Occasional patients develop severe manifestations of secondary hyperparathyroidism, including hypercalcemia, pruritus, extraskeletal calcifications, and painful bones, despite aggressive medical efforts to suppress the hyperparathyroidism. It is now recognized that a true clonal outgrowth (irreversible) can arise in long-standing, inadequately treated CKD. PTH hypersecretion no longer responsive to medical therapy, a state of severe hyperparathyroidism in patients with CKD that requires surgery, has been referred to as *tertiary hyperparathyroidism*.

TREATMENT

Hypercalcemia in Tertiary Hyperparathyroidism

Medical therapy to reverse secondary hyperparathyroidism in CKD includes reduction of excessive blood phosphate by restriction of dietary phosphate, the use of nonabsorbable phosphate binders, and careful, selective addition of calcitriol (0.25–2 μg/d) or related analogues. Calcium carbonate became preferred over aluminum-containing antacids to prevent aluminum-induced bone disease. However, synthetic gels that also bind phosphate (such as sevelamer; Chap. 322) are now widely used, with the advantage of avoiding not only aluminum retention but also excess calcium loading, which may contribute to cardiovascular calcifications. Intravenous calcitriol (or related analogues), administered as several pulses each week, helps control secondary hyperparathyroidism. Aggressive but carefully administered medical therapy can often, but not always, reverse hyperparathyroidism and its symptoms and manifestations.

Parathyroid surgery is necessary to control tertiary hyperparathyroidism. Based on genetic evidence from examination of tumor samples in these patients, the emergence of autonomous parathyroid function is due to a monoclonal outgrowth of one or more previously hyperplastic parathyroid glands. The adaptive response has become an independent contributor to disease; this finding seems to emphasize the importance of optimal medical management to reduce the proliferative response of the parathyroid cells that enables the irreversible genetic change.

OTHER CAUSES OF HYPERCALCEMIA

Aluminum Intoxication Aluminum intoxication (and often hypercalcemia as a complication of medical treatment) in the past occurred in patients on chronic dialysis; manifestations included acute dementia and unresponsive and severe osteomalacia. Bone pain, multiple nonhealing fractures, particularly of the ribs and pelvis, and a proximal myopathy occur. Hypercalcemia develops when these patients are treated with vitamin D or calcitriol because of impaired skeletal responsiveness. Aluminum is present at the site of osteoid mineralization, osteoblastic activity is minimal, and calcium incorporation into the skeleton is impaired. The disorder is now rare because of the avoidance of aluminum-containing antacids or aluminum excess in the dialysis regimen.

Milk-Alkali Syndrome The milk-alkali syndrome is due to excessive ingestion of calcium and absorbable antacids such as milk or calcium carbonate. It is much less frequent since proton pump inhibitors and other treatments became available for peptic ulcer disease. For a time, the increased use of calcium carbonate in the management of secondary hyperparathyroidism led to reappearance of the syndrome. Several clinical presentations—acute, subacute, and chronic—have been described, all of which feature hypercalcemia, alkalosis, and renal failure. The chronic form of the disease, termed *Burnett's syndrome*, is associated with irreversible renal damage. The acute syndromes reverse if the excess calcium and absorbable alkali are stopped.

Individual susceptibility is important in the pathogenesis, as some patients are treated with calcium carbonate and alkali regimens without developing the syndrome. One variable is the fractional calcium absorption as a function of calcium intake. Some individuals absorb a high fraction of calcium, even with intakes ≥2 g of elemental calcium per day, instead of reducing calcium absorption with high intake, as occurs in most normal individuals. Resultant mild hypercalcemia after meals in such patients is postulated to contribute to the generation of alkalosis. Development of hypercalcemia causes increased sodium excretion and some depletion of total-body water. These phenomena

and perhaps some suppression of endogenous PTH secretion due to mild hypercalcemia lead to increased bicarbonate resorption and to alkalosis in the face of continued calcium carbonate ingestion. Alkalosis per se selectively enhances calcium resorption in the distal nephron, thus aggravating the hypercalcemia. The cycle of mild hypercalcemia → bicarbonate retention → alkalosis → renal calcium retention → severe hypercalcemia perpetuates and aggravates hypercalcemia and alkalosis as long as calcium and absorbable alkali are ingested.

DIFFERENTIAL DIAGNOSIS OF HYPERCALCEMIA

Differential diagnosis of hypercalcemia is best achieved by using clinical criteria, but immunometric assays to measure PTH are especially useful in distinguishing among major causes **(Fig. 422-6)**. The clinical features that deserve emphasis are the presence or absence of symptoms or signs of disease and evidence of chronicity. If one discounts fatigue or depression, >90% of patients with primary hyperparathyroidism have *asymptomatic hypercalcemia*; symptoms of malignancy are usually present in cancer-associated hypercalcemia. Disorders other than hyperparathyroidism and malignancy cause <10% of cases of hypercalcemia, and some of the nonparathyroid causes are associated with clear-cut manifestations such as renal failure.

Hyperparathyroidism is the likely diagnosis in patients with *chronic hypercalcemia*. If hypercalcemia has been manifesting for >1 year, malignancy as the underlying cause is very unlikely. A striking feature of malignancy-associated hypercalcemia is the rapidity of the course, whereby signs and symptoms of the underlying malignancy are evident within months of the detection of hypercalcemia. Although clinical considerations are helpful in arriving at the correct diagnosis of the cause of hypercalcemia, appropriate laboratory testing is essential for definitive diagnosis. The immunoassay for PTH usually separates primary hyperparathyroidism from all other causes of hypercalcemia (exceptions are very rare reports of ectopic production of excess PTH by nonparathyroid tumors). Patients with hyperparathyroidism have elevated (or nonsuppressed) PTH levels despite hypercalcemia, whereas patients with malignancy and the other causes of hypercalcemia (except for disorders mediated by PTH such as lithium-induced hypercalcemia) have very low or undetectable levels. Intact PTH assays, based on the double-antibody method for PTH, exhibit very high sensitivity (especially if serum calcium is simultaneously evaluated) and specificity for the diagnosis of primary hyperparathyroidism (Fig. 422-4).

In summary, PTH values are elevated in >90% of parathyroid-related causes of hypercalcemia, undetectable or low in malignancy-related, vitamin D–related and high-bone-turnover causes of hypercalcemia. In view of the specificity of the PTH immunoassay and the high frequency of hyperparathyroidism in hypercalcemic patients, it is cost-effective to measure the PTH level in all hypercalcemic patients unless malignancy or a specific nonparathyroid disease is obvious. False-positive PTH assay results are rare but can be due to heterotopic antibodies. Immunoassays for PTHrP are helpful in diagnosing certain types of malignancy-associated hypercalcemia. Although FHH is parathyroid-related, the disease should be managed distinctively from primary hyperparathyroidism. Clinical features, family history, and the low urinary calcium excretion can help make the distinction, and genetic testing confirms the diagnosis. Because the incidence of malignancy and hyperparathyroidism both increase with age, they can coexist as two independent causes of hypercalcemia.

$1,25(OH)_2D$ levels are in the upper range of normal or frankly elevated in many (but not all) patients with primary hyperparathyroidism. In other disorders associated with hypercalcemia, concentrations of $1,25(OH)_2D$ are low or, at the most, normal. However, this test is of low specificity and is not cost-effective, as not all patients with hyperparathyroidism have elevated $1,25(OH)_2D$ levels and not all nonparathyroid hypercalcemic patients have suppressed $1,25(OH)_2D$. Measurement of $1,25(OH)_2D$ is, however, critically valuable in establishing the cause of hypercalcemia in sarcoidosis and certain lymphomas.

A useful general approach is outlined in Fig. 422-6. If the patient is *asymptomatic* and there is evidence of *chronicity* to the hypercalcemia, hyperparathyroidism is likely the cause and FHH needs to be excluded. If PTH levels (usually measured at least twice) are elevated, the clinical impression is confirmed, and little additional diagnostic evaluation is necessary. If there is only a short history or no data as to the duration of the hypercalcemia, *occult malignancy* must be considered; if the PTH levels are suppressed then a thorough workup must be undertaken for malignancy, which may include chest x-ray, CT of chest and abdomen, and bone scan. Immunoassays for PTHrP may be especially useful in such situations. Attention should also be paid to clues for underlying hematologic disorders such as anemia, increased plasma globulin, and abnormal serum immunoelectrophoresis; bone scans can be negative

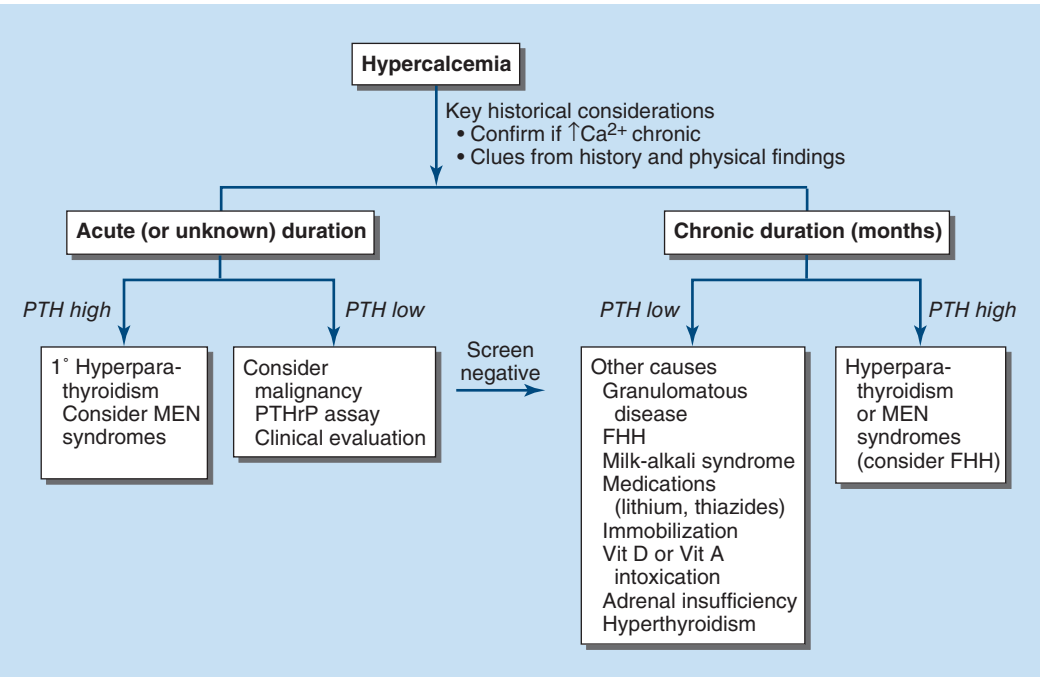

FIGURE 422-6 Algorithm for the evaluation of patients with hypercalcemia. PTH levels (high or low) should be interpreted in the context of serum calcium levels, as they may be inappropriately high or low for the level of serum calcium. See text for details. FHH, familial hypocalciuric hypercalcemia; MEN, multiple endocrine neoplasia; PTH, parathyroid hormone; PTHrP, parathyroid hormone–related peptide; Vit, vitamin.

in some patients with metastases such as in multiple myeloma. Finally, if a patient with chronic hypercalcemia is asymptomatic and malignancy therefore seems unlikely on clinical grounds, but PTH values are not elevated, it is useful to search for other chronic causes of hypercalcemia such as occult sarcoidosis. A careful history of dietary supplements and drug use may suggest intoxication with vitamin D or vitamin A or the use of thiazides.

TREATMENT

General Approach to Hypercalcemic States

The approach to medical treatment of hypercalcemia varies with its severity. Mild hypercalcemia, <3 mmol/L (12 mg/dL), can usually be managed by hydration. More severe hypercalcemia (levels of 3.2–3.7 mmol/L [13–15 mg/dL]) must be managed more aggressively; above that level, hypercalcemia can be life-threatening and requires emergency measures **(Table 422-4)**. By using a combination of approaches in severe hypercalcemia, the serum calcium concentration can be decreased within 24–48 h in most patients, enough to relieve acute symptoms, prevent death from hypercalcemic crisis, and permit diagnostic evaluation. Therapy can then be directed at the underlying disorder—the second priority.

Hypercalcemia develops because of excessive skeletal calcium release, increased intestinal calcium absorption, or inadequate renal calcium excretion. Understanding the particular pathogenesis helps guide therapy. For example, hypercalcemia in patients with malignancy is primarily due to excessive skeletal calcium release and is, therefore, minimally improved by restriction of dietary calcium. On the other hand, patients with vitamin D hypersensitivity or vitamin D intoxication have excessive intestinal calcium absorption, and restriction of dietary calcium is beneficial. Decreased renal function or ECF depletion decreases urinary calcium excretion. In such situations, rehydration may rapidly reduce or reverse the hypercalcemia, even though increased bone resorption persists. As outlined below, the more severe the hypercalcemia, the greater the need for a combination of therapies. Rapid-acting (hours) approaches—rehydration, forced diuresis, and calcitonin—can be used with the most effective antiresorptive agents such as bisphosphonates (since severe hypercalcemia usually involves excessive bone resorption).

HYDRATION, INCREASED SALT INTAKE, AND MILD AND FORCED DIURESIS

The first principle of treatment is to restore normal hydration. Many hypercalcemic patients are dehydrated because of vomiting, inanition, and/or hypercalcemia-induced defects in urinary concentrating ability. The resultant drop in glomerular filtration rate is accompanied by an additional decrease in renal tubular sodium and calcium clearance. Restoring a normal ECF volume corrects these abnormalities and increases urine calcium excretion by 2.5–7.5 mmol/d (100–300 mg/d). Increasing urinary sodium excretion to 400–500 mmol/d increases urinary calcium excretion even further than simple rehydration. After rehydration has been achieved, saline can be administered, or furosemide or ethacrynic acid can be given to depress the tubular reabsorptive mechanism for calcium (care must be taken to prevent dehydration). The combined use of these therapies can increase urinary calcium excretion to ≥12.5 mmol/d (500 mg/d) in most hypercalcemic patients. Since this is a substantial percentage of the exchangeable calcium pool, the serum calcium concentration usually falls 0.25–0.75 mmol/L (1–3 mg/dL) within 24 h. Precautions should be taken to prevent potassium and magnesium depletion; calcium-containing renal calculi are a potential complication.

Under life-threatening circumstances, the preceding approach can be pursued more aggressively, but the availability of effective agents to block bone resorption (such as bisphosphonates) has reduced the need for extreme diuresis regimens (Table 422-4). Depletion of potassium and magnesium is inevitable unless replacements are given; pulmonary edema can be precipitated. The potential complications can be reduced by careful monitoring of central venous pressure and plasma or urine electrolytes; catheterization of the bladder may be necessary. Dialysis treatment may be needed when renal function is compromised.

BISPHOSPHONATES

The bisphosphonates are analogues of pyrophosphate, with high affinity for bone, especially in areas of increased bone turnover,

TABLE 422-4 Therapies for Severe Hypercalcemia

TREATMENT	ONSET OF ACTION	DURATION OF ACTION	ADVANTAGES	DISADVANTAGES
Most Useful Therapies				
IV hydration with normal saline	Hours	During infusion	Rehydration invariably needed	Volume overload
Forced diuresis; normal saline plus loop diuretic	Hours	During treatment	Rapid action	Volume overload, cardiac decompensation, intensive monitoring, electrolyte disturbance, inconvenience
Pamidronate	1–2 days	10–14 days to weeks	High potency; intermediate onset of action	Fever in 20%, hypophosphatemia, hypocalcemia, hypomagnesemia, rarely jaw necrosis
Zoledronate	1–2 days	>3 weeks	Same as for pamidronate (lasts longer)	Same as pamidronate above
Denosumab	1–2 days	>3 weeks	Strongest antiresorptive	Occasional severe hypocalcemia, rarely jaw necrosis, skin infections
Special Use Therapies				
Calcitonin	Hours	1–2 days	Rapid onset of action; useful as adjunct in severe hypercalcemia	Rapid tachyphylaxis
Phosphate oral	24 h	During use	Chronic management (with hypophosphatemia); low toxicity if P <4 mg/dL	Limited use except as adjuvant or chronic therapy
Glucocorticoids	Days	Days, weeks	Oral therapy, antitumor agent	Active only in certain malignancies, vitamin D excess, and sarcoidosis; glucocorticoid side effects
Dialysis	Hours	During use and 24–48 h afterward	Useful in renal failure; onset of effect in hours; can immediately reverse life-threatening hypercalcemia	Complex procedure, reserved for extreme or special circumstances

where they are powerful inhibitors of bone resorption. These bone-seeking compounds are stable in vivo because phosphatase enzymes cannot hydrolyze the central carbon-phosphorus-carbon bond. The bisphosphonates are concentrated in areas of high bone turnover and are taken up by and inhibit osteoclast action; the mechanism of action is complex. The bisphosphonate molecules that contain amino groups in the side chain structure (see below) interfere with prenylation of proteins and can lead to cellular apoptosis. The highly active non-amino-group–containing bisphosphonates are also metabolized to cytotoxic products.

A number of second- or third-generation compounds have become the mainstays of antiresorptive therapy for treatment of hypercalcemia and osteoporosis. The newer bisphosphonates have a highly favorable ratio of blocking resorption versus inhibiting bone formation; they inhibit osteoclast-mediated skeletal resorption yet do not cause mineralization defects at ordinary doses. Though the bisphosphonates have similar structures, the routes of administration, efficacy, toxicity, and side effects vary. Compounds commonly used are pamidronate, alendronate, and zoledronate. The IV use of pamidronate and zoledronate is approved for the treatment of hypercalcemia; between 30 and 90 mg pamidronate, given as a single IV dose over a few hours, returns serum calcium to normal within 24–48 h with an effect that lasts for weeks in 80–100% of patients. Zoledronate given as an infusion in doses of 5 mg has a more rapid and more sustained effect that lasts longer than pamidronate in direct comparison.

These drugs are used extensively in cancer patients. Absolute survival improvements are noted with pamidronate and zoledronate in multiple myeloma, for example. However, though rare, osteonecrosis of the jaw, especially after dental surgery, mainly in cancer patients treated with multiple doses of the more potent bisphosphonates, and atypical femoral fractures are potential side effects.

DENOSUMAB

Denosumab is the most recent antiresorptive therapy to be approved for the treatment of hypercalcemia, a monoclonal antibody that binds to RANK ligand (RANKL) and prevents it from binding to the receptor RANK on osteoclast precursors and mature osteoclasts. The inhibition of differentiation, activation, and function of osteoclasts leads to a reduction in bone resorption. It has a profound suppressive effect on biochemical markers of bone resorption and is the most powerful antiresorptive agent currently available. Repeated doses of denosumab, 120 mg given subcutaneously, may be effective in patients with hypercalcemia of malignancy who are not controlled by bisphosphonates. There are currently uncertainties how to manage rebound effects (fractures, hypercalcemia) after stopping denosumab, but antiresorptives such as alendronate and zoledronic acid can mitigate these effects.

OTHER THERAPIES

Calcitonin acts within a few hours of its administration, principally through receptors on osteoclasts, to block bone resorption. *Calcitonin*, after 24–48 h of use, is no longer effective in lowering calcium. Tachyphylaxis, a known phenomenon with this drug, seems to explain the results since the drug is initially often effective. Therefore, in life-threatening hypercalcemia, calcitonin can be used effectively within the first 24–48 h in combination with rehydration and saline diuresis while waiting for more sustained effects from simultaneously administered antiresorptives. Usual doses of calcitonin are 2–8 U/kg of body weight IV, SC, or IM every 6–12 h.

Glucocorticoids have utility, especially in hypercalcemia complicating certain malignancies. They increase urinary calcium excretion and decrease intestinal calcium absorption when given in pharmacologic doses, but they also cause negative skeletal calcium balance. In normal individuals and in patients with primary hyperparathyroidism, glucocorticoids neither increase nor decrease the serum calcium concentration. In patients with hypercalcemia due to certain osteolytic malignancies, however, glucocorticoids may be effective as a result of antitumor effects. The malignancies in which hypercalcemia responds to glucocorticoids include multiple myeloma, leukemia, Hodgkin's disease, other lymphomas, and carcinoma of the breast, at least early in the course of the disease. Glucocorticoids are also effective in treating hypercalcemia due to vitamin D intoxication and sarcoidosis. Glucocorticoids are also useful in the rare form of hypercalcemia, now recognized in certain autoimmune disorders in which inactivating antibodies against the receptor imitate FHH. Elevated PTH and calcium levels are effectively lowered by the glucocorticoids. In all the preceding situations, the hypocalcemic effect develops over several days, and the usual glucocorticoid dosage is 40–100 mg prednisone (or its equivalent) daily in divided doses. The side effects of chronic glucocorticoid therapy may be acceptable in some circumstances.

For patients with hypercalcemia due to CYP24A1 mutations, avoidance of sun, vitamin D intake, and reducing calcium intake are recommended. Fluconazole and ketoconazole, inhibitors of CYP27B1, and rifampin (an inducer of CYP3A4) have been reported to be beneficial; particular attention should be given to potential side effects of each of these medications.

Dialysis is often the treatment of choice for severe hypercalcemia complicated by renal failure, which is difficult to manage medically. Peritoneal dialysis with calcium-free dialysis fluid can remove 5–12.5 mmol (200–500 mg) of calcium in 24–48 h and lower the serum calcium concentration by 0.7–2.2 mmol/L (3–9 mg/dL). Large quantities of phosphate are lost during dialysis, and serum inorganic phosphate concentration usually falls, potentially aggravating hypercalcemia. Therefore, the serum inorganic phosphate concentration should be measured after dialysis, and phosphate supplements should be added to the diet or to dialysis fluids if necessary.

Phosphate therapy, PO or IV, has a limited role in certain circumstances **(Chap. 421)**. Correcting hypophosphatemia lowers the serum calcium concentration by several mechanisms, including bone/calcium exchange. The usual oral treatment is 1–1.5 g phosphorus per day for several days, given in divided doses. It is generally believed, but not established, that toxicity does not occur if therapy is limited to restoring serum inorganic phosphate concentrations to normal.

Raising the serum inorganic phosphate concentration above normal decreases serum calcium levels, sometimes strikingly. Intravenous phosphate is one of the most dramatically effective treatments available for severe hypercalcemia but is toxic and even dangerous (fatal hypocalcemia). For these reasons, it is used rarely and only in severely hypercalcemic patients with cardiac or renal failure where dialysis, the preferable alternative, is not feasible or is unavailable.

SUMMARY

The various therapies for hypercalcemia are listed in Table 422-4. The choice depends on the underlying disease, the severity of the hypercalcemia, the serum inorganic phosphate level, and the renal, hepatic, and bone marrow function. Mild hypercalcemia (≤3 mmol/L [12 mg/dL]) can usually be managed by hydration. Severe hypercalcemia (≥3.7 mmol/L [15 mg/dL]) requires rapid correction. IV pamidronate or zoledronate or subcutaneous denosumab should be administered. In addition, for the first 24–48 h, aggressive sodium-calcium diuresis with IV saline should be given. Following rehydration, furosemide or ethacrynic acid can be added, but only if appropriate monitoring is available and cardiac and renal function are adequate. For intermediate degrees of hypercalcemia between 3 and 3.7 mmol/L (12 and 15 mg/dL), vigorous hydration is recommended. Depending on symptoms and underlying causes, this may be combined with antiresorptives and other previously mentioned treatments.

HYPOCALCEMIA

(See also Chap. 57).

Pathophysiology *Chronic hypocalcemia* is less common than hypercalcemia; causes include CKD, hereditary and acquired hypoparathyroidism, vitamin D deficiency, PTH resistance, and hypomagnesemia.

Acute rather than chronic hypocalcemia is seen in critically ill patients or as a consequence of certain medications and often does not require specific treatment. Transient hypocalcemia is seen with severe sepsis, burns, acute kidney injury, and extensive transfusions with citrated blood. Although as many as one-half of patients in an intensive care setting are reported to have calcium concentrations of <2.1 mmol/L (8.5 mg/dL), most do not have a reduction in ionized calcium. Patients with severe sepsis may have a decrease in ionized calcium (true hypocalcemia), but in other severely ill individuals, hypoalbuminemia is the primary cause of the reduced total calcium concentration. Alkalosis increases calcium binding to proteins.

Medications such as protamine, heparin, and glucagon may cause transient hypocalcemia. These forms of hypocalcemia are usually not associated with tetany and resolve with improvement in the overall medical condition. The hypocalcemia after repeated transfusions of citrated blood usually resolves quickly.

Patients with *acute pancreatitis* have hypocalcemia that persists during the acute inflammation and varies in degree with disease severity. The cause of hypocalcemia remains unclear but may include saponification and systemic inflammation. PTH values are reported to be low, normal, or elevated, and both resistance to PTH and impaired PTH secretion have been postulated.

Chronic hypocalcemia, however, is usually symptomatic and requires treatment. Neuromuscular and neurologic manifestations of chronic hypocalcemia include tingling, muscle spasms, carpopedal spasm, and, in extreme cases, laryngeal spasm and convulsions. Increased intracranial pressure occurs in some patients with long-standing hypocalcemia, often in association with papilledema. Mental changes include irritability, depression, and psychosis. The QT interval on the electrocardiogram is prolonged, in contrast to its shortening with hypercalcemia. Arrhythmias occur, and digitalis effectiveness may be reduced. Intestinal cramps and chronic malabsorption may occur. Chvostek's or Trousseau's sign can be used to confirm latent tetany; the latter is more specific and sensitive for hypocalcemia.

Classification of Hypocalcemia The classification of hypocalcemia shown in Table 422-5 is based on an organizationally useful premise that hypocalcemia may be primarily due to one of the two main calcium-regulating hormones, PTH and vitamin D, or other causes.

PTH-related Hereditary or acquired forms of hypoparathyroidism have a number of common components. The disease is rare with estimates from all causes to be ~25–35 patients/100,000 of the population (based on U.S. and Danish estimates). Symptoms of untreated hypocalcemia are shared by both types of hypoparathyroidism, although the onset of hereditary hypoparathyroidism can be more gradual and associated with other developmental defects. Basal ganglia calcification and extrapyramidal syndromes are more common and earlier in onset in hereditary hypoparathyroidism. Acquired hypoparathyroidism secondary to surgery in the neck is the most common cause of hypoparathyroidism, but the frequency of surgically induced parathyroid failure has diminished as a result of improved surgical techniques that spare the parathyroid glands and increased use of nonsurgical therapy for hyperthyroidism. PHP, an example of resistance to PTH action rather than a failure of production by the parathyroid gland, may share several features with hypoparathyroidism, including extraosseous calcification and extrapyramidal manifestations such as choreoathetotic movements and dystonia but circulating PTH is increased rather than decreased in the other conditions.

Papilledema, raised intracranial pressure, and lenticular cataracts may occur in both hereditary and acquired hypoparathyroidism, as do chronic changes in fingernails and hair, the latter usually reversible with treatment of hypocalcemia. Certain skin manifestations, including alopecia and candidiasis, are characteristic of hereditary hypoparathyroidism associated with autoimmune polyglandular failure (Chap. 401).

Hypocalcemia associated with hypomagnesemia is associated with both deficient PTH release and impaired responsiveness to the hormone and is reversible with normalization of serum magnesium. Patients with hypocalcemia secondary to hypomagnesemia have low levels of circulating PTH, indicative of diminished hormone release despite a maximum physiologic stimulus by hypocalcemia. Hypermagnesemia, which can be iatrogenic, may inhibit PTH release leading to hypocalcemia.

TABLE 422-5 Functional Classification of Hypocalcemia (Excluding Neonatal Conditions)

1. **PTH-Related**
   - a. Absence of parathyroid glands or inactive PTH
     - i. Congenital: 22q11 deletion syndrome (DS), isolated hypoparathyroidism, PTH mutations, mutations in specific transcription factors (GCM2, GATA3)
     - ii. Destruction of glands: postsurgical, APECED, infiltrative disorders
   - b. Impaired secretion
     - i. Congenital: autosomal-dominant hypocalcemia
     - ii. Functional: hypomagnesemia, hypermagnesemia
   - c. Target organ resistance
     - i. Pseudohypoparathyroidism
     - ii. Hypomagnesemia
2. **Vitamin D–related**
   - a. Vitamin D deficiency: nutritional deficiency, impaired cutaneous production, malabsorption
   - b. Accelerated loss: impaired enterohepatic recirculation; increased metabolism due to anticonvulsants or antituberculosis therapy (e.g., rifampin)
   - c. Impaired 25-hydroxylation: severe liver disease, *CYP2R1* mutations
   - d. Impaired 1α-hydroxylation: renal insufficiency, azole antifungal medications that inhibit CYP27B1 (e.g., ketoconazole), genetic 1α hydroxylase deficiency, FGF23-related (TIO, XLH, CKD)
   - e. Target organ resistance: VDR mutations
3. **Others**
   - a. Impaired bone resorption: denosumab, antiresorptives
   - b. Excessive deposition into the skeleton: hungry bone syndrome (e.g., after parathyroidectomy for primary hyperparathyroidism), osteoblastic malignancies
   - c. Chelation: infusion of citrated blood products or EDTA, phosphate infusion
   - d. Critical illness: pancreatitis, ICU patients

Abbreviations: 22q11DS, 22q11 deletion syndrome; APECED, autoimmune polyendocrinopathy candidiasis ectodermal dystrophy; CKD, chronic kidney disease; EDTA, ethylenediaminetetraacetic acid; FGF23, fibroblast growth factor 23; ICU, intensive care unit; PTH, parathyroid hormone; TIO, tumor-induced osteomalacia; VDR, vitamin D receptor; XLH, X-linked hypophosphatemic rickets.

GENETIC CAUSES Hereditary hypoparathyroidism can occur as an isolated entity without other endocrine or dermatologic manifestations or in association with other abnormalities.

Hypoparathyroidism Associated with Other Abnormalities Hypoparathyroidism associated with defective development of both the thymus and the parathyroid glands is termed *DiGeorge syndrome*, *velocardiofacial syndrome, or 22q11 deletion syndrome*. Congenital cardiovascular, facial, and other developmental defects are present, and patients may die in early childhood with severe infections, hypocalcemia and seizures, or cardiovascular complications. Patients can survive into adulthood, and milder, incomplete forms may become manifest in childhood or adolescence. Most cases are sporadic, but autosomal dominant forms involving microdeletions of chromosome 22q11.2 or point mutations in the transcription factor TBX1 within that chromosomal region exist. Another autosomal dominant developmental defect with hypoparathyroidism, deafness, and renal dysplasia (HDR) is caused by mutations in the transcription factor GATA3 (chromosome 10p14), which is important in embryonic development and is expressed in developing kidney, ear structures, and the parathyroids. Autosomal recessive disorders comprising hypoparathyroidism include *Kenney-Caffey syndrome type 1*, which also features short stature, osteosclerosis, and thick cortical bones, and the related *Sanjad-Sakati syndrome*, which also exhibits growth failure and other dysmorphic features. Both syndromes involve mutations in a chaperone protein called *TBCE* (chromosome 1q42-q43), which is relevant to tubulin function. FAM111A defects (chromosome 11q12.1) were identified as the cause of *Kenney-Caffey syndrome type 2*.

Hypoparathyroidism that can occur in association with a monogenetic autoimmune syndrome involving failure of the adrenals, the ovaries, the immune system, and the parathyroids in association with recurrent mucocutaneous candidiasis, alopecia, vitiligo, and pernicious anemia is commonly referred to as *polyglandular autoimmune type 1 deficiency* or *autoimmune polyendocrinopathy candidiasis ectodermal dystrophy (APECED)* **(Chap. 401)**. This disorder is caused by mutations in the *AIRE* gene (chromosome 21q22.3). A stop codon mutation occurs in many Finnish families with the disorder, while another mutation (Y85C) is typically observed in Jews of Iraqi and Iranian descent.

Hypoparathyroidism is also seen in two disorders associated with mitochondrial dysfunction and myopathy, one termed *Kearns-Sayre syndrome* (KSS), with ophthalmoplegia and pigmentary retinopathy, and the other termed *MELAS syndrome* (*m*itochondrial *e*ncephalopathy, *l*actic *a*cidosis, and *s*troke-like episodes). Mutations or deletions in mitochondrial genes have been identified.

Isolated Hypoparathyroidism Several forms of hypoparathyroidism, each rare in frequency, are seen as isolated defects; the genetic mechanisms are varied. The inheritance includes autosomal dominant, autosomal recessive, and X-linked modes.

PTH Mutations Several autosomal defects involving the preproPTH sequence or the mature PTH have been recognized. The dominant forms are caused by point mutations in a critical region involved in intracellular transport of the hormone precursor. For example, an Arg for Cys mutation interferes with processing of the precursor and is believed to trigger an apoptotic cellular response, hence acting as a dominant negative. Recessive forms require both PTH alleles encoding the prepro sequence to be mutated. Only three homozygous mutations affecting the mature PTH have been described that lead to an autosomal recessive form of hypoparathyroidism. The defect for an X-linked recessive form of hypoparathyroidism has been localized to chromosome Xq26-q27, perhaps involving the *SOX3* gene.

CaSR Mutations Different gain-of-function mutations in the CaSR gene have been found in one form of hypocalcemia termed *autosomal dominant hypocalcemia (ADH) type 1*. The mutant receptor senses the ambient calcium level as excessive and suppresses PTH secretion, leading to hypocalcemia. The hypocalcemia is aggravated by constitutive receptor activity in the renal tubule causing excretion of inappropriate amounts of calcium. Recognition of the syndrome is important because efforts to treat the hypocalcemia with vitamin D analogues and increased oral calcium exacerbate the already excessive urinary calcium excretion leading to irreversible renal damage from stones and ectopic calcification. The orally available negative allosteric modulator (NAM) on the CaSR encaleret has been shown to normalize serum and urine calcium, as well as serum phosphate and magnesium in a phase 2 trial in patients with ADH1.

Other Causes of Isolated Hypoparathyroidism These include homozygous, inactivating mutations in the parathyroid-specific transcription factor GCM2 or heterozygous point mutations in this protein, which have a dominant-negative effect on the wild-type protein and thus lead to an autosomal dominant form of hypoparathyroidism. Furthermore, heterozygous mutations in Gα11, one of the two signaling proteins downstream of the CaSR, have been identified as a cause of autosomal dominant hypocalcemia, now referred to as ADH type 2. The *Bartter syndrome* is a group of disorders associated with disturbances in electrolyte and acid-base balance, sometimes with nephrocalcinosis and other features. Several types of ion channels or transporters are involved. Curiously, *Bartter syndrome type V* has electrolyte and pH disturbances but is caused by a gain-of-function mutation in the CaSR. The defect may be more severe than in ADH1 and explains the additional features seen beyond hypocalcemia and hypercalciuria. As with autoimmune disorders that block the CaSR (discussed above under hypercalcemic conditions), there are autoantibodies that at least transiently activate the CaSR, leading to suppressed PTH secretion and hypocalcemia.

Acquired chronic hypoparathyroidism is usually the result of inadvertent surgical removal of or damage to all the parathyroid glands; in some instances, not all the tissue is removed, but the remainder undergoes vascular supply compromise secondary to fibrotic changes in the neck after surgery. In the past, the most frequent cause of acquired hypoparathyroidism was surgery for hyperthyroidism. Hypoparathyroidism can also occur after surgery for hyperparathyroidism when the surgeon, facing the dilemma of removing too little tissue and thus not curing the hyperparathyroidism, removes too much. Parathyroid function may not be totally absent in all patients with postoperative hypoparathyroidism.

Very rare causes of acquired chronic hypoparathyroidism include radiation-induced damage subsequent to radioiodine therapy of hyperthyroidism and glandular damage in patients with hemochromatosis or hemosiderosis after repeated blood transfusions.

Transient hypoparathyroidism is frequent following surgery for hyperparathyroidism. After a variable period of hypoparathyroidism, normal parathyroid function may return due to hyperplasia or recovery of remaining tissue. Occasionally, recovery occurs months after surgery.

TREATMENT

Acquired and Hereditary Hypoparathyroidism

Conventional treatment has involved increasing serum calcium by administration of active vitamin D (calcitriol) combined with oral calcium supplementation. In many patients, blood calcium and phosphate levels are maintained satisfactorily, but some patients show a tendency to alternate between hypocalcemia and hypercalcemia, thus requiring close monitoring. Treatment with active vitamin D (calcitriol or alpha-calcidol) is preferred over high-dose plain vitamin D, which was standard in the past, particularly since calcitriol is cleared much more rapidly from the circulation than vitamin D. PTH analogues are being incorporated into the range of treatment options for this disease (see below).

Oral calcium and vitamin D increase serum calcium but do not address other functions of PTH. This current standard of care treatment exacerbates hypercalciuria, does not normalize hyperphosphatemia, and does not normalize the low bone turnover of hypoparathyroidism. Because of the hypercalciuria, blood calcium levels should be maintained at the lower end of the normal range or just below normal in these patients to avoid excessive urinary calcium excretion; otherwise, nephrocalcinosis and kidney stones can develop, and the risk of CKD is increased. Thiazide diuretics lower urine calcium by as much as 100 mg/d in hypoparathyroid patients on calcium and vitamin D, provided they are maintained on a low-sodium diet.

Until recently, hypoparathyroidism was the only endocrine disorder not being treated with the missing hormone. After the initial experimental use of PTH(1–34), the synthetic PTH fragment used in treatment of osteoporosis, showed promise, full-length PTH(1–84) has been shown to be effective and was approved by the U.S. Food and Drug Administration for therapy of hypoparathyroidism. The effective half-life of these PTH analogues is not long enough to achieve effective PTH effects over 24 h with one injection. Moreover, they are not approved or no longer available in the United States. Long-acting PTH molecules have been developed and are in clinical trials. Palopegteriparatide, an inactive prodrug that is given as an SC injection once daily and releases PTH(1–34) from an inert carrier in a sustained manner, showed normalization of blood and urine calcium in a phase 3 clinical trial and is approved in the US and Europe. Eneboparatide, a biased peptide agonist to the PTH receptor with a prolonged intracellular signaling, showed normalization of blood and urine calcium in patients with hypoparathyroidism in a phase 2 clinical trial and is currently undergoing a phase 3 trial.

HYPOMAGNESEMIA Severe hypomagnesemia (<0.4 mmol/L; <0.8 meq/L) is associated with hypocalcemia (see above). Restoration of the total-body magnesium deficit leads to rapid reversal of hypocalcemia. There are at least two causes of the hypocalcemia in severe

hypomagnesemia—impaired PTH secretion and reduced responsiveness to PTH. **For further discussion of causes and treatment of hypomagnesemia, see Chap. 421.**

PTH levels are undetectable or inappropriately low in severe hypomagnesemia despite the stimulus of severe hypocalcemia, and acute repletion of magnesium leads to a rapid increase in PTH level. Serum phosphate levels are often not elevated, in contrast to the situation with acquired or idiopathic hypoparathyroidism, probably because phosphate deficiency is often seen in hypomagnesemia. In addition to diminished PTH secretion, some patients with low calcium and magnesium levels show a blunted peripheral response to exogenous PTH as documented by subnormal response in urinary phosphorus and urinary cyclic AMP excretion.

TREATMENT

Hypomagnesemia

Repletion of magnesium cures the condition. Repletion should be parenteral. Attention must be given to restoring the intracellular deficit, which may be considerable. After IV magnesium administration, serum magnesium may return transiently to the normal range, but unless replacement therapy is adequate, serum magnesium will again fall. If the cause of the hypomagnesemia is renal magnesium wasting, magnesium may have to be given long-term to prevent recurrence **(Chap. 421)**.

PTH TARGET ORGAN RESISTANCE PHP refers to a group of distinct inherited disorders that resemble hypoparathyroidism (in which PTH synthesis is deficient) and is manifested by hypocalcemia and hyperphosphatemia yet elevated PTH levels.

Patients affected by PHP type Ia (PHP1A) develop symptoms and signs of hypocalcemia in association with distinctive skeletal and developmental defects, referred to as Albright's hereditary osteodystrophy (AHO). The hypocalcemia is due to a deficient PTH response in the proximal renal tubules, probably leading to insufficient $1,25(OH)_2D$ production and thus impaired intestinal calcium absorption. Furthermore, PTH resistance in this portion of the kidney impairs urinary phosphate excretion, thus leading to elevated serum phosphate levels. Patients affected by PHP type Ib (PHP1B) also present with hypocalcemia and hyperphosphatemia but less frequently with obvious AHO features. In response to the hypocalcemia observed in either disorder, PTH levels increase, leading to parathyroid hyperplasia and, in some cases, to autonomous PTH secretion. Studies, both clinical and basic, have clarified some aspects of these disorders, including the variable clinical spectrum, the pathophysiology, the genetic defects, and their mode of inheritance.

A working classification of the various PHP forms is given in **Table 422-6**. The classification scheme is based on the signs of ineffective PTH action (low calcium and high phosphate), low or normal urinary cyclic AMP response to exogenous PTH, the presence or absence of AHO, and assays to measure the concentration of the Gsα subunit. Using these criteria, there are four types: PHP types Ia and Ib (PHP1A and PHP1B); pseudopseudohypoparathyroidism (PPHP), and PHP type II (PHP2). Another classification has been proposed recently, which is being debated.

PHP1A and PHP1B Individuals with PHP type I (PHP1), the most common of the disorders, show deficient urinary cyclic AMP excretion in response to administration of exogenous PTH. Patients with PHP1 are divided into PHP1A and PHP1B. Most patients with PHP1A show evidence for AHO and reduced amounts of Gsα protein/activity, as previously determined in readily accessible tissues such as erythrocytes, lymphocytes, or fibroblasts. Only some PHP1B patients show typical AHO features, but they usually have normal Gsα activity. PHP1C, sometimes listed as a third form of PHP1, is really a variant of PHP1A, although the mutant Gsα shows normal activity in certain in vitro assays.

Most patients who have PHP1A reveal characteristic features of AHO, which consist of short stature, early-onset obesity, round face, obesity, skeletal anomalies (brachydactyly), intellectual impairment, and/or heterotopic calcifications. Patients have low calcium and high phosphate levels, as with true hypoparathyroidism. PTH levels, however, are elevated, reflecting resistance to hormone action. In addition, hormonal resistance is observed at other Gsα-coupled receptors, particularly at the TSH receptor, leading to elevated levels of this hormone.

Calcium and phosphate deposits are frequently found in the basal ganglia. The typical shortening of metacarpal and metatarsal bones is caused by premature closing of the epiphyses and is probably a particularly sensitive sign of overall advanced skeletal maturation resulting in adult short stature.

INHERITANCE AND GENETIC DEFECTS Multiple defects at the *GNAS* locus have now been identified in PHP1A, PHP1B, and PPHP patients. This gene, which is located on chromosome 20q13.3, encodes the α-subunit of the stimulatory G protein (Gsα), among other products (see below). Mutations involving the *GNAS* exons encoding Gsα, which are the cause of PHP1A and PPHP, include abnormalities at splice junctions, point mutations, insertions, and/or deletions that all result in a Gsα protein with defective function, resulting in a 50% reduction of in vitro Gsα activity in erythrocytes or other cells. While PHP1A is caused by inactivating Gsα mutations on the maternal allele, PPHP is caused by the same or similar mutations on the paternal *GNAS* allele **(Fig. 422-7)**. The Gsα transcript is biallelically expressed in most tissues; however, expression from paternal allele is silenced through as-of-yet-unknown mechanisms in some tissues, including proximal renal tubules, thyroid, and pituitary. Consequently, inheritance of a molecular defect involving the paternal exons encoding Gsα has no implications with regard to hormone function, while inactivating Gsα mutations involving the maternal *GNAS* allele lead to little or no Gsα protein in these tissues **(Chap. 479)**. Thus, females affected by either PHP1A or PPHP will have offspring with PHP1A, if these children inherit the allele carrying the *GNAS* mutation; in contrast, if the mutant allele is inherited from a male affected by either disorder, the offspring will exhibit PPHP. However, patients affected by both disease subtypes develop some but not

TABLE 422-6 Classification of Pseudohypoparathyroidism (PHP) and Pseudopseudohypoparathyroidism (PPHP)

TYPE	HYPOCALCEMIA, HYPERPHOSPHATEMIA	RESPONSE OF URINARY cAMP TO PTH	SERUM PTH	Gsα SUBUNIT DEFICIENCY	AHO	RESISTANCE TO HORMONES OTHER THAN PTH
PHP1A	Yes	↓	↑	Yes	Yes	Yes
PPHP	No	Normal	Normal	Yes	Yes	No
PHP1B	Yes	↓	↑	No	Yes (less frequently and usually less severe)	Yes (in some patients)
PHP2	Yes	Normal (but ↓ phosphaturic response)	↑	No	No	No
Acrodysostosis due to *PRKAR1A* mutations with hormonal resistance	Yes	Normal (but ↓ phosphaturic response)	↑	No	Yes	Yes

Abbreviations: ↓, decreased; ↑, increased; AHO, Albright's hereditary osteodystrophy; cAMP, cyclic adenosine monophosphate; PTH, parathyroid hormone.

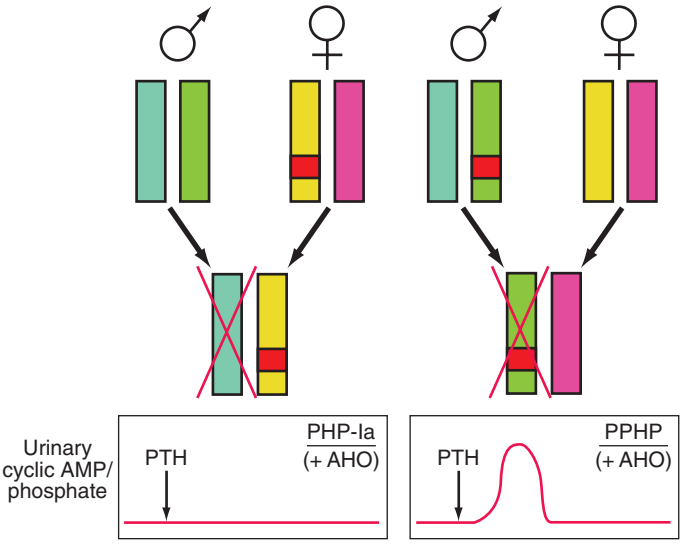

FIGURE 422-7 Paternal imprinting of renal parathyroid hormone (PTH) resistance (*GNAS* gene for Gsα subunit) in pseudohypoparathyroidism (PHP1A and PHP1B). An impaired excretion of urinary cyclic AMP and phosphate is observed in patients with PHP type I. In the renal cortex, there is selective silencing of paternal Gsα expression; consequently, mutations involving the maternal *GNAS* exons encoding Gsα or loss of methylation at *GNAS* exon A/B leads to reduced or completely absent Gsα protein in this portion of the kidney. The disease becomes manifest only in patients who inherit the defective gene from an obligate female carrier (*left*). If a genetic defect involving *GNAS* exons encoding Gsα is inherited from an obligate male carrier of the mutation (PHP1A or PPHP patient), no biochemical abnormality is encountered, and the administration of PTH causes an appropriate increase in the urinary cyclic AMP and phosphate concentration (pseudoPHP [PPHP]; *right*). Both patterns of inheritance lead to some but not all features of Albright's hereditary osteodystrophy (AHO), most likely because of haploinsufficiency; for example, Gsα protein derived from both parental *GNAS* alleles must be active for normal bone development. Maternal inheritance of a mutation (deletion, duplication, or inversion within or upstream of the *GNAS* locus) causes AD-PHP1B, while paternal inheritance does not lead to any detectable abnormality.

all AHO features, making it likely that Gsα haploinsufficiency becomes apparent during embryonic or postnatal development.

The complex mechanisms that control the *GNAS* gene contributed particularly to challenges involved in unraveling the pathogenesis of PHP1B. Analysis of families in which multiple members are affected by PHP1B, as well as studies of the complex parent-specific methylation of four regions within the complex *GNAS* locus, revealed that the autosomal dominant forms of PHP1B (AD-PHP1B) are caused by microdeletions, duplications, retrotransposon insertions, or inversions within or upstream of the *GNAS* locus. These genetic mutations are associated with a loss of DNA methylation at one or several loci on the maternal *GNAS* allele (Table 422-6). These abnormalities in methylation silence maternal Gsα expression, thus leading in the proximal renal tubules—where Gsα appears to be expressed predominantly from the maternal allele—to PTH resistance. While most cases of AD-PHP1B are by now resolved at the molecular level, the genetic defect responsible for the sporadic variant of PHP1B (sporPHP1B), the most frequent form of PHP1B, remains to be defined, except for those sporPHP1B cases that are caused by paternal uniparental isodisomy/heterodisomy of chromosome 20q (patUPD20q).

PHP1B patients, who rarely develop an AHO phenotype as severe as in PHP1A, develop hypocalcemia and hyperphosphatemia caused by PTH resistance and thus elevated PTH levels. The previously used Ellsworth-Howard test to assess the presence or absence of hormone resistance is used much less frequently, largely because of routinely available sensitive PTH assays (Table 422-6). As for PHP1A, these endocrine abnormalities become apparent only if disease-causing mutations are inherited maternally. Bone responsiveness may be excessive rather than blunted in PHP1B (and in PHP1A) patients, based on case reports that have emphasized an osteitis fibrosa–like pattern in several PHP1B patients. Some patients present with PTH resistance in the absence of AHO features and without *GNAS* methylation changes; it remains unclear why this PHP variant readily resolves upon treatment with vitamin D supplements.

PHP2 refers to patients with hypocalcemia and hyperphosphatemia, who have normal urinary cyclic AMP excretion, but an impaired urinary phosphaturic response to PTH. In one PHP2 variant, referred to as acrodysostosis with hormonal resistance, patients have a heterozygous defect in the regulatory subunit of PKA (PRKAR1A) that mediates the response to PTH distal to cyclic AMP production. Acrodysostosis without or with only mild hormonal resistance can be caused by heterozygous mutations in the cyclic AMP–selective phosphodiesterase 4D. Patients with one variant of acrodysostosis that is associated with hypertension, were shown to have heterozygous phosphodiesterase 3A mutations.

The diagnosis of these hormone-resistant states can usually be made when there is a positive family history for signs and symptoms of hypocalcemia with or without AHO features. In both categories—PHP1A and PHP1B—serum PTH levels are elevated, particularly when patients start to experience hypocalcemia during childhood. In PHP1A and PHP1B, the response of urinary cyclic AMP to the administration of exogenous PTH is blunted. The diagnosis of PHP2, in the absence of acrodysostosis, is more complex, and vitamin D deficiency must be excluded before such a diagnosis can be entertained.

TREATMENT

Pseudohypoparathyroidism

Treatment of PHP is similar to that of hypoparathyroidism, except that calcium and activated vitamin D analogues are usually given at higher doses to maintain blood calcium levels within the normal range and PTH levels in the upper end of normal or slightly elevated. Patients with PHP1 show no PTH resistance in the distal tubules—hence, urinary calcium clearance is typically not elevated, and these individuals are not at risk of developing nephrocalcinosis, as are patients with hypoparathyroidism, unless overtreatment occurs, for example, after the completion of pubertal development and skeletal mutation, when calcium and $1,25(OH)_2D$ treatment should be reduced. Variability in response makes it necessary to establish the optimal regimen for each patient.

Vitamin D Related • VITAMIN D DEFICIENCY DUE TO INADEQUATE DIET AND/OR SUNLIGHT Vitamin D deficiency due to inadequate intake of dairy products enriched with vitamin D, lack of vitamin supplementation, and reduced sunlight exposure in the elderly, particularly during winter in northern latitudes, is more common in the United States than previously recognized. Biopsies of bone in elderly patients with hip fracture (documenting osteomalacia) and abnormal levels of vitamin D metabolites, PTH, calcium, and phosphate indicate that vitamin D deficiency may occur in as many as 25% of elderly patients, particularly in northern latitudes in the United States. Concentrations of 25(OH)D are low or low-normal in these patients. Quantitative histomorphometric analysis of bone biopsy specimens from such individuals reveals widened osteoid seams consistent with osteomalacia (Chap. 421). PTH hypersecretion compensates for the tendency for the blood calcium to fall but also increases renal phosphate excretion and thus causes osteomalacia.

Treatment involves adequate replacement with vitamin D and calcium until the deficiencies are corrected. Severe hypocalcemia rarely occurs in moderately severe vitamin D deficiency of the elderly, but vitamin D deficiency must be considered in the differential diagnosis of mild hypocalcemia.

Mild hypocalcemia, secondary hyperparathyroidism, severe hypophosphatemia, and a variety of nutritional deficiencies occur with gastrointestinal diseases. Hepatocellular dysfunction can lead to reduction in 25(OH)D levels, as in portal or biliary cirrhosis of the liver, and malabsorption of vitamin D and its metabolites, including $1,25(OH)_2D$, may occur in a variety of bowel diseases, hereditary or acquired. Depending on the disorder, vitamin D or its metabolites can be given parenterally, guaranteeing adequate blood levels of active metabolites.

 Anticonvulsant therapy with any of several agents induces acquired vitamin D deficiency by increasing the conversion of vitamin D to inactive compounds and/or causing resistance to its action. The more marginal the vitamin D intake in the diet, the more likely that anticonvulsant therapy will lead to abnormal mineral and bone metabolism.

Vitamin D–Dependent Rickets Type I Vitamin D–dependent rickets type I, previously termed *pseudo-vitamin D–resistant rickets*, is caused by homozygous or compound heterozygous mutations in the gene CYP27B1 encoding 25(OH)D-1α-hydroxylase. It differs from true vitamin D–resistant rickets (vitamin D–dependent rickets type II, see below) in that it is typically less severe and the biochemical and radiographic abnormalities can be readily reversed with physiologic doses of the vitamin's active metabolite, $1,25(OH)_2D$ **(Chap. 421)**. Clinical features include hypocalcemia, often with tetany or convulsions; hypophosphatemia due to secondary hyperparathyroidism; and thus, osteomalacia and increased levels of alkaline phosphatase.

Vitamin D–Dependent Rickets Type II Vitamin D–dependent rickets type II results from end-organ resistance to the active metabolite $1,25(OH)_2D$. The clinical features resemble those of the type I disorder and include hypocalcemia, hypophosphatemia, secondary hyperparathyroidism, and rickets but also partial or total alopecia. Plasma levels of $1,25(OH)_2D$ are elevated, in keeping with the refractoriness of the end organs. This disorder is caused by homozygous or compound heterozygous mutations in the gene encoding the vitamin D receptor; treatment requires regular, usually nocturnal calcium infusions, which normalize PTH levels, thus reducing urinary phosphate excretion and thereby improving rickets and thus growth, but do not restore hair growth **(Chap. 421)**.

CKD Improved medical management of CKD allows many patients to survive for decades and, hence, provides time enough to develop features of renal osteodystrophy, which must be controlled to avoid additional morbidity. Impaired production of $1,25(OH)_2D$ is a principal factor that causes calcium deficiency, secondary hyperparathyroidism, and bone disease; hyperphosphatemia, which lowers further blood calcium levels, typically occurs only in the later stages of the disease. Low levels of $1,25(OH)_2D$ due to increased FGF23 production in bone (and possibly other tissues) are critical in the development of hypocalcemia. It is notable that FGF23 levels are often dramatically elevated in end-stage kidney disease (ESKD). The uremic state also causes impairment of intestinal absorption by mechanisms other than defects in vitamin D metabolism. Nonetheless, treatment with supraphysiologic amounts of vitamin D or calcitriol can correct impaired calcium absorption. Increased FGF23 levels are seen already during the early CKD stages and have been reported to correlate with kidney disease progression, increased mortality, and left ventricular hypertrophy. Strategies involving different oral phosphate binders have therefore been pursued to lower intestinal phosphate absorption early during the course of kidney disease and to thereby lower FGF23 levels. However, these approaches have been largely disappointing. Furthermore, there is concern as to whether supplementation with activated vitamin D analogues increases further the circulating FGF23 levels and their "off-target" effects in CKD patients.

TREATMENT

Chronic Kidney Disease

Therapy of CKD **(Chap. 322)** involves appropriate management of patients prior to dialysis and adjustment of regimens once dialysis is initiated. Attention should be paid to restriction of phosphate in the diet; avoidance of aluminum-containing phosphate-binding antacids; provision of an adequate calcium intake by mouth, usually around 1 g/d; and supplementation with 0.25–1 μg/d calcitriol or other activated forms of vitamin D. The aim of therapy is to restore normal calcium balance to prevent osteomalacia and severe secondary hyperparathyroidism (it is usually recommended to maintain PTH levels between 100 and 300 pg/mL) and, in light of evidence of genetic changes and monoclonal outgrowths of parathyroid glands in CKD patients, to prevent secondary hyperparathyroidism from becoming autonomous hyperparathyroidism. Reduction of hyperphosphatemia and restoration of normal intestinal calcium absorption by calcitriol can improve blood calcium levels and reduce the manifestations of secondary hyperparathyroidism. Since adynamic bone disease can occur in association with low PTH levels, it is important to avoid excessive suppression of the parathyroid glands while recognizing the beneficial effects of controlling the secondary hyperparathyroidism. These patients should be closely monitored with intact PTH assays. Oral phosphate-binding agents such as sevelamer lower blood phosphate levels in ESKD, but their use in earlier CKD stages does not seem to be beneficial in lowering blood phosphate levels and to prevent the rise in FGF23.

Other Causes Treatment of patients using antiresorptives, such as bisphosphonates and denosumab, my result in hypocalcemia. Risk factors for this condition include vitamin D deficiency, low calcium intake, or advanced chronic kidney disease.

Increased enteric loss of 25-hydroxyvitamin D and 1,25(OH)2D due to intestinal disease and increased metabolism due to anticonvulsants or antituberculosis therapy can also lead to hypocalcemia.

Impaired 25-hydroxylation due to severe liver disease or mutations in CYP2R1, the 25-hydroxylase, are rare causes of hypocalcemia. Impaired 1α-hydroxylation is not uncommon and occurs in renal insufficiency, certain antifungals, and FGF23-related disorders.

Occasionally, loss of calcium from the ECF is so severe that PTH cannot compensate. Such situations include acute pancreatitis and severe, acute hyperphosphatemia, often in association with renal failure, conditions in which there is rapid efflux of calcium from the ECF. Severe hypocalcemia can occur quickly; PTH rises in response to hypocalcemia but does not return blood calcium to normal.

SEVERE, ACUTE HYPERPHOSPHATEMIA Severe hyperphosphatemia is associated with extensive tissue damage or cell destruction **(Chap. 421)**. The combination of increased release of phosphate from muscle and impaired ability to excrete phosphorus because of renal failure causes moderate to severe hyperphosphatemia, the latter causing calcium loss from the blood and mild to moderate hypocalcemia. Hypocalcemia is usually reversed with tissue repair and restoration of renal function as phosphorus and creatinine values return to normal. There may even be a mild hypercalcemic period in the oliguric phase of renal function recovery. This sequence, severe hypocalcemia followed by mild hypercalcemia, reflects widespread deposition of calcium in muscle and subsequent redistribution of some of the calcium to the ECF after phosphate levels return to normal.

Other causes of hyperphosphatemia include hypothermia, massive hepatic failure, and hematologic malignancies, either because of high cell turnover of malignancy or because of cell destruction by chemotherapy.

TREATMENT

Severe, Acute Hyperphosphatemia

Treatment is directed toward lowering of blood phosphate by the administration of phosphate-binding antacids or dialysis. Although calcium replacement may be necessary if hypocalcemia is severe and symptomatic, calcium administration during the hyperphosphatemic period tends to increase extraosseous calcium deposition and aggravate tissue damage. The levels of $1,25(OH)_2D$ may be low during the hyperphosphatemic phase and return to normal during the oliguric phase of recovery.

OSTEITIS FIBROSA AFTER PARATHYROIDECTOMY Severe hypocalcemia after parathyroid surgery is rare now that osteitis fibrosa cystica is an infrequent manifestation of hyperparathyroidism. When osteitis fibrosa cystica is severe, however, bone mineral deficits can be large. After parathyroidectomy, hypocalcemia can persist for days if calcium replacement is inadequate. Treatment may require parenteral administration of calcium; addition of calcitriol and oral calcium

supplementation is sometimes needed for weeks to a month or two until bone defects are filled (which, of course, is of therapeutic benefit in the skeleton), making it possible to discontinue parenteral calcium and/or reduce the amount.

Differential Diagnosis Care must be taken to ensure that true hypocalcemia is present; in addition, acute transient hypocalcemia can be a manifestation of a variety of severe, acute illnesses, as discussed above. *Chronic hypocalcemia*, however, can usually be ascribed to a few disorders associated with absent or ineffective PTH. Important clinical criteria include the duration of the illness, signs or symptoms of associated disorders, and the presence of features that suggest a hereditary abnormality. A nutritional history can be helpful in recognizing a low intake of vitamin D and calcium in the elderly, and a history of excessive alcohol intake may suggest magnesium deficiency.

Differential Diagnosis Inherited hypoparathyroidism and PHP are lifelong illnesses, usually (but not always) appearing by adolescence; hence, a recent onset of hypocalcemia in an adult is more likely due to nutritional deficiencies, CKD, or intestinal disorders that result in deficient or ineffective vitamin D. Neck surgery, even long past, however, can be associated with a delayed onset of postoperative hypoparathyroidism. A history of seizure disorder raises the issue of anticonvulsive medication. Developmental defects may point to the diagnosis of PHP1A. Rickets and a variety of neuromuscular syndromes and deformities may indicate ineffective vitamin D action, either due to defects in vitamin D metabolism or to vitamin D deficiency.

A pattern of *low calcium with high phosphorus* in the absence of renal failure or massive tissue destruction almost invariably means hypoparathyroidism or PHP. A *low calcium and low phosphorus* pattern points to absent or ineffective vitamin D, thereby impairing the action of PTH on calcium metabolism (but not phosphate clearance). The relative ineffectiveness of PTH in calcium homeostasis in vitamin D deficiency, anticonvulsant therapy, gastrointestinal disorders, and hereditary defects in vitamin D metabolism leads to secondary hyperparathyroidism as a compensation. The excess PTH on renal tubule phosphate transport accounts for renal phosphate wasting and hypophosphatemia.

423 Osteoporosis

Peter R. Ebeling

Osteoporosis, a condition characterized by decreased bone strength and fragility fractures, is most common among postmenopausal women, but 30% of fragility fractures occur in men. Other underlying diseases can result in secondary osteoporosis. The clinical manifestations of osteoporosis are primarily vertebral, nonvertebral, and hip fractures. Osteoporosis affects >10 million individuals in the United States, but only a minority are currently diagnosed and treated.

DEFINITION

Osteoporosis is defined as a reduction in the strength of bone that leads to skeletal fragility and fractures. Despite bone mineral density being used to define osteoporosis, other important factors such as microarchitectural deterioration and misalignment of bone components also contribute. Thus, relying solely on the measure of bone mineral density may underestimate bone fragility. The World Health Organization (WHO) operationally defined osteoporosis as a bone density that falls 2.5 standard deviations (SDs) or more below the mean for young healthy adults (age 30 years) of the same sex and race—also referred to as a *T-score* of –2.5. Postmenopausal women in the lower end of the young normal range (a T-score <–1.0 to –2.5) are defined as having low bone density or osteopenia, a risk factor for developing osteoporosis. Despite a lower fracture risk in this group, >50% of fractures among postmenopausal women, including hip fractures, occur in individuals with osteopenia because the size of that population is much larger than the group defined as having osteoporosis by bone density T-score. This has led to a greater emphasis on absolute fracture risk, incorporating age, sex, and other major clinical risk factors with or without bone mineral density (BMD) to calculate the 10-year risk of hip or major osteoporotic fractures. The calculation of absolute fracture risk with tools such as FRAX® or the Garvan Fracture Risk Calculator has allowed the development of intervention thresholds for osteoporosis treatment that may be country specific and may differ from diagnostic thresholds (e.g., T-score <–2.5).

Fragility fractures are defined as fractures in adults occurring following a fall from standing height or less, but exclude finger, toes, face, and skull fractures. However, recent studies also indicate traumatic fractures should also be regarded as indicative of underlying skeletal fragility and require further evaluation.

EPIDEMIOLOGY

In the United States, as many as 10.8 million women and 2.5 million men have osteoporosis (BMD T-score <–2.5 at lumbar spine, total hip, or femoral neck). This does not include additional people who present with an osteoporosis-related fracture but with osteopenia (T-score <–1.0 to –2.5). It is estimated that 2 million osteoporosis-related fractures occur each year in the United States at a cost of $19 billion, a problem that will increase as the population ages. Globally, hip fractures are increasing and are associated with high costs. The failure to identify the first fragility fracture and intervene is estimated to cost $6 billion to Medicare alone for secondary fractures. Another 40 million Americans have osteopenia that potentially puts them at increased of fracture and of developing osteoporosis. Although osteoporosis is mostly age-related, some individuals appear more at risk. In women, the rapid loss of ovarian function during the perimenopause (on average around age 50 years) precipitates rapid bone loss over the next 5–7 years such that most women will have osteoporosis by age 70–80 years. As the population is aging, the number of individuals with osteoporosis and fractures is rising. As many fragility fractures due to osteoporosis occur in individuals with osteopenia, identification of those individuals with a high absolute fracture risk and their evaluation and treatment are important.

Most fractures, especially those of the hip and vertebrae, show exponential increases with advancing age **(Fig. 423-1)**. Lifetime osteoporotic fracture risk for a Caucasian woman who reaches the age of 50 years is ~50%, while the corresponding risk for a 50-year-old man is ~25%. Recent data suggest that fractures, including hip fractures, are increasing despite age-related fracture rates decreasing. This may be related to the aging of the population globally or to failure to evaluate and treat patients with a high absolute fracture risk.

About 300,000 hip fractures occur each year in the United States, almost all requiring hospital admission and surgical intervention. The lifetime probability that a 50-year-old white individual will have a hip fracture is 14% for women and 5% for men; the risk for African

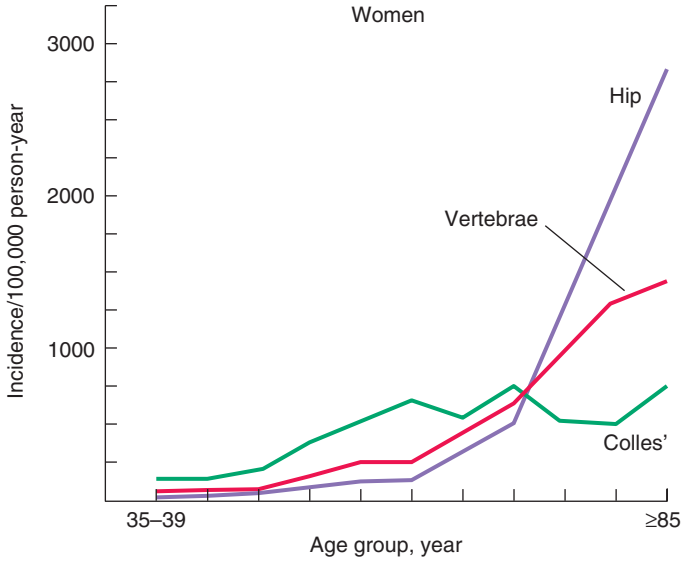

FIGURE 423-1 Epidemiology of vertebral, hip, and Colles' fractures with age. *(Reproduced with permission from C Cooper, LJ Melton 3rd: Epidemiology of osteoporosis. Trends Endocrinol Metab 3:224, 1992.)*

Americans is about half of those rates, and the risk for Asians and non-black Hispanics appears to be like that for Caucasians. Hip fractures are associated with a high incidence of mortality and morbidity, with 20–25% of patients dying in the year following the injury, with higher mortality rates among males and African Americans. Hip fracture rates and mortality also demonstrate high global variability. About 30% of survivors require long-term care (at least temporarily), and many never regain the independence that they had prior to the fracture. This sequela is the one most feared by patients.

There are ~500,000 symptomatic vertebral fractures per year in the United States, but >1,000,000 vertebral fractures may occur annually since only one-third are recognized clinically. The vast majority are clinically "silent" vertebral fractures identified incidentally during spinal radiography **(Fig. 423-2)** or may be suggested by significant height loss (>4 cm). However, even asymptomatic vertebral fractures are a major sign of skeletal fragility and increase the risk for subsequent fracture. Vertebral fractures, like other fragility fractures, are also associated with long-term morbidity and an increase in mortality. The occurrence of the first fracture greatly increases the risk of further fractures, especially in the first year. The consequence is height loss,

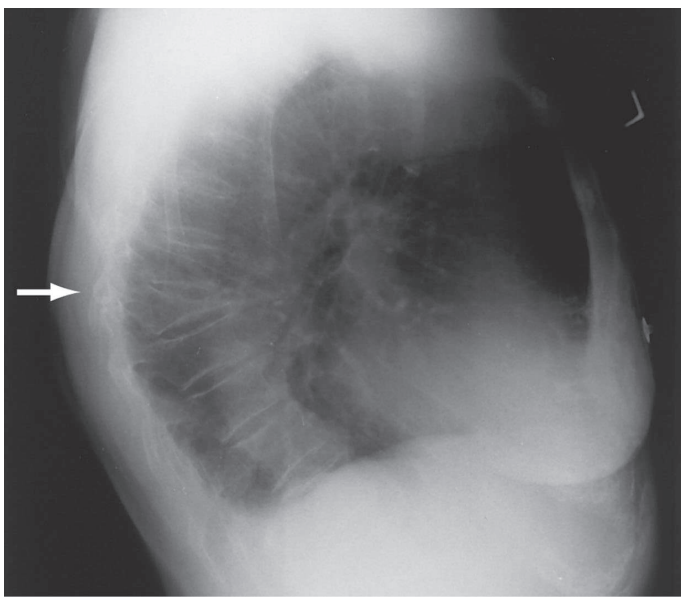

FIGURE 423-2 Lateral spine x-ray showing severe osteopenia and a severe wedge-type deformity (severe anterior compression).

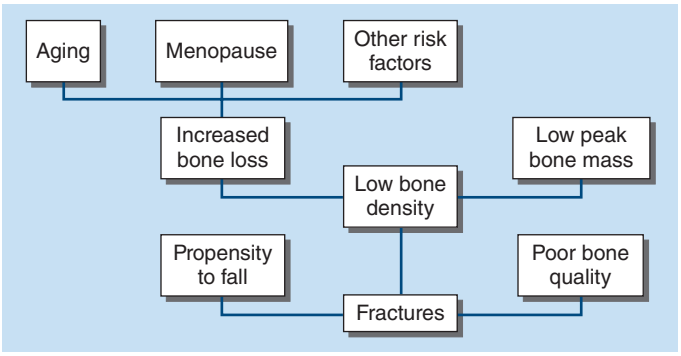

FIGURE 423-3 Factors leading to osteoporotic fractures.

kyphosis, and secondary pain and discomfort related to altered spinal biomechanics. Thoracic fractures can be associated with restrictive lung disease, whereas lumbar fractures are associated with abdominal symptoms including distention, early satiety, and constipation.

Approximately 400,000 wrist fractures occur in the United States each year. Fractures of other bones (including ~150,000 pelvic fractures and >100,000 proximal humerus fractures) also occur due to osteoporosis. The threshold for fracture is reduced in osteoporotic bone **(Fig. 423-3)** due to increased skeletal fragility. Traumatic fractures are also increased in patients at risk of osteoporosis. Fewer than 20% of patients with a fracture are currently either investigated for osteoporosis or started on treatment within 6 months. A number of clinical risk factors for fracture exist; the common ones are summarized in **Table 423-1**. Prior fragility fractures, a family history of hip fracture, low body mass index, cigarette smoking, and excessive alcohol consumption are all independent predictors. Chronic inflammatory diseases, such as rheumatoid arthritis, increase the risk of osteoporosis, as do diseases associated with malabsorption (e.g., celiac disease) and male hypogonadism. Chronic diseases that increase the risk of falling or frailty, including dementia, Parkinson's disease, and multiple sclerosis, also increase fracture risk (Table 423-1). Many other risk factors for osteoporosis have been described including glucocorticoids, aromatase inhibitors, androgen deprivation therapy, air pollution, triclosan, bariatric surgery, diabetes mellitus, cerebrovascular accidents, dementia (including Alzheimer's), the death of a spouse, depression and its treatment with selective serotonin reuptake inhibitors (SSRIs), and proton pump inhibitors, to name a few.

Increasing frailty with age is a potent risk factor for fracture, as is sensory inattention (e.g., walking while looking at mobile phone).

Globally, fragility fractures are more common among women than men, presumably due to a lower peak bone mass as well as rapid postmenopausal bone loss in women. However, this sex difference in bone density and hip fracture incidence is not apparent in all countries, possibly due to genetics, physical activity levels, or diet.

Fragility fractures increase the risk for future fractures (Table 423-1). Vertebral fractures increase the risk of other vertebral fractures as well

TABLE 423-1 Risk Factors for Osteoporosis Fracture

NONMODIFIABLE	POTENTIALLY MODIFIABLE
Personal history of fracture as an adult	Current cigarette smoking
History of fracture in first-degree relative	Estrogen deficiency
Female gender	Early menopause (<45 years) or bilateral ovariectomy
Advanced age	Prolonged premenstrual amenorrhea (>1 year)
White race	Poor nutrition especially low calcium and vitamin D intake
Dementia	Alcoholism
	Impaired eyesight despite adequate correction
	Recurrent falls
	Inadequate physical activity
	Poor health/frailty

as fractures of the peripheral skeleton such as the hip and wrist. Wrist fractures also increase the risk of vertebral and hip fractures. Among individuals aged >50 years, any fracture (except those of the fingers, toes, face, and skull) should be considered as fragility fractures. Any fracture in a woman aged >50 years or a man aged >60 years should trigger investigations for osteoporosis. However, this does not occur in the majority as postfracture care is fragmented. Recent attempts to coordinate care using fracture liaison services to guide patients with fragility fractures through health care systems and ensure their investigation and initiate treatment for osteoporosis have been shown to improve outcomes but may be difficult to implement in countries without single-payor systems or closed health care systems.

The risk for future fracture after a first fracture is exponentially increased in the first 12–24 months, leading to the concept of imminent fracture risk. A recent large Medicare database study indicated that almost 20% of women will have a second fracture within 2 years after the first. Risk diminishes to less than half of that rate in the subsequent 3 years but remains persistently elevated after a vertebral or hip fracture.

PATHOPHYSIOLOGY

BONE REMODELING

A low peak bone mass may underlie the development of osteoporosis due to hormonal, genetic, or nutritional influences. Age-related changes in bone remodeling as well as extrinsic and intrinsic factors may then be superimposed. Consequently, an appreciation of bone remodeling is fundamental to developing an understanding of both the pathophysiology of bone loss **(Chap. 421)** and mechanisms of pharmacologic intervention. During growth, the skeleton increases in size by linear growth and by apposition of new bone tissue on the cortical periosteum **(Fig. 423-4)**. The latter process is called *modeling*, a process that also allows the long bones to adapt in shape to the stresses placed on them. Increased sex hormone production at puberty is required for skeletal maturation, with peak bone mass being achieved by early adulthood. Recent data suggest delayed puberty may be associated with low bone peak mass that persists into adulthood in both sexes. Sexual dimorphism in skeletal size occurs after puberty with larger bones in males, although true bone mineral density remains similar in both sexes. Nutrition and exercise also play an important role in growth, although genetic factors primarily determine peak bone mass.

Numerous genes control skeletal growth, peak bone mass, and body size, as well as skeletal structure and density. Heritability estimates of 50–80% for bone mineral density and size have been derived from twin studies. Though peak bone mass is often lower among individuals with a family history of osteoporosis, association studies of candidate genes (vitamin D receptors; type I collagen, estrogen receptors [ERs], and interleukin 6 [IL-6]; and insulin-like growth factor I [IGF-I]) and bone mass, bone turnover, and fracture prevalence have been inconsistent. There is no panel of genetic markers that can be used to diagnose osteoporosis. Linkage studies suggest that a genetic locus on chromosome 11 is associated with high bone mass. Families with high bone mass and lacking age-related bone loss have been shown to have an activating mutation in LRP5, low-density lipoprotein receptor–related protein 5. Conversely, an inactivating mutation results in osteoporosis-pseudoglioma syndrome, and LRP5 signaling is important in controlling bone formation. Genome-wide scans for low bone mass suggest multiple genes are involved, many of which are also implicated in control of body size.

In adults, bone *remodeling*, not modeling, is the principal metabolic skeletal process. Bone remodeling has two critical functions: (1) to repair bone microdamage to maintain skeletal strength and (2) to supply calcium from the skeleton when required to maintain serum calcium. Remodeling may be activated by bone microdamage due to excessive or accumulated mechanical stress. Acute demands for calcium involve osteoclast-mediated resorption as well as calcium transport by osteocytes. Chronic demands for calcium can result in secondary hyperparathyroidism, increased bone remodeling, and bone loss. Bone remodeling occurs through the well-coordinated activity of osteocytes, osteoblasts, and osteoclasts. Osteocytes are the terminal-differentiated

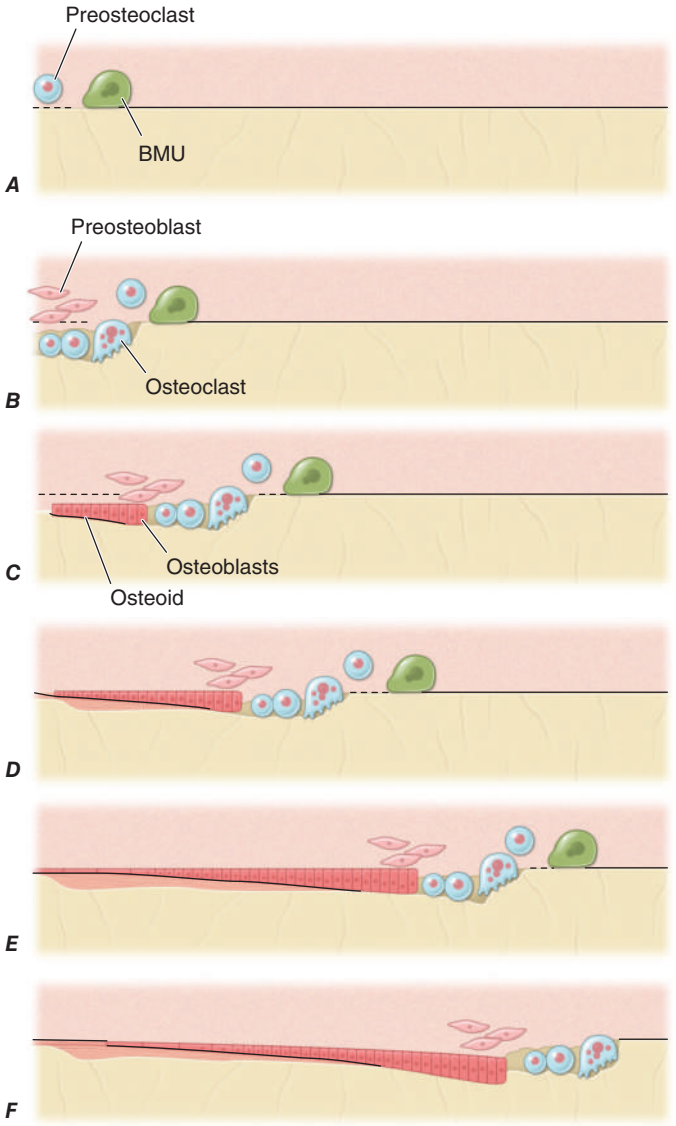

FIGURE 423-4 Mechanism of bone remodeling. The basic molecular unit (BMU) moves along the trabecular surface at a rate of ~10 μm/d. The figure depicts remodeling over ~120 days. ***A.*** Origination of BMU-lining cells contracts to expose collagen and attract preosteoclasts. ***B.*** Osteoclasts fuse into multinucleated cells that resorb a cavity. Mononuclear cells continue resorption, and preosteoblasts are stimulated to proliferate. ***C.*** Osteoblasts align at bottom of cavity and start forming osteoid (black). ***D.*** Osteoblasts continue formation and mineralization. Previous osteoid starts to mineralize (*horizontal lines*). ***E.*** Osteoblasts begin to flatten. ***F.*** Osteoblasts turn into lining cells; bone remodeling at initial surface (left of drawing) is now complete, but BMU is still advancing (to the right). *(Reproduced with permission from SM Ott, in JP Bilezikian, LG Raisz, GA Rodan: Principles of Bone Biology, vol. 18. San Diego, CA: Academic Press; 1996.)*

cells derived from osteoblasts after incorporation into newly formed bone tissue. Osteoblasts derive from mesenchymal cell lineage and osteoclasts from monocyte/macrophage lineage. Remodeling sites are discrete units with osteoclasts initiating the process by removal of damaged bone tissue and osteoblasts synthesizing new organic bone that becomes gradually mineralized.

Bone remodeling is regulated by multiple hormones, including estrogens (in both sexes), androgens, vitamin D, and parathyroid hormone (PTH), as well as locally produced bone-derived growth factors, such as IGF-I, transforming growth factor β (TGF-β), PTH-related peptide (PTHrP), interleukins (ILs), prostaglandins, and members of the tumor necrosis factor (TNF) superfamily. These factors primarily modulate the rate at which new remodeling sites are activated, a process that results initially in bone resorption by osteoclasts, followed by a period of repair during which new bone tissue is synthesized by osteoblasts **(Chap. 421)**. The cytokine responsible for communication

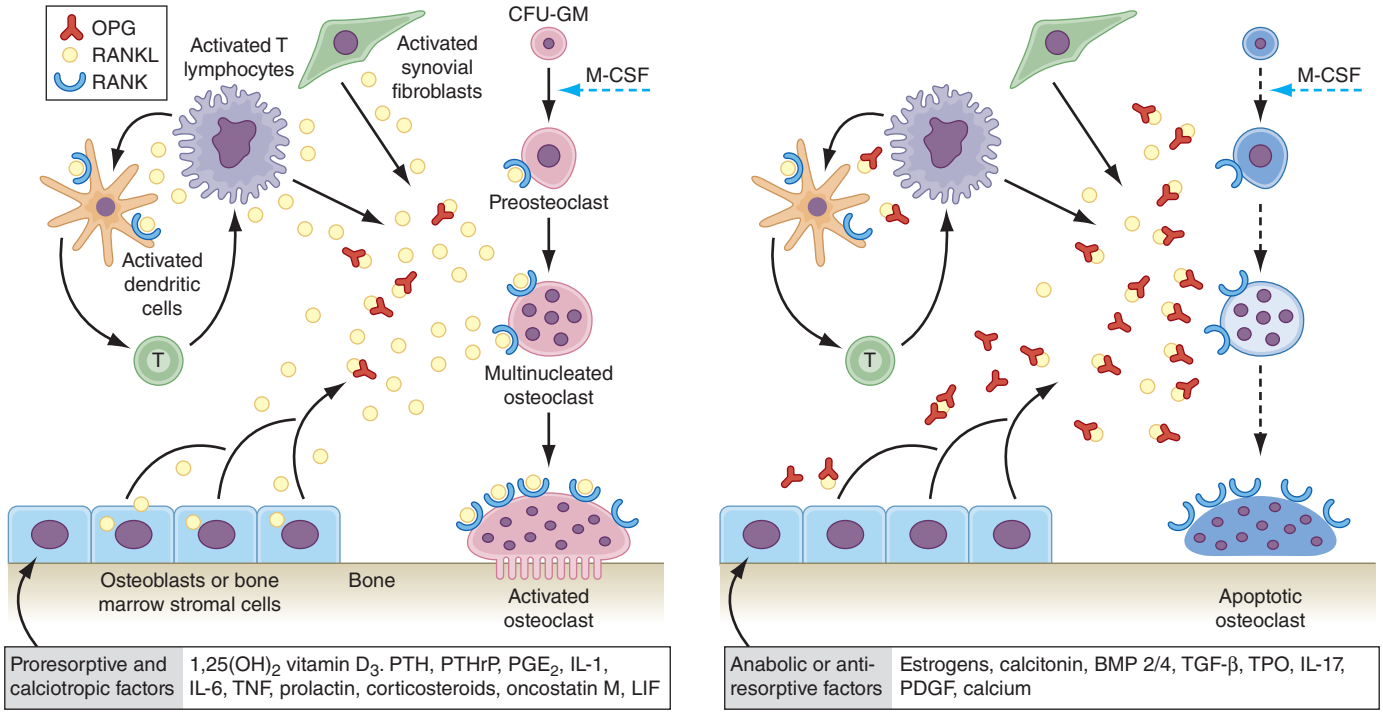

FIGURE 423-5 Hormonal control of bone resorption. ***A.*** Proresorptive and calciotropic factors. ***B.*** Anabolic and antiosteoclastic factors. RANKL expression is induced in osteoblasts, activated T cells, synovial fibroblasts, and bone marrow stromal cells. It binds to membrane-bound receptor RANK to promote osteoclast differentiation, activation, and survival. Conversely, osteoprotegerin (OPG) expression is induced by factors that block bone catabolism and promote anabolic effects. OPG binds and neutralizes RANKL, leading to a block in osteoclastogenesis and decreased survival of preexisting osteoclasts. CFU-GM, colony-forming units, granulocyte macrophage; IL, interleukin; LIF, leukemia inhibitory factor; M-CSF, macrophage colony-stimulating factor; OPG-L, osteoprotegerin ligand; PDGF, platelet-derived growth factor; PGE_2, prostaglandin E_2; PTH, parathyroid hormone; RANKL, receptor activator of nuclear factor-κB; TGF-β, transforming growth factor β; TNF, tumor necrosis factor; TPO, thrombospondin. *(Reproduced with permission from WJ Boyle et al: Osteoclast differentiation and activation. Nature 423:337, 2003.)*

between the osteoblasts, other marrow cells, and osteoclasts is receptor activator of nuclear factor-κB (RANK) ligand (RANKL). RANKL, a member of the TNF family, is secreted by osteocytes, osteoblasts, and certain immune cells. The osteoclast receptor for this protein is referred to as *RANK*. Activation of RANK by RANKL is a final common path in osteoclast development and activation. A humoral decoy for RANKL, also secreted by osteoblasts, is referred to as *osteoprotegerin* (Fig. 423-5). Modulation of osteoclast recruitment and activity appears to be related to the interplay among these three factors (RANKL, RANK, and osteoprotegerin). Additional influences include nutrition (particularly calcium intake) and physical activity level. RANKL production is in part regulated by the canonical Wnt signaling pathway. Wnt activation through mechanical loading or by hormonal or cytokine factors stimulates bone formation by increasing formation and activity of osteoblasts and decreases RANKL secretion, which inhibits osteoclast formation and activity. Sclerostin, also an osteocyte protein, is a major inhibitor of Wnt activation and bone formation. Its secretion is inhibited by weight-bearing physical activity and PTH. Both the RANKL and Wnt pathways have become major targets for osteoporosis treatment (see below).

In young adults, bone remodeling is balanced with resorbed bone being replaced by an equal amount of new bone. Thus, the mass of the skeleton remains constant after peak bone mass is achieved. However, after age 30–45 years, bone resorption exceeds formation, resulting in bone loss. This imbalance may begin at different ages, varies at different skeletal sites, and becomes exaggerated in women due to estrogen deficiency. Bone loss can be due to an increase in osteoclastic activity and/or a decrease in osteoblastic activity. In addition, an increase in remodeling activation frequency, and thus the number of remodeling sites, can magnify small imbalances seen at the individual remodeling unit. Increased bone remodeling can result in permanent bone loss and disrupted skeletal microarchitecture, with an imbalance between resorption and formation within each cycle. In trabecular bone, if the osteoclasts penetrate trabeculae, rapid bone loss ensues and cancellous connectivity is reduced. A higher number of remodeling sites increases the likelihood of this event. In cortical bone, increased activation of bone remodeling creates more porous bone. The effect of this increased cortical porosity on cortical bone strength may be modest if the overall diameter of the bone is not changed. However, decreased apposition of new bone on the periosteal surface coupled with increased endocortical resorption of bone decreases the biomechanical strength of long bones. Even a slight exaggeration in normal bone loss increases the risk of osteoporosis-related fractures because of microarchitectural changes, and osteoporosis is largely a disease of disordered skeletal microarchitecture. Currently the predominant clinical tool (dual-energy x-ray absorptiometry [DXA]) measures bone mass rather than bone microarchitecture. Several additional tools are available to estimate bone microarchitecture (including the trabecular bone score [TBS], a noninvasive addition to spinal DXA measurements, and high-resolution peripheral quantitative computerized tomography [HR-pQCT], which has limited availability).

CALCIUM NUTRITION

Peak bone mass may be impaired by inadequate dietary calcium intake during growth among other nutritional factors (calories, protein, and other minerals), leading to increased risk of osteoporosis later in life. During the adult phase of life, insufficient calcium intake contributes to secondary hyperparathyroidism and an increase in bone remodeling rate. PTH stimulates the 1-alpha hydroxylation of vitamin D in the kidney, leading to increased levels of 1,25-dihydroxyvitamin D [$1,25(OH)_2D$] and enhanced gastrointestinal calcium absorption. PTH also reduces renal calcium loss. Although these are appropriate compensatory homeostatic responses for improving calcium economy, the long-term effects are detrimental to the skeleton because the increased remodeling rates and the ongoing imbalance between resorption and formation at remodeling sites combine to accelerate bone loss.

Total daily calcium intakes <400 mg are detrimental to the skeleton, and intakes in the range of 600–800 mg, which is about the average intake among adults in the United States, are also probably suboptimal. The recommended daily required intake of 1000–1200 mg for adults

accommodates population heterogeneity in controlling calcium balance. Such intakes should preferentially come from dietary sources, with supplements used only when dietary intakes fall short and cannot be modified easily. The supplement should be enough to bring total intake to ~1200 mg/d. Recent studies have suggested that there may be differences in safety based on calcium source so that increasing dietary calcium is preferred; higher intakes from supplement sources appear to result in a greater risk of renal stones and perhaps cardiovascular events (although the literature is inconsistent and controversial); however, supplement doses below about 700 mg/d have not been associated with cardiovascular events. Increasing calcium intake above this level does not have any benefit. Increasing calcium intake by itself will not prevent bone loss due to other factors (e.g., postmenopausal status)

VITAMIN D

(See also Chap. 421) Severe vitamin D deficiency causes rickets in children and osteomalacia in adults. However, vitamin D insufficiency (circulating levels of 25-hydroxyvitamin D [25(OH)D] that may be inadequate [<75 nmol/L or 30 ng/mL] but above the level that results in rickets) may be more prevalent than previously thought, particularly among individuals at increased risk such as the elderly; those living in northern or southern latitudes; and individuals with poor nutrition, obesity, malabsorption, or chronic liver or renal disease. Dark-skinned individuals are also at high risk of vitamin D in the insufficiency range or lower, but African Americans have a low risk of osteoporosis, with better calcium homeostasis than Caucasians.

Although there is considerable controversy about overall optimal health targets for serum 25(OH)D, there is evidence that for optimal skeletal health, serum 25(OH)D should be >75 nmol/L (30 ng/mL). To achieve this level for most adults requires limited skin exposure to sunlight (estimated to be exposure of face and arms for at least one-half hour each day) or an intake of at least 800–1000 units/d, or even higher in individuals with risk factors (as above), particularly obesity.

Vitamin D insufficiency leads to compensatory secondary hyperparathyroidism and is an important risk factor for osteoporosis and fractures. Some studies have shown that >50% of inpatients on a general medical service exhibit biochemical features of vitamin D deficiency, including increased levels of PTH and alkaline phosphatase and lower levels of ionized calcium. Among those living in northern and southern latitudes, vitamin D levels decline during the winter months without supplementation due to insufficient ultraviolet B radiation. This is associated with seasonal bone loss, reflecting increased bone turnover. Even among healthy ambulatory individuals, mild vitamin D deficiency is increasing in prevalence. In part, this is due to decreased exposure to sunlight. Treatment with vitamin D can return levels to normal (>75 nmol/L [30 ng/mL]) and prevent the associated increase in bone remodeling, bone loss, and fractures. Reduced falls and fracture rates also have been documented among individuals in northern latitudes who have greater vitamin D intake and have higher 25(OH)D levels (though one study suggested an increased fall risk with 25[OH]D levels >70 ng/mL or >175 nmol/L). Although vitamin D levels are suspected to affect risk and/or severity of other diseases, including cancers (colorectal, prostate, and breast), autoimmune diseases, multiple sclerosis, and cardiovascular disease, most controlled clinical trials have not confirmed these effects. However, vitamin D does prevent progression of prediabetes to diabetes in those with vitamin D deficiency (25[OH]D levels <12 ng/mL or <30 nmol/L). Treating vitamin D–sufficient individuals with vitamin D does not reduce fractures. For most adults, supplements of 1000–2000 IU/d are adequate and safe.

ESTROGEN STATUS

Estrogen deficiency causes bone loss by two distinct but interrelated mechanisms: (1) activation of new bone remodeling sites and (2) initiation or exacerbation of an imbalance between bone formation and resorption, in favor of the latter. The change in activation frequency causes a transient bone loss until a new steady state between resorption and formation is achieved. This commences in the perimenopause prior to cessation of periods. This remodeling imbalance results in a permanent decrement in mass. In addition, the increase in remodeling sites in the skeleton alone increases the probability of trabecular perforation, eliminating the template on which new bone can be formed and accelerating bone loss. The consequence is degraded skeletal microarchitecture, particularly affecting trabecular bone, so that at any given bone density, the risk of a fracture is greater in those who have experienced rapid bone loss than in those who have not. The addition of the TBS to spinal DXA measurements is an attempt to indirectly capture these microarchitectural changes, while HR-pQCT scans measure these directly.

The most common cause of estrogen deficiency is the menopause, which occurs on average at age 51 years **(Chap. 407)**. Thus, with current life expectancy, an average woman will spend ~35 years without an ovarian estrogen supply. Breast cancer treatment with either bilateral ovariectomies and/or aromatase inhibitors is an increasingly common cause of even more severe estrogen deficiency. The mechanism by which estrogen deficiency causes bone loss is summarized in Fig. 423-5. Bone marrow cells (macrophages, monocytes, osteoclast precursors, mast cells) as well as bone cells (osteoblasts, osteocytes, osteoclasts) express both ERs (α and β). Loss of estrogen increases RANKL production but also reduces osteoprotegerin production, increasing osteoclast formation and recruitment. Estrogen also may play a role in determining the life span of bone cells by controlling their rate of apoptosis. Thus, in situations of estrogen deprivation, the life span of osteoblasts may be decreased, whereas the longevity and activity of osteoclasts are increased. The rate and duration of bone loss after menopause are heterogeneous and unpredictable. Once surfaces are lost from trabecular bone, the rate of bone loss declines. In cortical bone, loss is slower but may continue for longer.

Since remodeling is initiated at the surface of bone, it follows that trabecular bone—which has a considerably larger surface area (80% of the total) than cortical bone—will be affected preferentially by estrogen deficiency. Fractures occur earliest at sites where trabecular bone contributes most to bone strength; consequently, vertebral fractures are the most common early skeletal consequence of estrogen deficiency.

In males, estrogen may have an important role in regulation of bone remodeling. In an experiment in which males were rendered estrogen and androgen deficient, restoring estrogen supply reduced remodeling rate more than restoring androgen.

PHYSICAL ACTIVITY

Inactivity, such as prolonged bed rest or paralysis, results in significant bone loss. Concordantly, athletes have higher bone mass than nonathletes. These increases in skeletal mass are most marked when the stimulus begins during growth in the years before puberty at the time of skeletal modeling and can result in a higher peak bone mass in both sexes. Adults are less able to increase bone mass after restoration of physical activity. Epidemiologic data support the beneficial effects on the skeleton of chronic high levels of physical activity. Fracture risk is lower in rural communities and in countries where physical activity is maintained into old age. However, when exercise is initiated during adult life, the effects of progressive resistance training on the skeleton are modest, with increases in spine and hip bone mass of 2–4% in short-term randomized trials of <2 years' duration. Muscle strength is also increased, while balance and functional exercises combined also reduce falls by about 25%. A Cochrane review showed balance and functional exercises reduced the number of people who experienced one or more fall-related fractures. Continuing physical activity into the later years may also slow cognitive decline, another major reason for including exercise programs for the aging population.

CHRONIC DISEASES

Various genetic and acquired diseases are associated with an increase in the risk of osteoporosis **(Table 423-2)**. Mechanisms that contribute to bone loss are unique for each disease and typically result from multiple factors, including nutrition, reduced physical activity levels, and factors that affect rates of bone remodeling or bone quality. In most, but not all circumstances, the primary diagnosis is made before osteoporosis presents clinically. Both type 1 and type 2 diabetes mellitus are associated with an increased fracture risk, with increased risk at higher

TABLE 423-2 Diseases Associated with an Increased Risk of Generalized Osteoporosis in Adults

Hypogonadal states	**Hematologic disorders/malignancy**
Turner's syndrome	Multiple myeloma
Klinefelter's syndrome	Lymphoma and leukemia
Anorexia nervosa	Malignancy-associated parathyroid hormone–related peptide (PTHrP) production
Hypothalamic amenorrhea	Mastocytosis
Hyperprolactinemia	Hemophilia
Other primary or secondary hypogonadal states	Thalassemia
Endocrine disorders	**Selected inherited disorders**
Cushing's syndrome	Osteogenesis imperfecta
Hyperparathyroidism	Marfan's syndrome
Thyrotoxicosis	Hemochromatosis
Diabetes mellitus (both type 1 and 2)	Hypophosphatasia
Acromegaly	Glycogen storage diseases
Adrenal insufficiency	Homocystinuria
Nutritional and gastrointestinal disorders	Ehlers-Danlos syndrome
Malnutrition	Porphyria
Parenteral nutrition	Menkes' syndrome
Malabsorption syndromes	Epidermolysis bullosa
Gastrectomy	**Other disorders**
Severe liver disease, especially biliary cirrhosis	Immobilization
	Chronic obstructive pulmonary disease
Pernicious anemia	Pregnancy and lactation
Rheumatologic disorders	Scoliosis
Rheumatoid arthritis	Multiple sclerosis
Ankylosing spondylitis	Sarcoidosis
	Amyloidosis

bone density than in the nondiabetic population. This is due to differences in collagen cross-linking in bone tissue due to accumulation of advanced glycation end products, making it more brittle than normal, a predilection for conversion of precursors to adipose cells rather than osteoblasts, and the sequelae of diabetes that increase the risk of falls and injury.

Severe bone loss occurs in quadriplegic and paraplegic individuals below the level of the injury. The combination of loss of muscle function and innervation of both muscle and bone contributes to failure to recover mobility, which leads to a high fracture risk in those attempting to pursue athletic activities despite their primary diagnosis (e.g., wheelchair athletes). Bone loss also follows a stroke and is again dependent on the severity of the paralysis. The risk of fracture can be predicted by the FRAX (Fracture Risk Assessment) score and seems highest in the first year after stroke. The increasing prevalence of transgender and gender nonconforming individuals has prompted a guideline for evaluation of bone density in that population by the International Society of Clinical Densitometry published in 2019.

MEDICATIONS

Many medications used in clinical practice have potentially detrimental effects on the skeleton (Table 423-3). *Glucocorticoids* are the most common cause of medication-induced osteoporosis. It is often not possible to determine the extent to which osteoporosis is related to glucocorticoid treatment or to other factors, as the effects of medication are superimposed on the effects of the primary disease, which may be associated with bone loss (e.g., rheumatoid arthritis). Excessive doses of thyroid hormone can accelerate bone remodeling and result in bone loss.

TABLE 423-3 Drugs Associated with an Increased Risk of Generalized Osteoporosis in Adults

Glucocorticoids	Excessive thyroxine
Cyclosporine	Aluminum
Cytotoxic drugs	Gonadotropin-releasing hormone agonists
Anticonvulsants	Heparin
Aromatase inhibitors	Lithium
Selective serotonin reuptake inhibitors	Protein pump inhibitors
	Thiazolidinediones
	Androgen deprivation therapies

Other medications have less detrimental effects on the skeleton than pharmacologic doses of glucocorticoids. *Anticonvulsants* are thought to increase the risk of osteoporosis, although many affected individuals have concomitant insufficiency of $1,25(OH)_2D$, as some anticonvulsants induce the cytochrome P450 system and vitamin D metabolism. Patients undergoing transplantation are at high risk for rapid bone loss and fracture not only from glucocorticoids but also from treatment with other *immunosuppressants* such as cyclosporine and tacrolimus (FK506). In addition, these patients often have preexisting metabolic abnormalities such as hepatic or renal failure predisposing to bone loss. Long-term use of proton pump inhibitors and selective serotonin reuptake inhibitors has been shown to be associated with a higher risk of fracture in observational studies. Given their frequent long-term use, their skeletal effects are important from a public health perspective and for individual fracture risk.

Aromatase inhibitors, which potently block the aromatase enzyme that converts androgens and other adrenal precursors to estrogen, reduce circulating postmenopausal estrogen levels severely. These agents, used to treat breast cancer, also cause declines in bone density and rapidly increase fracture risk. Androgen deprivation therapy, used to treat men with prostate cancer, also results in rapid bone loss and increased fracture risk. The diabetes medications, thiazolidinediones and insulin, also increase the risk of fracture; however, metformin and glucagon-like peptide-1 receptor agonists decrease risk. It is difficult in some cases to separate the risk accrued by the underlying disease from that attributable to the medication. For example, both depression and diabetes are risk factors for fracture by themselves.

SMOKING

Smoking produces detrimental effects on bone mass mediated directly by toxic effects on osteoblasts or indirectly by modifying estrogen metabolism. On average, cigarette smokers reach menopause 1–2 years earlier than the general population. Cigarette smoking also results in intercurrent respiratory and other illnesses, frailty, decreased exercise, poor nutrition, and the need for additional medications (e.g., glucocorticoids for lung disease) that can all increase fracture risk.

OTHER POTENTIAL FACTORS

In the past few years, many potential risk factors for fracture have been identified. These include excessive alcohol intake and other drugs of abuse, pollution, use of triclosan, chronic obstructive pulmonary disease, excess vitamin B, and hormonal therapies utilized among the transgender population.

DIAGNOSIS

MEASUREMENT OF BONE MASS

Several noninvasive techniques are available for estimating skeletal mass or BMD. They include DXA, quantitative computed tomography (QCT), peripheral QCT, HR-pQCT, and ultrasound. DXA is a highly accurate x-ray technique that has become the standard for measuring bone density. Though it can be used for measurement in any skeletal site, clinical determinations usually are made of the lumbar spine and hip. DXA also can be used to measure the radius, total body bone mass, and body composition (lean mass, fat mass). Two x-ray energies are used to estimate mineralized tissue, allowing for correction for attenuation through soft tissue. The mineral content is divided by bone area, which partially corrects for body and bone size. However, this correction is only partial since DXA is a two-dimensional scanning technique and cannot estimate the depth of the bone. Thus, small slim people tend to have lower than average BMD, a feature that is important in interpreting BMD measurements. Bone spurs, which are common in osteoarthritis (spinal spondylosis), tend to falsely increase

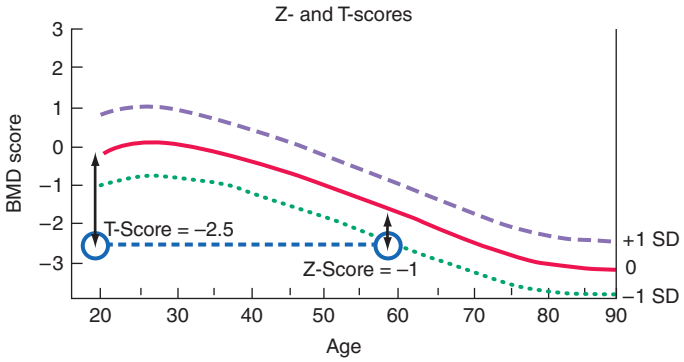

FIGURE 423-6 Relationship between Z-scores and T-scores in a 60-year-old woman. BMD, bone mineral density; SD, standard deviation.

bone density, mostly of the spine, which is a particular problem in measuring spine BMD in older individuals. Because DXA measurement devices are provided by different manufacturers, the output varies in absolute terms. Absolute bone density results are related to "normal" values by using T-scores (a T-score of 1 equals 1 SD), which compare individual results to those in a young adult population (age 30 years) matched for race and sex. The mean value is given a score of zero and the range is +2.5 to −2.5 (i.e., 2.5 SDs above or below the mean). Z-scores (also SDs) compare individual results to those of an age- and sex-matched reference population. Thus, a 60-year-old woman with a Z-score of −1 (1 SD below mean for age) has a T-score of −2.5 (2.5 SDs below mean for a young adult population) **(Fig. 423-6)**. A T-score ≤−2.5 in the lumbar spine, femoral neck, or total hip has been defined as osteoporosis, whereas a T-score of −1.0 to −2.5 has been defined as low bone density or osteopenia. Although the outputs from different instruments and, more importantly, different manufacturers correlate well, different machines used over time may show changes in BMD that may be attributed to biological changes or simply the result of differences between machines. This is particularly true with measurements of the femoral neck. Consequently, it is recommended that serial measurements be performed on the same machine and preferably by the same technician.

As noted above, since >50% of fractures occur in individuals with osteopenia (e.g., a T-score between −1.0 and −2.5), it is important to consider absolute fracture risk in addition to BMD. The most commonly used absolute fracture risk assessment tool is FRAX, which includes age, sex, height, weight, fracture history, hip fracture in a parent, glucocorticoid use, rheumatoid arthritis, and other secondary causes, with or without bone density of the femoral neck. The program calculates the estimated risk over a 10-year time frame for major osteoporosis-related fractures (clinical spine, hip, wrist, and proximal humerus) and for hip fracture.

Computed tomography (CT) can also be used to measure the spine and hip but is rarely used clinically, in part because the radiation exposure and cost are both much higher than with DXA. HR-pQCT measures cortical and trabecular bone variables in the forearm or tibia and provides information on skeletal microarchitecture noninvasively. Magnetic resonance imaging (MRI) can also be used to obtain some architectural information on the forearm and perhaps the hip but is primarily a research tool.

Ultrasound can be used to measure bone mass by calculating the attenuation of the signal as it passes through bone or the speed with which it traverses the bone. Although the ultrasound technique was purported to assess properties of bone other than mass (e.g., quality), this has not been confirmed. Because of its relatively low cost and mobility, ultrasound bone density measurement is amenable for use as a screening tool.

All these techniques for measuring BMD have been approved by the U.S. Food and Drug Administration (FDA) based on their capacity to predict fracture risk. The total hip is the preferred site of measurement, since it allows the best prediction of hip fracture risk. When hip measurements are performed by DXA, the spine is usually measured at the same time. In younger individuals such as perimenopausal or early postmenopausal women, spine measurements may be more sensitive. When the spine or hip is not measurable due to severe degenerative spine disease or scoliosis, or prior spine or hip surgery, wrist BMD is often measured.

TABLE 423-4 Indications for Bone Mineral Density Testing

- Women aged ≥65 and men aged ≥70; regardless of clinical risk factors
- Younger postmenopausal women, women in the menopausal transition, and men aged from 50 to 69 with clinical risk factors for fracture
- Adults who have a fracture at or after age 50
- Adults with a condition (e.g., rheumatoid arthritis) or taking a medication (e.g., glucocorticoids at a daily dose >5 mg prednisone or equivalent for >3 months associated with low bone mass or bone loss

INDICATIONS FOR BONE MASS MEASUREMENT

Several clinical guidelines have been developed for the use of bone densitometry in clinical practice **(Table 423-4)**. The National Osteoporosis Foundation (NOF) guidelines recommend bone mass measurements in postmenopausal women who have one or more risk factors for osteoporosis in addition to age, sex, and estrogen deficiency. The guidelines further recommend that bone mass measurement be considered in *all* women by age 65, a position ratified by the U.S. Preventive Health Services Task Force. In males, the use of bone density determination is not recommended until the age of 70 years in the absence of multiple risk factors or the occurrence of a fragility fracture.

The FRAX score incorporates clinical risk factors (age, prior fracture, family history of hip fracture, low body weight, tobacco use, excessive alcohol use, glucocorticoid use, and rheumatoid arthritis) with or without BMD to assess the 10-year fracture probabilities for major osteoporotic (hip, clinical spine, wrist, or humerus) and hip fractures. Fracture risk probability calculators are available as part of the report from all DXA machines and available online (*https://www.sheffield.ac.uk/FRAX/*) **(Fig. 423-7)**. In the United States, cost-effective treatment thresholds occur if the 10-year major osteoporotic fracture risk from FRAX is ≥20% and/or the 10-year risk of hip fracture is ≥3%. FRAX is an imperfect tool, as it does not include any assessment of fall risk, and secondary causes are excluded when BMD is entered. It also does not account for glucocorticoid dose or diabetes. Most importantly, it does not increase the absolute fracture risk conferred by a recent fracture versus the lesser risk conferred by a more remote fracture. Moreover, there is no mandate for vertebral fracture diagnosis and no additional fracture probability estimated for patients who have had multiple fragility fractures. Many of these deficiencies are likely to be corrected in the next version of FRAX (FRAX Plus and FRAX 2.0).

VERTEBRAL IMAGING

DXA equipment can also be used to obtain lateral images of the thoracic and lumbar spine, a technique called vertebral fracture assessment (VFA). While not as definitive as a radiograph, it is an excellent screening tool for vertebral abnormality in both women and men. It is an important assessment as the majority of vertebral fractures are asymptomatic (70%). Furthermore, VFA can detect vertebral abnormalities causing height loss or back pain that may be indicative of an undiagnosed vertebral fracture.

Because most vertebral fractures are asymptomatic, the diagnosis of vertebral fracture is rarely made when they first occur. However, vertebral fractures, whether symptomatic or asymptomatic, are associated with the same clinical sequelae, so it is critical they are identified. Vertebral fracture prevalence in the United States based on the National Health and Nutrition Evaluation Studies (NHANES) population appears to be 20% in the 1980s, when the strictest criteria for diagnosis are utilized. It is recommended that women aged 65 years or older and men aged 70 years or older undergo vertebral imaging if there is a T-score is ≤−1.5 at the spine, hip, or femoral neck. Vertebral imaging is also recommended for women by the age of 70 years and men by the age of 80 years if a T-score is <−1.0. For younger individuals, vertebral imaging is recommended for those with a fragility fracture, height loss, or glucocorticoid use. **(See Table 423-5.)**

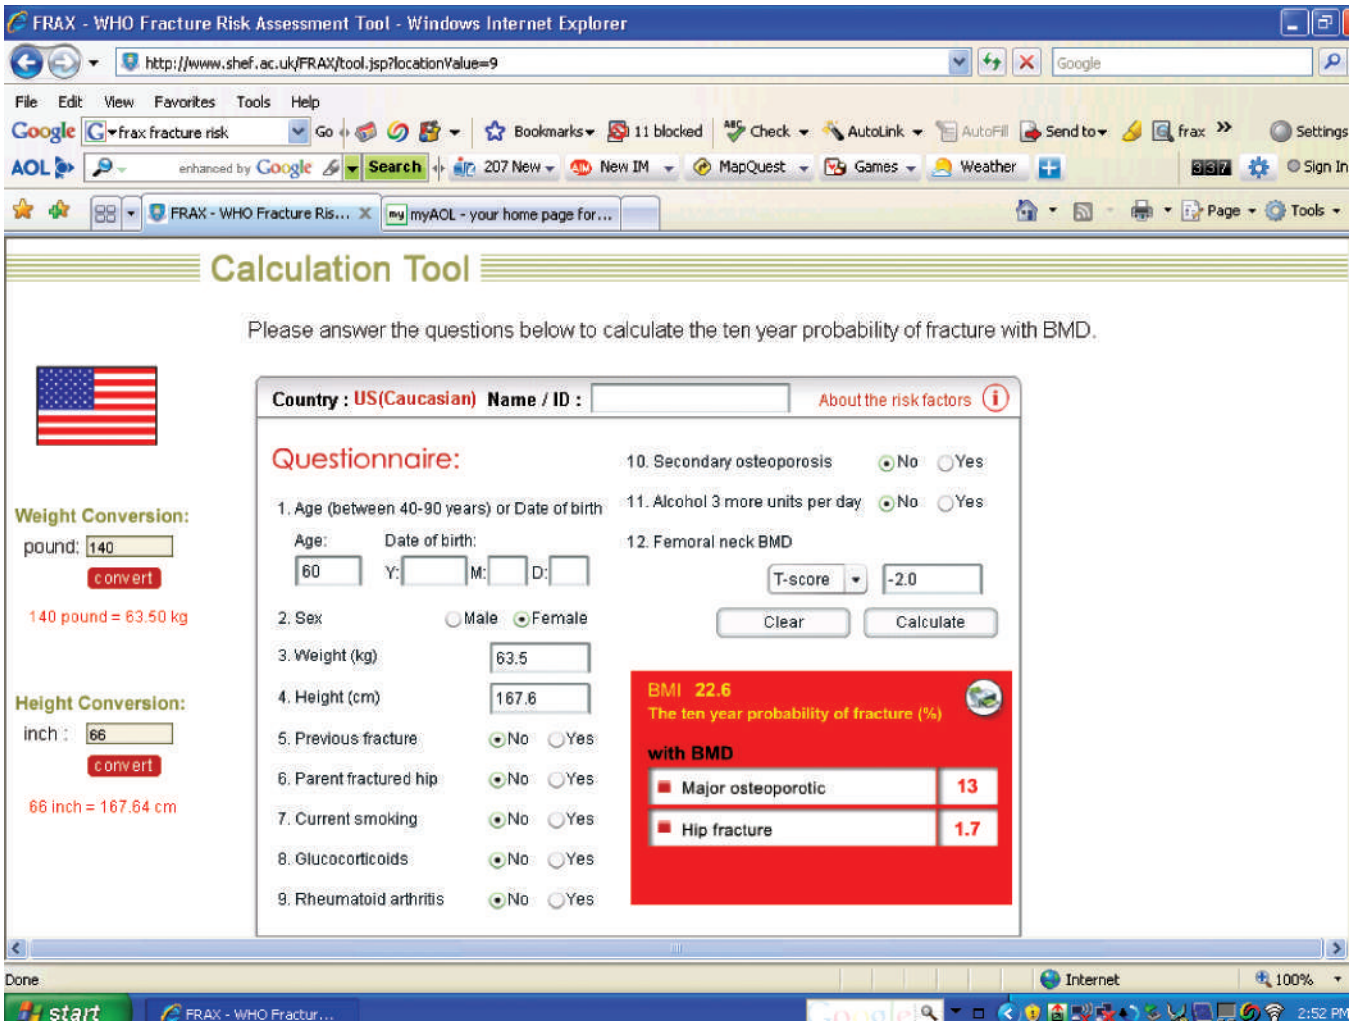

FIGURE 423-7 FRAX calculation tool. When the answers to the indicated questions are filled in, the calculator can be used to assess the 10-year probability of fracture. The calculator (available online at *http://www.shef.ac.uk/FRAX/tool.jsp?locationValue=9*) also can risk adjust for various ethnic groups.

APPROACH TO THE PATIENT

Osteoporosis

The development of osteoporosis is a gradual process occurring under a variety of genetic and environmental influences throughout life. Just prior to and at the time of puberty are important times to affect accrual of peak bone mass while the perimenopause and menopause in women are important times to reduce bone loss. Recognition of these influences allows intervention at several points, although the type of intervention depends on a careful evaluation of each individual patient.

TABLE 423-5 Indications for Vertebral Testing

Consider vertebral imaging tests for the following individuals[a]

- All women aged ≥70 and all men aged ≥80 if bone mineral density (BMD) T-score at the spine, total hip, or femoral neck is <1.0
- Women aged from 65 to 69 and men aged from 70 to 79 if BMD T-score at the spine, total hip, or femoral neck is <1.5
- Postmenopausal women and men aged ≥50 with specific risk factors:
  - Low-trauma fracture during adulthood (aged ≥50)
  - Historical height loss of ≥1.5 in. (4 cm)[b]
  - Prospective height loss of ≥0.8 in. (2 cm)[c]
  - Recent or ongoing long-term glucocorticoid treatment

[a]If bone density testing is not available, vertebral imaging may be considered based on age alone. [b]Current height compared to peak height during childhood. [c]Cumulative height loss measured during interval medical assessment.

The menopausal transition affects all women by their late 50s and represents an opportunity to initiate a discussion about bone loss, the role of estrogen loss, and other clinical risk factors. Assessment of fracture risk with FRAX (with or without bone density) provides a 10-year estimate of hip and major osteoporosis-related fracture risk and opens the discussion about preventive steps including, if required, the use of medication. If risk is low, then nutrition and resistance training exercise are the focus. If menopausal symptoms are prominent and estrogen intervention is needed, then the added protection against bone loss and fragility fractures should be emphasized.

Among older women with a fracture, an evaluation of skeletal status including bone density testing should proceed. In this case, any fracture, whether traumatic or not, should trigger this assessment. Although osteoporosis is associated with a risk of fragility fracture, individuals with osteoporosis are also more likely to experience traumatic fractures, and such individuals should not be excluded from osteoporosis evaluation simply because of the level of trauma. This concept, while obvious and evidence-based, still needs emphasis with individual patients, physicians, and payors.

Patients who present with hip or spine fractures by definition have osteoporosis and will require treatment for both the fracture itself and the underlying skeletal disorder. Other long bone fractures (e.g., distal radius) are triggers for evaluation of the skeleton upon which treatment decisions can be based.

In all individuals presenting with a fracture as a result of a fall, fall prevention strategies including balance exercises are an important adjunct to other lifestyle and nutritional interventions.

ROUTINE LABORATORY EVALUATION

There is no established algorithm for the evaluation of women or men who present with osteoporosis. A general evaluation that includes complete blood count, serum and 24-h urine calcium, and renal and liver function tests is useful for identifying selected secondary causes of low bone mass, particularly for those with fractures or unexpectedly low Z-scores. An elevated serum calcium level suggests hyperparathyroidism or malignancy, whereas a reduced serum calcium level may reflect malnutrition or a malabsorption disease, such as celiac disease. In the presence of hypercalcemia, a serum PTH level differentiates between hyperparathyroidism (PTH↑) and malignancy (PTH↓), and a high PTHrP level can help document the presence of humoral hypercalcemia of malignancy **(Chap. 422)**. A low urine calcium (<50 mg/24 h) suggests malnutrition, or malabsorption; a high urine calcium (>300 mg/24 h) during normal calcium intake (excluding calcium supplements for at least a week before the urine collection) is indicative of hypercalciuria. Hypercalciuria occurs primarily in three situations: (1) a renal calcium leak; more common in males with osteoporosis; (2) absorptive hypercalciuria, which can be idiopathic or associated with increased $1,25(OH)_2D$ in granulomatous disease; or (3) hematologic malignancies or conditions associated with excessive bone turnover such as Paget's disease, hyperparathyroidism, hyperthyroidism, and iron chelation therapy (desferoxamine) for thalassemia. Renal hypercalciuria is treated with thiazide diuretics, which lower urine calcium and help improve calcium economy. In this setting, thiazides alone can improve bone mass and possibly reduce risk of fracture. They might also reduce renal stone risk.

Individuals who have fragility fractures or bone density in the osteoporotic range should have a measurement of serum 25(OH) D level since serum 25(OH)D levels <30 ng/mL (vitamin D insufficiency) are common, particularly in older adults. Hyperthyroidism should be evaluated by measuring thyroid-stimulating hormone (TSH).

When there is clinical suspicion of Cushing's syndrome, 24-h urinary free cortisol levels or a fasting serum cortisol should be measured after taking 1 mg dexamethasone at midnight. When bowel disease, malabsorption, or malnutrition is suspected, serum albumin, cholesterol, and a complete blood count should be checked. Asymptomatic malabsorption may be heralded by anemia (macrocytic—vitamin B_{12} or folate deficiency; microcytic—iron deficiency) or low serum cholesterol or urinary calcium levels. If these or other features suggest malabsorption, further evaluation is required. Asymptomatic celiac disease with selective malabsorption is being found with increasing frequency; the diagnosis can be made by testing for transglutaminase IgA antibodies but may require confirmation by endoscopic biopsy. A trial of a gluten-free diet can also be confirmatory **(Chap. 336)**. When osteoporosis is found associated with symptoms of rash, multiple allergies, diarrhea, or flushing, mastocytosis should be considered and excluded by using 24-h urine histamine collection or serum tryptase.

Myeloma can masquerade as generalized osteoporosis, although it more commonly presents with bone pain and characteristic "punched-out" lesions on radiography. Serum and urine electrophoresis and/or evaluation for serum free light chains in serum are required to exclude this diagnosis. More commonly, a monoclonal gammopathy of undetermined significance (MGUS) is found, and the patient is subsequently monitored to ensure that this is not an incipient myeloma. MGUS itself may be associated with an increased risk of osteoporosis. A bone marrow biopsy may be required to rule out myeloma (in patients with equivocal electrophoretic results) and can be used to exclude mastocytosis, leukemia, and other marrow infiltrative disorders, such as Gaucher's disease. Testosterone levels should be checked in men with osteoporosis.

An important cause of fracture among the aging population is diabetes, both type 1 and type 2. Patients with diabetes appear, at any given bone density, to be at higher risk of fracture than nondiabetics. The reasons include the effects on muscle and nerve that increase the risk of falls, but it can also be due to an underlying skeletal fragility as part of the metabolic consequences of diabetes with deposition of advanced glycation end products in bone.

BONE BIOPSY

Double tetracycline labeling of the skeleton allows determination of the rate of remodeling as well as evaluation for other metabolic bone diseases. However, the current use of BMD, in combination with hormonal evaluation and biochemical markers of bone remodeling, has largely replaced the clinical use of bone biopsy, although it remains an important tool in the diagnosis of chronic kidney disease–mineral bone disease (CKD-MBD), in evaluating the mechanism of action of osteoporosis pharmacology and in clinical research.

BIOCHEMICAL MARKERS

Several biochemical tests are available that provide an index of the overall rate of bone remodeling **(Table 423-6)**. Biochemical markers usually are characterized as those related primarily to *bone formation* or *bone resorption*. These tests measure the overall state of bone remodeling at a single point in time. Clinical use of these tests has been hampered by biologic variability (in part related to circadian rhythm and food consumption) as well as analytic variability, although the latter has improved.

For the most part, remodeling markers do not predict rates of bone loss well enough in individuals to make accurate assessment of potential future changes in bone density. However, they do provide adjunct information that assists in both evaluation of the patient and in assessment of treatment response. Markers of bone resorption may help in the prediction of fracture risk, independently of bone density, particularly in older individuals. In women ≥65 years, when bone density results are greater than the usual treatment thresholds noted above, a high level of bone resorption should prompt consideration of treatment. However, the primary use of biochemical markers is for monitoring treatment response. With the introduction of antiresorptive drugs, bone remodeling declines rapidly, with the fall in resorption occurring earlier than the fall in formation. Inhibition of bone resorption is maximal within 3 months or so. Thus, measurement of bone resorption (serum C-terminal telopeptide measured in a fasting specimen at 9 A.M. is the preferred marker) before initiating therapy and 3–6 months after starting therapy provides an earlier estimate of patient response than does bone densitometry. A decline in bone resorption markers can be ascertained after treatment with bisphosphonates, denosumab, or estrogen; this effect is less marked after treatment with weaker agents such as raloxifene or calcitonin. Bone turnover markers are also useful in monitoring the effects of anabolic drugs [hPTH(1–34) or teriparatide or romosozumab], which both rapidly increases bone formation (P1NP is the most sensitive, but osteocalcin is also a very good bone remodeling marker), while teriparatide increases bone resorption and romosozumab decreases bone resorption. The recent suggestion of "drug holidays" (see below) has opened another use for biochemical markers, allowing evaluation of the offset of effect of drugs such as oral and intravenous bisphosphonates. Drug holidays should be avoided for denosumab or anabolic drugs because of a more rapid offset effect observed with these drugs.

TREATMENT

Osteoporosis

MANAGEMENT OF PATIENTS WITH FRACTURES

Treatment of a patient with osteoporosis frequently involves management of acute fractures as well as treatment of the underlying disease. Hip fractures almost always require surgical repair. Depending on the location and severity of the fracture, condition of the neighboring joint, and general status of the patient, procedures may include open reduction and internal fixation with pins and plates, hemiarthroplasties, and total arthroplasties. These surgical procedures are followed by intense rehabilitation to return patients to their prefracture functional level. Long bone fractures often require either external or internal fixation. Other fractures (e.g., vertebral, rib, and pelvic fractures) can often be managed with supportive care, requiring no specific orthopedic treatment.

Only ~30% of vertebral compression fractures present with sudden-onset back pain. For acutely symptomatic fractures, treatment with analgesics is required, including nonsteroidal anti-inflammatory agents and/or acetaminophen, sometimes with the addition of a narcotic agent. (A few small, randomized clinical trials suggest that calcitonin may reduce pain related to acute vertebral compression fracture). Vertebral augmentation with the percutaneous injection of artificial cement (polymethylmethacrylate) into the vertebral body (vertebroplasty or kyphoplasty) may offer significant pain relief in a subset of patients with continuing pain; however, systematic reviews of controlled trials of both procedures have provided doubt about their efficacy. Furthermore, risks include acute extravasation of cement outside of the vertebral body with neurologic impairment and possibly an increased risk of vertebral fracture in adjacent vertebrae due to increased rigidity of the treated vertebral body. Short periods of bed rest may be helpful for pain management, but in general, early mobilization is recommended as it helps prevent further bone loss associated with immobilization. Occasionally, use of a soft elastic-style back brace may facilitate earlier mobilization. Muscle spasms often occur with acute compression fractures and can be treated with muscle relaxants and heat treatments. Severe pain usually resolves within 6–10 weeks. More chronic severe pain might suggest the possibility of multiple myeloma or other underlying bone conditions.

Vertebral fractures cause height loss because of the loss of vertebral body height during compression of the vertebral body. These fractures can produce a kyphosis, particularly when wedge shaped, or just loss of thoracic height. Chronic pain following vertebral fracture is probably not bony in origin; instead, it is related to abnormal strain on muscles, ligaments, and tendons and to secondary facet-joint arthritis associated with alterations in thoracic and/or abdominal shape. Chronic pain may also be the result of ribs sitting right on top of the iliac crest bones, particularly in patients who have had multiple vertebral compression fractures. Chronic pain is difficult to treat effectively and may require analgesics, sometimes including narcotic analgesics with the attendant risk of addiction. Frequent intermittent rest in a supine or semireclining position is often required to allow the soft tissues, which are under tension, to relax. Back and core-strengthening exercises may be beneficial. Heat treatments help relax muscles and reduce the muscular component of discomfort. Various physical modalities, such as ultrasound and transcutaneous nerve stimulation, may be beneficial in some patients. Pain also occurs in the neck region, not as a result of compression fractures (which almost never occur in the cervical spine as a result of osteoporosis) but because of chronic strain associated with trying to elevate the head in a person with a significant thoracic kyphosis.

Multiple vertebral fractures often are associated with often neglected psychological symptoms. Changes in body configuration and back pain can lead to marked loss of self-image and a secondary depression. Altered balance, precipitated by the kyphosis and the anterior movement of the body's center of gravity, leads to a fear of falling, a consequent tendency to remain indoors, and the onset of social isolation. These symptoms sometimes can be alleviated by family support and/or psychotherapy. Medication may be necessary when depressive features are present.

A MISSED OPPORTUNITY

Multiple studies show most patients presenting with fractures after age 50 years (even fractures traditionally linked to osteoporosis) are not screened or treated for osteoporosis. Only <25% of fracture patients receive follow-up care. Recently, several studies have demonstrated the effectiveness of a relatively simple and inexpensive program that reduces the risk of subsequent fractures. In the Kaiser system, it is estimated that a 20% decline in hip fracture occurrence was seen with the introduction of a fracture liaison service. This approach has also been successful in other non-U.S. health systems, including the United Kingdom and New Zealand. This involves a health care professional (usually a nurse or physician's assistant) whose job is to educate patients and coordinate evaluation and osteoporosis treatment as patients move through the emergency room, inpatient care in an acute care hospital, rehabilitation hospital care, and/or orthopedic practice to outpatient management. If the Kaiser experience can be repeated, there would not only be significant savings of health care dollars but also a dramatic drop in hip fracture incidence and a marked improvement in morbidity and mortality among the aging population. Initiatives to obtain Medicare funding for fracture liaison services in the United States are continuing but have not yet been successful.

MANAGEMENT OF THE UNDERLYING DISEASE

Risk Factor Reduction After risk assessment, patients should be thoroughly educated to reduce the impact of modifiable risk factors associated with bone loss and falling. Medications should be reviewed to ensure that all are necessary and taken at the lowest required dose. Glucocorticoid medication, if present, should be evaluated to determine that it is truly indicated and is being given in doses as low as possible. For those on thyroid hormone replacement, TSH testing should be performed to determine that an excessive dose is not being used, as iatrogenic thyrotoxicosis can be associated with increased bone loss. In patients who smoke, efforts should be made to facilitate smoking cessation. Reducing risk factors for falling also includes alcohol abuse treatment and a review of the medical regimen for any drugs that might be associated with orthostatic hypotension and/or sedation, including hypnotics, antipsychotics, and anxiolytics. If nocturia occurs, the frequency should be reduced, if possible (e.g., by decreasing or modifying diuretic use), as arising in the middle of sleep is a common precipitant of a fall. Patients should be instructed about environmental safety, such as eliminating exposed wires, curtain strings, slippery rugs, and mobile tables. Avoiding stocking feet on wood floors, checking carpet condition (particularly on stairs), and providing good light in paths to bathrooms and outside the home are important preventive measures. Treatment for impaired vision is recommended, particularly a problem with depth perception, which is specifically associated with increased falling risk. Patients with neurologic impairment (e.g., stroke, Parkinson's disease, Alzheimer's disease, multiple sclerosis) are particularly at risk of falling and require specialized supervision and care. In patients with risk factors for falls, especially those who live alone or spend significant time alone, medical alert systems should be prescribed.

Nutritional Recommendations • **Calcium** A large body of data indicates that less than optimal calcium intake results in bone loss. Consequently, an adequate intake suppresses bone turnover. Recommended intakes from an Institute of Medicine report are shown in **Table 423-7**. The NHANES have consistently documented that average calcium intakes fall considerably short of these recommendations. The preferred source of calcium is diet, but many patients require calcium supplementation to bring intake to ~1000 mg/d. Calcium supplement doses of ≤600 mg/d are likely to be safe. Best sources of

TABLE 423-7 Adequate Calcium Intake	
LIFE STAGE GROUP	ESTIMATED ADEQUATE DAILY CALCIUM INTAKE, mg/d
Young children (1–3 years)	500
Older children (4–8 years)	800
Adolescents and young adults (9–18 years)	1300
Men and women (19–50 years)	1000
Men and women (51 years and older)	1200

Note: Pregnancy and lactation needs are the same as for nonpregnant women (e.g., 1300 mg/d for adolescents/young adults and 1000 mg/d for those ≥19 years old).

Source: Data from Institute of Medicine. Dietary Reference Intakes for Calcium, Phosphorus, Magnesium, Vitamin D, and Fluoride. Washington, DC: The National Academies Press; 1997.

calcium include dairy products (milk, yogurt, and cheese), nondairy milks (almond, rice, soy), nuts, and fortified foods such as certain cereals, waffles, snacks, juices, and crackers. Some of these fortified foods contain as much calcium per serving as milk. Various vegetables and fruits, such as kale, broccoli, and dried figs, contain reasonably high calcium content, although some of it may not be fully bioavailable. Calcium intake calculators are available at *NOF.org* or *NYSOPEP.org* and will give a rough idea of total calcium intake.

If calcium supplements are required, they should be taken in doses sufficient to bring total intake to the required level (~1000 mg/d). Doses of supplements should be ≤600 mg per single dose, as the calcium absorption fraction decreases at higher doses. Calcium supplements should be calculated on the basis of the elemental calcium content of the supplement, not the weight of the calcium salt **(Table 423-8)**. Calcium supplements containing carbonate are best taken with food since they require acid for solubility. Calcium citrate supplements can be taken at any time, although taking calcium supplements in the evening may reduce nocturnal increases in PTH.

Several controlled clinical trials of calcium, mostly with accompanying vitamin D, have confirmed reductions in clinical fractures, including fractures of the hip (~20–30% risk reduction), particularly in elderly individuals who are likely to be dietarily deficient. The majority of recent studies of pharmacologic agents have been conducted in the context of calcium replacement (± vitamin D). Thus, it is standard practice to ensure an adequate calcium and vitamin D intake in patients with osteoporosis whether they are receiving additional pharmacologic therapy or not. A systematic review confirmed a greater BMD response to antiresorptive therapy when calcium intake was adequate.

Although side effects from supplemental calcium are minimal (eructation and constipation mostly with carbonate salts), individuals with a history of kidney stones should have a 24-h urine calcium determination before starting increased calcium to avoid exacerbating hypercalciuria. A recent analysis of published data has suggested that high intakes of calcium from supplements are associated with an increase in the risk of renal stones, calcification in arteries, and potentially an increased risk of heart disease and stroke. This is controversial, with recent meta-analyses showing no effect of calcium supplements on cardiovascular events. Daily doses of <700 mg appear safe. However, since high calcium intakes also increase the risk of renal stones and confer no extra benefit to the skeleton, the recommendation that total intakes should be between 1000 and 1500 mg/d seems reasonable.

TABLE 423-8 Elemental Calcium Content of Various Oral Calcium Preparations	
CALCIUM PREPARATION	ELEMENTAL CALCIUM CONTENT
Calcium citrate	60 mg/300 mg
Calcium lactate	80 mg/600 mg
Calcium gluconate	40 mg/500 mg
Calcium carbonate	400 mg/g
Calcium carbonate + 5 μg vitamin D_2 (OsCal 250)	250 mg/tablet
Calcium carbonate (Tums 500)	500 mg/tablet

Vitamin D Diet alone is inadequate to maintain vitamin D sufficiency (serum 25[OH]D consistently >75 μmol/L [30 ng/mL]). Vitamin D is synthesized from a precursor in the skin under the influence of heat and ultraviolet light **(Chap. 421)**. Production is blocked by sunscreen and sun avoidance. However, large segments of the population do not obtain sufficient vitamin D from either skin production or dietary sources. Since vitamin D supplementation at doses that would achieve these serum levels is safe and inexpensive, the National Academy of Medicine recommends daily intakes of 200 IU for adults <50 years of age, 400 IU for those 50–70 years, and 600 IU for those >70 years (based on obtaining a serum level of 20 ng/mL, lower than the level recommended by most other guidelines). Multivitamin tablets usually contain 400 IU, and many calcium supplements also contain vitamin D. Some data suggest that higher doses (≥1000 IU) may be required, particularly in the obese, elderly, and chronically ill. A daily intake of up to 4000 IU/d is safe. For those with osteoporosis or those at risk, 1000–2000 IU/d can usually maintain serum 25(OH)D above 30 ng/mL. Recent large randomized controlled trials show vitamin D supplementation by itself at doses equivalent to 2000 IU/d does not appear to reduce fracture risk in older individuals with normal baseline vitamin D levels. However, the combination of adequate calcium intake and vitamin D does decrease fracture risk in those with vitamin D deficiency, particularly the institutionalized elderly population. Although low vitamin D levels appear associated with more serious outcomes in response to COVID-19, trials of vitamin D supplementation have been inconsistent and largely negative.

Other Nutrients Other nutrients such as salt, high animal protein intakes, and caffeine may have modest effects on calcium excretion or absorption. Adequate vitamin K status is required for optimal carboxylation of osteocalcin. States in which vitamin K nutrition or metabolism is impaired, such as with long-term warfarin therapy, have been associated with reduced bone mass. However, a recent trial showed no benefit of vitamin K_2 on BMD when added to calcium and vitamin D supplementation. Research concerning cola-based soda beverage intake is controversial but suggests a possible link to reduced bone mass through factors that appear independent of caffeine.

Magnesium is abundant in foods, and magnesium deficiency is quite rare in the absence of a serious chronic disease. Magnesium supplementation may be warranted in patients with inflammatory bowel disease, celiac disease, chemotherapy, severe diarrhea, malnutrition, or alcoholism. Dietary phytoestrogens, which are derived primarily from soy products and legumes (e.g., garbanzo beans [chickpeas] and lentils), exert some estrogenic activity but are insufficiently potent to justify their use in place of a pharmacologic agent in the treatment of osteoporosis.

Patients with hip fractures are often frail and relatively malnourished. Some data suggest an improved outcome in such patients when they are provided calorie and protein supplementation. Excessive protein intake can increase renal calcium excretion, but this can be corrected by an adequate calcium intake.

Exercise Exercise in young individuals prior to and at the time of puberty increases the likelihood that they will attain the maximal genetically determined peak bone mass. Meta-analyses of studies performed in postmenopausal women indicate that progressive high-intensity resistance training results in small gains in bone mass of 3–4%. However, this beneficial effect wanes if exercise is discontinued. Most of the studies are relatively short term, and a more substantial effect on bone mass is likely if exercise is continued over a long period. Exercise also has beneficial effects on neuromuscular function, and it improves coordination, balance, and strength,

thereby reducing the risk of falling. A walking program is a practical way to start. Other activities such as dancing, racquet sports, cross-country skiing, and progressive high-intensity resistance training are also recommended, depending on the patient's personal preference and general condition. Even women who cannot walk benefit from swimming or water exercises, not so much for the effects on bone, which are quite minimal, but because of effects on muscle. Exercise habits should be consistent, optimally at least three times a week. For most patients, participation in exercise regimens that the patient enjoys is recommended in order to improve adherence. We also emphasize the importance of making exercise a social activity, again to improve adherence. Many individuals experience a fear of falling that can lead to social isolation and depression. Group exercise can help to alleviate this problem by providing a sense of social connectivity among participants.

Tai chi is a traditional Chinese martial art that utilizes a series of gentle, flowing movements to promote and maintain flexibility, balance, endurance, proprioception, and strength. It involves constant movement through all three spatial dimensions. As a three-dimensional exercise, tai chi may be incorporated as part of balance training program for individuals with osteoporosis. Tai chi is generally considered a safe activity. The evidence for fall prevention in tai chi has been evaluated in randomized controlled trials, and systematic reviews indicate tai chi can significantly reduce the risk of falls in older adults, particularly when it is practiced with increased frequency.

It is recommended that individuals with osteoporosis or osteoporotic vertebral fractures participate in exercise programs that involve both high-intensity progressive resistance and balance training. Slow, controlled movements are recommended in order to avoid injuries. Exercise modifications and avoidance of certain postures (such as spinal flexion) may be advised. Caution should be taken to avoid activities that can lead to potential fractures, such as performing activities on slippery surfaces, or twisting or bending the spine quickly while transitioning between different positions. Precautions should be taken to avoid injury when exercising with loads and performing exercises that challenge balance. For individuals with osteoporosis who have a high risk for fracture, vertebral fractures, sedentary lifestyle, or comorbid conditions that impact exercise tolerance, consultation with physical therapists to learn safe exercise programs is recommended.

PHARMACOLOGIC TREATMENT OF OSTEOPOROSIS

Several international osteoporosis management guidelines have been published. They recommend patients with fractures of the hip and spine should be evaluated for treatment. Patients with minimal trauma fractures in the setting of a BMD in the osteopenia or osteoporosis range should be treated with pharmacologic agents. Most guidelines also suggest that patients be considered for treatment when BMD T-score is ≤–2.5, a level consistent with the diagnosis of osteoporosis. Treatment should also be considered in postmenopausal women with a minimal trauma fracture or multiple risk factors even if BMD is not in the osteoporosis range. Treatment thresholds depend on cost-effectiveness analyses but, in the United States, are a >20% 10-year major fracture probability and >3% 10-year hip fracture probability. It must be emphasized, however, that as with other diseases, risk assessment is an inexact science when applied to the individual. As a result, patients often accept fracture risks that are higher than the physician might like out of concern for the usually considerably lower but better publicized risks of adverse events of drugs.

Pharmacologic therapies for osteoporosis are either antiresorptive or anabolic. The antiresorptive agents include medications that have broad effects such as hormone/estrogen therapy and selective estrogen receptor modulators (SERMS) as well as specific agents for osteoporosis treatment (bisphosphonates, denosumab, and calcitonin). The anabolic agents are teriparatide, abaloparatide, and romosozumab. Denosumab allows bone formation to continue, and thus, there is an increase in bone density beyond that occurring with agents that inhibit resorption directly leading to a reduction in bone formation like bisphosphonates.

Antiresorptive Agents • **Estrogens** A large body of clinical trial data indicates that various types of estrogens (conjugated equine estrogens, estradiol, estrone, esterified estrogens, ethinyl estradiol, and mestranol) reduce bone turnover, prevent bone loss, and induce small increases in bone mass of the spine, hip, and total body. The effects of estrogen are seen in women with natural or surgical menopause and in late postmenopausal women with or without established osteoporosis. Estrogens are efficacious when administered orally, transdermally, or by subcutaneous implant. For both oral and transdermal routes of administration, combined estrogen/progestin preparations are now available in many countries, obviating the problem of taking two tablets or using a patch and oral progestin.

For oral estrogens, the standard recommended doses have been 0.3 mg/d for esterified estrogens, 0.625 mg/d for conjugated equine estrogens, and 5 μg/d for ethinyl estradiol. For transdermal estrogen, the commonly used dose supplies 50 μg of estradiol per day, but a lower dose may be appropriate for some individuals. Dose-response data for conjugated equine estrogens indicate that lower doses (0.3 and 0.45 mg/d) are also effective. Doses even lower have also been shown to slow bone loss.

Fracture Data Epidemiologic databases indicate that women who take estrogen replacement have a 50% reduction, on average, of osteoporosis-related fractures, including hip fractures. The beneficial effect of estrogen is greatest among those who start replacement early and continue the treatment; the benefit declines after discontinuation to the extent that there is no residual protective effect against fracture by 10 years after discontinuation. The first clinical trial evaluating fractures as secondary outcomes, the Heart and Estrogen-Progestin Replacement Study (HERS) trial, showed no effect of hormone therapy on hip or other clinical fractures in women with established coronary artery disease. These data made the results of the Women's Health Initiative (WHI) exceedingly important **(Chap. 395)**. The estrogen-progestin arm of the WHI in >16,000 postmenopausal healthy women not selected based on low bone mass indicated that hormone therapy reduces the risk of hip and clinical spine fracture by 34% and that of all clinical fractures by 24%.

A few smaller clinical trials have evaluated spine fracture occurrence as an outcome with estrogen therapy. They have consistently shown that estrogen treatment reduces vertebral fracture incidence.

The WHI has provided a vast amount of data on the multisystemic effects of hormone therapy. Although earlier observational studies suggested that estrogen replacement might reduce heart disease, the WHI showed that combined estrogen-progestin treatment increased risk of fatal and nonfatal myocardial infarction by ~29%, confirming data from the HERS study. Other important relative risks included a 40% increase in stroke, a 100% increase in venous thromboembolic disease, and a 26% increase in risk of breast cancer. Subsequent analyses have confirmed the increased risk of stroke and, in a substudy, showed a twofold increase in dementia. Benefits other than the fracture reductions noted above included a 37% reduction in the risk of colon cancer. These relative risks must be interpreted in light of absolute risk **(Fig. 423-8)**. For example, out of 10,000 women treated with estrogen-progestin for 1 year, there will be 8 excess heart attacks, 8 excess breast cancers, 18 excess venous thromboembolic events, 5 fewer hip fractures, 44 fewer clinical fractures, and 6 fewer colorectal cancers. These numbers must be multiplied by the number of years of hormone treatment. There was no effect of combined hormone treatment on the risk of uterine cancer or total mortality.

It is important to note that these WHI findings apply specifically to hormone treatment in the form of conjugated equine estrogen plus medroxyprogesterone acetate. The relative benefits and risks of unopposed estrogen in women who had hysterectomies vary somewhat. They still show benefits against fracture occurrence

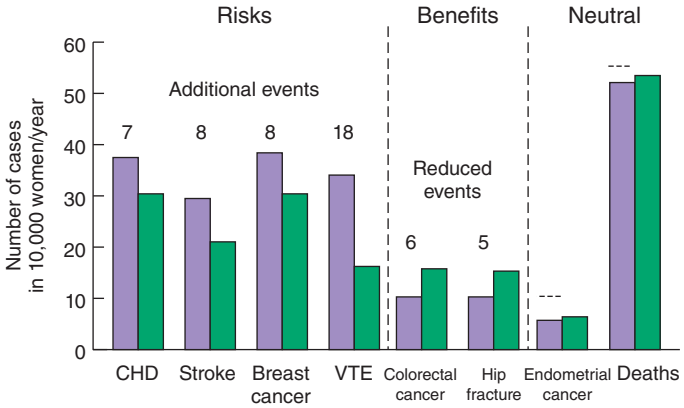

FIGURE 423-8 Effects of hormone therapy on event rates: green, placebo; purple, estrogen and progestin. CHD, coronary heart disease; VTE, venous thromboembolic events. *(Adapted from Women's Health Initiative. WHI HRT Update.)*

and increased risk of venous thrombosis and stroke, similar in magnitude to the risks for combined hormone therapy. In contrast, though, the estrogen-only arm of WHI indicated no increased risk of heart attack and a decreased risk of breast cancer. The data suggest that at least some of the detrimental effects of combined therapy are related to the progestin component. In addition, there is the possibility, suggested by primate data, that the risk accrues mainly to women who have some years of estrogen deficiency before initiating treatment. Therefore, the benefit/risk ratio of hormone therapy is improved if it is commenced before the age of 60 years or within 10 years of menopause. Nonetheless, there has been marked reluctance among women for estrogen therapy/hormone therapy, and the U.S. Preventive Services Task Force has specifically suggested that estrogen therapy/hormone therapy not be used for disease prevention.

Mode of Action Two subtypes of ERs, α and β, have been identified in bone and other tissues. Cells of monocyte lineage express both ERα and ERβ, as do osteoblasts. Estrogen-mediated effects vary with the receptor type. Using ER knockout mouse models, elimination of ERα produces a modest reduction in bone mass, whereas mutation of ERβ has less of an effect on bone. A man with a homozygous mutation of ERα had markedly decreased bone density as well as abnormalities in epiphyseal closure, confirming the important role of ERα in bone biology. The mechanism of estrogen action in bone is an area of active investigation (Fig. 423-5). Although data are conflicting, estrogens may inhibit osteoclasts directly. However, most estrogen (and androgen) effects on bone resorption are mediated indirectly through paracrine factors produced by osteoblasts. These actions include (1) increasing the inhibitor of RANK-L, osteoprotegerin, production by osteoblasts, (2) increasing IGF-I and TGF-β, and (3) suppressing IL-1 (α and β), IL-6, TNF-α, and osteocalcin synthesis. These indirect estrogen actions primarily decrease bone resorption.

Progestins In women with a uterus, daily progestin or cyclical progestins at least 12 days per month are prescribed in combination with estrogens to reduce the risk of uterine cancer. Medroxyprogesterone acetate and norethindrone acetate blunt the high-density lipoprotein response to estrogen, but micronized progesterone does not. Neither medroxyprogesterone acetate nor micronized progesterone appears to have an independent effect on bone; at lower doses of estrogen, norethindrone acetate may have an additive benefit. In breast tissue, progestins may account for the increased risk of breast cancer with combination treatment.

SERMs Two SERMs are used currently in postmenopausal women: raloxifene, which is approved by the FDA for the prevention and treatment of osteoporosis as well as the prevention of breast cancer, and tamoxifen, which is approved for the prevention and treatment of breast cancer. A third SERM, bazedoxifene, is marketed in combination with conjugated estrogen for treatment of menopausal symptoms and prevention of bone loss. Bazedoxifene protects the uterus and breast from effects of estrogen and makes the use of progestin unnecessary.

Tamoxifen reduces bone turnover and bone loss in postmenopausal women compared with placebo groups. These findings support the concept that tamoxifen acts as an estrogenic agent in bone. There are limited data on the effect of tamoxifen on fracture risk, but the Breast Cancer Prevention study indicated a possible reduction in clinical vertebral, hip, and Colles' fractures. Tamoxifen is not FDA approved for prevention or treatment of osteoporosis. The major benefit of tamoxifen is on breast cancer occurrence and recurrence in women with ER-positive tumors. The breast cancer prevention trial indicated that tamoxifen administration over 4–5 years reduced the incidence of new invasive and noninvasive breast cancer by ~45% in women at increased risk of breast cancer. The incidence of ER-positive breast cancers was reduced by 65%. Tamoxifen increases the risk of uterine cancer in postmenopausal women, limiting its use for breast cancer prevention in women at low or moderate risk.

Raloxifene (60 mg/d) has effects on bone turnover and bone mass that are very similar to those of tamoxifen, indicating that this agent is also estrogenic on the skeleton. The effect of raloxifene on bone density (+1.4–2.8% vs. placebo in the spine, hip, and total body) is somewhat less than that seen with standard doses of estrogens. Raloxifene reduces the occurrence of vertebral fracture by 30–50%, depending on the population; however, there are no data confirming that raloxifene can reduce the risk of nonvertebral fractures after 8 years of observation.

Raloxifene, like tamoxifen and estrogen, has effects on other organ systems. The most beneficial effect appears to be a reduction in invasive breast cancer (mainly decreased ER-positive) occurrence of ~65% in women who take raloxifene compared with placebo. In a head-to-head study, raloxifene was as effective as tamoxifen in preventing breast cancer in high-risk women, and raloxifene is FDA approved for this indication. In a further study, raloxifene had no effect on heart disease in women with increased risk for this outcome. In contrast to tamoxifen, raloxifene is not associated with an increase in the risk of uterine cancer or benign uterine disease. Raloxifene increases the occurrence of hot flashes but reduces serum total and low-density lipoprotein cholesterol, lipoprotein(a), and fibrinogen. Raloxifene, with its positive effects on breast cancer and vertebral fractures, has become a useful agent for the treatment of the younger asymptomatic postmenopausal woman. In some women, a recurrence of menopausal symptoms may occur. Usually this is evanescent but occasionally is sufficiently impactful on daily life and sleep that the drug must be withdrawn. Raloxifene increases the risk of deep-vein thrombosis and may increase the risk of death from stroke among older women. Consequently, it is not usually recommended for women over age 70 years.

MODE OF ACTION OF SERMS

All SERMs bind to the ER, but each agent produces a unique receptor-drug conformation. As a result, specific coactivator proteins or co-repressor proteins are bound to the receptor **(Chap. 389)**, resulting in differential effects on gene transcription that vary depending on other transcription factors present in the cell. Another aspect of selectivity is the affinity of each SERM for the different ERα and ERβ subtypes, which are expressed differentially in various tissues. These tissue-selective effects of SERMs offer the possibility of tailoring estrogen therapy to best meet the needs and risk factor profile of an individual patient.

Bisphosphonates Bisphosphonates have become the mainstay of osteoporosis treatment globally, in part related to cost as they have become generic. Alendronate, risedronate, ibandronate, and zoledronic acid are approved for the prevention and treatment of postmenopausal osteoporosis. Alendronate, risedronate, and zoledronic acid are also approved for the treatment of glucocorticoid-induced osteoporosis, and risedronate and zoledronic acid are approved for prevention of glucocorticoid-induced osteoporosis. Alendronate,

risedronate, and zoledronic acid are also approved for treatment of osteoporosis in men.

Alendronate decreases bone turnover and increases bone mass by up to 8 and 6% versus placebo in the spine and hip, respectively. Multiple trials have evaluated its effect on fracture occurrence. The Fracture Intervention Trial provided evidence in >2000 women with prevalent vertebral fractures that daily alendronate treatment (5 mg/d for 2 years and 10 mg/d for 9 months afterward) reduces vertebral fracture risk by ~50%, multiple vertebral fractures by up to 90%, and hip fractures by up to 50%. Several subsequent trials have confirmed these findings **(Fig. 423-9)**. For example, in a study of >1900 women with low bone mass treated with alendronate (10 mg/d) versus placebo, the incidence of all nonvertebral fractures was reduced by ~47% after only 1 year. In the United States, the 70-mg weekly dose is approved for treatment of osteoporosis and the dose of 35 mg per week is approved for prevention, with those doses showing equivalence to daily dosing based on bone turnover and bone mass response.

Consequently, once-weekly therapy generally is preferred because of lower incidence of gastrointestinal side effects, ease of administration, and improved persistence with therapy. Alendronate should be taken with a full glass of water before breakfast after an overnight fast, as bisphosphonates are poorly absorbed. Because of the potential for esophageal irritation, alendronate is contraindicated in patients who have stricture, achalasia, or inadequate emptying of the esophagus. It is recommended that patients remain upright (standing or sitting) for at least 30 min after taking the medication to avoid esophageal irritation and that food and fluids (other than water) be avoided for the same duration. In clinical trials, overall gastrointestinal symptomatology was no different with alendronate than with placebo, but in practice, all oral bisphosphonates have been associated with esophageal irritation and inflammation.

Risedronate also reduces bone turnover and increases bone mass. Controlled clinical trials have demonstrated 40–50% reduction in vertebral fracture risk over 3 years, accompanied by a 40% reduction in clinical nonspine fractures. The only clinical trial specifically designed to evaluate hip fracture outcome (HIP) indicated that risedronate reduced hip fracture risk in women in their seventies with confirmed osteoporosis by 40%. In contrast, risedronate was not effective at reducing hip fracture occurrence in older women (80+ years) without proven osteoporosis. Studies have shown that 35 mg of risedronate administered once weekly is therapeutically equivalent to 5 mg/d. The instructions for oral administration noted for alendronate apply to all three oral bisphosphonates. There is also a preparation of risedronate with an enteric coating (35 mg) that can be taken after breakfast. Risedronate is the only bisphosphonate that has this dosing flexibility.

Ibandronate is the third amino-bisphosphonate approved in the United States. Ibandronate (2.5 mg/d) has been shown in clinical trials to reduce vertebral fracture risk by ~40% but with no overall effect on nonvertebral fractures. In a post hoc analysis of subjects with a femoral neck T-score of ≤–3, ibandronate reduced the risk of nonvertebral fractures by ~60%. In clinical trials, ibandronate doses of 150 mg per month PO or 3 mg every 3 months IV had greater effects on turnover and bone mass than did 2.5 mg/d. Patients should take oral ibandronate in the same way as other bisphosphonates but with 1 h elapsing before other food or drink (other than plain water).

Zoledronic acid is a potent bisphosphonate with a unique administration regimen (5 mg by 30-min IV infusion at most annually). Zoledronic acid data confirm that it is highly effective in fracture risk reduction. In a study of >7000 women followed for 3 years, zoledronic acid (5 mg IV annually) reduced the risk of vertebral fractures by 70%, nonvertebral fractures by 25%, and hip fractures by 40%. These results were associated with less height loss and disability. In the treated population, there was an increased risk of almost 25% of an acute phase response (APR) in patients with no prior bisphosphonate exposure (fever, myalgias, headache, malaise), but effects were short-lived (2–3 days). A recent study shows the APR can be eliminated by the administration of dexamethasone (4 mg) for 3 days commencing 90 min before the infusion. Although there was also an increased risk of atrial fibrillation in this trial, detailed evaluation of all bisphosphonates has failed to confirm a risk of atrial fibrillation. Zoledronic acid has also been studied in a placebo-controlled trial of older women and men within 3 months of an acute hip fracture. The risk of recurrent fracture was reduced by 35%, and there was a 28% reduction in mortality that was associated with a reduction in infections and cardiovascular events. In older postmenopausal women with osteopenia, the risk of nonvertebral, vertebral, or clinical fragility fractures was significantly lower in women with osteopenia who received zoledronate every 18 months for 6 years than in women who received placebo. In an extension study of the women who had received zoledronic acid infusions for 6 years, the risk of nonvertebral fractures remained low for up to 3.5 years after the last dose but increased after that time. This suggests less frequent dosing may be required after an initial course of three or four zoledronic acid infusions.

Common Bisphosphonate Adverse Events All bisphosphonates have been associated with some musculoskeletal and joint pains of unclear etiology, which are occasionally severe. There is potential for renal toxicity, particularly in women with stage 3 chronic kidney disease (CKD), and bisphosphonates are contraindicated in those with an estimated glomerular filtration rate <30–35 mL/min. Hypocalcemia can occur.

Two potential side effects have been associated with bisphosphonate use. The first is medication-related osteonecrosis of the jaw (MRONJ). MRONJ usually follows a dental procedure in which bone is exposed (dental extractions and implants). It is presumed that the exposed bone becomes infected and dies. MRONJ is more common among cancer patients receiving high doses of bisphosphonates for skeletal metastases. It is rare among persons with osteoporosis on usual doses of bisphosphonates. Additional risk factors for MRONJ are poor dental hygiene, diabetes, and glucocorticoids. Oral antibiotic rinses and oral systemic antibiotics may be useful to prevent this rare adverse event if risk is perceived to be particularly high. In addition, any invasive dental procedures should be performed prior to commencement of bisphosphonate therapy. Because bisphosphonates have a long skeletal half-life, it is unlikely that withholding therapy prior to an invasive procedure will reduce MRONJ risk; however, this is often recommended by dentists and faciomaxillary surgeons. Teriparatide treatment for 2 months has been shown to reduce bone lesions associated with MRONJ versus placebo. The second side effect is called atypical femoral fracture. These are stress fractures occurring in the subtrochanteric femoral region or across the femoral shaft distal to the lesser trochanter. They are often preceded by pain in the lateral thigh or groin that can be present for weeks, months, or even years before the fracture. The fractures occur following either no or trivial trauma, are predominantly horizontal with a medial beak, and are noncomminuted. An American Society for Bone and Mineral Research Task Force described the major and minor criteria for these fractures, which are related to duration of bisphosphonate therapy and increase after 5–7 years of treatment, but only after 3 years of exposure in Asian patients. The overall risk appears quite low, especially when compared with the number of hip fractures prevented by these therapies, but they often require surgical fixation and show delayed healing. The risk is also increased with Asian ethnicity, rheumatoid arthritis, glucocorticoids, proton pump inhibitors, and SSRIs. In some cases (10–30%), there is no bisphosphonate exposure, and in some of these cases, there may be an underlying rare monogenetic bone disease such as osteogenesis imperfecta, hypophosphatasia, X-linked hypophosphatemic rickets, X-linked osteoporosis, or pycnodysostosis. Other genetic risk factors for atypical femur fractures have been identified in families with bisphosphonate-associated atypical femur fractures. If the fractures are found early, when there is evidence of periosteal stress reaction or stress fracture, prior to the occurrence of overt fracture, surgical intervention may be

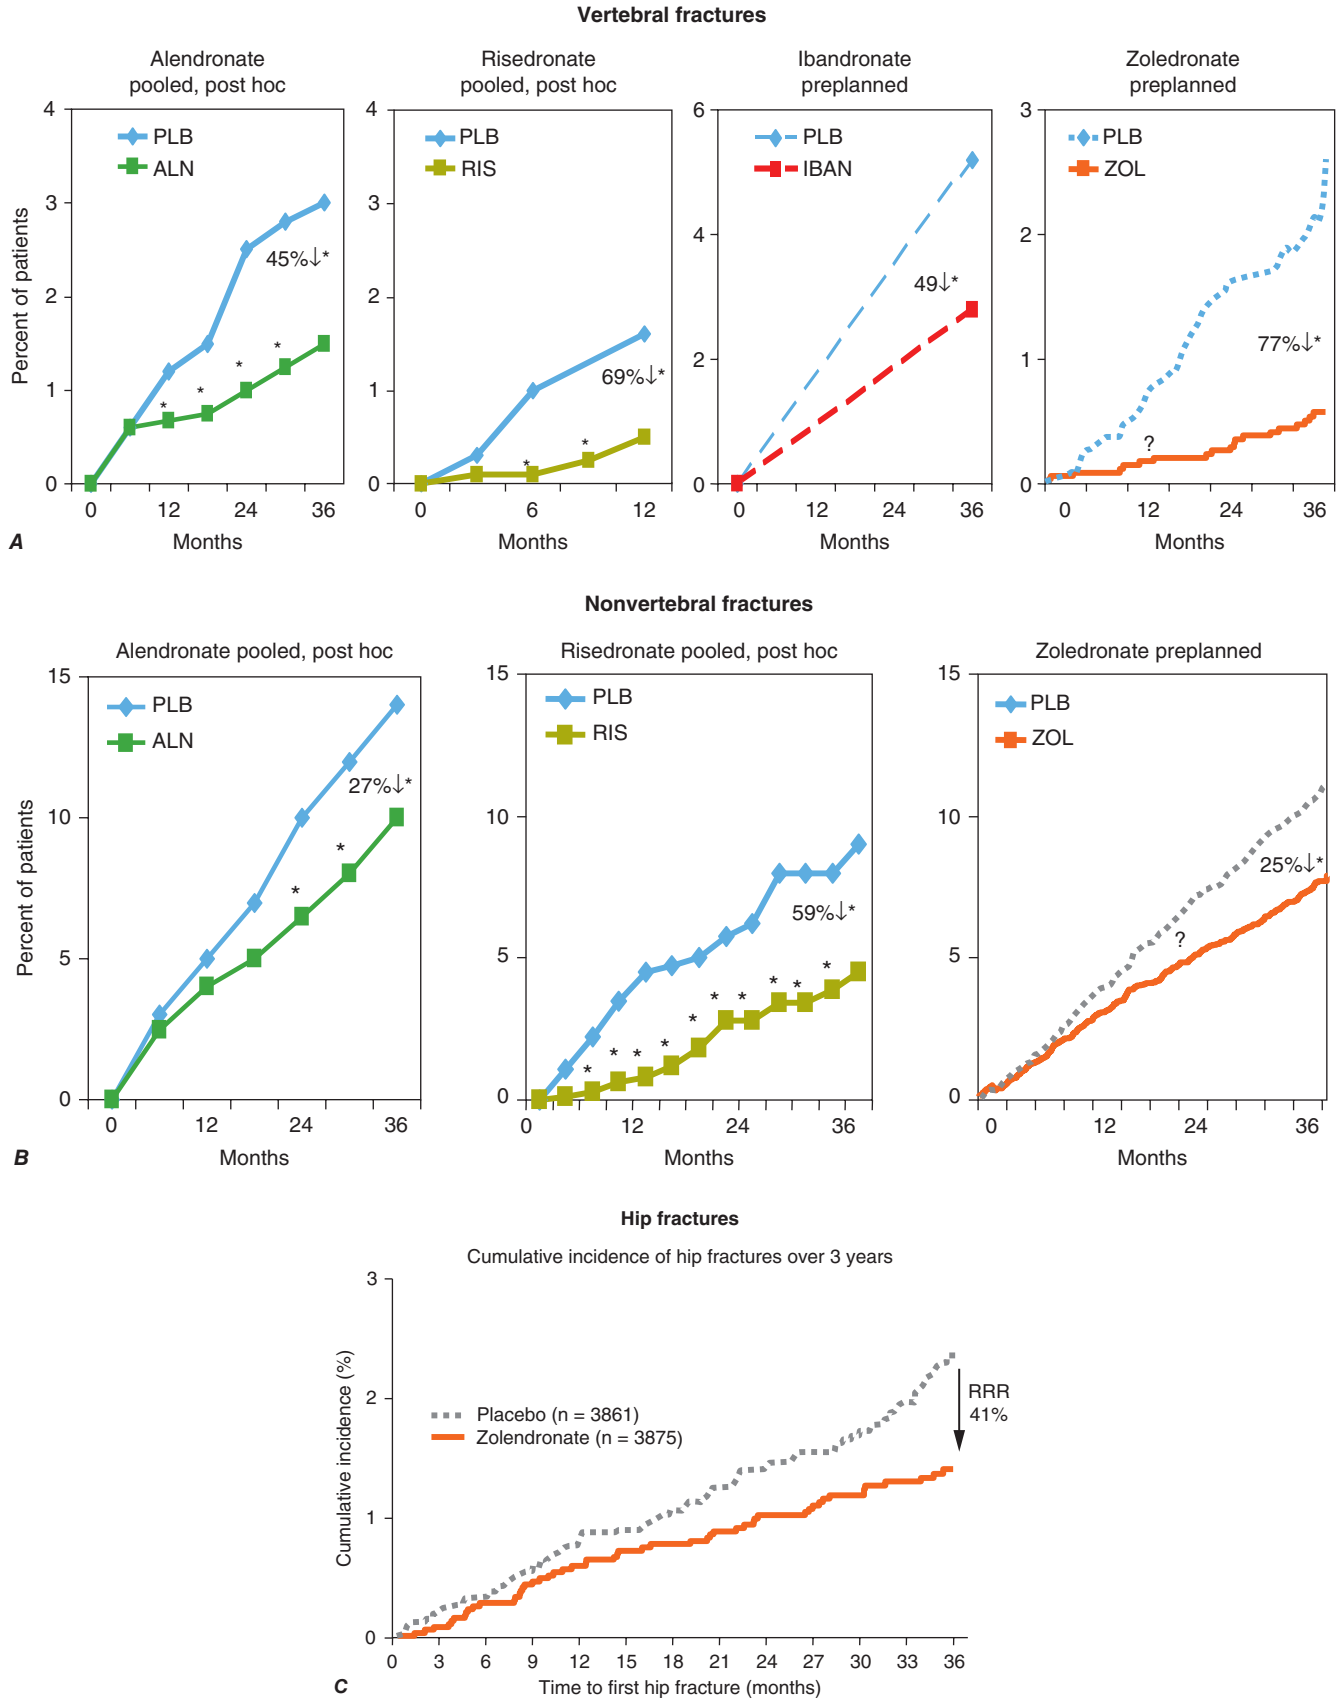

FIGURE 423-9 Effects of various bisphosphonates on fractures. ***A.*** Clinical vertebral fractures. ***B.*** Nonvertebral fractures. ***C.*** Hip fractures. Plb, placebo; RRR, relative risk reduction. *(Data from DM Black et al: J Clin Endocrinol Metab 85:4238, 2000; C Roux et al: Curr Med Res Opin 4:433, 2004; CH Chesnut et al: J Bone Miner Res 19: 1241, 2004; DM Black et al: N Engl J Med 356:1809, 2007; JT Harrington et al: Calcif Tissue Int 74:129, 2003.)*

required. The evidence that teriparatide can help heal the fracture and preclude the need for surgical repair from case series is mixed, and published trial data are not available. When patients initiate bisphosphonates, they should be informed that if they develop thigh or groin pain, they should inform their health care professional. Routine x-rays will sometimes detect cortical thickening or even a stress fracture, but MRI or technetium bone scans are more sensitive. The presence of an abnormality requires, at minimum, a period of modified weight-bearing and may need prophylactic rodding of the femur. It is important to realize that these may often be bilateral (~50% of the time), and when an abnormality is found, the other femur should be checked. It is unknown whether patients who have these atypical femur fractures can ever receive antiresorptive therapies again in the future, but it seems prudent to avoid their use for most of these individuals.

Mode of Action Bisphosphonates are structurally related to pyrophosphates, compounds that are incorporated into bone matrix. Bisphosphonates are taken up at sites of active bone remodeling and specifically impair osteoclast function and reduce osteoclast number, in part by inducing apoptosis. Recent evidence suggests that the nitrogen-containing bisphosphonates also inhibit protein prenylation, one of the end products in the mevalonic acid pathway, by inhibiting the enzyme farnesyl pyrophosphate synthase. This effect disrupts intracellular protein trafficking and ultimately may lead to apoptosis. Some bisphosphonates have very long retention in the skeleton and may exert long-term effects via recirculation of bisphosphonates retained in bone when bone remodeling recurs at that site.

Calcitonin Calcitonin is a polypeptide hormone produced in the thyroid gland **(Chap. 422)**. Its physiologic role is unclear as no skeletal disease has been described in association with calcitonin deficiency or excess. Calcitonin preparations are approved by the FDA for Paget's disease, hypercalcemia, and osteoporosis in women >5 years past menopause.

Injectable calcitonin produces small increments in bone mass of the lumbar spine. However, difficulty of administration and frequent reactions, including nausea and facial flushing, make general use limited. A nasal spray containing calcitonin (200 IU/d) is available for treatment of osteoporosis in postmenopausal women. One study suggests that nasal calcitonin produces small increments in bone mass and a small reduction in new vertebral fractures in calcitonin-treated patients (at one dose) versus those on calcium alone. There has been no proven effectiveness against nonvertebral fractures. Calcitonin is not indicated for prevention of osteoporosis and is not sufficiently potent to prevent bone loss in early postmenopausal women. Calcitonin might have an analgesic effect on bone pain, both in the subcutaneous and possibly in the nasal form. Concerns have been raised about an increase in the incidence of cancer associated with calcitonin use. Initially, the cancer noted was of the prostate, but an analysis of all data suggested a more general increase in cancer risk. In Europe, the European Medicines Agency has removed the osteoporosis indication, and an FDA Advisory Committee has voted for a similar change in the United States.

Mode of Action Calcitonin suppresses osteoclast activity by direct action on the osteoclast calcitonin receptor. Osteoclasts exposed to calcitonin cannot maintain their active ruffled border, which normally maintains close contact with underlying bone.

Denosumab Denosumab is a human monoclonal antibody that inhibits RANKL, a potent stimulus of osteoclast activity. It is administered twice yearly by subcutaneous injection. In a randomized controlled trial in postmenopausal women with osteoporosis, it has been shown to increase BMD at the spine, hip, and forearm and reduce vertebral, hip, and nonvertebral fractures over a 3-year period by 68, 40, and 20%, respectively **(Fig. 423-10)**. Unlike bisphosphonates in which BMD plateaus after 4–5 years of treatment, bone density continues to increase as long as denosumab treatment is continued. In a long-term extension of the pivotal fracture trial, BMD increased by 21.7 and 9.2% at the spine and hip, respectively, after 10 years of denosumab treatment. Over the 10 years, fracture rates also remained at least as low as those seen with denosumab during the active placebo-controlled portion of the trial. Other clinical trials indicate ability to increase bone mass in postmenopausal women with osteopenia and in postmenopausal women with breast cancer treated with aromatase inhibitors. In the oncology literature, denosumab reduces the risk of fractures in women on aromatase inhibitors. In a study of men with prostate cancer treated with androgen deprivation therapy, denosumab increased bone mass and reduced vertebral fracture incidence over 3 years. An analysis of five placebo-controlled studies has also

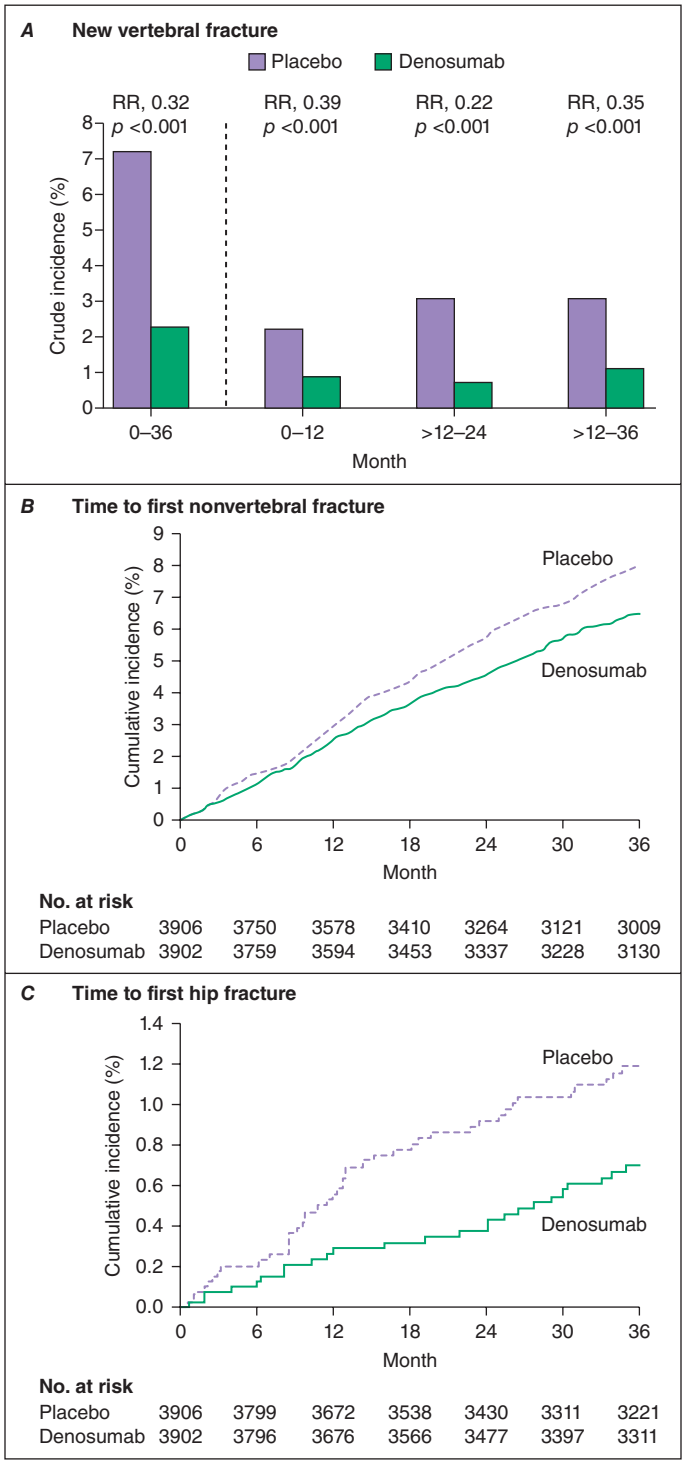

FIGURE 423-10 Effects of denosumab on the following: *A.* new vertebral fractures; and ***B.*** and ***C.*** times to nonvertebral and hip fracture. RR, relative risk. *(From SR Cummings et al: Denosumab for prevention of fractures in postmenopausal women with osteoporosis. N Engl J Med 361:756, 2009. Copyright © 2009 Massachusetts Medical Society. Reprinted with permission from Massachusetts Medical Society.)*

suggested reduced risk of falls in patients with osteoporosis treated with denosumab.

Denosumab was approved by the FDA in 2010 for the treatment of postmenopausal women who have a high risk for osteoporotic fractures, including those with a history of fracture or multiple risk factors for fracture, and those who have failed or are intolerant to other osteoporosis therapy. Denosumab is also approved for the treatment of osteoporosis in men at high risk for fracture, women with breast cancer on aromatase inhibitors, and men with prostate cancer on androgen deprivation treatment.

Denosumab may increase the risk of MRONJ and atypical femur fractures similarly to bisphosphonates. Estimated incidence is 5/10,000 patient-years for MRONJ and 1/10,000 patient-years for atypical femur fractures. Denosumab can cause hypersensitivity reactions, hypocalcemia, and skin reactions including dermatitis, rash, and eczema. Early concerns about an imbalance in infections with denosumab have largely been allayed. Severe hypocalcemia may occur in patients with CKD and an estimated glomerular filtration rate <30 mL/min, particularly in those on hemodialysis. Serum calcium levels should be monitored if denosumab is used in such patients, and active vitamin D analogues and calcium may be required for its treatment.

Unlike bisphosphonates, when denosumab is discontinued, there is a rebound increase in bone turnover and an acceleration of bone loss. This likely reflects the maturation of accumulated osteoclast precursors (osteomorphs) in bone marrow when the drug was administered that then coalesce to become mature bone resorbing cells once denosumab is withdrawn. Other mechanisms involving reduced osteoprotegerin levels and osteocytes may also be involved. The consequences of this rebound increase in remodeling-associated bone loss are trabecular perforation and a rapid increase in the risk of fracture, particularly vertebral fracture, with a specific increase in multiple vertebral fractures. In patients who need to stop denosumab or in patients in whom BMD and fracture risk reduction goals have been met, temporary use of bisphosphonate treatment may prevent the rebound increase in remodeling and rapid bone loss. In clinical practice, a single infusion of zoledronic acid at the time of the missed denosumab dose seems to maintain BMD for 1–2 years but may need to be repeated after 3 months, or more often, if bone turnover markers remain elevated. Oral bisphosphonates can also be used for 12–24 months to maintain bone density. In both cases, the required duration of bisphosphonate use to eliminate the rebound effect is not clear and may vary considerably among patients so bone density should continue to be monitored.

Mode of Action Denosumab is a fully human monoclonal antibody to RANKL, the final common effector of osteoclast formation, activity, and survival. Denosumab binds to RANKL, inhibiting its ability to initiate formation of mature osteoclasts from osteoclast precursors and to bring mature osteoclasts to the bone surface and initiate bone resorption. Denosumab also plays a role in reducing osteoclast survival. Through these actions on the osteoclast, denosumab induces a potent and rapid antiresorptive action, as assessed biochemically and histomorphometrically.

Anabolic Agents • **Parathyroid Hormone** Endogenous PTH is an 84-amino-acid peptide that is largely responsible for calcium homeostasis (Chap. 422). Although chronic elevation of PTH, as occurs in hyperparathyroidism, is associated with bone loss (particularly at cortical bone sites such as the femoral neck and radius), PTH also can exert anabolic effects on bone if administered intermittently. Consistent with this, some observational studies have indicated that mild endogenous hyperparathyroidism is associated with maintenance of trabecular bone mass but loss of cortical bone. Based on these findings, early small-scale observational studies showed that PTH analogues could augment trabecular BMD. Subsequent controlled clinical trials have confirmed that PTH can increase bone mass and reduce fracture incidence. The first randomized controlled trial in postmenopausal women showed that PTH (1–34) (teriparatide), when superimposed on ongoing estrogen therapy, produced substantial increments in bone mass (13% over a 3-year period compared with estrogen alone) and reduced the risk of vertebral compression fractures. In the pivotal study (median, 19 months' duration), 20 μg PTH (1–34) daily by subcutaneous injection (with no additional therapy) reduced vertebral fractures by 65% and nonvertebral fractures by 53% (Fig. 423-11). Teriparatide produces rapid and robust increases in bone formation and then bone remodeling overall, resulting in substantial increases in bone mass and improvements in microarchitecture, including cancellous connectivity and cortical width. The BMD effects, particularly in the hip, are lower when patients switch from bisphosphonates to teriparatide, possibly in proportion to the potency of the antiresorptive agent. The hip BMD effect is particularly impaired and may result in transient bone loss, when patients switch from

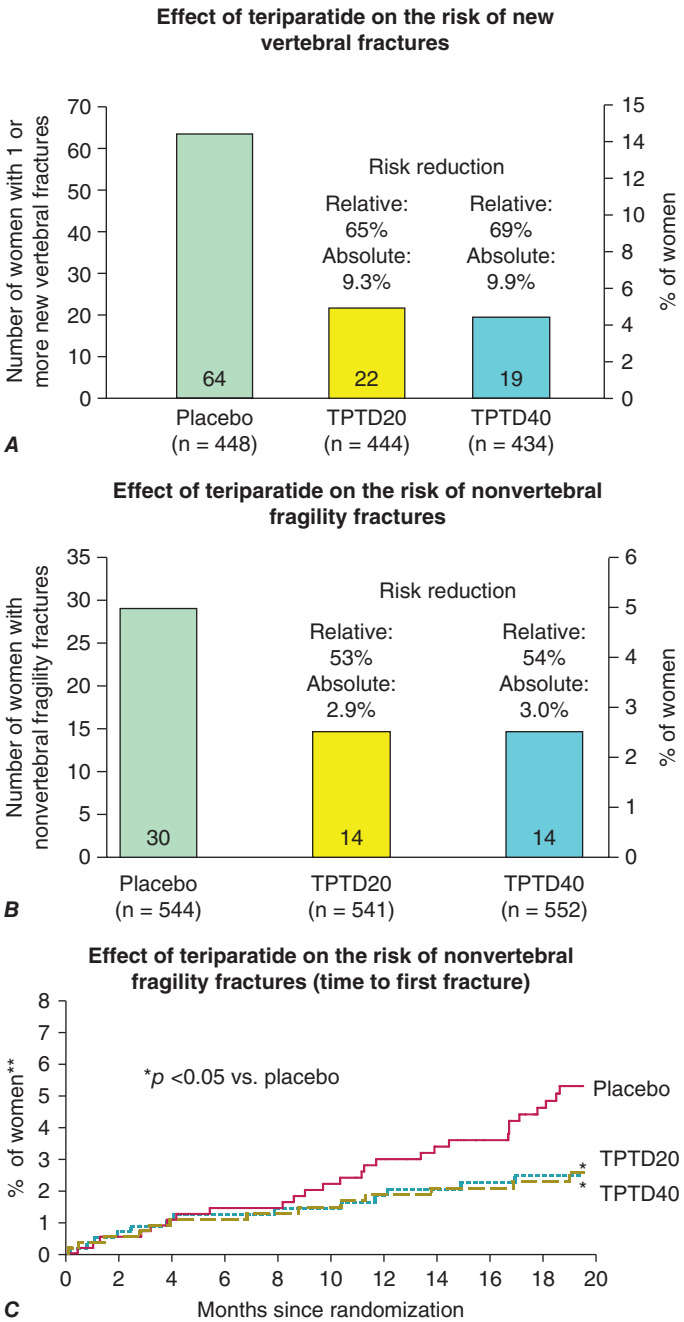

FIGURE 423-11 Effects of teriparatide (TPT) on the following: *A.* new vertebral fractures; and ***B.*** and ***C.*** nonvertebral fragility fractures. *(A and B are data from RM Neer et al: Effect of parathyroid hormone (1–34) on fractures and bone mineral density in postmenopausal women with osteoporosis. N Engl J Med May 344:1434, 2001. C From New England Journal of Medicine RM Neer et al: Effect of parathyroid hormone (1-34) on fractures and bone mineral density in postmenopausal women with osteoporosis, 344:1434-1441. denosumab to teriparatide. In patients on denosumab who need teriparatide treatment, there may be a role for combination therapy. In previously untreated women, teriparatide is administered as monotherapy and followed by a potent antiresorptive agent such as denosumab or an oral or intravenous bisphosphonate. Combination therapy is generally avoided because of cost and potential inhibition of the anabolic activity of teriparatide.

Comparison with Antiresorptive Therapy In women with painful acute osteoporotic vertebral fractures, teriparatide reduced subsequent vertebral fractures by ~50% compared with risedronate. There was no difference in nonvertebral fracture outcome between the two medications. A study comparing teriparatide with risedronate in patients with prevalent vertebral fractures showed significant benefit for teriparatide against vertebral fractures (Fig. 423-12) and clinical fractures with a trend for a benefit of teriparatide against nonvertebral fractures.

Side effects of teriparatide are generally mild and can include muscle pain, weakness, dizziness, headache, and nausea. These tend to remit with continuing treatment but may be mitigated by giving injections at night. Rodents given prolonged treatment with PTH in high doses (3–60 times the human dose) developed osteogenic sarcomas after ~18 months of treatment. Rare cases of osteosarcoma have been described in patients treated with teriparatide consistent with the background incidence of osteosarcoma in adults. Long-term surveillance studies of a high proportion of patients diagnosed with osteosarcoma as adults in both the United States and Scandinavia reveal no prior exposure to teriparatide in any of the cases.

Teriparatide use may be limited by cost and its mode of administration (daily subcutaneous injection). Alternative modes of delivery have been investigated, but none have proven successful. Because of the rodent osteosarcoma data and the maximum duration of teriparatide in the pivotal trial of 2 years, the FDA previously limited teriparatide treatment to 2 years in a lifetime. However, registry data confirming no increased risk of osteogenic sarcoma in humans treated with teriparatide have allowed the FDA to drop this restriction on duration of use. As a result, consideration may be given to using intermittent courses of teriparatide therapy. In many other countries, however, teriparatide use is still restricted to 2 years in a lifetime.

Mode of Action Exogenously administered PTH appears to have direct actions on osteoblast activity, with biochemical and histomorphometric evidence of de novo bone formation within a week or two in response to teriparatide. There is subsequently resorption.

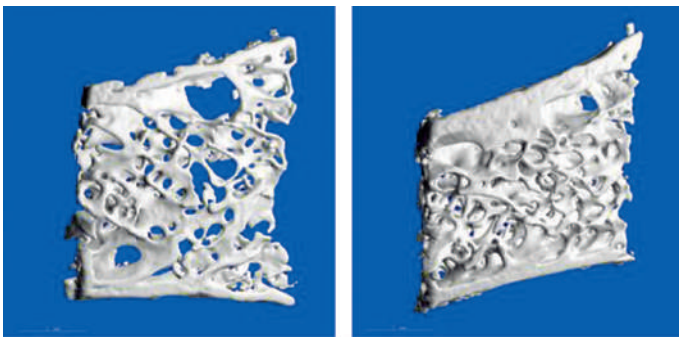

FIGURE 423-13 Effect of parathyroid hormone (PTH) treatment on bone microarchitecture. Paired biopsy specimens from a 64-year-old woman before (***A***) and after (***B***) treatment with PTH. *(Reproduced with permission from DW Dempster et al: Effects of daily treatment with parathyroid hormone on bone microarchitecture and turnover in patients with osteoporosis: A paired biopsy study. J Bone Miner Res 16:1846, 2001.)*

Subsequently, teriparatide primarily activates remodeling-based bone formation, favoring bone formation over bone resorption. Teriparatide given by daily injection stimulates osteoblast recruitment and activity through activation of Wnt signaling. Teriparatide produces a true increase in bone tissue and an apparent restoration of bone microarchitecture (Fig. 423-13).

Abaloparatide Abaloparatide is a synthetic analogue of human PTHrP, which has significant homology to PTH and binds the PTH type 1 receptor. Abaloparatide and teriparatide exert different binding affinities to the two different receptor conformations, R^0 and RG. Compared with teriparatide, abaloparatide binds with similar high affinity to the RG conformation but with much lesser affinity to the R^0 conformation. These differences appear to result in a similar bone formation stimulus but lesser bone resorption stimulus, and abaloparatide was specifically chosen for development among many PTH and PTHrP analogues for what appeared to be an optimized anabolic profile.

In the phase 3 Abaloparatide Comparator Trial in Vertebral Endpoints (ACTIVE) study, 2463 postmenopausal women with osteoporosis were randomized to blinded daily subcutaneous abaloparatide versus placebo or open-label teriparatide. At 18 months, spine BMD increase was similar with abaloparatide and teriparatide (11.2% with abaloparatide and 10.5% with teriparatide); in the total hip, BMD increments were slightly larger with abaloparatide

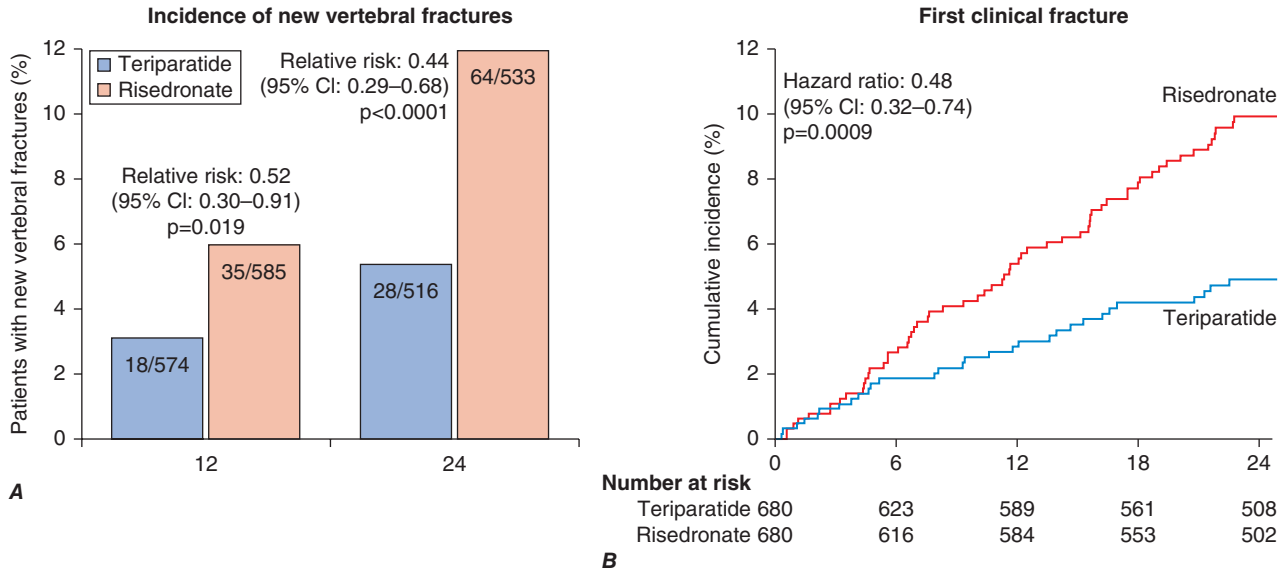

FIGURE 423-12 Effect of parathyroid hormone (PTH) treatment on vertebral fracture incidence at 12 and 24 months (***A***) and clinical fractures (***B***) compared with risedronate. *(Reproduced with permission from D Kendler et al: Effects of teriparatide and risedronate on new fractures in post-menopausal women with severe osteoporosis (VERO): A multicentre, double-blind, double-dummy, randomised controlled trial. Lancet 391:230, 2018.)*

(4.2 vs 3.3%). New vertebral fracture incidence was reduced by 86% with abaloparatide and 80% with teriparatide compared with placebo (both p <.001). The hazard ratio for abaloparatide versus teriparatide was not quoted. Nonvertebral fractures were reduced by 43% with abaloparatide (p = .05) and by 28% with teriparatide (not significant; p = .22). The ACTIVE study was extended, with 92% of eligible participants from the abaloparatide and placebo arms transitioned to open-label alendronate for a total treatment period of 24 months of alendronate. Both vertebral and nonvertebral fractures were less common in the group who transitioned from abaloparatide to alendronate, suggesting that the fracture benefit of abaloparatide can be maintained with antiresorptive treatment.

Romosozumab Romosozumab is a humanized antibody that blocks the osteocyte production of sclerostin, resulting in a unique action, with an increase in bone formation and decrease in bone resorption. In the pivotal trial (FRAME), 7180 postmenopausal women with osteoporosis were randomized to receive blinded monthly subcutaneous romosozumab (210 mg) or placebo for 1 year followed by transition to open-label subcutaneous denosumab (60 mg) every 6 months for an additional year. BMD increased by over 13% in the spine and almost 7% in the hip in 1 year with romosozumab. At 1 year, the incidence of new vertebral fractures in the romosozumab group was significantly reduced by 73% compared with placebo. Clinical fracture risk (nonvertebral fractures and clinical vertebral fractures combined) was significantly reduced by 36%. Nonvertebral fractures were also reduced, but the difference just missed statistical significance perhaps due to geographical differences; in the high-enrolling Latin American region, there was no significant reduction in nonvertebral fractures, probably due to a very low background incidence in that region. In the rest of the world, nonvertebral fractures were significantly reduced by >40%. During the second year of the FRAME study, both groups transitioned to denosumab. Over 24 months, women who had received romosozumab during the first 12 months and then denosumab had 75% fewer new vertebral fractures than those who had received placebo for a year followed by denosumab. There were also nearly significant trends toward reduced clinical and nonvertebral fractures in the romosozumab/denosumab group. Compared with baseline, BMD increased by 17.6% in the spine and 8.8% in the total hip in the romosozumab/denosumab group. Safety and tolerability of the two drugs were similar, with a slightly higher incidence of injection site reactions in the denosumab group. There was no increase of cardiovascular events in patients treated with romosozumab. The FRAME extension study where all participants received continued denosumab for an additional year (2 years in total) showed significant decreases in vertebral, clinical, and nonvertebral fractures with a trend for hip fracture reduction.

Comparison with Antiresorptive Therapy The ARCH trial of very-high-risk patients, all of whom have prevalent vertebral fractures, compared romosozumab with alendronate for 1 year, followed by transition to, or continuation of, alendronate for at least 2 additional years. This study showed increases in bone density that were comparable with the FRAME study and significant reductions in vertebral, nonvertebral, clinical, and hip fractures compared with alendronate **(Fig. 423-14)**. In this study, there was an increase in cardiovascular adverse events in patients treated with romosozumab, prompting a warning on the label and avoidance of this medication in patients with a past history of acute myocardial infarction or stroke.

Comparison with Other Anabolic Therapy No studies have compared romosozumab with other anabolic drugs with fractures as the primary outcome. One study compared the effects of romosozumab with teriparatide in postmenopausal women with osteoporosis who had been previously treated with bisphosphonates, including 12 months of alendronate immediately prior to the study. Effects of both anabolic drugs on BMD were attenuated by prior bisphosphonate therapy, but the increases in spine, total hip, and femoral neck BMD were greater with romosozumab than with teriparatide. Increases in cortical bone mineral content and bone strength at the hip were also greater with romosozumab than with teriparatide.

Sequence of Therapy Because teriparatide and romosozumab have greater efficacy at reducing vertebral and clinical fractures, and vertebral, clinical, nonvertebral, and hip fractures, respectively, compared with bisphosphonates, they are now being considered as first-line therapy for patients with severe osteoporosis. Increases in BMD also occur more rapidly and to a greater extent with anabolic drugs than with antiresorptive drugs, although the relative risk reduction for vertebral fractures is similar for zoledronic acid, denosumab, teriparatide, and romosozumab at about 70%. When their use is second-line following antiresorptive drugs, improvements in BMD are attenuated, particularly following denosumab therapy. In response to these clinical data, initiatives have been made to identify patients at very high risk for fracture who would derive the most benefit from these greater improvements in BMD and more rapid reductions in fracture risk. Both U.S. and international guidelines have therefore focused on defining a group of individuals at very high fracture risk who could be selected for anabolic therapy as first-line treatment. The definitions vary between these guidelines, but the criteria showing the most agreement are a recent fracture within the last 12–24 months, multiple fragility fractures (two or more), fractures while on antiresorptive therapy, or high absolute fracture risk (FRAX-derived 10-year risks of >4.5% or >30% for hip and major osteoporotic fractures, respectively).

There has also been a focus on a goal-directed approach to long-term management of fracture risk. This helps ensure the most appropriate initial treatment and treatment sequence is selected for individual patients. Importantly, the selection of initial treatment should focus on reducing fracture risk rapidly for patients at very high and/or imminent risk, such as in those with recent fractures. Initial treatment selection should also consider the likelihood that a BMD treatment target can be attained relatively rapidly and needs to consider differences in fracture risk reduction and BMD increases with anabolic versus antiresorptive therapy. In conclusion, for those patients with a very high and/or imminent fracture risk, the ideal treatment sequence would be anabolic followed by antiresorptive therapy. However, reimbursement considerations may limit the implementation of this approach.

OTHER PHARMACOLOGIC AGENTS NOT APPROVED IN THE UNITED STATES

Testosterone has been used to treat osteoporosis associated with low testosterone levels in men. There are data that indicate that testosterone can increase bone density, but there are no data indicating reductions in fractures. In fact, a recent large study showed fracture incidence was numerically higher among men who received testosterone than among those who received placebo. Since there are many other effects of testosterone, especially in older men (including prostate hypertrophy), decisions to use it for treatment of osteoporosis must take these multisystemic effects into account. In hypogonadal men with a high or very high fracture risk, anti-osteoporosis therapy should be used in addition to testosterone therapy.

Sodium fluoride was tested in two large parallel clinical trials in the late 1980s. Although BMD increased substantially, the increase was in part due to fluoride incorporation in the hydroxyapatite crystal. Fracture risk was not reduced and, in fact, was increased in nonvertebral sites. Therefore, fluoride is no longer considered a viable option for osteoporosis treatment.

Several small studies of growth hormone, alone or in combination with other agents, have not shown consistent or substantial positive effects on bone mass.

NONPHARMACOLOGIC APPROACHES

Protective pads worn around the outer thigh, which cover the trochanteric region of the hip, can prevent hip fractures in elderly residents in nursing homes. They are only effective when worn, and their use is limited largely by issues of compliance and comfort, but

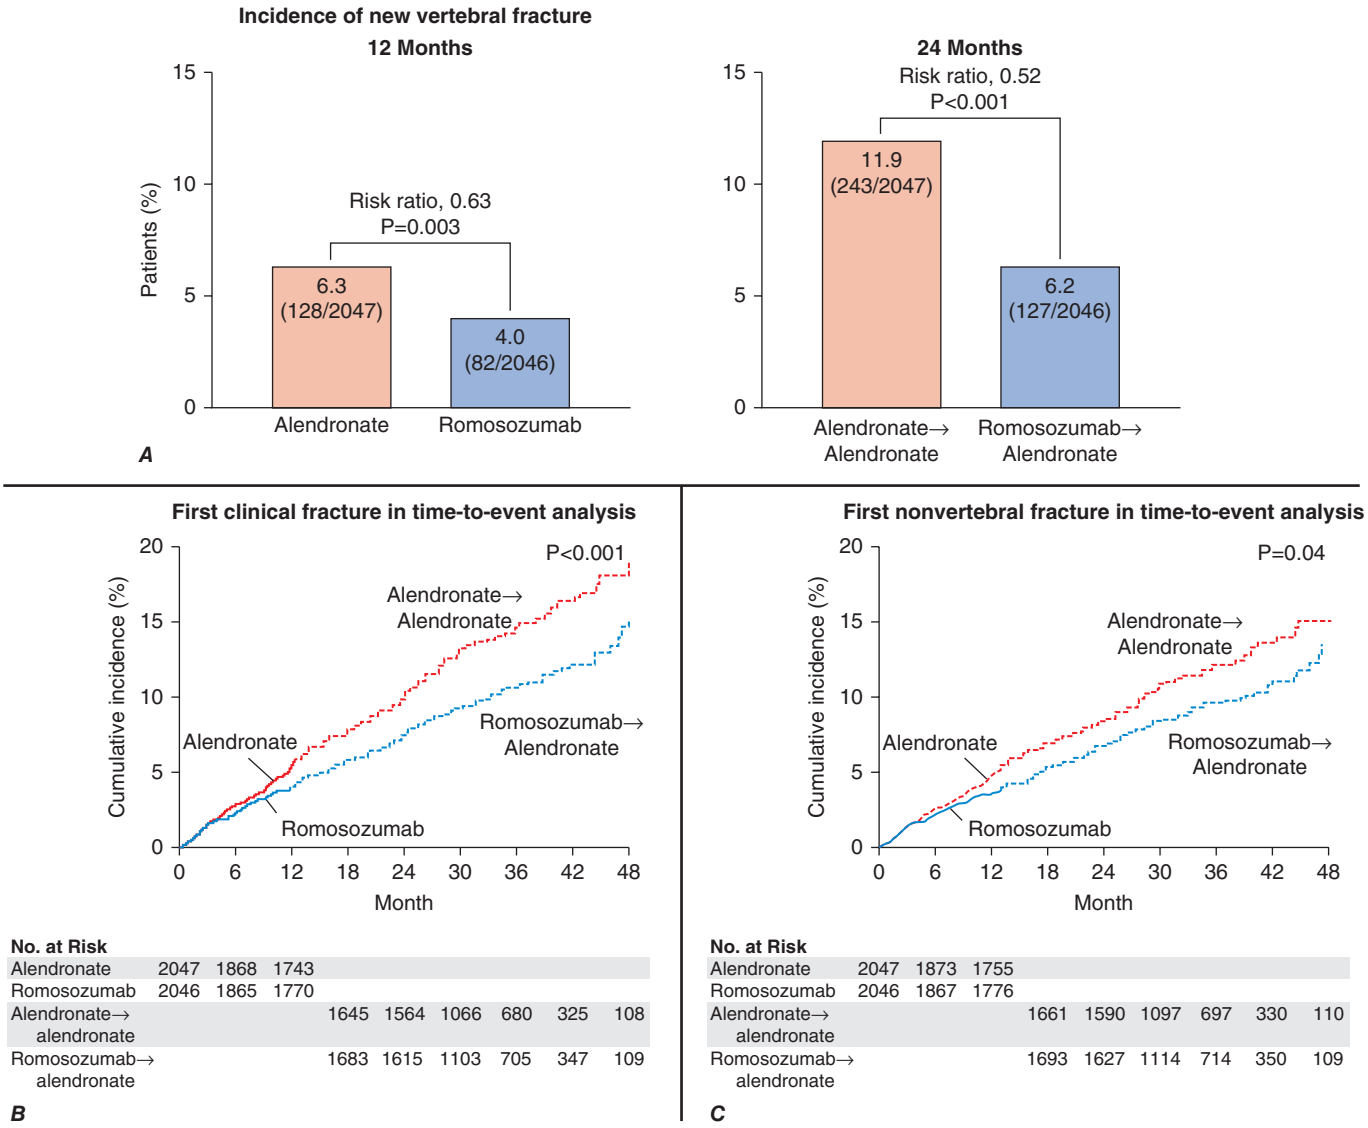

FIGURE 423-14 Effect of romosozumab versus alendronate for 12 months followed by alendronate on vertebral, clinical, and nonvertebral fracture incidence. *(From The New England Journal of Medicine, Romosozumab or Alendronate for Fracture Prevention in Women with Osteoporosis, KG Saag et al: 377:1417. Copyright @2017 Massachusetts Medical Society. Reprinted with permission from Massachusetts Medical Society.)*

new devices are being developed that may circumvent these problems and provide adjunctive treatments.

Kyphoplasty and *vertebroplasty* are nonpharmacologic approaches for the treatment of painful vertebral fractures. The overall data do not support routine surgical intervention for painful vertebral fractures since, while this can reduce pain, there is concern about long-term vertebral fracture risk. Vertebral augmentation should be avoided in patients with vertebral fractures associated with denosumab discontinuation as it can increase the risk of adjacent vertebral fractures in this setting.

TREATMENT MONITORING

There are currently no well-accepted guidelines for monitoring treatment of osteoporosis. Because most osteoporosis treatments produce small or moderate bone mass increments on average, it is reasonable to consider BMD as a monitoring tool. Changes must exceed ~3% in the spine and 6% in the hip to be considered significant in any individual. The total hip is the preferred site due to larger surface area and greater reproducibility. Medication-induced increments may require several years to produce changes of this magnitude. Consequently, it can be argued that BMD should be repeated at intervals of every 2 years. Only significant BMD reductions (>~3% or ~6% at the spine and or hip, respectively) should prompt a change in therapy, as it is expected that some individuals will not show responses greater than the detection limits of the current measurement techniques.

Biochemical markers of bone turnover can help in treatment monitoring, with significant changes seen within 3 months of initiating treatment with approved medications and the possible benefit of improving adherence. It remains unclear which endpoint is most useful. If bone turnover markers are used, a determination should be made before therapy is started and repeated ≥3–4 months after therapy is initiated. In general, a change in bone turnover markers must be 30–40% lower than the baseline, or in the lower part of the standardized premenopausal range, to be significant because of the biologic and analytic variability in these tests. Because markers change more rapidly than bone density, they are often early signs of treatment effect. Currently collagen C-telopeptide (CTX) measured on a fasting serum sample in the morning is the preferred marker of bone resorption, and the propeptide of type 1 collagen (P1NP) is the preferred marker for bone formation.

GLUCOCORTICOID-INDUCED OSTEOPOROSIS

Osteoporotic fractures are a well-characterized consequence of the hypercortisolism associated with Cushing's syndrome. However, the therapeutic use of glucocorticoids is by far the most common form of glucocorticoid-induced osteoporosis (GCIOP). Glucocorticoids are used widely in the treatment of a variety of disorders, including chronic lung disorders, rheumatoid arthritis and other connective tissue diseases, and inflammatory bowel disease, and after transplantation.

Osteoporosis and related fractures are serious side effects of chronic glucocorticoid therapy. Because the effects of glucocorticoids on the skeleton are often superimposed on the consequences of aging and menopause, it is not surprising that postmenopausal women and older men are most frequently affected. The skeletal response to glucocorticoids is remarkably heterogeneous, however, and even young, growing individuals treated with glucocorticoids can present with fractures.

The risk of fractures depends on the dose and duration of glucocorticoid therapy, although recent data suggest that there may be no completely safe dose. Bone loss is more rapid during the early months of treatment, and trabecular bone is affected more severely than cortical bone. As a result, fractures have been shown to increase within 3 months of glucocorticoid treatment. There is an increase in fracture risk in both the axial skeleton and the appendicular skeleton, including risk of hip fracture. Bone loss can occur with any route of glucocorticoid administration, including high-dose inhaled glucocorticoids and intra-articular injections. Alternate-day delivery does not appear to ameliorate the skeletal effects of glucocorticoids.

PATHOPHYSIOLOGY

Glucocorticoids increase bone loss by multiple mechanisms, including (1) inhibition of osteoblast function and an increase in osteoblast apoptosis, resulting in impaired synthesis of new bone; (2) stimulation of bone resorption, probably as a secondary effect; (3) impairment of the absorption of calcium across the intestine, probably by a vitamin D–independent effect; (4) increase of urinary calcium loss and perhaps induction of some degree of secondary hyperparathyroidism; (5) reduction of adrenal androgens and suppression of ovarian and testicular secretion of estrogens and androgens; and (6) induction of glucocorticoid myopathy, which may exacerbate effects on skeletal and calcium homeostasis as well as increase the risk of falls.

EVALUATION OF THE PATIENT

Because of the high prevalence of GCIOP, it is important to evaluate the status of the skeleton in all patients starting or already receiving long-term glucocorticoid therapy. Modifiable risk factors should be identified, including those for falls. Examination should include testing of height and muscle strength. Laboratory evaluation should include an assessment of 24-h urinary calcium. All patients on long-term (>3 months) glucocorticoids should have measurement of bone mass at both the spine and the hip using DXA. If only one skeletal site can be measured, it is best to assess the spine in individuals <60 years and the hip in those >60 years.

PREVENTION

Bone loss caused by glucocorticoids can be prevented, and the risk of fractures significantly reduced. Strategies must include using the lowest dose of glucocorticoid for disease management. Topical and inhaled routes of administration are preferred, where appropriate. Risk factor reduction is important, including smoking cessation, limitation of alcohol consumption, and participation in weight-bearing and resistance exercise, when appropriate. All patients should receive an adequate calcium and vitamin D intake from the diet or from supplements.

TREATMENT

Glucocorticoid-Induced Osteoporosis

Several bisphosphonates (alendronate, risedronate, and zoledronic acid) have been demonstrated in large clinical trials to reduce the risk of fractures in patients being treated with glucocorticoids and are FDA approved for the treatment of GCIOP. Teriparatide is also approved for treatment of GCIOP. In one trial comparing teriparatide with alendronate, BMD increases were much greater and vertebral fracture risk reduction was greater with teriparatide compared with alendronate. A study of denosumab indicates greater efficacy of denosumab compared with risedronate for treatment of GCIOP. There are no data for romosozumab in GCIOP. The American College of Rheumatology has published guidelines for the management of GCIOP.

Acknowledgment

424 Paget's Disease and Other Dysplasias of Bone

Rajesh K. Jain, Tamara J. Vokes

PAGET'S DISEASE OF BONE

Paget's disease is a localized bone-remodeling disorder that affects widespread, noncontiguous areas of the skeleton. The pathologic process is initiated by overactive osteoclastic bone resorption followed by a compensatory increase in osteoblastic new bone formation, resulting in a structurally disorganized mosaic of woven and lamellar bone. Pagetic bone is expanded, less compact, and more vascular; thus, it is more susceptible to deformities and fractures. Although most patients are asymptomatic, symptoms resulting directly from bony involvement (bone pain, secondary arthritis, fractures) or secondarily from the expansion of bone causing compression of surrounding neural tissue are not uncommon.

Epidemiology There is a marked geographic variation in the frequency of Paget's disease, with high prevalence in Western Europe (Great Britain, France, and Germany, but not Switzerland or Scandinavia) and among those who have immigrated to Australia, New Zealand, South Africa, and North and South America. The disease is rare in native populations of the Americas, Africa, Asia, and the Middle East; when it does occur, the affected subjects usually have evidence of

European ancestry, supporting the migration theory. For unclear reasons, the prevalence and severity of Paget's disease are decreasing, and the age of diagnosis is increasing.

The prevalence is greater in males and increases with age. Autopsy series reveal Paget's disease in ~3% of those over age 40. Prevalence of positive skeletal radiographs in patients aged >55 years is 2.5% for men and 1.6% for women. Elevated alkaline phosphatase (ALP) levels in asymptomatic patients have an age-adjusted incidence of 12.7 and 7 per 100,000 person-years in men and women, respectively.

Etiology The etiology of Paget's disease of bone remains unknown, but evidence supports both genetic and viral etiologies. A positive family history is found in 15–25% of patients and, when present, raises the prevalence of the disease seven- to tenfold among first-degree relatives.

A clear genetic basis has been established for several rare familial bone disorders that clinically and radiographically resemble Paget's disease but have more severe presentation and earlier onset. A homozygous deletion of the *TNFRSF11B* gene, which encodes osteoprotegrin **(Fig. 424-1)**, causes *juvenile Paget's disease*, also known as *familial idiopathic hyperphosphatasia*, a disorder characterized by uncontrolled osteoclastic differentiation and resorption. Familial patterns of disease in several large kindred are consistent with an autosomal dominant pattern of inheritance with variable penetrance. *Familial expansile osteolysis, expansile skeletal hyperphosphatasia, and early-onset Paget's disease* are associated with mutations in the *TNFRSF11A* gene, which encodes RANK (receptor activator of nuclear factor-κB), a member of the tumor necrosis factor superfamily critical for osteoclast differentiation (Fig. 424-1). A mutation in profilin 1, a small actin protein that acts as a tumor suppressor, also causes early-onset Paget's disease with a predisposition for the development of osteosarcoma. Finally, mutations in the gene for valosin-containing protein cause a rare syndrome with autosomal dominant inheritance and variable penetrance known as *inclusion body myopathy with Paget's disease and frontotemporal dementia* (*IBMPFD*). The role of genetic factors is less clear in the more common form of late-onset Paget's disease. The most common mutations identified in familial and sporadic cases of Paget's disease have been in the *SQSTM1* gene (sequestasome-1 or p62 protein) in the C-terminal ubiquitin-binding domain. The other candidate genes include *CSF1* (1p13), which encodes macrophage colony-stimulating factor (M-CSF), a cytokine that is required for osteoclast differentiation; *RIN3* (14q32), which encodes a guanine exchange factor called Rab and Ras interactor 3; *OPTN* (10p13), which is involved in regulating nuclear factor (NF)-κB; *TNFRSF11A*, mentioned earlier; and *TM7SF4*, which encodes dendritic cell–specific transmembrane protein (DC-STAMP), a molecule that is essential for fusion of the osteoclast. The phenotypic variability in patients with *SQSTM1* mutations suggests that additional factors, such as other genetic influences or viral infection, may influence clinical expression of the disease.

Several lines of evidence suggest that a viral infection may contribute to the clinical manifestations of Paget's disease, including (1) the presence of cytoplasmic and nuclear inclusions resembling paramyxoviruses (measles, respiratory syncytial virus, canine distemper virus) in pagetic osteoclasts and (2) viral mRNA in precursor and mature osteoclasts. The viral etiology is further supported by conversion of osteoclast precursors to pagetic-like osteoclasts by vectors containing the measles virus nucleocapsid or matrix genes. The decline in the incidence of Paget's disease coincides with the widespread vaccination against measles, also consistent with the potential role of virus in the development of the disease. However, the viral etiology has been questioned by the inability to culture a live virus from pagetic bone and by failure to clone the full-length viral genes from material obtained from patients with Paget's disease. Furthermore, patients with Paget's disease do not have higher antibody levels against paramyxoviruses or measles as compared to controls, nor do antibody levels correlate with disease severity in those with Paget's disease.

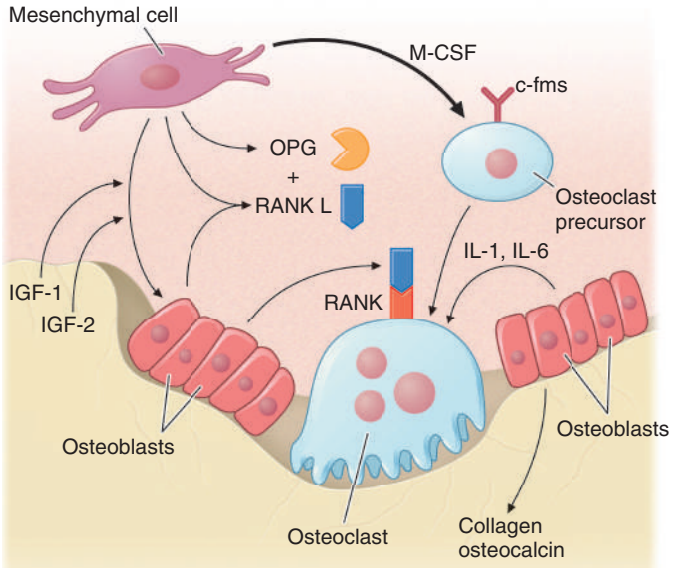

FIGURE 424-1 Diagram illustrating factors that promote differentiation and function of osteoclasts and osteoblasts and the role of the RANK pathway. Stromal bone marrow (mesenchymal) cells and differentiated osteoblasts produce multiple growth factors and cytokines, including macrophage colony-stimulating factor (M-CSF), to modulate osteoclastogenesis. RANKL (receptor activator of nuclear factor-κB [NF-κB] ligand) is produced by osteoblast progenitors and mature osteoblasts and can bind to a soluble decoy receptor known as osteoprotegerin (OPG) to inhibit RANKL action. Alternatively, a cell-cell interaction between osteoblast and osteoclast progenitors allows RANKL to bind to its membrane-bound receptor, RANK, thereby stimulating osteoclast differentiation and function. RANK binds intracellular proteins called tumor necrosis factor receptor–associated factors (TRAFs) that mediate receptor signaling through transcription factors such as NF-κB. M-CSF binds to its receptor, c-fms, which is the cellular homologue of the *fms* oncogene. See text for the potential role of these pathways in disorders of osteoclast function such as Paget's disease and osteopetrosis. IGF, insulin-like growth factor; IL, interleukin.

Pathophysiology The principal abnormality in Paget's disease is the increased number and activity of osteoclasts. Pagetic osteoclasts are large, increased 10- to 100-fold in number, and have a greater number of nuclei (as many as 100 compared to 3–5 nuclei in the normal osteoclast). The overactive osteoclasts may create a sevenfold increase in resorptive surfaces and an erosion rate of 9 μg/d (normal is 1 μg/d). Several causes for the increased number and activity of pagetic osteoclasts have been identified: (1) osteoclastic precursors are hypersensitive to $1,25(OH)_2D_3$; (2) osteoclasts are hyperresponsive to RANK ligand (RANKL), the osteoclast stimulatory factor that mediates the effects of most osteotropic factors on osteoclast formation; (3) marrow stromal cells from pagetic lesions have increased RANKL expression; (4) osteoclast precursor recruitment is increased by interleukin (IL) 6, which is increased in the blood of patients with active Paget's disease and is overexpressed in pagetic osteoclasts; (5) expression of the proto-oncogene c-*fos*, which increases osteoclastic activity, is increased; and (6) the antiapoptotic oncogene *Bcl*-2 in pagetic bone is overexpressed. Numerous osteoblasts are recruited to active resorption sites and produce large amounts of new bone matrix. As a result, bone turnover is high, and bone mass is normal or increased, not reduced, unless there is concomitant deficiency of calcium and/or vitamin D.

The characteristic feature of Paget's disease is increased bone resorption accompanied by accelerated bone formation. An initial osteolytic phase involves prominent bone resorption and marked hypervascularization. Radiographically, this manifests as an advancing lytic wedge, or "blade of grass" lesion. The second phase is a period of very active bone formation and resorption that replaces normal lamellar bone with haphazard (woven) bone. Fibrous connective tissue may replace normal bone marrow. In the final sclerotic phase, bone resorption declines progressively and leads to a hard, dense, less vascular pagetic or mosaic bone, which represents the so-called burned-out phase of Paget's disease. All three phases may be present at the same time at different skeletal sites.

Clinical Manifestations Diagnosis is often made in asymptomatic patients because they have elevated ALP levels on routine blood chemistry testing or an abnormality on a skeletal radiograph obtained

for another indication. The skeletal sites most commonly involved are the pelvis, vertebral bodies, skull, femur, and tibia. Familial cases with an early presentation often have numerous active sites of skeletal involvement.

The most common presenting symptom is pain, which may result from increased bony vascularity, expanding lytic lesions, fractures, bowing, or other deformities. Bowing of the femur or tibia causes gait abnormalities and abnormal mechanical stresses with secondary osteoarthritis of the hip or knee joints. Long bone bowing also causes extremity pain by stretching the muscles attached to the bone softened by the pagetic process. Back pain results from enlarged pagetic vertebrae, vertebral compression fractures, spinal stenosis, degenerative changes of the joints, and altered body mechanics with kyphosis and forward tilt of the upper back. Rarely, spinal cord compression may result from bone enlargement or from the vascular steal syndrome. Skull involvement may cause headaches, symmetric or asymmetric enlargement of the parietal or frontal bones (frontal bossing), and increased head size. Cranial expansion may narrow cranial foramens and cause neurologic complications including hearing loss from cochlear nerve damage from temporal bone involvement, cranial nerve palsies, and softening of the base of the skull (*platybasia*) with the risk of brainstem compression. Pagetic involvement of the facial bones may cause facial deformity; loss of teeth and other dental conditions; and, rarely, airway compression.

Fractures are serious complications of Paget's disease and usually occur in long bones at areas of active or advancing lytic lesions. Common fracture sites are the femoral shaft and subtrochanteric regions. Neoplasms arising from pagetic bone are rare (<0.5%). The incidence of sarcoma appears to be decreasing, possibly because of earlier, more effective treatment with potent antiresorptive agents. The majority of tumors are osteosarcomas, which usually present with new pain in a long-standing pagetic lesion. Osteoclast-rich benign giant cell tumors may arise in areas adjacent to pagetic bone, and they respond to glucocorticoid therapy.

Cardiovascular complications may occur in patients with involvement of large (15–35%) portions of the skeleton and a high degree of disease activity (e.g., ALP four times above normal). The extensive arteriovenous shunting and marked increases in blood flow through the vascular pagetic bone lead to a high-output state and cardiac enlargement. However, high-output heart failure is relatively rare and usually develops in patients with concomitant cardiac pathology. In addition, calcific aortic stenosis and diffuse vascular calcifications have been associated with Paget's disease.

Diagnosis The diagnosis may be suggested on clinical examination by the presence of an enlarged skull with frontal bossing, bowing of an extremity, or short stature with simian posturing. An extremity with an area of warmth and tenderness to palpation may suggest an underlying pagetic lesion. Other findings include bony deformity of the pelvis, skull, spine, and extremities; arthritic involvement of the joints adjacent to lesions; and leg-length discrepancy resulting from deformities of the long bones.

Paget's disease is usually diagnosed from radiologic and biochemical abnormalities. Radiographic findings typical of Paget's disease include enlargement or expansion of an entire bone or area of a long bone, cortical thickening, coarsening of trabecular markings, and typical lytic and sclerotic changes. Skull radiographs **(Fig. 424-2)** reveal regions of "cotton wool," or osteoporosis circumscripta, thickening of diploic areas, and enlargement and sclerosis of a portion or all of one or more skull bones. Vertebral cortical thickening of the superior and inferior end plates creates a "picture frame" vertebra. Diffuse radiodense enlargement of a vertebra is referred to as "ivory vertebra." Pelvic radiographs may demonstrate disruption or fusion of the sacroiliac joints; porotic and radiodense lesions of the ilium with whorls of coarse trabeculation; thickened and sclerotic iliopectineal line (brim sign); and softening with protrusio acetabuli, with axial migration of the hips and functional flexion contracture. Radiographs of long bones reveal bowing deformity and typical pagetic changes of cortical thickening and expansion and areas of lucency and sclerosis **(Fig. 424-3)**. Radionuclide ^{99m}Tc bone scans are less specific but are more sensitive than standard radiographs for identifying sites of active skeletal lesions. Although computed tomography (CT) and magnetic resonance imaging (MRI) studies are not necessary in most cases, CT may be useful for the assessment of possible fracture, and MRI is necessary to assess the possibility of sarcoma, giant cell tumor, or metastatic disease in pagetic bone. Definitive diagnosis of malignancy often requires bone biopsy.

Biochemical evaluation is useful in the diagnosis and management of Paget's disease. The marked increase in bone turnover can be monitored using biochemical markers of bone formation and resorption. The parallel rise in markers of bone formation and resorption confirms the coupling of bone formation and resorption in Paget's disease. The degree of bone marker elevation reflects the extent and severity of the disease. For most patients, serum total ALP remains the test of choice both for diagnosis and assessing response to therapy. Occasionally, a symptomatic patient with evidence of progression at a single site may have a normal total ALP level but increased bone-specific ALP. For unclear reasons, serum osteocalcin, another marker of bone formation, is not always elevated and is not recommended for use in diagnosis or management of Paget's disease. In contrast, bone formation marker P1NP does reflect the activity of the disease and can be used instead of total ALP. Bone resorption markers (serum or urine N-telopeptide or C-telopeptide measured in the blood or urine) are also elevated in active Paget's disease and decrease more rapidly in response to therapy than does ALP.

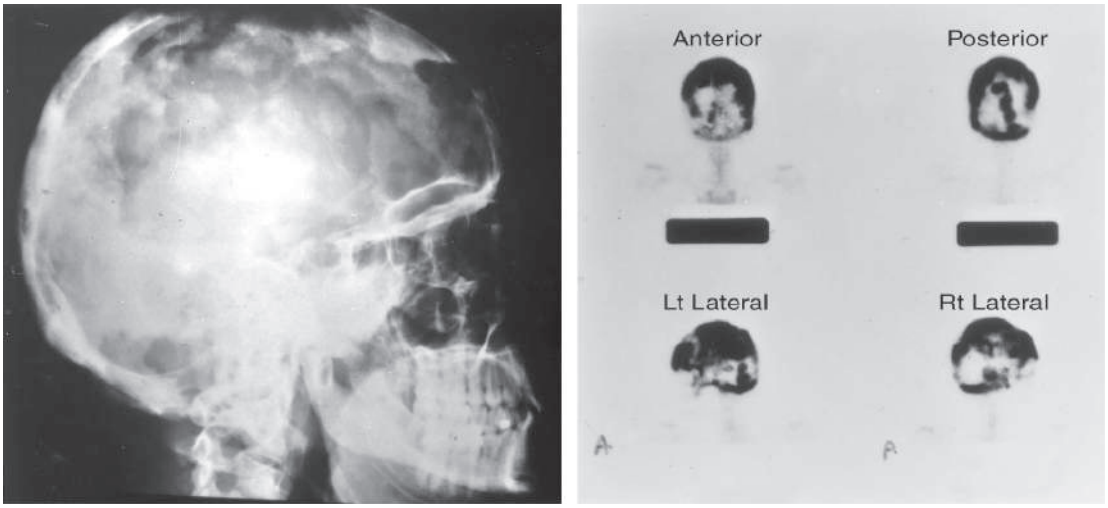

FIGURE 424-2 A 48-year-old woman with Paget's disease of the skull. ***Left.*** Lateral radiograph showing areas of both bone resorption and sclerosis. ***Right.*** ^{99m}Tc hydroxymethylene diphosphonate (HDP) bone scan with anterior, posterior, and lateral views of the skull showing diffuse isotope uptake by the frontal, parietal, occipital, and petrous bones.

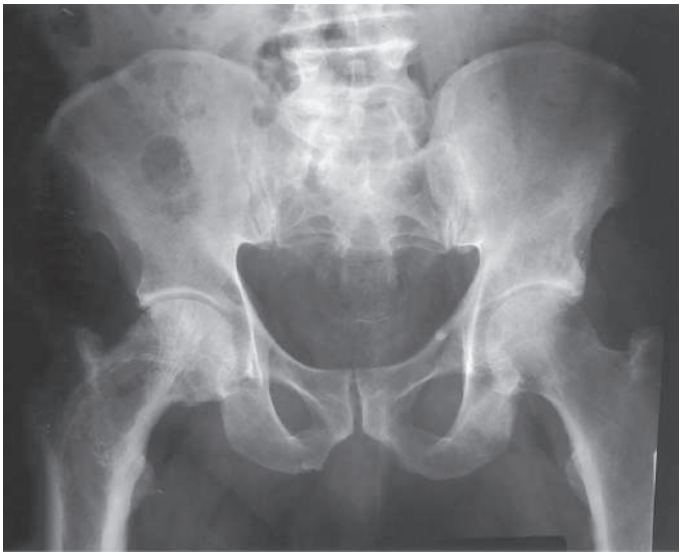

FIGURE 424-3 Radiograph of a 73-year-old man with Paget's disease of the right proximal femur. Note the coarsening of the trabecular pattern with marked cortical thickening and narrowing of the joint space consistent with osteoarthritis secondary to pagetic deformity of the right femur.

Serum calcium and phosphate levels are normal in Paget's disease. Immobilization of a patient with active Paget's disease may rarely cause hypercalcemia and hypercalciuria and increase the risk for nephrolithiasis. However, the discovery of hypercalcemia, even in the presence of immobilization, should prompt a search for another cause of hypercalcemia. In contrast, hypocalcemia or mild secondary hyperparathyroidism may develop in Paget's patients with very active bone formation and insufficient calcium and vitamin D intake, particularly during bisphosphonate therapy when bone resorption is rapidly suppressed and active bone formation continues. Therefore, adequate calcium and vitamin D intake should be instituted prior to administration of bisphosphonates.

TREATMENT

Paget's Disease of Bone

The development of effective and potent pharmacologic agents (Table 424-1) has changed the treatment philosophy from treating only symptomatic patients to treating asymptomatic patients who are at risk for complications. According to the Endocrine Society Clinical Practice Guidelines published in 2014, pharmacologic therapy is indicated for most patients with active Paget's disease who are at risk of complications. Treatment may be initiated to control symptoms caused by metabolically active Paget's disease such as bone pain, fracture, headache, pain from pagetic radiculopathy or arthropathy, or neurologic complications; to decrease local blood flow and minimize operative blood loss in patients who need surgery at an active pagetic site; to reduce hypercalciuria that may occur during immobilization; and to decrease the risk of complications when disease activity is high (elevated ALP) and when the site of involvement involves weight-bearing bones, areas adjacent to major joints, vertebral bodies, and the skull. Whether or not early therapy prevents late complications remains to be determined. Randomized studies from the United Kingdom showed no difference in bone pain, fracture rates, quality of life, and hearing loss between patients who received pharmacologic therapy to control symptoms (bone pain) and those receiving bisphosphonates to normalize serum ALP. However, the conclusions of these studies are debatable since the majority of subjects had already received bisphosphonate therapy in the past, perhaps limiting generalizability, and because the bone deformities that occur with Paget's disease may take many years to manifest. It seems likely that the restoration of normal bone architecture following suppression of pagetic activity will prevent further deformities and complications.

TABLE 424-1 Pharmacologic Agents Approved for Treatment of Paget's Disease

NAME	DOSE AND MODE OF DELIVERY	NORMALIZATION OF ALKALINE PHOSPHATASE (ALP)
Zoledronic acid	5 mg IV over 15 min	90% of patients at 6 mo
Pamidronate	30 mg/d IV over 4 h on 3 days	~50% of patients
Risedronate	30 mg/d PO for 2 mo	73% of patients
Alendronate	40 mg/d PO for 6 mo	63% of patients
Tiludronate	800 mg/d PO for 3 mo	35% of patients
Etidronate	200–400 mg/d PO × 6 mo	15% of patients
Calcitonin (Miacalcin)	100 U SC daily for 6–18 mo (may reduce to 50 U 3× per week)	(Reduction of ALP by up to 50%)

Agents approved for treatment of Paget's disease suppress the very high rates of bone resorption and secondarily decrease the high rates of bone formation (Table 424-1). As a result of decreasing bone turnover, pagetic structural patterns, including areas of poorly mineralized woven bone, are replaced by more normal cancellous or lamellar bone. Reduced bone turnover can be documented by a decline in serum formation markers (ALP and P1NP) and urine or serum resorption markers (N-telopeptide, C-telopeptide).

Bisphosphonates are the mainstay of pharmacologic therapy of Paget's disease. Among them, zoledronic acid is currently recommended as the first choice, particularly for those who have severe disease or need rapid normalization of bone turnover (neurologic symptoms, severe bone pain due to a lytic lesion, risk of an impending fracture, or pretreatment prior to elective surgery in an area of active disease). Zoledronic acid normalized bone turnover faster and in a high proportion of patients (>90%) than oral bisphosphonates with the therapeutic effect persisting for months or even years. It is given at a dose of 5 mg as an intravenous infusion over 20 min, although slower rates of infusion are recommended for elderly or those with mild impairment of renal function. More significant renal impairment (glomerular filtration rate <35 mL/min) is a contraindication for use of zoledronic acid due to higher risk of further deterioration of renal function. About 20–25% of patients experience a flulike syndrome after the first infusion, which can be partly ameliorated by pretreatment with acetaminophen, nonsteroidal anti-inflammatory drugs (NSAIDs), or glucocorticoids. Oral bisphosphonates, alendronate and risedronate, can be used in subjects who have mild disease or some degree of renal impairment. Oral bisphosphonates should be taken first thing in the morning on an empty stomach, followed by maintenance of upright posture with no food, drink, or other medications for 30–60 min. The efficacy of different agents, based on their ability to normalize or decrease ALP levels, is summarized in Table 424-1, although the response rates are not comparable because they are obtained from different studies.

The subcutaneous injectable form of salmon calcitonin is approved for the treatment of Paget's disease but is rarely used due to its low potency and should be reserved for patients who either do not tolerate bisphosphonates or have a contraindication to their use. For patients with contraindication to bisphosphonates, another alternative is denosumab, an antibody to RANKL, which has been reported to result in reduction in ALP. However, it has not been approved for this indication and has less complete and less durable effects than bisphosphonates.

SCLEROSING BONE DISORDERS

OSTEOPETROSIS

Osteopetrosis refers to a group of disorders caused by severe impairment of osteoclast-mediated bone resorption. Other terms that are often used include marble bone disease, which captures the solid x-ray

appearance of the involved skeleton, and Albers-Schonberg disease, which refers to the milder, adult form of osteopetrosis also known as autosomal dominant osteopetrosis type II. The major types of osteopetrosis include malignant (severe, infantile, autosomal recessive) osteopetrosis and benign (adult, autosomal dominant) osteopetrosis types I and II. A rare autosomal recessive intermediate form has a more benign prognosis. Autosomal recessive carbonic anhydrase (CA) II deficiency produces osteopetrosis of intermediate severity associated with renal tubular acidosis and cerebral calcification.

Etiology and Genetics Naturally occurring and gene-knockout animal models with phenotypes similar to those of the human disorders have been used to explore the genetic basis of osteopetrosis. The primary defect in osteopetrosis is the loss of osteoclastic bone resorption and preservation of normal osteoblastic bone formation. Osteoprotegerin (OPG) is a soluble decoy receptor that binds osteoblast-derived RANK ligand, which mediates osteoclast differentiation and activation (Fig. 424-1). Transgenic mice that overexpress OPG develop osteopetrosis, presumably by blocking RANK ligand. Mice deficient in RANK lack osteoclasts and develop severe osteopetrosis.

Recessive mutations of CA II prevent osteoclasts from generating an acid environment in the clear zone between its ruffled border and the adjacent mineral surface. Absence of CA II, therefore, impairs osteoclastic bone resorption. Other forms of human disease have less clear genetic defects. About one-half of the patients with malignant infantile osteopetrosis have a mutation in the *TCIRG1* gene encoding the osteoclast-specific subunit of the vacuolar proton pump, which mediates the acidification of the interface between bone mineral and the osteoclast ruffled border. Mutations in the *CLCN7* chloride channel gene cause autosomal dominant osteopetrosis type II. A drug-induced version of osteopetrosis has been reported in children with osteogenesis imperfecta who receive repeated doses of bisphosphonates.

Clinical Presentation The incidence of autosomal recessive severe (malignant) osteopetrosis ranges from 1 in 200,000 to 1 in 500,000 live births. As bone and cartilage fail to undergo modeling, paralysis of one or more cranial nerves may occur due to narrowing of the cranial foramens. Failure of skeletal modeling also results in inadequate marrow space, leading to extramedullary hematopoiesis with hypersplenism and pancytopenia. Hypocalcemia due to lack of osteoclastic bone resorption may occur in infants and young children. The untreated infantile disease is fatal, often before age 5.

Adult (benign) osteopetrosis is an autosomal dominant disease that is usually diagnosed by the discovery of typical skeletal changes in young adults who undergo radiologic evaluation of a fracture. The prevalence is 1 in 100,000 to 1 in 500,000 adults. The course is not always benign, because fractures may be accompanied by loss of vision, deafness, psychomotor delay, mandibular osteomyelitis, and other complications usually associated with the juvenile form. In some kindred, nonpenetrance results in skip generations, while in other families, severely affected children are born into families with benign disease. The milder form of the disease does not usually require treatment.

Radiography Typically, there are generalized symmetric increases in bone mass with thickening of both cortical and trabecular bone. Diaphyses and metaphyses are broadened, and alternating sclerotic and lucent bands may be seen in the iliac crests, at the ends of long bones, and in vertebral bodies. The cranium is usually thickened, particularly at the base of the skull, and the paranasal and mastoid sinuses are underpneumatized.

Laboratory Findings The only significant laboratory findings are elevated serum levels of osteoclast-derived tartrate-resistant acid phosphatase (TRAP) and the brain isoenzyme of creatine kinase. Serum calcium may be low in severe disease, and parathyroid hormone and 1,25-dihydroxyvitamin D levels may be elevated in response to hypocalcemia.

TREATMENT

Osteopetrosis

Allogeneic human leukocyte antigen (HLA)–identical bone marrow transplantation has been successful in some children. Following transplantation, the marrow contains progenitor cells and normally functioning osteoclasts. With long-term follow-up after transplantation, radiographic improvements, such as improvements in Erlenmeyer flask deformities, are seen, although there is not complete normalization. A cure is most likely when children are transplanted before age 4. Marrow transplantation from nonidentical HLA-matched donors has a much higher failure rate. Limited studies in small numbers of patients have suggested variable benefits following treatment with interferon γ-1β, 1,25-dihydroxyvitamin D (which stimulates osteoclasts directly), methylprednisolone, and a low-calcium/high-phosphate diet.

Surgical intervention is indicated to decompress optic or auditory nerve compression. Orthopedic management is required for the surgical treatment of fractures and their complications, including malunion and postfracture deformity.

PYKNODYSOSTOSIS

This is an autosomal recessive form of osteosclerosis that is believed to have affected the French impressionist painter Henri de Toulouse-Lautrec. The molecular basis involves mutations in the gene that encodes cathepsin K, a lysosomal metalloproteinase highly expressed in osteoclasts and important for bone-matrix degradation. Osteoclasts are present but do not function normally. Pyknodysostosis is a form of short-limb dwarfism that presents with frequent fractures but usually a normal life span. Clinical features include short stature; kyphoscoliosis and deformities of the chest; high arched palate; proptosis; blue sclerae; dysmorphic features including small face and chin, frontooccipital prominence, pointed beaked nose, large cranium, and obtuse mandibular angle; and small, square hands with hypoplastic nails. Radiographs demonstrate a generalized increase in bone density, but in contrast to osteopetrosis, the long bones are normally shaped. Separated cranial sutures, including the persistent patency of the anterior fontanel, are characteristic of the disorder. There may also be hypoplasia of the sinuses, mandible, distal clavicles, and terminal phalanges. Persistence of deciduous teeth and sclerosis of the calvarium and base of the skull are also common. Histologic evaluation shows normal cortical bone architecture with decreased osteoblastic and osteoclastic activities. Serum chemistries are normal, and unlike osteopetrosis, there is no anemia. There is no known treatment for this condition, and there are no reports of attempted bone marrow transplant.

PROGRESSIVE DIAPHYSEAL DYSPLASIA

Also known as *Camurati-Engelmann disease*, progressive diaphyseal dysplasia is an autosomal dominant disorder that is characterized radiographically by diaphyseal hyperostosis and a symmetric thickening and increased diameter of the endosteal and periosteal surfaces of the diaphyses of the long bones, particularly the femur and tibia, and, less often, the fibula, radius, and ulna. The genetic defect responsible for the disease has been localized to the area of chromosome 19q13.2 encoding transforming growth factor (TGF)-β1. The mutation promotes activation of TGF-β1. The clinical severity is variable. The most common presenting symptoms are pain and tenderness of the involved areas, fatigue, muscle wasting, and gait disturbance. The weakness may be mistaken for muscular dystrophy. Characteristic body habitus includes thin limbs with little muscle mass yet prominent and palpable bones and, when the skull is involved, large head with prominent forehead and proptosis. Patients may also display signs of cranial nerve palsies, hydrocephalus, central hypogonadism, and Raynaud's phenomenon. Radiographically, patchy progressive endosteal and periosteal new bone formation is observed along the diaphyses of the long bones. Bone scintigraphy shows increased radiotracer uptake in involved areas.

Treatment with low-dose glucocorticoids relieves bone pain and may reverse the abnormal bone formation. Intermittent bisphosphonate

therapy has produced clinical improvement in a limited number of patients. Disease activity may also attenuate as patients enter adulthood.

HYPEROSTOSIS CORTICALIS GENERALISATA

This is also known as *van Buchem's disease*; it is an autosomal recessive disorder characterized by endosteal hyperostosis in which osteosclerosis involves the skull, mandible, clavicles, and ribs. The major manifestations are due to narrowed cranial foramens with neural compressions that may result in optic atrophy, facial paralysis, and deafness. Adults may have an enlarged mandible. Serum ALP levels may be elevated, which reflect the uncoupled bone remodeling with high osteoblastic formation rates and low osteoclastic resorption. As a result, there is increased accumulation of normal bone. Endosteal hyperostosis with syndactyly, known as *sclerosteosis*, is a more severe form. The genetic defects for both sclerosteosis and van Buchem's disease have been associated with mutations in the *SOST* gene.

MELORHEOSTOSIS

Melorheostosis (Greek, "flowing hyperostosis") may occur sporadically or follow a pattern consistent with an autosomal recessive disorder. The major manifestation is progressive linear hyperostosis in one or more bones of one limb, usually a lower extremity. The name comes from the radiographic appearance of the involved bone, which resembles melted wax that has dripped down a candle. Symptoms appear during childhood as pain or stiffness in the area of sclerotic bone. There may be associated ectopic soft tissue masses, composed of cartilage or osseous tissue, and skin changes overlying the involved bone, consisting of scleroderma-like areas and hypertrichosis. The disease does not progress in adults, but pain and stiffness may persist. Laboratory tests are unremarkable. Somatic mutations in *MAP2K1*, which increases MEK1 activity downstream of the RAS pathway, and *SMAD3*, which upregulates the TGF-β/SMAD pathway, have been identified in affected bone in patients with melorheostosis. There is no specific treatment. Surgical interventions to correct contractures are often unsuccessful.

OSTEOPOIKILOSIS

The literal translation of osteopoikilosis is "spotted bones"; it is a benign autosomal dominant condition in which numerous small, variably shaped (usually round or oval) foci of bony sclerosis are seen in the epiphyses and adjacent metaphyses. The lesions may involve any bone except the skull, ribs, and vertebrae. They may be misidentified as metastatic lesions. The main differentiating points are that bony lesions of osteopoikilosis are stable over time and do not accumulate radionucleotide on bone scanning. In some kindred, osteopoikilosis is associated with connective tissue nevi known as *dermatofibrosis lenticularis disseminata*, also known as *Buschke-Ollendorff syndrome*. Most cases are caused by mutations in *LEMD3*, which is involved with bone morphogenetic protein (BMP) signaling. Histologic inspection reveals thickened but otherwise normal trabeculae and islands of normal cortical bone. No treatment is indicated.

HEPATITIS C–ASSOCIATED OSTEOSCLEROSIS

Hepatitis C–associated osteosclerosis (HCAO) is a rare acquired diffuse osteosclerosis in adults with prior hepatitis C infection. After a latent period of several years, patients develop diffuse appendicular bone pain and a generalized increase in bone mass with elevated serum ALP. Bone biopsy and histomorphometry reveal increased rates of bone formation, decreased bone resorption with a marked decrease in osteoclasts, and dense lamellar bone. One patient had increased serum OPG levels, and bone biopsy showed large numbers of osteoblasts positive for OPG and reduced osteoclast number. Empirical therapy includes pain control, and there may be beneficial response to bisphosphonate. Long-term antiviral therapy may reverse the bone disease.

DISORDERS ASSOCIATED WITH DEFECTIVE MINERALIZATION

HYPOPHOSPHATASIA

This is a rare inherited disorder that presents as rickets in infants and children or osteomalacia in adults with paradoxically low serum levels of ALP. The frequency of the severe neonatal and infantile forms is about 1 in 100,000 live births in Canada, where the disease is most common because of its high prevalence among Mennonites and Hutterites. It is rare in African Americans. The severity of the disease is remarkably variable, ranging from intrauterine death associated with profound skeletal hypomineralization at one extreme to premature tooth loss as the only manifestation in some adults. Severe cases are inherited in an autosomal recessive manner, but the genetic patterns are less clear for the milder forms. The disease is caused by a deficiency of tissue nonspecific (bone/liver/kidney) ALP (TNSALP), which, although ubiquitous, results only in bone abnormalities. Protein levels and functions of the other ALP isozymes (germ cell, intestinal, placental) are normal. Defective ALP permits accumulation of its major naturally occurring substrates including phosphoethanolamine (PEA), inorganic pyrophosphate (PPi), and pyridoxal 5′-phosphate (PLP). The accumulation of PPi interferes with mineralization through its action as a potent inhibitor of hydroxyapatite crystal growth.

Perinatal hypophosphatasia becomes manifest during pregnancy and is often complicated by polyhydramnios and intrauterine death. The infantile form becomes clinically apparent before the age of 6 months with failure to thrive, rachitic deformities, functional craniosynostosis despite widely open fontanels (which are actually hypomineralized areas of the calvarium), raised intracranial pressure, and flail chest with predisposition to pneumonia. Hypercalcemia and hypercalciuria are common. This form has a mortality rate of ~50%. Prognosis seems to improve for the children who survive infancy. Childhood hypophosphatasia has variable clinical presentation. Premature loss of deciduous teeth (before age 5) is the hallmark of the disease. Rickets causes delayed walking with waddling gait, short stature, and dolichocephalic skull with frontal bossing. The disease often improves during puberty but may recur in adult life. Adult hypophosphatasia presents during middle age with painful, poorly healing metatarsal stress fractures or thigh pain due to femoral pseudofractures. Presentation may be subtle with muscle pain or recurring headaches as the predominant symptoms. It is important to recognize hypophosphatasia in adults because treatment with bisphosphonates can result in increased rather than decreased bone fragility.

Laboratory investigation reveals low ALP levels and normal or elevated levels of serum calcium and phosphorus despite clinical and radiologic evidence of rickets or osteomalacia. Serum parathyroid hormone, 25-hydroxyvitamin D, and 1,25-dihydroxyvitamin D levels are normal. The elevation of PLP is specific for the disease and may even be present in asymptomatic parents of severely affected children. Because vitamin B_6 increases PLP levels, vitamin B_6 supplements should be discontinued 1 week before testing. Clinical testing is available to detect loss-of-function mutation(s) within the *ALPL* gene that encodes TNSALP.

In contrast to other forms of rickets and osteomalacia, calcium and vitamin D supplementation should be avoided because they may aggravate hypercalcemia and hypercalciuria. A low-calcium diet, glucocorticoids, and calcitonin have been used in a small number of patients with variable responses. Because fracture healing is poor, placement of intramedullary rods is best for acute fracture repair and for prophylactic prevention of fractures. In 2015, asfotase alfa, a TNSALP, was approved as enzyme replacement therapy for the perinatal/infantile- and juvenile-onset forms. With 7 years of therapy, children with perinatal/infantile forms showed sustained improvements in mineralization, along with improvements in other features, such as respiratory function and growth. In adolescents and adults, 5 years of therapy demonstrated improved functional abilities, such as increases in 6-min walk time.

AXIAL OSTEOMALACIA

This is a rare disorder characterized by defective skeletal mineralization despite normal serum calcium and phosphate levels. Clinically, the disorder presents in middle-aged or elderly men with chronic axial skeletal discomfort. Cervical spine pain may also be present. Radiographic findings are mainly osteosclerosis due to coarsened trabecular patterns typical of osteomalacia. Spine, pelvis, and ribs are most commonly affected. Histologic changes show defective mineralization

and flat, inactive osteoblasts. The primary defect appears to be an acquired defect in osteoblast function. The course is benign, and there is no established treatment. Calcium and vitamin D therapies are not effective.

FIBROGENESIS IMPERFECTA OSSIUM

This is a rare condition of unknown etiology. It presents in both sexes; in middle age or later; and with progressive, intractable skeletal pain and fractures; worsening immobilization; and a debilitating course. The only biochemical abnormality is elevated ALP. Radiographic evaluation reveals generalized osteomalacia, osteopenia, and occasional pseudofractures. Histologic features include a tangled pattern of collagen fibrils with abundant osteoblasts and osteoclasts. Use of growth hormone led to substantial short-term clinical improvement in two adult patients, but long-term outcomes are unknown. No other effective treatment is known. Spontaneous remission has been reported in a small number of patients.

FIBROUS DYSPLASIA AND MCCUNE-ALBRIGHT SYNDROME

Fibrous dysplasia is a sporadic disorder characterized by the presence of one (monostotic) or more (polyostotic) expanding fibrous skeletal lesions composed of bone-forming mesenchyme. The association of the polyostotic form with café au lait spots and hyperfunction of an endocrine system such as pseudoprecocious puberty of ovarian origin is known as *McCune-Albright syndrome* (MAS). A spectrum of the phenotypes is caused by activating mutations in the *GNAS1* gene, which encodes the α subunit of the stimulatory G protein ($G_s\alpha$). As the postzygotic mutations occur at different stages of early development, the extent and type of tissue affected are variable and explain the mosaic pattern of skin and bone changes. GTP binding activates the $G_s\alpha$ regulatory protein and mutations in regions of $G_s\alpha$ that selectively inhibit GTPase activity, which results in constitutive stimulation of the cyclic AMP–protein kinase A signal transduction pathway. Such mutations of the $G_s\alpha$ protein–coupled receptor may cause autonomous function in bone (parathyroid hormone receptor); skin (melanocyte-stimulating hormone receptor); and various endocrine glands including ovary (follicle-stimulating hormone receptor), thyroid (thyroid-stimulating hormone receptor), adrenal (adrenocorticotropic hormone receptor), and pituitary (growth hormone–releasing hormone receptor). The skeletal lesions are composed largely of mesenchymal cells that do not differentiate into osteoblasts, resulting in the formation of imperfect bone. In some areas of bone, fibroblast-like cells develop features of osteoblasts in that they produce extracellular matrix that organizes into woven bone. Calcification may occur in some areas. In other areas, cells have features of chondrocytes and produce cartilage-like extracellular matrix.

Clinical Presentation Fibrous dysplasia occurs with equal frequency in both sexes, whereas MAS with precocious puberty is more common (10:1) in girls. The monostotic form is the most common and is usually diagnosed in patients between 20 and 30 years of age without associated skin lesions. The polyostotic form typically manifests in children <10 years old and may progress with age. Early-onset disease is generally more severe. Lesions may become quiescent in puberty and progress during pregnancy or with estrogen therapy. In polyostotic fibrous dysplasia, the lesions most commonly involve the maxilla and other craniofacial bones, ribs, and metaphyseal or diaphyseal portions of the proximal femur or tibia. Expanding bone lesions may cause pain, deformity, fractures, and nerve entrapment. Sarcomatous degeneration involving the facial bones or femur is infrequent (<1%). The risk of malignant transformation is increased by radiation, which has proven to be ineffective treatment. In rare patients with widespread lesions, renal phosphate wasting and hypophosphatemia may cause rickets or osteomalacia. Hypophosphatemia may be due to production of a phosphaturic factor by the abnormal fibrous tissue.

MAS patients may have café au lait spots, which are flat, hyperpigmented skin lesions that have rough borders ("coast of Maine") in contrast to the café au lait lesions of neurofibromatosis that have smooth borders ("coast of California"). The most common endocrinopathy is isosexual pseudoprecocious puberty in girls. Other less common endocrine disorders include thyrotoxicosis, Cushing's syndrome, acromegaly, hyperparathyroidism, hyperprolactinemia, and pseudoprecocious puberty in boys.

FIGURE 424-4 Radiograph of a 16-year-old male with fibrous dysplasia of the right proximal femur. Note the multiple cystic lesions, including the large lucent lesion in the proximal midshaft with scalloping of the interior surface. The femoral neck contains two lucent cystic lesions.

Radiographic Findings In long bones, the fibrous dysplastic lesions are typically well-defined, radiolucent areas with thin cortices and a ground-glass appearance. Lesions may be lobulated with trabeculated areas of radiolucency (Fig. 424-4). Involvement of facial bones usually presents as radiodense lesions, which may create a leonine appearance (leontiasis osea). Expansile cranial lesions may narrow foramens and cause optic lesions, reduce hearing, and create other manifestations of cranial nerve compression.

Laboratory Results Serum ALP is occasionally elevated, but calcium, parathyroid hormone, 25-hydroxyvitamin D, and 1,25-dihydroxyvitamin D levels are normal. Patients with extensive polyostotic lesions may have hypophosphatemia, hyperphosphaturia, and osteomalacia. The hypophosphatemia and phosphaturia are directly related to the levels of fibroblast growth factor 23 (FGF23). Biochemical markers of bone turnover may be elevated.

TREATMENT

Fibrous Dysplasia and MAS

Spontaneous healing of the lesions does not occur, and there is no established effective treatment. Improvement in bone pain and partial or complete resolution of radiographic lesions have been reported after IV bisphosphonate therapy. Denosumab given monthly or every 3 months is effective in reducing bone turnover markers and leads to some clinical improvement, though subsequent discontinuation of denosumab occasionally results in hypercalcemia. Surgical stabilization is used to prevent pathologic fracture or destruction of a major joint space and to relieve nerve root or cranial nerve compression or sinus obstruction.

OTHER DYSPLASIAS OF BONE AND CARTILAGE

PACHYDERMOPERIOSTOSIS

Pachydermoperiostosis, or hypertrophic osteoarthropathy (primary or idiopathic), is an autosomal dominant disorder characterized by periosteal new bone formation that involves the distal extremities. The lesions present as clubbing of the digits and hyperhidrosis and thickening of the skin, primarily of the face and forehead. The changes usually appear during adolescence, progress over the next decade, and then become quiescent. During the active phase, progressive enlargement of the hands and feet produces a paw-like appearance, which may be mistaken for acromegaly. Arthralgias, pseudogout, and limited mobility may also occur. The disorder must be differentiated from secondary hypertrophic osteopathy that develops during the course of serious pulmonary disorders. The two conditions can be differentiated by standard radiography of the digits in which secondary pachydermoperiostosis has exuberant periosteal new bone formation and a smooth and undulating surface. In contrast, primary hypertrophic osteopathy has an irregular periosteal surface.

The disease is genetically heterogeneous and is related to increases in prostaglandin E2. Synovial fluid does not have an inflammatory profile. There is no specific therapy, although a limited experience with colchicine suggests some benefit in controlling the arthralgias.

OSTEOCHONDRODYSPLASIAS

These include several hundred heritable disorders of connective tissue. These primary abnormalities of cartilage manifest as disturbances in cartilage and bone growth. Selected growth-plate chondrodysplasias are described here. **For discussion of chondrodysplasias, see Chap. 425.**

Achondrodysplasia This is a relatively common form of short-limb dwarfism that occurs in 1 in 15,000 to 1 in 40,000 live births. The disease is caused by a mutation of the fibroblast growth factor receptor 3 (*FGFR3*) gene that results in a gain-of-function state. Most cases are sporadic mutations. However, when the disorder appears in families, the inheritance pattern is consistent with an autosomal dominant disorder. The primary defect is abnormal chondrocyte proliferation at the growth plate that causes development of short, but proportionately thick, long bones. Other regions of the long bones may be relatively unaffected. The disorder is manifest by the presence of short limbs (particularly the proximal portions), normal trunk, large head, saddle nose, and an exaggerated lumbar lordosis. Severe spinal deformity may lead to cord compression. The homozygous disorder is more serious than the sporadic form and may cause neonatal death. Vosoritide, an analog of C-type natriuretic peptide, increased growth among children in phase 3 clinical trials and was approved in 2021. Treatment is controversial among patient support communities. Infigratinib, a selective FGFR1-3 tyrosine kinase inhibitor, is in clinical trials. Pseudoachondroplasia clinically resembles achondrodysplasia but has no skull abnormalities.

Enchondromatosis This is also called *dyschondroplasia* or *Ollier's disease*; it is also a disorder of the growth plate in which the primary cartilage is not resorbed. Cartilage ossification proceeds normally, but it is not resorbed normally, leading to cartilage accumulation. The changes are most marked at the ends of long bones, where the highest growth rates occur. Chondrosarcoma develops infrequently. The association of enchondromatosis and cavernous hemangiomas of the skin and soft tissues is known as *Maffucci's syndrome*. Both Ollier's disease and Maffucci's syndrome are associated with various malignancies, including granulosa cell tumor of the ovary and cerebral glioma.

Multiple Osteochondromas This is also called *multiple exostoses* or *diaphyseal aclasis*; it is a genetic disorder that follows an autosomal dominant pattern of inheritance. In this condition, areas of growth plates become displaced, presumably by growing through a defect in the perichondrium. The lesion begins with vascular invasion of the growth-plate cartilage, resulting in a characteristic radiographic finding of a mass that is in direct communication with the marrow cavity of the parent bone. The underlying cortex is resorbed. The disease is caused by inactivating mutations of the *EXT1* and *EXT2* genes, whose products normally synthesize heparan sulfate chains. The resulting heparan sulfate deficiency impacts signaling pathways and leads to ectopic chondrogenesis. Solitary or multiple lesions are located in the metaphyses of long bones. Although usually asymptomatic, the lesions may interfere with joint or tendon function or compress peripheral nerves. The lesions stop growing when growth ceases but may recur during pregnancy. There is a small risk for malignant transformation into chondrosarcoma. Palovarotene, a retinoic acid receptor agonist, is in clinical trials.

EXTRASKELETAL (ECTOPIC) CALCIFICATION AND OSSIFICATION

Deposition of calcium phosphate crystals (*calcification*) or formation of true bone (*ossification*) in nonosseous soft tissue may occur by one of three mechanisms: (1) metastatic calcification due to a supranormal calcium × phosphate concentration product in extracellular fluid; (2) dystrophic calcification due to mineral deposition into metabolically impaired or dead tissue despite normal serum levels of calcium and phosphate; and (3) ectopic ossification, or true bone formation. Disorders that may cause extraskeletal calcification or ossification are listed in **Table 424-2**.

METASTATIC CALCIFICATION

Soft tissue calcification may complicate diseases associated with significant hypercalcemia, hyperphosphatemia, or both. In addition, vitamin D and phosphate treatments or calcium administration in the presence of mild hyperphosphatemia, such as during hemodialysis, may induce ectopic calcification. Calcium phosphate precipitation may complicate any disorder when the serum calcium × phosphate concentration product is >75. The initial calcium phosphate deposition is in the form of small, poorly organized crystals, which subsequently organize into hydroxyapatite crystals. Calcifications that occur in hypercalcemic states with normal or low phosphate have a predilection for kidney, lungs, and gastric mucosa. Hyperphosphatemia with normal or low serum calcium may promote soft tissue calcification with predilection for the kidney and arteries. The disturbances of calcium and phosphate in renal failure and hemodialysis are common causes of soft tissue (metastatic) calcification.

TUMORAL CALCINOSIS

This is a rare genetic disorder characterized by masses of metastatic calcifications in soft tissues around major joints, most often shoulders, hips, and ankles. Tumoral calcinosis differs from other disorders in that the periarticular masses contain hydroxyapatite crystals or amorphous calcium phosphate complexes, whereas in fibrodysplasia ossificans progressiva (below), true bone is formed in soft tissues. About one-third of tumoral calcinosis cases are familial, with both autosomal recessive and autosomal dominant modes of inheritance reported. The disease is also associated with a variably expressed abnormality of dentition marked

TABLE 424-2 Diseases and Conditions Associated with Ectopic Calcification and Ossification

Metastatic calcification	Dystrophic calcification
Hypercalcemic states	Inflammatory disorders
Primary hyperparathyroidism	Scleroderma
Sarcoidosis	Dermatomyositis
Vitamin D intoxication	Systemic lupus erythematosus
Milk-alkali syndrome	Trauma-induced
Renal failure	Ectopic ossification
Hyperphosphatemia	Myositis ossificans
Tumoral calcinosis	Postsurgery
Secondary hyperparathyroidism	Burns
Pseudohypoparathyroidism	Neurologic injury
Renal failure	Other trauma
Hemodialysis	Fibrodysplasia ossificans progressiva
Cell lysis following chemotherapy	
Therapy with vitamin D and phosphate	

by short bulbous roots, pulp calcification, and radicular dentin deposited in swirls. The disorder is caused by gene mutations in *GALNT3*, *FGF23*, or *α-Klotho*, leading to FGF23 deficiency or resistance. The reduced activity of FGF23 leads to increased renal tubular reabsorption of phosphate, elevated serum phosphate, and spontaneous soft tissue calcification from elevated calcium-phosphate concentration product.

The disease usually presents in childhood and continues throughout the patient's life. The calcific masses are typically painless and grow at variable rates, sometimes becoming large and bulky. The masses are often located near major joints but remain extracapsular. Joint range of motion is not usually restricted unless the tumors are very large. Complications include compression of neural structures and ulceration of the overlying skin with drainage of chalky fluid and risk of secondary infection. Small deposits not detected by standard radiographs may be detected by ^{99m}Tc bone scanning. The most common laboratory findings are hyperphosphatemia and elevated serum 1,25-dihydroxyvitamin D levels. Serum calcium, parathyroid hormone, and ALP levels are usually normal. Renal function is also usually normal. Urine calcium and phosphate excretions are low, and calcium and phosphate balances are positive.

An acquired form of the disease may occur with other causes of hyperphosphatemia, such as secondary hyperparathyroidism associated with hemodialysis, hypoparathyroidism, pseudohypoparathyroidism, and massive cell lysis following chemotherapy for leukemia. Tissue trauma from joint movement may contribute to the periarticular calcifications. Metastatic calcifications are also seen in conditions associated with hypercalcemia, such as in sarcoidosis, vitamin D intoxication, milk-alkali syndrome, and primary hyperparathyroidism. In these conditions, however, mineral deposits are more likely to occur in proton-transporting organs such as kidney, lungs, and gastric mucosa in which an alkaline milieu is generated by the proton pumps.

TREATMENT

Tumoral Calcinosis

Therapeutic successes have been achieved with surgical removal of subcutaneous calcified masses, which tend not to recur if all calcification is removed from the site. Reduction of serum phosphate by chronic phosphorus restriction may be accomplished using low dietary phosphorus intake alone or in combination with oral phosphate binders. The addition of the phosphaturic agent acetazolamide may be useful. Limited experience using the phosphaturic action of calcitonin deserves further testing.

DYSTROPHIC CALCIFICATION

Posttraumatic calcification may occur with normal serum calcium and phosphate levels and normal ion-solubility product. The deposited mineral is either in the form of amorphous calcium phosphate or hydroxyapatite crystals. Soft tissue calcification complicating connective tissue disorders such as scleroderma, dermatomyositis, and systemic lupus erythematosus may involve localized areas of the skin or deeper subcutaneous tissue and is referred to as *calcinosis circumscripta*. Mineral deposition at sites of deeper tissue injury including periarticular sites is called *calcinosis universalis*.

ECTOPIC OSSIFICATION

True extraskeletal bone formation that begins in areas of fasciitis following surgery, trauma, burns, or neurologic injury is referred to as *myositis ossificans*. The bone formed is organized as lamellar or trabecular, with normal osteoblasts and osteoclasts conducting active remodeling. Well-developed haversian systems and marrow elements may be present. A second cause of ectopic bone formation occurs in an inherited disorder, *fibrodysplasia ossificans progressiva*.

FIBRODYSPLASIA OSSIFICANS PROGRESSIVA

This is also called *myositis ossificans progressiva*; it is a rare autosomal dominant disorder characterized by congenital deformities of the hands and feet and episodic soft tissue swellings that ossify. The disorder is caused by an activating mutation in activin receptor A type 1. Ectopic bone formation occurs in fascia, tendons, ligaments, and connective tissue within voluntary muscles. Tender, rubbery induration, sometimes precipitated by trauma, develops in the soft tissue and gradually calcifies. Eventually, heterotopic bone forms at these sites of soft tissue trauma. Morbidity results from heterotopic bone interfering with normal movement and function of muscle and other soft tissues. Mortality is usually related to restrictive lung disease caused by an inability of the chest to expand. Laboratory tests are unremarkable.

Until recently, there was no effective approved medical therapy. Bisphosphonates, glucocorticoids, and a low-calcium diet have largely been ineffective in halting progression of the ossification. Palovarotene has been shown to reduce new heterotopic ossification by 60% versus historical controls but increased premature epiphyseal closure in children. In 2023, the therapy was approved in the United States for females over age 8 and males over age 10. Another potential therapeutic option, REGN2477 (also known as garetosmab), an anti–activin A antibody, is in clinical trials. Surgical removal of ectopic bone is not recommended because the trauma of surgery may precipitate formation of new areas of heterotopic bone. Dental complications, including frozen jaw, may occur following injection of local anesthetics.

425 Heritable Disorders of Connective Tissue

Joan C. Marini, Fransiska Malfait

CLASSIFICATION OF CONNECTIVE TISSUE DISORDERS

Some of the most common conditions that are transmitted genetically in families are disorders that produce clinically obvious changes in the bone, cartilage, skin, or relatively acellular tissues such as tendons

that have been loosely defined as connective tissues. Because of their heritability, some of the disorders were recognized as potentially traceable to mutated genes soon after the principles of genetics were introduced into medicine by Garrod and others. About half a century later, McKusick emphasized the specificity of many of the diseases for selective connective tissues and suggested that they were probably caused by mutations in genes coding for the major proteins found in those tissues. In the past several decades, mutations in several hundred different genes expressed in connective tissues have been identified as the cause of many connective tissue disorders. However, classifying the disorders on the basis of either their clinical presentations or the mutations causing them continues to present a challenge for both the clinician and the molecular biologist.

Information on the disorders has continued to develop on two levels. The initial clinical classifications suggested by McKusick and many others had to be refined as more patients were examined. For example, some patients had skin changes similar to those commonly seen in Ehlers-Danlos syndrome (EDS), but this feature was overshadowed by other features such as extreme hypotonia or sudden rupture of large blood vessels. To account for the full spectrum of presentations in patients and families, many of the disorders have been reclassified several times, dividing each into a series of subtypes.

The identification of mutations causing the diseases has developed on a parallel track. The first genes cloned for connective tissues were the two genes coding for type I collagen (*COL1A1* and *COL1A2*), the most abundant protein in bones, skin, tendons, and several other tissues. This facilitated early studies in patients with osteogenesis imperfecta (OI) that revealed mutations in type I collagen genes. Biochemical data, developed primarily with cultures of skin fibroblasts from affected individuals, demonstrated that the mutations dramatically altered the synthesis of collagen α-chains or the structure of collagen fibers. The results stimulated efforts to identify additional mutations in genes coding for structural proteins. Genes for collagens provided an attractive paradigm to search for mutations, since a series of different types of collagens were found in different connective tissues and the collagen genes were readily isolated by their unique signature sequences. Also, the collagen genes were vulnerable to a large number of different mutations because of unusual structural requirements of the protein. The search for mutations in collagen genes proved fruitful in that mutations were found in most patients with OI, in many patients with hyperextensible skin and hypermobile joints, in some patients with dwarfism, and in patients with other disorders, including some such as Alport syndrome (AS) that were not initially classified as disorders of connective tissue. Also, mutations in collagen genes were found in subset of patients presenting with osteoarthritis (OA) or osteoporosis, likely representing the mildest end of the syndromic spectrum. However, the search for mutations quickly expanded to hundreds of other genes that included genes for other structural proteins, for the posttranslational modification and processing of the structural proteins, for chaperones, and for growth factors and their receptors and other genes whose functions are still not fully understood.

In many instances, the mutations helped to define the clinical subtype of the disorder, while in others, they revealed the genetic heterogeneity of the same clinical presentations. Conversely, some patients with different manifestations were found to have mutations in the same genes. In noncollagenous genes, it was sometimes difficult to establish whether a change in the structure of a gene caused the phenotypic changes in the patients or was simply a neutral polymorphism. Therefore, there has been a continuing debate as to whether the disorders should be classified by their clinical presentations or by the causative genes. As an illustration of the problems, mutations in 552 genes have now been found associated with 771 defined disorders of the skeleton. The latest (2023) nosology for the disorders, which adopted a dyadic naming system, systematically associating a phenotypic entity with the gene it arises from, remains "hybrid" in nature in the sense that the classification is not always based on the same criteria. Some diseases are grouped based on the causal gene, others are listed together, because they share common radiographic features, and still others are brought together because of a similar clinical course (lethality) or involvement of similar parts of the skeleton. A simpler system of classification proved feasible for one rare heritable disorder of skin, epidermolysis bullosa. The disorder was first defined clinically into subtypes based on the layers of the skin that were cleaved in friction-induced blisters. Most patients in each subtype were subsequently shown to have mutations in genes expressed in the corresponding layer of skin. Even with these patients, the strength of the genotype-phenotype correlation varies and mutations have not yet been found in every patient.

The best pathway through this maze of information is probably to begin by matching the signs and symptoms in a patient with the presentations that define each clinical classification. A major focus should be on the most common disorders, recognizing that the signs and symptoms may vary among different individuals and family members with the same diagnosis. Then, attempt to reach a decision, in consultation with the patient, parents, and specialist, as to whether a DNA analysis for the probable mutation is indicated. Among the considerations are the cost, the rigor with which the clinical classification has been linked to mutated genes, the reassurance the diagnosis can bring to patients and their families, the use of the genetic information for prenatal diagnosis, and the possibility that mutation-specific therapies may be developed in the future. For individuals affected with these disorders, consulting a specialist in the disease is highly recommended to determine a multidisciplinary program for management and therapy. Patient support groups have formed for many of the diseases and are an important source of information.

Patients with the most common forms of the disorders have mutations in a limited number of genes. This chapter will focus primarily on these. Also, it will provide a brief summary of biosynthesis and structure of connective tissues that may help guide the physician from the nature of the mutations to their clinical presentations.

COMPOSITION OF CONNECTIVE TISSUES

Connective tissues such as skin, bone, cartilage, ligaments, and tendons are the critical structural frameworks of the body. They consist of a complex interacting extracellular matrix network of collagens, proteoglycans, and a large number of noncollagenous glycoproteins and proteins. While these precise combinations of up to ~500 potential extracellular matrix building blocks, collectively called "the matrisome," provide tissue-specific function, there are many overarching similarities in composition such as the role of composite collagen fibrils in providing strength and form, elastin fibrils and proteoglycans and other interacting proteins, and glycoproteins that fine-tune function **(Table 425-1)**. The most abundant components of many connective tissues are three similar fibrillar collagens (types I, II, and III). They have a similar tensile strength that is comparable to that of steel wires. The three fibrillar collagens are distributed in a tissue-specific manner: type I collagen accounts for most of the protein of dermis, ligaments, tendons, and demineralized bone; type I and type III are the most abundant proteins of large blood vessels; and type II is the most abundant protein of cartilage.

BIOSYNTHESIS AND TURNOVER OF CONNECTIVE TISSUES

Connective tissues are among the most stable components in living organisms, but they are not inert. During embryonic development, connective tissue membranes appear as early as the four-cell blastocyst to provide a structural scaffold for the developing embryo. With the development of blood vessels and skeleton, there is a rapid increase in the synthesis, degradation, and resynthesis of connective tissues. The turnover continues at a slower, but still rapid pace throughout postnatal development and then spikes during the growth spurt of puberty. During adulthood, the metabolic turnover of most connective tissues is slow, but it continues at a moderate pace in bone. With age, malnutrition, physical inactivity, and low gravitational stress, the rate of degradation of most connective tissues, especially in bone and skin, begins to exceed the rate of synthesis and the tissues shrink. In starvation, a large fraction of the collagen in skin and other connective tissues is degraded and provides amino acids for gluconeogenesis **(Chap. 345)**. In both OA and rheumatoid arthritis, there is extensive degradation of

TABLE 425-1 Constituents of Connective Tissues and Their Associated Heritable Conditions

PROTEIN	TISSUE DISTRIBUTION	DISEASE	KEY MANIFESTATIONS
Collagen I	Bone, cornea, dermis, tendon	Osteogenesis imperfecta	Bone fragility with fractures and deformity; blue sclerae; dentinogenesis imperfecta; hearing loss
		EDS (various rare types)	Joint hypermobility; skin hyperextensibility; skin fragility; soft connective tissue fragility
		Caffey disease	Subperiosteal new bone formation; soft tissue swelling; fever and irritability
Collagen II	Cartilage, vitreous	Various chondrodysplasias	Skeletal dysplasia; ocular manifestations; hearing loss; orofacial findings
Collagen III	Dermis, aorta, uterus, intestine	Vascular EDS	Arterial, intestinal, and uterine fragility; thin translucent skin; easy bruising
Collagen IV	Basement membranes	Alport syndrome (*COL4A3/A4/A5*)	Hematuria; hearing loss; ocular abnormalities
		Brain small-vessel disease (*COL4A1/A2*)	Porencephaly; intracerebral hemorrhage; retinal arterial tortuosity; (congenital) cataract; Axenfeld-Rieger anomaly; hematuria; renal cysts; muscle cramps
Collagen V	Placental tissue, bone, dermis, cornea	Classic EDS	Joint hypermobility; skin hyperextensibility; atrophic scarring
Collagen VI	Uterus, dermis, cornea, cartilage	Bethlem myopathy and Ullrich congenital muscular dystrophy	Muscle weakness; joint contractures; joint hypermobility
Collagen VII	Skin, amniotic membrane, mucosal epithelium	Dystrophic epidermolysis bullosa	Skin blistering; oral and esophageal blistering; corneal erosions
Collagen VIII	Descemet's membrane, endothelial cells	Corneal dystrophy	Corneal endothelial dystrophy; stromal edema
Collagen IX	Cartilage, vitreous	Stickler syndrome	Spondyloepiphyseal dysplasia; early-onset osteoarthritis; high myopia; vitreoretinal abnormalities; hearing loss; cleft palate; midfacial hypoplasia
Collagen X	Calcifying cartilage	Multiple epiphyseal dysplasia	Epiphyseal dysplasia; early-onset osteoarthritis
Collagen XI	Cartilage, intervertebral disk	Various chondrodysplasias	Skeletal dysplasia; ocular manifestations; hearing loss; orofacial findings
Collagen XII	Dermis, tendon, cartilage	Myopathic EDS	Joint hypermobility; congenital muscle hypotonia and/or atrophy; proximal joint contractures
Collagen XVII	Corneal epithelial cells	Junctional epidermolysis bullosa	Blistering of the skin and mucosae (mild to severe)
Collagen XVIII	Pia, blood vessels of the developing human cerebral cortex	Knobloch syndrome	Early-onset severe myopia; vitreoretinal degeneration with retinal detachment; hydrocephalus; structural brain defects; epilepsy; cognitive dysfunction
Collagen XXVII	Chondrocytes, epithelial cell layers in developing tissues, including stomach, lung, gonad, skin, cochlea, and tooth	Steel syndrome	Osteochondrodysplasia with hip dislocations; dislocations of radial heads; carpal coalition; short stature; facial dysmorphism; scoliosis
Cartilage oligomeric matrix protein (COMP)	Cartilage, tendon, ligament, bone	Pseudoachondroplasia	Short-limb dwarfism; early-onset osteoarthritis
		Multiple epiphyseal dysplasia	Mildly short stature; early-onset osteoarthritis
Elastin	Dermis, arterial wall, lung	Cutis laxa	Wrinkled, redundant, sagging inelastic skin
		Williams syndrome	Cardiovascular disease (especially supravalvular aortic stenosis); orofacial features; intellectual deficit; connective tissue abnormalities; endocrine abnormalities
Fibrillin 1	Dermis, arterial wall, lung	Marfan syndrome	Aortic root aneurysm or dissection; ectopia lentis; marfanoid habitus
		Weill-Marchesani-syndrome	Short stature; joint stiffness; lens abnormalities; cardiovascular features
		Stiff skin syndrome	Progressive rock-hard skin; flexion contractures; hypertrichosis
		Geleophysic dysplasia	Short stature; joint stiffness; thickened skin; progressive cardiac valvular disease; orofacial features
Fibrillin 2	Bruch membrane	Congenital contractural arachnodactyly (CCA) or Beals-Hecht syndrome	Tall stature; arachnodactyly; (kypho)scoliosis; pectus deformities; contractures; muscle hypoplasia; mild cardiovascular involvement; long, narrow face, highly arched palate, micrognathia, crumpled external ears
		Acromelic dysplasia	Relative short stature; brachydactyly; toe walking; early onset carpal tunnel syndrome; short palpebral fissures
Fibronectin	Dermis, tendons, ligaments	Glomerulopathy with fibronectin deposits	Glomerulopathy with fibronectin deposits
		Spondylometaphyseal dysplasia, corner fracture type	Spondylometaphyseal dysplasia characterized by flake-like, triangular, or curvilinear ossification centers at the edges of irregular metaphyses that simulate fractures; short stature

(*Continued*)

TABLE 425-1 Constituents of Connective Tissues and Their Associated Heritable Conditions (Continued)

PROTEIN	TISSUE DISTRIBUTION	DISEASE	KEY MANIFESTATIONS
Aggrecan	Cartilage	Spondyloepiphyseal dysplasia, Kimberley type	Short stature; habitus; progressive osteoarthropathy; spondyloepiphyseal dysplasia
		Short stature; advanced bone age, with or without early-onset osteoarthritis and/or osteochondritis dissecans	Short stature and advanced bone age, with or without early-onset osteoarthritis and/or osteochondritis dissecans
		Spondyloepimetaphyseal dysplasia, aggrecan type	Severe short stature; spondyloepimetaphyseal dysplasia
Decorin	Dermis, tendons, ligaments, cornea	Congenital stromal corneal dystrophy	Corneal stromal opacification; visual loss; increased corneal thickness
Biglycan	Bone, cartilage, tendons	Meester-Loeys syndrome	Aortic aneurysm or dissection; orofacial features; joint hypermobility; ventricular dilatation on brain imaging; relative macrocephaly; hip dislocation; platyspondyly; phalangeal dysplasia; dysplastic epiphyses of the long bones
		X-linked spondyloepimetaphyseal dysplasia	Severe short-trunked dwarfism; brachydactyly; spondyloepimetaphyseal dysplasia

Abbreviation: EDS, Ehlers-Danlos syndromes.

articular cartilage collagen. Glucocorticoids weaken most tissues by decreasing collagen synthesis. In some pathologic states, however, collagen is deposited in excess. With most injuries to tissues, inflammatory and immune responses stimulate the deposition of collagen fibrils in the form of fibrotic scars. In humans, as distinct from many other species, the deposition of the fibrils is largely irreversible and prevents regeneration of normal tissues in diseases such as hepatic cirrhosis, pulmonary fibrosis, atherosclerosis, and nephrosclerosis.

Structure and Biosynthesis of Fibrillar Collagens The tensile strength of collagen fibers derives primarily from the self-assembly of protein monomers into large fibril structures in a process that resembles crystallization. The self-assembly requires monomers of highly uniform and relatively rigid structure. It also requires a complex series of posttranslational processing steps that maintain the solubility of the monomers until they are transported to the appropriate extracellular sites for fibril assembly. Because of the stringent requirements for correct self-assembly, it is not surprising that mutations in genes for fibrillar collagens cause many of the heritable diseases of connective tissues.

The monomers of the three fibrillar collagens are formed from three polypeptide chains, called α chains, that are wrapped around each other into a rope-like triple-helical conformation. The triple helix is a unique structure among proteins, and it provides rigidity to the molecule. It also orients the side chains of amino acids in an "inside out" manner relative to most other proteins so that the charged and hydrophobic residues on the surface can direct self-assembly of the monomers into fibrils. The triple-helical conformation of the monomer is generated because each of the α chains has a repetitive amino acid sequence in which glycine (Gly) appears as every third amino acid. Each α chain contains ~1000 amino acids. Therefore, the sequence of each α chain can be designated as $(\text{-Gly-X-Y-})_n$, where X and Y represent amino acids other than glycine and n is >338. The presence of glycine, the smallest amino acid, in every third position in the sequence is critical because this residue must fit into a sterically restricted space in the interior of the helix where the three chains come together. The requirement for a glycine residue at every third position explains the significant clinical effects of mutations that convert a glycine residue to an amino acid with a bulkier side chain (see below). Many of the X- and Y-position amino acids are proline and hydroxyproline, which, because of their ring structures, provide additional rigidity to the triple helix. Other X- and Y-positions are occupied by charged or hydrophobic amino acids that precisely direct lateral and longitudinal assembly of the monomers into highly ordered fibrils. Mutations that substitute amino acids in some X- and Y-positions, particularly arginine-to-cysteine substitutions, can also produce genetic diseases.

The fibers formed by the three fibrillar collagens differ in thickness and length, but they have a similar fine structure. As viewed by electron microscopy, they all have a characteristic pattern of cross-striations that are about one-quarter the length of the monomers and reflect the precise packing into fibrils. The three fibrillar collagens, however, differ in sequences found in the X- and Y-positions of the α chains and therefore in some of their physical properties. Type I collagen is a heterotrimer, composed of two identical α1(I) chains and a third α2(I) chain that differs slightly in its amino acid sequence. Types II and III collagen are homotrimers, each composed of three identical α chains distinct to that type of collagen.

To deliver a monomer of the correct structure to the appropriate site of fibril assembly, the biosynthesis of fibrillar collagens involves a large number of unique processing steps **(Fig. 425-1)**. The monomer, first synthesized as a soluble precursor called *procollagen*, contains an additional globular domain at each end. As the pre-proα chains of procollagen are synthesized on ribosomes, the free N-terminal ends move into the cisternae of the rough endoplasmic reticulum (ER). Signal peptides at the N-termini are cleaved, and additional posttranslational reactions begin. Proline and lysine residues in the Y-position of the Gly-X-Y repeating triplet are hydroxylated along the length of the helix by the enzymes prolyl 4-hydroxylase (P4H1) and lysyl hydroxylase (LH1), respectively. Hydroxyproline residues are essential for the three α chains of the monomer to fold into a triple helix at body temperature. P4H1 requires ascorbic acid as an essential cofactor, an observation that explains why wounds fail to heal in scurvy **(Chap. 344)**. In scurvy, some of the underhydroxylated and unfolded protein accumulates in the cisternae of the rough ER and is degraded. Many hydroxylysine residues are glycosylated with galactose or with galactose and glucose. Also, a large mannose-rich oligosaccharide is assembled on the C-terminal propeptide of each chain. The proα chains are assembled by interactions among these C-terminal propeptides that control the selection of the appropriate partner chains to form hetero- or homotrimers and provide the correct chain registration required for subsequent formation of the collagen triple helix. After the C-terminal propeptides assemble the three proα chains, a nucleus of triple helix is formed near the C-terminus, and the helical conformation is propagated toward the N-terminus in a zipper-like manner that resembles crystallization. The folding into the triple helix is spontaneous in solution, but as discussed below, identification of rare mutations causing OI demonstrated that the folding *in cellulo* is assisted by a number of ancillary proteins that also prevent collagen fibril formation within the ER. The fully folded procollagen is then transported to the Golgi via a specific COPII vesicle process. After further modifications in the Golgi stack, the procollagen is secreted into the pericellular space where distinct proteases remove the N- and C-propeptides at specific cleavage sites. The release of the propeptides decreases the solubility of the resulting collagen ~1000-fold. The entropic energy that is released drives the self-assembly of the collagen into fibrils. Self-assembled collagen fibers have considerable tensile strength, but their strength is increased further by cross-linking reactions that form covalent bonds between α chains in one molecule and α chains in adjacent molecules.

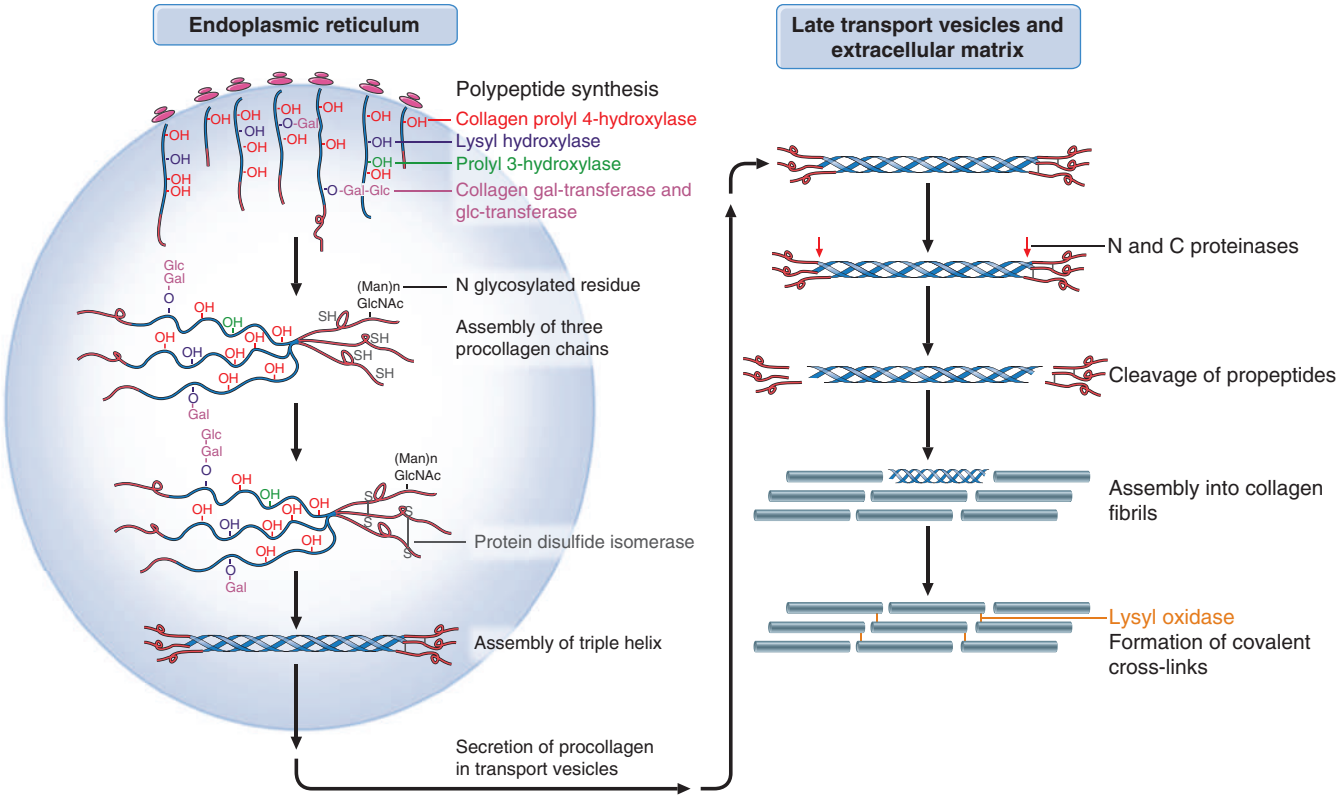

FIGURE 425-1 Schematic summary of biosynthesis of fibrillar collagens. *(Reproduced with permission from J Myllyharju, KI Kivirikko: Collagens, modifying enzymes and their mutations in humans, flies and worms. Trends Genet 20:33, 2004.)*

The resulting fibers, composed of hundreds or thousands of triple-helical monomers, have some of the properties of a crystal but have innate imperfections that make them highly flexible.

Although the assembly of collagen monomers into fibers is largely a spontaneous reaction, the process in tissues is modulated by the presence of less abundant collagens (type V with type I, and type XI with type II) and by other components such as a series of small leucine-rich proteins (SLRPs). Some of the less abundant components alter the rate of fibril assembly, whereas others change the morphology of the fibers or their interactions with cells and other molecules. The presence of these other components is one explanation for why, in some tissues, the fibers are further assembled into large tendons; in others, into sheets; and in still others, into complex structures such as the hexagonal array of fibers that provide both the strength and transparency of the cornea.

Collagen fibers are resistant to most proteases, but during degradation of connective tissues, they are cleaved by specific matrix metalloproteinases (collagenases) that cause partial unfolding of the triple helices into gelatin-like structures that are further degraded by less specific proteinases.

OTHER COLLAGENS AND RELATED MOLECULES

The unique properties of the triple helix are used to define a family of at least 28 collagens that contain repetitive -Gly-X-Y- sequences and form triple helices of varying length and complexity. The proteins are heterogeneous both in structure and function, and many are the sites of mutations causing genetic diseases. For example, the type IV collagen found in basement membranes is composed of three α chains synthesized from any of six different genes. Mutations in the *COL4A3*, *COL4A4*, or *COL4A5* genes cause AS, while mutations in *COL4A1* and rarely *COL4A2* are associated with a spectrum of phenotypes including small-vessel brain disease of varying severity including porencephaly, variably associated with eye defects (retinal arterial tortuosity, Axenfeld-Rieger anomaly, cataract) and systemic findings (kidney involvement, muscle cramps, cerebral aneurysms, Raynaud phenomenon, cardiac arrhythmia, and hemolytic anemia).

Fibrillin Aggregates and Elastin In addition to tensile strength, many tissues such as the lung, large blood vessels, and ligaments require elasticity. The elasticity was originally ascribed to an amorphous rubber-like protein named elastin. Subsequent analyses, largely sparked by discoveries of mutations causing the Marfan syndrome (MFS), demonstrated that the elasticity resided in thin fibrils composed primarily of large glycoproteins named fibrillins. The fibrillins contain large numbers of epidermal growth factor–like domains interspersed with characteristic cysteine-rich domains that are also found in latent transforming growth factor β (TGF-β) binding proteins. The fibrillins assemble into long beadlike strands that also contain numerous other components including small and variable amounts of elastin, bone morphogenic proteins (BMPs), and microfibril-associated glycoproteins (MAGPs). Besides contributing to extracellular matrix structure, a major role for fibrillins in TGF-β signaling was emphasized by the discovery of mutations in genes coding for proteins involved in canonical TGF-β signaling in patients with Marfan-like manifestations, including thoracic aortic aneurysm.

Proteoglycans The resiliency to compression of connective tissues such as cartilage or the aorta is largely explained by the presence of proteoglycans. Proteoglycans are composed of a core protein to which are attached a large series of negatively charged polymers of disaccharides (largely chondroitin sulfates). At least 30 proteoglycans have been identified. They vary in their binding to collagens and other components of matrix, but specific functions have not been assigned to most. The major proteoglycan of cartilage, called aggrecan, has a core protein of 2000 amino acids that is decorated with ~100 side chains of chondroitin sulfate and keratin sulfate. The core protein, in turn, binds to long chains of the polymeric disaccharide hyaluronan to form proteoglycan aggregates, one of the largest soluble macromolecular structures in nature. Because of its highly negative charge and extended structure, the proteoglycan aggregate binds large amounts of water and small ions to distend the three-dimensional arcade of collagen fibers found in the same tissues. It thereby makes the cartilage resilient to pressure.

OSTEOGENESIS IMPERFECTA

OI is a phenotypically and genetically heterogeneous generalized connective tissue disorder. The hallmark features of OI are increased susceptibility to skeletal fractures, bone deformity, and growth deficiency. Bone fragility is based on decreased bone mass and increased bone brittleness due to defective mineralization. Secondary features of OI are highly variable even within a type and include blue sclerae, dentinogenesis imperfecta, hearing loss, basilar invagination, pulmonary function impairment, cardiac valve abnormalities, and ligamentous laxity. Most patients have defects in the structure or quantity of type I collagen.

Classification OI was originally classified into *congenita* and *tarda* subtypes depending on the age of symptom onset. Sillence proposed the classification that bears his name for four types based on clinical and radiologic findings and mode of inheritance. The extension of the Sillence classification was first based on distinctive bone histology (types V and VI OI) and subsequently on the discovery of new recessive genes (types VII–XXII). The debate between classification by phenotypic severity or gene defects has resulted in clinical and genetic classifications. The clinical classification can be useful for management but results in different type assignments in the same family or even in the same individual over their lifetime. The genetic classification **(Table 425-2)** groups patients by the causative gene. Because related causative genes were discovered close in time to each other, the genetic classification consequently groups types by overall mechanism and features OI as a collagen-related disorder.

Types I–IV OI are due to quantitative or structural defects in type I collagen itself. Type I is the mildest subtype, with reduced quantity of structurally normal collagen, and can produce mild or inapparent skeletal deformities. Most patients have distinctly blue sclerae. Types II, III, and IV are all caused by structural defects in one of the type I collagen α chains. Type II produces bone so brittle that infants have in utero fractures of ribs and long bones and die in the perinatal period. Type III is progressively deforming with moderate to severe bone deformity, and type IV has mild to moderate bone fragility and secondary features. Subsequent rare recessive OI types are all collagen-related. Types V and VI (*ITITM5* and *SERPINF1*) particularly compromise matrix mineralization. Types VII, VIII, and IX (*CRTAP, P3H1,* and *PPIB*) represent defects in the components of the procollagen prolyl 3-hydroxylation complex that modifies collagen posttranslationally. Types X–XII and XXI (*SERPINH1, FKBP10, BMP1,* and *KDELR1*) have compromised procollagen processing and cross-linking. The final grouping of types XIII–XVIII (*SP7, TMEM38B, WNT1, CREBL1, SPARC, MBTPS2, TEMTSA, MESD, CCDS134*) alter osteoblast differentiation and impair collagen matrix quality.

The clinical heterogeneity of affected individuals within a particular OI type and even with the same mutation is not understood, with unknown modifying factors presumably involved. Among adults with OI, women are prone to fracture during pregnancy and after menopause. Some variants of mild OI are first detected perimenopausally and must be distinguished from postmenopausal osteoporosis.

Incidence In North America and Europe, the estimated incidence of OI is 1 per 10,000–15,000 births, based on a combination of cases recognized at birth and population surveys for milder cases. In populations with a high level of consanguinity or a founder mutation, the incidence of the rare recessive forms of OI is a significant addition to the prevalence of dominant collagen defects.

Effects on Tissue Systems The phenotypic features of OI are highly variable, even within the types caused by defects in type I collagen. The following section generally focuses on dominant forms comprising the majority of cases, except as specified, but the descriptions can be generalized to a large extent.

Musculoskeletal Effects Bone in OI is both weak and brittle. At the mildest end of the spectrum (type I OI), individuals may have only several childhood fractures and be limited only from contact sports. More severe forms of OI require bone to be partially unloaded with assistive devices such as walkers or canes; many severe patients use electric chairs for both the weight bearing and the normal speed of mobility. In dominant OI, fragility fractures often decrease sharply after adequate bone mass is gained at puberty. Radiographs generally show osteopenia in all types, with disordered matrix organization detected most easily in lower long bones in moderate and severe forms. In lethal OI, radiographs show continuous beading of ribs from healing fractures and crumpled and undertubulated long bones. Lateral skull radiographs may show islands of Wormian bones, even in mild forms. The appearance of "popcorn" at the metaphyses of long bones occurs in many type III and IV children and coincides with increased growth deficiency. Often these bones are so soft that normal muscle pull can produce severe deformities. Kyphoscoliosis is associated with vertebral compressions but is not prevented by bisphosphonates, suggesting a contribution from ligamentous laxity.

OI bone is weak, in that it fractures with a lower load than normal, and brittle, in that it does not tolerate postyield displacement and snaps like chalk. The brittleness results from the paradoxical increased mineralization of OI bone. While dual-energy x-ray absorptiometry (DXA) bone density measurements uniformly return a reduced value for OI bone, it is performed with a phantom and detects mineral crystals that are in proper alignment. In contrast, quantitative backscattered electron imaging or three-dimensional (3D) computed tomography (CT), which detect all mineral in 3D, reveals that both dominant and recessive (except types XIV and XV) OI bone is hypermineralized. On histomorphometry, dominant OI bone has proper formation of lamellae but increased turnover, causing decreased bone volume. Type V OI has mesh-like bone lamellae, as well as a dislocated radial head, and may have hyperplastic callus formation, while type VI OI has distinctive fish scale lamellae on polarized light microscopy.

Many OI patients across the severity spectrum have increased ligamentous laxity. Patients with defects in processing the N-terminal propeptide of type I procollagen have large and small joint hypermobility similar to EDS. Muscle weakness of unknown etiology also occurs in OI, and the weakness and ligamentous laxity contribute to delayed motor development.

Pulmonary The leading cause of death in OI is pulmonary disease. Young children with severe OI often have repeated pneumonia; restrictive or obstructive disease develops in most older children and adults. Pulmonary function is impaired by marked scoliosis and chest wall deformity but also arises from intrinsic defects of lung parenchyma containing type I collagen, as shown by declining pulmonary function over time in children without scoliosis. More recent studies have reinforced the significant role of intrinsic lung abnormalities in OI, demonstrating reduced gas exchange, reduced airflow in small airways, and atelectasis in most individuals with collagen structural abnormalities. Bronchial thickening at the level of subsegmental bronchi in almost all patients further indicates the critical role of small airways. Mice with null *CRTAP* mutations (type VII OI) have abnormal alveolar development, and patients with recessive forms also have pulmonary complications. Evaluation of even asymptomatic moderate to severe OI patients by spirometry should initiate standard pulmonary interventions.

Cardiovascular Cardiovascular effects of OI manifest predominantly in adults. With type I collagen as a major component of matrix in cardiac valves and aortic wall, the most frequent manifestations are valvular, especially mitral regurgitation and aortic root dilatation. Impaired mechanical properties occasionally lead to aortic dissection. Echocardiography is appropriate with heart murmurs or cardiac symptoms and every 3–5 years in asymptomatic patients.

Dentinogenesis Imperfecta Dentinogenesis imperfecta (DI) is associated with types III and IV OI and recessive types with collagen processing defects. Tooth agenesis, especially of premolars, is also found in types III/IV OI. Teeth with disturbed formation of dentin during development may be translucent gray or have yellowish or brownish discoloration. Defects are manifest predominantly in primary teeth; detection in secondary teeth may require radiographs to identify

TABLE 425-2 Different Types of Osteogenesis Imperfecta (OI)

	OI TYPE	INHERITANCE	DEFECTIVE GENE	PROTEIN	OMIM	LOCUS	HYPERMINERALIZATION	DISTINGUISHING FEATURES
Defects in collagen structure and processing	I	AD	*COL1A1*	Collagen α1	166200	17q21.33	Yes	Loss of function of one of the COL1A1 alleles
	II–IV	AD	*COL1A1, COL1A2*	Collagen α1 or α2	166210, 259420, 166220	17q21.33, 7q21.3	Yes	Structural defects in collagen helix or C-propeptides
Procollagen processing defects	OI/EDS	AD	*COL1A1, COL1A2*	Procollagen α1 or α2	NA	17q21.33, 7q21.3	Yes	Defects in 90 residues at N-terminus of collagen helix that decrease pN-processing
	HBM	AD	*COL1A1, COL1A2*	Collagen α1 or α2	NA	17q21.33	Yes	Defects in C-propeptide cleavage site, DXA normal to increased
	XII	AR	*BMP1*	BMP1	614856	8p21.3	Yes	Deficiency of C-propeptidase; skeletal deformity severe plus rhizomelia, scoliosis; overlaps AD defects in type I collagen C-propeptide cleavage site
Bone mineralization defects	V	AD	*IFITM5*	BRIL (BRIL5′ MALEP)	610967	11p15.5	Yes	Calcification of interosseous membrane, dense metaphyseal band, hyperplastic callus, mesh-like pattern in lamellar bone
	Atypical VI	AD	*IFITM5*	BRIL (BRIL Ser40Leu)	610967	11p15.5	Yes	Increased osteoid, fish scale pattern in lamellar bone, increased ALP levels in childhood, symptom onset at birth
	VI	AR	*SERPINF1*	PEDF	613982	17p13.3	Yes	PEDF deficiency, increased osteoid, fish scale pattern in lamellar bone, increased ALP levels in childhood, onset after age 1 year
Defects in collagen modification	VII	AR	*CRTAP*	CRTAP	610682	3q22.3	Yes	Absent procollagen prolyl 3-hydroxylation; full OM, rhizomelia, white sclerae
	VIII	AR	*LERPE1*	P3H1	610915	1p34.2	Yes	Absent procollagen prolyl 3-hydroxylation; full OM, rhizomelia, "popcorn" metaphyses; white sclerae
	IX	AR	*PPIB*	CyPB	259440	15q22.31	Yes	Absent procollagen prolyl 3-hydroxylation; helix modification varies, without rhizomelia, white sclerae
	XIV	AR	*TMEM38B*	TRIC-B	615066	9q31.2	No	Decreased modification of collagen helix; Bedouin founder mutation; normal teeth, hearing
Defects in collagen folding and cross-linking	X	AR	*SERPINH1*	HSP47	613848	11q13.5	ND	Severe skeletal deformity, blue sclerae, DI, skin abnormalities, inguinal hernias
	XXI	AR	*KDELR2*	KDEL ER protein retention receptor; interacts with HSP47	619131	7p22.1	ND	Short stature, progressive skeletal deformation; dysmorphic facies, failure to thrive, hypotonia, joint hypermobility
	XI	AR	*FKBP10*	FKBP65	610968	17q21.2	Yes	May have congenital contractures
	NA	AR	*PLOD2*	LH2	609220	3q24	Yes	Progressive joint contractures
Osteoblast function and differentiation	XIII	AR	*SP7*	OSTERIX	613849	12q13.13	ND	Severe skeletal deformity, delayed tooth eruption, facial hypoplasia
	XV	AD/AR	*WNT1*	WNT1	615220	12q13.12	No	AR cases have severe progressive OI; may have neurologic defects
	XVI	AR	*CREB3L1*	OASIS	616215	11p11.2	Yes	Defect in RIP pathway; Oasis substrate of S1P/S2P; severe skeletal fragility and deformity
	XVII	AR	*SPARC*	SPARC	616507	5q33.1	Yes	Progressive severe bone fragility; hypotonia, joint laxity
	XVIII	XR	*MBTPS2*	S2P	301014	Xp22.12	Yes	X-linked OI, defect in RIP pathway; moderate to severe fragility, bowing; rhizomelia
Unclassified disorders	XIX	AR	*TEMT5A*	FAM46A	617952	6q14.1	ND	Defect in BMP/TGF-β signaling pathway; poly-adenylates transcripts of type I collagen, *SERPINF1*, and *SPARC*; severe to lethal OI; hyperlaxity, motor delay
	XX	AR	*MESD*	LRP chaperone MESD	618644	15q25.1	ND	Progressive deforming OI; severe to lethal; survivors have dental disorganization and intellectual disability; also classified with LRP5/6-related disorders
	XXII	AR	*CCDC134*	Coiled-coil domain-containing protein 134	618788	22q13.2	ND	Severe OI with pseudoarthrosis; could also be classified with MAPK/ERK skeletal dysplasias

Abbreviations: AD, autosomal dominant; ALP, alkaline phosphatase; AR, autosomal recessive; BMP, bone morphogenetic protein; DI, dentinogenesis imperfect; DXA, dual-energy x-ray absorptiometry; EDS, Ehlers-Danlos syndrome; HBM, high bone mass; NA, not applicable; ND, not determined; OI, osteogenesis imperfecta; OM, overmodification; OMIM, Online Mendelian Inheritance in Man; TGF, transforming growth factor.

characteristic narrow or obliterated pulp chambers. Crumbling at the dentin-enamel junction may require capping of teeth. Hypoplastic maxilla and relative mandibular prognathism in moderate to severe OI can result in type III malocclusion and impair normal chewing, requiring surgical correction.

Hearing Loss About half of patients with types I, III, and IV OI develop hearing loss, but its incidence in recessive types is unknown. Hearing loss usually begins in the second decade and progresses. The initial conductive loss, based on changes in the inner ear leading to stapes footplate fixation, can evolve into a mixed conductive and sensorineural loss. Regular screening allows referral for hearing aids, stapes surgery, or cochlear implants, as appropriate.

Other Features A variable intensity of blue or grayish sclerae is a well-known feature of OI. The color is most striking with collagen defects, especially types I and II OI and defects that affect N-terminal procollagen processing. Blue sclerae often occur in other connective tissue disorders such as EDS or MFS and may occur in individuals without connective tissue defects. Severe neonatal OI with white sclerae should prompt consideration of recessive forms, especially prolyl 3-hydroxylation defects. Abnormalities of the skull base, such as platybasia and basilar invagination, sometimes progress to clinically devasting basilar impression. Patients with height *Z*-scores of <–3 should be CT scanned at 3- to 5-year intervals. Significant growth deficiency is a cardinal feature of OI, ranging from minimally shorter than siblings in mild forms to greater extents in some severe cases, with adults shorter than 5-year-old children. There is both end-organ resistance to growth hormone (GH) and defective transition to bone at the growth plate. Types I and IV OI are often responsive to recombinant GH therapy.

Molecular Defects The great majority (80–85%) of cases of OI are caused by heterozygous mutations in either of the genes coding for the chains of type I procollagen, *COL1A1* or *COL1A2* (Table 425-2). Although thousands of unique mutations have been identified in type I collagen, they fall into several structural types. Null mutations in collagen chains are less detrimental than structural defects. Null mutations in *COL1A1* result in about half the normal level of collagen synthesis, but the collagen in matrix is structurally normal. These patients have mild type I OI. Null *COL1A2* mutations are rare, leading to an EDS-like condition with progressive cardiac-valvular defects when present in homozygous state.

Mutations that produce structural changes in type I collagen α chains cause types II, III, and IV OI. The most common of these are mutations resulting in substitutions for glycine residues required at every third residue along the helix. In effect, any of the 338 glycine residues in the helical domain of either the proα1 or proα2 chain of type I procollagen is a potential site for a disease-producing mutation. Other mutations affect the splicing of the exons encoding the α chains. Because each collagen exon encodes a discrete set of Gly-X-Y triplets, the abnormal splice products are most often in-frame and cause severe structural abnormalities. Use of alternative splice sites may lead to premature termination, mimicking null mutations, and a milder phenotype. Structural abnormalities in the procollagen helical region delay collagen folding and expose chains to posttranslational hydroxylation/glycosylation for a longer time. The abnormal procollagen triggers a cascade of intracellular and extracellular events including delayed collagen folding, ER stress, abnormal interaction with noncollagenous molecules, impaired osteoblast development and cross-talk with osteoclasts, and abnormal mineralization. There are some special sets of procollagen structural mutations with distinct mechanisms within types II, III, and IV. Mutations in the C-propeptide significantly delay chain assembly, and resulting procollagen is mislocalized to the ER lumen. Some of this procollagen is targeted for degradation by the ER-associated proteosomal pathway, while the secreted molecules delay pericellular processing of the C-propeptide. Mutations in the C-propeptide cleavage site itself prevent processing of the propeptide, leaving pC-collagen to be incorporated into matrix. This affects matrix mineralization, resulting in an unusual high bone mass form of OI that falls at the milder end of the type IV OI phenotype. Not surprisingly, null mutations in the C-propeptidase enzyme, BMP1, cause recessive type XII OI. Type XII OI is a severe condition because BMP1 is the cleavase for types I, II, and III procollagens and the glycoprotein decorin, which is a regulator of fibrillogenesis. Processing defects of the N-propeptide occur in the cleavage site itself or the 90 helix residues at the amino end. The persistence of the N-propeptide on a fraction of the molecules interferes with the self-assembly of normal collagen so that thin and irregular collagen fibrils are formed. They cause extreme laxity of large and small joints, intensely blue sclerae, and an OI severity comparable to type III/IV. Rare substitutions of charged amino acids (Asp, Arg) or a branched amino acid (Val) in X- or Y-positions produce lethal phenotypes, apparently because they are located at sites for lateral assembly of the monomers or binding of other components of the matrix.

Starting in 2006, a series of noncollagenous genes have been identified that cause (mostly) recessive OI. Importantly, all the genes have encoded proteins or cellular processes related to collagen, shifting the OI paradigm to dominant OI caused by collagen defects or *IFITM5* and recessive OI caused by proteins related to collagen modification, processing, folding, and cross-linking and osteoblast differentiation. The largest group of patients with OI not caused by collagen gene mutations have types V and VI OI, affecting bone mineralization. Type V OI, with dominant inheritance, is unusual in that all patients have the same recurrent mutation at the 5′-end of *IFITM5,* which generates a novel start codon in the transmembrane protein BRIL. The gain-of-function mutation causes distinctive radiologic (ossification of interosseus membrane and dense metaphyseal band) and phenotypic findings (hypertrophic callus). Osteoblasts with type V OI have increased mineralization and differentiation in culture. Type VI OI is a recessive form caused by null mutations in PEDF, a collagen-interacting molecule with a known antiangiogenic effect. A connection between types V and VI OI has been revealed by a set of patients with a BRIL p.S42L substitution who have clinical, histologic, serum marker, and phenotypic features of type VI OI. Both type VI OI osteoblasts and BRIL p.S42L osteoblasts have decreased cellular mineralization and SERPINF1 expression, while classic type V OI osteoblasts have the opposite findings. All three types decrease collagen production.

Types VII, VIII, and IX OI are severe recessive forms caused by deficiency of one of the components of the procollagen prolyl 3-hydroxylation complex, P3H1, CRTAP, or cyclophilin B (*PPIB*/CyPB). This complex 3-hydroxylates one proline residue per α chain, most critically α1(I)P986, in contrast to the proline 4-hydroxylation of multiple helical residues by P4H1. In murine models, loss of complex function results in a severe phenotype, while mutation of the P986 residue impairs collagen cross-linking and fine-tuning of collagen alignment in fibrils. The phenotype of these patients is distinctive for white sclerae, rhizomelia, and lack of relative macrocephaly; they share the bone fragility, high bone turnover, and elevated bone mineralization of classical OI.

Some recessive OI types that impair osteoblast function are caused by mutation in genes not previously understood to affect bone. Regulatory intramembrane proteolysis (RIP) is well known for its role in cholesterol synthesis, in which cells transport regulatory proteins from the ER membrane to the Golgi membrane in times of cell stress, where S1P and S2P Golgi proteases sequentially cleave the transcription factors, activating them to enter the nucleus. X-linked type XVIII OI with defective *MBTPS2*/S2P and type XVI OI with deficiency of an RIP substrate Oasis, a member of the ATF6 family of stress sensors, indicate the importance of RIP for bone formation (Table 425-2). For more recently identified OI types, the relationship of the causative gene to collagen has extended the spectrum of matrix abnormality. FAM46A (type XIX OI) polyadenylates collagen transcripts; defects lead to collagen deficiency approaching a null COL1A1 allele that does not fully explain the severe disorganization of collagen in bone matrix. Since FAM46A also polyadenylates the transcripts of other OI-causative genes, SERPINF1 and SPARC, the matrix defect may be multifactorial. For type XX OI, MESD is a direct cytosolic chaperone of pro-alpha1(I) chains, but several bone features that are not typical of OI, such as oligodontia and

cartilage remnants, may reflect MESD's role as a chaperone for LRP5. KDELR2 defects (OI type XXI) have impaired retrograde transport of ER resident proteins, such as HSP47, because KDELR2 is a component of CopI vesicles. Collagen quantity in matrix is lower because of reduced collagen expression, but the impaired collagen fibrillogenesis may be caused by increased interaction of HSP47 with collagen monomers in the extracellular space. The causative gene for type XXII OI, *CCDC134*, is involved in the MAPK signaling pathway. The osteoblasts of affected individuals have increased ERK1/2 phosphorylation as well as reduced COL1A1 and osteopontin expression.

Inheritance and Mosaicism in Germline Cells and Somatic Cells Types I–V OI are inherited as autosomal dominant traits, while the rare forms are mostly recessive. Many patients with mild dominant OI represent familial traits, while sporadic new mutations are often responsible for dominant severe or lethal cases. Germline mosaicism in one parent may be the etiology of a severe dominant mutation in the child; in this circumstance, a second child may be affected with the same dominant mutation from unaffected parents. Recessive mutations in genes causing the rare forms of OI lead to more severe clinical outcomes; many of these offspring do not survive childhood, but moderately to severely affected young adults show us that these conditions must also be considered.

Diagnosis OI is usually diagnosed on the basis of clinical and radiographic criteria. The presence of fractures together with blue sclerae, DI, or family history of the disease is usually sufficient to make the diagnosis. X-rays reveal a decrease in bone density that can be verified by DXA bone densitometry, as well as characteristic deformities of long bones, thorax, and cranium. The differential diagnosis varies with age, including battered child syndrome, nutritional deficiencies, malignancies, and other inherited disorders such as chondrodysplasias and hypophosphatasia that can have overlapping presentations. A molecular diagnosis is now routinely obtained using targeted candidate gene sequencing, sometimes beginning with the dominant collagen and *IFITM5* panel. Skeletal disorder gene panels and whole-exome sequencing may be financially advantageous and pick up additional skeletal gene variants as well as the OI-causative gene. Although almost all cases can be diagnosed by sequencing, some may require bone histology and exome sequencing.

TREATMENT

Osteogenesis Imperfecta

Therapy should be directed toward maximizing the function of each individual, which includes decreasing fractures and deformity that interfere with function. Physical and occupational therapy are critical modalities. They are most commonly utilized after severe fractures or major surgery and should also be engaged consistently throughout the life span for maximizing mobility, functions of daily living, and the extent of physical conditioning possible. Water therapy is particularly useful at all ages. Diet should include adequate intake of calcium and vitamin D. Many patients are underweight for height as young children but overweight as adults, and nutritional management may be useful. Orthopedic procedures are required for deformities of long bone that interfere with standing or walking or when a bone has sustained repeated fractures. Intramedullary rods are often inserted when children are ready to stand and as needed thereafter to keep bone segments in good alignment and provide partial unloading of weight from bones. If scoliosis progresses, stabilization of the spine may be needed to maintain the curve at <60°. Medical management should also include presymptomatic screening for hearing loss, cardiac valve dysfunction, pulmonary function, and, in severe individuals, basilar invagination.

Drugs that have been developed for the therapy of postmenopausal osteoporosis are beneficial for some patients. Bisphosphonates, antiresorptive drugs that inhibit osteoclasts, increase DXA bone density and relieve vertebral compressions in most patients. They are regarded as a mainstay of care in many pediatric centers. However, several Cochran reports have not supported a clear reduction in fracture rate or bone pain from their use, and the dosing and duration of use are controversial. Currently, drugs with a bone-forming mechanism are in trials for OI, especially monoclonal antibodies to sclerostin that relieve its inhibition of osteoblast Wnt/β-catenin signaling, TGF-β inhibitors, and a PTH analogue that stimulates osteoblasts and is most beneficial for adults with milder OI. Potential therapies under investigation in animal models include chemical chaperones and mesenchymal stem cell therapy, and, currently in murine models, correction of specific defects in collagen by CRISPR.

EHLERS-DANLOS SYNDROMES

The Ehlers-Danlos syndromes (EDS) comprise a genetically heterogeneous group of heritable conditions that share several characteristics such as soft and hyperextensible skin, abnormal wound healing, easy bruising, and joint hypermobility. Additional clinical features that differ among the EDS types include fragility of soft tissues, blood vessels, and hollow organs and involvement of the musculoskeletal system and the eye. Mutations in genes coding for fibrillar collagens (type I, III, or V) are found in many patients, but other genes are affected in rare forms.

Classification Several types of EDS have been defined, based on clinical characteristics, mode of inheritance, and molecular defects (Table 425-3), and the classification of these types has been a dynamic process. The current classification defines 13 clinical EDS types that are caused by alterations in 19 different genes, but a recent study described another genetically distinct EDS type, bringing the total number of EDS-associated genes to 20. The EDS classification guides the clinical diagnosis, molecular confirmation, and genetic counseling of affected individuals and their family members.

Incidence An incidence of about 1 in 5000 individuals for all forms of EDS was proposed, with no apparent ethnic predisposition. The diagnosis of hypermobile EDS is more common in females than in males, but whether this is due to an increased incidence or more severe manifestation is unknown. The incidence for other types of EDS is similar in males and females. With incidences of 1 in 20,000 and 1 in 50,000–200,000 respectively, classic and vascular EDS are the most common genetically elucidated types of EDS. For the other types of EDS for which causative variants have been identified, there are no incidence estimates, but the numbers of people who have been reported worldwide with these disorders range between ~5 and ~100 individuals per EDS type. Patients with milder forms frequently do not seek medical attention.

Skin One of the principal features of EDS is skin hyperextensibility, that is, the skin stretches easily but snaps back after release. The skin often has a smooth, soft, or velvety feel to it and can be thin and translucent. It is fragile and tears easily, even after minor trauma, and heals slowly. Widened and thin atrophic scars are frequently observed in different types of EDS. Especially in classic EDS, atrophic scarring may be widespread, especially over pressure points and exposed areas such as the forehead, elbows, knees, and shins, with marked widening of the scars, which are covered by a very thin inelastic skin (papyraceous scars). Individuals with vascular EDS usually do not have a velvety hyperextensible skin, but skin can be thin and translucent with visible superficial veins. Easy bruising is common to most types of EDS and may manifest itself as spontaneous or recurring hematomas. These may cause discoloration of the skin due to deposition of hemosiderin, often referred to as "hemosiderotic" scars, especially in classic, vascular, and periodontic EDS.

Ligament and Joint Changes Joint hypermobility, another cardinal sign, is variable in severity and usually, but not always, generalized. While often an "asset" in childhood, it can become a serious burden over time, often complicated by repetitive subluxations, dislocations, sprains, and chronic joint pain that is difficult to treat. Other observed musculoskeletal features include congenital bilateral hip dislocation,

TABLE 425-3 Different Types of Ehlers-Danlos Syndrome (EDS)

	EDS TYPE	INHERITANCE	OMIM	LOCUS	GENE	PROTEIN	KEY MANIFESTATIONS
Defects in collagen primary structure and collagen processing	Classic EDS (cEDS)	AD	130000 130010	9q34.3 2q32.2	*COL5A1* *COL5A2*	Proα1(V) Proα2(V)	Skin hyperextensibility with atrophic scarring Generalized joint hypermobility

Abbreviations: AD, autosomal dominant; AR, autosomal recessive; ECM, extracellular matrix; OMIM, Online Mendelian Inheritance in Man.

spine deformities (scoliosis, kyphosis), pectus deformities (pectus carinatum, pectus excavatum), club feet and other contractures, and in some rare types, a (mild) skeletal dysplasia. Muscle hypotonia is observed in a number of EDS types and, in combination with joint laxity, may cause floppy infant syndrome or a delay in motor development.

Other Features Signs of more generalized connective tissue weakness and fragility can be observed in varying degrees and may help to distinguish between the different EDS types. Rupture of medium and large-sized arteries is typical of vascular EDS but has been reported in a few other types as well, i.e., classic and kyphoscoliotic type. Vascular EDS patients are also at increased risk for rupture of the gastrointestinal tract, especially the sigmoid colon, the gravid uterus, and, more rarely, other internal organs such as liver or spleen. Valvular defects and aortic root dilatation are rare and are also restricted to some of the rarer types of EDS. Obstetrical and pelvic complications such as cervical insufficiency, premature rupture of membranes, vaginal lacerations, and organ prolapses (uterus, bladder, rectum) may occur. Sclerae may be blue, and more severe ophthalmologic complications, including keratoconus, keratoglobus, and scleral or corneal rupture, may be observed in some rare types.

Molecular Defects Subsets of patients with different types of EDS have mutations in the structural genes for fibrillar collagen types I, III, and V (Table 425-3). About 90% of classic EDS patients harbor a heterozygous mutation in *COL5A1* or *COL5A2* coding for type V collagen, a minor collagen found in association with type I collagen. Heterozygous mutations in the *COL3A1* gene for type III collagen, which is abundant in the blood vessel wall, are responsible for vascular EDS. Arthrochalasia EDS is caused by heterozygous mutations in either *COL1A1* or *COL1A2* that make type I procollagen resistant to cleavage by the procollagen N-proteinase ADAMTS2, whereas dermatosparaxis EDS is caused by biallelic mutations in the gene that codes for the ADAMTS2 itself, thereby reducing its enzyme activity. The persistence of the N-propeptide causes the formation of collagen fibrils that are thin and irregular. Other specific mutations in either *COL1A1* or *COL1A2* give rise to a few rare types of EDS. These include the cardiac-valvular type, which is caused by biallelic *COL1A2* mutations, leading to a complete absence of α2(I) chains. Patients with this condition are at risk for severe, progressive cardiac-valvular disease necessitating valve replacement. A specific arginine-to-cysteine substitution in the type I collagen α chain (p.Arg312Cys) is associated with an EDS phenotype that resembles that of classic EDS, but patients appear at increased risk for vascular rupture of medium-sized arteries. A few patients with a phenotype that couples EDS with signs of moderate to severe myopathy harbor heterozygous or homozygous mutations in *COL12A1*, coding for type XII collagen, a fibril-associated collagen with interrupted triple helices. Kyphoscoliotic EDS is caused by biallelic mutations either in the *PLOD1* gene, which encodes procollagen-lysine 5-dioxygenase (lysyl hydroxylase 1), an enzyme required for formation of stable cross-links in collagen fibers, or in the *FKBP14* gene, which encodes FKBP22, an endoplasmic resident molecular chaperone that acts as a quality control on the folded triple helix of type III collagen. Some patients with clinical characteristics that resemble those of classic EDS harbor biallelic mutations in either *TNXB*, encoding tenascin X, an extracellular matrix glycoprotein that appears to regulate the assembly of collagen fibers, or in *AEBP1*, which encodes the extracellular matrix–associated adipocyte enhancer-binding protein (AEBP1), which assists in collagen polymerization. Spondylodysplastic EDS is caused by biallelic mutations in *B3GALT7*, coding for galactosyltransferase I, or in *B3GALT6*, coding for galactosyltransferase II, both key enzymes in the biosynthesis of the linker region of glycosaminoglycans. Musculocontractural EDS results from mutations in genes coding enzymes responsible for dermatan biosynthesis: *CHST14*, dermatan 4-*O*-sulfotransferase 1, and *DSE*, dermatan sulfate epimerase. A rare spondylodysplastic type of EDS is caused by biallelic mutations in *SLC39A13*, encoding the intracellular zinc transporter ZIP13. Brittle cornea syndrome is caused by biallelic mutations in either *ZNF469* or *PRDM5*, both (putative) transcriptional regulators. Finally, periodontal EDS is caused by heterozygous mutations in *C1R* or *C1S*, coding for the complement pathway components C1q and C1s, respectively.

Diagnosis Diagnostic workup comprises clinical examination and should be followed by genetic testing in individuals who are suspected to have an EDS type. Genetic testing can include targeted mutation analysis in those with a family history of EDS caused by a known genetic variant or, more frequently, next-generation sequencing using multigene panels. Genetic diagnosis should lead to family testing. Of note, the genetic cause of hypermobile EDS has not been determined, and therefore, diagnosis of this condition is based on the presence of clinical manifestations and the exclusion of other types of EDS or other conditions associated with joint hypermobility. Correlations between genotype and phenotype are challenging and only starting to emerge, and as with other heritable diseases of connective tissue, there is a large degree of variability among members of the same family carrying the same mutation.

TREATMENT

Ehlers-Danlos Syndrome

All patients with EDS should receive multidisciplinary care and, if available, be part of a patient advocacy community. The precise treatment depends on the type of EDS and the clinical manifestations. Physiotherapy is essential for patients with musculoskeletal problems. Helmets and/or skin protections or joint protections, braces, or splints can be used to reduce the risk of injury in patients with skin fragility or joint hypermobility. Low-resistance exercises (such as walking or swimming) can improve joint stability, although exercises that place considerable strain on the joints (such as gymnastics or weightlifting) should be avoided. Monitoring for cardiovascular alterations using noninvasive procedures is recommended in patients at risk of adverse cardiovascular events only. Given the rarity of vascular EDS, referral to a center with EDS expertise is of vital importance. A clear protocol for emergency room evaluation in the case of major complications should be established, and patients should carry documentation of their genetic diagnosis, such as a MedicAlert. The psychosocial impact of a vascular EDS diagnosis often requires psychological care.

CHONDRODYSPLASIAS

(See also Chap. 424) Chondrodysplasias (CDs), also referred to as skeletal dysplasias or osteochondrodysplasias, encompass a heterogeneous group of disorders characterized by intrinsic abnormalities of cartilage and bone and are generally characterized by dwarfism and abnormal body proportions (disproportionate short stature). Many affected individuals develop degenerative joint changes, and mild CD in adults may be difficult to differentiate from primary generalized OA.

Classification The Nosology and Classification of Genetic Skeletal Disorders comprises 771 distinct disorders based on clinical, radiographic, and/or molecular phenotypes. Pathogenic variants have currently been found in 551 different genes. The conditions are divided into 41 groups based on gene/protein families (e.g., the type II collagen group), phenotypic presentation (e.g., spondylometaphyseal dysplasia), and pathophysiology (i.e., lysosomal storage disorders). One gene may be responsible for more than one condition (e.g., *COL2A1* mutations may cause a number of CDs including achondrogenesis, hypochondrogenesis, spondyloepiphyseal dysplasia congenita, Kniest and Stickler syndromes), or a condition may be due to mutations in more than one gene (e.g., geleophysic dysplasia can be caused by mutations in *ADAMTSL2, FBN1,* and *LTBP3*).

Incidence The overall incidence of all forms of CD ranges from 1 per 2500 to 1 per 4000 births. Data on the frequency of individual CDs are incomplete. The most common form of inherited disproportionate short stature is achondroplasia, with an estimated incidence of 1 per 26,000 to 1 per 28,000 live births.

Molecular Defects Mutations in the *COL2A1* gene, coding for the α chain of type II collagen of cartilage, are found in a group of patients with both mild and severe CDs. For example, a mutation in *COL2A1* substituting a cysteine residue for an arginine was found in a few unrelated families with spondyloepiphyseal dysplasia (SED) and precocious generalized OA. Mutations in the gene were also found in some lethal CDs characterized by gross deformities of bones and cartilage, such as those found in SED congenita, spondyloepimetaphyseal dysplasia congenita, hypochondrogenesis/achondrogenesis type II, and Kniest syndrome. The highest incidence of *COL2A1* mutations, however, occurs in patients with the distinctive features of the Stickler syndrome, which is characterized by skeletal changes, orofacial abnormalities, and ophthalmologic and auditory abnormalities. Most of the mutations in *COL2A1* are premature stop codons that produce haploinsufficiency. In addition, some of the patients with Stickler syndrome or a closely related syndrome have mutations in two genes specific for type XI collagen (*COL11A1* and *COL11A2*), which is an unusual heterotrimer formed from α chains encoded by *COL2A1, COL11A1,* and *COL11A2*. Mutations in the *COL11A1* gene are also found in patients with Marshall syndrome, which is similar to classic Stickler syndrome, but with more severe hearing loss and dysmorphic features, such as a flat or retracted midface with a flat nasal bridge, short nose, anteverted nostrils, long philtrum, and large-appearing eyes.

CDs are also caused by mutations in the less abundant collagens found in cartilage. For example, patients with Schmid metaphyseal CD have mutations in the gene for type X collagen, a short, network-forming collagen found in the hypertrophic zone of endochondral cartilage. The syndrome is characterized by short stature, coxa vara, flaring metaphyses, and waddling gait. As with other collagen genes, the most common mutations are of two types: nonsense mutations that lead to haploinsufficiency and structural mutations that compromise collagen assembly.

Some patients have mutations in genes for proteins that interact with collagens. Patients with pseudoachondroplasia or autosomal dominant multiple epiphyseal dysplasia have mutations in the gene for the cartilage oligomeric matrix protein (*COMP*), a protein that interacts with both collagens and proteoglycans in cartilage. However, some families with multiple epiphyseal dysplasia have a defect in one of the three genes for type IX collagen (*COL9A1*, *COL9A2*, and *COL9A3*) or in matrilin-3, another extracellular protein found in cartilage.

Some CDs are caused by mutations in genes that affect early development of cartilage and related structures. Achondroplasia is caused by mutations in the gene for a receptor for a fibroblastic growth factor (*FGFR3*). The mutations in the *FGFR3* gene causing achondroplasia are unusual in several respects. More than 99% of individuals with achondroplasia have one of two pathogenic variants (c.1138G> or c.1138G>C) in *FGFR3*, both resulting in the amino acid change p.Gly380Arg. Most patients harbor a sporadic new (de novo) mutation, and therefore, this nucleotide change is one of the most common recurring mutations in the human genome. The mutation causes unregulated signal transduction through the receptor and inappropriate development of cartilage. Mutations that alter other domains of *FGFR3* have been found in patients with the more severe disorders of hypochondroplasia and thanatophoric dysplasia and in a few families with a variant of craniosynostosis. However, most patients with craniosynostosis appear to have mutations in the related *FGFR2* gene. The similarities between the phenotypes produced by mutations in genes for fibroblast growth factor (FGF) receptors and mutations in structural proteins of cartilage are probably explained by the observation that the activity of FGFs is regulated in part by binding of FGFs to proteins sequestered in the extracellular matrix. Therefore, the situation parallels the interactions between transforming growth factors (TGFs) and fibrillin in MFS (see below).

Other mutations involve the proteoglycans of cartilage, aggrecan (*AGC1*) and perlecan (*HSPG2*), and in the proteoglycan posttranslational sulphation pathway (*DTDST*, *PAPSS2*, and *CHST3*).

Diagnosis The diagnosis of CDs is made on the basis of the physical appearance, slit-lamp eye examinations, x-ray findings, histologic changes, and clinical course. Targeted gene and exome sequencing or more global sequencing strategies are used for molecular diagnosis. Given the wide spectrum of CD phenotypes, these genetic tests are becoming critical diagnostic tools. For Stickler syndrome, more precise diagnostic criteria have made it possible to identify type I variants with mutations in the *COL2A1* gene with a high degree of accuracy. It has been suggested that the type II variant with mutations in the *COL11A1* gene can be identified on the basis of a "beaded" vitreous phenotype and that the type III variant with mutations in the *COL11A2* gene can be identified on the basis of the characteristic systemic features without the ocular involvement. Prenatal diagnosis based on analysis of DNA obtained from chorionic villus or amniotic fluid is possible.

TREATMENT

Chondrodysplasias

The treatment of CDs is symptomatic and is directed to secondary features such as degenerative arthritis. Many patients require joint replacement surgery and corrective surgery for cleft palate. The eyes should be monitored carefully for the development of cataracts and the need for laser therapy to prevent retinal detachment. In general, patients should be advised to avoid obesity and contact sports. Counseling for the psychological problems of short stature is critical. A randomized, double-blind, phase 3, placebo-controlled, multicenter trial with vosoritide, a biologic analogue of C-type natriuretic peptide, which is a potent stimulator of endochondral ossification, in children with achondroplasia showed that this is an effective and safe treatment to increase growth in children with achondroplasia.

HERITABLE THORACIC AORTIC ANEURYSM DISEASE

Heritable thoracic aortic aneurysm disease (HTAD) encompasses conditions in which aortic disease has a familial occurrence, due to an underlying genetic defect. HTAD is classified as syndromic or nonsyndromic. Syndromic HTAD may be associated with ocular, craniofacial, musculoskeletal, and skin features, with a recognizable, yet sometime subtle, phenotype. They are caused by mutations in genes that code for extracellular matrix proteins. Besides syndromic HTAD, there are several nonsyndromic forms of HTAD; patients with these conditions do not display an outward recognizable phenotype and are classified as having familial thoracic aortic aneurysm (FTAA). More extensive genetic screening in cohorts of patients with thoracic aortic aneurysm is, however, slowly revealing that there is no strict boundary between syndromic and nonsyndromic HTAD entities **(Table 425-4) (Chap. 291)**.

Classification The most common form of syndromic HTAD is MFS, caused by mutations in the gene for fibrillin-1 (*FBN1*). MFS was initially characterized by a triad of features: (1) skeletal changes that include long, thin extremities, frequently associated with loose joints; (2) reduced vision as the result of dislocations of the lenses (ectopia lentis); and (3) aortic aneurysms. An international panel has developed a series of revised Ghent criteria that are useful in classifying patients. Other major syndromic HTADs include the different genetic variants of Loeys-Dietz syndrome (LDS) (*TGFBR1, TGFBR2, TGFB2, TGFB3, SMAD2,* and *SMAD3*). Rare forms of syndromic HTAD include Shprintzen-Goldberg syndrome (*SKI*), Meester-Loeys syndrome (*BGN*), and arterial tortuosity syndrome (ATS) (*SLC2A10*).

Incidence and Inheritance The incidence of MFS is among the highest of any heritable disorder: ~1 in 3000–5000 births in most racial and ethnic groups. The related syndromes are less common. Mutations are generally inherited as autosomal dominant traits, but about one-fourth of patients have sporadic new mutations. The LDSs are less common, but their exact incidence is currently unknown.

Skeletal Effects Patients with MFS typically display a marfanoid habitus with tall stature and long limbs. The ratio of the upper segment (top of the head to the top of the pubic ramus) to the lower segment

Abbreviations: EDS, Ehlers-Danlos syndromes; OMIM, Online Mendelian Inheritance in Man; TGF, transforming growth factor.

(top of the pubic ramus to the floor) is usually 2 standard deviations below mean for age, race, and sex. The fingers and hands are long and slender and have a spider-like appearance (arachnodactyly). Overlapping features in MFS and LDS include scoliosis or kyphoscoliosis; anterior chest deformities, including pectus excavatum, pectus carinatum, or asymmetry; pes planus; pneumothorax; and dural ectasia. A few patients have severe joint hypermobility similar to EDS. Clubfeet, joint contractures, and cervical spine instability are more frequently observed in LDS. Patients with *SMAD3* mutations are particularly prone to premature OA.

Cardiovascular Features Cardiovascular abnormalities are the major source of morbidity and mortality both in MFS and LDS (Chap. 291). Patients with MFS often have mitral valve prolapse that develops early in life and that progresses to mitral valve regurgitation of increasing severity in about one-quarter of patients. Dilation of the root of the aorta and the sinuses of Valsalva are characteristic and ominous features of MFS that can develop at any age. The rate of dilation is unpredictable, but it can lead to aortic regurgitation, dissection of the aorta, and rupture. Dilation is probably accelerated by physical and emotional stress as well as by pregnancy. Cardiovascular features of LDS also include dilatation of the aortic root at the level of the sinus of Valsalva, which can progress to dissection or rupture when left untreated. LDS is also known for its involvement of aneurysms affecting arterial branches of head, neck, thoracic and abdominal aorta, lung, and lower extremities and for the presence or tortuosity of these vessels. In contrast to MFS, congenital heart malformations are often noted.

Ocular Features Myopia is the most common ocular feature of MFS and often presents in early childhood. Displacement of the lens from the center of the pupil (ectopia lentis) occurs in ~60% of MFS patients. The ocular globe is frequently elongated. Retinal detachment, early cataract formation, and glaucoma can occur. Ectopia lentis does not usually occur in LDS, but other ocular features may be present, such as blue sclerae, strabismus, amblyopia, and myopia.

Other Features MFS patients typically have a high arched palate. Patients with LDS characteristically display hypertelorism (widely spaced eyes) and cleft palate or bifid (split) uvula. They may also have craniosynostosis. Shared mucocutaneous features include striae, typically over the shoulders and buttocks, and inguinal and incisional hernias. Patients with LDS may display more EDS-like skin features, such as thin translucent skin and widened scars.

Molecular Defects Approximately 95% of MFS patients are explained by *FBN1* defects, and so far, over 2000 different *FBN1* mutations have been described. Mutations in the same gene are found in a few patients who do not meet the Ghent criteria. Most *FBN1* gene mutations are unique and are scattered throughout its 65 coding exons. Approximately 10% are recurrent mutations that are largely located in CpG sequences known to be "hot spots." About one-third of the mutations introduce premature termination codons, and about two-thirds are missense mutations that alter calcium-binding domains in the repetitive epidermal growth factor–like domains of the protein. Rarer mutations alter the processing of the protein. As in many genetic diseases, the severity of the phenotype cannot be predicted from the nature of the mutation. In LDS, components of the TGF-β signaling pathway are mutated, including the cytokines (TGFβ2, TGFβ3), the receptors (TGFBR1, TGFBR2), and the downstream effectors (SMAD2, SMAD3).

The discovery that various conditions with pronounced clinical overlap with MFS were caused by mutations in genes coding for direct effectors and/or regulators of TGFβ signaling, including LDS, revealed that *FBN1* mutations not only lead to weakening of the extracellular matrix structure, but also influence the bioavailability of TGFβ. As a result, some of the manifestations of MFS have been shown to arise from alterations in binding sites that modulate TGFβ bioavailability during development of the skeleton and other tissues. In aortic tissues, reduced or altered forms of fibrillin-1 can stimulate the release of sequestered TGFβ and increase its activity. This results in altered transcription of target genes, including connective tissue growth factor and matrix metalloproteinases MMP2 and MMP9. The aortic phenotype is therefore caused by vascular remodeling due to a combination of structural microfibril changes, excess TGFβ, and overexpression of MMP-2 and MMP-9. The role of TGFβ in the pathophysiology of MFS has been further solidified by therapeutic use of angiotensin 2 receptor blockers (ARBs), proven to decrease TGFβ activity, to reduce the progression of aortic dilation. However, clinical trials with ARBs did not provide evidence of a dramatic decrease or prevention of aortic growth with ARBs.

Diagnosis When HTAD is present, genetic testing can confirm the diagnosis and allow identification of at-risk individuals. Referral to a specialty genetics service is critically important, and genetic counseling before testing is recommended. In view of phenotypic overlap between the syndromic HTAD, a multigene panel (usually including genes for syndromic and nonsyndromic HTAD) is recommended. All patients with a suspected diagnosis of MFS should have a slit-lamp examination and an echocardiogram. Also, homocystinuria should be ruled out by amino acid analysis of plasma (Chap. 431). The diagnosis of MFS according to the international Ghent standards places emphasis on two cardinal features, dilation of the ascending aorta with or without dissection and ectopia lentis. Other cardiovascular and ocular manifestations and findings in other organ systems such as the skeleton, dura, skin, and lungs contribute to a systemic score that guides diagnosis when aortic disease is present but ectopia lentis is not.

TREATMENT

Marfan and Loeys-Dietz Syndromes

Patients should be advised that vascular risks are increased by severe physical exertion, smoking, emotional stress, and pregnancy. Low-level moderate aerobic exercise and limits on isometric exercise are recommended. Prophylactic beta blocker and/or angiotensin II receptor blocker therapy are prescribed in normotensive individuals, and blood pressure control is important for those with hypertension. Surgical correction of the aorta, aortic valve, and mitral valve has been successful in many patients, but tissues are frequently friable. The scoliosis tends to be progressive, and surgical stabilization may be required. Dislocated lenses rarely require surgical removal, but patients should be followed closely for retinal detachment.

426 Hemochromatosis

Darrell H. G. Crawford, David M. Frazer

DEFINITION

Hemochromatosis is a relatively common inherited disorder of iron metabolism more prevalent in European populations. It is now known to be an iron-storage disorder with underlying genetic heterogeneity that, in nearly all cases, causes inappropriately high cellular release of iron from iron exporting cells such as enterocytes and macrophages. The increase in intestinal iron absorption results in the deposition of excess iron in parenchymal cells with eventual cellular injury, tissue fibrosis, and organ failure. Cirrhosis of the liver, diabetes mellitus, arthritis, cardiomyopathy, and hypogonadotropic hypogonadism are the most important clinical consequences.

The term *hemochromatosis* describes the unique genetic clinicalpathologic condition with features of increased serum transferrin saturation, iron overload in the liver but not the spleen, prevalent involvement of periportal hepatocytes with iron sparing of Kupffer cells, and/or signs and symptoms of iron overload. These characteristics should occur in the absence of a primary/predominant red blood cell disorder to distinguish hemochromatosis from other iron overload conditions, which are also often genetic in origin.

The condition is most often caused by a mutation in the homeostatic iron regulator (*HFE*) gene, which is tightly linked to the HLA-A locus on chromosome 6p. Persons who are homozygous for the mutation are at increased risk of iron overload and account for 80–90% of hemochromatosis in persons of northern European descent. In such subjects, the presence of hepatic fibrosis, cirrhosis, arthropathy, or hepatocellular carcinoma constitutes iron overload–related disease. Rarer forms of non-*HFE* hemochromatosis are caused by mutations in other genes involved in iron metabolism **(Table 426-1)**. The disease is now often diagnosed during its early stages when iron overload and organ damage are minimal.

Secondary iron overload occurs as a result of an iron-loading anemia, such as thalassemia or sideroblastic anemia, in which erythropoiesis is ineffective and causes increased intestinal iron absorption. In the acquired iron-loading disorders, massive iron deposits in parenchymal tissues can lead to the same clinical and pathologic features as in hemochromatosis.

PREVALENCE

The prevalence of *HFE*-associated hemochromatosis mutations varies among different ethnic groups. It is most common in populations of northern European extraction in whom ~1 in 10 persons are heterozygous carriers and 0.3–0.5% are homozygotes, with even higher percentages in some Celtic populations such as those residing in Ireland and Brittany. The expression of the disease is variable and modified by several factors, especially alcohol consumption, dietary iron intake, blood loss associated with menstruation and pregnancy, and blood donation. Recent population studies indicate that ~40% of homozygous men develop iron overload–related complications and about 6% develop hepatic cirrhosis. For women, iron overload–related complications occur in ~10%. In addition, there are as yet unidentified modifying genes responsible for variable disease expression. Nearly 70% of untreated patients develop the first symptoms between ages 40 and 60. The disease is rarely evident before age 20, although with family screening (see "Screening for Hemochromatosis," below) and periodic

TABLE 426-1 Classification of Iron Overload States

Hereditary Hemochromatosis	
Hemochromatosis, *HFE*-related (type 1)	
C282Y homozygosity	
C282Y/H63D compound heterozygosity	
Hemochromatosis, non-*HFE*-related	
Juvenile hemochromatosis (type 2A) (hemojuvelin mutations)	
Juvenile hemochromatosis (type 2B) (hepcidin mutation)	
Mutated transferrin receptor 2, *TFR2* (type 3)	
Mutated ferroportin 1 gene, *SLC40A1* (type 4)	
Acquired Iron Overload	
Iron-loading anemias	Chronic liver disease
Thalassemia major	Hepatitis C
Sideroblastic anemia	Alcoholic cirrhosis, especially when advanced
Chronic hemolytic anemias	Nonalcoholic steatohepatitis
Transfusional and parenteral iron overload	Porphyria cutanea tarda
Dietary iron overload	Dysmetabolic iron overload syndrome
	Post-portacaval shunting

Aceruloplasminemia	
Congenital atransferrinemia	

health examinations, asymptomatic subjects with iron overload can be identified, including young menstruating women.

Mutations in other genes involved in iron metabolism are responsible for non-*HFE*-associated hemochromatosis. In contrast to *HFE*-associated hemochromatosis, the non-*HFE*-associated forms of hemochromatosis (Table 426-1) are rare, but they affect all populations and may affect young people (juvenile hemochromatosis). These conditions result from mutations in one or more of the genes encoding proteins in the hepcidin pathway (Fig. 426-1), including hepcidin, hemojuvelin, and transferrin receptor 2 (TFR2). The resultant clinical disease is very similar to HFE-related disease because they all lead to hepcidin deficiency via a final common pathway (Fig. 426-1).

A rare autosomal dominant form of hemochromatosis results from two types of mutations in the gene for the iron transporter ferroportin. Loss-of-function mutations decrease the cell surface localization of ferroportin in certain tissues, thereby reducing its ability to export iron ("ferroportin disease") and causing cellular iron retention, particularly in macrophages. A second mutation abolishes the hepcidin-induced ferroportin internalization and degradation resulting in a "gain of function." Here the tissue iron distribution is similar to that in HFE-related disease (e.g., in parenchymal cells).

GENETIC BASIS

The most common mutation in the *HFE* gene is a homozygous G to A transition that leads to a cysteine to tyrosine substitution at position 282 (C282Y) of the HFE protein. It has been identified in 85–90% of patients with hereditary hemochromatosis in populations of northern European descent but is found in only 60% of cases from Mediterranean populations. A second, relatively common *HFE* variant (H63D) results in a substitution of aspartic acid for histidine at residue 63 of the HFE protein. Homozygosity for H63D is not associated with clinically significant iron overload. Some compound heterozygotes (i.e., one copy each of C282Y and H63D) have mild to moderately increased body-iron stores but develop clinical disease only in association with

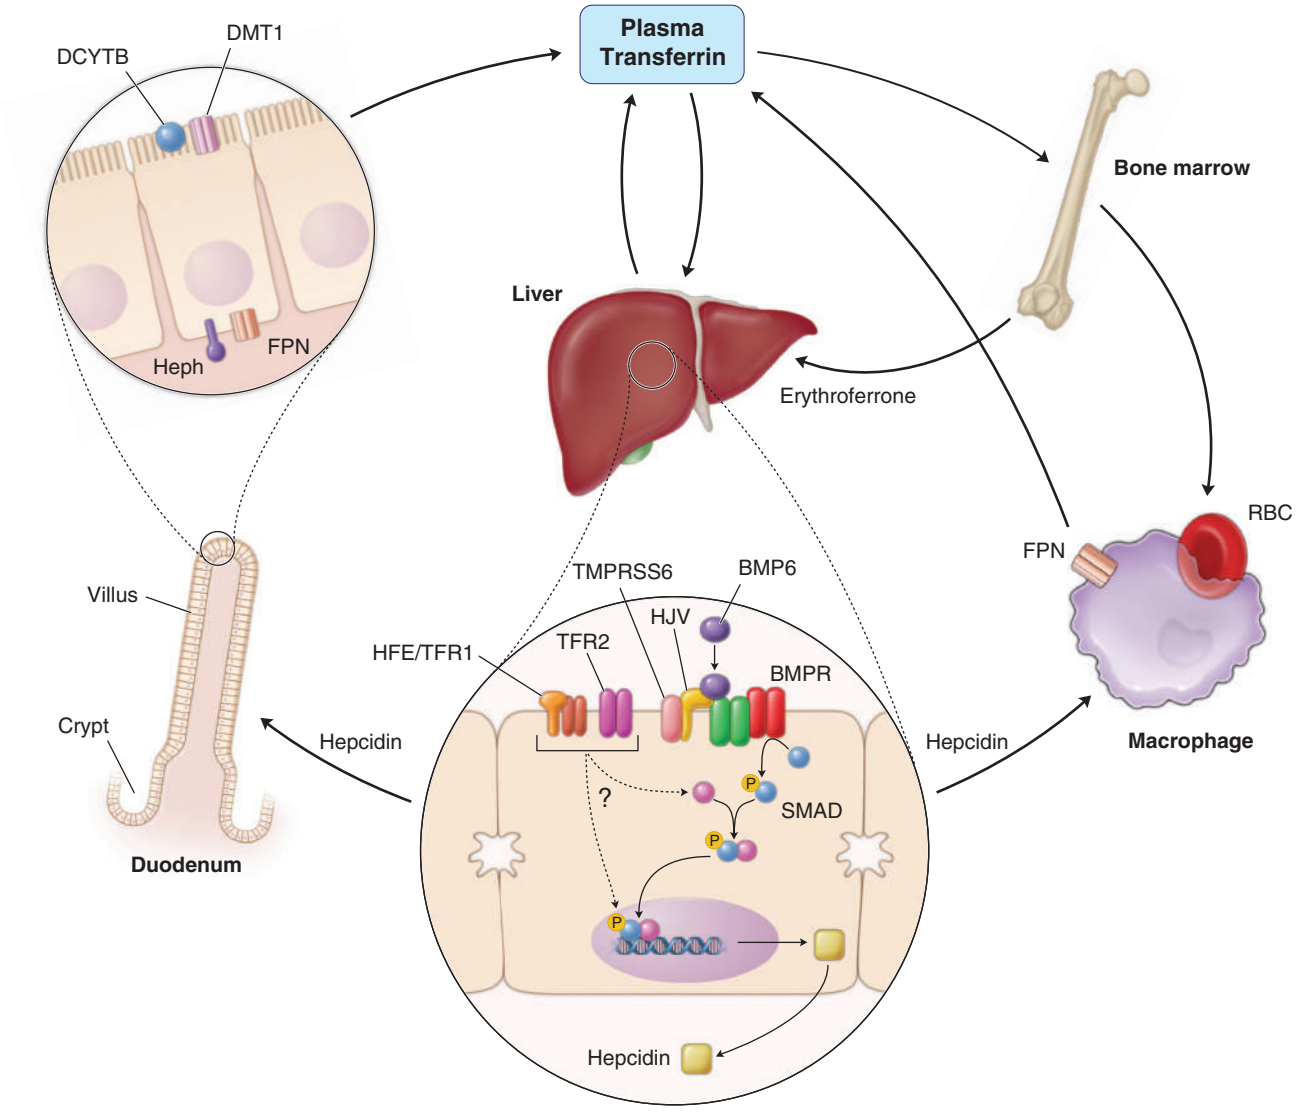

FIGURE 426-1 Pathways of normal iron homeostasis. Dietary inorganic iron traverses the brush border membrane of duodenal enterocytes via divalent metal-ion transporter 1 (DMT1) after reduction of ferric (Fe^{3+}) iron to the ferrous (Fe^{2+}) state by intestinal ferrireductases such as duodenal cytochrome B (DCYTB). Iron then moves from the enterocyte to the circulation via a process requiring the basolateral iron exporter ferroportin (FPN) and the iron oxidase hephaestin (Heph). In the circulation, iron binds to plasma transferrin and is thereby distributed to sites of iron utilization and storage. Much of the diferric transferrin supplies iron to immature erythrocyte cells in the bone marrow for hemoglobin synthesis. At the end of their life, senescent red blood cells (RBCs) are phagocytosed by macrophages, and iron is returned to the circulation after export through ferroportin. The liver-derived peptide hepcidin represses basolateral iron transport in the gut as well as iron released from macrophages and other cells and serves as a central regulator of body-iron traffic. At least two separate signals regulate hepcidin production in response to changes in body-iron requirements. The first involves the detection of circulating diferric transferrin by HFE and TFR2. A second relies on hepatic iron stores activating the hemojuvelin (HJV)-dependent bone morphogenetic protein (BMP)/SMAD pathway. This pathway is modified by erythroferrone released from erythroid precursor cells, which binds to BMP6 and inhibits its function. TMPRSS6 is a protease that regulates hepcidin production, possibly by modulating HJV activity. Heme is metabolized by heme oxygenase within the enterocytes, and the released iron then follows the same pathway. Mutations in the genes encoding HFE, TFR2, HJV, and hepcidin all lead to decreased hepcidin release and increased iron absorption, resulting in hemochromatosis (Table 426-1).

cofactors such as heavy alcohol intake or hepatic steatosis. *HFE*-associated hemochromatosis is inherited as an autosomal recessive trait, and heterozygotes have no, or minimal, increase in iron stores. However, this slight increase in hepatic iron can act as a cofactor that may modify the expression of other diseases such as porphyria cutanea tarda (PCT) or metabolic dysfunction associated steatohepatitis (MASH).

PATHOPHYSIOLOGY AND THE ROLE OF HEPCIDIN

Normally, the body-iron content of 3–4 g is maintained as a result of intestinal mucosal absorption of iron being equal to iron loss. This amount is ~1 mg/d in men and 1.5 mg/d in menstruating women. In hemochromatosis, intestinal iron absorption is greater than body requirements and amounts to ≥4 mg/d. The progressive accumulation of iron increases plasma iron concentration and saturation of transferrin and results in a progressive increase of plasma ferritin **(Fig. 426-2)**. Hepcidin is a key regulatory hormone that allows the bone marrow and other tissues to communicate their iron requirements. It was called hepcidin based upon its antibacterial activity ("HEPatic bacterioCIDal proteIN"). This liver-derived peptide represses basolateral iron export from intestinal enterocytes and iron release from macrophages and other cells by binding to ferroportin. Hepcidin, in turn, responds to signals in the liver mediated by HFE, TFR2, and hemojuvelin (Fig. 426-1). The development of hepcidin agonists represents a promising new therapeutic approach for iron overload disorders caused by low hepcidin levels.

The *HFE* gene encodes a 343-amino-acid protein that is structurally related to MHC class I proteins. The basic defect in *HFE*-associated hemochromatosis is a lack of cell surface expression of HFE (due to the C282Y mutation). The normal (wild-type) HFE protein forms a complex with β_2-microglobulin and transferrin receptor 1 (TFR1), and the C282Y mutation completely abrogates this interaction. As a result, the mutant HFE protein remains trapped intracellularly. Although the precise function of HFE at the cell surface is not known, mutations in this protein reduce hepcidin production leading to increased dietary iron absorption (Fig. 426-1). In advanced disease, the body may contain 20 g or more of iron, which is deposited mainly in parenchymal cells of the liver, pancreas, and heart. Iron deposition in the pituitary causes hypogonadotropic hypogonadism in both men and women. Tissue injury results from disruption of iron-laden lysosomes, lipid peroxidation of subcellular organelles by excess iron, and stimulation of collagen synthesis by activated hepatic stellate cells.

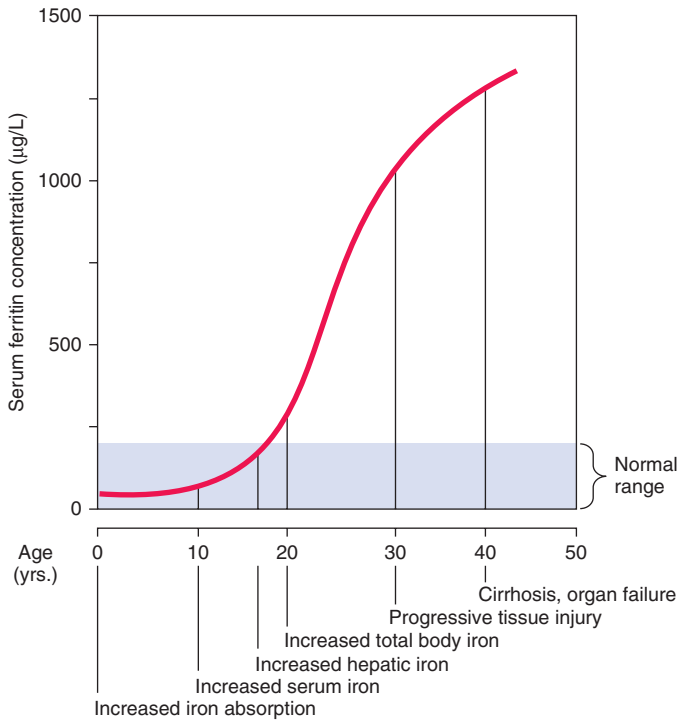

FIGURE 426-2 Sequence of events in genetic hemochromatosis and their correlation with the serum ferritin concentration. Increased iron absorption is present throughout life. Overt, symptomatic disease usually develops between ages 40 and 60, but latent disease can be detected long before this.

Secondary iron overload with iron deposition in parenchymal cells occurs in chronic disorders of erythropoiesis, particularly in those with defects in hemoglobin synthesis and ineffective erythropoiesis such as sideroblastic anemia and thalassemia **(Chap. 103)**. In these disorders, iron absorption is increased. Moreover, these patients require blood transfusions and are frequently treated inappropriately with iron. PCT, a disorder characterized by a defect in porphyrin biosynthesis **(Chap. 428)**, can also be associated with excessive parenchymal iron deposits. The magnitude of the iron load in PCT is usually insufficient to produce tissue damage. However, some patients with PCT also have mutations in the *HFE* gene, and some have associated hepatitis C virus (HCV) infection. Although the relationship between these disorders remains to be clarified, iron overload accentuates the inherited enzyme deficiency in PCT and should be avoided along with other agents (alcohol, estrogens, haloaromatic compounds) that may exacerbate PCT. Another cause of hepatic parenchymal iron overload is hereditary aceruloplasminemia. In this disorder, impairment of iron mobilization due to deficiency of ceruloplasmin (a ferroxidase) causes iron overload in hepatocytes and a range of other cell types.

Excessive iron ingestion over many years rarely results in hemochromatosis. An important exception has been reported in South Africa among groups who brew fermented beverages in vessels made of iron. Hemochromatosis has been described in apparently normal persons who have taken medicinal iron over many years, but such individuals probably had genetic disorders.

The common denominator in all patients with hemochromatosis is *excessive amounts of iron in parenchymal tissues*. Parenteral administration of iron in the form of blood transfusions or iron preparations results predominantly in reticuloendothelial cell iron overload. This appears to lead to less tissue damage than iron loading of parenchymal cells.

In the liver, parenchymal iron is in the form of ferritin and hemosiderin. In the early stages, these deposits are seen in the periportal parenchymal cells, especially within lysosomes in the pericanalicular cytoplasm of the hepatocytes. This stage progresses to perilobular fibrosis and the formation of fibrous septa due to activation of hepatic stellate cells. In the advanced stage, a macronodular or mixed macro- and micronodular cirrhosis develops. The underlying hepatic iron concentration is an important determinant of the risk of the development of hepatic fibrosis and cirrhosis.

Histologically, iron is increased in many organs, particularly in the liver, heart, and pancreas, and, to a lesser extent, in the endocrine glands. The epidermis of the skin is thin, and melanin is increased in the cells of the basal layer and dermis. Deposits of iron are present around the synovial lining cells of the joints.

CLINICAL MANIFESTATIONS

C282Y homozygotes can be characterized by their stage in the progression of disease as follows: (1) a genetic predisposition without biochemical or clinical abnormalities; (2) iron overload without symptoms; (3) iron overload with symptoms (e.g., arthritis and fatigue); and (4) iron overload with organ damage—in particular, cirrhosis. Many subjects with significant iron overload are asymptomatic. For example, in a study of 672 asymptomatic C282Y homozygous subjects (identified by either family screening or routine health examinations), there was hepatic iron overload (grades 2–4) in 56% and 34.5% of male and female subjects, respectively, hepatic fibrosis (stages 2–4) in 18.4% and 5.4%, respectively, and cirrhosis in 5.6% and 1.9%, respectively.

Initial symptoms of hemochromatosis are often nonspecific and include lethargy, arthralgia, skin pigmentation, loss of libido, and features of diabetes mellitus. Hepatomegaly, increased pigmentation, spider angiomas, splenomegaly, arthropathy, ascites, cardiac arrhythmias, congestive heart failure, loss of body hair, testicular atrophy, and jaundice are prominent in advanced disease.

Hepatocellular carcinoma develops in ~30% of patients with cirrhosis, and it is the most common cause of death in treated patients with cirrhosis—hence the importance of early diagnosis and therapy. The incidence increases with age, it is more common in men, and it occurs almost exclusively in cirrhotic patients.

Excessive skin pigmentation is present in patients with advanced disease. The characteristic metallic or slate-gray hue is sometimes referred to as *bronzing* and results from increased melanin and iron in the dermis. Pigmentation usually is diffuse and generalized.

Diabetes mellitus occurs in ~65% of patients with advanced disease and is more likely to develop in those with a family history of diabetes, suggesting that direct damage to the pancreatic islets by iron deposition occurs in combination with other risk factors. The management is similar to that of other forms of diabetes.

Arthropathy develops in 25–50% of symptomatic patients. It usually occurs after age 50 but may occur as a first manifestation or long after therapy. The joints of the hands, especially the second and third metacarpophalangeal joints, are usually the first joints involved, a feature that helps to distinguish the chondrocalcinosis associated with hemochromatosis from the idiopathic form **(Chap. 384)**. A progressive polyarthritis involving the wrists, hips, ankles, and knees may also ensue. Acute attacks of synovitis may be associated with deposition of calcium pyrophosphate (chondrocalcinosis or pseudogout), mainly in the knees. Radiologic manifestations include cystic changes of the subchondral bones, loss of articular cartilage with narrowing of the joint space, diffuse demineralization, hypertrophic bone proliferation, and calcification of the synovium. The arthropathy tends to progress despite removal of iron by phlebotomy. Although the relation of these abnormalities to iron metabolism is not known, the fact that similar changes occur in other forms of iron overload suggests that iron is directly involved.

Cardiac involvement is the presenting manifestation in ~15% of symptomatic patients. The most common manifestation is congestive heart failure, which occurs in ~10% of young adults with the disease, especially those with juvenile hemochromatosis. Symptoms of congestive heart failure may develop suddenly, with rapid progression to death if untreated. The heart is diffusely enlarged. This may be misdiagnosed as idiopathic cardiomyopathy if other overt manifestations are absent. Cardiac arrhythmias include premature supraventricular beats, paroxysmal tachyarrhythmias, atrial flutter, atrial fibrillation, and varying degrees of atrioventricular block.

Hypogonadism occurs in both sexes and may antedate other clinical features. Manifestations include loss of libido, impotence, amenorrhea, testicular atrophy, gynecomastia, and sparse body hair. These changes are primarily the result of decreased production of gonadotropins due to impairment of hypothalamic-pituitary function by iron deposition.

DIAGNOSIS

The association of (1) hepatomegaly, (2) skin pigmentation, (3) diabetes mellitus, (4) heart disease, (5) arthritis, and (6) hypogonadism should suggest the diagnosis. However, as stated above, significant iron overload may exist with none or only some of these manifestations. Therefore, a high index of suspicion is needed to make the diagnosis early. Treatment before permanent organ damage occurs can reverse the iron toxicity and restore life expectancy to normal.

The history should be particularly detailed in regard to disease in other family members and should include information on alcohol ingestion; iron intake; and ingestion of large doses of ascorbic acid, which promotes iron absorption **(Chap. 344)**. Appropriate tests should be performed to exclude iron deposition due to hematologic disease. The presence of liver, pancreatic, cardiac, and joint disease should be confirmed by physical examination, radiography, and standard function tests of these organs.

The degree of increase in total body iron stores can be assessed by (1) measurement of serum iron and the percent saturation of transferrin (or the unsaturated iron-binding capacity), (2) measurement of serum ferritin concentration, (3) liver biopsy with measurement of the iron concentration **(Table 426-2)**, and (4) magnetic resonance imaging (MRI) of the liver to quantify hepatic iron stores. In addition, a retrospective assessment of body-iron storage is also provided by performing weekly phlebotomy and calculating the amount of iron removed before iron stores are exhausted (1 mL blood = ~0.5 mg iron).

Each of these methods for assessing iron stores has advantages and limitations. The serum iron level and percent saturation of transferrin are elevated early in the course, but their specificity is reduced by significant false-positive and false-negative rates. For example, serum iron concentration may be increased in patients with alcoholic liver disease without iron overload (Table 426-2). In otherwise healthy persons, a fasting serum transferrin saturation >45% is abnormal and suggests homozygosity for hemochromatosis.

The serum ferritin concentration is used as an index of body-iron stores, whether decreased or increased. In fact, an increase of 1 μg/L in serum ferritin level reflects an increase of ~8–10 mg in body stores. In most untreated patients with hemochromatosis, the serum ferritin level is significantly increased (Fig. 426-2 and Table 426-2), and a serum ferritin level >1000 μg/L is a strong predictor of cirrhosis among individuals homozygous for the C282Y mutation. However, in patients with hepatic necroinflammatory conditions such as alcoholic liver disease and metabolic dysfunction–associated steatotic liver disease, acute hepatocellular necrosis, or systemic inflammatory conditions, serum ferritin levels may be elevated out of proportion to body iron stores due to increased release from tissues. Therefore, a repeat determination of serum ferritin should be carried out after acute hepatocellular damage has subsided (e.g., in alcoholic liver disease). Ordinarily, the combined measurements of the percent transferrin saturation and serum ferritin level provide a simple and reliable screening test for hemochromatosis, including the precirrhotic phase of the disease. If either of these tests is abnormal, genetic testing for hemochromatosis should be performed **(Fig. 426-3)**.

The role of liver biopsy in the diagnosis and management of hemochromatosis has been reassessed as a result of the widespread availability of genetic testing for the C282Y mutation. The absence of severe fibrosis can be accurately predicted in most patients using clinical and biochemical variables. Thus, there is virtually no risk of severe fibrosis in a C282Y homozygous subject with (1) serum ferritin level

TABLE 426-2 Representative Iron Values in Normal Subjects, Patients with Hemochromatosis, and Patients with Alcoholic Liver Disease

DETERMINATION	NORMAL	SYMPTOMATIC HEMOCHROMATOSIS	HOMOZYGOTES WITH EARLY, ASYMPTOMATIC HEMOCHROMATOSIS	HETEROZYGOTES	ALCOHOLIC LIVER DISEASE
Plasma iron, μmol/L (μg/dL)	9–27 (50–150)	32–54 (180–300)	Usually elevated	Elevated or normal	Often elevated
Total iron-binding capacity, μmol/L (μg/dL)	45–66 (250–370)	36–54 (200–300)	36–54 (200–300)	Normal	45–66 (250–370)
Transferrin saturation, %	22–45	50–100	50–100	Normal or elevated	27–60
Serum ferritin, μg/L		1000–6000	200–500	Usually <500	10–500
Men	20–250				
Women	15–150				
Liver iron, μg/g dry wt	300–1400	6000–18,000	2000–4000	300–3000	300–2000
Hepatic iron index	<1.0	>2	1.5–2	<2	<2

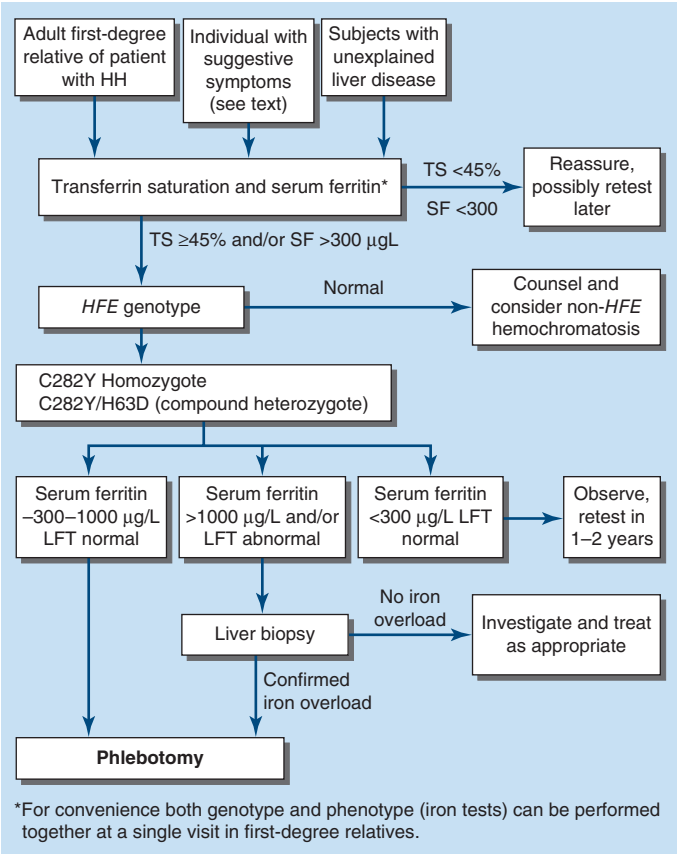

FIGURE 426-3 Algorithm for screening for *HFE*-associated hemochromatosis. HH, hereditary hemochromatosis, homozygous subject (C282Y +/+); LFT, liver function test; SF, serum ferritin concentration; TS, transferrin saturation.

<1000 μg/L, (2) normal serum alanine aminotransferase values, (3) no hepatomegaly, and (4) no excess alcohol intake. However, it should be emphasized that liver biopsy is the most reliable method for establishing or excluding the presence of hepatic cirrhosis, which is the critical factor determining prognosis and the risk of developing hepatocellular carcinoma. Biopsy also permits histochemical estimation of tissue iron and measurement of hepatic iron concentration. Serum tests for liver fibrosis and transient elastography can guide decisions about the need for liver biopsy in affected patients. Increased density of the liver due to iron deposition can be demonstrated by computed tomography (CT) or MRI, and with improved technology, MRI can accurately determine hepatic iron concentration.

SCREENING FOR HEMOCHROMATOSIS

When the diagnosis of hemochromatosis is established, it is important to counsel and screen other family members **(Chap. 480)**. Asymptomatic and symptomatic family members with the disease usually have an increased saturation of transferrin and an increased serum ferritin concentration. These changes occur even before iron stores are greatly increased (Fig. 426-2). All adult first-degree relatives of patients with hemochromatosis should be tested for the C282Y and H63D mutations and counseled appropriately (Fig. 426-3). In affected individuals, it is important to confirm or exclude the presence of cirrhosis and begin therapy as early as possible. For children of an identified proband, testing for *HFE* mutations in the other parent is helpful because if normal, the child is an obligate heterozygote and at no risk. Otherwise, for practical purposes, children need not be checked before they are 18 years old.

The role of population screening for hemochromatosis is controversial. Recent studies indicate that it is highly effective for primary care physicians to screen subjects using transferrin saturation and serum ferritin levels. Such screening also detects iron deficiency. Genetic screening of the normal population is feasible but remains controversial in terms of cost-effectiveness.

TREATMENT

Hemochromatosis

The therapy of hemochromatosis involves removal of the excess body iron and supportive treatment of damaged organs. Iron removal is best accomplished by weekly or, with gross iron loading, twice-weekly phlebotomy of 500 mL. Although there is an initial modest decline in the volume of packed red blood cells to about 35 mL/dL, the level stabilizes after several weeks. The plasma transferrin saturation remains increased until the available iron stores are depleted. In contrast, the plasma ferritin concentration falls progressively, reflecting the gradual decrease in body-iron stores. One 500-mL unit of blood contains 200–250 mg of iron, and ≥25 g of iron may have to be removed. Therefore, in patients with advanced disease, weekly phlebotomy may be required for 1–2 years, and it should be continued until the serum ferritin level is ≤100 μg/L. Thereafter, phlebotomies are performed at appropriate intervals to maintain ferritin levels at ≤100 μg/L. The transferrin saturation fluctuates and may still be elevated but should not dictate further therapy unless it is persistently at 100% when free unbound iron may circulate. Usually, one phlebotomy every 3 months will suffice. It is important, however, not to overtreat and render the patient iron deficient.

Chelating agents such as deferoxamine, when given parenterally, remove 10–20 mg of iron per day, which is much less than that mobilized by once-weekly phlebotomy. Phlebotomy is also less expensive, more convenient, and safer for most patients. However, chelating agents may be indicated when anemia or hypoproteinemia is severe enough to preclude phlebotomy.

Effective oral iron chelating agents, deferasirox (Exjade) and deferiprone, are now available. These agents are effective in thalassemia and secondary iron overload but are expensive and carry the risk of significant side effects.

Alcohol consumption should be severely curtailed or eliminated because it increases the risk of cirrhosis in hereditary hemochromatosis nearly tenfold. Dietary adjustments are unnecessary, although vitamin C and iron supplements should be avoided. The management of hepatic failure, cardiac failure, and diabetes mellitus is similar to conventional therapy for these conditions. Loss of libido and change in secondary sex characteristics are managed with testosterone replacement or gonadotropin therapy **(Chap. 403)**.

End-stage liver disease may be an indication for liver transplantation, although results are improved if the excess iron can be removed beforehand. The available evidence indicates that the fundamental metabolic abnormality in hemochromatosis is reversed by successful liver transplantation.

PROGNOSIS

The principal causes of death are cardiac failure, hepatocellular failure, or portal hypertension and hepatocellular carcinoma.

Life expectancy is improved by removal of excessive iron stores and maintenance of these stores at near-normal levels. The 5-year survival rate with therapy increases from 33 to 89%. With repeated phlebotomy, the liver decreases in size, liver function improves, pigmentation of skin decreases, and cardiac failure may be reversed. Diabetes improves in ~40% of patients, but removal of excess iron has little effect on hypogonadism or arthropathy. Hepatic fibrosis may decrease, and cirrhosis may regress with adequate phlebotomy therapy. Hepatocellular carcinoma occurs as a late sequela in patients who are cirrhotic at presentation. The apparent increase in its incidence in treated patients is probably related to their increased life span. Hepatocellular carcinoma rarely develops if the disease is treated in the precirrhotic stage. Indeed, the life expectancy of homozygotes treated before the development of cirrhosis is normal.

The importance of family screening and early diagnosis and treatment cannot be overemphasized. Asymptomatic individuals detected by family studies should have phlebotomy therapy if iron stores are moderately to severely increased. Assessment of iron stores at appropriate intervals is also important. With this management approach, most manifestations of the disease can be prevented.

ROLE OF *HFE* MUTATIONS IN OTHER LIVER DISEASES

There is considerable interest in the role of *HFE* mutations and hepatic iron in several other liver diseases. Several studies have shown an increased prevalence of *HFE* mutations in PCT patients. Iron accentuates the inherited enzyme deficiency in PCT and clinical manifestations of PCT. The situation in metabolic dysfunction–associated steatohepatitis is less clear, but some studies have shown an increased prevalence of *HFE* mutations. Available evidence does not support a role for phlebotomy therapy unless there is a proven increase in hepatic iron stores.

HFE mutations are not increased in frequency in alcoholic liver disease. However, alcohol does reduce hepcidin expression, which accounts for increased iron absorption and hepatic iron sometimes seen in alcoholic liver disease. Hemochromatosis in a heavy drinker can be distinguished from alcoholic liver disease by the presence of the C282Y mutation.

End-stage liver disease may also be associated with iron overload of the degree seen in hemochromatosis. The mechanism is uncertain, although studies have shown reduced hepcidin and intestinal iron transporter expression. Hemolysis also plays a role. *HFE* mutations are uncommon.

GLOBAL CONSIDERATIONS

The *HFE* mutation is of northern European origin (Celtic or Nordic) with a heterozygous carrier rate of ~1 in 10 (1 in 8 in Ireland). Thus, *HFE*-associated hemochromatosis is quite rare in non-European populations, e.g., Asia. However, non-*HFE*-associated hemochromatosis resulting from mutations in other genes involved in iron metabolism (Fig. 426-1) is ubiquitous and should be considered when one encounters iron overload.

African iron overload occurs primarily in sub-Saharan Africa and was previously thought to be due to the consumption of an iron-rich fermented maize beverage. However, recent evidence suggests that it is primarily the result of a non-*HFE*-related genetic trait that is exacerbated by dietary iron loading. A similar form of iron overload has been described in African Americans.

Acknowledgment

The authors extend their gratitude to the late Professor Lawrie W. Powell and recognize his outstanding contributions to previous versions of this chapter.

427 Wilson's Disease

Stephen G. Kaler

Wilson's disease is an autosomal recessive inherited disorder of copper transport that primarily impacts the liver and brain. This reflects the critical need for homeostatic mechanisms to properly utilize this trace metal, both systemically and in the central nervous system. Since the initial detailed clinical description in 1912, Wilson's disease has emerged as arguably one of the best-characterized and most effectively managed human inborn errors of metabolism. The condition results from variants in *ATP7B*, a highly evolutionarily conserved P-type ion-motive ATPase that normally mediates copper removal from the liver via biliary excretion and prevents brain copper accumulation. Prompt diagnosis in the presymptomatic or early symptomatic phase of the illness and lifelong treatment are needed to prevent premature mortality in affected individuals.

HISTORY OF WILSON'S DISEASE

Wilson's disease (hepatolenticular degeneration) was first described in 1912 by neurologist S.A.K. Wilson, who recognized the heritable aspect of the condition. In 1948, the pathologist J.N. Cumings proposed an etiologic connection with copper overload. Several years later, a metal chelator developed to counteract an arsenic-based chemical warfare agent (lewisite) was used to successfully treat advanced Wilson's disease. In 1956, copper chelation by D-penicillamine was introduced and found preferable to anti-lewisite with respect to route of administration and side effect profile. In the early 1970s, an alternative copper chelator, triethylene tetramine, became the second U.S. Food and Drug Administration (FDA)–approved treatment for Wilson's disease. Also in the early 1970s, the first liver transplants were performed for Wilson's disease, with resultant correction of both hepatic failure and crippling neurologic impairments in patients unresponsive to medical therapies. The treatment potential of zinc salts to reduce gastrointestinal copper absorption in Wilson's disease was recognized in the early 1960s, eventually leading to FDA approval for this indication. Tetrathiomolybdate, which forms a tripartite complex with copper and albumin, and a bacterial peptide, methanobactin, which traverses mitochondrial membranes, are more recently proposed copper chelators with potential for treatment of Wilson's disease.

In 1993, the gene for Wilson's disease was identified and found to encode a copper-transporting ATPase, ATP7B, expressed primarily in liver and kidney. In addition to providing a molecular basis for diagnosis and genotype-phenotype correlations, the finding presents current opportunities for viral gene therapy that could impact future management of this illness.

PHENOTYPES

CLINICAL

Presenting clinical features of Wilson's disease include nonspecific liver disease, neurologic abnormalities, psychiatric illness, hemolytic anemia, renal tubular Fanconi syndrome, and various skeletal abnormalities. Age influences the specific presentation in Wilson's disease. Nearly all individuals who present with liver disease are <30 years of age, whereas those presenting with neurologic or psychiatric signs may range in age from the first to the fifth decade. This reflects the sequence of events in the pathogenesis of the illness. However, regardless of clinical presentation, some degree of liver disease is invariably present.

Hepatic Presentation With hepatic presentations, signs and symptoms include jaundice, hepatomegaly, edema, or ascites. Viral hepatitis and cirrhosis are often initial diagnostic considerations in individuals who, in fact, have Wilson's disease.

Neurologic Presentation In patients with neurologic presentations, abnormalities include distinctive speech difficulties (dysarthria), dystonia, rigidity, tremor (e.g., wing-beating) or choreiform movements, abnormal gait, and uncoordinated handwriting. Wilson's disease can properly be classified as a movement disorder. The neurologic signs and symptoms reflect the predilection for basal ganglia (e.g., caudate, putamen) involvement in the brains of affected persons. Wilson's disease may be mistakenly diagnosed as Parkinson disease or other movement disorders.

Psychiatric Presentation In psychiatric presentations, changes in personality (irritability, anger, poor self-control) or school performance, depression, and anxiety are common symptoms. Typically, patients presenting in this fashion are in their late teens or early

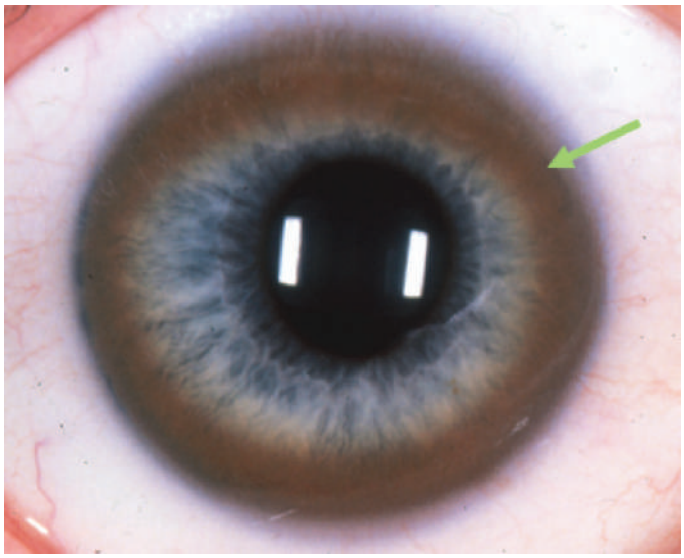

FIGURE 427-1 Kayser-Fleischer ring in Wilson's disease, representing copper deposition in Descemet membrane of the cornea. *(Image courtesy of Tjaard U. Hoogenraad MD, PhD, Department of Neurology, University Medical Centre Utrecht, Utrecht, The Netherlands.)*

twenties, a period during which substance abuse is also a diagnostic consideration. Wilson's disease should be formally excluded in all teenagers and young adults with new-onset psychiatric signs.

Ocular Manifestations The eye is a primary site of copper deposition in Wilson's disease, producing a pathognomonic sign, the Kayser-Fleischer ring (Fig. 427-1), a golden to greenish-brown band in the peripheral cornea. This important diagnostic sign first appears as a superior crescent, then develops inferiorly, and ultimately becomes circumferential. Slit-lamp or optical coherent tomography examinations are required to detect rings in their early stage of formation. Copper can also accumulate in the lens and produce "sunflower" cataracts. Approximately 95% of Wilson's disease patients with neurologic signs manifest the Kayser-Fleischer ring compared to two-thirds of those with hepatic presentations. Copper chelation therapy causes fading and eventual disappearance of corneal copper.

Other Clinical Manifestations Secondary endocrine effects of Wilson-associated liver disease may include delayed puberty or amenorrhea. Renal tubular dysfunction in Wilson's disease leads to abnormal losses of amino acids, electrolytes, calcium, phosphorus, and glucose. Presumably, this effect is related to renal copper toxicity; high copper levels have been noted previously in the kidneys of patients with Wilson's disease. Treatment with copper chelation often improves the renal disturbances. There also can be skeletal effects of Wilson's disease, including osteoporosis and rickets, which may be attributable to renal losses of calcium and phosphorus. Osteoarthritis, primarily affecting the knees and wrists, may involve excess copper deposition in the bone and cartilage.

Hemolytic anemia due to the direct toxic effects of copper on red blood cell membranes is usually associated with release of massive quantities of hepatic copper into the circulation, a phenomenon that can be sudden and catastrophic.

BIOCHEMICAL

Laboratory findings that support the diagnosis of Wilson's disease include low levels of serum copper and serum ceruloplasmin, elevated hepatic transaminase levels, aminoaciduria, and hemolytic anemia. Incorporation of radiolabeled ^{64}Cu into serum ceruloplasmin, measured as the appearance of copper in the serum after an oral load, is a highly specific diagnostic test; patients with Wilson's disease incorporate very little ^{64}Cu into ceruloplasmin.

Increased urinary excretion of copper (>100 μg/24 h) is an easily performed and important diagnostic test for Wilson's disease. Acid-washed (copper-free) collection containers should be used. The penicillamine challenge is a variation using serial urine copper measurements in which 500 mg of penicillamine are administered orally after collecting a baseline 24-h urine. The penicillamine dose is repeated after 12 h, the midpoint of the second 24-h urine collection. A several-fold increase in copper excretion in the second collection suggests the diagnosis.

Although invasive, percutaneous needle liver biopsy for measurement of hepatic copper remains a gold standard technique for biochemical diagnosis of Wilson's disease. Hepatic copper values >200 μg per gram of dry weight (normal 20–50 μg) are characteristic of Wilson's disease. Inductively coupled plasma mass spectrometry and atomic absorption spectrometry are preferred quantitative methods; histochemical staining for copper in liver biopsy specimens is considered less reliable.

MOLECULAR

Wilson's disease is caused by loss-of-function variants in *ATP7B*. Despite similar genomic structures, large deletions are much less common in *ATP7B* than in *ATP7A*, the closely related X-linked gene responsible for Menkes disease. Several *ATP7B* missense variants are common (H1069Q, M645R, and R778L), with various allelic frequencies reflecting geographic, racial, and/or ethnic differences. Major *ATP7B* databases list >650 pathogenic or likely pathogenic variants. Population-based and genomic-based estimates of prevalence range from 1 in 7000 to 1 in 30,000, with genome-based ascertainments supporting the higher prevalence. This disparity may reflect incomplete penetrance, although there is little doubt that some affected individuals unfortunately escape medical attention. Advances in the application of whole genome sequencing (and/or measurement of ATP7B peptides) from newborn dried blood spots may transform presymptomatic diagnostic screening for Wilson disease in the future.

DIAGNOSIS

Currently, a formal diagnosis of Wilson's disease relies on a combination of clinical, biochemical, and molecular features (Table 427-1). A scoring system (Leipzig) that weights and collates various signs and symptoms was produced by an international expert group in 2001 and remains a valuable guide to diagnosis that is endorsed by the European Association for the Study of the Liver (EASL).

TABLE 427-1 Main Diagnostic Features of Wilson's Disease

CLINICAL SIGNS AND SYMPTOMS	BIOCHEMICAL FINDINGS	MOLECULAR FINDINGS
Hepatic: Jaundice Anorexia Vomiting Ascites and/or edema Splenomegaly Neurologic: Dysarthria Facial grimace (risus sardonicus) Drooling Dysphagia Dysgraphia Dystonia Tremor ("wing-beating") Ataxia Seizures (rare) Ocular: Kayser-Fleischer ring Sunflower cataract (rare) Psychiatric: Decline in school performance Personality change Mood disorder Schizophrenia	Low serum copper Low serum ceruloplasmin Increased urinary copper excretion Elevated liver enzymes Hypoalbuminemia Increased liver copper Fatty liver Cirrhotic liver Hemolytic anemia Renal Fanconi syndrome	Variants in *ATP7B* on both chromosomes Variants or polymorphisms in other genes (e.g., *CAT, SOD2, MTHFR*) may influence clinical expression of Wilson's disease in some individuals

TREATMENT

Wilson's Disease

COPPER CHELATION

The era of successful treatment of Wilson's disease began with the use of British anti-lewisite (BAL) by a defined regimen of intramuscular injections. An orally administered alternative was D-penicillamine (Cuprimine), a free thiol that binds copper. This chelating drug does not formally correct the basic defect of impaired copper excretion in the bile. However, it greatly enhances urinary excretion of copper and thereby corrects and prevents copper overload and its effects. Pyridoxine (vitamin B_6) is usually prescribed concomitantly to counter the tendency for deficiency of this vitamin to develop during chronic penicillamine administration.

Certain individuals are intolerant of penicillamine, however, encountering significant side effects that include nephrotoxicity, hematologic abnormalities, and a distinctive rash, *elastosis perforans serpiginosa* (usually involving the neck and axillae). Furthermore, in some Wilson's disease patients with neurologic presentations, penicillamine treatment induces paradoxical worsening of neurologic status. Triethylenetetramine dihydrochloride (trientine hydrochloride [Syprine]) is a suitable alternative chelating agent with a somewhat better side effect profile.

Tetrathiomolybdate (TM) is another molecule in the Wilson's disease therapeutic armamentarium. TM forms stable tripartite complexes among albumin, copper, and itself. This drug functions both to decrease copper absorption and to reduce circulating free copper. It is fast-acting and can restore normal copper balance within several weeks compared to the several months required with other copper chelators or with zinc.

Copper Chelation Treatment During Pregnancy The rate of spontaneous miscarriage is increased in pregnant women with untreated Wilson's disease. From a benefit/risk perspective, it is important to maintain copper chelation treatment during pregnancy to prevent hepatic or neurologic relapse, as well as to lower risk of pregnancy loss. Some academic centers favor reduction of copper chelator dose during pregnancy, although if zinc monotherapy (see below) is in place at the time of conception, evidence suggests it is safe to maintain the usual daily dose. Since all anticopper medications enter breast milk, breastfeeding is not recommended for mothers with Wilson's disease.

REDUCTION OF COPPER ABSORPTION

Zinc acetate (Galzin) has proven highly effective for treatment of Wilson's disease. The mechanism involves induction of metallothionein synthesis in intestinal epithelial cells; increased metallothionein synthesis results in greater binding of dietary copper and thus decreased absorption. Zinc therapy has particular value in (1) young, presymptomatic patients; (2) patients who are pregnant given the possible fetal teratogenic effects of other compounds; and (3) as maintenance therapy for patients after their initial "de-coppering" is accomplished. Zinc acetate has minimal side effects. The sole drawback is the relatively long time (4–6 months) needed for restoration of proper copper balance when used as monotherapy in the initial stages of treatment.

LIVER TRANSPLANTATION

Liver transplantation is a consideration for Wilson's disease in advanced stages and/or when the condition is unresponsive to medical therapy. This is generally necessary only in cases where delayed diagnosis or poor medication compliance results in irreversible hepatic damage. A recently proposed alternative for this circumstance is methanobactin, a bacterial peptide that binds copper avidly and dramatically improves mitochondrial copper overload and restores normal mitochondrial morphology in a preclinical (rat) model of advanced Wilson's disease.

GENE THERAPY

In a preclinical (mouse) model of Wilson's disease, adeno-associated virus-mediated *ATP7B* introduction into hepatocytes was shown to be effective. Transduction of only 20% of hepatocytes was sufficient to normalize copper homeostasis in the animal model. Those results potentially pave the way for viral gene therapy in Wilson's disease patients, and clinical trials to evaluate this approach are underway.

FUTURE OUTLOOK

Wilson's disease is arguably one of the best-characterized human inborn errors of metabolism from combined clinical, biochemical, and molecular perspectives, related to the detailed attention devoted to this condition. As noted, novel copper chelators are still being evaluated, and generic formulations of established drugs are contributing to increased affordability for patients and their families. Viral gene therapy to provide working versions of *ATP7B* to the liver, kidney, and brain or that delivers gene-editing molecules to correct specific mutant alleles is now an emerging prospect. In addition, advances in newborn screening technology may eventually enable wider population-based screening for Wilson's disease, which would help address lingering questions about clinical penetrance. Such future progress in newborn screening would also avert the tragedy that missed diagnoses of this eminently treatable disorder of copper transport represent.

428 The Porphyrias

Robert J. Desnick, Manisha Balwani

The porphyrias are metabolic disorders, each resulting from the deficiency or increased activity of a specific enzyme in the heme biosynthetic pathway **(Fig. 428-1 and Table 428-1)**. These enzyme disorders are inherited as autosomal dominant, autosomal recessive, or X-linked traits, with the exception of porphyria cutanea tarda (PCT), which is usually sporadic (Table 428-1). The porphyrias are classified as either *hepatic* or *erythropoietic*, depending on the primary site of overproduction and accumulation of their respective porphyrin precursors or porphyrins **(Tables** 428-1 and **428-2)**, although some have overlapping features. For example, PCT is hepatic and presents with blistering cutaneous photosensitivity, which is typically characteristic of the erythropoietic porphyrias.

The major manifestations of the acute hepatic porphyrias are neurologic, including neuropathic abdominal pain, peripheral motor neuropathy, and mental disturbances, with attacks often precipitated by dieting, certain porphyrinogenic drugs, and hormonal changes. While hepatic porphyrias are symptomatic primarily in adults, rare homozygous variants of the autosomal dominant hepatic porphyrias

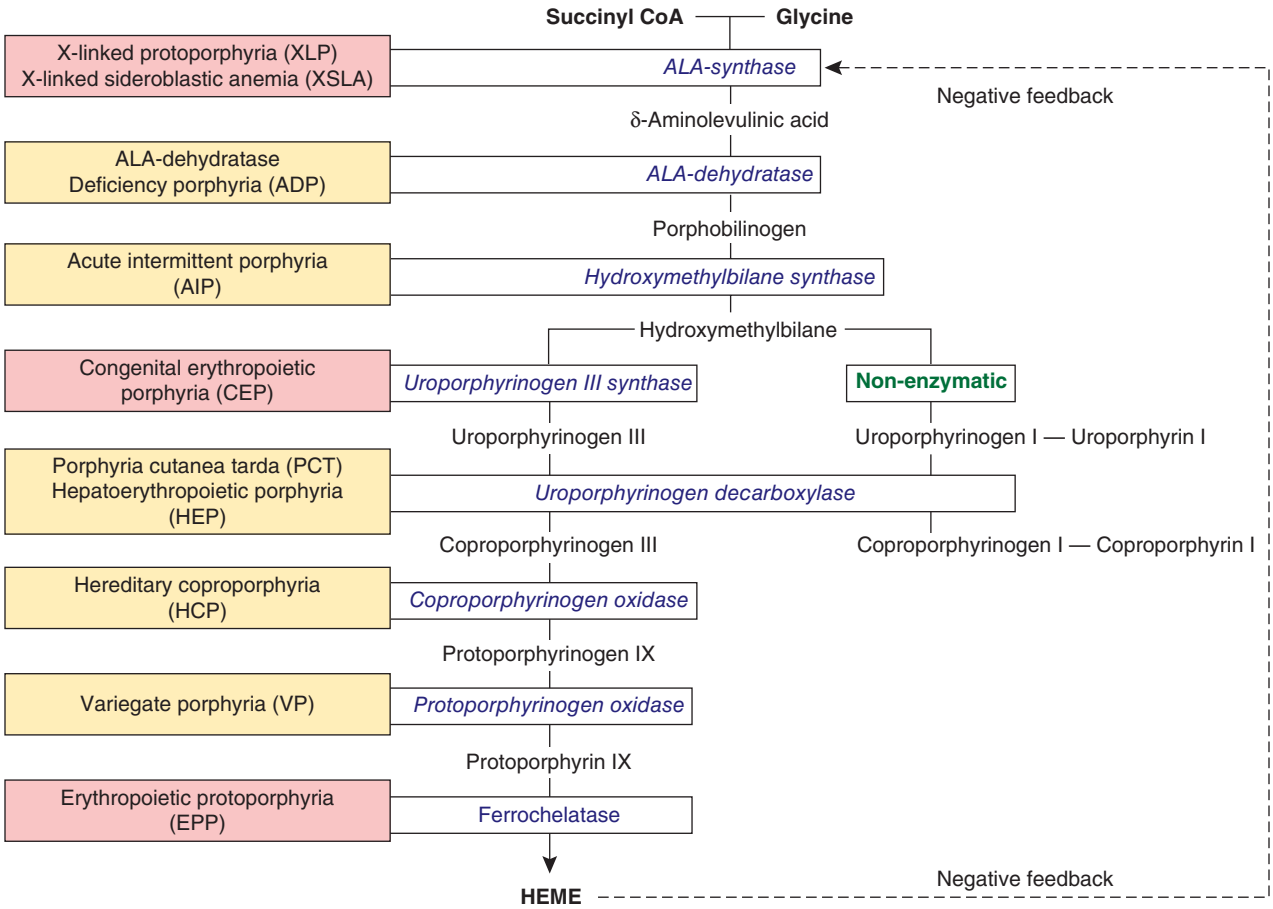

FIGURE 428-1 The human heme biosynthetic pathway indicating in *linked boxes* the enzyme that, when deficient or overexpressed, causes the respective porphyria. Hepatic porphyrias are shown in *yellow boxes* and erythropoietic porphyrias in *pink boxes*.

usually manifest clinically prior to puberty. In contrast, the erythropoietic porphyrias usually present at birth or in early childhood with cutaneous photosensitivity or, in the case of congenital erythropoietic porphyria (CEP), even in utero as nonimmune hydrops fetalis. Cutaneous sensitivity to sunlight results from excitation of excess porphyrins in the skin by long-wave ultraviolet light, leading to cell damage, scarring, and disfigurement. Thus, the porphyrias are metabolic disorders in which environmental, physiologic, and genetic factors interact to cause disease.

Because many symptoms of the porphyrias are nonspecific, diagnosis is often delayed. Laboratory measurement of porphyrin precursors (5′-aminolevulinic acid [ALA] and porphobilinogen [PBG]) in

the urine or porphyrins in the urine, plasma, erythrocytes, or feces is required to confirm or exclude the various types of porphyria (see below). However, a definite diagnosis requires demonstration of the specific gene defect **(Table 428-3)**. The genes encoding all the heme biosynthetic enzymes have been characterized, permitting identification of the mutations causing each porphyria (Table 428-2). Molecular genetic analyses now make it possible to provide precise heterozygote or homozygote identification and prenatal diagnoses in families with known mutations.

In addition to recent reviews of the porphyrias, informative and up-to-date websites are sponsored by the United Porphyrias Association (*www.porphyria.org*) and the European Porphyria Network (*https://porphyria.eu/*). An extensive list of unsafe and safe drugs for individuals with acute porphyrias is provided at the Drug Database for Acute Porphyrias (*www.drugs-porphyria.org*).

GLOBAL CONSIDERATIONS

The porphyrias are panethnic metabolic diseases that affect individuals globally. The acute hepatic porphyrias—acute intermittent porphyria (AIP), hereditary coproporphyria (HCP), and variegate porphyria (VP)—are autosomal dominant disorders. The frequency of AIP, the most common acute hepatic porphyria, is ~1 in 20,000 among Caucasian individuals of Western European ancestry, and it is particularly frequent in Scandinavians, where the frequency in Sweden is ~1 in 10,000. VP is particularly frequent in South Africa, and its high prevalence (>10,000 affected patients) is in part due to a genetic "founder effect." The autosomal recessive acute hepatic porphyria, ALA-dehydratase-deficient porphyria (ADP), is extremely rare, and <20 patients have been identified worldwide.

The erythropoeitic protoporphyrias—CEP, erythropoietic protoporphyria (EPP), and X-linked protoporphyria (XLP)—also are panethnic. EPP is likely the most common porphyria, while CEP is very rare with about 200 reported cases worldwide. The frequency of EPP varies globally since most patients have the common low expression *FECH* allele, which ranges in frequency in different populations. This allele rarely occurs in Africans, is present in ~10% of the Caucasians, and is frequent (~30%) in the Japanese.

The autosomal recessive porphyrias, ADP, CEP, EPP, and hepatoerythropoietic porphyria (HEP), are more frequent in regions with high rates of consanguineous marriages. PCT, which is typically sporadic, occurs more frequently in countries in which its predisposing risk factors such as hepatitis C and HIV are more prevalent. The reported prevalence of EPP in the Caucasian population ranges from 1 in ~75,000 to 1 in ~150,000.

HEME BIOSYNTHESIS

Heme biosynthesis involves eight enzymatic steps in the conversion of glycine and succinyl-CoA to heme (**Fig. 428-2** and Table 428-2). These eight enzymes are encoded by nine genes, as the first enzyme in the pathway, ALA-synthase, has two genes that encode unique housekeeping (*ALAS1*) and erythroid-specific (*ALAS2*) isozymes. The first and last three enzymes in the pathway are located in the mitochondria, whereas the other four are in the cytosol. Heme is required for a variety of hemoproteins such as hemoglobin, myoglobin, respiratory cytochromes, and the cytochrome P450 (CYP) enzymes. Hemoglobin synthesis in erythroid precursor cells accounts for ~85% of daily heme synthesis in humans. Hepatocytes account for most of the rest, primarily for the synthesis of CYPs, which are especially abundant in the liver endoplasmic reticulum, and turn over more rapidly than many other hemoproteins, such as the mitochondrial respiratory cytochromes. As shown in Fig. 428-2, the pathway intermediates are the porphyrin precursors, ALA and PBG, and porphyrins (mostly in their reduced forms, known as *porphyrinogens*). At least in humans, these intermediates do not accumulate in significant amounts under normal conditions or have important physiologic functions.

The first enzyme, ALA-synthase, catalyzes the condensation of glycine, activated by pyridoxal phosphate and succinyl-coenzyme A, to form ALA. In the liver, this rate-limiting enzyme can be induced by a variety of drugs, steroids, and other chemicals. Distinct nonerythroid (e.g., housekeeping) and erythroid-specific forms of ALA-synthase are encoded by separate genes located on chromosome 3p21.1 (*ALAS1*) and Xp11.2 (*ALAS2*), respectively. Defects in the erythroid gene *ALAS2* that decrease its activity cause an X-linked sideroblastic anemia (XLSA). Gain-of-function mutations in the last exon (11) of *ALAS2* that increase its activity cause an X-linked form of EPP, known as XLP.

The second enzyme, ALA-dehydratase, catalyzes the condensation of two molecules of ALA to form PBG. Hydroxymethylbilane synthase (HMB-synthase; also known as PBG-deaminase) catalyzes

the head-to-tail condensation of four PBG molecules by a series of deaminations to form the linear tetrapyrrole, HMB. Uroporphyrinogen III synthase (URO-synthase) catalyzes the rearrangement and rapid cyclization of HMB to form the asymmetric, physiologic, octacarboxylate porphyrinogen, uroporphyrinogen (URO'gen) III.

The fifth enzyme in the pathway, uroporphyrinogen decarboxylase (URO-decarboxylase), catalyzes the sequential removal of the four carboxyl groups from the acetic acid side chains of URO'gen III to form coproporphyrinogen (COPRO'gen) III, a tetracarboxylate porphyrinogen. This compound then enters the mitochondrion via a specific transporter, where COPRO-oxidase, the sixth enzyme, catalyzes the decarboxylation of two of the four propionic acid groups to form the two vinyl groups of protoporphyrinogen (PROTO'gen) IX, a decarboxylate porphyrinogen. Next, PROTO-oxidase oxidizes PROTO'gen to protoporphyrin IX by the removal of six hydrogen atoms. The product of the reaction is a porphyrin (oxidized form), in contrast to the preceding tetrapyrrole intermediates, which are porphyrinogens (reduced forms). Finally, ferrous iron is inserted into protoporphyrin IX to form heme, a reaction catalyzed by the eighth enzyme in the pathway, FECH (also known as heme synthase or protoheme ferrolyase).

REGULATION OF HEME BIOSYNTHESIS

Regulation of heme synthesis differs in the two major heme-forming tissues, the liver and erythron. In the liver, the concentration of "free" heme regulates the synthesis and mitochondrial translocation of the housekeeping form of ALA-synthase 1. Heme represses the synthesis of the ALA-synthase 1 messenger RNA (mRNA) and interferes with the transport of the enzyme from the cytosol into mitochondria. Hepatic ALA-synthase 1 is increased by many of the same chemicals that induce the CYP enzymes in the endoplasmic reticulum of the liver. Because most of the heme in the liver is used for the synthesis of CYP enzymes, hepatic ALA-synthase 1 and the CYPs are regulated in a coordinated fashion, and many drugs that induce hepatic ALA-synthase 1 also induce CYP gene expression. The other hepatic heme biosynthetic enzymes are presumably expressed at constant levels, although their relative activities and kinetic properties differ. For example, normal individuals have high activities of ALA-dehydratase but low activities of HMB-synthase, the latter being the second rate-limiting step in the pathway.

In the erythron, novel regulatory mechanisms allow for the production of the very large amounts of heme needed for hemoglobin synthesis. The response to stimuli for hemoglobin synthesis occurs during cell differentiation, leading to an increase in cell number. In contrast, the erythroid-specific ALA-synthase 2 is expressed at higher levels than the housekeeping enzyme, and erythroid-specific control mechanisms regulate other pathway enzymes as well as iron transport into erythroid cells. Separate erythroid-specific and nonerythroid or "housekeeping" transcripts are known for the first four enzymes in the pathway. As noted above, housekeeping- and erythroid-specific ALA-synthases are encoded by genes on different chromosomes, but for each of the

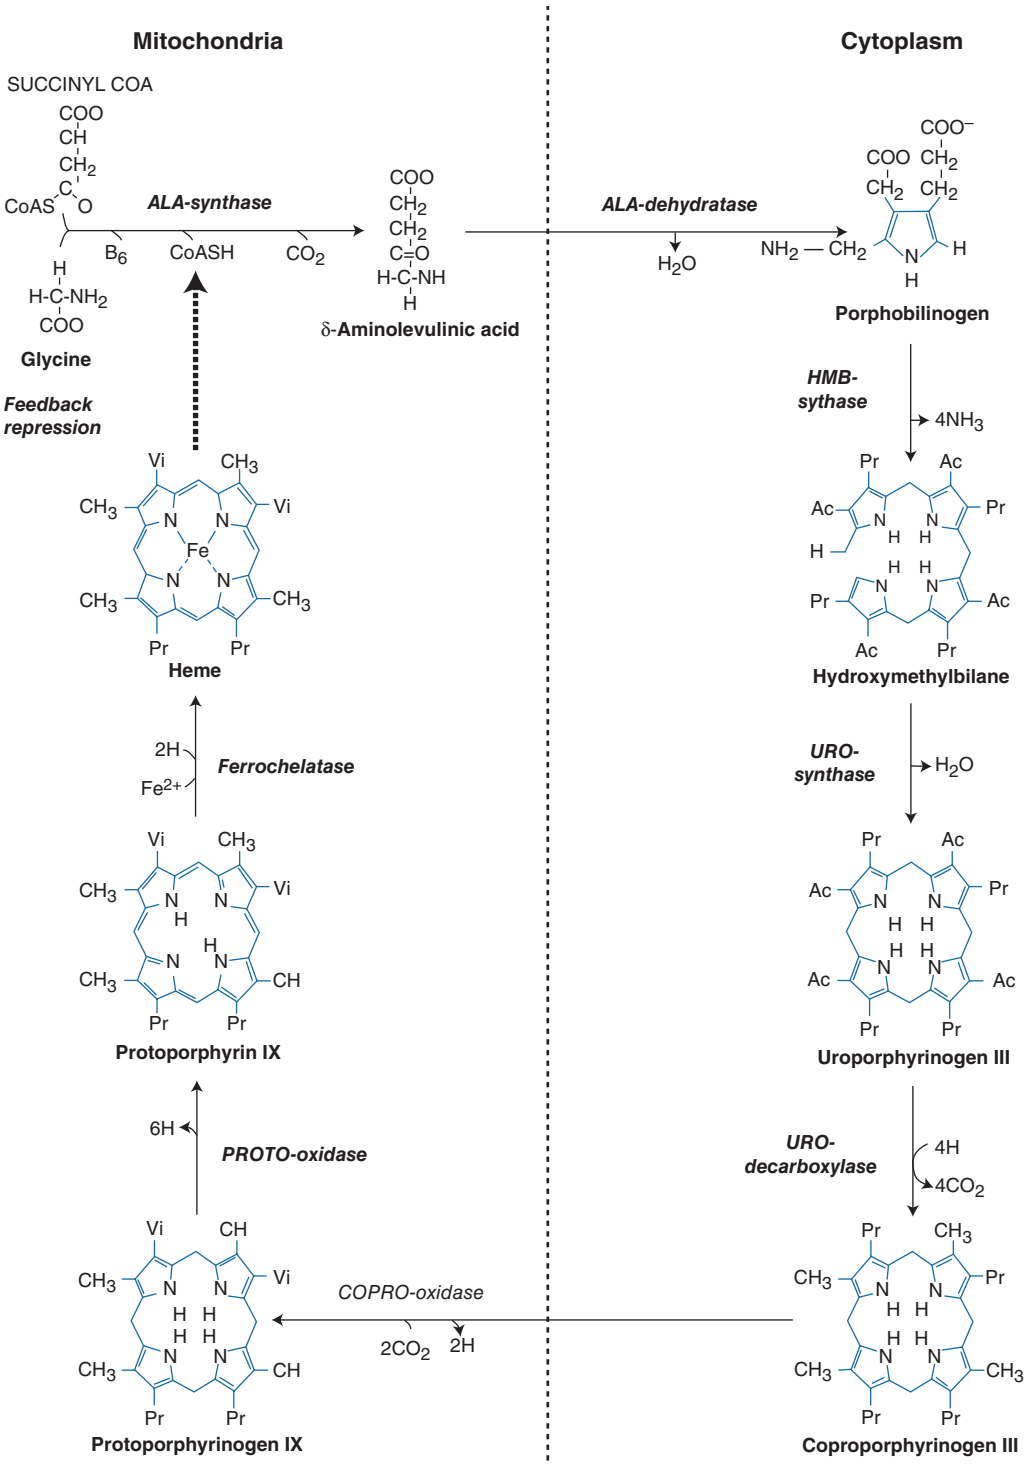

FIGURE 428-2 The heme biosynthetic pathway showing the eight enzymes and their substrates and products. Four of the enzymes are localized in the mitochondria and four in the cytosol.

next three genes in the pathway, both erythroid and nonerythroid transcripts are transcribed by alternative promoters from their single respective genes (Table 428-2).

CLASSIFICATION OF THE PORPHYRIAS

As mentioned above, the porphyrias can be classified as either *hepatic* or *erythropoietic*, depending on whether the heme biosynthetic intermediates that accumulate arise initially from the liver or developing erythrocytes, or as *acute* or *cutaneous*, based on their clinical manifestations. Table 428-1 lists the porphyrias, their principal symptoms, and major biochemical abnormalities. Three of the five hepatic porphyrias—AIP, HCP, and VP—usually present during adult life with acute attacks of neurologic manifestations and elevated levels of one or both of the porphyrin precursors, ALA and PBG, and are thus classified as *acute hepatic porphyrias*. Patients with ADP have presented in infancy and adolescence and typically have elevated ALA with normal or slightly elevated PBG levels. The fifth hepatic disorder, PCT, presents with blistering skin lesions. HCP and VP also may have cutaneous manifestations similar to PCT.

The erythropoietic porphyrias—CEP, EPP, and XLP—are characterized by elevations of porphyrins in bone marrow and erythrocytes and present with cutaneous photosensitivity. The skin lesions in CEP resemble PCT but are usually much more severe, whereas EPP and XLP cause a more immediate, severe, painful, and nonblistering type of photosensitivity. EPP is the most common porphyria to cause symptoms before puberty. About 20% of EPP patients develop minor

abnormalities of liver function, with up to ~5% developing hepatic complications that can lead to liver failure requiring liver transplantation. XLP has a clinical presentation similar to EPP causing photosensitivity and liver disease.

DIAGNOSIS OF PORPHYRIA

A few specific and sensitive first-line laboratory tests should be used whenever symptoms or signs suggest the diagnosis of porphyria (Table 428-3). If a first-line test is significantly abnormal, more comprehensive testing should follow to establish the type of porphyria, including the specific causative gene mutation.

Acute Hepatic Porphyrias An acute hepatic porphyria should be suspected in patients with neurovisceral symptoms after puberty. Symptoms include acute abdominal pain, nausea, vomiting, tachycardia, hypertension, and motor neuropathy. As these symptoms are common, other causes should be ruled out. The diagnosis is made by measuring urinary porphyrin precursors (ALA and PBG) in a spot sample of urine (Fig. 428-2). Urinary PBG is always increased during acute attacks of AIP, HCP, and VP and is not substantially increased in any other medical condition. Therefore, this measurement is both sensitive and specific. Results from spot (single-void) urine specimens are highly informative because very substantial increases in PBG are expected during acute attacks of porphyria. A 24-h collection is unnecessary. The same spot urine specimen should be saved for quantitative determination of ALA, PBG, and creatinine, in order to confirm the qualitative PBG result and also to detect patients with ADP. Urinary porphyrins may remain increased longer than porphyrin precursors in HCP and VP. Therefore, it is useful to measure total urinary porphyrins in the same sample, keeping in mind that urinary porphyrin increases are often nonspecific. Measurement of urinary porphyrins alone should be avoided for screening, because these may be increased in disorders other than porphyrias, such as chronic liver disease, and misdiagnoses of porphyria can result from minimal increases in urinary porphyrins that have no diagnostic significance. Measurement of erythrocyte HMB-synthase is not useful as a first-line test. Moreover, the enzyme activity is not decreased in all AIP patients, a borderline low normal value is not diagnostic, and the enzyme is not deficient in other acute porphyrias.

More extensive testing is justified when an initial test is positive. A substantial increase in PBG may be due to AIP, HCP, or VP. These acute porphyrias can be distinguished by measuring urinary porphyrins (using the same spot urine sample), fecal porphyrins, and plasma porphyrins. Assays for COPRO-oxidase or PROTO-oxidase are not available for clinical testing. More specifically, mutation analysis by sequencing the genes encoding HMB-synthase, COPRO-oxidase, and PROTO-oxidase will detect almost all disease-causing mutations and is diagnostic even when the levels of urinary ALA and PBG have returned to normal or near normal.

Cutaneous Porphyrias Blistering skin lesions due to porphyria are virtually always accompanied by increases in total plasma porphyrins. A fluorometric method is preferred, because the plasma porphyrins in VP are mostly covalently linked to plasma proteins and may be less readily detected by high-performance liquid chromatography (HPLC). The normal range for plasma porphyrins is somewhat increased in patients with end-stage renal disease.

Although a total plasma porphyrin determination will usually detect EPP and XLP, an erythrocyte protoporphyrin determination is more sensitive. Increases in erythrocyte protoporphyrin occur in many other conditions. Therefore, the diagnosis of EPP must be confirmed by showing a predominant increase in free protoporphyrin rather than zinc protoporphyrin. In XLP, both free and zinc protoporphyrin are markedly increased. Interpretation of laboratory reports can be difficult, because the term *free erythrocyte protoporphyrin* sometimes actually represents zinc protoporphyrin.

The various porphyrias that cause blistering skin lesions can be differentiated by measuring porphyrins in urine, feces, and plasma. The porphyrias should be confirmed by genetic testing and the demonstration of the causative pathogenic variant. It is often difficult to diagnose or "rule out" porphyria in patients who have had suggestive symptoms months or years in the past and in relatives of patients with acute porphyrias, because porphyrin precursors and porphyrins may be normal. In those situations, detection of the specific gene mutation in the index case can make the diagnosis and facilitate the diagnosis and genetic counseling of at-risk relatives. With the increased access and accuracy of genetic testing, this often precedes secondary biochemical testing in clinical practice. Consultation with a specialist laboratory and physician will assist in selecting the heme biosynthetic gene or genes to be sequenced.

THE HEPATIC PORPHYRIAS

Markedly elevated plasma and urinary concentrations of the porphyrin precursors, ALA and/or PBG, which originate from the liver, are especially evident during attacks of neurologic manifestations of the four acute porphyrias—ADP, AIP, HCP, and VP. In PCT, excess porphyrins also accumulate initially in the liver and cause chronic blistering of sun-exposed areas of the skin.

ALA-DEHYDRATASE-DEFICIENT PORPHYRIA

ADP is a rare, autosomal recessive, acute hepatic porphyria caused by a severe deficiency of ALA-dehydratase activity. To date, there are only a dozen documented cases, some in children or young adults, in which specific gene mutations have been identified. These affected homozygotes had <10% of normal ALA-dehydratase activity in erythrocytes, but their clinically asymptomatic parents and heterozygous relatives had about half-normal levels of activity and did not excrete increased levels of ALA. The frequency of ADP is unknown, but the frequency of heterozygous individuals with <50% normal ALA-dehydratase activity was ~2% in a screening study in Sweden. Because there are multiple causes for deficient ALA-dehydratase activity, it is important to confirm the diagnosis of ADP by mutation analysis.

Clinical Features The clinical presentation depends on the amount of residual ALA-dehydratase activity. Four of the documented patients were male adolescents with symptoms resembling those of AIP, including abdominal pain and neuropathy. One patient was an infant with more severe disease, including failure to thrive beginning at birth. The earlier age of onset and more severe manifestations in this patient reflect a more significant deficiency of ALA-dehydratase activity. Another patient developed an acute motor polyneuropathy at age 63 that was associated with a myeloproliferative disorder. He was heterozygous for an δ-aminolevulinic acid dehydratase (*ALAD*) mutation that presumably was present in erythroblasts that underwent clonal expansion due to the bone marrow malignancy.

Diagnosis All patients had significantly elevated levels of plasma and urinary ALA and urinary coproporphyrin (COPRO) III; ALAD activities in erythrocytes were <10% of normal. Hereditary tyrosinemia type 1 (fumarylacetoacetase deficiency) and lead intoxication should be considered in the differential diagnosis because either succinylacetone (which accumulates in hereditary tyrosinemia and is structurally similar to ALA) or lead can inhibit ALA-dehydratase, increase urinary excretion of ALA and COPRO III, and cause manifestations that resemble those of the acute porphyrias. Heterozygotes are clinically asymptomatic and do not excrete increased levels of ALA but can be detected by demonstration of intermediate levels of erythrocyte ALA-dehydratase activity or a specific mutation in the *ALAD* gene. To date, molecular studies of ADP patients have identified 12 pathogenic mutations, including missense mutations, splice-site mutations, and a two-base deletion in the *ALAD* gene (Human Gene Mutation Database; *www.hgmd.org*). The parents in each case were not consanguineous, and the index cases had inherited a different *ALAD* mutation from each parent. Prenatal diagnosis of this disorder is possible by determination of ALA-dehydratase activity and/or gene mutations in cultured chorionic villi or amniocytes.

Treatment The treatment of ADP acute attacks is similar to that of AIP (see below). The severely affected infant referred to above was supported by hyperalimentation and periodic blood transfusions but did not respond to intravenous hemin and died after liver transplantation.

ACUTE INTERMITTENT PORPHYRIA

This hepatic porphyria is an autosomal dominant condition resulting from the half-normal level of HMB-synthase activity. The disease is widespread but is especially common in Scandinavia and Great Britain. Clinical expression is highly variable, and activation of the disease is often related to environmental or hormonal factors, such as drugs, diet, and steroid hormones. Attacks can be prevented by avoiding known precipitating factors. Rare homozygous dominant AIP also has been described in children (see below).

Clinical Features Induction and increased expression of the rate-limiting hepatic gene *ALAS1* in heterozygotes who have half-normal HMB-synthase activity is thought to underlie the acute attacks in AIP. The disorder remains latent (or asymptomatic) in the great majority of those who are heterozygous for pathogenic *HMBS* mutations, and this is almost always the case prior to puberty. In patients with no history of acute symptoms, porphyrin precursor excretion is usually normal, suggesting that half-normal hepatic HMB-synthase activity is sufficient and that hepatic ALA-synthase activity is not increased. However, under conditions where heme synthesis is increased in the liver, half-normal HMB-synthase activity may become limiting, and ALA, PBG, and other heme pathway intermediates may accumulate and be excreted in the urine. Common precipitating factors include endogenous and exogenous steroids, porphyrinogenic drugs, alcohol ingestion, and low-calorie diets, usually instituted for weight loss.

The fact that AIP is almost always latent before puberty suggests that adult levels of steroid hormones are important for clinical expression. Symptoms are more common in women, suggesting a role for estrogens or progestins. Premenstrual attacks are probably due to increasing endogenous progesterone during the luteal phase of the menstrual cycle. Acute porphyrias are sometimes exacerbated by exogenous steroids, including oral contraceptive preparations containing progestins. Surprisingly, pregnancy is usually well tolerated, suggesting that beneficial metabolic changes may ameliorate the effects of high levels of progesterone. Extensive lists of unsafe and safe drugs are available on websites sponsored by the United Porphyria Association (*www.porphyria.org*) and the European Porphyria Network (*https://porphyria.eu/*), and at the Drug Database for Acute Porphyrias website (*www.drugs-porphyria.org*). Reduced intake of calories and carbohydrate, as may occur with illness or attempts to lose weight, can also increase porphyrin precursor excretion and induce attacks of porphyria. Studies in a knockout AIP mouse model indicate that the hepatic *ALAS1* gene is regulated, in part, by the peroxisome proliferator-activated receptor γ coactivator 1α (PGC-1α). Hepatic PGC-1α is induced by fasting, which in turn activates *ALAS1* transcription, resulting in increased heme biosynthesis. This finding suggests an important link between nutritional status and the attacks in acute porphyrias. Attacks also can be provoked by infections, surgery, and ethanol.

Because the neurovisceral symptoms rarely occur before puberty and are often nonspecific, a high index of suspicion is required to make the diagnosis. The disease can be disabling but is rarely fatal. Abdominal pain, the most common symptom, is poorly localized but may be associated with cramping, ileus, abdominal distention, and decreased bowel sounds. However, increased bowel sounds and diarrhea may occur. Abdominal tenderness, fever, and leukocytosis are usually absent or mild because the symptoms are neurologic rather than inflammatory. Nausea; vomiting; constipation; tachycardia; hypertension; mental symptoms; pain in the limbs, head, neck, or chest; muscle weakness; sensory loss; dysuria; and urinary retention are characteristic. Tachycardia, hypertension, restlessness, tremors, and excess sweating are due to sympathetic overactivity.

The peripheral neuropathy is due to axonal degeneration (rather than demyelinization) and primarily affects motor neurons. Significant neuropathy does not occur with all acute attacks; abdominal symptoms are usually more prominent. Motor neuropathy affects the proximal muscles initially, more often in the shoulders and arms. The course and degree of involvement are variable and sometimes may be focal and involve cranial nerves. Deep tendon reflexes initially may be normal or hyperactive but become decreased or absent as the neuropathy advances. Sensory changes such as paresthesia and loss of sensation are less prominent. Progression to respiratory and bulbar paralysis and death occurs especially when the diagnosis and treatment are delayed. Sudden death may result from sympathetic overactivity and cardiac arrhythmia.

Mental symptoms such as anxiety, insomnia, depression, disorientation, hallucinations, and paranoia can occur in acute attacks. Seizures can be due to neurologic effects or to hyponatremia. Treatment of seizures is difficult because most antiseizure drugs can exacerbate AIP (clonazepam may be safer than phenytoin or barbiturates). Hyponatremia results from hypothalamic involvement and inappropriate vasopressin secretion or from electrolyte depletion due to vomiting, diarrhea, poor intake, or excess renal sodium loss. When an attack resolves, abdominal pain may disappear within hours, and paresis begins to improve within days and may continue to improve over several years.

Homozygous dominant AIP (HD-AIP) is a rare form of AIP in which patients inherit *HMBS* mutations from each of their heterozygous parents and, therefore, have very low (<2%) enzyme activity. The disease has been described in a Dutch girl, two young British siblings, and a Spanish boy. In these homozygous affected patients, the disease presented in infancy with failure to thrive, developmental delay, bilateral cataracts, and/or hepatosplenomegaly. Urinary ALA and PBG concentrations were markedly elevated. All of these patients' *HMBS* mutations (R167W, R167Q, and R172Q) were in exon 10 within five bases of each other. Studies of the brain magnetic resonance images (MRIs) of children with homozygous AIP have suggested damage primarily in white matter that was myelinated postnatally, while tracks that myelinated prenatally were normal. Most children with homozygous AIP die at an early age. Recently, later-onset HD-AIP was described in an adult with leukoencephalopathy.

Diagnosis ALA and PBG levels are substantially increased in plasma and urine, especially during acute attacks. For example, urinary PBG excretion during an attack is usually 50–200 mg/24 h (220–880 μmol/24 h) (normal, 0–4 mg/24 h [0–18 μmol/24 h]), and urinary ALA excretion is 20–100 mg/24 h (150–760 μmol/24 h) (normal, 1–7 mg/24 h [8–53 μmol/24 h]). Because levels often remain high after symptoms resolve, the diagnosis of an acute attack in a patient with biochemically proven AIP is based primarily on clinical features. Excretion of ALA and PBG decreases over a few days after intravenous hemin administration or in a day after subcutaneous givosiran (see below). A normal urinary PBG level before hemin effectively excludes AIP as a cause for current symptoms. Fecal porphyrins are usually normal or minimally increased in AIP, in contrast to HCP and VP. Most AIP heterozygotes with no history of symptoms have normal urinary excretion of ALA and PBG and are classified as "latent" or "asymptomatic heterozygotes." Patients can also have high levels of urinary PBG and ALA with no clinical symptoms. These patients may have a previous history of an acute attack and are classified as asymptomatic high excretors (ASHE) or chronic high excretors (CHE). Therefore, the detection of the family's *HMBS* mutation will diagnose heterozygous asymptomatic family members. A urinary ALA and PBG will diagnosis CHE patients who may have a higher risk of an attack if they experience a precipitating factor such as administration of a porphyrinogenic drug.

Patients with *HMBS* mutations in the initiation of translation codon in exon 1 and in the intron 15′-splice donor site have normal enzyme levels in erythrocytes and deficient activity only in nonerythroid tissues. This occurs because the erythroid and housekeeping forms of HMB-synthase are encoded by a single gene, which has two promoters. Thus, the enzyme assay may not be diagnostic, and genetic testing should be used to confirm the diagnosis.

More than 550 *HMBS* mutations have been identified in AIP, including missense, nonsense, AND splicing lesions, insertions, and deletions, with most mutations found in only one or a few families (Human Gene Mutation Database, *www.hgmd.org*). The prenatal diagnosis of a fetus at risk can be made by analysis of the familial mutation in cultured amniotic cells or chorionic villi. However, this is seldom done because the prognosis of individuals with *HMBS* mutations is generally favorable.

TREATMENT

Acute Intermittent Porphyria

During acute attacks, narcotic analgesics may be required for abdominal pain, and phenothiazines are useful for nausea, vomiting, anxiety, and restlessness. Chloral hydrate can be given for insomnia, and benzodiazepines are probably safe in low doses if a minor tranquilizer is required. Carbohydrate loading, usually with intravenous glucose (at least 300 g daily), may be effective in milder acute attacks of porphyria (without paresis, hyponatremia, etc.) if hemin or givosiran (see below) is not available. Intravenous hemin was approved by the U.S. Food and Drug Administration (FDA) in 1984 to treat acute attacks and has been used effectively as a first-line therapy for acute attacks. The standard regimen is 3–4 mg/kg per d of heme, in the form of lyophilized hematin (Panhematin, Recordati Rare Diseases), heme albumin (hematin reconstituted with human albumin), or heme arginate (Orphan Europe), infused daily for 4 days or longer to reduce the pain. Heme arginate and heme albumin are chemically stable and are less likely than hematin to produce phlebitis or an anticoagulant effect. Recovery depends on the degree of neuronal damage and usually occurs in days, if therapy is started early. Recovery from severe motor neuropathy may require months or years. Identification and avoidance of inciting factors can hasten recovery from an attack and prevent future attacks. Inciting factors are usually multiple, and removal of one or more hastens recovery and helps prevent future attacks. Frequent attacks that occur during the luteal phase of the menstrual cycle may be prevented with a gonadotropin-releasing hormone analogue, which prevents ovulation and progesterone production, or by prophylactic hematin or givosiran administration.

In 2019, a hepatocyte-targeted RNA interference (RNAi) therapy, givosiran (Givlarri, Alnylam Pharmaceuticals), was approved by the FDA and the European Medicines Agency (EMA) for the treatment of the acute hepatic porphyrias. Givosiran, a monthly subcutaneous injection of 2.5 mg/kg, is designed to silence the expression of hepatic *ALAS1* mRNA and was initially shown in clinical trials to markedly reduce ALA and PBG levels in CHE patients and in patients with recurrent attacks. In a phase 3 trial in acute hepatic porphyria patients with recurrent attacks, the RNAi therapy significantly reduced the frequency of acute attacks, decreased hemin utilization, and improved daily pain scores.

The long-term risk of hypertension and chronic renal disease is increased in AIP; a number of patients have undergone successful renal transplantation. Studies have shown that up to 59% of symptomatic AIP patients will develop chronic kidney disease. The PEPT2 receptor polymorphic genotype affects the severity and prognosis of porphyria-associated kidney disease with the high affinity polymorphic PEPT2 *1 allele and the PEPT2 genotypes *1*1 and, to a lesser degree, *1*2 associated with decreasing kidney function. Chronic, low-grade abnormalities in liver function tests are common, and the risk of hepatocellular carcinoma is increased. Hepatic imaging is recommended at least every 6 months for early detection of these tumors. Other long-term complications include neuropathy, fatigue, chronic pain, nausea, depression, and/or anxiety.

Orthotopic liver transplantation (OLT) has been effective in patients with severe, disabling, intractable attacks that are refractory to hemin therapy. Reports from both the United Kingdom and the United States show a marked improvement with no subsequent attacks, an improvement in the neuropathic manifestations, and normalization of the urinary PBG and ALA levels after liver transplantation. OLT is associated with morbidity and mortality and should be considered a treatment of last resort in these patients. In addition, patients who already have advanced neuropathy are considered poor risks for transplantation. Of note, the effectiveness of givosiran in such patients has not been described. Some patients with both recurrent attacks and end-stage renal disease have benefitted from combined liver and kidney transplantation.

Liver-directed gene therapy has proven successful in the prevention of drug-induced biochemical attacks in a murine model of human AIP, and clinical trials of adeno-associated virus vector (AAV)-*HMBS* gene transfer were carried out over a decade ago. Although the therapy was safe, there was essentially no biochemical evidence of its effectiveness, nor did it prevent recurrent attacks in the treated patients. Recent advances have led to FDA-approved gene-editing/gene therapies for genetic disorders and may lead to future treatments and/or cures for the acute hepatic and erythropoietic porphyrias.

PORPHYRIA CUTANEA TARDA

PCT, the most common of the porphyrias, can be either sporadic (type 1) or familial (type 2) and can also develop after exposure to halogenated aromatic hydrocarbons. Hepatic URO-decarboxylase is deficient in all types of PCT, and for clinical symptoms to manifest, this enzyme deficiency must be substantial (~20% of normal activity or less). Its deficiency is currently attributed to generation of an URO-decarboxylase inhibitor in the liver, which forms a uroporphomethene in the presence of iron and under conditions of oxidative stress. The majority of PCT patients (~80%) have no *UROD* mutations and are said to have sporadic (type 1) disease. PCT patients heterozygous for *UROD* mutations have the familial (type 2) PCT. In these patients, inheritance of a *UROD* mutation from one parent results in half-normal enzymatic activity in liver and all other tissues, which is a significant predisposing factor, but is insufficient by itself to cause symptomatic PCT. As discussed below, other genetic and environmental factors contribute to susceptibility for both types of PCT. Because penetrance of the genetic trait is low, many patients with familial (type 2) PCT have no family history of the disease. HEP is an autosomal recessive form of porphyria due to the inheritance of two pathogenic *UROD* mutations resulting in the marked systemic deficiency of URO-decarboxylase activity with clinical symptoms in childhood.

Clinical Features Blistering skin lesions that appear most commonly on the backs of the hands are the major clinical feature (Fig. 428-3). These rupture and crust over, leaving areas of atrophy and scarring. Lesions may also occur on the forearms, face, legs, and feet. Skin friability and small white papules termed milia are common, especially on the backs of the hands and fingers. Hypertrichosis and hyperpigmentation, especially of the face, are especially troublesome in women. Occasionally, the skin over sun-exposed areas becomes severely thickened, with scarring and calcification that resembles systemic sclerosis. Neurologic features are absent.

A number of susceptibility factors, in addition to inherited *UROD* mutations in type 2 PCT, are recognized clinically and can affect management. These include hepatitis C, HIV, excess alcohol, elevated

FIGURE 428-3 Typical cutaneous lesions in a patient with porphyria cutanea tarda. Chronic, crusted lesions resulting from blistering due to photosensitivity on the dorsum of the hand of a patient with porphyria cutanea tarda. *(Used with permission from Dr. Karl E. Anderson.)*

iron levels, and estrogens. The importance of excess hepatic iron as a precipitating factor is underscored by the finding that the incidence of the common hemochromatosis-causing mutations, hemochromatosis gene (*HFE*) mutations p.C282Y and p.H63D, are increased in patients with types 1 and 2 PCT **(Chap. 426)**. Excess alcohol is a long-recognized contributor, as is estrogen use in women. HIV is probably an independent but less common risk factor that, like hepatitis C, does not cause PCT in isolation. Multiple susceptibility factors that appear to act synergistically can be identified in individual patients. PCT patients characteristically have chronic liver disease and sometimes cirrhosis and are at risk for hepatocellular carcinoma. Various chemicals can also induce PCT; an epidemic of PCT occurred in eastern Turkey in the 1950s as a consequence of wheat contaminated with the fungicide hexachlorobenzene. PCT also occurs after exposure to other chemicals, including di- and trichlorophenols and 2,3,7,8-tetrachlorodibenzo-(*p*)-dioxin (TCDD, dioxin).

Diagnosis Porphyrins are increased in the liver, plasma, urine, and stool. The urinary ALA level may be slightly increased, but the PBG level is normal. Urinary porphyrins consist mostly of uroporphyrins and heptacarboxylate porphyrin, with lesser amounts of coproporphyrin and hexa- and pentacarboxylate porphyrins. Plasma porphyrins are also increased, and fluorometric scanning of diluted plasma at neutral pH can rapidly distinguish VP and PCT (Table 428-3). Isocoproporphyrins, which are increased in feces and sometimes in plasma and urine, are diagnostic for hepatic URO-decarboxylase deficiency.

Type 2 PCT and HEP can be distinguished from type 1 by finding decreased URO-decarboxylase in erythrocytes. URO-decarboxylase activity in liver, erythrocytes, and cultured skin fibroblasts in type 2 PCT is ~50% of normal in affected individuals and in asymptomatic heterozygous family members. In HEP, the URO-decarboxylase activity is markedly deficient, with typical levels of 3–10% of normal. Over 150 mutations have been identified in the *UROD* gene (Human Gene Mutation Database; *www.hgmd.org*). Of the mutations listed in the database, ~65% are missense or nonsense, and ~8% are splice-site mutations. Many *UROD* mutations have been identified in only one or two families.

TREATMENT

Porphyria Cutanea Tarda

Alcohol, estrogens, iron supplements, and, if possible, any drugs that may exacerbate the disease should be discontinued, but this step does not always lead to improvement. A complete response can almost always be achieved by the standard therapy, repeated phlebotomy, to reduce hepatic iron. A unit (450 mL) of blood can be removed every 1–2 weeks. The aim is to gradually reduce excess hepatic iron until the serum ferritin level reaches the lower limits of normal. Because iron overload is not marked in most cases, remission may occur after only five or six phlebotomies; however, PCT patients with hemochromatosis may require more treatments to bring their iron levels down to the normal range. To document improvement in PCT, it is most convenient to follow the total plasma porphyrin concentration, which becomes normal sometime after the target ferritin level is reached. Hemoglobin levels or hematocrits and serum ferritin should be followed closely to prevent development of iron deficiency and anemia. After remission, continued phlebotomy may not be needed. Plasma porphyrin levels are followed at 6- to 12-month intervals for early detection of recurrences, which are treated by additional phlebotomy.

An alternative when phlebotomy is contraindicated or poorly tolerated is a low-dose regimen of chloroquine or hydroxychloroquine, both of which complex with the excess porphyrins and promote their excretion. Small doses (e.g., 125 mg chloroquine phosphate twice weekly) should be given, because standard doses can induce transient, sometimes marked increases in photosensitivity and hepatocellular damage. Studies indicate that low-dose hydroxychloroquine is as safe and effective as phlebotomy in PCT. Hepatic imaging can diagnose or exclude complicating hepatocellular carcinoma. Treatment of PCT in patients with end-stage renal disease is facilitated by administration of erythropoietin.

Because hepatitis C virus (HCV) is a common precipitating factor causing PCT, the recent development of oral direct-acting antivirals for HCV has proven effective as a first primary treatment in HCV-infected PCT patients.

HEREDITARY COPROPORPHYRIA

HCP is an autosomal dominant hepatic porphyria that results from the half-normal activity of COPRO-oxidase. The disease presents with acute attacks, as in AIP. Cutaneous photosensitivity also may occur, but much less commonly than in VP. HCP patients may have acute attacks and cutaneous photosensitivity together or separately. HCP is less common than AIP and VP. Homozygous dominant HCP and harderoporphyria, a biochemically distinguishable variant of HCP, present with clinical symptoms in children (see below).

Clinical Features HCP is influenced by the same factors that cause attacks in AIP. The disease is latent before puberty, and symptoms, which are virtually identical to those of AIP, are more common in women. HCP is generally less severe than AIP. Blistering skin lesions are identical to PCT and VP and begin in childhood in rare homozygous cases.

Diagnosis COPRO III is markedly increased in the urine and feces in symptomatic patients and often persists, especially in feces, when there are no symptoms. Urinary ALA and PBG levels are increased (but less than in AIP) during acute attacks but may revert to normal more quickly than in AIP when symptoms resolve. Plasma porphyrins are usually normal or only slightly increased, but they may be higher in cases with skin lesions. The diagnosis of HCP is readily confirmed by increased fecal porphyrins consisting almost entirely of COPRO III, which distinguishes it from other porphyrias.

Although the diagnosis can be confirmed by measuring COPRO-oxidase activity, the assays for this mitochondrial enzyme are not available and require cells other than erythrocytes. To date, >95 mutations have been identified in the *CPOX* gene, ~70% of which are missense or nonsense (Human Gene Mutation Database; *www.hgmd.org*). Detection of a *CPOX* mutation in a symptomatic individual permits the identification of asymptomatic family members.

TREATMENT

Hereditary Coproporphyria

Neurologic symptoms are treated as in AIP (see above). Phlebotomy and chloroquine are not effective for the cutaneous lesions.

VARIEGATE PORPHYRIA

VP is an autosomal dominant hepatic porphyria that results from the deficient activity of PROTO-oxidase, the seventh enzyme in the heme biosynthetic pathway, and can present with neurologic symptoms, photosensitivity, or both. VP is particularly common in South Africa, where 3 of every 1000 whites have the disorder. Most are descendants of a couple who emigrated from the Netherlands to South Africa in 1688. In other countries, VP is less common than AIP. Rare cases of homozygous dominant VP, presenting in childhood with cutaneous symptoms, also have been reported.

Clinical Features VP can present with skin photosensitivity, acute neurovisceral crises, or both. In two large studies of VP patients, ~60% had only skin lesions, 20% had only acute attacks, and ~20% had both. Acute attacks are identical to those in AIP and are precipitated by the same factors as AIP (see above). Blistering skin manifestations are similar to those in PCT but are more difficult to treat and usually are of longer duration. Homozygous VP is associated with photosensitivity, neurologic symptoms, and developmental disturbances, including growth retardation, in infancy or childhood; all cases had increased

erythrocyte levels of zinc protoporphyrin, a characteristic finding in all homozygous porphyrias so far described.

Diagnosis Urinary ALA and PBG levels are increased during acute attacks but may return to normal more quickly than in AIP. Increases in fecal protoporphyrin and COPRO III and in urinary COPRO III are more persistent. Plasma porphyrin levels also are increased, particularly when there are cutaneous lesions. VP can be distinguished rapidly from all other porphyrias by examining the fluorescence emission spectrum of porphyrins in plasma since VP has a unique fluorescence peak at neutral pH.

Assays of PROTO-oxidase activity in cultured fibroblasts or lymphocytes are not widely available. Over 215 mutations have been identified in the *PPOX* gene from unrelated VP patients (Human Gene Mutation Database; *www.hgmd.org*). The missense mutation encoding p.R59W is the common mutation in most South Africans with VP of Dutch descent. Five missense mutations were common in English and French VP patients; however, most mutations have been found in only one or a few families.

TREATMENT

Variegate Porphyria

Acute attacks are treated as in AIP, and hemin should be started early in most cases. Givosiran has proven effective in clinical trials for patients with recurrent attacks. Other than avoiding sun exposure, there are few effective measures for treating the skin lesions. β-Carotene, phlebotomy, and chloroquine are not helpful.

THE ERYTHROPOIETIC PORPHYRIAS

In the erythropoietic porphyrias, excess porphyrins from bone marrow erythrocyte precursors are transported via the plasma to the skin and lead to cutaneous photosensitivity.

X-LINKED SIDEROBLASTIC ANEMIA

XLSA results from the deficient activity of the erythroid form of ALA-synthase (ALA-synthase 2) and is associated with ineffective erythropoiesis, weakness, and pallor.

Clinical Features Typically, males with XLSA develop refractory hemolytic anemia, pallor, and weakness during infancy. They have secondary hypersplenism, become iron overloaded, and can develop hemosiderosis. The severity depends on the level of residual erythroid ALA-synthase activity and on the responsiveness of the specific mutation to pyridoxal 5′-phosphate supplementation (see below). Peripheral blood smears reveal a hypochromic, microcytic anemia with striking anisocytosis, poikilocytosis, and polychromasia; the leukocytes and platelets appear normal. Hemoglobin content is reduced, and the mean corpuscular volume and mean corpuscular hemoglobin concentration are decreased. Patients with milder, later-onset disease have been reported recently.

Diagnosis Bone marrow examination reveals hypercellularity with a left shift and megaloblastic erythropoiesis with an abnormal maturation. A variety of Prussian blue–staining sideroblasts are observed. Levels of urinary porphyrin precursors and of both urinary and fecal porphyrins are normal. The activity of erythroid ALA-synthase 2 is decreased in bone marrow, but this enzyme is difficult to measure in the presence of the normal ALA-synthase 1 housekeeping enzyme. Definitive diagnosis requires the demonstration of loss-of-function mutations in the erythroid *ALAS2* gene, of which >120 have been identified.

Treatment The severe anemia may respond to pyridoxine supplementation. This cofactor is essential for ALA-synthase activity, and mutations in the pyridoxine binding site of the enzyme have been found in several responsive patients. Cofactor supplementation may make it possible to eliminate or reduce the frequency of transfusions. Unresponsive patients may be transfusion dependent and require chelation therapy.

CONGENITAL ERYTHROPOIETIC PORPHYRIA

CEP, also known as Günther's disease, is an autosomal recessive disorder. It is due to the markedly deficient, but not absent, activity of URO-synthase and the resultant accumulation of URO I and COPRO I isomers. CEP is associated with hemolytic anemia and cutaneous lesions.

Clinical Features Severe cutaneous photosensitivity typically begins from birth. The skin over light-exposed areas is friable, and bullae and vesicles are prone to rupture and infection. Skin thickening, focal hypo- and hyperpigmentation, and hypertrichosis of the face and extremities are characteristic. Secondary infection of the cutaneous lesions can lead to disfigurement of the face and hands. Porphyrins are deposited in teeth and in bones. As a result, the teeth are brownish and fluoresce on exposure to long-wave ultraviolet light. Hemolysis is due to the marked increase in erythrocyte porphyrins and leads to splenomegaly. Adults with a milder later-onset form of the disease also have been described, including late-onset patients with myelodysplasias.

Diagnosis URO and COPRO (mostly type I isomers) accumulate in the bone marrow, erythrocytes, plasma, urine, and feces. The predominant porphyrin in feces is COPRO I. The diagnosis of CEP can be confirmed by demonstration of markedly deficient URO-synthase activity and/or by the identification of specific mutations in the *UROS* gene. The disease can be detected in utero by measuring porphyrins in amniotic fluid and URO-synthase activity in cultured amniotic cells or chorionic villi or by the detection of the family's specific gene mutations. Molecular analyses of the mutant alleles from unrelated patients have revealed the presence of >65 mutations in the *UROS* gene, including six in the erythroid-specific promoter of the *UROS* gene. Genotype/phenotype correlations can predict the severity of the disease. The CEP phenotype may be increased by the presence of exon 10 variants in the erythroid-specific ALA-synthase 2, mutations that typically cause XLP. One mutation (p.Arg216Trp) in *GATA1*, encoding the X-linked erythroid-specific transcription factor GATA binding protein 1 (GATA1), has been identified in two individuals with CEP who both also had other hematologic abnormalities.

TREATMENT

Congenital Erythropoietic Porphyria

Transfusion-dependent patients require periodic transfusions for anemia. Chronic transfusions of sufficient fresh packed erythrocytes to suppress erythropoiesis are effective in reducing porphyrin production but result in iron overload. Oral iron chelation is recommended. Splenectomy may reduce hemolysis and decrease transfusion requirements. Protection from sunlight and from minor skin trauma is essential to avoid/minimize cutaneous blistering. Complicating bacterial infections should be treated promptly. Recently, non-transfusion-dependent patients have been treated by periodic phlebotomies to decrease iron levels, thereby decreasing erythropoiesis and porphyrin accumulation. This approach has not been evaluated in clinical trials to date. Bone marrow and hematopoietic stem cell transplantation has proven curative in transfusion-dependent children, providing the rationale for future stem cell gene therapy.

ERYTHROPOIETIC PROTOPORPHYRIA

EPP is an autosomal recessive disorder resulting from the deficient activity of FECH, the last enzyme in the heme biosynthetic pathway. As noted above, EPP is likely the most common porphyria with onset typically in early childhood. EPP patients have FECH activities as low as 15–30% of normal in lymphocytes and cultured fibroblasts. Protoporphyrin IX accumulated in bone marrow reticulocytes and circulating erythrocytes is released into the plasma and then is taken up in the

liver where it is excreted in the bile and feces. Plasma protoporphyrin IX taken up by the vascular cells in the skin is photoactivated on exposure to sunlight causing phototoxic cellular damage and excruciatingly painful nonblistering phototoxicity. In most symptomatic patients (>95%) with this disorder, a deleterious mutation in one *FECH* allele was inherited with the relatively common (~10% of Caucasians) intronic 3 (IVS3) variant (IVS3–48T>C) on the other allele; together, they result in the low expression of the normal enzyme. In ~2% of EPP families, two *FECH* deleterious mutations have been found.

XLP is a less common condition with the same phenotype in affected males, including increased erythrocyte protoporphyrin IX levels resulting from gain-of-function mutations in the last exon of the erythroid-specific form of 5-aminolevulinate-synthase 2 (*ALAS2*). These mutations delete or alter the ALAS2 C-terminal amino acids, resulting in its increased activity and the subsequent accumulation of protoporphyrin IX. Manifestations in female heterozygotes with XLP can range from asymptomatic to as severe as their affected male relatives. The variation in the presence and severity of manifestations in XLP heterozygotes results primarily from random X-chromosomal inactivation. XLP accounts for ~2–10% of cases with the EPP phenotype in Europe and North America. Rare patients with EPP symptoms and elevated erythrocyte protoporphyrin IX levels do not have mutations in *FECH* or *ALAS2* on genetic testing. In an affected family with EPP symptoms and accumulation of protoporphyrin IX, an autosomal dominant mutation was found in human CLPX, a modulator of heme biosynthesis.

Clinical Features In EPP and male XLP patients, skin photosensitivity, which differs from that in other cutaneous porphyrias, usually begins in early childhood. The initial symptoms on sun exposure consist of tingling, stinging, itching, or heat/burning sensations on the exposed skin occurring within <10 to 30 min of exposure in >60% of patients; most will have these prodromal symptoms within an hour of sun exposure. The prodromal symptoms are the "warning signal" to get out of the sun, thereby avoiding a severe incapacitating painful attack that can last from 2–5 days. Photosensitivity is associated with substantial elevations in erythrocyte protoporphyrin IX and occurs only in patients with genotypes that result in FECH activities below ~35% of normal. Vesicular lesions are uncommon. Redness and swelling develop after prolonged sun exposure and resemble angioedema **(Fig. 428-4)**. Pain symptoms may seem out of proportion to the visible skin involvement. Chronic skin changes may include lichenification, leathery pseudovesicles, labial grooving, and nail changes. Severe scarring is rare, as are pigment changes, friability, and hirsutism. Unless hepatic or other complications develop, protoporphyrin IX levels and symptoms of photosensitivity tend to remain remarkably stable over many years in most patients. Factors that exacerbate the hepatic porphyrias play no role in EPP or XLP.

FIGURE 428-4 Erythema and edema of the hands due to acute photosensitivity in a 10-year-old boy with erythropoietic protoporphyria. *(Reproduced with permission from P Poblete-Gutiérrez et al: The porphyrias: clinical presentation, diagnosis and treatment. Eur J Dermatol 16:230, 2006.)*

The primary source of excess protoporphyrin is the bone marrow erythroid cells. In EPP patients, erythrocyte protoporphyrin IX is free (not complexed with zinc) and is mostly bound to hemoglobin. In plasma, protoporphyrin IX is bound to albumin. Hemolysis and anemia are absent or usually mild.

Although EPP is an erythropoietic porphyria, up to 27% of EPP patients may have minor abnormalities of liver function, and in ~2–5% of these patients, the accumulation of protoporphyrins causes chronic liver disease that can progress to liver failure requiring transplantation. Protoporphyrin IX is insoluble, and excess amounts form crystalline structures in liver cells (Fig. 428-4) and can decrease hepatic bile flow. Studies in the mouse model of EPP have shown that the bile duct epithelium may be damaged by toxic bile, leading to biliary fibrosis. Thus, rapidly progressive liver disease appears to be related to the cholestatic effects of protoporphyrins and is associated with increasing hepatic protoporphyrin IX levels due to impaired hepatobiliary excretion and increased photosensitivity. The hepatic complications also are often characterized by increasing levels of protoporphyrins in erythrocytes and plasma as well as severe abdominal and back pains, especially in the right upper quadrant. Gallstones composed at least in part of protoporphyrin IX occur in some patients. Hepatic complications appear to be higher in EPP due to two pathogenic *FECH* mutations and in males with XLP.

Diagnosis A substantial increase in erythrocyte protoporphyrin IX, which is predominantly free and not complexed with zinc, is the hallmark of EPP. Protoporphyrin levels also are variably increased in bone marrow, plasma, bile, and feces. Erythrocyte protoporphyrin IX concentrations are increased in other conditions such as lead poisoning, iron deficiency, various hemolytic disorders, all homozygous forms of other porphyrias, and sometimes even in acute porphyrias. In all these conditions, however, in contrast to EPP, protoporphyrin IX is complexed with zinc. Therefore, after an increase in erythrocyte protoporphyrin IX is found in a suspected EPP patient, it is important to confirm the diagnosis by an assay that distinguishes free and zinc-complexed protoporphyrin. Erythrocytes in EPP also exhibit red fluorescence under fluorescence microscopy at 620 nm. Urinary levels of porphyrins and porphyrin precursors are normal. FECH activity in cultured lymphocytes or fibroblasts is decreased (<30% of normal mean). DNA diagnosis by mutation analysis is recommended to detect the causative *FECH* mutation(s) and/or the presence of the IVS3–48T>C low expression allele. To date, >235 mutations have been identified in the *FECH* gene, many of which result in an unstable or absent enzyme protein (null alleles) (Human Gene Mutation Database; *www.hgmd.org*).

In XLP, the erythrocyte protoporphyrin levels appear to be higher than in EPP, and the proportions of free and zinc protoporphyrin IX may reach 50%. XLP accounts for ~2% of patients with the EPP phenotype in Western Europe. Recent studies show that ~10% of North American patients with the EPP phenotype have XLP.

TREATMENT

Erythropoietic Protoporphyria

Avoiding sunlight exposure and wearing clothing designed to provide protection for conditions with chronic phototoxicity are essential. Various other treatments, including oral β-carotene and cimetidine, have proven of little benefit. Afamelanotide, an α-melanocyte-stimulating hormone (MSH) analogue that

stimulates tanning, is administered subcutaneously every 2 months and has been approved for the treatment of EPP and XLP by the EMA and the FDA. Dersimelagon, an orally administered, small-molecule, selective melanocortin-1 receptor (MC1R) agonist that increases skin melanin without sun exposure, is currently in phase 3 clinical trials for EPP and XLP. Bitopertin, an orally administered glycine reuptake inhibitor, recently was shown to reduce blood protoporphyrin IX levels in clinical studies and is currently in phase 3 clinical trials.

Treatment of hepatic complications, which may be accompanied by motor neuropathy, is difficult. Cholestyramine and other porphyrin absorbents such as activated charcoal may interrupt the enterohepatic circulation of protoporphyrin and promote its fecal excretion, leading to some improvement. Plasmapheresis and intravenous hemin are sometimes beneficial.

Liver transplantation has been carried out in some EPP and XLP patients with severe liver complications and is often successful in the short term. However, the disease often recurs in the transplanted liver due to continued bone marrow production of excess protoporphyrin. In a retrospective study of 17 liver-transplanted EPP patients, 11 (65%) had recurrent EPP liver disease. Posttransplantation treatment with hematin and plasmapheresis should be considered to prevent the recurrence of liver disease. However, bone marrow transplantation, which has been successful in human EPP and which prevented liver disease in a mouse model, should be considered after liver transplantation, if a suitable donor can be found.

429 Lysosomal Storage Diseases

Robert J. Hopkin, Gregory A. Grabowski

Lysosomes are heterogeneous subcellular organelles containing specific hydrolases that allow selective processing or degradation of proteins, nucleic acids, carbohydrates, and lipids. There are >50 different lysosomal storage diseases, now termed lysosomal system diseases (LSDs), classified according to the nature of the major accumulated materials **(Table 429-1)**. Although all are rare diseases, an overview of several are provided here: Tay-Sachs disease, Fabry disease, Gaucher disease, Niemann-Pick disease, the mucopolysaccharidoses, Pompe disease, lysosomal acid lipase deficiency (LALD), Krabbe disease, CLN2-related Batten disease, and α-mannosidosis. LSDs should be considered in the differential diagnosis of patients with neurologic, renal, or muscular degeneration and/or unexplained hepatomegaly, splenomegaly, cardiomyopathy, or skeletal dysplasias and deformations. Physical findings are disease specific, and enzyme assays or genetic testing can be used to make a definitive diagnosis. Although the nosology of LSDs segregates the variants into distinct phenotypes, these are heuristic; in the clinic, each disease exhibits—to varying degrees—a spectrum of manifestations, from severe to attenuated variants.

PATHOGENESIS

Lysosomal biogenesis involves ongoing synthesis of lysosomal hydrolases, membrane constitutive proteins, and new membranes. Lysosomes originate from the fusion of trans-Golgi network vesicles with late endosomes. Progressive acidification accompanies the maturation of these vesicles; this gradient facilitates the pH-dependent dissociation of receptors and ligands and also activates lysosomal hydrolases. Lysosomes are components of the lysosome/autophagy/mitophagy system that are regulated by the mTORC1 modulation, via phosphorylation, of the transcription factors TFEB/TFE3 and the resultant control of the balance between anabolic and catabolic pathways. This regulation is disrupted to varying degrees in specific tissues affected by individual LSDs.

Abnormalities at any biosynthetic step can impair lysosomal enzyme function and lead to an LSD. After leader sequence clipping from the primary protein, remodeling of complex oligosaccharides (including the lysosomal targeting ligand mannose-6-phosphate as well as high-mannose oligosaccharide chains of many soluble lysosomal hydrolases) occurs during transit through the Golgi. Lysosomal integral or associated membrane proteins are sorted to the membrane or interior of the lysosome by several different peptide signals. Phosphorylation, sulfation, additional proteolytic processing, and macromolecular assembly of heteromers occur concurrently. Such posttranslational modifications are critical to enzyme function, and defects in these processes can result in multiple enzyme/protein deficiencies.

The final common pathway for LSDs is the accumulation of specific macromolecules within selected tissues and cells that normally have a high flux of these substrates. The majority of lysosomal enzyme deficiencies result from point mutations or genetic rearrangements at a locus that encodes a single lysosomal hydrolase or protein subunit. However, some mutations cause deficiencies of several different lysosomal hydrolases by alteration of the enzymes/proteins involved in targeting, active site modifications, macromolecular association, or trafficking. Nearly all LSDs are inherited as autosomal recessive disorders, except for Hunter (mucopolysaccharidosis type II), Danon, and Fabry diseases that are X-linked, and two autosomal dominant conditions causing Parry type neuronal ceroid lipofuscinosis (CLN) due to mutations in *DNAJC5* or frontotemporal dementia and CLN11 due to *GRN* (progranulin) mutations. Substrate accumulations lead to lysosomal distortions/dysfunctions that have significant pathophysiologic

					CLINICAL FEATURES					
DISORDER[a]	ENZYME DEFICIENCY (*GENE*) [SPECIFIC THERAPY]	PRIMARY ACCUMULATED MATERIALS	CLINICAL TYPES (ONSET)	INHERITANCE	NEUROLOGIC	LIVER, SPLEEN ENLARGEMENT	SKELETAL DYSPLASIA	OPHTHALMOLOGIC	HEMATOLOGIC	UNIQUE FEATURES
Mucopolysaccharidoses (MPS)										
MPS I H, Hurler	α-L-Iduronidase (*IDUA*) [ET, HSCT]	Dermatan sulfate Heparan sulfate	Infantile Intermediate	AR	Cognitive degeneration	+++	++++	Corneal clouding	Vacuolated lymphocytes	Coarse facies; cardiovascular involvement; joint stiffness
MPS I H/S, Hurler/Scheie			Childhood/adult		Cognitive degeneration					
MPS I S, Scheie					None					
MPS II, Hunter	Iduronate sulfatase (IDS) [ET]	Dermatan sulfate Heparan sulfate	Severe infantile Mild juvenile	X-linked	Cognitive degeneration, less in mild form	+++	++++	Retinal degeneration, no corneal clouding	Granulated lymphocytes	Coarse facies; cardiovascular involvement; joint stiffness; distinctive pebbly skin lesions
MPS III A, Sanfilippo A	Heparan-*N*-sulfatase (*SGSH*)	Heparan sulfate	Late infantile	AR	Severe cognitive degeneration	+	+	None	Granulated lymphocytes	Mild coarse facies
MPS III B, Sanfilippo B	*N*-Acetyl-α-glucosaminidase (*NGALU*)	Heparan sulfate	Late infantile	AR	Severe cognitive degeneration	+	+	None	Granulated lymphocytes	Mild coarse facies
MPS III C, Sanfilippo C	Acetyl-CoA: α-glucosaminide *N*-acetyltransferase (*HGSNAT*)	Heparan sulfate	Late infantile	AR	Severe cognitive degeneration	+	+	None	Granulated lymphocytes	Mild coarse facies
MPS III D, Sanfilippo D	*N*-Acetylglucosamine-6-sulfate sulfatase (*GNS*)	Heparan sulfate	Late infantile	AR	Severe cognitive degeneration	+	+	None	Granulated lymphocytes	Mild coarse facies
MPS IV A, Morquio A	*N*-Acetylgalactosamine-6-sulfate sulfatase (*GALNS*) [ET]	Keratan sulfate Chondroitin-6 sulfate	Childhood	AR	None	+	++++	Corneal clouding	Granulated neutrophils	Distinctive skeletal deformity; odontoid hypoplasia; aortic valve disease
MPS IV B, Morquio	β-Galactosidase (*GLB1*)		Childhood	AR	None	±	++++			
MPS VI, Maroteaux-Lamy	Arylsulfatase B (*ARSB*) [ET, HSCT]	Dermatan sulfate	Late infantile	AR	None	++	++++	Corneal clouding	Granulated neutrophils and lymphocytes	Coarse facies; valvular heart disease
MPS VII Sly	β-Glucuronidase (*GUS*) [ET]	Dermatan sulfate Heparan sulfate	Neonatal Infantile Adult	AR	Cognitive degeneration, absent in some adults	+++	+++	Corneal clouding	Granulated neutrophils	Coarse facies; vascular involvement; hydrops fetalis in neonatal form
GM_2 Gangliosidoses										
Tay-Sachs disease	β-Hexosaminidase A (*HEXA*)	GM_2 gangliosides	Infantile Juvenile	AR	Cognitive degeneration; seizures; later juvenile form	None	None	Cherry red spot in infantile form	None	Macrocephaly; hyperacusis in infantile form
Sandhoff disease	β-Hexosaminidases A and B (*HEXB*)	GM_2 gangliosides	Infantile	AR	Cognitive degeneration; seizures	++	±	Cherry red spot	None	Macrocephaly; hyperacusis

Neutral Glycosphingolipidoses										
Fabry disease	α-Galactosidase A (*GLA*) [ET, Chaperone]	Globotriaosylceramide	Childhood	X-linked	Painful acroparesthesias	None	None	Corneal dystrophy, vascular lesions	None	Cutaneous angiokeratomas; hypohydrosis
Gaucher disease	Acid β-glucosidase (*GBA*, a.k.a. *GBA1*) [ET, SRT]	Glucosylceramide, Glucosylsphingosine	Type 1 Type 2 Type 3	AR	None ++++ –/+++	++++ +++ ++++	++++ + ++++	None Strabismus Supranuclear gaze palsy	Gaucher cells in bone marrow; cytopenias	Types 1 and 3 highly variable
Niemann-Pick disease A and B	Acid sphingomyelinase (*SMPD1*) [ET]	Sphingomyelin	Neuronopathic, type A Nonneuronopathic, type B	AR	Cognitive degeneration; seizures	++++	None Osteoporosis	Macular degeneration	Foam cells in bone marrow	Pulmonary infiltrates Lung failure
Glycoproteinoses										
Fucosidosis	α-Fucosidase (*FUCA1*)	Glycopeptides; oligosaccharides	Infantile Juvenile	AR	Cognitive degeneration	++	++	None	Vacuolated lymphocytes; foam cells	Coarse facies; angiokeratomas in juvenile form
α-Mannosidosis	α-Mannosidase (*MAN2B1*) [ET]	Oligosaccharides	Infantile Milder variant	AR	Cognitive degeneration	+++	+++	Cataracts, corneal clouding	Vacuolated lymphocytes, granulated neutrophils	Coarse facies; enlarged tongue
β-Mannosidosis	β-Mannosidase (*MANBA*)	Oligosaccharides		AR	Seizures; cognitive degeneration		++	None	Vacuolated lymphocytes, foam cells	Angiokeratomas
Aspartylglucosaminuria	Aspartylglucosaminidase (*AGA*)	Aspartylglucosamine; glycopeptides	Young adult	AR	Cognitive degeneration	±	++	None	Vacuolated lymphocytes, foam cells	Coarse facies
Sialidosis	Neuraminidase (*NEU1*)	Sialyloligosaccharides	Type I, congenital Type II, infantile and juvenile	AR	Myoclonus; cognitive degeneration	++, less in type I	++, less in type I	Cherry red spot	Vacuolated lymphocytes	MPS phenotype in type II
Mucolipidoses (ML)										
ML-II, I-cell disease	UDP-*N*-Acetylglucosamine-1-phosphotransferase (*GNPTAB*)	Glycoprotein; glycolipids	Infantile	AR	Cognitive degeneration	+	++++	Corneal clouding	Vacuolated and granulated neutrophils	Coarse facies; absence of mucopolysacchariduria; gingival hypoplasia
ML-III, pseudo-Hurler polydystrophy	UDP-*N*-Acetylglucosamine-1-phosphotransferase (*GNPTAB*)	Glycoprotein; glycolipids	Late infantile	AR	Mild cognitive degeneration	None	+++	Corneal clouding, mild retinopathy, hyperopic astigmatism		Coarse facies; stiffness of hands and shoulders
Leukodystrophies										
Krabbe disease	Galactosylceramidase (*GALC*) [BMT/HSCT]	Galactosylceramide Galactosylsphingosine, a.k.a., psychosine	Infantile	AR	Cognitive degeneration, CNS, PNS dysmyelination	None	None	None	None	White matter globoid cells
Metachromatic leukodystrophy	Arylsulfatase A (*ARSA*)	Cerebroside sulfate	Infantile Juvenile Adult	AR	Cognitive degeneration; dementia; psychosis in adult	None	None	Optic atrophy	None	Gait abnormalities in late infantile form

[a]Comprehensive reviews of these lysosomal storage diseases can be found in DL Valle et al: *The Online Metabolic and Molecular Bases of Inherited Disease*, New York, McGraw-Hill, https://ommbid.mhmedical.com/book.*aspx?bookID=2709#225069419*.

Abbreviations: AR, autosomal recessive; BMT/HSCT, bone marrow or hematopoietic stem cell transplantation; ET, enzyme therapy; ICV ET, intracerebroventricular enzyme therapy; LALD, lysosomal acid lipase deficiency; SRT, substrate synthesis inhibition therapy (a.k.a., substrate reduction therapy).

consequences. In addition, abnormal amounts of metabolites may also have pharmacologic effects important to disease pathophysiology and propagation, particularly activation of the innate immune responses.

For many LSDs, the accumulated substrates are synthesized within particular tissue sites of pathology. Other diseases have greater exogenous substrate supplies. For example, substrates are delivered by low-density lipoprotein receptor–mediated uptake in Fabry and LALD or by phagocytosis in Gaucher disease type 1. The threshold hypothesis refers to a level of enzyme activity below which disease develops. Small changes in enzyme activity near that threshold can lead to or modify disease. A critical element of this model is that enzymatic activity can be challenged by changes in substrate flux based on genetic background, cell turnover, recycling, or metabolic demands. Thus, a set level of residual enzyme may be adequate for substrate in some tissues or cells but not in others. In addition, several variants of each LSD exist at the clinical level. These disorders therefore represent a spectrum of manifestations that are not easily dissociated into discrete entities. The molecular/genetic bases for such variations have not been elucidated in any detail.

Treatments approved by the European Medicines Agency (EMA) and U.S. Food and Drug Administration (FDA) are available for several LSDs. The first was enzyme replacement therapy (ET) for Gaucher disease; this has been followed by additional ETs, but subsequent developments have included modified enzyme infusion, substrate synthesis inhibition, hematopoietic stem cell transplant (HSCT), pharmacologic chaperone therapy (which use small molecules to stabilize or enhance enzyme function resulting from the mutated gene), intrathecal enzyme delivery, Trojan-horse strategies for blood-brain barrier penetration for central nervous system (CNS) delivery, and gene therapy. The technical ability to intervene for most LSDs now exists but with highly variable impact, i.e., therapeutic outcome, particularly in bones and the CNS. Significant additional research is needed to reach the goals of long-term survival with good function and quality of life.

SELECTED DISORDERS

TAY-SACHS DISEASE

About 1 in 30 Ashkenazi Jews is a carrier for Tay-Sachs disease (total hexosaminidase A [Hex A] deficiency), resulting from α-chain gene mutations. The infantile form is a neurodegenerative disease that results in death in infancy. It is characterized by macrocephaly, loss of motor skills, increased startle reaction, and a macular cherry red spot. The juvenile-onset form presents as ataxia and dementia, with death by age 10–15 years. The adult-onset disorder is characterized by clumsiness in childhood; progressive motor weakness in adolescence; and additional spinocerebellar and lower-motor-neuron signs and dysarthria in adulthood; intelligence declines slowly, and psychiatric disorders are common. Screening for Tay-Sachs disease carriers is recommended in the Ashkenazi Jewish population. Sandhoff disease, due to a deficiency in both Hex A and Hex B resulting from defective β-chains, is phenotypically similar to Tay-Sachs disease with the addition of hepatosplenomegaly and bony dysplasias.

FABRY DISEASE

Fabry disease, an X-linked disorder and likely the most prevalent LSD, results from mutations in *GLA*, which encodes α-galactosidase A. The estimated prevalence of hemizygous males ranges from 1 in 40,000 to 1 in 3500 in selected populations. Females have a higher prevalence of mutations, but more variable manifestations due to Lyonization effects. The disease manifests with angiokeratomas (telangiectatic skin lesions), hypohidrosis, corneal and lenticular opacities, acroparesthesia, and progressive disease of the kidney, heart, and brain vascular systems. Abdominal pain, recurrent diarrhea, and acroparesthesias (debilitating episodic burning pain of the hands and feet) may appear in childhood. In females, the overall manifestations vary greatly. Angiokeratomas are punctate, dark red to blue-black, and flat or slightly raised skin lesions; they do not blanch with pressure. They can be easily overlooked. They usually are most dense between the umbilicus and the knees—the "bathing suit area"—but may occur anywhere. Angiokeratomas also occur in several other very rare LSDs. Corneal and lenticular lesions, detectable on slit-lamp examination, may help in establishing a diagnosis of Fabry disease. Acroparesthesia can last from minutes to days and can be precipitated by changes in temperature, exercise, fatigue, or fever. Abdominal pain can resemble appendicitis or renal colic. Proteinuria, isosthenuria, and progressive renal dysfunction occur in the second to fourth decades; ~5% of male patients with "idiopathic renal failure" have *GLA* mutations. Hypertension, left ventricular hypertrophy, anginal chest pain, and congestive heart failure can occur in the third to fourth decades. About 1–3% of patients with "idiopathic hypertrophic myocardiopathy" have Fabry disease. Similarly, ~2–5% of patients with "idiopathic stroke" at 35–50 years of age have *GLA* mutations. Leg lymphedema occurs without hypoproteinemia. Death is due to cardiovascular, renal, or cerebrovascular disease. Variants with residual α-galactosidase A activity may have late-onset manifestations that are most prominent in the cardiovascular system and resemble hypertrophic cardiomyopathy. Cases with predominant cardiac, renal, or CNS manifestations have been reported. Up to 70% of heterozygous females exhibit clinical manifestations. However, in females, heart disease is the most common life-threatening manifestation. In males, it is renal disease followed by cardiovascular disease.

Gabapentin and carbamazepine diminish chronic and episodic acroparesthesias. Chronic hemodialysis or kidney transplantation can be lifesaving in patients with renal failure. Intravenous ET clears stored lipids from a variety of cells. More recently a chaperone therapy (migalastat) that stabilizes the residual enzyme made by the patient's body has allowed oral therapy for some patients with amenable mutations. Renal insufficiency, cardiac fibrosis, and stroke are irreversible; therefore, early institution of therapy provides the best opportunity to prevent or slow the progression of life-threatening complications.

GAUCHER DISEASE

Gaucher disease, a panethnic autosomal recessive disorder, results from defective activity of acid β-glucosidase; ~600 *GBA*, a.k.a. *GBA1*, mutations have been described in such patients. Clinically, disease variants are classified by the absence or presence and progression of primary CNS involvement.

Gaucher disease type 1 is a nonneuronopathic disease (i.e., absence of early-onset or progressive CNS disease) presenting in childhood to adulthood as slowly to rapidly progressive visceral disease. About 55–60% of patients are diagnosed at <20 years of age in white populations and at even younger ages in other groups. This pattern of presentation is distinctly bimodal, with peaks at <10–15 years and at ~25 years. Younger patients tend to have greater degrees of hepatosplenomegaly and accompanying blood cytopenias. In contrast, older patients have a greater tendency for chronic bone disease. Hepatosplenomegaly occurs in virtually all clinically identified patients and can be minor or massive. Accompanying anemia and thrombocytopenia are variable and are not directly related to liver or spleen volumes. Severe liver dysfunction is unusual, but progressive cirrhosis can occur. Splenic infarctions can resemble an acute abdomen. Pulmonary hypertension and alveolar Gaucher cell accumulation are uncommon but life-threatening and can occur at any age; this is more common in females who have been splenectomized. *GBA1* mutations in the heterozygous or homozygous states lead to a significantly increased lifetime risk for developing Parkinson disease. The complex mechanisms for this major risk require elucidation.

All patients with Gaucher disease have nonuniform infiltration of bone marrow by lipid-laden macrophages, termed Gaucher cells. This phenomenon can lead to marrow packing with subsequent infarction, ischemia, necrosis, and cortical bone destruction. Bone marrow involvement spreads from proximal to distal in the limbs and can involve the axial skeleton extensively, causing vertebral collapse. In addition to bone marrow involvement, bone remodeling is defective, with loss of total bone calcium leading to osteopenia, osteonecrosis, avascular infarction, and vertebral compression fractures with spinal cord involvement. Aseptic necrosis of the femoral head is common, as is fracture of the femoral neck. The mechanism by which diseased bone marrow macrophages interact with osteoclasts and/or osteoblasts

to cause bone disease is not well understood. Chronic, ill-defined bone pain can be debilitating and poorly correlated with radiographic findings. "Bone crises" are associated with localized excruciating pain and, on occasion, local erythema, fever, and leukocytosis. These crises represent acute infarctions of bone, as evidenced in nuclear scans by localized absent uptake of pyrophosphate agents. Decreased acid β-glucosidase activity (0–20% of normal) in nucleated cells establishes the diagnosis. The enzyme is not normally present in bodily fluids. The sensitivity of enzyme testing is poor for heterozygote detection; molecular testing by whole *GBA1* sequencing is the standard. The disease frequency varies from ~1 in 1000 among Ashkenazi Jews to <1 in 100,000 in other populations; ~1 in 12–15 Ashkenazi Jews carries a Gaucher disease allele. Four common mutations account for ~85% of the mutations in that population of affected patients: p.N370S (a.k.a. p.N409S), 84GG (a G insertion at cDNA position 84), p.L444P (also known as p.L483P), and IVS-2^{+1} (an intron 2 splice junction mutation).

Genotype/phenotype studies indicate a significant, though not absolute, correlation between disease type and severity and the *GBA1* genotype. The most common mutation in the Ashkenazi Jewish population (p.N370S) shares, either homozygously or heteroallelically, a 100% association with nonneuronopathic or type 1 Gaucher disease. The N370S/N370S and N370S/other mutant allele genotypes are associated with later-onset/less severe disease and with earlier-onset/severe disease, respectively. As many as 40% of individuals with the N370S/N370S genotype do not present clinically. Other alleles include L444P (very low activity), 84GG (null), or IVS-2 (null) and rare/private or uncharacterized alleles. The L444P/L444P patients frequently have life-threatening to very severe/early-onset disease, and many, though not all, develop CNS involvement in the first two decades of life.

Symptom-based treatment of blood cytopenias and joint replacement surgeries continue to have important roles in management. However, regular intravenous ET has been the first-line treatment for significantly affected patients and is highly efficacious and safe in diminishing hepatosplenomegaly and improving hematologic values. An oral substrate reduction therapy (SRT; eliglustat tartrate), which inhibits glucosylceramide synthesis, is approved as a first-line therapy for adults. Bone disease is decreased and can be prevented, but irreversible damage cannot be reversed, by ET. Adult patients may benefit from adjunctive treatment with bisphosphonates or other interventions to improve bone density. Adults who cannot be treated with enzyme, either because it is not effective or because they have developed an allergy or other hypersensitivities to the enzyme, may receive SRT with either eliglustat tartrate or miglustat; the latter is approved as a second-line oral therapy.

Gaucher disease type 2 is a rare, severe, progressive CNS disease that leads to death by 2 years of age, depending on supportive care. Gaucher disease type 3 has highly variable manifestations in the CNS and viscera. It can present in early childhood with rapidly progressive, massive visceral disease and slowly progress to static CNS involvement that may not be evident by standard IQ evaluations; in adolescence with dementia; or in early adulthood with rapidly progressive, uncontrollable myoclonic seizures and mild visceral disease. Visceral disease in type 3 is nearly identical to that in type 1 but is generally more severe. Early CNS findings may be limited to defects in lateral gaze tracking (supranuclear lateral gaze palsy), which may remain static for decades. Cognitive degeneration can be slowly progressive or static. Type 3 is much more frequent among individuals of non–Western world descent. Visceral—but not CNS—involvement responds to ET.

NIEMANN-PICK DISEASES

Niemann-Pick diseases (acid sphingomyelinase deficiency [ASMD]) are autosomal recessive disorders that result from defects in acid sphingomyelinase (ASM). Types A and B are distinguished by the early age of onset and progressive CNS disease in type A. Type A typically has its onset in the first 6 months of life, with rapidly progressive CNS deterioration, spasticity, failure to thrive, and massive hepatosplenomegaly. Type B has a later, more variable onset and is characterized by a progression of hepatosplenomegaly, with eventual development of cirrhosis and hepatic parenchymal and Kupffer cell replacement by foam cells filled with sphingomyelin. Affected patients develop potentially lethal progressive pulmonary disease with dyspnea, hypoxemia, and a reticular infiltrative pattern on chest x-ray. Foam cells are present in alveoli, lymphatic vessels, and pulmonary arteries. Progressive hepatic or lung disease can lead to death in adolescence or early adulthood. The "type B" phenotype includes some patients with slowly progressive CNS involvement, termed A/B variant.

The diagnosis is established by markedly decreased (1–10% of normal) ASM activity in nucleated cells. Intravenous ET improves nonneurologic manifestations, including pulmonary disease. The efficacies of hepatic transplant (HT) or bone marrow transplantation (BMT/HSCT) are not established. More complications than expected have occurred with these interventions due to either (1) recurrence of hepatic disease in the transplant following HT due to repopulation of bone marrow–derived ASM-deficient myeloid cells or (2) lack of clearance of sphingomyelin in hepatocytes by ASM cross-correction following the BMT/HSCT of ASM-normal bone marrow stem cells.

Niemann-Pick C diseases are progressive CNS diseases due to mutations in either of the genes encoding NPC1 or NPC2, lysosomal proteins involved in free cholesterol and selected sphingolipid transport out of the lysosome. They can present with liver or splenic disease, but their major manifestations are progressive CNS disease over one to two decades. Treatment with substrate inhibition agents (e.g., miglustat) has shown minor CNS effects, and substrate depletion with cyclodextrin is in clinical trials for NPC1 disease.

MUCOPOLYSACCHARIDOSES

Mucopolysaccharidosis type I (MPS I) is an autosomal recessive disorder caused by deficiency of α-L-iduronidase (IDU). The spectrum of involvement traditionally has been divided into three categories: (1) Hurler disease (MPS I H) for severe deficiency with neurodegeneration, (2) Scheie disease (MPS I S) for later-onset disease without neurologic involvement and with relatively less severe disease in other organ systems, and (3) Hurler-Scheie syndrome (MPS I H/S) for patients intermediate between these extremes. MPS I H/S is characterized by severe somatic disease, usually without major overt neurologic deterioration. MPS I often presents in infancy or early childhood as chronic rhinitis, clouding of the corneas, hepatosplenomegaly, and progressive dysmorphia. As the disease progresses, nearly every organ system can be affected. In the more severe forms, cardiac and respiratory diseases become life threatening in childhood. Skeletal disease can be severe, resulting in very limited mobility. There are two current treatments for the MPS I diseases. HSCT is the standard treatment for patients presenting at <2 years of age who appear to have or are at risk for neurologic degeneration. Because early diagnosis and intervention are essential, MPS I has been added to the recommended newborn screen (NBS). HSCT results in stabilization of CNS disease, reverses hepatosplenomegaly, and improves cardiac and respiratory disease. HSCT does not eliminate corneal disease or result in the resolution of progressive skeletal disease. ET effectively addresses hepatosplenomegaly and alleviates cardiac and respiratory disease. The enzyme does not penetrate the blood-brain barrier and does not directly affect CNS disease. ET and HSCT appear to have similar effects on visceral signs and symptoms. ET poses a lower risk of life-threatening complications and may therefore be advantageous for patients without CNS disease. A combination of ET and HSCT has been used, with ET initiated prior to transplantation in an attempt to reduce the disease burden. The experience with this approach is not well documented, but it appears to have advantages over HSCT alone. It is clear that HSCT has benefited patients. However, late cardiac and respiratory complications of MPS I are being reported including obstructive breathing requiring pressure support, cardiomyopathy, and/or valve disease. Regular follow-up for patients with MPS I is required throughout their lives even after successful HSCT.

Hunter disease (MPS II) is an X-linked disorder due to deficiency in iduronate sulfate sulfatase (IDS) and has manifestations similar to those of MPS I, including some variants with neurologic degeneration. There is no corneal clouding or other eye disease. Like MPS I, MPS II is clinically variable, with CNS and non-CNS variants. HSCT has not

been successful in treating CNS disease associated with MPS II. The FDA and EMA have approved ET for the visceral manifestations of MPS II.

MPS IV or Morquio syndrome is a rare autosomal recessive condition (1 in 200,000–300,000) and is different than the other mucopolysaccharidoses in presenting as a spondyloepiphyseal skeletal dysplasia and hyperextensibility of all joints. There are also major heart and respiratory complications. This disorder often presents in childhood, but the age of onset and rate of progression are quite variable. Two variants, type A and type B, are caused by deficiencies in *N*-acetyl-galactosamine-6-sulfatase (*GALNS*) and an acid β-galactosidase, respectively. A recombinant human GALNS ET (elosulfase alfa) is approved for the treatment of MPS IVA, making it essential to confirm the specific enzyme diagnosis. Treatment has been shown to improve ambulatory mobility and decrease pain. There is no current specific treatment for MPS IVB.

ET for Maroteaux-Lamy disease (MPS VI), arylsulfatase B (ARSB) deficiency, has received FDA approval as well as approval by similar agencies in other countries. This very rare autosomal recessive disorder is characterized by hepatosplenomegaly, bone disease, heart disease, and respiratory compromise. Short stature is also an important manifestation. Visceral signs and symptoms are similar to those in MPS I; however, MPS VI is not associated with neurologic degeneration.

MPS VII, Sly syndrome, is due to mutations in *GUSB*, which encodes β-glucuronidase. Severe deficiency in this enzyme may present with fetal hydrops, which can lead to stillbirth or perinatal demise. Other patients with MPS VII may present later with short stature, coarse facial features, and hepatosplenomegaly. There is ET for this disorder (vestronidase alfa-vjbk).

POMPE DISEASE

Acid maltase (acid α-glucosidase deficiency) due to *GAA* mutations, also called Pompe disease, is the only LSD leading to primary glycogen storage. The classic severe infantile form presents with hypotonia, myocardiopathy, and hepatosplenomegaly, as well as total deficiency of the enzyme. This variant is rapidly progressive and generally results in death in the first year of life. However, as with other LSDs, there are early- and late-onset forms of this disorder.

The late-onset variants may be as common as 1 in 40,000; patients typically present with a slowly progressive myopathy that may resemble limb-girdle muscular dystrophy. Respiratory insufficiency may be the presenting sign or may develop with advancing disease. In late stages of the disease, patients may require mechanical ventilation, report swallowing difficulties, and experience loss of bowel and bladder control. Myocardiopathy is not usually present in late-onset variants of Pompe disease.

The FDA, EMA, and similar agencies have approved ETs for Pompe disease patients of all ages. This treatment clearly prolongs life in the infantile form, consistently resulting in improved cardiac function. Respiratory function is also improved in most treated infants if instituted before age 6 months. Some infants demonstrate marked improvement in motor functions, while others have minor changes in muscle tone or strength. Many states have instituted NBS for Pompe disease. In addition, newer protocols for treatment with methotrexate and rituximab have greatly decreased antidrug antibody reactions, particularly in the enzyme-absent infantile variants. The combination of NBS and immunomodulation preceding ET has greatly improved therapeutic response and long-term survival. Prevention of deterioration has been shown with GAA ET in the late-onset forms. Early intervention with acid α-glucosidase ET in such patients may limit or prevent deterioration, but very advanced disease will have significant irreversible components.

LYSOSOMAL ACID LIPASE DEFICIENCY

Wolman syndrome (now infantile-onset LALD) and cholesterol ester storage disease (now childhood/adult-onset LALD) are caused by deficiency of lysosomal acid lipase (LAL) due to autosomal recessive mutations in *LIPA*. The diagnosis is established by enzyme or gene analyses of LAL or *LIPA* in serum/plasma or nucleated cells, respectively. LAL hydrolyzes cholesterol esters (CEs) and triglycerides (TGs) delivered to the lysosome via the LDLR pathway. Accumulation of these in the tissues leads to progressive organ dysfunction including liver disease, intestinal malabsorption, heart dysfunction, and other manifestations. The most severe form presents in early infancy as a medical emergency with severe failure to thrive, vomiting, and hepatosplenomegaly. The infantile-onset LALD patients die without specific treatment by age 1 year (median age of death, 3.7 months) from tissue accumulations of CEs and TGs and near total absence of LAL. Childhood/adult-onset LALD can have a variable age of initial presentation with nonspecific signs but often involves elevated liver enzymes, microvesicular fatty liver disease, cryptogenic cirrhosis, and varying severities of hepato-/splenomegaly, due to massive accumulations of CEs secondary to the LAL substrate preference for TGs by the low LAL levels. Importantly, neither clinical variant manifests primary CNS disease. Without treatment, disease progresses throughout life and may result in early (adolescence, mean ~13 years) liver cirrhosis and (early adulthood) atherosclerosis or early death. Importantly, statins can decrease the hypercholesterolemia but do not alter the basic progressive tissue (e.g., liver) pathology. The majority of the later onset patients are evaluated by hepatology or lipidology physicians. ET for LALD has major effects in reversing disease manifestations and is approved for patients at all ages by the EMA, FDA, and several other country agencies.

KRABBE DISEASE

Deficiency in β-galactocerebrosidase (GALC) causes Krabbe disease, an autosomal recessive neurodegenerative disorder due to mutations in *GALC*. Krabbe disease is panethnic but quite rare. The early infantile form presents at an average age of 4 months and progresses rapidly, with death at an average age of 18 months. Later onset forms also exist and have onsets and survival that are highly variable. The early-onset form presents with hyperirritability, feeding problems, fever, seizures, and neurodegeneration. Blindness, hypotonia, and loss of voluntary movement develop over time. Later onset forms present with spasticity, ataxia, vision loss, and behavioral problems and progress to dementia and early death. There is no FDA-approved treatment, but early, i.e., first or second month after birth, presymptomatic HSCT has been used. This results in improved survival, but neurologic problems are still common and slowly progressive in the CNS and more severe in the peripheral nervous system. More recently, studies in mouse and dog models have used gene therapy with dramatic improvement in both neurologic function and survival. Human studies are in clinical trials.

NEURONAL CEROID LIPOFUSCINOSIS TYPE 2 (NCL2 OR CLN2)

There are at least 13 mutant genes that have been associated with storage of neuronal ceroid lipofuscin. CLN2 is due to mutations in *TPP1* and deficiency in tripeptidyl peptidase 1. This autosomal recessive neurodegenerative disorder typically presents between age 2 and 4 years, most commonly with seizures, ataxia, myoclonus, and vision loss. Motor skill losses include sitting, walking, speech, and feeding and lead to severe disability and eventually death at an average age of 12 years. Intellectual disability and behavioral problems also become increasingly severe with age. Most affected children are wheelchair bound in late childhood, and survival beyond adolescence is rare. There are also later onset patients, and there is significant clinical overlap between CLN2 and other CLNs; confirmation of the diagnosis by gene sequencing is essential. FDA/EMA-approved treatment of CLN2 is with cerliponase alfa, an ET that is administered by intracerebroventricular infusions over several hours every 2 weeks. Administration of cerliponase alfa is facilitated by placement of an indwelling intracerebroventricular port to allow reliable access. Currently, this is the only approved ET that is intrathecally administered. CLN2 is the only neuronal ceroid lipofuscinosis that has a specific treatment. Several others are in preclinical development.

ALPHA MANNOSIDOSIS

Alpha mannosidosis is a very rare disorder caused by deficiency in α-D-mannosidase due to biallelic loss of function of MAN2B1. This leads to buildup of mannose-rich oligosaccharides in the cells, blood,

and urine. The clinical manifestations include intellectual disability, skeletal changes that can be incapacitating, immunodeficiency, ataxia, poor balance, hearing loss, neurodegeneration, and psychosis. Early treatment with ET has been shown to improve mobility, immune function, and quality of life.

430 Glycogen Storage Diseases and Other Inherited Disorders of Carbohydrate Metabolism

Rebecca L. Koch, Priya S. Kishnani

Carbohydrate metabolism plays a vital role in cellular function by providing the energy required for most metabolic processes. The relevant biochemical pathways involved in the metabolism of these carbohydrates are shown in **Fig. 430-1**. Glucose is the principal substrate of energy metabolism in humans. Metabolism of glucose generates ATP through glycolysis and mitochondrial oxidative phosphorylation. The body obtains glucose primarily through the ingestion of polysaccharides (e.g., starch) and disaccharides (e.g., lactose, maltose, and sucrose). Galactose and fructose are two other monosaccharides that serve as sources of fuel and precursors for cellular metabolism. However, their role as fuel sources is less significant than that of glucose. Galactose is primarily derived from lactose—a disaccharide (galactose + glucose) found in dairy products—and it is an important component of certain glycolipids, glycoproteins, and glycosaminoglycans. Fructose is naturally found in fruits, vegetables, and honey, as well as in foods containing sucrose (fructose + glucose).

The symptoms of the various disorders of carbohydrate metabolism range from minimally harmful to lethal. Clinical and biochemical manifestations of these disorders reflect the enzymatic defect, and as such, there are similarities being recognized in disorders falling along the same metabolic pathways, such as the similar phenotypes observed in disorders of glycogenolysis. Many disorders of carbohydrate metabolism are managed with specific dietary interventions. However, diet therapy alone does not prevent long-term complications, and there is a need for definitive therapies. Genes and corresponding pathogenic variants responsible for inherited defects of carbohydrate metabolism have been identified. With the use of tools such as DNA sequencing panels, whole exome sequencing, whole genome sequencing, and RNA-Seq, new disorders in carbohydrate metabolism continue to be identified and the phenotype of known disorders continues to expand. Advances in the molecular basis of these diseases are now being used to improve diagnosis and management. Some of these disorders are candidates for enzyme replacement therapy, substrate reduction therapy, mRNA therapy, gene replacement therapy, and other genomic tools, such as small interfering RNA (siRNA) technology and genome editing technology.

GLYCOGEN STORAGE DISEASES

Glycogen, the storage form of glucose in animal cells, is a tree-like molecule composed of glucose residues joined in straight chains by α-1,4 linkages and branched at intervals of 4–10 residues by α-1,6 linkages. Inherited defects in glycogen metabolism are referred to as *glycogen storage diseases* (GSDs), also referred to as *glycogenoses*. The glycogen in GSDs may be abnormal in quality (i.e., abnormal structure) and/or quantity. GSDs were historically classified in order of when the enzymatic defects were identified. GSDs are also classified based on the primary organs involved (liver or muscle) as well as clinical manifestations **(Table 430-1)**. The overall prevalence of all forms of GSDs is not known but is estimated to be 1 in 10,000 to 1 in 25,000 live births, with most inherited in an autosomal recessive manner and a few in an X-linked or autosomal dominant manner. With increased access to genetic testing and newborn screening programs, understanding the prevalence of all GSDs will improve. GSDs are pan-ethnic disorders but may have a relatively higher prevalence in certain populations, such as the adult-onset form of GSD IV (adult polyglucosan body disease [APBD]) in individuals of Ashkenazi Jewish ancestry or GSD VI in the Mennonite community. The most common childhood disorders are glucose-6-phosphatase deficiency (GSD type I), lysosomal acid α-glucosidase deficiency (GSD type II), debrancher enzyme deficiency (GSD type III), and liver phosphorylase kinase (PhK) deficiency (GSD type IX). The most common adult disorder is myophosphorylase deficiency (GSD type V).

LIVER GLYCOGEN STORAGE DISEASES

GSD Type I (Glucose-6-Phosphatase or Translocase Deficiency, Von Gierke Disease) GSD type I is an autosomal recessive disorder caused by glucose-6-phosphatase or translocase deficiency in liver, kidney, and intestinal mucosa. There are two subtypes of GSD I: type Ia, in which the glucose-6-phosphatase enzyme is defective (Online Mendelian Inheritance in Man [OMIM] #232200), and type Ib, in which the translocase that transports glucose-6-phosphate from the cytoplasm into the lumen of the endoplasmic reticulum is defective (OMIM #232220). The defects in both subtypes lead to inadequate conversion of glucose-6-phosphate to glucose and thus make affected individuals susceptible to fasting hypoglycemia.

Persons with GSD I typically present with hepatomegaly between 3 and 4 months of age but may present earlier with hypoglycemia and lactic acidosis during the neonatal period. Hypoglycemia and lactic acidosis can develop after a short fast, typically when infants start sleeping through the night or due to an intercurrent illness. Liver biopsy reveals hepatocytes distended by glycogen and fat with large and prominent lipid vacuoles. These children usually have doll-like facies with round cheeks, relatively thin extremities, short stature, and a protuberant abdomen that is due to massive hepatomegaly. The kidneys are enlarged, but the spleen and heart are of normal size. Easy bruising and epistaxis are associated with prolonged bleeding time as a result of impaired platelet aggregation/adhesion and/or an acquired von Willebrand–like disease. Laboratory abnormalities include hyperuricemia, hypertriglyceridemia, lactic acidosis, and lipid profile abnormalities including elevated total and low-density lipoprotein (LDL) cholesterol compared to the lower level of high-density lipoprotein (HDL) cholesterol. The serum of untreated patients is cloudy/milky due to the high concentrations of lipids. Type Ib patients have additional findings of neutropenia and impaired neutrophil function with associated recurrent bacterial infections and chronic oral and intestinal mucosal ulceration with risk for mouth sores, severe diarrhea, and

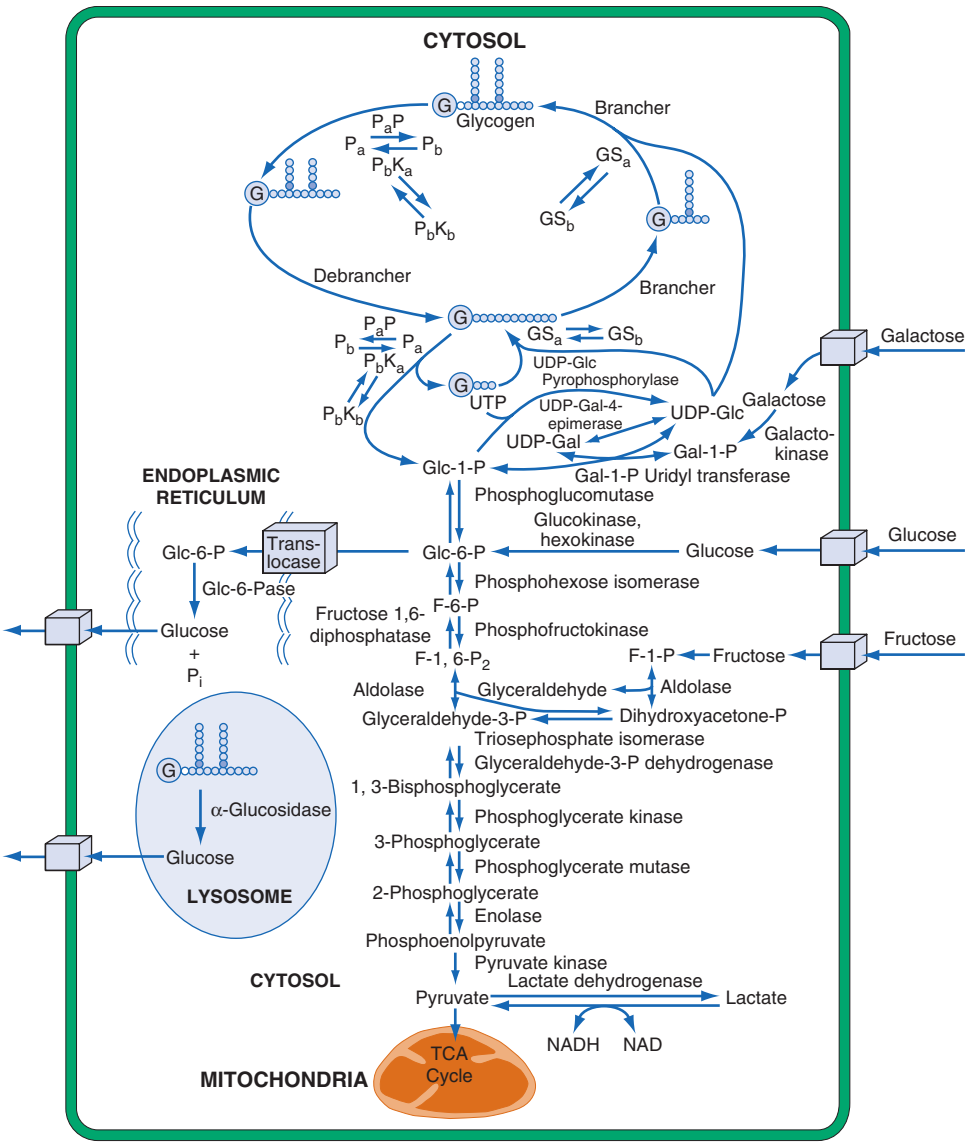

FIGURE 430-1 Metabolic pathways related to glycogen storage diseases and galactose and fructose disorders. Nonstandard abbreviations are as follows: GS_a, active glycogen synthase; GS_b, inactive glycogen synthase; P_a, active phosphorylase; P_b, inactive phosphorylase; P_aP, phosphorylase α phosphatase; P_bK_a, active phosphorylase β kinase; P_bK_b, inactive phosphorylase β kinase; G, glycogenin, the primer protein for glycogen synthesis. *(Modified from AR Beaudet, in KJ Isselbacher et al: Harrison's Principles of Internal Medicine, 13th ed. New York, NY: McGraw Hill; 1994.)*

that fertility is not affected, although symptoms may be exacerbated due to pregnancy-related increases in renal perfusion and maternal blood volume.

The first line of treatment in GSD I is avoidance of fasting and frequent feedings. Due to fasting intolerance, continuous glucose monitoring is useful for monitoring blood glucose levels and trends. GSD I affects both glycogenolysis and gluconeogenesis, and therefore, a diet high in complex carbohydrates supplemented by uncooked cornstarch in small, frequent feedings provides a source of glucose and is used for treatment of both GSD Ia and GSD Ib. Modified, extended-release cornstarch products that are longer acting and better tolerated are available and may help extend the duration of euglycemia and improve metabolic control. Aminotransferase levels may be elevated at baseline, yet often quickly return to normal with treatment. Lipid profile abnormalities and levels of lactate and uric acid can also improve with good metabolic control yet remain a significant concern. Treatment of complications with medications may be necessary, such as citrate supplementation to prevent and/or treat nephrocalcinosis, allopurinol to control hyperuricemia, HMG-CoA reductase inhibitors and fibrate to reduce lipids, and angiotensin-converting enzyme inhibitors to treat microalbuminuria. Surgical resection, percutaneous ethanol injections, and radiofrequency ablation can be used to treat HCA. Liver transplantation can be lifesaving for those with HCA with the risk of malignant transformation to HCC, rapid growth in size or number, and/or severe/chronic poor metabolic control. Dialysis or kidney transplantation may be required in those with renal glomerular dysfunction progressing to end-stage renal disease. Gene replacement therapy and mRNA therapy are in clinical trials as treatment modalities for GSD Ia. Individuals with GSD Ib may require further intervention due to the consequences of neutropenia and neutrophil dysfunction. Historically, granulocyte colony-stimulating factor treatment was used, but empagliflozin, a renal sodium-glucose cotransporter 2 (SGLT2) inhibitor has recently been used to effectively treat the neutrophil dysfunction in GSD Ib. Though less common, there are reports of patients with GSD Ia homozygous for p.G188R variants developing neutropenia, neutrophil dysfunction, and recurrent infections traditionally characteristic of GSD Ib.

malnutrition. Genetic testing provides a noninvasive means of reaching a definitive diagnosis for most patients with GSD types Ia and Ib.

Puberty and growth are often delayed in individuals with GSD I. Long-term complications include gout, which becomes symptomatic at puberty as a result of long-term hyperuricemia in untreated patients. Secondary to lipid abnormalities, there is an increased risk of pancreatitis. Patients with GSD I may be at increased risk for cardiovascular disease such as systemic hypertension and vascular dysfunction, though the latter remains debated. Pulmonary hypertension—although rare—has been reported. In adult patients, frequent fractures can occur, and radiographic evidence of osteopenia/osteoporosis can be found; in prepubertal patients, bone mineral content is significantly reduced. By the second or third decade of life, many patients with GSD I develop hepatocellular adenomas (HCA) that can hemorrhage and, in some cases, patients can develop hepatocellular carcinoma (HCC). End-stage renal disease is a serious late complication. Almost all patients aged >20 years have proteinuria, and many have hypertension, kidney stones, nephrocalcinosis, and altered creatinine clearance. Other complications include thyroid autoimmunity, particularly in GSD Ib, as well as hypercalcemia. Some women with GSD I have polycystic ovaries and menorrhagia; several reports of successful pregnancies suggest

GSD Type III (Debranching Enzyme Deficiency, Limit Dextrinosis, Cori or Forbes Disease) GSD type III (OMIM #232400) is an autosomal recessive disorder caused by a deficiency of glycogen debranching enzyme. PhK, glycogen phosphorylase, and debranching enzyme are collectively responsible for the complete degradation of glycogen into glucose (glycogenolysis). When debranching enzyme is defective, glycogen breakdown is incomplete, resulting in abnormal glycogen accumulation with short outer chains, resembling limit dextrin. GSD III is mainly classified as (1) GSD IIIa, with liver, cardiac, and skeletal muscle involvement (~85% of cases), and (2) GSD IIIb, with primarily liver involvement (~15% of cases). The initial

TABLE 430-1 Features of Glycogen Storage Diseases, Galactose Metabolism Disorders, and Fructose Metabolism Disorders

TYPE	EPONYM	DEFICIENT ENZYME	CLINICAL FEATURES	COMMENTS
Liver Glycogen Storage Diseases				
0a		Glycogen synthase 2	Fasting ketotic hypoglycemia, growth retardation, postprandial hyperglycemia, lactic acidosis, and hyperalaninemia with normal insulin levels	Rare; no hepatomegaly
Ia	von Gierke	Glucose-6-phosphatase-α	Fasting hypoketotic hypoglycemia, lactic acidosis, hypercholesterolemia, hypertriglyceridemia, hyperuricemia, hepatomegaly and renomegaly, hepatic steatosis, short stature, doll-like facies with round cheeks, thin extremities	~80% of type I cases; complications in adolescence and adulthood include HCA with risk for HCC transformation in some, gout, osteoporosis, pulmonary hypertension, renal stones, hyperfiltration injury in early stages that can progress to renal failure, pancreatitis
Ib		Glucose-6-phosphate translocase	As for Ia, with additional findings of neutropenia and neutrophil dysfunction, inflammatory bowel disease, and increased risk for infections, mucosal ulceration, and periodontal disease	~20% of type I cases
IIIa	Cori or Forbes	Glycogen debranching enzyme (liver and muscle)	*Childhood:* Fasting ketotic/nonketotic hypoglycemia, hepatomegaly, short stature, muscle weakness, cardiomyopathy, cardiac arrhythmia, elevated aminotransferases, CK, and urine Glc_4 levels, hyperlipidemia *Adulthood:* Variable progression of liver fibrosis, cirrhosis with risk for liver failure, risk for HCC and HCA noted in some; progression of proximal and distal muscle atrophy and weakness, peripheral neuropathy with preferential median nerve involvement; variable cardiac arrhythmia and cardiomyopathy, PCOS	~85% of type III cases; muscle weakness is both proximal and distal and can progress to need for ambulatory aids such as wheelchair; risk of sudden death from cardiac arrhythmia
IIIb		Glycogen debranching enzyme (liver)	Liver symptoms same as in type IIIa; no skeletal muscle or cardiac symptoms	~15% of type III cases
IV	Andersen	Glycogen branching enzyme	Clinical continuum whereby hepatic, neurologic, cardiac, and muscular involvement can occur to varying degrees *Hepatic form:* Failure to thrive, hepatomegaly, elevated aminotransferase levels, progressive liver fibrosis and liver failure (death usually before age 5 years without liver transplantation); some do not progress to liver failure but may develop extrahepatic involvement such as myopathy and cardiomyopathy and are at risk for hepatic disease progression. Progression to APBD noted in some in adulthood. *Neuromuscular forms:* Perinatal and congenital forms lead to death in the neonatal period/infancy. Less severe involvement may present in early to late childhood with myopathy, neuromuscular dysfunction, and/or cardiomyopathy. *Adult-onset (APBD):* Progressive bilateral lower limb weakness and spasticity, neurogenic bladder (urinary incontinence and/or retention), peripheral neuropathy, cognitive impairment	Rare; APBD is prevalent in individuals of Ashkenazi Jewish ancestry
VI	Hers	Glycogen phosphorylase (liver)	Fasting ketotic/nonketotic hypoglycemia, hepatomegaly, liver fibrosis, hyperlipidemia, short stature	Often underdiagnosed; high prevalence in the Mennonite community; severe cases being recognized; cirrhosis, with progression to HCC has been reported in some; focal nodular hyperplasia and HCA also reported
IX α2 (previously known as IXa) IX γ2 (previously known as IXc) IX β (previously known as IXb)		Phosphorylase kinase (liver) Phosphorylase kinase (liver) Phosphorylase kinase (liver and muscle)	Fasting ketotic/nonketotic hypoglycemia, hepatomegaly, liver fibrosis, hyperlipidemia, elevated aminotransferase and urine Glc_4 levels, short stature In addition to features of liver disease observed in IX α2 and IX γ2, may have mild muscle weakness and hypotonia	GSD IX α2 is more common in males (X-linked, *PHKA2*); clinical phenotype of IX γ2 is often more severe than IX α2 and IX β, yet there is significant clinical variability within and between subtypes with severe cases being recognized in all subtypes; cirrhosis with progression to HCC has been reported; HCA also noted; catch-up growth is common
Fanconi-Bickel syndrome	Fanconi-Bickel	Glucose transporter 2 (GLUT2)	Rickets, short stature, failure to thrive, fasting hypoglycemia, postprandial hyperglycemia (impaired glucose and galactose utilization), hepatomegaly, hypophosphatemia, proximal tubular nephropathy, metabolic acidosis	Rare

TABLE 430-1 Features of Glycogen Storage Diseases, Galactose Metabolism Disorders, and Fructose Metabolism Disorders (Continued)

TYPE	EPONYM	DEFICIENT ENZYME	CLINICAL FEATURES	COMMENTS
Muscle Glycogen Storage Diseases				
0b		Glycogen synthase 1	Cardiomyopathy, cardiac arrythmia, muscle weakness, exercise intolerance	Rare
II	Pompe	Lysosomal acid α-glucosidase	*Classic infantile-onset:* Hypotonia, muscle weakness, cardiomyopathy, fatal within first 2 years of life *Nonclassic infantile-onset:* Presentation within first year of life with less severe cardiomyopathy and slower progression than the classic form *Late-onset:* Absence of cardiomyopathy in first year of life; kinematic/muscle weakness noted as early as first year of life, progressive skeletal muscle weakness, early involvement of proximal lower extremity muscles and respiratory muscles, especially the diaphragm	Higher frequency being reported since advent of newborn screening; enzyme (GAA) levels are undetectable or very low in infantile-onset form and variable in late-onset form when measured in skin or muscle
V	McArdle	Muscle phosphorylase	Exercise intolerance, myalgia, cramps, myoglobinuria with strenuous exercise, increased CK levels; "second wind" phenomenon	
VII	Tarui	Phosphofructokinase-M subunit	As for type V, with additional findings of compensated hemolysis, hyperuricemia; "out of wind" phenomenon rather than "second wind" phenomenon observed in GSD V	Rare, prevalent in individuals of Ashkenazi Jewish ancestry
IX α1 (previously known as IXd)		Phosphorylase kinase (muscle)	Exercise intolerance, myalgia, cramps, muscle weakness and atrophy, myoglobinuria with strenuous exercise	More common in males (X-linked, *PHKA1*)
X		Phosphoglycerate mutase 2	Exercise intolerance, cramps, myoglobinuria with strenuous exercise	Rare, most patients African American
XI – Lactate dehydrogenase A deficiency		Lactate dehydrogenase A	Exercise intolerance, cramps, myoglobinuria with strenuous exercise, dermatitis	Rare; reports of uterine stiffness and pain in pregnant patients
XII		Aldolase A	Muscle weakness, myoglobinuria with strenuous exercise, with additional finding of hemolytic anemia	Rare
XIII		β-enolase	Exercise intolerance, myalgia, cramps, myoglobinuria with strenuous exercise	Rare
XV (also known as polyglucosan body myopathy 2)		Glycogenin-1	Often classified as two subtypes: *GSD XV:* Progressive cardiac arrhythmia and/or cardiomyopathy causing heart failure and necessitating cardiac transplantation in some cases *Polyglucosan body myopathy 2:* Progressive myopathy with proximal and distal muscle weakness	Rare
Danon disease		Lysosomal-associated membrane protein 2	Severe progressive cardiomyopathy with WPW pattern progressing to heart failure, cardiac arrythmia, and heart failure in early childhood/adolescence; myopathy with muscle weakness, retinopathy, intellectual disability, and developmental delay	More common in males (X-linked, *LAMP2*)
PRKAG2 deficiency		AMP-activated gamma 2 protein kinase	Progressive cardiac arrhythmia and cardiomyopathy progressing to heart failure in childhood to adulthood; congenital/infantile form is rapidly fatal with hypertrophic cardiomyopathy with WPW pattern; other involvement includes myalgia and seizures	Autosomal dominant
Galactose Metabolism Disorders				
I (classical galactosemia)		Galactose-1-phosphate uridyltransferase (GALT)	Vomiting, jaundice, sepsis, cataracts, aminoaciduria, hepatomegaly, failure to thrive	Increased risk for developmental delays, speech problems, and motor dysfunction despite early diagnosis and treatment
Clinical variant galactosemia				Less severe disease course compared to classic galactosemia; caused by homozygous p.Ser135Leu variants, most common in African Americans and native South Africans
Biochemical variant galactosemia	Duarte	Galactose-1-phosphate uridyltransferase (GALT)	Asymptomatic	Caused by heterozygous or homozygous c.940A>G;-16_119delGTCA (Duarte variant)
II		Galactokinase (GALK)	Cataracts and pseudotumor cerebri	Clinical continuum with very mild to severe phenotype
III		Uridine diphosphate galactose-4-epimerase (GALE)	Similar to galactosemia type I; additional findings of hypotonia and hearing loss	Benign in some cases; more severe phenotype has been reported in others
IV		Galactose mutarotase (GALM)	Cataracts	Identified in Japan; considered to be mild

(*Continued*)

TABLE 430-1 Features of Glycogen Storage Diseases, Galactose Metabolism Disorders, and Fructose Metabolism Disorders (Continued)

TYPE	EPONYM	DEFICIENT ENZYME	CLINICAL FEATURES	COMMENTS
Fructose Metabolism Disorders				
Essential/benign fructosuria		Fructokinase	Asymptomatic	Benign, incidental finding made through detection of reducing substance in urine
Hereditary fructose intolerance		Aldolase B	Vomiting, jaundice, hepatomegaly, aversion to sweets, failure to thrive, convulsions, postprandial hypoglycemia	Severity of symptoms depending on age and quantity of fructose ingested; prognosis good with early diagnosis and fructose restriction

Abbreviations: APBD, adult polyglucosan body disease; CK, creatine kinase; GSD, glycogen storage disease; HCA, hepatocellular adenoma; HCC, hepatocellular carcinoma; PCOS, polycystic ovarian syndrome; PhK, phosphorylase kinase; WPW, Wolff-Parkinson-White.

presentation of GSD III is similar to that of GSD I with hypoglycemia (typically ketotic, yet some may present with nonketotic hypoglycemia), hepatomegaly, hyperlipidemia, and short stature occurring in infancy and early childhood. A distinguishing feature from GSD I is normal lactate and uric acid, and patients with GSD III have marked elevated aminotransferase levels in early stages that persist and then decrease over time. Levels of urine glucose tetrasaccharide (Glc_4), a breakdown product of glycogen, are typically elevated but follow the same pattern as aminotransferases and decrease over time. In most patients with GSD III, there is an apparent improvement in hepatomegaly and liver enzymes with age; however, there is now a recognition that patients develop progressive liver fibrosis and cirrhosis progressing to liver failure, and some can develop HCC. HCA may occur, although less commonly than in GSD I. Polycystic ovaries are reported in female patients with GSD III, and some patients develop features of polycystic ovarian syndrome, such as hirsutism and irregular menstrual cycles. Reports of successful pregnancy in women with GSD III suggest that fertility is normal.

Patients with GSD IIIa also have a variable skeletal myopathy and cardiomyopathy that can present in the first decade of life; these are often overlooked due to the significant hepatomegaly. Serum creatine kinase (CK) levels can be used to identify patients with muscle involvement, but normal levels are often noted in patients with muscle involvement. Left ventricular hypertrophy, significant scarring of the myocardium, and life-threatening arrhythmias resulting in death have been reported. Patients with GSD IIIa may experience exercise intolerance and muscle weakness in early childhood that can become severe after the third or fourth decade of life, resulting in use of assistive devices and wheelchair dependence. The pattern of muscle weakness is variable, and both proximal and distal muscle weakness are seen. Peripheral neuropathy with preferential median nerve involvement may become discernible later in life; however, there are opposing views concerning the existence of peripheral neuropathy in GSD III. Individuals with GSD IIIa are at an increased risk of osteoporosis.

In the past, diagnosis of GSD IIIa versus IIIb was confirmed by deficient or absent debranching enzyme activity in liver or skeletal muscle (enzyme activity is low in liver and normal in muscle in IIIb). However, with the availability of molecular genetic testing, reliance on invasive tissue biopsies is declining and DNA-based analyses now provide a noninvasive way of subtyping most patients. Specific variants in exon 2 of *AGL* are associated with the GSD IIIb phenotype and can occur with other variants in *AGL*. Liver histology reveals distended hepatocytes due to glycogen buildup and may show fat infiltration; fibrosis is present early on in the disease and has a variable rate of progression.

Debrancher enzyme deficiency prevents complete glycogenolysis in GSD III, but gluconeogenesis is intact. Hence, a high-protein diet with complex carbohydrates supplemented with uncooked cornstarch in small, frequent feedings is effective in preventing hypoglycemia. Individuals with GSD IIIa may benefit from dietary lipid manipulation, such as through the implementation of a high-fat, high-protein diet or use of medium-chain triglyceride supplementation. Careful monitoring of liver function, morphology, lipid profile, and growth is necessary given the potential impact on underlying liver disease and muscle disease progression. Diet therapy is not effective in preventing the overall progression of hepatic disease, cardiomyopathy, and myopathy. Just as in GSD I, continuous glucose monitoring is useful for monitoring blood glucose levels and trends. Blood ketones and glucose should be carefully evaluated during times of stress. Liver and heart transplantation may be considered in those with severe hepatic or cardiac involvement, respectively. Even with liver or heart transplantation, muscle disease continues to progress and is a significant unmet need for these patients.

GSD Type IV (Glycogen Branching Enzyme Deficiency, Andersen Disease, Adult Polyglucosan Body Disease, Amylopectinosis) GSD type IV (OMIM #232500) is caused by deficiency of branching enzyme, leading to accumulation of abnormal glycogen with poor solubility (polyglucosan). The disease is clinically heterogeneous, with multisystem organ involvement, yet the primary presentation was traditionally characterized by manifestations in either liver or muscle; thus, two main types—hepatic and neuromuscular—have been recognized. Individuals with the "classic progressive" hepatic subtype typically present in the first 18 months of life with failure to thrive, hepatosplenomegaly, and progressive liver cirrhosis leading to liver failure and death in the first 5 years of life without liver transplantation. Extrahepatic manifestations including cardiac and nervous system involvement may present and progress after liver transplantation. A less severe hepatic form referred to as the "nonprogressive" hepatic subtype has been observed; in these individuals, liver disease is slowly progressive or attenuated and liver transplantation is not considered urgent. Lifelong monitoring is imperative as there are reports of individuals with hepatic GSD IV that developed HCC, progressed to liver failure, and developed extrahepatic disease manifestations. Some patients have gone on to develop symptoms consistent with APBD.

The neuromuscular forms of the disease have four recognized subtypes: perinatal, congenital, childhood, and adult forms. The perinatal and congenital forms are lethal, and death occurs in the neonatal period. The childhood form presents with myopathy or cardiomyopathy, with typical systemic findings. The adult form is known as APBD (OMIM #263570) and includes central and peripheral nervous system involvement characterized by gait abnormalities due to spastic paraplegia, neurogenic bladder, peripheral neuropathy, leukodystrophy, autonomic dysfunction, and, in the advanced stages, cognitive impairment. Life expectancy is considered to be shortened. APBD has a high prevalence in the Ashkenazi Jewish population (estimated carrier rate 1 in 48).

Definitive diagnosis of GSD IV requires demonstration of pathogenic variants in the *GBE1* gene. Enzyme activity demonstrating reduced glycogen branching enzyme activity in cultured skin fibroblasts, leukocytes, liver, or muscle is supportive of a GSD IV diagnosis. Treatment for all forms of GSD IV is symptomatic. Recently, our understanding of the natural history has improved, and patients with GSD IV are no longer classified by the traditional discrete hepatic/neuromuscular subtypes; rather, GSD IV is conceptualized as a multidimensional clinical continuum whereby hepatic, neuromuscular, and cardiac involvement occurs to varying degrees in different patients.

GSD Type VI (Liver Phosphorylase Deficiency) GSD type VI (OMIM #232700) is an autosomal recessive disorder caused by liver glycogen phosphorylase deficiency. PhK regulates liver glycogen phosphorylase activity by converting the inactive glycogen phosphorylase b form to the active a form (phosphorylated glycogen phosphorylase). Therefore, the clinical presentation of GSD VI is very similar to liver

GSD IX (PhK deficiency) and includes variable fasting hypoglycemia (ketotic or nonketotic), hepatomegaly, elevated aminotransferases, and hyperlipidemia. Historically, GSD VI was thought to have a benign course, but clinical heterogeneity in symptom severity has been observed. Liver fibrosis, cirrhosis, focal nodular hyperplasia, HCA, and HCC have been reported. Diagnosis is confirmed by identifying two pathogenic variants in the *PYGL* gene. Glycogen phosphorylase enzyme levels will be reduced or deficient in liver tissue. It is thought that GSD VI is generally underdiagnosed and has a high prevalence in the Mennonite community (1 in 1000). Just like in other disorders of glycogenolysis (GSD III and IX), gluconeogenesis is intact, and therefore, a high-protein diet is recommended along with small frequent meals with complex carbohydrates and avoidance of fasting to prevent hypoglycemia. Uncooked cornstarch supplementation may be needed to maintain euglycemia, and continuous glucose monitoring is useful for monitoring blood glucose levels and trends. Blood ketones and glucose should be carefully evaluated during times of stress.

GSD Type IX (Liver Phosphorylase Kinase Deficiency) Deficiency of the PhK causes GSD IX, a heterogeneous group of disorders. Similar to patients with GSD VI, patients with hepatic GSD IX typically present with fasting hypoglycemia (ketotic or nonketotic), hepatomegaly, and elevated aminotransferase, cholesterol, triglyceride, and urine Glc_4 levels. The PhK enzyme complex consists of four subunits (α, β, γ, and δ), and each subunit is encoded by different genes that are differentially expressed in various tissues. GSD IX can thus be divided into several subtypes on the basis of the gene/subunit involved.

The most common subtype is GSD IX α2 (also known as GSD IXa; OMIM #306000), an X-linked liver PhK deficiency caused by pathogenic variants in the *PHKA2* gene. PhK activity may also be deficient in erythrocytes and leukocytes but is normal in skeletal muscle. Much like GSD VI, GSD IX α2 has historically been considered to have a benign course, but clinical heterogeneity in symptom severity is being increasingly recognized, with severe disease involvement in some cases. Liver histology shows distention of hepatocytes due to excess glycogen accumulation as well as fibrosis ranging from mild to severe. Other subtypes of type IX liver GSD include GSD IX β (also known as GSD IXb; OMIM #261750) and GSD IX γ2 (also known as IXc; OMIM #613027). GSD IX β is an autosomal recessive form of liver and muscle PhK deficiency caused by *PHKB* pathogenic variants. The affected gene *PHKB* is expressed in the liver and muscle so myopathy may be observed but is typically less severe compared to the liver disease. GSD IX γ2 accounts for 25% of GSD IX and is an autosomal recessive form of liver PhK deficiency due to pathogenic variants in *PHKG2*. GSD IX γ2 is typically a more severe phenotype when compared to GSD IX α2 and GSD IX β due to defects in the catalytic domain of PhK. Affected patients often present with severe liver fibrosis and may progress to cirrhosis. Previously, infants with severe isolated cardiomyopathy and low PhK activity in the heart and muscle were considered to have a subtype of GSD IX; however, there were no pathogenic variants in the genes encoding for the PhK subunits. This presentation was later classified as *PRKAG2 syndrome*, which causes a secondary decrease in PhK activity. Details about PRKAG2 syndrome are described later in the "Muscle Glycogen Storage Diseases" section.

Treatment of liver GSD IX (types α2, β, and γ2) is symptom based. Like in other disorders of glycogenolysis (GSD III and VI), gluconeogenesis is intact, and therefore, a high-protein diet with complex carbohydrates in small, frequent feedings is needed to prevent hypoglycemia. Uncooked cornstarch supplementation may be needed to maintain euglycemia, and continuous glucose monitoring is useful for monitoring blood glucose levels and trends. Blood ketones and glucose should be carefully evaluated during times of stress. Liver transplantation may be considered in those with liver failure. In addition to fibrosis and cirrhosis, HCA and HCC have been observed in adolescents and adults with hepatic GSD IX, and therefore, it is recommended that patients be monitored for hepatic complications with regular computed tomography (CT) or magnetic resonance imaging (MRI) scans.

Though previously thought to be a mild disease, a broad clinical spectrum of presentations is now being recognized in hepatic GSD IX, with more severe cases coming to light, even in the X-linked form. Further research is needed to completely understand the natural history and long-term complications of liver GSD IX.

Other Liver GSDs GSD 0a is a rare disorder caused by deficiency in glycogen synthase 2 (GYS2; OMIM #240600) resulting in abnormal glycogen synthesis in the liver. Clinical features of GSD 0a include fasting ketotic hypoglycemia, short stature, postprandial hyperglycemia, lactic acidosis, and hyperalaninemia with normal insulin levels. Unlike many liver GSDs, hepatomegaly is not a feature of GSD 0a. Fanconi-Bickel syndrome (OMIM #227810), previously referred to as GSD XI-Fanconi-Bickel syndrome, is caused by defects in the facilitative glucose transporter 2 (GLUT-2), which transports glucose in and out of hepatocytes, pancreatic cells, and the basolateral membranes of intestinal and renal epithelial cells. Patients with Fanconi-Bickel syndrome may have increased renal clearance of glucose, amino acids, calcium, phosphate, bicarbonate, and uric acid due to proximal renal tubular dysfunction, impaired glucose and other monosaccharide utilization, and accumulation of glycogen in liver and kidney. Clinical presentations include rickets, short stature, failure to thrive, postprandial hyperglycemia, fasting hypoglycemia, hepatomegaly, hypophosphatemia, proximal tubular nephropathy, and metabolic acidosis.

MUSCLE GLYCOGEN STORAGE DISEASES

GSD Type II (Acid α-1,4 Glucosidase Deficiency, Pompe Disease) Pompe disease (OMIM #232300) is an autosomal recessive lysosomal and glycogen storage disorder caused by a deficiency of lysosomal acid α-glucosidase, an enzyme responsible for the degradation of glycogen to glucose in the lysosomes. This disease is characterized by the accumulation of glycogen in the lysosomes as opposed to primary accumulation in cytoplasm (as in the other GSDs).

At the most severe end of the disease spectrum is classic infantile-onset Pompe disease (IOPD) in which infants present with cardiomyopathy at birth or within the first few weeks of life. Patients develop a generalized muscle weakness with feeding difficulties, macroglossia, and congestive heart failure due to the rapidly progressive hypertrophic cardiomyopathy. Without treatment, patients with IOPD do not survive beyond 2 years of life. A variant form, known as nonclassic IOPD, also presents in the first year of life with less severe cardiomyopathy and slower disease progression. Patients with late-onset Pompe disease (LOPD) can present as early as the first few months of life to as late as the sixth decade. The distinguishing feature of LOPD from IOPD is the absence of cardiomyopathy in the first year of life. The clinical picture in LOPD is dominated by slowly progressive, predominantly proximal limb girdle muscle weakness. The pelvic girdle, paraspinal muscles, and diaphragm are most seriously affected. Respiratory symptoms include sleep apnea, sleep disordered breathing, decreased forced vital capacity, somnolence, morning headache, orthopnea, and exertional dyspnea. Respiratory failure causes significant morbidity and mortality in LOPD. In rare instances, patients present with respiratory insufficiency as the initial symptom. Young children with LOPD may have delayed motor milestones and difficulty in walking. With the advent of newborn screening for Pompe disease, delayed motor milestones and other kinematic/musculoskeletal findings such as scapular winging and weakness of pelvic girdle and core are being recognized as early as the first year of life in some babies with LOPD.

As the disease advances in LOPD, patients may require some form of ventilatory support and become dependent on a walking aid or wheelchair. Basilar artery aneurysms and dilation of the ascending aorta have been observed in some patients. Ptosis, lingual weakness, hypernasality, speech and articulation difficulties, gastrointestinal dysmotility, and bladder/bowel incontinence due to poor sphincter tone are now being recognized as part of the clinical spectrum. There is increasing recognition of central and peripheral nervous system involvement in IOPD with white matter hyperintensities, learning disabilities, slow processing speeds, sensorineural hearing loss, foot-slapping gait, bulbar weakness with dysarthria and dysphagia, and small-fiber neuropathy.

Laboratory findings include elevated levels of serum CK and aminotransferases as well as urine Glc_4, especially at the severe end of

the disease spectrum, and they can be used as biomarkers to monitor disease progression and treatment responsiveness. In IOPD, chest x-ray shows massive cardiomegaly, echocardiogram shows severely elevated left ventricular mass index, and electrocardiographic findings include a high-voltage QRS complex and a shortened PR interval. Electromyography reveals myopathic features, with irritability of muscle fibers and pseudomyotonic discharges, which appears early in the paraspinal muscles. Muscle biopsy typically shows vacuoles that stain positive for glycogen, rupture of lysosomal membranes, and accumulation of glycogen in the cytoplasm from lysosomal spillover; the muscle acid phosphatase level is increased, presumably from a compensatory increase of lysosomal enzymes. Note that serum CK is not always elevated in LOPD, and depending on the muscle biopsied or tested, muscle histology or electromyography results may appear normal due to heterogeneity in muscle disease severity, and therefore, normal results do not rule out a diagnosis. There is an increasing role of muscle ultrasound and MRI as noninvasive biomarkers to assess extent and progression of disease involvement.

The confirmatory step for a diagnosis of Pompe disease is enzyme testing demonstrating deficient acid α-glucosidase (GAA), which can be measured in muscle, cultured skin fibroblasts, or blood; the latter is increasingly being used and is very reliable when performed in laboratories with experience. Enzyme levels when measured in skin or muscle are undetectable or very low in IOPD (typically <1%), whereas they are more variable in LOPD (typically 2–35%). In addition, gene sequencing can identify two pathogenic variants in the *GAA* gene and confirms the diagnosis.

The approval of enzyme replacement therapy (ERT) with alglucosidase alfa in 2006 has been lifesaving and has changed the clinical course of Pompe disease with substantial improvements in prognosis of IOPD and LOPD. Two next-generation ERT therapies have recently received approval by the U.S. Food and Drug Administration and the European Medicines Agency (avalglucosidase alfa and cipaglucosidase alfa with miglustat); both have improved targeting to the skeletal muscle. Patients with IOPD who make no endogenous GAA protein are classified as cross-reactive immunologic material (CRIM) negative. As a result of their CRIM-negative status, their immune system recognizes the recombinant GAA in ERT as a foreign protein and they typically develop high and sustained antibody titers to ERT that renders the treatment ineffective. Immunomodulation at the time of ERT initiation is used to induce immune tolerance in CRIM-negative patients. It is also used in some CRIM-positive patients who are considered at risk of mounting an immune response. Other adjunctive treatment options for Pompe disease include use of β_2 agonists, dietary modifications, submaximal aerobic exercise, and respiratory muscle strength training. Early diagnosis with early ERT initiation is the key to treatment efficacy. Gene replacement therapy, substrate reduction therapy (GYS1 inhibition), and therapies that can cross the blood brain barrier are being studied in early-phase clinical studies as additional treatment modalities.

Pompe disease is now part of the recommended uniform screening panel (RUSP) for newborns in the United States. In Taiwan where newborn screening for Pompe disease is performed routinely for all infants, early disease detection and treatment initiation have led to better treatment outcomes in patients with Pompe disease. Similar evidence is also emerging in the United States.

GSD Type V (Muscle Phosphorylase Deficiency, McArdle Disease) GSD type V (OMIM #232600) is an autosomal recessive disorder caused by deficiency of muscle phosphorylase. McArdle disease is a prototypical muscle-energy disorder, as the enzyme deficiency limits ATP generation by glycogenolysis and results in glycogen accumulation.

There can be a broad, heterogeneous spectrum of clinical presentations in the neonatal period with rapidly fatal at one extreme and the classical form (myalgia, cramps, and myoglobinuria) at the other. Symptom onset as late as the eighth decade has been reported. Patients typically develop muscle stiffness, pain, and weakness induced by exercise. The degree of muscle involvement is variable among the symptomatic patients; however, the exercise intolerance typically worsens over time due to inability to break down glycogen to glucose and thus a defect in the ability to convert glucose to lactate. Symptoms can be precipitated by (1) brief, high-intensity activity, such as sprinting or carrying heavy loads; and/or (2) less intense but sustained activity, such as climbing stairs or walking uphill. Most patients can engage in moderate exercise, such as walking on level ground, for extended periods. Patients often exhibit the "second wind" phenomenon in which they are able to continue the activity without pain after taking a short break from the initiation of strenuous physical effort; this phenomenon is unique to GSD V and is due to fatty acid oxidation becoming the main energy source, rather than glycogenolysis and anaerobic glycolysis, as exercise progresses. Burgundy-colored urine resulting from myoglobinuria secondary to rhabdomyolysis is reported after strenuous exercise. Acute renal failure and acute compartment syndrome can result from intense myoglobinuria after vigorous exercise. Although most patients experience episodic muscle pain and cramping because of exercise, 35% report permanent pain that seriously affects sleep and other activities. In rare cases, electromyographic findings may suggest inflammatory myopathy, a diagnosis that may be confused with polymyositis. Patients with GSD V are at risk for statin-induced myopathy and rhabdomyolysis as well as malignant hyperthermia warranting precautions for halogenated anesthetics and muscle relaxants.

At rest, the serum CK level is usually elevated; after exercise, the CK level increases even more. Exercise leads to an increase in levels of blood ammonia, inosine, hypoxanthine, and uric acid; these abnormalities reflect residues of accelerated muscle purine nucleotide recycling as a result of insufficient ATP production. Lack of increase in blood lactate suggests a defect in the conversion of glycogen/glucose to lactate. NADH is also underproduced during physical exertion. Historically, exaggerated blood ammonia elevations after an ischemic exercise test were indicative of a muscle GSD and suggested a defect in the conversion of glycogen or glucose to lactate. An ischemic exercise test is typically no longer used; instead, a noninvasive, nonischemic forearm exercise test has been developed and is easy to perform, has high sensitivity, and is cost-effective. However, the abnormal exercise response does not exclude other muscle GSDs and includes some risk. The cycle test detects the hallmark heart rate observed during the second-wind phenomenon.

A diagnostic confirmation is established by demonstration of pathogenic variants in the myophosphorylase gene (*PYGM*) or by enzymatic assay in muscle tissue. Clinically asymptomatic individuals with absent muscle phosphorylase activity have been identified due to elevated serum CK levels.

Treatment for GSD V consists of pre-exercise consumption of simple carbohydrates (e.g., sucrose or sports drinks) to protect muscles and improve exercise tolerance prior to the onset of the second wind. Regular exercise at moderate intensity is recommended to improve exercise capacity. Compared to patients who are physically inactive, those who are physically active are known to have improved cardiorespiratory fitness and a better long-term clinical course. Patients with GSD V are considered to have an increased risk of coronary artery disease. Additionally, poor bone health, reduced lean body mass, and increased body mass index (BMI) have been observed in inactive patients. Ocular involvement, including ptosis and retinal abnormalities, is becoming increasingly recognized.

GSD VII (Phosphofructokinase Deficiency, Tarui Disease) GSD type VII (Tarui disease; OMIM #232800) is an autosomal recessive disorder caused by phosphofructokinase M subunit deficiency, which results in impaired glycolysis in the skeletal muscle and red blood cells. Clinical presentations are similar to GSD V, with exercise intolerance, fatigue, myalgia, cramps, and increased CK and myoglobinuria with strenuous exercise, increasing risk for life-threatening complications including acute renal failure and compartment syndrome. However, there are some key differences that are important to recognize and consider when managing the disease. Unlike GSD V, an "out of wind" phenomenon occurs where exercise intolerance is particularly worse after meals rich in carbohydrates because increased

glucose levels inhibit lipolysis and deprive skeletal muscle of fatty acid and ketones. Additionally, unlike in GSD V, in GSD VII, there is no spontaneous "second wind" phenomenon because of the inability of muscle to metabolize glucose efficiently. Therefore, consumption of simple carbohydrates prior to or during exercise can be detrimental and worsen exercise capability. Compensatory hemolysis and hyperuricemia are also observed in GSD VII. Gouty arthritis associated with hyperuricemia is more prominent in GSD VII compared to GSD V. Like GSD V, patients with GSD VII are at risk for statin-induced myopathy and rhabdomyolysis as well as malignant hyperthermia. Diagnosis is confirmed through genetic testing of the *PFKM* gene. Unlike in GSD V, muscle glycogen content is not markedly elevated in GSD VII. Treatment includes avoidance of strenuous exercise, compressive devices, and tourniquets. The use of IV dextrose in the clinical setting should be avoided. The use of dietary therapy remains unclear.

GSD Type IX (Muscle Phosphorylase Kinase Deficiency) GSD IX α1 (also known as GSD IXd; OMIM #300559) is an X-linked disorder due to muscle PhK deficiency caused by pathogenic variants in the *PHKA1*. There are limited cases of GSD IX α1 reported in the literature. Patients can present at any time from early childhood to adulthood with symptoms including exercise intolerance, fatigue, cramps, hypotonia, and progressive muscle weakness and atrophy. They are at risk for rhabdomyolysis. Electromyographic findings may be normal. Treatment for muscle PhK deficiency is symptomatic. Long-term natural history data are needed to better understand GSD IX α1.

GSD Type XV (Polyglucosan Body Myopathy 2) GSD type XV (OMIM #613507) is an autosomal recessive myopathy caused by variants in the *GYG1* gene impairing glycogenin-1 function. *GYG1* pathogenic variants result in a reduced or complete absence of glycogenin-1, which impacts its autoglycosylation and/or its interaction with glycogen synthase, resulting in impaired glycogen synthesis and formation of polyglucosan. Historically, polyglucosan body myopathy 2 (OMIM #616199) was termed for individuals with pathogenic variants in the *GYG1* gene who have progressive skeletal myopathy. Limited cases have been reported, and affected individuals commonly present with adult-onset proximal and distal muscle weakness predominantly affecting the hip and shoulder girdles. The disease course is often progressive, with the most disabling muscle weakness found at older age. Alternatively, GSD XV is often termed for individuals with pathogenic variants in the *GYG1* gene who have severe cardiac involvement without musculoskeletal manifestations. In these cases, cardiomyopathy, cardiac arrhythmia, and cardiac failure have necessitated cardiac transplantation. Further natural history data on GSD XV are needed. There is increasing awareness of GSD XV as a spectrum disorder with different degrees of both cardiac and skeletal muscle involvement.

Danon Disease Danon disease (OMIM #300257) is an X-linked lysosomal and glycogen storage disorder caused by pathogenic variants in the *LAMP2* gene. Deficiency of lysosomal-associated membrane protein 2 (LAMP2) results in defective autophagosomal-lysosomal fusion and excessive accumulation of autophagosomes in the heart and skeletal muscle. Patients with Danon disease present primarily with hypertrophic cardiomyopathy but can be distinguished by electrophysiologic abnormalities, particularly ventricular preexcitation and conduction defects. In Danon disease, Wolff-Parkinson-White (WPW) syndrome pattern is five times greater in prevalence than in idiopathic and familial hypertrophic cardiomyopathy. Therefore, in a young male with hypertrophic cardiomyopathy, the presence of WPW pattern on electrocardiogram strongly suggests Danon disease. The onset of cardiac symptoms in males typically occurs in childhood or adolescence and includes chest pain, palpitations, syncope, and cardiac arrest. Ocular manifestations are often underrecognized and include peripheral pigmentary retinopathy, lens changes, and abnormal electroretinograms. Elevated aminotransferase and CK levels and respiratory weakness have been observed due to underlying muscle involvement as well as sequelae of progressive cardiac disease. Mild learning disability and cognitive deficits have been noted, as well as speech and language delays, attention deficits, behavioral problems, and dysmetria. The prognosis for Danon disease is poor, with progressive end-stage heart failure in early adulthood. Female carriers can also be symptomatic; although the disease is less severe compared to males, cardiomyopathy, skeletal myopathy, retinopathy, and cognitive dysfunction have been described. Treatment is symptomatic and involves management of heart failure, correction of conduction abnormalities, and physical therapy, among others. Heart transplantation can be considered for cases with rapid progression or end-stage heart failure. Neuropsychological evaluations and special education support may be required for those with intellectual disabilities. Gene replacement therapy is under early-phase clinical studies.

PRKAG2 Syndrome AMP-activated protein kinase gamma 2 (PRKAG2; OMIM #261740) deficiency, known as PRKAG2 syndrome, is an autosomal dominant disorder caused by pathogenic variants in the *PRKAG2* gene. PRKAG2 is important in many cellular ATP metabolic pathways, and affected individuals present with cardiac abnormalities including hypertrophic cardiomyopathy and conduction system abnormalities, particularly WPW syndrome. The extent of cardiac involvement in PRKAG2 syndrome is variable and includes supraventricular tachycardia, sinus bradycardia, left ventricular dysfunction, or even sudden cardiac death in some cases. In addition to cardiac involvement, there is a broad spectrum of phenotypic presentations including myopathy, myalgia, and seizures. Other manifestations include developmental delays, hypotonia, areflexia, tremors, feeding difficulties, frequent respiratory infections, and failure to thrive. Unlike Danon disease, cardiomyopathy due to *PRKAG2* pathogenic variants is compatible with longer-term survival except for a congenital form that presents in early infancy with a rapid fatal course due to massive glycogen deposition in the myocardium. PRKAG2 syndrome should be considered as a differential diagnosis in infants presenting with severe hypertrophic cardiomyopathy. Cardiac biopsy may reveal the presence of glycogen and polyglucosan in vacuoles in cardiomyocytes. In rare instances, patients with PRKAG2 syndrome may be misdiagnosed as having IOPD due to phenotypical similarity. Treatment is symptomatic, and heart transplantation is indicated for those in end-stage heart failure.

Other Muscle GSDs GSD IIIa, IV, and IX β have muscle involvement as mentioned in each respective subsection under "Liver Glycogen Storage Diseases." GSD 0b is a rare disorder caused by deficiency in muscle glycogen synthase (GYS1; OMIM #138570). The skeletal and cardiac muscles are affected. Only a handful of cases with GSD 0b have been described, and clinical presentations include sudden cardiac death in middle childhood. Additional enzyme defects produce muscle glycogenosis with muscle energy impairment, namely deficiencies in phosphoglycerate mutase (GSD X; OMIM #261670), lactate dehydrogenase A (GSD XI-lactate dehydrogenase A deficiency; OMIM #612933), aldolase A (GSD XII; OMIM #611881), and β-enolase (GSD XIII; OMIM #612932). Clinical presentations include myopathy and risk for rhabdomyolysis similar to GSD V and VII. Deficiency of aldolase A is also associated with hemolytic anemia.

DISORDERS OF GALACTOSE METABOLISM

Galactose is found in high concentrations in foods that contain lactose, such as dairy products. The term *galactosemia* refers to four distinct inborn errors of galactose metabolism; however, *galactosemia* has historically been designated galactose-1-phosphate uridyltransferase (GALT) deficiency (galactosemia type I) because it is the most prevalent form.

GALACTOSEMIA TYPE I (GALACTOSE-1-PHOSPHATE URIDYLTRANSFERASE DEFICIENCY)

GALT deficiency (OMIM #230400) encompasses three subtypes: classical, clinical variant, and biochemical variant galactosemia. *Classic galactosemia* is caused by GALT deficiency with a GALT enzyme activity that is absent or barely detectable. It is a severe disease with an incidence of 1 in 16,000 to 60,000 and an early onset of symptoms. A newborn infant typically receives up to 40% of total daily energy intake

as lactose (glucose plus galactose) through breastmilk or milk-based formulas. Without the functional GALT enzyme, the infant is unable to metabolize galactose-1-phosphate (Fig. 430-1), which consequently accumulates and results in injury to the kidneys, liver, central nervous system, eyes, and, in the long term, the ovaries. After the first feeding, infants can present with vomiting, diarrhea, jaundice, hepatomegaly, aminoaciduria, lethargy, and feeding difficulties. There is an increased risk for susceptibility to infection with gram-negative organisms, such as *Escherichia coli*, often with the onset of sepsis preceding the diagnosis of galactosemia. Additional findings may include convulsions/seizures, failure to thrive, cataracts, bleeding diathesis, hypoglycemia, and cerebral edema. Widespread newborn screening (NBS) for galactosemia has identified these infants early and permitted prompt placement on dietary restriction. Elimination of galactose from the diet reverses growth failure as well as renal and hepatic dysfunction, improving the prognosis. However, even with early dietary treatment, long-term developmental outcomes in classic galactosemia are poor, with most patients having motor speech disorders and learning disabilities that may increase in severity with age. The development of cataracts, tremors, and low bone density is common in adults. Impaired motor function and balance (with or without overt ataxia) is frequently seen. Ovarian dysfunction manifesting as primary or secondary amenorrhea is seen in females, with 80–90% or more of women reporting hypergonadotropic hypogonadism. While most female patients are subfertile due to primary ovarian insufficiency, a few successful pregnancies have been reported. The treatment of galactosemia to prevent long-term complications remains a challenge.

Genotype and phenotype relationship is well established in galactosemia with the Q188R mutation in homozygosity causing classic galactosemia. The p.Ser135Leu variant causes *clinical variant galactosemia*, which is more common in the African American and native South African populations and is associated with a less severe disease course due to residual GALT activity (typically absent or barely detectable in erythrocytes but ~10% in liver and intestinal tissue). Elimination of galactose from the diet is recommended for clinical variant galactosemia. African Americans with clinical variant galactosemia (homozygous p.Ser135Leu variants) and adequate early treatment do not typically develop the long-term complications observed in classic galactosemia, including primary ovarian insufficiency. The *Duarte variant* (c.940A>G;-16_119delGTCA), also known as the *D variant* or *D_2 variant*, is considered to be protective and causes the *biochemical variant galactosemia*, which is asymptomatic despite reduced GALT enzyme activity (typically ~25%) and elevated galactose-1-phosphate levels in red blood cells. Dietary therapy for the biochemical variant galactosemia is no longer recommended.

GALACTOSEMIA TYPE II (GALACTOKINASE DEFICIENCY)

Galactokinase (GALK) deficiency (galactosemia type II; OMIM #230200) has an estimated prevalence of 1 in 50,000 to 2,200,000. A higher incidence is observed in individuals of Romanian origin (estimated carrier rate 1 in 47). Unlike the multisystemic symptoms associated with galactosemia type I, the only consistently reported abnormalities in GALK deficiency are cataracts without visual impairment and, rarely, pseudotumor cerebri. Other findings include hyperbilirubinemia, bleeding diathesis, and elevated aminotransferases. There have been reports of intellectual impairments, which can be severe in some cases. Since many NBS programs measure GALT activity and not galactose levels directly, diagnosing GALK deficiency often entails ruling out GALT deficiency. Elimination of galactose in the diet is recommended.

GALACTOSEMIA TYPE III (URIDINE DIPHOSPHATE GALACTOSE-4-EPIMERASE DEFICIENCY)

Deficiency of uridine diphosphate galactose-4-epimerase (GALE) causes galactosemia type III (OMIM #606953), which is considered to be rare but more common than GALK deficiency. The benign form (also known as peripheral GALE deficiency) is incidentally discovered through NBS; the enzyme deficiency is limited to white and red blood cells, and no dietary treatment is required. The intermediate form is associated with reduced GALE activity in white and red blood cells as well as in other tissue cells. Neonates with the intermediate form may be asymptomatic despite consuming galactose-containing foods. A more severe form has also been recognized and is due to generalized GALE deficiency in all tested tissues. Clinical manifestations resemble GALT deficiency with cataracts and damage to the liver, kidney, and brain. Hypotonia and sensorineural hearing loss have also been observed. Dietary restriction—not elimination—of galactose is indicated for both the intermediate and severe forms. Galactose is an essential component of many structural proteins in the nervous system, and patients with GALE deficiency cannot synthesize UDP-galactose from glucose; therefore, complete elimination of galactose is not recommended.

GALACTOSEMIA TYPE IV (GALACTOSE MUTAROTASE DEFICIENCY)

Galactosemia type IV (OMIM #618881) is a newly recognized autosomal recessive conditionm and there are few documented cases. Deficiency of galactose mutarotase (GALM) was incidentally identified through NBS in Japan. GALM deficiency is considered to be mild, and cataracts are the only reported persistent symptom.

DISORDERS OF FRUCTOSE METABOLISM

Fructose naturally occurs in high concentrations in fruits and foods containing sucrose. Two inborn errors of the metabolism are associated with the fructose metabolism pathway: essential/benign fructosuria and hereditary fructose intolerance as a part of glycolysis. Fructolysis occurs predominantly in the liver.

ESSENTIAL/BENIGN FRUCTOSURIA

Essential/benign fructosuria (OMIM #229800) is an autosomal recessive condition affecting the *KHK* gene causing deficiency of ketohexokinase, commonly referred to as fructokinase (Fig. 430-1). It is a benign condition incidentally diagnosed from the presence of fructose as a reducing substance in the urine. No treatment is necessary.

HEREDITARY FRUCTOSE INTOLERANCE

Deficiency of fructose-1,6-bisphosphate aldolase (aldolase B; hereditary fructose intolerance; OMIM #229600) is a severe disease in infants. These patients are healthy and asymptomatic until fructose is ingested, usually from fruit, fruit juice, sweetened cereal, or sucrose-containing formula. Aldolase B deficiency causes fructose-1-phosphate accumulation and ATP depletion, which inhibits gluconeogenesis and glycogenolysis and can lead to a rapid drop in blood glucose shortly after consumption of fructose or related sugars. Clinical manifestations resemble galactosemia and include jaundice, hepatomegaly, vomiting, lethargy, irritability, and convulsions. Ingestion of large amounts of fructose can result in progressive coma. Laboratory findings show prolonged clotting time, hypoalbuminemia, elevation of bilirubin and aminotransferase levels, and proximal renal tubular dysfunction. If the disease goes undiagnosed and the intake of fructose continues, postprandial hypoglycemic episodes recur, and eventually death can occur from progressive liver and renal failure. Hepatomegaly, liver fibrosis, Fanconi-like syndrome, and nephrocalcinosis have been observed. The mainstay of treatment is the elimination of all sources of sucrose, fructose, and sorbitol from the diet and medications. Older patients tend to develop an aversion to fructose-containing foods. With early and consistent dietary treatment, liver and kidney dysfunction improve and catch-up growth is common. Hepatic steatosis has been observed even in treated individuals. The long-term prognosis of treated individuals is good. The incidence of celiac disease is higher among patients with hereditary fructose intolerance (>10%) than in the general population (1–3%).

GLOBAL CONSIDERATIONS

GSDs and other inherited disorders of carbohydrate metabolism, although individually rare, are reported in most ethnic populations. The prevalent genetic variants for each disease may vary in different

ethnic populations, but clinical symptoms are remarkably similar, and treatment guidelines apply to all. Symptomatic treatment is available for these disorders, and today, advances in the field including newborn screening have resulted in more definitive diagnosis and better treatment approaches. There are many promising therapies on the horizon with several ongoing clinical trials, including those investigating the use of ERT, mRNA therapy, gene replacement therapy, gene editing, and substrate reduction therapy. In the past, prognosis for many disorders of carbohydrate metabolism was guarded, but with early diagnosis and better management, survival rates have improved and many affected children are surviving into adulthood.

431 Inherited Disorders of Amino Acid Metabolism in Adults

Nicola Longo

Amino acids are the building blocks of proteins and serve as neurotransmitters (glycine, glutamate, γ-aminobutyric acid) or as precursors of hormones, coenzymes, pigments, purines, or pyrimidines. Eight amino acids, referred to as *essential* (histidine, isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine), cannot be synthesized by humans and must be obtained from dietary sources. The others can be formed endogenously. Each amino acid has a unique degradative pathway by which its nitrogen and carbon components are used for the synthesis of other amino acids, carbohydrates, and lipids. Disorders of amino acid metabolism and transport **(Chap. 432)** are individually rare—the incidences range from 1 in 10,000 for cystinuria or phenylketonuria to 1 in 200,000 for homocystinuria or alkaptonuria—but collectively, they affect perhaps 1 in 4000 newborns. Almost all are transmitted as autosomal recessive traits.

The features of inherited disorders of amino acid catabolism are summarized in **Table 431-1**. In general, these disorders are named for the compound that accumulates to highest concentration in blood (*-emias*) or urine (*-urias*). In the aminoacidopathies, the parent amino acid is found in excess, whereas products in the catabolic pathway accumulate in organic acidemias. Which compound(s) accumulates depends on the site of the enzymatic block, the reversibility of the reactions proximal to the lesion, and the availability of alternative pathways of metabolic "runoff." Biochemical and genetic heterogeneity are common. Six distinct forms of hyperphenylalaninemia and nine forms of homocystinuria (with or without methylmalonic acidemia) are recognized. Such heterogeneity reflects the complexity of amino acid metabolism requiring multiple enzymes (gene products) for proper functioning.

The manifestations of these conditions differ widely (Table 431-1). Some, such as sarcosinemia, produce no clinical consequences. At the other extreme, complete deficiency of ornithine transcarbamylase is lethal in the untreated neonate. Central nervous system (CNS) dysfunction, in the form of delays in development/intellectual disability, seizures, or behavioral disturbances, is present in more than half the disorders. Protein-induced vomiting, neurologic dysfunction, and hyperammonemia occur in many disorders of the urea cycle. Metabolic ketoacidosis, often accompanied by hyperammonemia, is frequent in organic acidemias. Some disorders produce focal tissue or organ involvement such as liver disease, renal failure, cutaneous abnormalities, or ocular lesions.

Defects in the synthesis of nonessential amino acids (asparagine, glutamine, proline, serine) involve predominantly the brain with neurologic symptoms, with other organs occasionally affected. Dominant mutations in at least one of these genes can cause tremor or spastic paraplegia in adults.

The analysis of plasma amino acids (by ion-exchange chromatography or liquid chromatography/tandem mass spectrometry), urine organic acids (by gas chromatography/mass spectrometry), and plasma acylcarnitine profile (by tandem mass spectrometry) is commonly used to diagnose and monitor most of these disorders. The diagnosis is confirmed by enzyme assay on cells or tissues from the patients or, more commonly, by DNA testing. The clinical manifestations in many of these conditions can be prevented or mitigated if a diagnosis is achieved early and appropriate treatment (e.g., dietary protein or amino acid restriction or vitamin supplementation) is instituted promptly. For this reason, newborn screening programs seek to identify several of these disorders. Infants with a positive screening test need additional metabolic testing (usually suggested by the newborn screening program) to confirm or exclude the diagnosis. Confirmed

TABLE 431-1 Inherited Disorders of Amino Acid Metabolism

AMINO ACID(S)	CONDITION	ENZYME DEFECT	CLINICAL FINDINGS	INHERITANCE
Phenylalanine	Phenylketonuria	Phenylalanine hydroxylase	Intellectual disability, microcephaly, hypopigmented skin and hairs, eczema, "mousy" odor	AR
	DHPR deficiency	Dihydropteridine reductase	Intellectual disability, hypotonia, spasticity, myoclonus	AR
	PTPS deficiency	6-Pyruvoyl-tetrahydropterin synthase	Dystonia, neurologic deterioration, seizures, intellectual disability	AR
	GTP cyclohydrolase 1 deficiency	GTP cyclohydrolase 1	Intellectual disability, seizures, dystonia, temperature instability	AR
	Carbinolamine dehydratase deficiency	Pterin-4α-carbinolamine dehydratase	Transient hyperphenylalaninemia (benign)	AR
	DNAJC12 deficiency	Hydroxylase co-chaperone	Dystonia, parkinsonism, intellectual disability	AR
Tyrosine	Tyrosinemia type 1 (hepatorenal)	Fumarylacetoacetate hydrolase	Liver failure, cirrhosis, rickets, failure to thrive, peripheral neuropathy, "boiled cabbage" odor	AR
	Tyrosinemia type 2 (oculocutaneous)	Tyrosine transaminase	Palmoplantar keratosis, painful corneal erosions with photophobia, learning disability	AR
	Tyrosinemia type 3	4-Hydroxyphenylpyruvate dioxygenase	Hypertyrosinemia with normal liver function, occasional mental delay	AR
	Hawkinsinuria	4-Hydroxyphenylpyruvate dioxygenase	Transient failure to thrive, metabolic acidosis in infancy	AD
	Alkaptonuria	Homogentisic acid oxidase	Ochronosis, arthritis, cardiac valve involvement, coronary artery calcification	AR
	Maleylacetoacetate isomerase deficiency	Maleylacetoacetate isomerase	No clinical symptoms, elevated succinylacetone in blood and urine	AR
	Albinism (oculocutaneous)	Tyrosinase	Hypopigmentation of hair, skin, and optic fundus; visual loss; photophobia	AR
	Albinism (ocular)	Different enzymes or transporters	Hypopigmentation of optic fundus, visual loss	AR, XL
	DOPA-responsive dystonia	Tyrosine hydroxylase	Rigidity, truncal hypotonia, tremor, intellectual disability	AR
GABA	4-Hydroxybutyric aciduria	Succinic semialdehyde dehydrogenase	Seizures, intellectual disability, hypotonia	AR
	ABAT deficiency	GABA transaminase	Seizures, intellectual disability, hypotonia	AR
Tryptophan	Hydroxykynureninuria	Kynureninase	Intellectual disability, spasticity	AR
Histidine	Histidinemia	Histidine-ammonia lyase	Benign	AR
	Urocanic aciduria	Urocanase	Occasional intellectual disability	AR
	Formiminoglutamic aciduria	Formiminotransferase	Occasional intellectual disability	AR
Glycine	Glycine encephalopathy	Glycine cleavage (4 enzymes)	Infantile seizures, lethargy, apnea, profound intellectual disability	AR
	Sarcosinemia	Sarcosine dehydrogenase	Benign	AR
	Hyperoxaluria type I	Alanine:glyoxylate aminotransferase	Calcium oxalate nephrolithiasis, renal failure	AR
	Hyperoxaluria type II	D-Glyceric acid dehydrogenase/ glyoxylate reductase	Calcium oxalate nephrolithiasis, renal failure	AR
Serine	3-PGDH deficiency	Phosphoglycerate dehydrogenase	Seizures, microcephaly, intellectual disability	AR
	PSAT1 deficiency	Phosphoserine aminotransferase	Seizures, microcephaly, intellectual disability	AR
	PSP deficiency	Phosphoserine phosphatase	Seizures, microcephaly, intellectual disability	AR
Proline	Hyperprolinemia type 1	Proline oxidase	Benign	AR
	Hyperprolinemia type 2	Δ^1-Pyrroline-5-carboxylate dehydrogenase	Febrile seizures, intellectual disability	AR
	Hyperhydroxyprolinemia	Hydroxyproline oxidase	Benign	AR
	Prolidase deficiency	Prolidase	Mild intellectual disability, chronic dermatitis, autoimmunity	AR
	PYCR1 deficiency	Pyrroline-5-carboxylate reductase 1	Wrinkly skin, joint laxity, typical facial features, intellectual disability, osteopenia, intrauterine growth retardation, hypotonia	AR
	PYCR2 deficiency	Pyrroline-5-carboxylate reductase 2	Microcephaly, hypomyelination, and reduced cerebral white matter volume, failure to thrive, intellectual disability, movement disorders, seizures	AR
Proline (ornithine, arginine, citrulline)	Δ^1-Pyrroline-5-carboxylate synthase deficiency	Δ^1-Pyrroline-5-carboxylate synthase	Hypotonia, seizures, neurodegeneration, peripheral neuropathy, joint laxity, skin hyperelasticity, subcapsular cataracts, hyperammonemia, adult spastic paraparesis (AD)	AR, AD
Methionine	Hypermethioninemia	Methionine adenosyltransferase	Usually benign	AR
	S-Adenosylhomocysteine hydrolase deficiency	*S*-Adenosylhomocysteine hydrolase	Hypotonia, intellectual disability, absent tendon reflexes, delayed myelination	AR
	Glycine *N*-methyltransferase deficiency	Glycine *N*-methyltransferase	Elevated liver transaminases	AR
	Adenosine kinase deficiency	Adenosine kinase	Intellectual disability, seizures, liver dysfunction	AR

(*Continued*)

TABLE 431-1 Inherited Disorders of Amino Acid Metabolism (Continued)

AMINO ACID(S)	CONDITION	ENZYME DEFECT	CLINICAL FINDINGS	INHERITANCE
Homocysteine	Homocystinuria	Cystathionine β-synthase	Lens dislocation, thrombotic vascular disease, intellectual disability, osteoporosis	AR
	Homocystinuria	5,10-Methylenetetrahydrofolate reductase	Intellectual disability, gait and psychiatric abnormalities, recurrent strokes	AR
	Homocystinuria	Methionine synthase and Methionine synthase reductase (cblE, G)	Intellectual disability, hypotonia, seizures, megaloblastic anemia	AR
	Homocystinuria and methylmalonic acidemia	Vitamin B_{12} lysosomal efflux and metabolism (cblC, -epiC, -D, -F, -J, -X)	Intellectual disability, lethargy, failure to thrive, hypotonia, seizures, megaloblastic anemia	AR, XL
Cystathionine	Cystathioninuria	β-Cystathioninase	Benign	AR
Cysteine	Sulfocystinuria	Sulfite oxidase or molybdenum cofactor deficiency	Seizures, intellectual disability, dislocated lenses	AR
Lysine	Hyperlysinemia, saccharopinuria	α-Aminoadipic semialdehyde synthase	Benign	AR
	Pyridoxine-dependent seizures	L-Δ^1-Piperideine-6-carboxilate dehydrogenase	Seizures, intellectual disability	AR
Lysine, tryptophan	α-Ketoadipic acidemia	α-Ketoadipic acid dehydrogenase DHTKD1	Benign	AR
Lysine, tryptophan	Glutaric acidemia type 1	Glutaryl-CoA dehydrogenase	Progressive severe dystonia and athetosis, motor delays	AR
Ornithine	Gyrate atrophy of the choroid and retina	Ornithine-Δ-aminotransferase	Myopia, night blindness, loss of peripheral vision, cataracts, chorioretinal degeneration	AR
Urea cycle	Carbamoylphosphate synthase-1 deficiency	Carbamoylphosphate synthase-1	Lethargy progressing to coma, protein aversion, intellectual disability, hyperammonemia	AR
	N-Acetylglutamate synthase deficiency	*N*-Acetylglutamate synthase	Lethargy progressing to coma, protein aversion, intellectual disability, hyperammonemia	AR
	Ornithine transcarbamylase deficiency	Ornithine transcarbamylase	Lethargy progressing to coma, protein aversion, intellectual disability, hyperammonemia	XL
	Citrullinemia type 1	Argininosuccinate synthase	Lethargy progressing to coma, protein aversion, intellectual disability, hyperammonemia, liver failure	AR
	Argininosuccinic acidemia	Argininosuccinate lyase	Lethargy progressing to coma, protein aversion, intellectual disability, hyperammonemia, trichorrhexis nodosa, liver failure	AR
	Arginase deficiency	Arginase	Spastic tetraparesis, microcephaly, intellectual disability, mild hyperammonemia	AR
	Hyperornithinemia, hyperammonemia, homocitrullinuria	Mitochondrial ornithine carrier ORNT1	Vomiting, lethargy, failure to thrive, intellectual disability, episodic confusion, hyperammonemia, protein intolerance	AR
	Citrullinemia type 2	Mitochondrial aspartate/glutamate carrier CTLN2	Neonatal intrahepatic cholestasis, adult presentation with sudden behavioral changes and stupor, coma, hyperammonemia, liver failure	AR
Glutamine	Glutamine synthetase deficiency	Glutamine synthase	Brain malformations, pachygyria, seizures, hypotonia, intellectual disability, dysmorphic features, low glutamine	AR
	Glutaminase deficiency	Glutaminase	Epileptic encephalopathy, intellectual disability, ataxia, elevated glutamine	AR
Asparagine	Asparagine synthetase deficiency	Asparagine synthase	Epileptic encephalopathy, seizures, microcephaly, simplified gyration pattern, hypotonia, tetraplegia, intellectual disability	
Valine	Isobutyryl-CoA dehydrogenase deficiency	Isobutyryl-CoA dehydrogenase	Benign	AR
Isoleucine, leucine, valine	Maple syrup urine disease	Branched chain ketoacid dehydrogenase (E1α, E1β, E2, E3 deficiency)	Lethargy, vomiting, encephalopathy, seizures, intellectual disability, "maple syrup" odor, protein intolerance	AR
Isoleucine, leucine, valine	Hypervalinemia	Branched-chain amino acid transferase 2 (BCAT2)	Autism, headaches, intellectual disability	AR
Isoleucine, leucine, valine	Branched-chain amino acid deficiency	Branched chain ketoacid dehydrogenase kinase (BCHDK)	Autism, epilepsy, intellectual disability, microcephaly	
Leucine	Isovaleric acidemia	Isovaleryl-CoA dehydrogenase	Acidosis, ketosis, vomiting, coma, hyperammonemia, "sweaty feet" odor, protein intolerance	AR
	3-Methylcrotonyl glycinuria	3-Methylcrotonyl-CoA carboxylase	Stress-induced metabolic acidosis, hypotonia, hypoglycemia, "cat's urine" odor	AR
	3-Methylglutaconic aciduria type I	3-Methylglutaconyl-CoA hydratase deficiency	Stress-induced acidosis, leukodystrophy, hypotonia, hepatomegaly	AR
	3-Hydroxy-3-methylglutaric aciduria	3-Hydroxy-3-methylglutaryl-CoA lyase	Stress-induced hypoketotic hypoglycemia and acidosis, encephalopathy, hyperammonemia	AR

TABLE 431-1 Inherited Disorders of Amino Acid Metabolism (Continued)

AMINO ACID(S)	CONDITION	ENZYME DEFECT	CLINICAL FINDINGS	INHERITANCE
Isoleucine	2-Methylbutyryl-glycinuria	2-Methylbutyryl-CoA dehydrogenase	Benign	AR
	2-Methyl-3-hydroxybutyryl-CoA dehydrogenase deficiency	2-Methyl-3-hydroxybutyryl-CoA dehydrogenase	Developmental regression, seizures, and rigidity sometimes triggered by illnesses	XL
	3-Oxothiolase deficiency	3-Oxothiolase	Fasting-induced acidosis and ketosis, vomiting, lethargy	AR
Isoleucine, methionine, threonine, valine	Propionic acidemia (pccA, -B)	Propionyl-CoA carboxylase	Metabolic ketoacidosis, hyperammonemia, hypotonia, lethargy, coma, protein intolerance, intellectual disability, hyperglycinemia	AR
	Multiple carboxylase/ biotinidase deficiency	Holocarboxylase synthase or biotinidase	Metabolic ketoacidosis, diffuse rash, alopecia, seizures, intellectual disability	AR
	Methylmalonic acidemia (mutase, cblA, B, racemase)	Methylmalonyl-CoA mutase/ racemase or cobalamin reductase/ adenosyltransferase	Metabolic ketoacidosis, hyperammonemia, hypertonia, lethargy, coma, protein intolerance, intellectual disability, hyperglycinemia	AR

Abbreviations: AD, autosomal dominant; AR, autosomal recessive; Cbl, cobalamin; DOPA, dihydroxyphenylalanine; GABA, γ-aminobutyric acid; GTP, guanosine 5′-triphosphate; XL, X-linked.

cases should be referred to a metabolic center for initiation of therapy. The parents need to be counseled about the natural history of the disease and its recurrence risk in future pregnancies. In some cases, parents need testing because they might have a disorder themselves (such as glutaric acidemia type 1, methylcrotonyl coenzyme A carboxylase deficiency, primary carnitine deficiency, or fatty acid oxidation defects) since mothers with these conditions can sometimes be identified by abnormal newborn screening results in their offspring. Some metabolic disorders can remain asymptomatic until adult age, presenting only when fasting or severe stress requires full activity of affected metabolic pathways to provide energy.

Selected disorders that illustrate the principles, properties, and problems presented by the disorders of amino acid metabolism are discussed in this chapter.

THE HYPERPHENYLALANINEMIAS

The hyperphenylalaninemias (Table 431-1) result from impaired conversion of phenylalanine to tyrosine. The most common and clinically important is *phenylketonuria* (frequency 1:16,500), which is an autosomal recessive disorder characterized by an increased concentration of phenylalanine and its by-products in body fluids and by severe intellectual disability if untreated in infancy. It results from reduced activity of phenylalanine hydroxylase. The accumulation of phenylalanine inhibits the transport of other amino acids required for protein or neurotransmitter synthesis, reduces synthesis and increases degradation of myelin, and leads to inadequate formation of norepinephrine and serotonin. Phenylalanine is a competitive inhibitor of tyrosinase, a key enzyme in the pathway of melanin synthesis, resulting in hypopigmentation of hair and skin. Untreated children with classic phenylketonuria are normal at birth but fail to attain early developmental milestones, develop microcephaly, and demonstrate progressive impairment of cerebral function. Hyperactivity, seizures, and severe intellectual disability are major clinical problems later in life. Electroencephalographic abnormalities; "mousy" odor of skin, hair, and urine (due to phenylacetate accumulation); and a tendency to develop hypopigmentation (compared to the family background) and eczema complete the devastating clinical picture. In contrast, affected children who are detected and treated at birth show none of these abnormalities.

TREATMENT

Phenylketonuria

To prevent intellectual disability, diagnosis and initiation of dietary treatment of classic phenylketonuria must occur before the child is 2 weeks of age. For this reason, newborns in North America, Australia, and Europe are screened by determinations of blood phenylalanine levels. Abnormal values are confirmed using quantitative analysis of plasma amino acids. Dietary phenylalanine restriction is usually instituted if blood phenylalanine levels are >360 μmol/L. Treatment consists of a special diet low in phenylalanine and supplemented with tyrosine since tyrosine becomes an essential amino acid in phenylalanine hydroxylase deficiency. With therapy, plasma phenylalanine concentrations should be maintained between 120 and 360 μmol/L for life. Compliance with the strict diet is often difficult as patients become older; increased levels of phenylalanine in adults can cause deficits in executive function or psychiatric symptoms. Oral tetrahydrobiopterin (5–20 mg/kg per d), an essential cofactor of phenylalanine hydroxylase, can reduce phenylalanine levels in some patients with phenylketonuria in conjunction with a low-protein diet. Pegvaliase is a pegylated form of phenylalanine ammonia lyase, a bacterial enzyme that converts phenylalanine to *trans*-cinnamic acid and ammonia. This injectable drug can substantially reduce phenylalanine levels, allowing a normal diet. The bacterial origin of pegvaliase can cause immune reactions that limit its use in some patients with phenylketonuria.

Women with phenylketonuria can become pregnant. If maternal phenylalanine levels are not strictly controlled before and during pregnancy, their offspring are at increased risk for congenital defects and microcephaly (*maternal phenylketonuria*). After birth, these children have severe intellectual disability and growth retardation. Pregnancy risks can be minimized by continuing lifelong phenylalanine-restricted diets and assuring strict phenylalanine restriction 2 months prior to conception and throughout gestation.

THE HOMOCYSTINURIAS (HYPERHOMOCYSTEINEMIAS)

The homocystinurias include 10 biochemically and clinically distinct disorders (Table 431-1) characterized by increased concentration of the sulfur-containing amino acid homocysteine in blood and urine.

Classic homocystinuria, the most common (frequency 1:450,000), results from reduced activity of cystathionine β-synthase **(Fig. 431-1)**, the pyridoxal phosphate–dependent enzyme that condenses homocysteine with serine to form cystathionine. Most patients present between 3 and 5 years of age with dislocated optic lenses and intellectual disability (in about half of cases). Some patients develop a marfanoid habitus and radiologic evidence of osteoporosis.

Life-threatening vascular complications (affecting coronary, renal, and cerebral arteries) can occur during the first decade of life and are the major cause of morbidity and mortality. Classic homocystinuria can be diagnosed with analysis of plasma amino acids, showing elevated methionine and presence of free homocystine. Total plasma homocysteine is also extremely elevated (usually >100 μ*M*). Elevated levels of methionine can be also detected by neonatal screening, but milder variants can be missed by this approach. Treatment consists of a special diet restricted in protein and methionine. In approximately half of patients, oral pyridoxine (25–500 mg/d) produces a fall in plasma methionine and homocysteine concentration in body fluids. Folate and vitamin B_{12} deficiency should be prevented by adequate supplementation. Betaine is also effective in reducing homocysteine levels by favoring its remethylation to methionine.

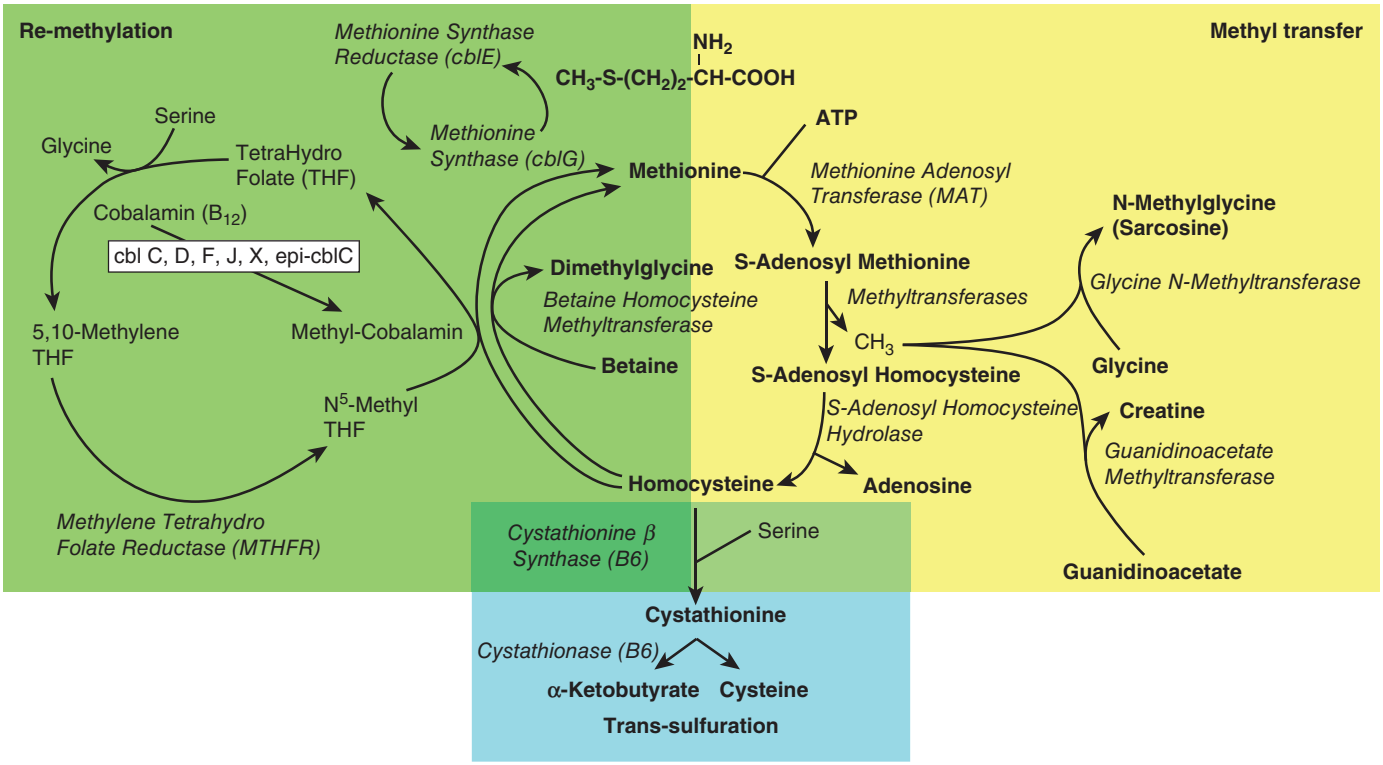

FIGURE 431-1 Pathways, enzymes, and coenzymes involved in the homocystinurias. Methionine transfers a methyl group during its conversion to homocysteine. Defects in methyl transfer or in the subsequent metabolism of homocysteine by the pyridoxal phosphate (vitamin B_6)-dependent cystathionine β-synthase increase plasma methionine levels. Homocysteine is transformed into methionine via remethylation. This occurs through methionine synthase, a reaction requiring methylcobalamin and folic acid. Deficiencies in these enzymes or lack of cofactors is associated with decreased or normal methionine levels. In an alternative pathway, homocysteine can be remethylated by betaine:homocysteine methyl transferase.

The other forms of homocystinuria are the result of impaired remethylation of homocysteine to methionine. This can be caused by defective methionine synthase or reduced availability of two essential cofactors, 5-methyltetrahydrofolate and methylcobalamin (methyl-vitamin B_{12}). In contrast to cystathionine β-synthase, elevated levels of free homocysteine are associated with low levels of methionine in the plasma amino acid profile in remethylation defects. Most of these conditions present with delays in development and some with megaloblastic anemia (methionine synthase-cblG and methionine synthase reductase-cblE deficiency, in addition to combined methylmalonic acidemia-homocystinuria- cblC, cblD, cblF, cblJ, see **Chap. 104**). Therapy in these cases requires administration of methylfolate, hydroxycobalamin (an activated form of vitamin B_{12}), and betaine.

Hyperhomocysteinemia refers to increased total plasma concentration of homocysteine with or without an increase in free homocysteine (disulfide form). Hyperhomocysteinemia, in the absence of significant homocystinuria, is found in some heterozygotes for the genetic defects noted above or in homozygotes for milder variants. Changes of homocysteine levels are also observed with deficiency of pyridoxine, folic acid, or vitamin B_{12}; with increasing age; with smoking; in postmenopausal women; in patients with renal failure, hypothyroidism, leukemias, autoinflammatory disorders; and during therapy with drugs such as methotrexate, nitrous oxide, givosiran, isoniazid, and some antiepileptic agents. Elevated homocysteine produces endothelial dysfunction, acting as an atherogenic and thrombophilic agent. Increased total plasma homocysteine has been associated with an increased risk for coronary, cerebrovascular, and peripheral arterial disease as well as for deep-vein thrombosis. In addition, hyperhomocysteinemia and folate and vitamin B_{12} deficiencies have been associated with an increased risk of neural tube defects in pregnant women and dementia (Alzheimer's type), as well as Parkinson's disease in the general population. Vitamin B_{12}, folic acids, and pyridoxine supplements can reduce total plasma homocysteine levels in these cases, with reduction of the risk of stroke when levels are more severely increased (>30 μ*M*).

ALKAPTONURIA

Alkaptonuria is a rare (frequency 1:250,000) disorder of tyrosine catabolism in which deficiency of homogentisate 1,2-dioxygenase (also known as *homogentisic acid oxidase*) leads to excretion of large amounts of homogentisic acid in urine and accumulation of oxidized homogentisic acid pigment in connective tissues (*ochronosis*). Alkaptonuria may go unrecognized until middle life, when degenerative joint disease develops. Prior to this time, about half of patients might be diagnosed for the presence of urine that becomes dark with standing or addition of alkali. Foci of gray-brown scleral pigment and generalized darkening of the concha, antihelix, and, finally, helix of the ear usually develop after age 30. Low back pain usually starts between 30 and 40 years of age. *Ochronotic arthritis* is heralded by pain, stiffness, and some limitation of motion of the hips, knees, and shoulders. Acute arthritis may resemble rheumatoid arthritis, but small joints are usually spared. Pigmentation of heart valves, larynx, tympanic membranes, and skin occurs, and occasional patients develop pigmented renal or prostatic calculi. Pigment deposition in the heart and blood vessels leads to aortic stenosis necessitating valve replacement, especially after 60 years of age. The diagnosis should be suspected in a patient whose urine darkens to blackness. Homogentisic acid in urine is identified by urine organic acid analysis. Ochronotic arthritis is treated symptomatically with pain medications, spinal surgery, and arthroplasty **(Chap. 383)**. Nitisinone (2-[2-nitro-4-trifluoromethylbenzoyl]-1,3-cyclohexanedione), a drug used in tyrosinemia type 1, at low dose (10 mg/d) reduces urinary excretion of homogentisic acid, delays progression, and improves clinical signs of alkaptonuria.

UREA CYCLE DEFECTS

Excess ammonia generated from protein nitrogen is removed by the urea cycle, a process mediated by several enzymes and transporters (**Fig. 431-2**, Table 431-1). Complete absence of any of these enzymes usually causes severe hyperammonemia in newborns, while milder variants can be seen in adults. The accumulation of ammonia and glutamine leads to direct neuronal toxicity and brain edema. Deficiencies

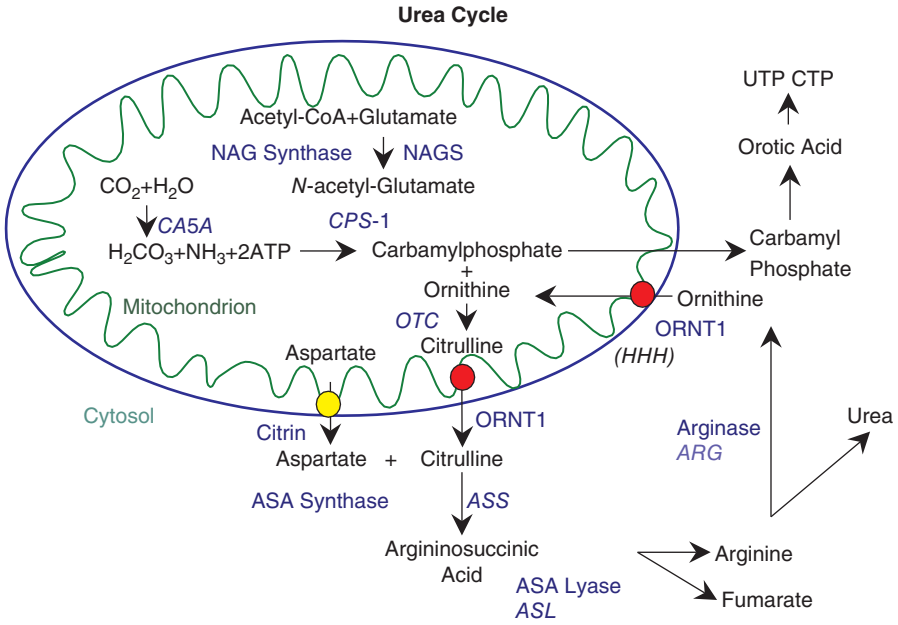

FIGURE 431-2 The urea cycle. This cycle, which is fully expressed only in the liver, forms urea starting from ammonia (NH_3) derived from the nitrogen group of all amino acids. It requires many enzymes and mitochondrial transporters, any of which can be defective and may impair the function of the urea cycle. Ammonia escaping the urea cycle in periportal hepatocytes is conjugated with glutamate by glutamine synthase in perivenous hepatocytes to generate glutamine. ARG, arginase; ASA, argininosuccinic acid; ASL, argininosuccinate lyase; ASS, argininosuccinate synthase; CA5A, carbonic anhydrase 5a; citrin (*SLC25A13*), aspartate/glutamate exchanger; CP, carbamylphosphate; CPS-1, carbamylphosphate synthase 1; CTP, cytidine triphosphate; HHH, hyperammonemia, hyperornithinemia, homocitrullinuria syndrome; NAG, *N*-acetylglutamate; NAGS, *N*-acetylglutamate synthase; ORNT1 (*SLC25A15*), ornithine/citrulline mitochondrial transporter; OTC, ornithine transcarbamylase; UTP, uridine triphosphate.

in urea cycle enzymes are individually rare, but as a group, they affect ~1:35,000 individuals. They are all transmitted as autosomal recessive traits, with the exception of ornithine transcarbamylase deficiency, which is X-linked and the most frequent urea cycle defect. Hepatocytes of females with ornithine transcarbamylase deficiency express either the normal or the mutant allele due to random X-inactivation and may be unable to remove excess ammonia if mutant cells are predominant.

Infants with classic urea cycle defects present at 1–4 days of life with refusal to eat and lethargy progressing to coma and death. Milder enzyme deficiencies present with protein avoidance, recurrent vomiting, migraine, mood swings, chronic fatigue, irritability, and disorientation that can progress to coma. Some cases have presented with acute or chronic hepatic dysfunction. Females with ornithine transcarbamylase deficiency can present at time of childbirth due to the combination of involuntary fasting and stress that favors catabolism. Administration of systemic corticosteroids or chemotherapy can precipitate hyperammonemia and can be fatal in previously asymptomatic individuals of any age. These patients may be misdiagnosed as having gastrointestinal disorders, food allergies, behavioral problems, or nonspecific hepatitis. The diagnosis requires measurement of plasma ammonia, plasma amino acids, and urine orotic acid, useful for differentiating ornithine transcarbamylase deficiency from carbamyl phosphate synthase-1 and *N*-acetylglutamate synthase deficiency. Increased plasma glutamine is seen with all urea cycle defects since ammonia not removed by the urea cycle in periportal hepatocytes is conjugated to glutamate by glutamine synthase in perivenous hepatocytes. Citrulline is low or undetectable in proximal defects of the urea cycle (*N*-acetylglutamate synthase, carbamylphosphate synthase 1, and ornithine transcarbamylase deficiency), with urine orotic acid being increased only in ornithine transcarbamylase deficiency. Plasma citrulline is markedly increased in argininosuccinic acid synthase deficiency (citrullinemia type 1), with a milder elevation in argininosuccinic acid lyase deficiency in the presence of argininosuccinic acid (argininosuccinic aciduria). Arginine levels are usually normal to low in these conditions and become markedly elevated only in patients with arginase deficiency. In addition to urea cycle defects, hyperammonemia can also be caused by liver disease from any cause and several organic acidemias and fatty acid oxidation defects (the latter two excluded by the analysis of urine organic acids and plasma acylcarnitine profile).

TREATMENT

Urea Cycle Defects

Therapy is aimed at stopping catabolism and ammonia production by providing adequate calories (as IV glucose and lipids in the comatose patient) and, if needed, insulin. Excess nitrogen is removed by IV phenylacetate and benzoate (0.25 g/kg for the priming dose and subsequently as an infusion over 24 h) that conjugate with glutamine and glycine, respectively, to form phenylacetylglutamine and hippuric acid, water-soluble molecules efficiently excreted in urine. Arginine (200 mg/kg per d) becomes an essential amino acid (except in arginase deficiency) and should be provided intravenously to resume protein synthesis. If these measures fail to reduce ammonia, hemodialysis should be initiated promptly. Chronic therapy consists of a protein-restricted diet, phenylbutyrate, glycerol phenylbutyrate (a liquid drug better tolerated by most patients), arginine, or citrulline supplements, depending on the specific diagnosis. Oral carglumic acid can restore a functional urea cycle in patients with *N*-acetylglutamate synthase deficiency and renders other therapies unnecessary. Liver transplantation should be considered in patients with severe urea cycle defects that are difficult to control medically.

Hyperammonemia due to a functional deficiency of glutamine synthase can occur in patients receiving chemotherapy for different malignancies or undergoing solid organ transplants. It can also be seen with hepatic cirrhosis. Several of these patients have been successfully rescued from hyperammonemia using the protocol described above for urea cycle defects.

432 Inherited Defects of Membrane Transport

Nicola Longo

Membrane transporters mediate the passage of amino acids, oligopeptides, sugars, cations, anions, vitamins, water, and other molecules across cellular membranes and are encoded by members of the solute-carrier gene (SLC) superfamily. These transporters are located on the plasma membrane or intracellular organelles, and their cellular and tissue distribution in addition to the presence (or absence) of redundant transporters explains organ involvement and possible metabolic disturbances. Transport processes are essential for the normal function of every organ, but especially the brain and sensory organs **(Table 432-1)**. Inherited defects impairing the transport of selected amino acids that can present in adults are discussed here as examples of the abnormalities encountered; others are considered elsewhere in this text.

CYSTINURIA

Cystinuria (worldwide frequency of 1 in 7000) is an autosomal recessive disorder caused by defective transporters in the apical brush border of proximal renal tubule and small intestinal cells. It is characterized by impaired reabsorption and excessive urinary excretion of the amino acids lysine, arginine, ornithine, and cystine that are dibasic in the physiologically acidic pH of urine. Because cystine is poorly soluble, its excess predisposes to the formation of renal, ureteral, and bladder stones. Such stones are responsible for the signs and symptoms of the disorder.

There are two variants of cystinuria. Homozygotes for both variants have high urinary excretion of cystine, lysine, arginine, and ornithine. Type A heterozygotes usually have normal urinary amino acid excretion, whereas most type B heterozygotes have moderately increased urinary excretion of cystine that, in some circumstances, can result in the formation of kidney stones. The gene for type A cystinuria (*SLC3A1*, chromosome 2p16.3) encodes a membrane glycoprotein. Type B cystinuria is caused by mutations in *SLC7A9* (chromosome 19q13) that encodes the $b^{0,+}$ amino acid transporter. The glycoprotein encoded by *SLC3A1* favors the correct processing of the $b^{0,+}$ membrane transporter and explains why mutations in two different genes cause a similar disease.

Cystine stones account for 1–2% of all urinary tract calculi and for ~4–5% of stones in children. Cystinuria homozygotes regularly excrete 2400–7200 μmol (600–1800 mg) of cystine daily. Since the maximum solubility of cystine in the physiologic urinary pH range of 4.5–7.0 is ~1200 μmol/L (300 mg/L), cystine needs to be diluted to 2.5–7 L of water to prevent crystalluria. Stone formation usually manifests in the second or third decade but may occur in the first year of life. Symptoms and signs are those typical of urolithiasis: hematuria, flank pain, renal colic, obstructive uropathy, and infection **(Chap. 330)**. Recurrent urolithiasis may lead to progressive renal insufficiency.

Cystinuria is suspected after observing typical hexagonal crystals in the sediment of acidified, concentrated, chilled urine or after performing a urinary nitroprusside test. Quantitative urine amino acid analysis shows selective overexcretion of cystine, lysine, arginine, and ornithine. Quantitative measurements are important for differentiating heterozygotes from homozygotes and for following free cystine excretion during therapy.

Management is aimed at preventing cystine crystal formation by increasing urinary volume and by maintaining an alkaline urine pH. Fluid ingestion in excess of 4 L/d is essential, and 5–7 L/d is optimal. Urinary cystine concentration should be <1000 μmol/L (250 mg/L). The daily fluid ingestion necessary to maintain this dilution of excreted cystine should be spaced over 24 h, with one-third of the total volume ingested between bedtime and 3 A.M. Cystine solubility rises sharply above pH 7.5, and urinary alkalinization (with potassium citrate) can be therapeutic. Penicillamine (1–3 g/d) and tiopronin (α-mercaptopropionylglycine, 800–1200 mg/d in four divided doses) undergo sulfhydryl-disulfide exchange with cystine to form mixed disulfides. Because these disulfides are much more soluble than cystine, pharmacologic therapy can prevent and promote dissolution of calculi. Penicillamine can have significant side effects and should be reserved for patients who fail to respond to hydration alone or who are in a high-risk category (e.g., one remaining kidney, renal insufficiency). When medical management fails, shock wave lithotripsy, ureteroscopy, and percutaneous nephrolithotomy are effective for most stones. Open urologic surgery is considered only for complex staghorn stones or when the patient has concomitant renal or ureteral abnormalities. Occasional patients progress to renal failure and require kidney transplantation.

LYSINURIC PROTEIN INTOLERANCE

Lysinuric protein intolerance is characterized by a defect in renal tubular reabsorption and intestinal transport of the three dibasic amino acids lysine, arginine, and ornithine but *not* cystine. It is most common in Finland (1 in 60,000), southern Italy, and Japan, but is rare elsewhere. The transport defect affects basolateral rather than luminal membrane transport and causes secondary impairment of the urea cycle. The defective gene (*SLC7A7*, chromosome 14q11.2) encodes the y^+LAT membrane transporter, which associates with the cell-surface glycoprotein 4F2 heavy chain to form the complete sodium-independent transporter y^+L.

Manifestations are related to impairment of the urea cycle and to immune dysfunction likely attributable to nitric oxide overproduction secondary to arginine intracellular trapping within white blood cells. Affected patients present in childhood with hepatosplenomegaly, protein intolerance, and episodic ammonia intoxication. Adults may present with severe osteoporosis, pancreatitis, impaired renal function, pulmonary alveolar proteinosis, various autoimmune disorders, and an incompletely characterized immune deficiency. Plasma concentrations of lysine, arginine, and ornithine are reduced, whereas urinary excretion of lysine, arginine, ornithine, and orotic acid is increased. Hyperammonemia may develop after the ingestion of protein loads or with infections, probably because of insufficient amounts of ornithine to maintain proper function of the urea cycle. Diagnosis is confirmed by sequencing of the *SLC7A7* gene that is included in most hyperammonemia panels. Therapy consists of dietary protein restriction, supplementation of citrulline (2–8 g/d), a neutral amino acid that fuels the urea cycle when metabolized to arginine and ornithine, and nitrogen scavengers (phenylbutyrate, benzoate) in case of persistent hyperammonemia. Pulmonary disease can respond to glucocorticoids or recombinant human granulocyte-macrophage colony-stimulating factor but might require broncho-alveolar or whole lung lavage in some patients. Women with lysinuric protein intolerance who become pregnant have an increased risk of anemia, toxemia, and bleeding complications during delivery. These can be minimized by aggressive nutritional therapy and control of blood pressure. Their infants can have intrauterine growth restriction but have normal neurologic function.

CITRULLINEMIA TYPE 2 (CITRIN DEFICIENCY)

Citrullinemia type 2 is a recessive condition caused by deficiency of the mitochondrial aspartate-glutamate carrier AGC2 (citrin). A defect in this transporter reduces the availability of cytoplasmic aspartate to combine with citrulline to form argininosuccinate **(see Fig. 431-2)**, impairing the urea cycle and decreasing the transfer of reducing equivalents from the cytosol to the mitochondria through the malate-aspartate NADH shuttle. Mutations in the *SLC25A13* gene on chromosome 7q21.3 that encodes for this transporter are rare in Caucasians but affect ~1:20,000 people with ancestry from Japan, China, and Southeast Asia with variable penetrance.

The disease can present in children with neonatal intrahepatic cholestasis, failure to thrive, and dyslipidemia but usually presents with sudden onset between 20 and 50 years of age with recurring episodes of hyperammonemia with associated neuropsychiatric symptoms such as altered mental status, irritability, seizures, or coma-resembling hepatic encephalopathy. Some patients might come to medical attention for

TABLE 432-1 Genetic Disorders of Amino Acid Transport

DISORDER	SUBSTRATES	TISSUES MANIFESTING TRANSPORT DEFECT	MOLECULAR DEFECT	MAJOR CLINICAL MANIFESTATIONS	INHERITANCE
Cystinuria	Cystine, lysine, arginine, ornithine	Proximal renal tubule, jejunal mucosa	Shared dibasic-cystine transporter *SLC3A1, SLC7A9*	Cystine nephrolithiasis	AR
Lysinuric protein intolerance	Lysine, arginine, ornithine	Proximal renal tubule, jejunal mucosa	Dibasic transporter *SLC7A7*	Protein intolerance, hyperammonemia, intellectual disability	AR
Hartnup disease	Neutral amino acids	Proximal renal tubule, jejunal mucosa	Neutral amino acid transporter *SLC6A19*	Constant neutral aminoaciduria, intermittent symptoms of pellagra	AR
Histidinuria	Histidine	Proximal renal tubule, jejunal mucosa	Histidine transporter	Intellectual disability	AR
Iminoglycinuria	Glycine, proline, hydroxyproline	Proximal renal tubule, jejunal mucosa	Shared glycine–amino acid transporter *SLC6A20, SLC6A18, SLC36A2*	None	AR
Dicarboxylic aminoaciduria	Glutamic acid, aspartic acid	Proximal renal tubule, jejunal mucosa	Shared dicarboxylic amino acid transporter *SLC1A1*	None	AR
Hyperargininemia	Arginine, lysine, ornithine	Ubiquitous	CAT2 cationic amino acid transporter *SLC7A2*	Hyperargininemia, Hyperammonemia (?)	AR
Brain branched-chain amino acid deficiency	Leucine, isoleucine, valine	Plasma membrane of blood-brain barrier	Branched-chain amino acid transporter *SLC7A5*	Microcephaly, intellectual disability, seizures, autism	AR
Citrullinemia type 2	Aspartate, glutamate, malate	Inner mitochondrial membrane	Mitochondrial aspartate/ glutamate carrier 2 *SLC25A13*	Sudden behavioral changes with stupor, coma, hyperammonemia	AR
Hyperornithinemia, hyperammonemia, homocitrullinuria	Ornithine, citrulline	Inner mitochondrial membrane	Mitochondrial ornithine carrier *SLC25A15*	Lethargy, failure to thrive, intellectual disability, episodic confusion, hyperammonemia, protein intolerance	AR
Epileptic encephalopathy	Aspartate, glutamate, malate	Inner mitochondrial membrane	Mitochondrial aspartate/ glutamate carrier 1 *SLC25A12*	Intellectual disability, epilepsy, hypotonia, cerebral atrophy, and hypomyelination	AR
Epileptic encephalopathy	Glutamate	Inner mitochondrial membrane	Mitochondrial glutamate carrier *SLC25A22*	Intellectual disability, epilepsy	AR
Epileptic encephalopathy	Glutamic acid, aspartic acid	Presynaptic glutamatergic nerve endings	EEAT2 Neuronal dicarboxylic amino acid transporter *SLC1A2*	Developmental and Epileptic Encephalopathy	AD
Episodic ataxia	Glutamic acid, aspartic acid	Presynaptic glutamatergic nerve endings	EEAT1 Neuronal dicarboxylic amino acid transporter *SLC1A3*	Episodic ataxia	AD
Brain serine deficiency	Alanine, serine, cysteine, threonine	Neuronal cells	ASCT neutral amino acid transporter *SLC1A4*	Progressive microcephaly, intellectual disability, spasticity	AR
Glycine encephalopathy with normal serum glycine	Glycine	Astrocytes and neuronal cells	GLYT1 astrocyte glycine transporter *SLC6A9*	Arthrogryposis, apnea, axial hypotonia, spasticity, intellectual disability	AR
Hyperekplexia-3	Glycine	Neuronal cells	GLYT2 Presynaptic glycine transporter *SLC6A5*	Exaggerated startle response, hypertonia, apnea	AR
Intellectual disability	Proline, glycine, leucine, and alanine, glutamine	Neuronal cells synaptic vesicles	NTT4 synaptic vesicle neutral amino acid transporter *SLC6A17*	Intellectual disability, tremor	AR
Deafness	Glutamic acid	Neuronal cortical synaptic vesicles	VGLUT3 vesicular glutamate transporter *SLC17A8*	Deafness	AD
Foveal hypoplasia	Glutamine	Retinal photoreceptors	*SLC38A8*	Foveal hypoplasia, optic nerve decussation defects, anterior segment dysgenesis	AR
Retinitis pigmentosa	Arginine, lysine, ornithine	Retinal photoreceptors	Cationic amino acid transporter *SLC7A14*	Retinitis pigmentosa, blindness	AR
Early retinal degeneration	Taurine	Retinal cells	TAUT taurine transporter *SLC6A6*	Nystagmus, vision loss, retinal degeneration	AR
Cystinosis	Cystine	Lysosomal membranes	Lysosomal cystine transporter	Renal failure, hypothyroidism, blindness	AR

Abbreviations: AD, autosomal dominant; AR, autosomal recessive.

hypertriglyceridemia, pancreatitis, hepatoma, or fatty liver histologically similar to nonalcoholic steatohepatitis. Without therapy, most symptomatic patients die with cerebral edema within a few years. Episodes are usually triggered by medications (such as acetaminophen), surgery, alcohol, or high sugar intake, with the latter conditions causing NADH production in the cytoplasm. NADH is not generated by the metabolism of proteins or fats, and individuals with citrullinemia type 2 spontaneously prefer foods such as meat, eggs, and fish and avoid carbohydrates.

Laboratory studies during an acute attack can show elevated ammonia, citrulline, and arginine with low or normal levels of glutamine (the latter is usually increased in classic urea cycle defects). Levels of galactose-1-phosphate in red blood cells are also increased, reflecting defective transfer of reducing equivalents from the cytosol to mitochondria. The diagnosis is confirmed by demonstrating pathogenic variants in the *SLC25A13* gene. Liver transplantation prevents progression of the disease and normalizes biochemical parameters. A ketogenic diet high in fats and proteins and low in carbohydrates with supplements of

medium-chain triglycerides, arginine, and pyruvate is also effective in preventing or delaying disease progression.

HARTNUP DISEASE

Hartnup disease (frequency 1 in 24,000) is an autosomal recessive disorder characterized by pellagra-like skin lesions, variable neurologic manifestations, and neutral and aromatic aminoaciduria. Alanine, serine, threonine, valine, leucine, isoleucine, phenylalanine, tyrosine, tryptophan, glutamine, asparagine, and histidine are excreted in urine in quantities 5–10 times greater than normal, and intestinal transport of these same amino acids is defective. The defective neutral amino acid transporter, B°AT1 encoded by the *SLC6A19* gene on chromosome 5p15, requires either collectrin or angiotensin-converting enzyme 2 (one of the binding sites for SARS-CoV-2) for surface expression in the kidney and intestine, respectively.

The clinical manifestations result from nutritional deficiency of the essential amino acid tryptophan, caused by its intestinal and renal malabsorption, and of niacin, which derives in part from tryptophan metabolism. Only a small fraction of patients with Hartnup disease develop symptoms, implying that manifestations depend on other factors in addition to the transport defect. The diagnosis of Hartnup disease should be suspected in any patient with clinical features of pellagra, recurrent diarrhea, and/or neurologic symptoms who does not have a history of dietary niacin deficiency **(Chap. 345)**. The neurologic and psychiatric manifestations range from attacks of spastic paraplegia to cerebellar ataxia to mild emotional lability to frank delirium, and they are usually accompanied by exacerbations of the erythematous, eczematoid skin rash. Fever, sunlight, stress, and sulfonamide therapy provoke clinical relapses. Diagnosis is made by detection of the neutral aminoaciduria (which does not occur in dietary niacin deficiency) and is confirmed by genetic testing of the *SLC6A19* or the *CTLRN* gene (coding for collectrin), whose deficiency produces a biochemical phenocopy. Treatment includes a high-protein diet and daily nicotinamide supplementation (50–250 mg).

CYSTINOSIS

Cystinosis (frequency 1 in 100,000–200,000) is an autosomal recessive disorder caused by mutations in the *CTNS* gene encoding the lysosomal cystine/proton transporter (cystinosin). In this condition, cystine derived from protein degradation accumulates inside lysosomes and forms crystals due to its poor solubility. Depending on the degree of impairment of transporter function, three clinical forms are recognized. The most severe form, classic nephropathic cystinosis, causes renal Fanconi syndrome with rickets during the first year of life and, without treatment, evolves to renal failure usually by 10 years of age. Juvenile nephropathic cystinosis presents with proteinuria slowly leading to kidney failure, whereas photophobia, caused by deposition of cystine crystals in the cornea, is the only manifestation of ocular nonnephropathic cystinosis. Cystinosis is suspected by the identification of cystine crystals in the cornea by slit lamp examination and diagnosed by measuring cystine content in white blood cells and/or DNA testing (including deletion analysis) of the *CTNS* gene. Therapy consists in the administration of extended release cysteamine bitartrate that enters lysosomes and forms a mixed disulfide with cysteine that is exported from the lysosome using a cationic amino acid transporter. This drug is given orally and should be slowly increased to the maintenance dose of 1.3 g/m^2 divided into two daily administrations while monitoring white blood cell (WBC) cystine levels for efficacy. This therapy delays renal failure and is more effective if started early in the course of the disease. Cysteamine eye drops can relieve photophobia. Renal replacement therapy with salts, alkali, and activated vitamin D is necessary for renal Fanconi syndrome. Cystine accumulation occurs in all organs and tissues, causing additional complications such as hypothyroidism, hypohydrosis, diabetes, and delayed puberty in both males and females with primary hypogonadism in males. Growth hormone replacement, L-thyroxine for hypothyroidism, insulin for diabetes mellitus, and testosterone for hypogonadism in males may be necessary. Despite therapy, many patients with cystinosis progress to end-stage renal failure and require kidney transplantation. Late-onset complications include hepatomegaly and splenomegaly that occur in approximately one-third of subjects and a vacuolar myopathy causing weakness (initially involving the distal extremities), swallowing difficulties, gastrointestinal dysmotility, and pulmonary insufficiency. Before the availability of cystine-depleting therapy and renal transplantation, the life span in nephropathic cystinosis was <10 years. With current therapies, affected individuals can survive into the late forties with satisfactory quality of life.

Section 1 Diagnosis of Neurologic Disorders

433 Approach to the Patient with Neurologic Disease

Daniel H. Lowenstein, S. Andrew Josephson, Stephen L. Hauser

Neurologic diseases are common and costly. According to estimates by the World Health Organization, neurologic disorders affect nearly one in three individuals and represent the leading cause of disability and the second leading cause of death worldwide (Fig. 433-1). These numbers have increased significantly over the past 30 years and are expected to double by 2050, due to multiple factors, including aging of the population, population growth, and a rising prevalence of metabolic risk conditions.

Because therapies now exist for many neurologic disorders, a skillful approach to diagnosis is essential. Errors commonly result from an overreliance on costly neuroimaging procedures and laboratory tests, which, while useful, do not substitute for an adequate history and examination. The proper approach begins with the patient and focuses the clinical problem, first in anatomic and then in pathophysiologic terms; only then should a specific neurologic diagnosis be entertained. This method ensures that technology is judiciously applied, a correct diagnosis is established in an efficient manner, and treatment is promptly initiated.

THE NEUROLOGIC METHOD

DEFINE THE ANATOMY

The first priority is to identify the region of the nervous system that is likely to be responsible for the symptoms. Can the disorder be mapped to one specific location, is it multifocal, or is a diffuse process present? Are the symptoms restricted to the nervous system, or do they arise in the context of a systemic illness? Is the problem in the central nervous system (CNS), the peripheral nervous system (PNS), or both? In the CNS, is the cerebral cortex, basal ganglia, brainstem, cerebellum, or spinal cord responsible? Are the pain-sensitive meninges involved? In the PNS, could the disorder be located in peripheral nerves and, if

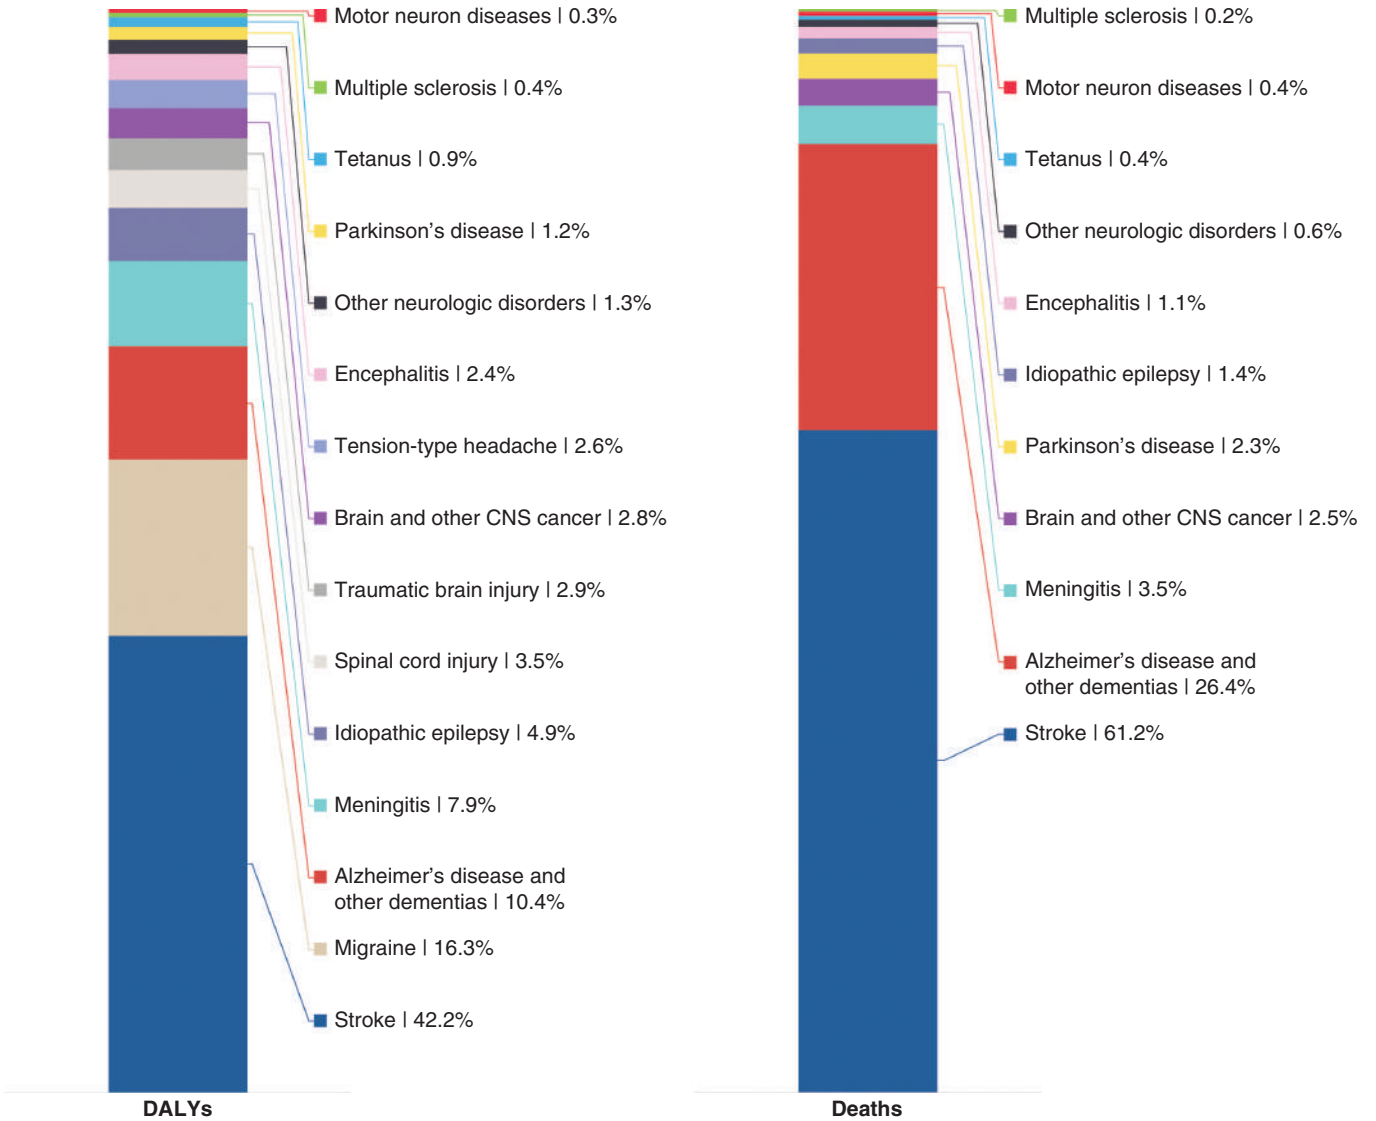

FIGURE 433-1 Proportional contributions to the overall global burden of neurologic disorders. Proportions (%) of disability-adjusted life-years (DALYs) and deaths. *(Based on data from GBD 2016 Neurology Collaborators: Lancet Neurol 18:459, 2019.)*

so, are motor or sensory nerves primarily affected, or is a lesion in the neuromuscular junction or muscle more likely?

The first clues to defining the anatomic area of involvement appear in the history, and the examination is then directed to confirm or rule out these impressions and to clarify uncertainties. A more detailed examination of a particular region of the CNS or PNS is often indicated. For example, the examination of a patient who presents with a history of ascending paresthesias and weakness should be directed toward deciding, among other things, if the lesion is in the spinal cord or peripheral nerves. Focal back pain, a spinal cord sensory level, and incontinence suggest a spinal cord origin, whereas a stocking-glove pattern of sensory loss suggests peripheral nerve disease; areflexia usually indicates peripheral neuropathy but may also be present, typically transiently, with acute spinal cord disorders.

Deciding "where the lesion is" accomplishes the task of limiting the possible etiologies to a manageable, finite number. In addition, this strategy safeguards against making serious errors. Symptoms of recurrent vertigo, diplopia, and nystagmus should not trigger "multiple sclerosis" as an answer (etiology) but "brainstem" or "pons" (location); then a diagnosis of brainstem arteriovenous malformation will not be missed for lack of consideration. Similarly, the combination of visual blurring and spastic ataxic paraparesis suggests possible optic nerve and spinal cord disease; multiple sclerosis (MS), CNS syphilis, and vitamin B_{12} deficiency are treatable disorders that can produce this syndrome. Once the question, "Where is the lesion?" is answered, then the question "What is the lesion?" can be addressed.

IDENTIFY THE PATHOPHYSIOLOGY

Clues to the pathophysiology of the disease process may also be present in the history. Primary neuronal (gray matter) disorders often present as early cognitive disturbances, movement disorders, or seizures, whereas disorders of the connecting pathways (white matter involvement) produce "long tract" motor, sensory, visual, and/or cerebellar manifestations. Progressive and symmetric symptoms often have a metabolic or degenerative origin; in such cases, lesions are usually not sharply circumscribed. Thus, a patient with paraparesis and a clear spinal cord sensory level is unlikely to have vitamin B_{12} deficiency as the explanation. A Lhermitte symptom (electric shock–like sensations evoked by neck flexion) is due to ectopic impulses that arise in white matter pathways and occurs with demyelination in the cervical spinal cord; among many possible causes, this symptom may indicate MS in a young adult or compressive cervical spondylosis in an older person. Symptoms that worsen after exposure to heat or exercise may indicate conduction block in demyelinated axons, as occurs in MS. A patient with recurrent episodes of diplopia and dysarthria associated with exercise or fatigue may have a disorder of neuromuscular transmission such as myasthenia gravis. Slowly advancing visual scotoma with luminous edges, termed *fortification spectra*, indicates spreading cortical depression, typically with migraine.

THE NEUROLOGIC HISTORY

Attention to the description of symptoms experienced by the patient and substantiated by family members and others often permits an accurate localization and determination of the probable cause, even before the neurologic examination is performed. The history also helps focus the neurologic examination that follows. Each complaint should be pursued as far as possible to identify the location of the lesion, the likely underlying pathophysiology, and potential etiologies. For example, a patient complains of weakness of the right arm. What are the associated features? Does the patient have difficulty with brushing hair or reaching upward (proximal) or fastening buttons or opening a plastic bottle (distal)? Negative associations may also be crucial. A right-handed patient with a right hemiparesis without a language deficit likely has a lesion (internal capsule, brainstem, or spinal cord) different from that of a patient with a right hemiparesis and aphasia (left hemisphere). Other pertinent features of the history include the following:

1. *Temporal course of the illness*. It is important to determine the precise time of appearance and rate of progression of the symptoms experienced by the patient. The rapid onset of a neurologic complaint, occurring within seconds or minutes, usually indicates a vascular event, a seizure, or migraine. The onset of sensory symptoms located in one extremity that spread over a few seconds to adjacent portions of that extremity and then to the other regions of the body suggests a seizure. A similar but slower temporal march of symptoms accompanied by headache, nausea, or visual disturbance suggests migraine. Less well-localized symptoms that are maximum at onset and persist for seconds, minutes, or much less commonly hours, point to the possibility of a transient ischemic attack (TIA). The presence of "positive" sensory symptoms (e.g., tingling or sensations that are difficult to describe) or involuntary motor movements suggests a seizure; in contrast, transient loss of function (negative symptoms) suggests a TIA. A stuttering onset where symptoms appear, stabilize, and then progress over hours or days also suggests cerebrovascular disease; an additional history of transient remission or regression indicates that the process is more likely due to ischemia rather than hemorrhage. A gradual evolution of symptoms over hours or days suggests a toxic, metabolic, infectious, or inflammatory process. Progressing symptoms associated with the systemic manifestations of fever, stiff neck, and altered level of consciousness imply an infectious process. Relapsing and remitting symptoms involving different levels of the nervous system suggest MS or other inflammatory processes. Slowly progressive symptoms without remissions are characteristic of neurodegenerative disorders, chronic infections, gradual intoxications, and neoplasms.
2. *Patients' descriptions of the complaint*. The same words often mean different things to different patients. "Dizziness" may imply impending syncope, a sense of disequilibrium, or true spinning vertigo. "Numbness" may mean a complete loss of feeling, a positive sensation such as tingling, or even weakness. "Blurred vision" may be used to describe unilateral visual loss, as in transient monocular blindness, or diplopia. The interpretation of the true meaning of the words used by patients to describe symptoms obviously becomes even more complex when there are differences in primary languages and cultures.
3. *Corroboration of the history by others*. It is almost always helpful to obtain additional information from family, friends, or other observers to corroborate or expand the patient's description. Memory loss, aphasia, loss of insight, intoxication, and other factors may impair the patient's capacity to communicate normally with the examiner or prevent openness about factors that have contributed to the illness. Episodes of loss of consciousness necessitate that details be sought from observers to ascertain precisely what has happened during the event.
4. *Family history*. Many neurologic disorders have an underlying genetic component. The presence of a Mendelian disorder, such as Huntington's disease or Charcot-Marie-Tooth neuropathy, is often obvious if family data are available. Clearly note if the family history has been fully ascertained or if some branches of the family could not be traced. More detailed questions about family history are often necessary in polygenic disorders such as MS, migraine, and many types of epilepsy. It is important to elicit family history about all illnesses, in addition to neurologic and psychiatric disorders. A familial propensity to hypertension or heart disease is relevant in a patient who presents with a stroke. Numerous inherited neurologic diseases are associated with multisystem manifestations that may provide clues to the correct diagnosis (e.g., neurofibromatosis, Wilson's disease, mitochondrial disorders).
5. *Medical illnesses*. Many neurologic diseases occur in the context of systemic disorders. Diabetes mellitus, hypertension, and abnormalities of blood lipids predispose to cerebrovascular disease. A solitary mass lesion in the brain may be an abscess in a patient with valvular heart disease, a primary hemorrhage in a patient with a coagulopathy, a lymphoma or toxoplasmosis in a patient with AIDS, or a metastasis in a patient with underlying cancer. Patients with malignancy may also present with a neurologic paraneoplastic syndrome **(Chap. 99)** or complications from chemotherapy, immunotherapy,

or radiotherapy. Marfan's syndrome and related collagen disorders predispose to dissection of the cranial arteries and aneurysmal subarachnoid hemorrhage; the latter may also occur with polycystic kidney disease and fibromuscular dysplasia. Various neurologic disorders occur with dysthyroid states or other endocrinopathies. It is especially important to look for the presence of systemic diseases in patients with peripheral neuropathy. Most patients with coma in a hospital setting have a metabolic, toxic, or infectious cause.

6. *Drug use and abuse and toxin exposure*. It is essential to inquire about the history of drug use, both prescribed and illicit. Sedatives, antidepressants, and other psychoactive medications are frequently associated with acute confusional states, especially in the elderly. Aminoglycoside antibiotics may exacerbate symptoms of weakness in patients with disorders of neuromuscular transmission, such as myasthenia gravis, and may cause dizziness secondary to ototoxicity. Vincristine and other antineoplastic drugs can cause peripheral neuropathy, immunosuppressive agents such as cyclosporine can produce encephalopathy, and immunotherapies with checkpoint inhibitors and chimeric antigen receptor (CAR) T cells are associated with various neurotoxicities including brain edema, inflammation, and demyelination **(Chap. 318)**. Excessive vitamin ingestion can lead to disease; examples include vitamin A and intracranial hypertension ("pseudotumor cerebri") or pyridoxine and peripheral neuropathy. Many patients are unaware that over-the-counter sleeping pills, cold preparations, and diet pills are actually drugs. Alcohol, the most prevalent neurotoxin, is often not recognized as such by patients, and other drugs of abuse such as cocaine, methamphetamine, and heroin can cause a wide range of neurologic abnormalities. A history of environmental or industrial exposure to neurotoxins may provide an essential clue; consultation with the patient's coworkers or employer may be required.
7. *Formulating an impression of the patient*. Use the opportunity while taking the history to form an impression of the patient. Is the information forthcoming, or does it take a circuitous course? Is there evidence of anxiety, depression, or hypochondriasis? Are there any clues to problems with language, memory, insight, comportment, or behavior? The neurologic assessment begins as soon as the patient comes into the room and the first introduction is made.

THE NEUROLOGIC EXAMINATION

The neurologic examination can be challenging and complex; it has many components and includes a number of skills that can be mastered only through repeated use of the same techniques on a large number of individuals with and without neurologic disease. Mastery of the complete neurologic examination is usually important only for physicians in neurology and associated specialties. However, knowledge of the basics of the examination, especially those components that are effective in screening for neurologic dysfunction, is essential for all clinicians, especially generalists.

There is no single, universally accepted sequence of the examination that must be followed, but most clinicians begin with assessment of mental status followed by the cranial nerves (CN), motor system, reflexes, sensory system, coordination, and gait. Whether the examination is basic or comprehensive, it is essential that it is performed in an orderly and systematic fashion to avoid errors and serious omissions. Thus, the best way to learn and gain expertise in the examination is to choose one's own approach and practice it frequently and do it in the same exact sequence each time. Essential tools for the examination should be accessible whenever the exam goes beyond screening, including a Snellen visual chart, portable ophthalmoscope, reflex hammer, a 128-Hz tuning fork, and disposable cotton wisps, tongue depressors, and pins.

The detailed description that follows describes the more commonly used parts of the neurologic examination, with a particular emphasis on the components that are considered most helpful for the assessment of common neurologic problems. Each section also includes a brief description of the minimal examination necessary to adequately screen for abnormalities in a patient who has no symptoms suggesting neurologic dysfunction. A screening examination done in this way can be completed in 3–5 min. *Video demonstrations of the neurologic screening examination (V6) and the detailed neurologic examination (V7) can be found in the Harrison's Video Collection included in this textbook*.

Several additional points about the examination are worth noting. First, in recording observations, it is important to describe what is found rather than to apply a poorly defined medical term (e.g., "patient groans to sternal rub" rather than "obtunded"). Second, subtle CNS abnormalities are best detected by carefully comparing a patient's performance on tasks that require simultaneous activation of both cerebral hemispheres (e.g., eliciting a pronator drift of an outstretched arm with the eyes closed; extinction on one side of bilaterally applied light touch, also with eyes closed; or decreased arm swing or a slight asymmetry when walking). Third, if the patient's complaint is brought on by some activity, reproduce the activity in the office. If the complaint is of dizziness when the head is turned in one direction, have the patient do this and also look for associated signs on examination (e.g., nystagmus or dysmetria). If pain or weakness occurs after walking two blocks, have the patient leave the office and walk this distance and immediately return, and repeat the relevant parts of the examination. Finally, the use of tests that are individually tailored to the patient's problem can be of value in assessing changes over time. Tests of walking a 7.5-m (25-ft) distance (normal, 5–6 s; note assistance, if any), repetitive finger or toe tapping (normal, 20–25 taps in 5 s), or handwriting are examples.

MENTAL STATUS EXAMINATION

- *The bare minimum: During the interview, look for difficulties with communication and determine whether the patient has recall and insight into recent and past events.*

The mental status examination is underway as soon as the physician begins observing and speaking with the patient. If the history raises any concern for abnormalities of higher cortical function or if cognitive problems are observed during the interview, then detailed testing of the mental status is indicated. The patient's ability to understand the language used for the examination, cultural background, educational experience, sensory or motor problems, or comorbid conditions must be factored into the applicability of the tests and interpretation of results.

The Mini-Mental State Examination (MMSE) is a standardized screening examination of cognitive function that is extremely easy to administer and takes <10 min to complete **(Chap. 31)**. Using age-adjusted values for defining normal performance, the test is ~85% sensitive and 85% specific for making the diagnosis of dementia that is moderate or severe, especially in educated patients. When there is sufficient time available in the outpatient setting, the MMSE is one of the best methods for documenting the current mental status of the patient, and this is especially useful as a baseline assessment to which future scores of the MMSE can be compared.

Individual elements of the mental status examination can be subdivided into level of consciousness, orientation, speech and language, memory, fund of information, insight and judgment, abstract thought, and calculations.

Level of consciousness is the patient's relative state of awareness of self and the environment, and ranges from fully awake to comatose. When the patient is not fully awake, the examiner should describe the responses to the minimum stimulus necessary to elicit a reaction, ranging from verbal commands to a brief, painful stimulus such as a squeeze of the trapezius muscle. Responses that are directed toward the stimulus and signify some degree of intact cerebral function (e.g., opening the eyes and looking at the examiner or reaching to push away a painful stimulus) must be distinguished from reflex responses of a spinal origin (e.g., triple flexion response—flexion at the ankle, knee, and hip in response to a painful stimulus to the foot).

Orientation is tested by asking the person to state their name, location, and time (day of the week and date); time is usually the first to be affected in a variety of conditions.

Speech is assessed by observing articulation, rate, rhythm, and prosody (i.e., the changes in pitch and accentuation of syllables and words).

Language is assessed by observing the content of the patient's verbal and written output, response to spoken commands, and ability to read. A typical testing sequence is to ask the patient to name successively more detailed components of clothing, a watch, or a pen; repeat the phrase "No ifs, ands, or buts"; follow a three-step, verbal command; write a sentence; and read and respond to a written command.

Memory should be analyzed according to three main time scales: (1) immediate memory is assessed by saying a list of three items and having the patient repeat the list immediately; (2) short-term memory is tested by asking the patient to recall the same three items 5 and 15 min later; and (3) long-term memory is evaluated by determining how well the patient is able to provide a coherent chronologic history of their illness or personal events.

Fund of information is assessed by asking questions about major historic or current events, with special attention to educational level and life experiences.

Abnormalities of *insight and judgment* are usually detected during the interview; a more detailed assessment can be elicited by asking the patient to describe how they would respond to situations having a variety of potential outcomes (e.g., "What would you do if you found a wallet on the sidewalk?").

Abstract thought can be tested by asking the patient to describe similarities between various objects or concepts (e.g., apple and orange, desk and chair, poetry and sculpture) or to list items having the same attributes (e.g., a list of four-legged animals).

Calculation ability is assessed by having the patient carry out a computation that is appropriate to the patient's age and education (e.g., serial subtraction of 7 from 100 or 3 from 20; or word problems involving simple arithmetic).

CRANIAL NERVE EXAMINATION

- *The bare minimum: Check the fundi, visual fields, pupil size and reactivity, extraocular movements, and facial movements.*

The CNs are best examined in numerical order, except for grouping together CN III, IV, and VI because of their similar function.

CN I (Olfactory) Testing is often omitted unless there is suspicion for inferior frontal lobe disease (e.g., meningioma). With eyes closed, ask the patient to sniff a mild stimulus such as toothpaste or coffee and identify the odorant.

CN II (Optic) Check visual acuity (with eyeglasses or contact lens correction) using a Snellen chart or similar tool. Test the visual fields by confrontation, i.e., by comparing the patient's visual fields to your own. As a screening test, it is usually sufficient to examine the visual fields of both eyes simultaneously; individual eye fields should be tested if there is any reason to suspect a problem of vision by the history or other elements of the examination, or if the screening test reveals an abnormality. Face the patient at a distance of ~0.6–1.0 m (2–3 ft) and place your hands at the periphery of your visual fields in the plane that is equidistant between you and the patient. Instruct the patient to look directly at the center of your face and to indicate when and where they see one of your fingers moving. Beginning with the two inferior quadrants and then the two superior quadrants, move your index finger of the right hand, left hand, or both hands simultaneously and observe whether the patient detects the movements. A single small-amplitude movement of the finger is sufficient for a normal response. Focal perimetry and tangent screen examinations should be used to map out visual field defects fully or to search for subtle abnormalities. Optic fundi should be examined with an ophthalmoscope, and the color, size, and degree of swelling or elevation of the optic disc noted, as well as the color and texture of the retina. The retinal vessels should be checked for size, regularity, arteriovenous nicking at crossing points, hemorrhage, and exudates.

CN III, IV, VI (Oculomotor, Trochlear, Abducens) Describe the size and shape of the pupils and reaction to light and accommodation (i.e., as the eyes converge while following your finger as it moves toward the bridge of the nose). To check extraocular movements, ask the patient to keep their head still while tracking the movement of the tip of your finger. Move the target slowly in the horizontal and vertical planes; observe any paresis, nystagmus, or abnormalities of smooth pursuit (saccades, oculomotor ataxia, etc.). If necessary, the relative position of the two eyes, both in primary and multidirectional gaze, can be assessed by comparing the reflections of a bright light off both pupils. However, in practice it is typically more useful to determine whether the patient describes diplopia in any direction of gaze; true diplopia should almost always resolve with one eye closed. Horizontal nystagmus is best assessed at 45° and not at extreme lateral gaze (which is uncomfortable for the patient); the target must often be held at the lateral position for at least a few seconds to detect an abnormality.

CN V (Trigeminal) Examine sensation within the three territories of the branches of the trigeminal nerve (ophthalmic, maxillary, and mandibular) on each side of the face. As with other parts of the sensory examination, testing of two sensory modalities derived from different anatomic pathways (e.g., light touch and temperature) is sufficient for a screening examination. Testing of other modalities, the corneal reflex, and the motor component of CN V (jaw clench—masseter muscle) is indicated when suggested by the history.

CN VII (Facial) Look for facial asymmetry at rest and with spontaneous movements. Test eyebrow elevation, forehead wrinkling, eye closure, smiling, and cheek puff. Look in particular for differences in the lower versus upper facial muscles; weakness of the lower two-thirds of the face with preservation of the upper third suggests an upper motor neuron lesion, whereas weakness of an entire side suggests a lower motor neuron lesion.

CN VIII (Vestibulocochlear) Check the patient's ability to hear a finger rub or whispered voice with each ear. Further testing for air versus mastoid bone conduction (Rinne) and lateralization of a 512-Hz tuning fork placed at the center of the forehead (Weber) should be done if an abnormality is detected by history or examination. Any suspected problem should be followed up with formal audiometry. **For further discussion of assessing vestibular nerve function in the setting of dizziness, coma, or hearing loss, see Chaps. 24, 30, and 36, respectively**.

CN IX, X (Glossopharyngeal, Vagus) Observe the position and symmetry of the palate and uvula at rest and with phonation ("aah"). The pharyngeal ("gag") reflex is evaluated by stimulating the posterior pharyngeal wall on each side with a sterile, blunt object (e.g., tongue blade), but the reflex may be absent in normal individuals.

CN XI (Spinal Accessory) Check shoulder shrug (trapezius muscle) and head rotation to each side (sternocleidomastoid) against resistance.

CN XII (Hypoglossal) Inspect the tongue for atrophy or fasciculations, position with protrusion, and strength when extended against the inner surface of the cheeks on each side.

MOTOR EXAMINATION

- *The bare minimum: Look for muscle atrophy and check extremity tone. Assess upper extremity strength by checking for pronator drift and strength of wrist or finger extensors. Assess lower extremity strength by checking strength of the toe extensors.*

The motor examination includes observations of muscle appearance, tone, and strength. Although gait is in part a test of motor function, it is usually evaluated separately at the end of the examination.

Appearance Inspect and palpate muscle groups under good light and with the patient in a comfortable and symmetric position. Check for muscle fasciculations, tenderness, and atrophy or hypertrophy. Involuntary movements may be present at rest (e.g., tics, myoclonus, choreoathetosis, pill-rolling tremor of Parkinson's disease), during maintained posture (essential tremor), or with voluntary movements (intention tremor of cerebellar disease or familial tremor).

Tone Muscle tone is tested by measuring the resistance to passive movement of a relaxed limb. Patients often have difficulty relaxing during this procedure, so it is useful to distract the patient to minimize active movements. In the upper limbs, tone is assessed by rapid pronation and supination of the forearm and flexion and extension at the wrist. In the lower limbs, while the patient is supine, the examiner's hands are placed behind the knees and rapidly raised; with normal tone, the ankles drag along the table surface for a variable distance before rising, whereas increased tone results in an immediate lift of the heel off the surface. Decreased tone is most commonly due to lower motor neuron or peripheral nerve disorders. Increased tone may be evident as spasticity (resistance determined by the angle and velocity of motion; corticospinal tract disease), rigidity (similar resistance in all angles of motion; extrapyramidal disease), or paratonia (fluctuating changes in resistance; frontal lobe pathways; or normal difficulty in relaxing). Cogwheel rigidity, in which passive motion elicits jerky interruptions in resistance, is seen in parkinsonism.

Strength Testing for pronator drift is an extremely useful method for screening upper limb weakness. The patient is asked to hold both arms fully extended and parallel to the ground with eyes closed. This position should be maintained for ~10 s; any flexion at the elbow or fingers or pronation of the forearm, especially if asymmetric, is a sign of potential weakness. Patients with shoulder pain or a limited range of motion may have an apparent pronator drift that is not due to true weakness. Muscle strength is further assessed by having the patient exert maximal effort for the particular muscle or muscle group being tested. It is important to isolate the muscles as much as possible, i.e., hold the limb so that only the muscles of interest are active. It is also helpful to palpate accessible muscles as they contract. Grading muscle strength and evaluating the patient's effort are an art that takes time and practice. Muscle strength is traditionally graded using the following scale:

0 = no movement
1 = flicker or trace of contraction but no associated movement at a joint
2 = movement with gravity eliminated
3 = movement against gravity but not against resistance
4– = movement against a mild degree of resistance
4 = movement against moderate resistance
4+ = movement against strong resistance
5 = full power

However, in many cases, it is more practical to use the following terms:

Paralysis = no movement
Severe weakness = movement with gravity eliminated
Moderate weakness = movement against gravity but not against mild resistance
Mild weakness = movement against moderate resistance
Full strength

Noting the pattern of weakness is as important as assessing the magnitude of weakness. Unilateral or bilateral weakness of the upper limb extensors and lower limb flexors ("pyramidal weakness") suggests a lesion of the pyramidal tract, bilateral proximal weakness suggests myopathy, and bilateral distal weakness suggests peripheral neuropathy.

REFLEX EXAMINATION

- *The bare minimum: Check the biceps, patellar, and Achilles reflexes.*

Muscle Stretch Reflexes Those that are typically assessed include the biceps (C5, C6), brachioradialis (C5, C6), triceps (C6, C7), and sometimes finger flexor (C8, T1) reflexes in the upper limbs and the patellar or quadriceps (L3, L4) and Achilles (S1, S2) reflexes in the lower limbs. The patient should be relaxed and the muscle positioned midway between full contraction and extension. Reflexes may be enhanced by asking the patient to voluntarily contract other, distant muscle groups (Jendrassik maneuver). For example, upper limb reflexes may be reinforced by voluntary teeth-clenching, and the Achilles reflex by hooking the flexed fingers of the two hands together and attempting to pull them apart. For each reflex tested, the two sides should be tested sequentially, and it is important to determine the smallest stimulus required to elicit a reflex rather than the maximum response. Reflexes are graded according to the following scale:

0 = absent
1 = present but diminished
2 = normoactive
3 = increased
4 = clonus

Cutaneous Reflexes The plantar reflex is elicited by stroking, with a noxious stimulus such as a tongue blade, the lateral surface of the sole of the foot beginning near the heel and moving across the ball of the foot to the great toe. The normal reflex consists of plantar flexion of the toes. With upper motor neuron lesions above the S1 level of the spinal cord, a paradoxical extension of the toe is observed, associated with fanning and extension of the other toes (termed an *extensor plantar response*, or *Babinski sign*). However, despite its popularity, the reliability and validity of the Babinski sign for identifying upper motor neuron weakness are limited—it is far more useful to rely on tests of tone, strength, stretch reflexes, and coordination. Superficial abdominal reflexes are elicited by gently stroking the abdominal surface near the umbilicus in a diagonal fashion with a sharp object (e.g., the wooden end of a cotton-tipped swab) and observing the movement of the umbilicus. Normally, the umbilicus will pull toward the stimulated quadrant. With upper motor neuron lesions, these reflexes are absent. They are most helpful when there is preservation of the upper (spinal cord level T9) but not lower (T12) abdominal reflexes, indicating a spinal lesion between T9 and T12, or when the response is asymmetric. Other useful cutaneous reflexes include the cremasteric (ipsilateral elevation of the testicle following stroking of the medial thigh; mediated by L1 and L2) and anal (contraction of the anal sphincter when the perianal skin is scratched; mediated by S2, S3, S4) reflexes. It is particularly important to test for these reflexes in any patient with suspected injury to the spinal cord or lumbosacral roots.

Primitive Reflexes With disease of the frontal lobe pathways, several primitive reflexes not normally present in the adult may appear. The suck response is elicited by lightly touching with a tongue blade the center of the lips, and the root response the corner of the lips; the patient will move the lips to suck or root in the direction of the stimulus. The grasp reflex is elicited by touching the palm between the thumb and index finger with the examiner's fingers; a positive response is a forced grasp of the examiner's hand. In many instances, stroking the back of the hand will lead to its release. The palmomental response is contraction of the mentalis muscle (chin) ipsilateral to a scratch stimulus diagonally applied to the palm.

SENSORY EXAMINATION

- *The bare minimum: Ask whether the patient can feel light touch and the temperature of a cool object in each distal extremity. Check double simultaneous stimulation using light touch on the hands. Perform the Romberg maneuver.*

Evaluating sensation is usually the most unreliable part of the examination because it is subjective and is difficult to quantify. In the compliant and discerning patient, the sensory examination can be extremely helpful for the precise localization of a lesion. With patients who are uncooperative or lack an understanding of the tests, it may be useless. The examination should be focused on the suspected lesion. For example, in spinal cord, spinal root, or peripheral nerve abnormalities, all major sensory modalities should be tested while looking for a pattern consistent with a spinal level and dermatomal or nerve distribution. In patients with lesions at or above the brainstem, screening the primary sensory modalities in the distal extremities along with tests of "cortical" sensation is usually sufficient.

The five primary sensory modalities—light touch, pain, temperature, vibration, and joint position—are tested in each limb. Light touch

is assessed by stimulating the skin with single, very gentle touches of the examiner's finger or a wisp of cotton. Pain is tested using a new pin, and temperature is assessed using a metal object (e.g., tuning fork) that has been immersed in cold and warm water. Vibration is tested using a 128-Hz tuning fork applied to the distal phalanx of the great toe or index finger just below the nail bed. By placing a finger on the opposite side of the joint being tested, the examiner compares the patient's threshold of vibration perception with their own. For joint position testing, the examiner grasps the digit or limb laterally and distal to the joint being assessed; small 1- to 2-mm excursions can usually be sensed. The Romberg maneuver is primarily a test of proprioception. The patient is asked to stand with the feet as close together as necessary to maintain balance while the eyes are open, and the eyes are then closed. A loss of balance with the eyes closed is an abnormal response.

"Cortical" sensation is mediated by the parietal lobes and represents an integration of the primary sensory modalities; testing cortical sensation is only meaningful when primary sensation is intact. Double simultaneous stimulation is especially useful as a screening test for cortical function; with the patient's eyes closed, the examiner lightly touches one or both hands and asks the patient to identify the stimuli. With a parietal lobe lesion, the patient may be unable to identify the stimulus on the contralateral side when both hands are touched. Other modalities relying on the parietal cortex include the discrimination of two closely placed stimuli as separate (two-point discrimination), identification of an object by touch and manipulation alone (stereognosis), and the identification of numbers or letters written on the skin surface (graphesthesia).

COORDINATION EXAMINATION

- *The bare minimum: Observe the patient at rest and during spontaneous movements. Test rapid alternating movements of the hands and feet and finger to nose.*

Coordination refers to the orchestration and fluidity of movements. Even simple acts require cooperation of agonist and antagonist muscles, maintenance of posture, and complex servomechanisms to control the rate and range of movements. Part of this integration relies on normal function of the cerebellar and basal ganglia systems. However, coordination also requires intact muscle strength and kinesthetic and proprioceptive information. Thus, if the examination has disclosed abnormalities of the motor or sensory systems, the patient's coordination should be assessed with these limitations in mind.

Rapid alternating movements in the upper limbs are tested separately on each side by having the patient make a fist, partially extend the index finger, and then tap the index finger on the distal thumb as quickly as possible. In the lower limb, the patient rapidly taps the foot against the floor or the examiner's hand. If these rapid alternating movements are imprecise or vary in amplitude or rhythm, a cerebellar lesion is suspected; if, however, they are slow compared with the other side, a lesion of the pyramidal tract is most likely. Finger-to-nose testing is primarily a test of cerebellar function; the patient is asked to touch their index finger repetitively to the nose and then to the examiner's outstretched finger, which moves with each repetition. A similar test in the lower extremity is to have the patient raise the leg and touch the examiner's finger with the great toe. Another coordination test in the lower limbs is the heel-knee-shin maneuver; in the supine position, the patient is asked to slide the heel of each foot from the knee down the shin of the other leg. For all these movements, the accuracy, speed, and rhythm are noted.

GAIT EXAMINATION

- *The bare minimum: Observe the patient while walking normally, on the heels and toes, and along a straight line.*

Watching the patient walk is the most important part of the neurologic examination. Normal gait requires that multiple systems—including strength, sensation, and coordination—function in a highly integrated fashion. Unexpected abnormalities may be detected that prompt the examiner to return in more detail to other aspects of the examination. The patient should be observed while walking and turning normally, walking on the heels, walking on the toes, and walking heel-to-toe along a straight line. The examination may reveal decreased arm swing on one side (corticospinal tract disease), a stooped posture and short-stepped gait (parkinsonism), a broad-based unstable gait (ataxia), scissoring (spasticity), or a high-stepped, slapping gait (posterior column or peripheral nerve disease), or the patient may appear to be stuck in place (apraxia with frontal lobe disease).

NEUROLOGIC DIAGNOSIS

The clinical data obtained from the history and examination are interpreted to arrive at an anatomic localization that best explains the clinical findings **(Table 433-1)**, to narrow the list of diagnostic possibilities, and to select the laboratory tests most likely to be informative. The laboratory assessment may include (1) serum electrolytes; complete blood count; and renal, hepatic, endocrine, and immune studies; (2) cerebrospinal fluid examination; (3) focused neuroimaging studies **(Chap. 434)**; or (4) electrophysiologic studies. The anatomic localization, mode of onset and course of illness, other medical data, and laboratory findings are then integrated to establish an etiologic diagnosis.

The neurologic examination may be normal even in patients with a serious neurologic disease, such as seizures, chronic meningitis, or a TIA. A comatose patient may arrive with no available history, and in such cases, the approach is as described in **Chap. 30**. In other patients, an inadequate history may be overcome by a succession of examinations from which the course of the illness can be inferred. In perplexing cases, it is useful to remember that uncommon presentations of common diseases are more likely than rare etiologies. Thus, even in

TABLE 433-1 Findings Helpful for Localizations within the Nervous System

	SIGNS
Cerebrum	Abnormal mental status or cognitive impairment Seizures Unilateral weakness[a] and sensory abnormalities including head and limbs Visual field abnormalities Movement abnormalities (e.g., diffuse incoordination, tremor, chorea)
Brainstem	Isolated cranial nerve abnormalities (single or multiple) "Crossed" weakness[a] and sensory abnormalities of head and limbs, e.g., weakness of right face and left arm and leg
Spinal cord	Back pain or tenderness Weakness[a] and sensory abnormalities sparing the head Mixed upper and lower motor neuron findings Sensory level Sphincter dysfunction
Spinal roots	Radiating limb pain Weakness[b] or sensory abnormalities following root distribution **(see Figs. 27-2 and 27-3)** Loss of reflexes
Peripheral nerve	Mid or distal limb pain Weakness[b] or sensory abnormalities following nerve distribution **(see Figs. 27-2 and 27-3)** "Stocking or glove" distribution of sensory loss Loss of reflexes
Neuromuscular junction	Bilateral weakness including face (ptosis, diplopia, dysphagia) and proximal limbs Increasing weakness with exertion Sparing of sensation
Muscle	Bilateral proximal or distal weakness Sparing of sensation

[a]Weakness along with other abnormalities having an "upper motor neuron" pattern, i.e., spasticity, weakness of extensors > flexors in the upper extremity and flexors > extensors in the lower extremity, and hyperreflexia. [b]Weakness along with other abnormalities having a "lower motor neuron" pattern, i.e., flaccidity and hyporeflexia.

tertiary care settings, multiple strokes are usually due to emboli and not vasculitis, and dementia with myoclonus is usually Alzheimer's disease and not a prion disorder or a paraneoplastic illness. Finally, the most important task of a primary care physician faced with a patient who has a new neurologic complaint is to assess the urgency of referral to a specialist. Here, the imperative is to rapidly identify patients likely to have nervous system infections, acute strokes, and spinal cord compression or other treatable mass lesions and arrange for immediate care.

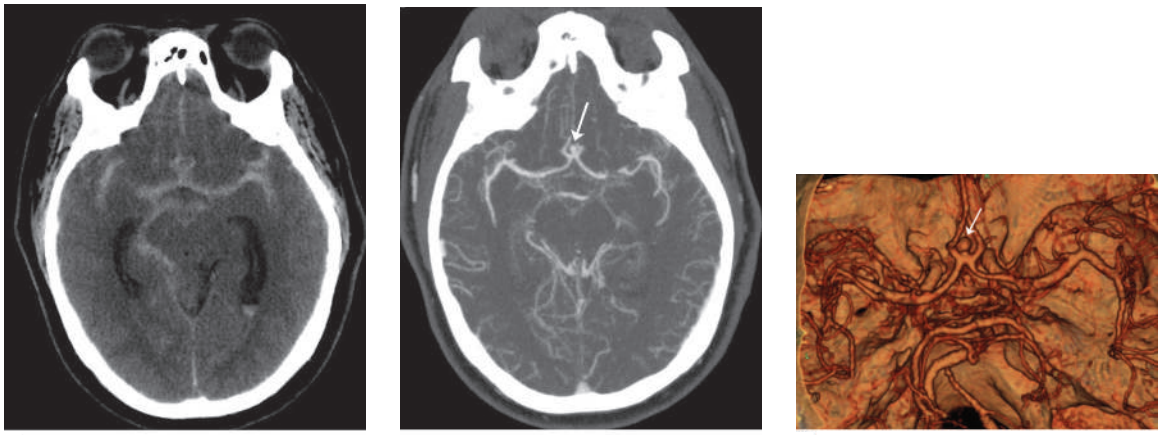
434 Neuroimaging in Neurologic Disorders

William P. Dillon

Numerous noninvasive imaging options are available to clinicians evaluating patients with neurologic disorders. These include computed tomography (CT) and magnetic resonance (MR) imaging (MRI), plus their variations, including CT angiography (CTA); perfusion CT (pCT); dual-energy CT; photon counting CT; MR angiography (MRA); MR vessel wall imaging; functional MRI (fMRI); MR spectroscopy (MRS); MR neurography (MRN); diffusion-weighted MR imaging (DWI); diffusion tensor MR imaging (DTI); susceptibility-weighted MR imaging (SWI); arterial spin label imaging (ASL); and perfusion MRI (pMRI). Furthermore, a number of interventional neuroradiologic techniques have matured including catheter embolization, stent retrieval thrombectomy, aneurysm coiling and stenting, as well as numerous techniques for spine disorders including CT and fluoroscopic myelography and CT-guided spine procedures for diagnosing and treating pain and oncology, including dynamic CT myelography, radiofrequency and cold ablation techniques, image-guided blood and fibrin glue patches and transvenous embolization of cerebrospinal fluid (CSF) venous fistulae. Multidetector CTA (MDCTA) and gadolinium-enhanced MRA techniques have reduced the need for catheter-based angiography, which is now reserved for patients in whom small-vessel detail is essential for diagnosis or for whom concurrent interventional therapy is planned (Table 434-1).

In general, MRI is more sensitive than CT for the detection of lesions affecting the peripheral and central nervous system (CNS). Diffusion MR, a sequence sensitive to the microscopic motion of water, is the most sensitive technique for detecting acute ischemic stroke of the brain or spinal cord and is also useful in the detection and characterization of encephalitis, abscess, Creutzfeldt-Jacob disease, cerebral tumors, and acute demyelinating lesions. CT, however, is acquired more quickly, making it a pragmatic choice for uncooperative patients, or those with suspected acute stroke, hemorrhage, and acute intracranial or spinal trauma. CT is also more sensitive than MRI for visualizing fine osseous detail and thus is appropriate for the initial imaging evaluation of conductive hearing loss, and lesions affecting the osseous skull and spine. MR may, however, add important diagnostic information regarding bone marrow infiltrative processes that can be difficult to detect on CT.

TABLE 434-1 Guidelines for the Use of CT, Ultrasound, and MRI



CONDITION	RECOMMENDED TECHNIQUE
Hemorrhage	
Acute parenchymal	CT, MR
Subacute/chronic	MRI
Subarachnoid hemorrhage	CT, CTA, lumbar puncture → angiography
Aneurysm	Angiography > CTA, MRA
Chronic subarachnoid blood	MR with SWI
Ischemic infarction	
Hemorrhagic infarction	CT or MRI
Bland infarction	MRI with diffusion > CT, CTA, angiography
Carotid or vertebral dissection	MRI/MRA> CTA
Vertebral basilar insufficiency	CTA, MRI with DWI MRA
Carotid stenosis	CTA, MRA > US
Suspected mass lesion	
Neoplasm, primary or metastatic	MRI ± contrast
Infection/abscess	MRI ± contrast
Immunosuppressed with focal findings	MRI ± contrast
Vascular malformation	MRI ± angiography
White matter disorders	MRI
Acute demyelinating disease	MRI ± contrast
Dementia	MRI > CT, contrast if mass
Trauma	
Acute trauma	CT
Shear injury/chronic hemorrhage	MRI + SWI
Headache/migraine	MRI > CT
Seizure	
First time, no focal neurologic deficits	MRI > CT
With neurologic deficit, or immunocompromised or cancer	MRI ± contrast > CT
Partial complex/refractory	MRI
Cranial neuropathy	MRI ± contrast
Meningeal disease	MRI ± contrast
Spine	
Low-back pain	
No neurologic deficits	MRI or CT after >6 weeks
With focal deficits	MRI > CT
Spinal stenosis	MRI or CT
Cervical spondylosis	MRI, CT, CT myelography
Infection	MRI ± contrast CT
Myelopathy	MRI ± contrast
Arteriovenous malformation	MRI ± contrast angiography

Abbreviations: CT, computed tomography; CTA, CT angiography; MRA, magnetic resonance angiography; MRI, magnetic resonance imaging; SWI, susceptibility-weighted imaging.

COMPUTED TOMOGRAPHY

TECHNIQUE

The CT image is a cross-sectional representation of anatomy created by a computer-generated analysis of the attenuation of x-ray beams passed through a section of the body. The x-ray beam, collimated to the desired slice width, rotates around the patient and passes through selected regions in the body. X-rays are variably attenuated by body structures and converted into light photons by ceramic scintillators as part of the detectors aligned 180° from the x-ray tube. These photons

A B C

FIGURE 434-1 Computed tomography (CT) angiography (CTA) of ruptured anterior cerebral artery aneurysm in a patient presenting with acute headache. ***A.*** Noncontrast CT demonstrates subarachnoid and intraventricular hemorrhage and mild obstructive hydrocephalus. ***B.*** Axial maximum-intensity projection from CTA demonstrates enlargement of the anterior cerebral artery (*arrow*). ***C.*** Three-dimensional surface reconstruction using a workstation confirms the anterior cerebral aneurysm and demonstrates its orientation and relationship to nearby vessels (*arrow*). CTA image is produced by 0.5- to 1-mm helical CT scans performed during a rapid bolus infusion of IV contrast medium.

are then converted into electric signals. A computer calculates a "back projection" image from the 360° x-ray attenuation profile. Greater x-ray attenuation (e.g., as caused by bone) results in areas of high "density" (whiter) on the scan, whereas soft-tissue structures that have poor attenuation of x-rays, such as organs and air-filled cavities, are lower (gray-black) in density. The resolution of an image depends on the radiation dose, the detector size, collimation (slice thickness), the field of view, and the matrix size of the display. A modern CT scanner can obtain sections as thin as 0.5–1 mm with 0.4-mm in-plane resolution at a speed of 0.3 s per rotation; complete studies of the brain are completed in 1–10 s.

Multidetector CT (MDCT) is now standard. Single or multiple (from 4 to 320) solid-state ceramic detectors positioned opposite to the x-ray source result in multiple slices per revolution of the beam around the patient. In helical mode, the table moves continuously through the rotating x-ray beam, generating a continuous "helix" of x-ray information that is reformatted into various slice thicknesses and planes. Advantages of MDCT include shorter scan times, reduced patient and organ motion, and the ability to acquire images dynamically during the infusion of intravenous (IV) contrast, the basis of CTA and CT perfusion **(Figs. 434-1*B* and *C*)**. CTA is displayed in three dimensions to yield angiogram-like images **(Figs. 434-1*C*, 434-2*E* and *F*, and see Fig. 438-3)**. However, the detectors, while numerous, have inefficiencies based on their physical architecture. New so-called photon-counting CT scanners use different technology for detectors, converting x-ray directly into an electric signal, rather than photon light, resulting in improved resolution, reduced electronic noise and thus dose reduction, improved spectral energy detection that reduces calcium and bone artifact, and improved contrast-to-noise ratio, which permits a reduction in the dose of contrast material required. Photon counting scanners are now able to produce CT images with 0.2 mm resolution often at reduced radiation dose **(Fig. 434-3)**.

IV iodinated contrast is used to identify vascular structures and to detect defects in the blood-brain barrier (BBB) that are caused by tumors, infarcts, and infections. In the normal CNS, only vessels and structures lacking a BBB (e.g., the pituitary gland, choroid plexus, and dura) enhance after contrast administration. While helpful in characterizing mass lesions as well as essential for the acquisition of CTA studies, the decision to use contrast material should always be considered carefully as it carries a small risk of allergic reaction and adds additional expense.

INDICATIONS

CT is the primary study of choice in the evaluation of an acute change in mental status, focal neurologic findings, acute trauma to the brain and spine, suspected subarachnoid hemorrhage, and conductive hearing loss (Table 434-1). CT often is complementary to MR in the evaluation of the skull base, orbit, and osseous structures of the spine. In the spine, CT is useful in evaluating patients with osseous spinal stenosis and spondylosis, as well as in patients with failed back surgery; however, MRI is often preferred when neurologic deficits are present. CT is often acquired following intrathecal contrast injection to evaluate for spinal and intracranial CSF fistula, as well as the spinal subarachnoid space (*CT myelography*) in failed back surgery syndromes.

COMPLICATIONS

CT is safe, fast, and reliable. Radiation exposure depends on the dose used but is normally 2–5 mSv (millisievert) for a routine brain CT study. In comparison, the average American receives about 6.2 mSv per year from all sources of radiation, including 3.1 mSv from naturally occurring sources and a similar amount from man-made sources and applications such as jet plane trips, smoke detectors, and medical imaging. While ionizing radiation can potentially induce damage to DNA, such risks are felt to be minimal at normal background radiation levels, especially at the low-dose levels related to diagnostic imaging. The risk of harm from radiation depends on the amount of dose, the delivery rate, the type of radiation, sensitivity of the tissue exposed, and the gender and age and health of the person exposed. Cancers that might develop from a radiation exposure usually have a latency period of 2–10 years or longer, after exposure. Nevertheless, for all patients, especially children, it is important to use as low a radiation dose as possible for diagnostic imaging purposes. Where feasible, MR or ultrasound is preferred. With the advent of MDCT, CTA, and CT perfusion, the diagnostic benefit must always be weighed against any increased radiation exposure. Advances in postprocessing software now permit acceptable diagnostic CT scans at 30–40% lower radiation doses compared with prior technology.

The most frequent CT-related complications are those associated with use of IV contrast agents. Ionic contrast agents have been largely replaced by safer nonionic compounds.

Contrast-associated acute kidney injury (CA-AKI) is a general term used to describe a sudden deterioration in renal function that occurs within 48 h following the intravascular administration of iodinated contrast medium. This rare complication appears to be more frequent with intraarterial injections during coronary angiography than with IV administration. CA-AKI from gadolinium-based contrast media probably does not occur or is exceptionally rare. CA-AKI is a correlative diagnosis and may result from hemodynamic changes, renal tubular obstruction and cell damage, or immunologic reactions to contrast agents. Although there is no accepted definition of CA-AKI, the diagnosis of AKI is made according to the Kidney Disease Improving Global Outcomes (KDIGO) criteria if one of the following occurs

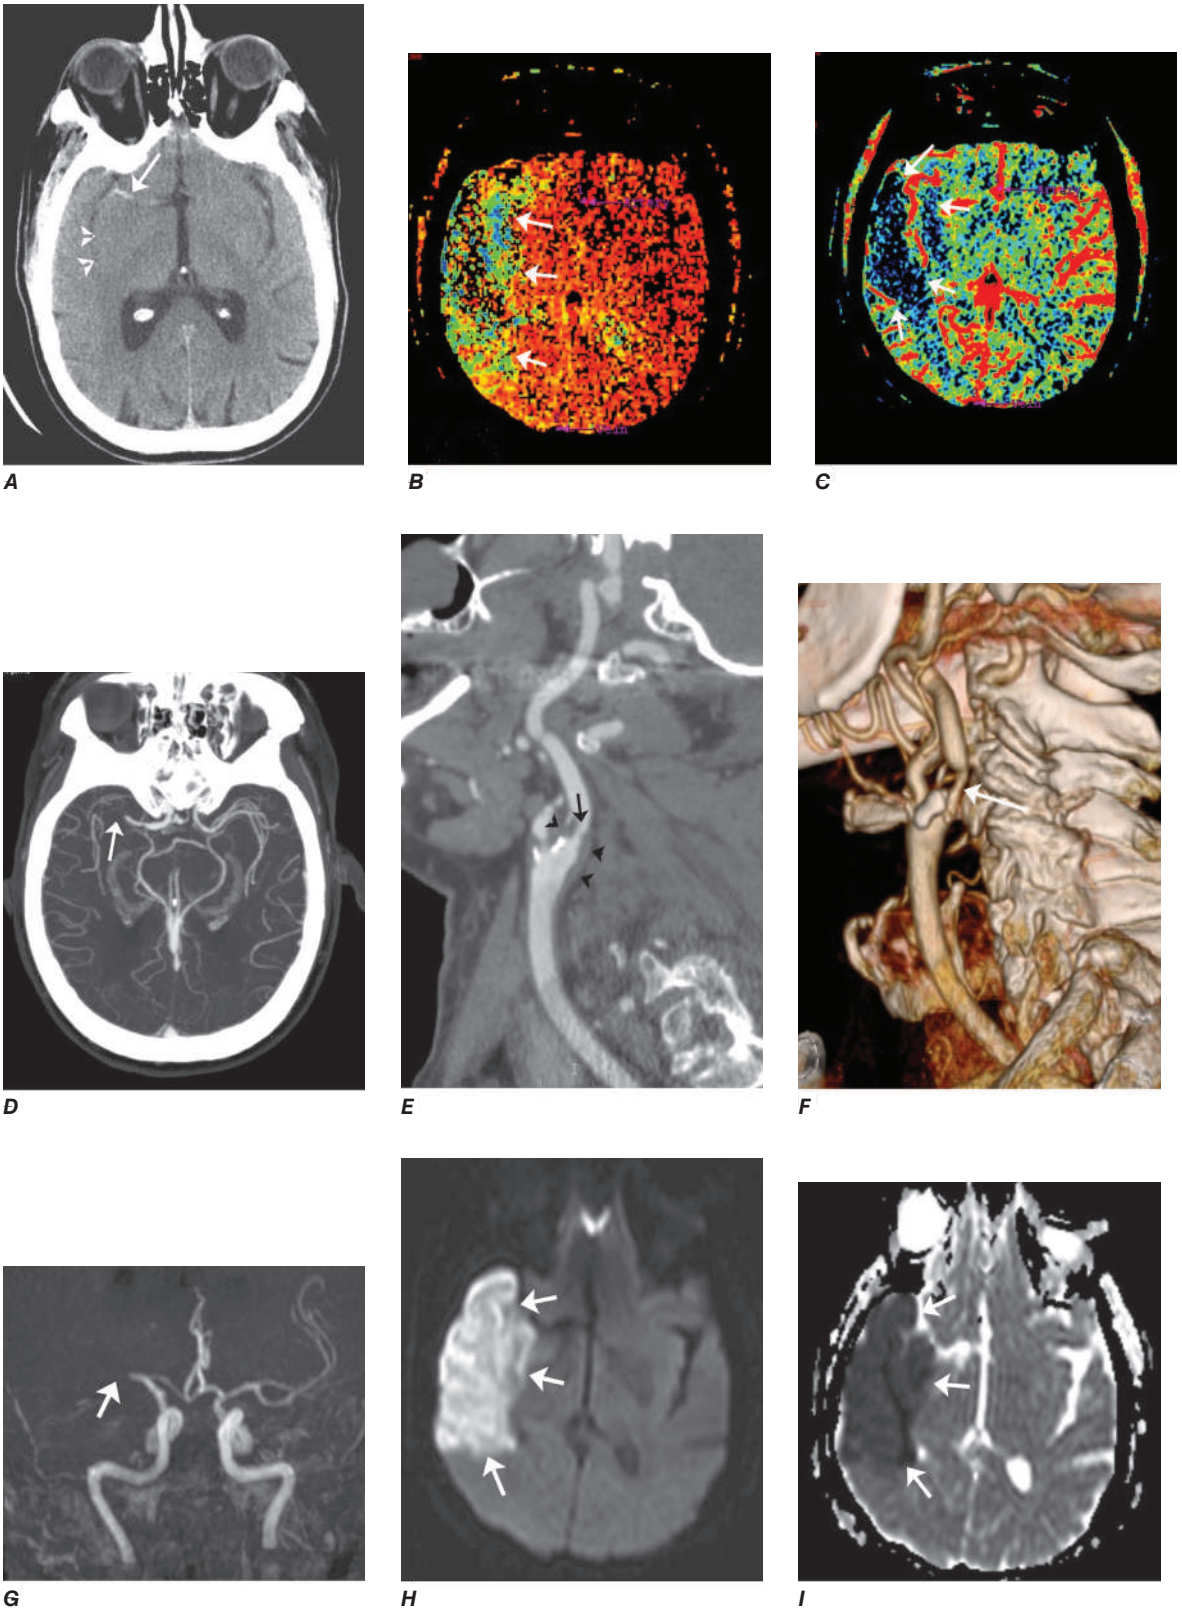


FIGURE 434-2 Acute left hemiparesis due to right middle cerebral artery occlusion. ***A.*** Axial noncontrast computed tomography (CT) scan demonstrates high density within the right middle cerebral artery (*arrow*) associated with subtle low density involving the right putamen (*arrowheads*). ***B.*** Mean transit time CT perfusion parametric map indicating prolonged mean transit time involving the right middle cerebral territory (*arrows*). ***C.*** Cerebral blood volume (CBV) map shows reduced CBV involving an area within the defect shown in ***B***, indicating a high likelihood of infarction (*arrows*). ***D.*** Axial maximum-intensity projection from a CT angiography (CTA) study through the circle of Willis demonstrates an abrupt occlusion of the proximal right middle cerebral artery (*arrow*). ***E.*** Sagittal reformation through the right internal carotid artery demonstrates a low-density lipid-laden plaque (*arrowheads*) narrowing the lumen (*black arrow*). ***F.*** Three-dimensional surface-rendered CTA image demonstrates calcification and narrowing of the right internal carotid artery (*arrow*), consistent with atherosclerotic disease. ***G.*** Coronal maximum-intensity projection from magnetic resonance angiography shows right middle cerebral artery (MCA) occlusion (*arrow*). ***H.*** and ***I.*** Axial diffusion-weighted image (***H***) and apparent diffusion-coefficient image (***I***) document the presence of a right middle cerebral artery infarction.

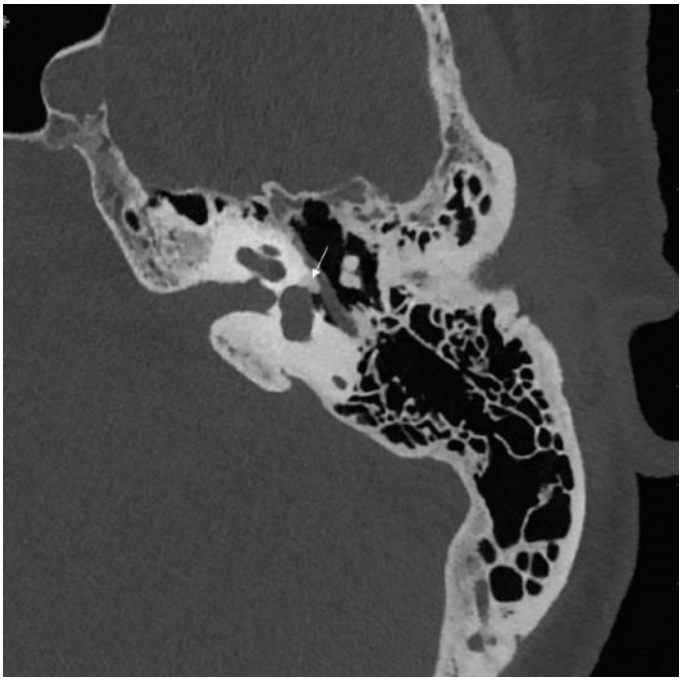

FIGURE 434-3 Photon-counting CT of the temporal bone. This 0.2-mm-thick image was obtained on a photon-counting CT scanner. It demonstrates an otosclerosis lesion (*arrow*) at the oval window in a patient with mixed hearing loss. The resolution of this image exceeds that of conventional 64-slice CT scanners (0.625 mm) due to improved detectors (see explanation in chapter). *(Courtesy of Ian Mark, MD, and the Mayo Clinic.)*

within 48 h after a nephrotoxic event (e.g., intravascular iodinated contrast medium exposure):

1. Absolute serum creatinine increase ≥0.3 mg/dL (>26.4 μmol/L)
2. A percentage increase in serum creatinine ≥50% (≥1.5-fold above baseline)
3. Urine output reduced to ≤0.5 mL/kg per h for at least 6 h

However, other causes of acute renal failure must be excluded. The prognosis is usually favorable, with serum creatinine levels returning to baseline within 1–2 weeks. Risk factors for contrast nephropathy are also controversial, but consensus is that the most important risk factor is preexisting severe renal insufficiency. Other proposed risk factors include diabetes mellitus, dehydration, cardiovascular disease, diuretic use, advanced age, hypertension, hyperuricemia, and multiple iodinated contrast medium doses in a short time interval (<24 h), but these have not been rigorously confirmed. Patients with diabetes and those with mild renal failure should be well hydrated prior to the administration of contrast agents; careful consideration should be given to alternative imaging techniques. Estimated glomerular filtration rate (eGFR) is a more reliable indicator of renal function compared to creatinine alone because it considers age and sex in the calculation. In one study, 15% of outpatients with a normal serum creatinine had an eGFR of ≤50 mL/min per 1.73 m^2 (normal is ≥90 mL/min per 1.73 m^2). The exact eGFR threshold, below which withholding IV contrast should be considered, is also controversial. The risk of contrast nephropathy is minimal in patients with eGFR >30 mL/min per 1.73 m^2; however, most of these patients will have only a temporary rise in creatinine. The risk of dialysis after receiving contrast significantly increases in patients with eGFR <30 mL/min per 1.73 m^2. Little evidence exists that IV iodinated contrast material is an independent risk factor for acute kidney injury in patients with eGFR ≥30 mL/min per 1.73 m^2. The American College of Radiology suggests, if a threshold for risk is used at all, an eGFR of <30 mL/min per 1.73 m^2 seems to have the greatest level of evidence. If contrast must be administered to a patient with an eGFR <30 mL/min per 1.73 m^2, the patient should be well hydrated. The decision to administer closely spaced contrast-enhanced studies is a clinical one, as there is insufficient data on this topic. High-risk patients should, however, be treated with greater caution than the general population. Use of other agents such as bicarbonate and acetylcysteine were previously thought to be protective against CA-AKI; however, recent meta-analyses have failed to show protection over normal saline. Patients with renal failure who require contrast administration should not have acute dialysis or continuous renal replacement therapy initiated, or alter their schedule due to the risks, costs, and lack of benefit.

Below are suggested guidelines for creatinine testing prior to contrast administration. If a recent serum creatinine (within 60 days in most clinical settings) is not available, creatinine testing should be performed *if* the patient has *any* of the following risk factors:

- Age >60 years or hypertension (however, this results in a large false-positive rate for those with eGFR <30 mL/min per 1.73 m^2)
- Personal history of "kidney disease" as an adult, including kidney surgery, ablation, transplant, or prior dialysis
- Diabetes mellitus treated with insulin or other prescribed medications
- Metformin or metformin-containing drug combinations
- Collagen vascular disease (e.g., systemic lupus erythematosus [SLE], scleroderma, rheumatoid arthritis)

Allergy Immediate reactions following IV contrast media occur through several mechanisms. The most severe are related to allergic hypersensitivity (anaphylaxis) and range from mild hives to bronchospasm and death. The pathogenesis of allergic hypersensitivity reactions is thought to include the release of mediators such as histamine, antibody-antigen reactions, and complement activation. Severe allergic reactions occur in ~0.04% of patients receiving nonionic media, sixfold lower than with ionic media. Risk factors include a history of prior contrast reaction (fivefold increased likelihood), food and or drug allergies, and atopy (asthma and hay fever). The predictive value of specific allergies, such as those to shellfish, once thought important, is now recognized to be unreliable. Nonetheless, in patients with a history worrisome for potential allergic reaction, a noncontrast CT or MRI procedure should be considered as an alternative to contrast administration. If iodinated contrast is absolutely required, a nonionic agent should be used in conjunction with pretreatment with glucocorticoids and antihistamines (Table 434-2); however, pretreatment does not guarantee safety. Patients with allergic reactions to iodinated contrast material do not usually react to gadolinium-based MR contrast material, although such reactions can occur. It would be wise to pretreat patients with a prior allergic history to MR contrast administration in a similar fashion. Subacute (>1 h after injection) reactions are frequent and probably related to T cell–mediated immune reactions. These are typically urticarial but can occasionally be more severe. Additives or contaminants, such as calcium-chelating substances or substances eluted from rubber stoppers in bottles or syringes, may be contributory in some allergy-like contrast reactions. Drug provocation and skin testing may be required to determine both the culprit agent involved and a safe alternative.

Other side effects of CT contrast include a sensation of warmth throughout the body and a metallic taste during IV administration. Extravasation of contrast media, although rare, can be painful and lead to a compartment syndrome. When this occurs, immediate consultation with plastic surgery is indicated. Patients with significant cardiac disease may be at increased risk for contrast reactions, and in these patients, limits to the volume and osmolality of the contrast media should be considered. Patients who may undergo systemic radioactive iodine therapy for thyroid disease or cancer should not receive iodinated contrast media, if possible, because this will decrease the uptake of the radioisotope into the tumor or thyroid (see the *American College of Radiology Manual on Contrast Media*, 2023; *https://www.acr.org/-/media/ACR/Files/Clinical-Resources/Contrast_Media.pdf*).

MAGNETIC RESONANCE IMAGING

TECHNIQUE

MRI is a complex interaction between protons in biologic tissues, a static magnetic field (the magnet), and energy in the form of radiofrequency (Rf) waves of a specific frequency introduced by coils placed next to the body part of interest. Images are made by computerized processing of resonance information received from protons (typically hydrogen)

TABLE 434-2 Guidelines for Premedication of Patients with Prior Contrast Allergy

13 h prior to examination:

Prednisone, 50 mg PO *or* methylprednisolone, 32 mg PO

7 h prior to examination:

Prednisone, 50 mg PO *or* methylprednisolone, 32 mg PO

1 h prior to examination:

Prednisone, 50 mg PO

Diphenhydramine, 50 mg intravenously, intramuscularly, or by mouth (optional)

Immediately prior to examination:

Benadryl, 50 mg IV (alternatively, can be given PO 2 h prior to exam)

If a patient is unable to take oral medication, 200 mg hydrocortisone IV for each dose of oral prednisone may be used

If a patient is allergic to diphenhydramine in a situation where diphenhydramine would otherwise be considered, an alternate antihistamine without cross-reactivity may be considered, or the antihistamine portion of the regimen may be removed

Accelerated IV Premedication

1. Methylprednisolone sodium succinate (e.g., Solu-Medrol) 40 mg IV

   or

   Hydrocortisone sodium succinate (e.g., Solu-Cortef) 200 mg IV immediately, and then every 4 h until contrast medium administration.

   plus

   Diphenhydramine 50 mg IV 1 h before contrast medium administration. This regimen is usually 4–5 h in duration.
2. Dexamethasone sodium sulfate (e.g., Decadron) 7.5 mg IV immediately, and then every 4 h until contrast medium administration

   plus

   Diphenhydramine 50 mg IV 1 h before contrast medium administration. This regimen may be useful in patients with an allergy to methylprednisolone and is also usually 4–5 h in duration.
3. Methylprednisolone sodium succinate (e.g., Solu-Medrol) 40 mg IV or hydrocortisone sodium succinate (e.g., Solu-Cortef) 200 mg IV

   plus

   Diphenhydramine 50 mg IV, each 1 h before contrast medium administration. This regimen, and all other regimens with a duration <4–5 h, has no evidence of efficacy. It may be considered in emergent situations when there are no alternatives.

Note: Premedication regimens <4–5 h in duration (oral or IV) have not been shown to be effective.

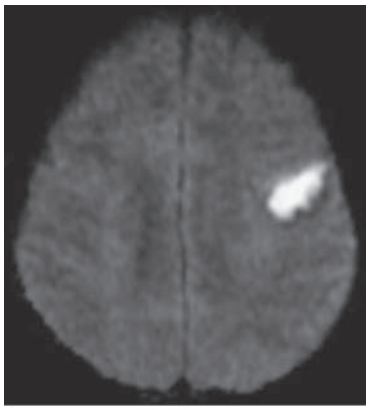
in the body. Field strength of the magnet is directly related to signal-to-noise ratio. While 1.5-Tesla (T) and 3-T magnets are now widely available and have distinct advantages in the brain and musculoskeletal systems, even higher field magnets (7 and 11+ T) and positron emission tomography (PET)-MR machines promise increased resolution and anatomic-functional information on a variety of disorders. Lower field strength magnets (0.55 T and lower) are available, having advantages of smaller size and weight, as well as improvement in signal-to-noise and susceptibility artifacts due to de-noising software and machine learning algorithms. Spatial localization of proton signal is achieved by magnetic gradients surrounding the main magnet, which impart slight changes in magnetic field throughout the imaging volume. Rf pulses transiently excite the energy state of the hydrogen protons in the body. Rf is administered at a frequency specific for the proton element (hydrogen) and the field strength of the magnet. The subsequent return to equilibrium energy state (*relaxation*) of the hydrogen protons results in a release of specific Rf energy (the *echo*), which is detected by the coils that delivered the Rf pulses. Fourier analysis is used to transform the echo into the information used to form an MR image. The MR image thus consists of a map of the distribution of hydrogen protons, with signal intensity imparted by both density of hydrogen protons and differences in the relaxation times and phase (see below) of hydrogen protons on different molecules. Although clinical MRI currently makes use of the ubiquitous hydrogen proton, sodium and carbon imaging and spectroscopy are also possible, but have yet to be integrated into mainstream practice.

T1 and T2 Relaxation Times The rate of return to equilibrium of perturbed protons is called the *relaxation rate*. The relaxation rate

TABLE 434-3 Some Common Intensities on T1- and T2-Weighted MRI Sequences

			SIGNAL INTENSITY			
IMAGE	TR	TE	CSF	FAT	BRAIN	EDEMA
T1W	Short	Short	Low	High	Low	Low
T2W	Long	Long	High	High	Medium	High
FLAIR (T2)	Long	Long	Low	High	Medium	High

Abbreviations: CSF, cerebrospinal fluid; FLAIR, fluid-attenuated inversion recovery; TE, interval between radiofrequency pulse and signal reception; TR, interval between radiofrequency pulses; T1W and T2W, T1- and T2-weighted.

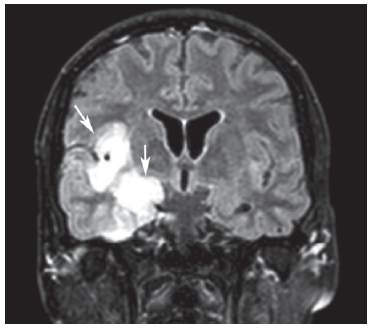


varies among normal and pathologic tissues. The relaxation rate of a hydrogen proton in a tissue is influenced by local interactions with surrounding molecules and atomic neighbors. Two relaxation rates, T1 and T2, influence the signal intensity of the image. The T1 relaxation time is the time, measured in milliseconds, for 63% of the hydrogen protons to return to their normal equilibrium state, whereas the T2 relaxation is the time for 63% of the protons to become dephased owing to interactions among nearby protons. The intensity and image contrast of the signal within various tissues can be modulated by altering acquisition parameters such as the interval between Rf pulses (TR) and the time between the Rf pulse and the signal reception (TE). T1-weighted (T1W) images are produced by keeping the TR and TE relatively short, whereas using longer TR and TE times produces T2-weighted (T2W) images. Fat and subacute hemorrhage have relatively shorter T1 relaxation rates and thus higher signal intensity than brain on T1W images. Structures containing more water, such as CSF and edema, have long T1 and T2 relaxation rates, resulting in relatively lower signal intensity on T1W images and higher signal intensity on T2W images **(Table 434-3)**. Gray matter contains 10–15% more water than white matter, which accounts for much of the intrinsic contrast between the two on MRI **(Fig. 434-5*A*)**. T2W images are more sensitive than T1W images to edema, demyelination, infarction, and chronic hemorrhage, whereas T1W imaging is more sensitive to subacute hemorrhage and fat-containing structures.

Many different MR pulse sequences exist, and each can be obtained with two-dimensional or three-dimensional techniques and in various planes **(Figs.** 434-2, **434-4, and 434-5)**. The selection of a proper protocol that will best answer a clinical question depends on an accurate clinical history and indication for the examination. Fluid-attenuated inversion recovery (FLAIR) is a very useful pulse sequence in which the normally high signal intensity of CSF on T2W images is suppressed, improving the conspicuity of edematous lesions **(Fig. 434-5*B*)**. FLAIR images are more sensitive than standard spin echo images for water-containing lesions or edema, especially those close to CSF-filled cisterns and sulci. Diffusion-weighted imaging is also routinely obtained in most brain protocols. This sequence interrogates the microscopic motion of water, which is reduced in areas of infarction, abscess, and some tumors. Susceptibility-weighted imaging (SWI) is a gradient echo sequence that is very sensitive to alterations in local magnetic field generated by blood, calcium, and air. SWI is routinely obtained to detect microhemorrhages, such as is typical of amyloid angiopathy, hypertension, hemorrhagic metastases, traumatic brain injury, and thrombotic states **(Fig. 434-6*C*)**. MR images can be generated in any plane without changing the patient's position. Each sequence, however, is currently obtained separately and takes 1–10 min on average to complete. Three-dimensional volumetric imaging is routine, resulting in a volume of data that can be reformatted in any orientation to highlight certain disease processes. Perfusion techniques such as arterial spin labeling also provide quantitative imaging information regarding cerebral blood flow, and fat-suppressed imaging obtained with T1W and T2W imaging is useful for detection of fat-containing structures as well as improving contrast with other structures such as nerves in the case of peripheral nerve imaging, skull base imaging, and spinal cord imaging.

MR Contrast Material The heavy-metal element gadolinium forms the basis of all currently approved IV MR contrast agents.

A



B

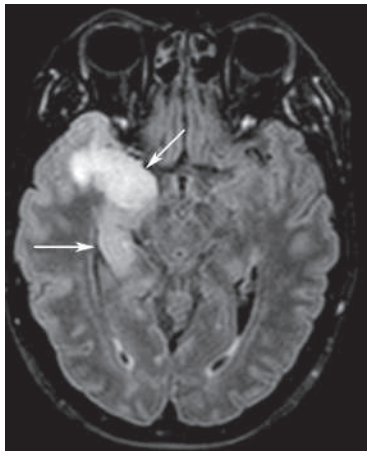


FIGURE 434-4 Cerebral abscess in a patient with fever and a right hemiparesis. ***A.*** Coronal postcontrast T1-weighted image demonstrates a ring-enhancing mass in the left frontal lobe. ***B.*** Axial diffusion-weighted image demonstrates restricted diffusion (high signal intensity) within the lesion, which in this setting is highly suggestive of cerebral abscess.

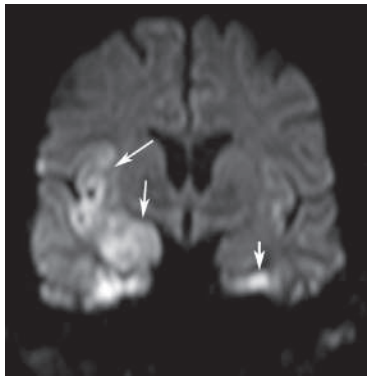
Gadolinium reduces the T1 and T2 relaxation times of nearby water protons in the presence of a magnetic field, resulting in a contrast enhancement on T1W images and a low signal on T2W images (the latter require a sufficient local concentration, usually in the form of an IV bolus). Unlike iodinated contrast agents, the effect of MR contrast agents depends on the presence of local hydrogen protons on which it must act to achieve the desired effect. There are multiple gadolinium agents approved in the United States for use with MRI. These differ according to the attached chelated moiety, which also affects the strength of chelation of the otherwise toxic gadolinium element. The chelating carrier molecule for gadolinium can be classified by whether it is macrocyclic or has linear geometry and whether it is ionic or nonionic. Macrocyclic ligands (group 2 agents) are considered more stable as the gadolinium ion is "caged" in the cavity of the ligand, and thus the rate of dissociation of gadolinium is slower compared to linear ligands (group 1 agents). Most agents are excreted by the renal system.



BRAIN ACCUMULATION OF GADOLINIUM It has been shown that gadolinium can accumulate in certain areas of the brain, primarily the dentate nuclei and globus pallidus, after serial administration of all types of gadolinium-based contrast agents (GBCAs). Autopsy studies have shown all GBCAs can lead to gadolinium deposition in brain; however, most clinical studies have demonstrated that linear GBCAs have more detectable gadolinium deposition than macrocyclic GBCAs. Gadolinium deposition in the brain appears to be dose dependent and occurs in patients with no clinical evidence of kidney or liver disease. To date, there have been no reports to suggest that these deposits are associated with histologic changes that would suggest neurotoxicity, even among agents with the highest rates of deposition. GBCAs can not only deposit in the brain but also in the skin, bone, liver, and other organs. This had importance in patients with renal failure who were exposed to linear gadolinium agents in the past, resulting in a rare but serious illness of the skin and organs secondary to accumulation of toxic gadolinium (nephrogenic systemic sclerosis).

A

B

C

FIGURE 434-5 Herpes simplex encephalitis in a patient presenting with altered mental status and fever. ***A.*** and ***B.*** Coronal (***A***) and axial (***B***) T2-weighted fluid-attenuated inversion recovery images demonstrate expansion and high signal intensity involving the right medial temporal lobe and insular cortex (*arrows*). ***C.*** Coronal diffusion-weighted image demonstrates high signal intensity indicating restricted diffusion involving the right medial temporal lobe and hippocampus (*arrows*) as well as subtle involvement of the left inferior temporal lobe (*arrowhead*). This is most consistent with neuronal death and can be seen in acute infarction as well as encephalitis and other inflammatory conditions. The suspected diagnosis of herpes simplex encephalitis was confirmed by cerebrospinal fluid polymerase chain reaction analysis.

ALLERGIC HYPERSENSITIVITY Gadolinium-DTPA (diethylenetriaminepentaacetic acid) does not normally cross the intact BBB immediately but will enhance lesions lacking a BBB **(Fig. 434-4*A*)** as well as areas of the brain that normally are devoid of the BBB (pituitary, dura, choroid plexus). However, gadolinium contrast slowly crosses an intact BBB over time and especially in the setting of reduced renal clearance or inflamed meninges. The agents are generally well tolerated; overall adverse events after injection range from 0.07–2.4%. True allergic reactions are rare (0.004–0.7%) but have been reported. Severe life-threatening reactions are exceedingly rare; in one report, only 55 reactions out of 20 million doses occurred. However, the adverse reaction rate in patients with a prior history of reaction to gadolinium is eight

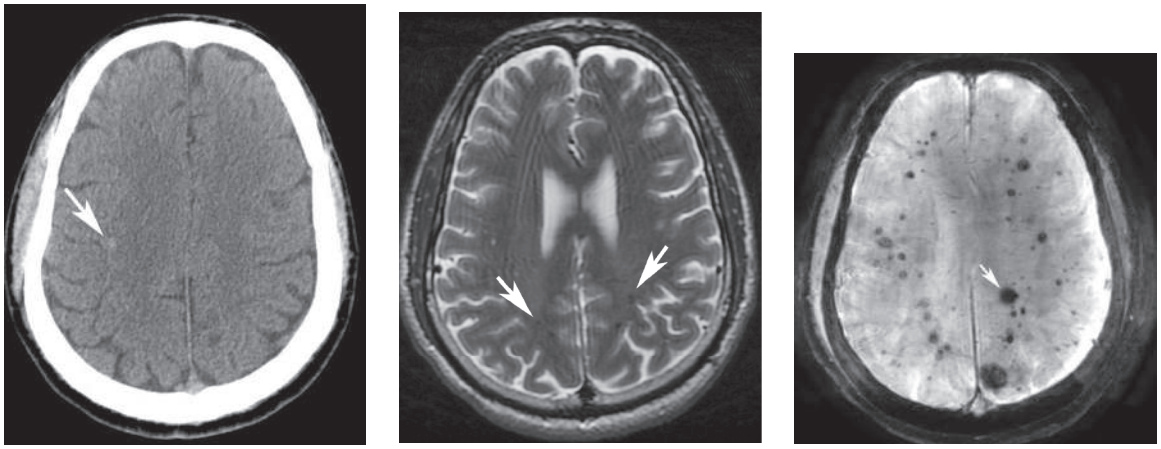


FIGURE 434-6 Susceptibility-weighted imaging in a patient with familial cavernous malformations. ***A.*** Noncontrast computed tomography scan shows one hyperdense lesion in the right hemisphere (*arrow*). ***B.*** T2-weighted fast-spin echo image shows subtle low-intensity lesions (*arrows*). ***C.*** Susceptibility-weighted image shows numerous low-intensity lesions consistent with hemosiderin-laden cavernous malformations (*arrow*).

times higher than normal. Other risk factors include atopy or asthma (3.7%). There is rare cross-reactivity between different classes of contrast media; a prior reaction to gadolinium-based contrast does not predict a future reaction to iodinated contrast medium, or vice versa, more than any other unrelated allergy. Gadolinium contrast material can be administered safely to children as well as adults, although these agents are generally avoided in those aged <6 months.

NEPHROTOXICITY Contrast-induced renal failure does not occur with gadolinium agents. A rare complication, nephrogenic systemic fibrosis (NSF), has occurred in patients with severe renal insufficiency who have been exposed to linear (group 1 and 3) gadolinium contrast agents. The onset of NSF has been reported between 5 and 75 days following exposure; histologic features include thickened collagen bundles with surrounding clefts, mucin deposition, and increased numbers of fibrocytes and elastic fibers in skin. In addition to dermatologic symptoms, other manifestations include widespread fibrosis of the skeletal muscle, bone, lungs, pleura, pericardium, myocardium, kidney, muscle, bone, testes, and dura. The American College of Radiology recommends that a glomerular filtration rate (GFR) assessment be obtained within 6 weeks prior to elective gadolinium-based MR contrast agent administration in patients with:

1. A history of renal disease (including solitary kidney, renal transplant, renal tumor)
2. Age >60 years
3. History of hypertension
4. History of diabetes
5. History of severe hepatic disease, liver transplantation, or pending liver transplantation; for these patients, it is recommended that the patient's GFR assessment be nearly contemporaneous with the MR examination.

The incidence of NSF in patients with severe renal dysfunction (GFR <30 mL/min per 1.73 m^2) varies from 0.19 to 4%. Other risk factors for NSF include acute kidney injury, the use of nonmacrocyclic agents, and repeated or high-dose exposure to gadolinium. The American College of Radiology Committee on Drugs and Contrast Media considers the risk of NSF among patients exposed to standard or lower doses of group 2 gadolinium agents (macrocyclic agents) to be sufficiently low or possibly nonexistent such that the assessment of renal function is optional prior to administration. Group 2 agents are strongly preferred in patients at risk for NSF. Renal function, dialysis status, or informed consent are not recommended prior to injection of group 2 agents, but deference is made to local practice preferences. Patients receiving any group 1 (linear) or 3 gadolinium-containing agents should be considered at risk of NSF if they are on dialysis (of any form); have severe or end-stage chronic renal disease (eGFR <30 mL/min per 1.73 m^2) without dialysis; have eGFR of 30–40 mL/min per 1.73 m^2 without dialysis (as the GFR may fluctuate); or have acute renal insufficiency. The use of gadolinium in young children and infants is discouraged due to the unknown risks and their immature renal systems.

COMPLICATIONS AND CONTRAINDICATIONS

From the patient's perspective, an MRI examination can be intimidating, and a higher level of cooperation is required than with CT. The patient lies on a table that is moved into a long, narrow gap within the magnet. Approximately 5% of the population experiences severe claustrophobia in the MR environment. This can be reduced by mild sedation but remains a problem for some. Movement of the patient during an MR examination may distort all the images in sequence; therefore, uncooperative patients should either be sedated for the MR study or scanned with CT. Generally, children aged <8 years usually require anesthesia monitored sedation to complete the MR examination without motion degradation.

MRI is considered safe for patients, even at 3- to 7-T field strengths. Serious injuries have been caused, however, by attraction of external ferromagnetic objects into the magnet, which act as missiles if brought too close to the magnet. Likewise, ferromagnetic implants, such as aneurysm clips, may torque within the magnet, causing damage to vessels and even death. Metallic foreign bodies in the eye have moved and caused intraocular hemorrhage; screening for ocular metallic fragments is indicated in those with a history of metal work or ocular metallic foreign bodies. Implanted cardiac pacemakers are generally a contraindication to MRI owing to the risk of induced arrhythmias; however, some newer pacemakers have been shown to be safe, and if necessary, MR may be performed if the pacemaker can be safely turned off during the scan. All health care personnel and patients must be screened and educated thoroughly to prevent such disasters because the magnet is always "on." **Table 434-4** lists common contraindications for MRI.

MAGNETIC RESONANCE ANGIOGRAPHY

On routine spin echo MR sequences, moving protons (e.g., flowing blood, CSF) exhibit complex MR signals that range from high to low signal intensity relative to background stationary tissue. Fast-flowing blood returns no signal (flow void) on routine T1W or T2W spin echo MR images. Slower-flowing blood, as occurs in veins or distal to arterial stenosis, may appear high in signal. *MR angiography* makes use of pulse sequences called *gradient echo sequences* that increase the signal intensity of moving protons in contrast to suppressed low signal background intensity of stationary tissue. This results in a stack of images, which can be reformatted in any plane to highlight vascular anatomy and relationships.

Several types of MRA techniques exist. *Time-of-flight* (TOF) MRA is normally done without contrast administration and relies on the suppression of nonmoving tissue to provide a low-intensity background

TABLE 434-4 Common Contraindications to Magnetic Resonance Imaging

Cardiac pacemaker or permanent pacemaker leads
Internal defibrillatory device
Cochlear prostheses
Bone growth stimulators
Spinal cord stimulators
Electronic infusion devices
Intracranial aneurysm clips (some but not all)
Ocular implants (some) or ocular metallic foreign body
McGee stapedectomy piston prosthesis
DuraPhase penile implant
Swan-Ganz catheter
Magnetic stoma plugs
Magnetic dental implants
Magnetic sphincters
Ferromagnetic inferior vena cava filters, coils, stents—safe 6 weeks after implantation
Tattooed eyeliner (contains ferromagnetic material and may irritate eyes)

Note: See also *http://www.mrisafety.com.*

for the high signal intensity of flowing blood entering the section. A typical TOF MRA sequence results in a series of contiguous, thin MR sections (0.6–0.9 mm thick), which can be viewed as a stack and manipulated to create an angiographic image data set that can be reformatted and viewed in various planes and angles, much like that seen with conventional angiography **(Fig. 434-2*G*)**.

Phase-contrast MRA has a longer acquisition time than TOF MRA, but in addition to providing anatomic information like that of TOF imaging, it can be used to reveal the velocity and direction of blood flow in each vessel.

MRA is also often acquired during infusion of IV gadolinium contrast material. Advantages include faster imaging times (1–2 min vs 10 min), fewer flow-related artifacts, and four-dimensional temporal imaging resulting in arterial and venous phases. Recently, contrast-enhanced MRA has become the standard for assessment of the extracranial vascular structures. This technique entails rapid imaging using coronal three-dimensional TOF sequences during a bolus infusion of gadolinium contrast agent.

MRA has lower spatial resolution compared with conventional film-based angiography and, therefore, is inherently less sensitive to detection of small-vessel abnormalities, such as vasculitis and distal vasospasm. MRA is also less sensitive to slowly flowing blood and thus may not reliably differentiate complete from near-complete occlusions. Motion, either by the patient or by anatomic structures, may distort the MRA images, creating artifacts. These limitations notwithstanding, MRA has proved useful in evaluation of the extracranial carotid and vertebral circulation as well as of larger-caliber intracranial arteries and dural sinuses. It has also proved useful in the noninvasive detection of intracranial aneurysms and vascular malformations.

Vessel wall MR imaging (VWI) is an MR technique that relies on suppression of all moving protons within vessels and CSF, combined with IV contrast administration **(Fig. 434-7)**. Unlike MRA, VWI is a high spatial resolution, three-dimensional, T1W technique used to assess pathology of the vessel wall itself. This technique can be used to detect, characterize, and differentiate such pathologies as atherosclerosis, vasculitis (e.g., primary angiitis of the central nervous system [PACNS]), and vasculopathies such as reversible cerebral vasoconstriction syndrome (RCVS) and has been used to assess the wall of aneurysms.

ECHO-PLANAR MRI

Echo-planar MRI (EPI) forms the basis of several important MR imaging sequences. EPI uses fast gradients that are switched on and off at high speeds to create the information used to form an image. With EPI, all the information required for processing an image is accumulated in milliseconds, and the information for the entire brain can be obtained in <1–2 min, depending on the degree of resolution required or desired. Fast MRI reduces patient and organ motion and is the basis of perfusion imaging during contrast infusion and kinematic motion studies. EPI is also the sequence used to obtain diffusion-weighted imaging (DWI) and tractography (DTI), as well as functional MRI (fMRI) and arterial spin-labeled (ASL) perfusion studies **(Figs. 434-2*H*,** 434-4, **434-5*C*,** and 434-7; and **Fig. 437-13)**.

Perfusion and diffusion imaging are EPI techniques that are useful in early detection of ischemic injury of the brain and may be useful together to demonstrate infarcted tissue as well as ischemic but potentially viable tissue at risk of infarction (e.g., the ischemic penumbra). DWI assesses microscopic motion of water; water protons that move reduce signal intensity on diffusion-weighted images. Pathology that reduces microscopic water motion results in relatively higher signal. Infarcted tissue reduces the water motion within cells and in the interstitial tissues, resulting in high signal on DWI. DWI is the most sensitive technique for detection of acute cerebral infarction of <7 days in duration (Fig. 434-2*H*). It is also quite sensitive for detecting dying or dead brain tissue secondary to encephalitis, as well as abscess and purulent formations (Fig. 434-4*B*).

Perfusion MRI can be performed by the acquisition of fast EPI during a rapid IV bolus of gadolinium contrast material or by noncontrast ASL techniques. With contrast perfusion imaging, parametric maps of relative cerebral blood volume, mean transit time (MTT), time to maximum (tMAX), and cerebral blood flow can be derived. Prolonged MTT and tMAX and reduction in cerebral blood volume and cerebral blood flow are typical of infarction. In the setting of reduced blood flow, a prolonged MTT of contrast but normal or elevated cerebral blood volume may indicate tissue supplied by slower collateral flow that is at risk of infarction. Perfusion MRI imaging can also be used in the assessment of brain tumors to differentiate intraaxial primary tumors, whose BBB is relatively intact, from extraaxial tumors or metastases, which demonstrate a relatively more permeable BBB.

DTI is derived from diffusion MRI sequences. This technique assesses the direction and integrity of protons flowing within white matter architecture. It has proven valuable in the assessment of subcortical white matter tract anatomy prior to brain tumor surgery, as well as in determining normal and abnormal white matter architecture in congenital and acquired pathologies such as traumatic brain injury and assessing the integrity of peripheral nerves and spinal cord lesions **(Fig. 434-8)**.

fMRI is an EPI technique that localizes regions of activity in the brain following task activation or at rest (so-called resting-state fMRI). Neuronal activity elicits a slight increase in the delivery of oxygenated blood flow to a specific region of activated brain. This results in an alteration in the balance of oxyhemoglobin and deoxyhemoglobin, which yields a 2–3% increase in signal intensity within veins and local capillaries. Currently, preoperative somatosensory, motor, and auditory cortex localization is performed, and methods to assess motor and language function are in development. This technique has proved useful to neuroscientists interested in interrogating the localization of specific brain functions.

ARTERIAL SPIN LABELING

ASL is a quantitative noninvasive MR technique that measures cerebral blood flow (Fig. 434-7). Blood traversing in the neck is labeled by an MR pulse and then imaged in the brain after a short (2 s) delay. The signal is reflective of blood flow. ASL has become almost standard in many MR protocols because it is relatively fast to acquire and does not require contrast administration. Increased cerebral flow is more easily identified than slow flow, which can be sometimes difficult to quantify. This technique has also been useful in detecting shunting in arteriovenous malformations and fistulas, as well as increased blood flow in brain tumors, and in patients after transient ischemic attack, seizure, or migraine.

MAGNETIC RESONANCE NEUROGRAPHY

MRN is an MR technique that shows promise in detecting increased signal in irritated, inflamed, or infiltrated peripheral nerves. T1W and T2W imaging are obtained with fat-suppressed fast-spin echo imaging or short inversion recovery sequences. Inflamed peripheral nerves will demonstrate high signal on T2W imaging. MRN is indicated in

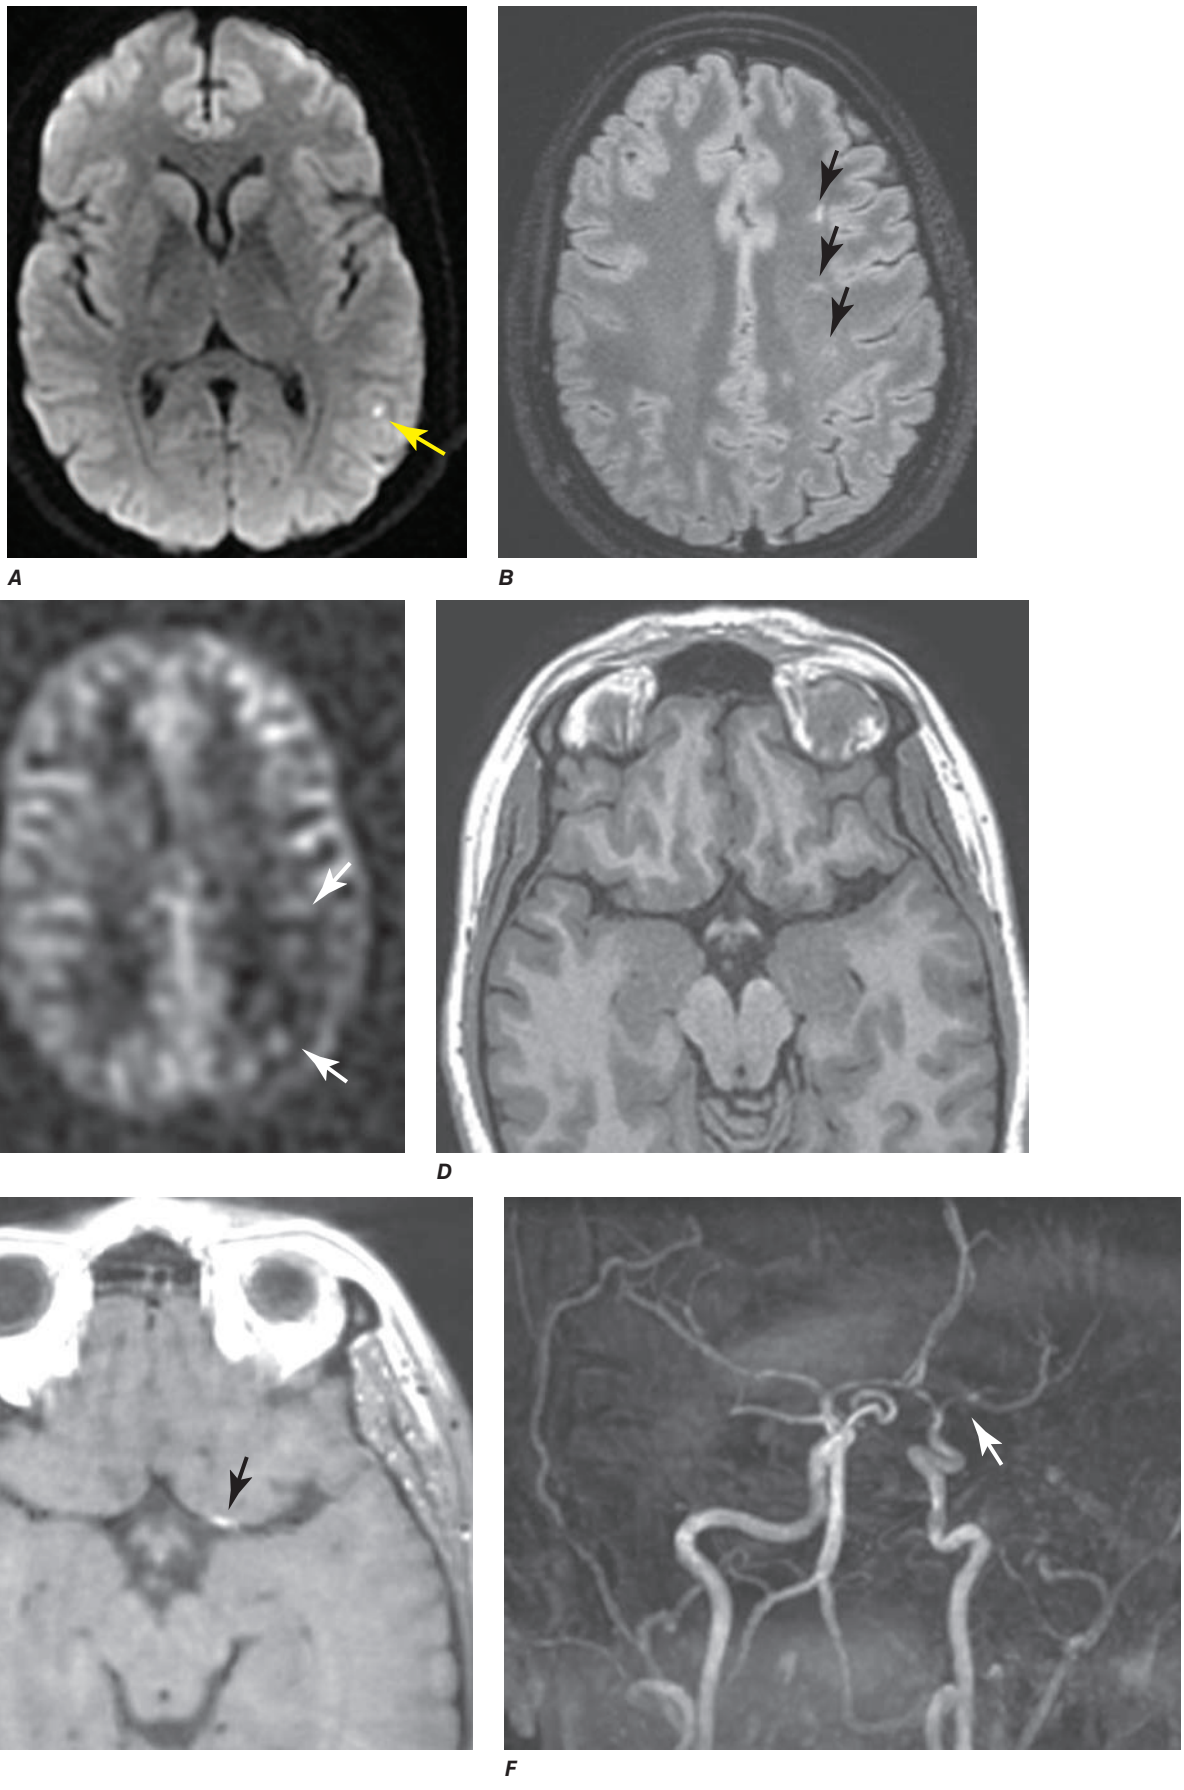

FIGURE 434-7 Arterial spin label and vessel wall imaging in a 25-year-old woman with focal cerebral arteriopathy. The patient had an 8-month history of intermittent weakness of the right side with spasms. Imaging shows evidence of cerebral ischemia. Cerebrospinal fluid was transiently inflammatory. ***A.*** Diffusion-weighted image shows focal region of reduced diffusion in left parietal lobe. ***B.*** T2 fluid-attenuated inversion recovery images show several foci of high signal in left deep subcortical white matter. ***C.*** Arterial spin label image demonstrates reduced cerebral blood flow in left parietal lobe (*arrows*). ***D.*** Three-dimensional (3D) T1 image without contrast administration. ***E.*** 3D T1-weighted cube vessel wall image following gadolinium contrast shows focal enhancement of the left proximal middle cerebral artery (*arrow*). ***F.*** 3D time-of-flight magnetic resonance angiography shows focal narrowing of the left supraclinoid internal carotid artery and proximal middle cerebral artery (*arrow*).

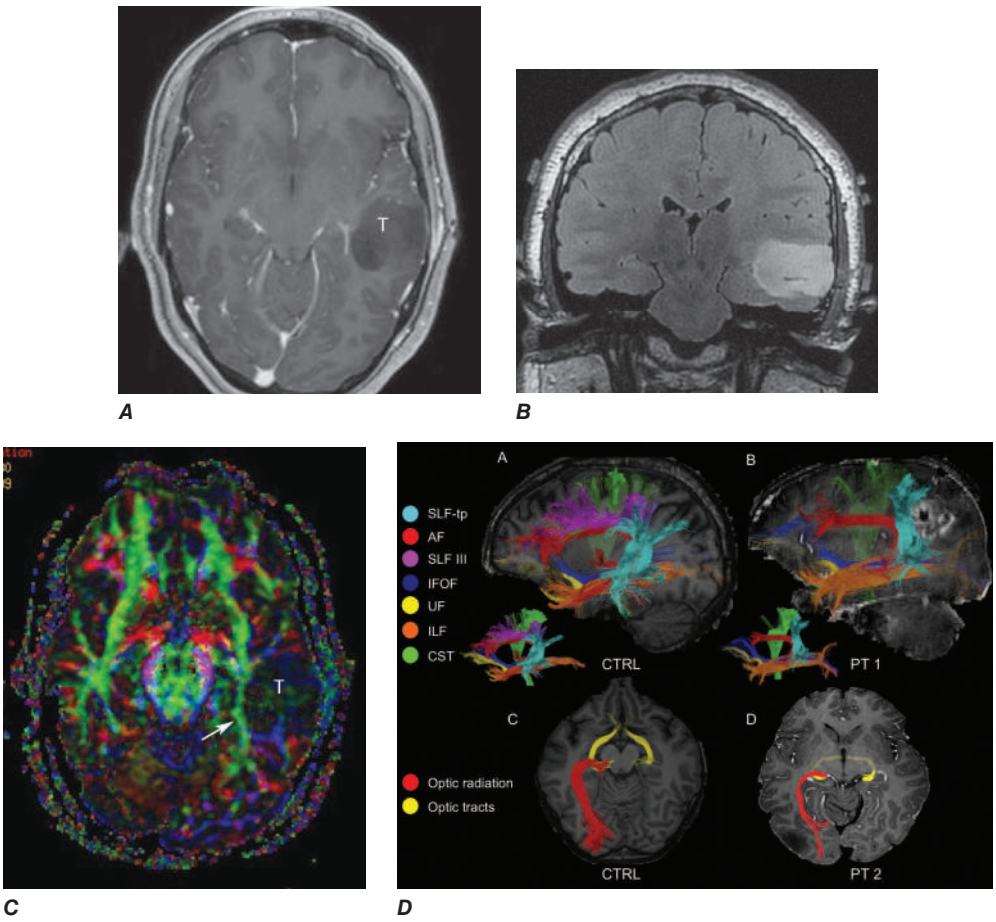

FIGURE 434-8 Diffusion tractography in cerebral glioma. A, B and C are images showing a left temporal mass lesion (T) that medially displaces the inferior longitudinal fasciculus (arrow). D. Different patient showing: Associative and descending pathways in a healthy subject (***A***) and in a patient with parietal lobe glioblastoma (***B***) presenting with a language deficit: the mass causes a disruption of the arcuate-SLF complex, in particular of its anterior portion (SLF III). Also shown are bilateral optic tract and left optic radiation pathways in a healthy subject (***C***) and in a patient with left occipital grade II oligoastrocytoma (***D***): the mass causes a disruption of the left optic radiation. *Shown in neurologic orientation, i.e., the left brain appears on the left side of the image.* AF, long segment of the arcuate fascicle; CST, corticospinal tract; IFOF, inferior fronto-occipital fascicle; ILF, inferior longitudinal fascicle; SLF III, superior longitudinal fascicle III or anterior segment of the arcuate fascicle; SLF-tp, temporo-parietal portion of the superior longitudinal fascicle or posterior segment of the arcuate fascicle; T, tumor; UF, uncinated fascicle. *(Part D used with permission from Eduardo Caverzasi and Roland Henry.)*

patients with radiculopathy whose conventional MR studies of the spine (cervical or lumbar) are normal or in those suspected of peripheral nerve entrapment or trauma. This technique is now also being used to assess peripheral nerve damage after trauma or from compressive and autoimmune neuropathies.

POSITRON EMISSION TOMOGRAPHY

PET relies on the detection of positrons emitted during the decay of a radionuclide that has been injected into a patient. The most frequently used moiety is 2-[^{18}F] fluoro-2-deoxy-D-glucose (FDG), which is an analogue of glucose and is taken up by cells competitively with 2-deoxyglucose. Many other radioisotopes are used in other indications. With FDG, multiple images of glucose uptake activity are formed 45–60 min after IV administration of FDG. Images reveal differences in regional glucose activity among normal and pathologic brain structures. FDG-PET is used primarily for the detection of extracranial metastatic disease; however, a lower activity of FDG in the parietal lobes is associated with Alzheimer's disease, a finding that may simply reflect atrophy that occurs in the later stages of the disease. Combination PET-CT scanners, in which both CT and PET are obtained at one sitting, have largely replaced PET scans alone. MR-PET scanners have also been developed and may prove useful for imaging the brain and other organs without the radiation exposure of CT. More recent PET ligand developments include beta-amyloid and tau PET tracers **(Chap. 442)**. Studies have shown an increased percentage of amyloid deposition in patients with Alzheimer's disease compared with mild cognitive impairment and healthy controls; however, up to 25% of cognitively "normal" older patients show abnormalities on amyloid PET imaging. This may either reflect subclinical disease processes or a variation of normal. Tau imaging may be more specific for Alzheimer's disease, and clinical studies are in progress.

MYELOGRAPHY

TECHNIQUE

Myelography involves the intrathecal instillation of specially formulated water-soluble iodinated contrast medium into the lumbar or cervical subarachnoid space. CT scanning is typically performed after myelography to better demonstrate the spinal cord and roots, which appear as filling defects in the opacified subarachnoid space. CT myelography, in which CT is performed after the subarachnoid injection of a small amount of contrast material, has replaced conventional myelography for many indications, thereby reducing exposure to radiation and contrast media. CT is obtained at a slice thickness of ~2.5 mm and reconstructed at 0.625-mm thick slices, which can quickly be reformatted in sagittal and coronal planes, equivalent to traditional myelography projections.

INDICATIONS

CT myelography and MRI have largely replaced conventional myelography for the diagnosis of diseases of the spinal canal and cord (Table 434-1). Remaining indications for conventional plain film myelography include the evaluation of suspected meningeal or arachnoid cysts and the localization of CSF fistulas. Conventional myelography and CT myelography provide the most precise information in patients with failed back syndrome following spinal fusion procedures.

CONTRAINDICATIONS

Myelography is relatively safe; however, it should be performed with caution in any patient with elevated intracranial pressure, evidence of a spinal block, or a history of allergic reaction to intrathecal contrast media. In patients with a suspected spinal block, MR is the preferred imaging technique. If myelography is necessary, only a small amount of contrast medium should be instilled below the block to minimize the risk of neurologic deterioration. Lumbar puncture (LP) is to be avoided in patients with bleeding disorders and those with infections of the overlying soft tissues. Anticoagulant therapy should be withheld prior to elective LP to avoid epidural or intradural hemorrhage, unless required in emergent situations **(Chap. S3)**.

COMPLICATIONS

Headache is the most frequent complication of myelography and is reported to occur in 5–30% of patients. Nausea and vomiting may also occur rarely. Postural headache (post-LP headache) is generally due to continued epidural leakage of CSF from the dural puncture site. A higher incidence is noted among younger women and with the use of larger gauge cutting-type spinal needles. If significant headache persists for >48 h, placement of an epidural blood patch should be considered. Vasovagal syncope may occur during LP; it is accentuated by the upright position used during conventional lumbar myelography. Adequate hydration before and after myelography will reduce the incidence of this complication. **Management of LP headache is discussed in Chap. 17.**

Hearing loss is a rare complication of myelography. It may result from a direct toxic effect of the contrast medium or from an alteration of the pressure equilibrium between CSF and perilymph in the inner ear. Puncture of the spinal cord is a rare but serious complication of cervical (C1–2) or high LP. The risk of cord puncture is greatest in patients with spinal stenosis, Chiari malformations, or conditions that reduce CSF volume. CT myelography following a lumbar injection and MRI are safer alternatives to cervical puncture. Reactions to intrathecal contrast administration are rare; aseptic meningitis and encephalopathy are reported rare complications. The latter is usually dose related and associated with contrast entering the intracranial subarachnoid space. Seizures rarely occur following myelography, historically reported in 0.1–0.3% of patients. Risk factors include a preexisting seizure disorder and the use of a total iodine dose of >4500 mg. Other reported complications include hyperthermia, hallucinations, depression, and anxiety states. These side effects have been reduced by the development of nonionic, water-soluble contrast agents as well as by head elevation and generous hydration following myelography.

SPINE INTERVENTIONS

DISKOGRAPHY

The evaluation of back pain and radiculopathy **(Chap. 18)** may require diagnostic procedures that attempt either to reproduce the patient's pain or relieve it, indicating its correct source prior to lumbar fusion. Diskography is now rarely indicated. It is performed by CT or fluoroscopic placement of a 22- to 25-gauge needle into the intervertebral disk and subsequent injection of 1–3 mL of contrast media. The intradiscal pressure is recorded, as is an assessment of the patient's response to the injection of contrast material. Little or no pain is felt during injection of a normal disk, which does not accept much more than 1 mL of contrast material, even at pressures as high as 415–690 kPa (60–100 lb./in^2). CT and plain films are obtained following the procedure. Concerns have been raised that diskography may contribute to an accelerated rate of disk degeneration; furthermore, patients who suffer from depression or anxiety are more likely to find diskography painful, and in some cases, the procedure-associated pain became persistent, lasting a year or longer. Thus, it is rarely used as a reliable biomarker of pain generation. Newer spectroscopic disc techniques are being explored for the detection of painful degenerative disks.

SELECTIVE NERVE ROOT AND EPIDURAL SPINAL INJECTIONS

Percutaneous selective nerve root and epidural administration of glucocorticoid and anesthetic mixtures may be both therapeutic and diagnostic. Typically, 1–2 mL of an equal mixture of a long-acting glucocorticoid such as betamethasone or dexamethasone combined with a long-acting anesthetic such as bupivacaine is instilled under CT or fluoroscopic guidance in the intraspinal epidural space or adjacent to an existing nerve root in question as a pain source. This can also be performed into the facet joints, or around the medial nerve branches that supply innervation to the facet joints as well. Radiofrequency ablation of the medial branches that supply sensation to the facet joints is commonly performed, and ablation techniques of the basivertebral nerves that conduct the sensation from degenerative disks have proven useful in certain cases of painful disk degeneration. Cement placement into compression fractures of the vertebral bodies, so-called vertebroplasty and kyphoplasty techniques, are commonly performed for pain-generating fractures, especially in elderly patients or those with pathologic fractures.

ANGIOGRAPHY

Catheter angiography is indicated for evaluating intracranial small-vessel pathology (e.g., vasculitis), for assessing vascular malformations and aneurysms, and in endovascular therapeutic procedures (Table 434-1). As noted above, angiography has been replaced for many indications by CT/CTA or MRI/MRA.

Angiography carries the greatest risk of morbidity of all diagnostic imaging procedures, owing to the necessity of inserting a catheter into a blood vessel, directing the catheter to the required location, injecting contrast material to visualize the vessel, and removing the catheter while maintaining hemostasis. Therapeutic transcatheter procedures (see below) have become important options for the treatment of some cerebrovascular diseases. The decision to undertake a diagnostic or therapeutic angiographic procedure requires careful assessment of the goals of the investigation and its attendant risks.

Patients undergoing angiography should be well hydrated before and after the procedure. Because the femoral route is used most, the femoral artery must be compressed after the procedure to prevent a hematoma from developing. The puncture site and distal pulses should be evaluated carefully after the procedure; complications can include thigh hematoma or lower-extremity emboli.

COMPLICATIONS

A common femoral arterial puncture provides retrograde access via the aorta to the aortic arch and great vessels. The most feared complication of cerebral angiography is stroke. Thrombus can form on or inside the tip of the catheter, rarely arterial dissection or perforation can occur, and atherosclerotic thrombus or plaque can be dislodged by the catheter or guide wire or by the force of injection and can embolize distally in the cerebral circulation. Risk factors for ischemic complications include limited experience on the part of the angiographer, atherosclerosis, vasospasm, low cardiac output, decreased oxygen-carrying capacity, advanced age, and prior history of migraine. The risk of a neurologic complication varies but is ~4% for transient ischemic attack and stroke, 0.5% for permanent deficit, and <0.1% for death.

Nonionic contrast material is used exclusively in cerebral angiography. Nonionic contrast injected into the cerebral vasculature can be neurotoxic if the BBB is breached, either by an underlying disease or by the injection of hyperosmolar contrast agent. Patients with dolichoectasia of the basilar artery can suffer reversible brainstem dysfunction and acute short-term memory loss during angiography, owing to the slow percolation of the contrast material and the consequent prolonged exposure of the brain. Rarely, an intracranial aneurysm ruptures during an angiographic contrast injection, causing subarachnoid hemorrhage, perhaps because of injection under high pressure.

SPINAL ANGIOGRAPHY

Spinal angiography is indicated to evaluate the location of vascular malformations and to identify the artery of Adamkiewicz **(Chap. 453)** prior to aortic aneurysm repair. The procedure is lengthy and requires the use of relatively large volumes of contrast; the incidence of serious complications, including paraparesis, subjective visual blurring, and altered speech, is <1%. Gadolinium-enhanced MRA has been

used successfully in this setting, as has iodinated contrast CTA, which has promise for replacing diagnostic spinal angiography for some indications.

INTERVENTIONAL NEURORADIOLOGY

This rapidly developing field is providing new therapeutic options for patients with challenging neurovascular problems. Available procedures include detachable coil therapy for aneurysms, particulate or liquid adhesive embolization of arteriovenous malformations, stent retrieval systems for embolectomy in acute stroke, balloon angioplasty and stenting of arterial stenosis or vasospasm, transarterial or transvenous embolization of dural arteriovenous fistulas and CSF-venous fistulas of the spine, balloon occlusion of carotid-cavernous and vertebral fistulas, endovascular treatment of vein-of-Galen malformations, preoperative embolization of tumors, and thrombolysis of acute arterial or venous thrombosis. Many of these disorders place the patient at high risk of cerebral hemorrhage, stroke, or death.

The highest complication rates are found with the therapies designed to treat the highest risk diseases. The advent of electrolytically detachable coils ushered in a new era in the treatment of cerebral aneurysms **(Chap. 440)**. Two randomized trials found reductions of morbidity and mortality at 1 year among those treated for aneurysm with detachable coils compared with neurosurgical clipping. In many centers, coiling has become standard therapy for many proximal circle of Willis aneurysms.

Finally, recent studies of stent retrieval systems used to withdraw emboli have shown improved clinical outcomes in patients presenting with large-vessel occlusions and signs of acute stroke **(Chap. 438)**.

435 Pathobiology of Neurologic Diseases

Stephen L. Hauser, Arnold R. Kriegstein, Stanley B. Prusiner

The human nervous system is the organ of consciousness, cognition, ethics, and behavior; as such, it is the most intricate structure known to exist. More than one-third of the 23,000 genes encoded in the human genome are expressed in the nervous system, and for many, different isoforms are expressed that further increase the resulting specificities and potential functionality. Each mature brain is composed of 100 billion neurons, several million miles of axons and dendrites, and $>10^{15}$ synapses. Neurons exist within a dense parenchyma of multifunctional glial cells that synthesize myelin, preserve homeostasis, and regulate immune responses. Measured against this background of complexity, the achievements of molecular neuroscience have been extraordinary. Advances have occurred in parallel with the development of new enabling technologies—in bioengineering and computational sciences; imaging; and cell, molecular, and chemical biology—and moving forward it is likely that the pace of new discoveries will only increase. This chapter reviews a few of the most dynamic areas in neuroscience, specifically highlighting advances in immunology and inflammation, neurodegeneration, and stem cell biology. In each of these areas, recent discoveries are providing context for an understanding of the triggers and mechanisms of disease and offering new hope for prevention, treatment, and repair of nervous system injuries. Discussions of the neurogenetics of behavior, advances in addiction science, and diseases caused by network dysfunction can be found in **Chap. 462** (Biology of Psychiatric Disorders); and new approaches to rehabilitation via harnessing of neuroplasticity, neurostimulation, and computer–brain interfaces are presented in **Chap. 500** (Emerging Neurotherapeutic Technologies).

NEUROIMMUNOLOGY AND NEUROINFLAMMATION

Neuroimmunology traditionally comprises the science of immune-mediated diseases of the nervous system, especially autoimmune diseases such as multiple sclerosis, myasthenia gravis, and Guillain-Barré syndrome, as well as disorders in which immune-mediated neurologic damage occurs in the context of infection or neoplasia. More recently, recognition that neuroinflammation and the innate immune system play key roles in an expanded category of neurologic disorders, and neurodegenerative disorders in particular, has focused renewed attention on the intrinsic cellular components in the central nervous system (CNS) that mediate tissue damage, especially microglia/macrophages and astrocytes, and also on oligodendrocytes, which are now recognized as central players across a wide range of brain disorders. It is also increasingly recognized that extensive networks of communication exist between each of these cell types and that resulting *non-cell-autonomous* pathologies are likely to underlie many human CNS disorders.

MICROGLIA AND MACROPHAGES

These represent the most abundant cell types in the nervous system responsible for antigen presentation and innate immunity. Brain microglia ("small glue") are derived from a primitive macrophage population in the yolk sac that migrates to the nervous system early in embryogenesis before the blood-brain barrier is formed. Once in the CNS, a variety of cell signals mediate microglial proliferation, migration, and differentiation. Microglia maintain their cell numbers primarily through self-renewal and not repopulation from the circulation; however, it is now also clear that under some conditions peripherally derived macrophages that become microglia-like can replace damaged or defective microglia throughout the life span. Most microglia receive survival signals through colony-stimulating factor 1 receptor (Csf1r), via its natural ligands Csf1 produced by astrocytes and oligodendrocytes, and interleukin (IL) 34 produced by neurons. Depletion of microglia by administration of a selective inhibitor of Csf1r (PLX5622) was followed by rapid repopulation, which led to identification of a second population of ramified microglial precursor cells that do not require Csf1r signaling. Microglia have traditionally been divided into "resting" and "activated" states, the former characterized by an extensively ramified appearance and the latter by a globular amoeboid phenotype. A variety of factors and cues, including type 1 interferons, can prime resting microglia toward an activated state, and these "primed" microglia are then hyperresponsive to a variety of secondary immune challenges including infection. Recently, single-cell transcriptome sequencing of microglia has also revealed a high degree of heterogeneity that was previously unappreciated, the functional consequences of which are largely unknown.

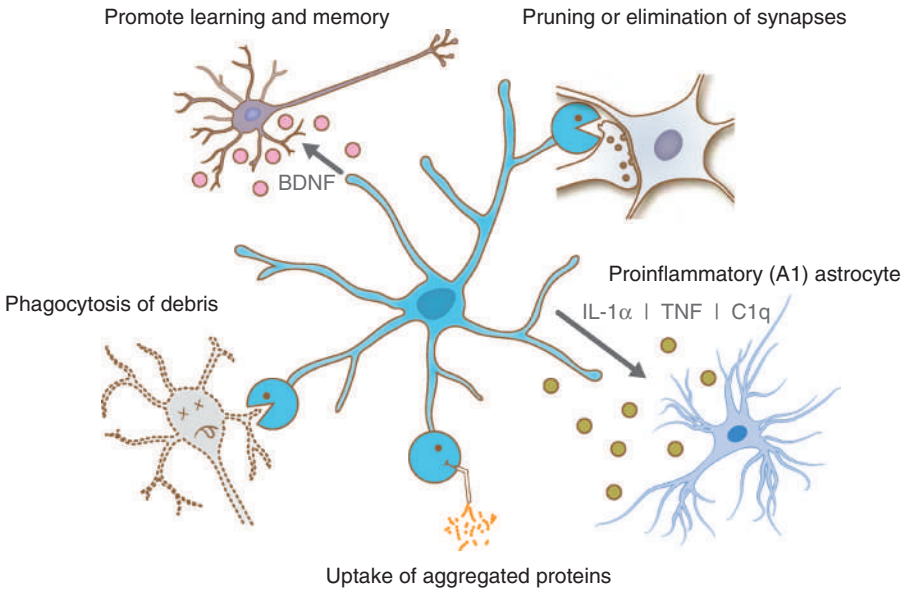

FIGURE 435-1 The multifunctional microglial cell. Microglia have diverse functions that can support healthy development and maintain homeostasis or contribute to tissue damage in pathologic conditions. Homeostatic functions include promotion of learning and memory through secretion of soluble proteins such as brain-derived neurotrophic factor (BDNF); participation in normal synaptic pruning; and clearing cellular debris and protein aggregates via phagocytosis. However, in pathologic states, activated microglia also contribute to tissue damage by targeting normal healthy neurons and synapses; by promoting formation of β-amyloid or other misfolded proteins deposited in neurodegenerative diseases; and by secreting cytokines (such as interleukin 1α, tumor necrosis factor, and the complement component C1q) incriminated in induction of neurotoxic A1 astrocytes. In addition, microglia have diverse functions in adaptive immunity, including roles in antigen presentation and immune regulation (Fig. 435-2). *(Reproduced with permission from J Herz et al: Myeloid cells in the central nervous system. Immunity 46:943, 2017.)*

Microglia play critical roles in sculpting neuronal populations during development and across the life span, through secretion of brain-derived neurotrophic factor (BDNF) and other trophic factors that promote neuronal survival, and also via production of reactive oxygen species (ROS) and other molecules that mediate cell death. Microglia regulate development and maintenance of neural circuits through pruning of excitatory synapses and control of dendritic spine densities **(Fig. 435-1)**. Mice depleted of microglia during development exhibit a variety of cognitive, learning, and behavioral deficits, including abnormal social behaviors. These processes are dependent on classical complement pathway molecules, including secretion of C1q and expression of complement receptor 3 (CR3) and CR5. Abnormalities in these microglial-dependent networks are now recognized as critical to the pathogenesis of most neurodegenerative and age-related pathologies.

Activation of the complement cascade has assumed a major place in current concepts of pathogenesis of Alzheimer's disease (AD) and other dementias, as follows. Synapses targeted for elimination are tagged by the complement proteins C1q and C3, the levels of which increase in the presence of excess β-amyloid. C3-bearing synapses are targeted for elimination by microglia that express CR3, and knockout of C1q or C3 can rescue the clinical and pathologic abnormalities associated with neurodegeneration. Modification of aberrant complement activity represents an attractive approach for treatment of neurodegeneration from multiple causes, not only AD, but also Parkinson's and Huntington's disease, among others, in which microglia are responsible for clearing pathologic protein aggregates. An ideal therapeutic would target the deleterious microglial functions while preserving ones that are central to homeostasis such as synaptic pruning. Another consideration, especially given the diverse roles of the complement system in all organs of the body, is potential off-target toxicities. Clinical trials are now underway with an inhibitory monoclonal antibody against C1q for Huntington's disease and amyotrophic lateral sclerosis (ALS). While the specific mechanisms of complement-dependent neurodegeneration will likely differ in distinct neurodegenerative conditions, these data provide hope that complement-pathway interventions could represent an approach to control of neurodegenerative pathologies mediated at least in part through the innate immune system.

Genetic evidence also supports a primary role for microglia in numerous neurodegenerative conditions and disease states, in contrast to earlier views in which their role was seen as largely secondary and involving phagocytosis of cell debris. More than half of all genes implicated in genome-wide association studies in AD implicate innate immune processes and microglia. One direct genetic link is the phagocytosis-associated gene *TREM2* (triggering receptor expressed on myeloid cells 2). TREM2 is a microglial receptor that can bind amyloid, induce proliferation and migration of microglia, and possibly limit the spread of disease-associated AD aggregates. Moreover, a soluble TREM2 cleavage product promotes neuroinflammation and inhibits aggregation of β-amyloid. Loss-of-function mutations in *TREM2* increase AD risk up to fourfold. In one mouse model of AD, overexpression of TREM2 blocked AD pathology and rescued performance on tests of learning and memory; however, in other models, including tau models, the effects of TREM2 targeting were found to be stage specific or inconsistent. A clinical trial of an agonist monoclonal antibody against TREM2 is underway.

Immune system genes implicated in susceptibility to other late-life dementias also represent promising targets for therapy. For example, ~10% of all cases of frontotemporal degeneration (FTD) are due to heterozygous mutations of the gene granulin (*GRN*), which encodes the protein progranulin expressed in neurons and microglial cells **(Chap. 443)**. Progranulin is a neurotrophic factor essential for lysosomal function and microglial homeostasis. *GRN* mutations with resulting haploinsufficiency of progranulin are highly penetrant for FTD. When progranulin is deleted in mice, an age-dependent microglial activation phenotype results, associated with upregulation of proinflammatory neurotoxic cytokines, complement components, and other genes associated with innate immunity, along with enhanced pruning of inhibitory synapses and behavioral manifestations reminiscent of human FTD. Remarkably, inhibition of complement activation can rescue all of these deficits. These data indicate a primary role for microglial activation in FTD caused by mutations in *GRN*, likely mediated through increased production of C3 complement, enhanced lysosomal trafficking, and excessive synaptic pruning in affected brain regions affected. Clinical trials underway for neurodegeneration due to progranulin deficiency include a monoclonal antibody to block lysosomal degradation of progranulin, as well as gene and protein replacement therapies.

Microglia are generally considered the most important source of antigen-presenting cells in the brain, as they express class II major histocompatibility complex molecules enabling antigen presentation

to CD4 T cells. In Parkinson's disease (PD), neurotoxic T cells reactive against epitopes of α-synuclein are commonly found, and it has been postulated that antigen presentation by microglia may have initiated this autoimmune response. Beyond a traditional role as antigen-presenting cells, microglia are now understood to also have a range of other interactions with T and B lymphocytes. For example, secretion of CCL3 by microglia, which is enhanced with aging, promotes the recruitment of memory CD8 T cells, which might account for the presence of CD8 T cells in a wide range of neuropathologic conditions including multiple sclerosis (MS).

Microglia are located throughout the brain parenchyma, while the closely related brain macrophages occur primarily in perivascular regions, including the meninges and choroid plexus. Like microglia, brain macrophages are derived from yolk sac precursors that appear to enter the brain at an early developmental stage and propagate locally, although some choroid plexus macrophages may also be replenished at low levels from the bloodstream on a continuing basis. Under inflammatory conditions, however, large numbers of hematogenously derived monocytes readily enter the brain parenchyma. In the disease model, experimental autoimmune encephalomyelitis (EAE), macrophages derived from bone marrow monocytes are the critical population that initiates inflammatory demyelination at paraxonal regions near nodes of Ranvier **(Fig. 435-2)**. Brain macrophages have multiple proinflammatory functions, including promoting adhesion, attraction, and activation of B and T lymphocytes; providing antigen-specific activation of T cells via antigen presentation of immunogenic peptides, including autoantigens, complexed to surface class II major histocompatibility complex (MHC II) molecules; and contributing to cell injury through generation of oxidative stress and cytotoxicity. By contrast, microglia have been traditionally thought to downregulate inflammatory responses and promote tissue repair in EAE. This model of the relative roles of macrophage and microglial cells is certainly an oversimplification, and more nuanced functions of these cell types have been revealed by single-cell sequencing methods, demonstrating previously unappreciated heterogeneity influenced by location, context, and environmental cues.

ASTROCYTES

Astrocytes represent half or more of all cells in the CNS. Thought earlier to function as simple interstitial supporting cells that provide scaffolds for neuronal migration and contribute to homeostasis, emerging data indicate far more pleiotropic functions for this cell type. Astrocytes, like microglia, play profound roles in the life of synapses by secreting factors (such as apolipoprotein E, thrombospondins, and glypicans) that regulate development, maintenance, and pruning of presynaptic and postsynaptic structures. Influenced by local neuronal activity, astrocytes actively phagocytose synapses. Pruning of synapses and clearance of apoptotic cells by astrocytes are mediated through the scavenger receptor multiple EGF-like domains 10 (Megf10), a high-affinity receptor for C1q. Astrocytes also participate in dynamic regulation of vascular tone, in part through astrocyte-astrocyte communication mediated through gap junctions and calcium waves modulated by neuronal activity; support blood-brain barrier and glymphatic (see below) integrity through extension of foot processes to vascular structures and expression of aquaporin-4 water channels; and carry out additional metabolic functions essential for maintenance of neuron health.

Recent work has highlighted the transcriptional and functional heterogeneity of reactive astrocytes that, depending on the context, could regulate inflammation, promote neurotoxicity, or aid in

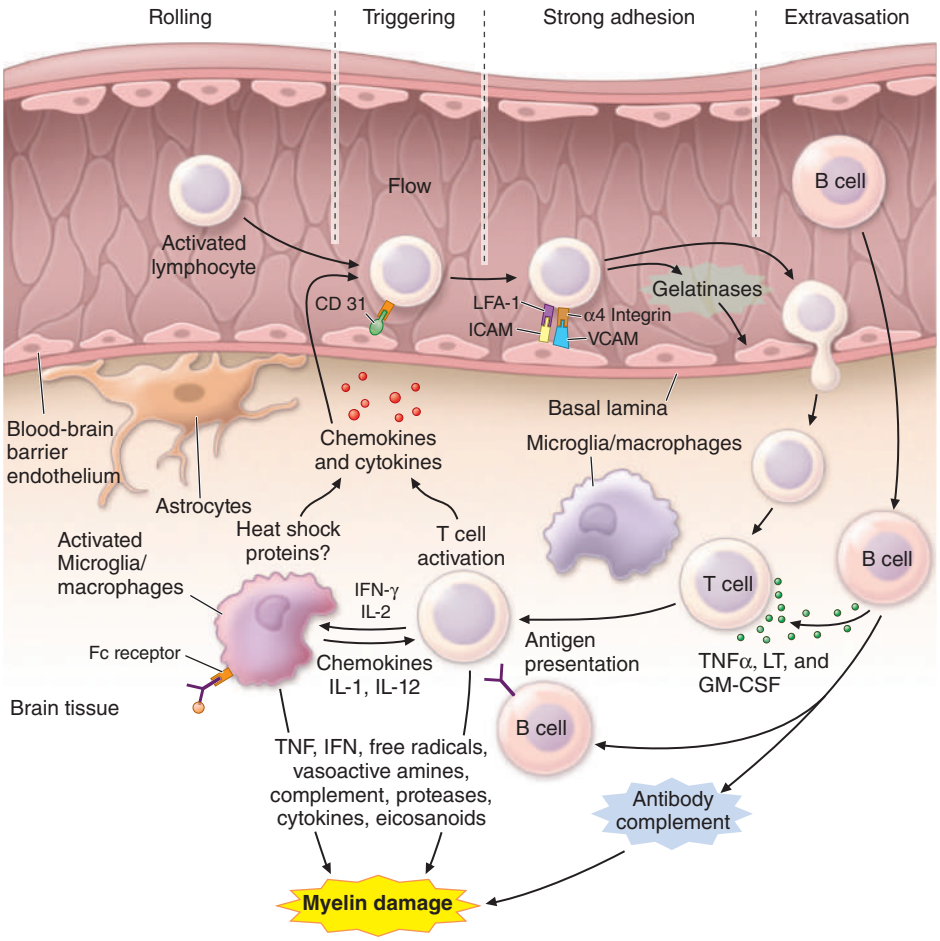

FIGURE 435-2 A model for experimental allergic encephalomyelitis (EAE). Crucial steps for disease initiation and progression include peripheral activation of preexisting autoreactive T cells; homing to the central nervous system (CNS) and extravasation across the blood-brain barrier; reactivation of T cells by exposed autoantigens; secretion of cytokines; activation of microglia and astrocytes and recruitment of a secondary inflammatory wave; and immune-mediated myelin destruction. ICAM, intercellular adhesion molecule; IFN, interferon; IL, interleukin; LFA-1, leukocyte function-associated antigen-1; TNF, tumor necrosis factor; VCAM, vascular cell adhesion molecule.

protection and repair. As examples, in response to cytokines such as granulocyte-macrophage colony-stimulating factor (GM-CSF) produced by infiltrating lymphocytes, astrocytes can augment neuroinflammation via secretion of chemokines such as CCL2 and CXCL10 that attract lymphocytes and monocytes to the CNS. In MS and other neuroimmune disorders, production of B-cell activation factor (BAFF) by astrocytes within lesions promotes the survival and activation of pathogenic autoreactive B cells. Under other conditions, astrocytes appear to limit inflammation, through expression of tumor necrosis factor (TNF)-related apoptosis-inducing ligand (TRAIL) induced by interferon γ produced by natural killer cells, or by secretion of the regulatory cytokine IL-27. And in still other settings, astrocytes can secrete factors that promote neuronal survival and axon regeneration, for example, by secretion of wingless-type MMTV integration site 1 (Wnt1), a neuroprotective factor for dopaminergic neurons.

It is also now clear that bidirectional crosstalk between immune system cells and astrocytes can profoundly influence the brain's response to injury. In the best-studied example, activated microglia, through secretion of IL-1a, TNF, and C1q, can induce astrocytes to transform to a reactive disease-promoting phenotype. Such cells lose the capacity to phagocytose synapses and myelin debris and become toxic in vitro to neurons and mature oligodendrocytes, via different mechanisms including complement-mediated damage and production of nitric oxide (NO) and free radicals. Interestingly, oligodendrocyte progenitor cells (OPCs), abundant in active lesions of MS **(Chap. 455)** within the inflammatory milieu, are resistant to astrocyte-mediated killing. In ALS models modeled on human ALS-causing mutations in *SOD1* and *C9orf72* genes, astrocyte expression of the mutant genes promoted neurotoxicity, indicating a non-cell-autonomous disease mechanism mediated through astrocytes. Similarly, in AD, astrocytes have been implicated in several genetic forms of AD, including amyloid accumulation mediated through apolipoprotein E (ApoE), which in the nervous system is expressed primarily in astrocytes. Thus, reactive astrocytes could promote damage in disorders as varied as MS **(Chap. 455)**, AD **(Chap. 442)**, PD **(Chap. 446)**, and ALS **(Chap. 448)**, despite the distinct etiologies and pathologies of these conditions.

OLIGODENDROCYTES AND MYELIN

Myelin is the multilayered insulating substance that surrounds axons and speeds impulse conduction by permitting action potentials to jump between naked regions of axons (nodes of Ranvier) and across myelinated segments. Oligodendrocytes contact axons at paranodes, where sodium and potassium channels essential for saltatory conduction are clustered. Molecular interactions between the myelin membrane and axon are required to maintain the stability, function, and normal life span of both structures. The process of myelination is directed both by axon-derived cues as well as the physical properties of the axon-membrane curvature. Importantly, ongoing neuronal activity influences both the differentiation of oligodendrocytes as well as the extent of myelination, a process referred to as *adaptive myelination*. A single oligodendrocyte usually ensheaths multiple axons in the CNS, whereas in the peripheral nervous system (PNS), each Schwann cell typically myelinates a single axon. Oligodendrocytes can increase their surface length by as much as 2000-fold, the maintenance of which places significant metabolic demands on the cell.

Myelin is a lipid-rich material formed by a spiraling process of the membrane of the myelinating cell around the axon, creating multiple membrane bilayers that are tightly apposed (compact myelin) by charged protein interactions. From an evolutionary perspective, an increase in the efficiency of nerve conduction enabled by CNS myelin has permitted expanded neuronal connectivity and brain complexity without the need to dramatically increase brain size. CNS myelin has also evolved to provide critical neuroprotective support to axons. Not surprisingly, myelin pathologies cause or contribute to many neurologic conditions. Several clinically important neurologic disorders result from inherited mutations in myelin proteins **(Chap. 457)**. Constituents of myelin have a propensity to be targeted as autoantigens in autoimmune demyelinating disorders, in part due to molecular similarities between myelin and microbial cell wall constituents **(Chaps. 455 and 456)**. Alterations in myelin are increasingly recognized as a contributor to cognitive changes associated with aging, including dementia. For example, in AD models, oligodendrocyte damage can promote the deposition of disease-associated amyloid plaques. Oligodendrocytes can also be the site of disease-associated protein deposition in some neurodegenerative disorders, for example, with toxic accumulation of α-synuclein aggregates in multiple system atrophy **(Chap. 451)**. Evidence also supports a role for oligodendrocyte and myelin pathology in disorders as varied as ALS **(Chap. 448)**, traumatic brain injury **(Chap. 454)**, and stroke **(Chap. 437)**, among other conditions.

Premyelinating OPCs are highly motile cells that migrate extensively during development and in the adult brain following injuries to the myelin sheath. OPCs migrate along the inner (or abluminal) surface of endothelial cells, a process regulated by *Wnt* pathway signaling and upregulation of the chemokine receptor Cxcr4 that drives their attachment and retention to the vasculature. In the normal adult brain, large numbers of OPCs are widely distributed. Following demyelination, remyelination is largely dependent on OPCs that differentiate into myelin-producing oligodendrocytes and produce characteristic thinly remyelinated fibers. In some situations, a second population of regenerating oligodendrocytes derived from neural stem cells can mediate more effective remyelination, with thicker lamellae and greater functional preservation of axons. A C^{14} labeling study from human MS lesions indicated that a third population of nonmitotic preexisting oligodendrocytes may represent an additional source of remyelinating cells.

Both acquired demyelinating disorders, such as MS, and inherited ones, such as Pelizaeus-Merzbacher disease (duplication or deletion of the CNS proteolipid protein gene) and adrenoleukodystrophy (mutations in the *ABCD1* gene responsible for transport of very-long-chain fatty acids into the peroxisome for degradation), are associated with progressive axonal loss. Loss of oligodendrocyte support can produce axonal damage through a variety of mechanisms, including reductions in the supply of glucose and other essential nutrients; an increased axonal workload; impaired glutamate and calcium buffering; mitochondrial damage; loss of neurotrophins; enhanced susceptibility to reactive oxygen species including nitric oxide; and failure to maintain normal synapses.

A number of molecules have been identified that regulate oligodendrocyte differentiation and myelination, including LINGO-1, hyaluronan, chondroitin sulfate proteoglycan, the *Wnt* pathway, Notch (and its receptor Jagged), fibrinogen, and the M1 muscarinic receptor Chrm1, all of which are inhibitory. Other targets are the retinoic acid receptor RXRγ, vitamin D, and thyroid hormone, all of which promote oligodendrocyte maturation. All are also potential targets for myelin repair therapies. In the EAE model of autoimmune demyelination (Fig. 435-2), oligodendrocyte-specific knockout of *Chrm1* improved remyelination, protected axons, and restored function, directly demonstrating that remyelination can be neuroprotective following injury. A pivotal trial of a monoclonal antibody against LINGO-1 in patients with acute optic neuritis failed to improve clinical outcomes, a disappointing result given that the antibody appeared to have promising clinical effects in an earlier phase 2 trial. In a preliminary trial of chronic optic neuritis, a promising result was reported with clemastine, an antihistamine and M1 muscarinic receptor antagonist, raising hope that clinically effective remyelination might be achievable even in a chronic demyelinating condition.

LYMPHATICS OF THE CENTRAL NERVOUS SYSTEM

Two recently identified lymphatic structures of the CNS are the glymphatic and deep dural lymphoid systems, responsible for clearance of debris in the CNS, and likely also serving roles in immune surveillance. The brain has traditionally been considered to lack a classical lymphatic system, and immune responses against antigens are less effectively generated in the CNS than in other organ systems, a concept termed *immune privilege*. However, the immune privilege status

of the brain is relative and not absolute. Also, given the high metabolic demands of the brain, some mechanism for efficient removal of solute and debris must be present. One well-established pathway involves the passive flow of solutes from the brain parenchyma into the cerebrospinal fluid (CSF), and their exit via the arachnoid granulations, as well as along cranial and spinal nerve roots to a series of lymphoid structures located in the cribriform plate, nasal mucosa, and elsewhere.

The *glymphatic system* derives its name from a distinctive architecture involving lymphoid-like structures and astroglial cells. CSF synthesized in the arachnoid villi circulates through the ventricles and subarachnoid space surrounding the convexities of the brain and spinal cord and exits through conduits surrounding arterioles penetrating into the brain parenchyma. These spaces are lined by endothelial cells internally and by astrocyte foot processes that form the external walls. Aided by arterial propulsion, CSF moves out of these specialized conduits and into astrocytes via foot processes rich in aquaporin-4 water channels, and then in the interstitium of brain parenchyma, picks up solutes and particulate debris that are then carried to perivenous spaces where they passage to exit the brain and drain into the lymphatic system. In mice, knockout of aquaporin-4 markedly reduced the flow of interstitial fluids in the brain, underscoring the critical role of astrocyte uptake of CSF in this process. Interstitial flow in the CNS is also impaired with aging, possibly related to changes in astrocytic aquaporin-4 expression. A fascinating aspect of the glymphatic system is that the transport of fluids and solutes accelerates with sleep, arguing for a critical role for sleep in promoting clearance of debris needed to meet the high metabolic demands of the nervous system. Furthermore, in disease models, aggregated proteins associated with neurodegenerative disease, such as β-amyloid associated with AD **(Chap. 442)**, were also more efficiently cleared during sleep. Indeed, in mice genetically engineered to produce excess β-amyloid and develop AD-like cognitive decline, sleep deprivation increased accumulation of amyloid plaques. Glymphatic pathways are also likely to represent an important egress pathway for lymphocytes in the CNS and a route for lymphocyte encounters with CNS antigens in cervical lymph nodes. In this regard, deep cervical lymph nodes may be a site for antigen-specific stimulation of B cells in MS **(Chap. 455)**.

A second pathway consists of a plexus of small lymphatic-like vessels located on the external surface of meningeal arteries and deep dural sinuses (including the sagittal and transverse sinuses), structures that exit the brain along the surface of veins and arteries and drain to the deep cervical lymph nodes. These conduits appear to represent a lymphoid drainage system distinct from vascular endothelium. These sinus-associated lymphoid structures may be most important in clearing solutes from the CSF, in contrast to the glymphatic system that likely functions to remove waste products from the brain interstitium; however, the exact functions of these two systems and their interrelationships are only beginning to be understood.

MICROBIOTA AND NEUROLOGIC DISEASE

The human microbiome **(Chap. 484)** represents the collective set of genes from the 10^{14} organisms living in our gut, skin, mucosa, and other sites. The aggregate number of genes encoded by bacteria living in and around us (i.e., the microbiome) outnumber our own genome by a factor of 100, and these can encode a wide variety of molecules that directly or indirectly affect nervous system development, maintenance, and function. Distinctive microbial communities have been found in individuals with different genetic backgrounds, ethnicities, diets, and environments. While progressively evolving with age, in any individual, the predominant gut microbiota can be remarkably stable over decades, but also can be altered by exposure to certain microbial species (e.g., by ingestion of probiotics) or the frequent use of antibiotics.

Gut microbes can shape immune responses through the interaction of their metabolism with that of humans. These gut–brain interactions are likely to be important in understanding the pathogenesis of many autoimmune neurologic diseases. For example, mice raised in a germ-free environment (or treated with broad-spectrum antibiotics) are resistant to EAE, an effect associated with decreased production of proinflammatory cytokines and conversely more production of the immunosuppressive cytokines IL-10 and IL-13 as well as an increase in regulatory T and B lymphocytes. Intestinal microbiota from patients with MS were found to promote EAE when transferred to germ-free mice, possibly due to imbalances between bacterial species that promote inflammation (e.g., *Akkermansia muciniphila* and *Acinetobacter calcoaceticus*) and those that induce regulatory immune responses (e.g., *Parabacteroides distasonis, Prevotella copri,* and certain species of *Clostridium*). Recent studies have shown that the transcription factor aryl hydrocarbon receptor (AHR) is an important regulator of the differentiation of murine and human regulatory T cells and microglia. AHR is activated by endogenous physiologic ligands, but also by metabolic products of the commensal flora.

In addition to nonspecific effects on immune homeostasis mediated by cytokines and regulatory lymphocytes, some microbial proteins could trigger a cross-reactive immune response against a homologous protein in the nervous system, a mechanism termed *molecular mimicry*. Examples include cross-reactivity between the astrocyte water channel aquaporin-4 and an ABC transporter permease from *Clostridia perfringens* in neuromyelitis optica **(Chap. 456)**; human leukocyte antigen (HLA) molecules with *A. muciniphila* peptides of *A. muciniphila* and Epstein-Barr virus in MS **(Chap. 455)**; the neural ganglioside Gm1 and similar sialic acid–containing structures from *Campylobacter jejuni* in Guillain-Barré syndrome **(Chap. 458)**; and the sleep-promoting protein hypocretin and hemagglutinin from an H1N1 influenza virus in narcolepsy **(Chap. 33)**.

Microbial genes also encode molecules that can affect development of neurons and glia, and influence myelination and plasticity. Bacterial-derived short-chain fatty acids, for example, regulate production of brain-derived neurotrophic factor (BDNF). Bacteria produce a variety of neurotransmitters including γ-aminobutyric acid (GABA) and serotonin and other neuroactive peptides that can modulate the hypothalamic-pituitary axis. Gut microbiota influence development and activity of the enteric nervous system, which communicates bidirectionally with the CNS via the vagus nerve that innervates the upper gut and proximal colon. As these gut–brain relationships become better defined, a role for the microbial environment in the pathogenesis of a much wider spectrum of neurologic conditions and behaviors seems likely, extending well beyond the traditional boundaries of immune-mediated pathologies. In this regard, it has long been known that gut bacteria can influence brain function, based mostly on classic studies demonstrating that products of gut microbes can worsen hepatic encephalopathy, forming the basis of treatment with antibiotics for this condition.

Mice that develop in a germ-free environment display less anxiety, lower responses to stressful situations, more exploratory locomotive behaviors, and impaired memory formation compared with non-germ-free counterparts. These behaviors were related to changes in gene expression in pathways related to neural signaling, synaptic function, and modulation of neurotransmitters. Moreover, this behavior could be reversed when the germ-free mice were co-housed with non-germ-free mice. As noted above, intestinal microbiota were found to be required for the normal development and function of brain microglia, potentially linking these behavioral effects to specific cellular targets in the CNS. Some actions of gut microbial species on microglia also appear to be sex- and age-specific.

The vagus nerve has been implicated in anxiety- and depression-like behaviors in mice. Ingestion of *Lactobacillus rhamnosus* induced changes in expression of the inhibitory neurotransmitter GABA1b in neurons of the limbic cortex, hippocampus, and amygdala, associated with reduced levels of corticosteroids and reduced anxiety- and depression-like behaviors. Remarkably, these changes could be blocked by vagotomy.

A related area of emerging interest is in a possible contribution of the gut microbiome to autism and related disorders. Children with autistic spectrum disorders (ASD) have long been known to have gastrointestinal disturbances, and the severity of dysbiosis appears to correlate with the severity of autism. In several murine models of autism,

manipulation of the gut microbiome ameliorated the behavioral abnormalities. A role for the proinflammatory cytokine IL-17 was implicated as a possible mediator in producing the ASD-like changes. In mice, an ASD-like disorder could be induced in offspring after injecting the pregnant mother with the viral RNA mimic, polyinosinic:polycytidylic acid (poly I:C); oral treatment of offspring with *Bacteroides fragilis* corrected a range of autistic behaviors in these mice and also improved gastrointestinal dysfunction. These preclinical data led to a small uncontrolled study of fecal gut transplantation in children with ASD that reported encouraging results but will need to be confirmed in rigorous controlled trials.

There has been considerable interest in the possible role of the microbiome in a variety of vascular, traumatic, and neurodegenerative diseases, possibly mediated through actions on innate immunity and microglia. In SOD1 transgenic ALS-prone mice, a germ-free environment exacerbated disease progression, and symptoms could be ameliorated by increasing levels of *A. muciniphila* or its nicotinamide (vitamin B_3) metabolite; a small preliminary clinical trial of nicotinamide supplementation subsequently reported encouraging results in ALS patients.

In a PD model, injection of misfolded α-synuclein into the gut triggered deposition of α-synuclein in the brain, an effect that was blocked when the vagus nerve was severed. This supported a prion mechanism (see below) for PD pathogenesis, in which vagal transport of aggregated α-synuclein might seed the CNS via the vagus nerve. The concept of a gut origin of PD is also consistent with clinical and pathologic studies, and by some epidemiologic data suggesting that vagotomy may be protective against PD. In transgenic mice that overexpress human α-synuclein, transplantation of intestinal microbiota from PD patients worsened motor deficits, α-synuclein deposition, and neuroinflammation, and conversely, pathology could be ameliorated with germ-free housing conditions or antibiotic treatment. In other work, a protein of *Escherichia coli*, named Curli, has been shown to misfold and potentially serve as a template for subsequent propagation of misfolded α-synuclein. The possibility that a bacterial protein could initiate the cascade of events leading to PD is an extraordinary, but still unproven, hypothesis.

Thus, there are a variety of mechanisms whereby the microbiome—in gut, skin, and other bodily surfaces—can modulate healthy brain function or influence susceptibility to and expression of a variety of brain diseases. The specific mechanisms are likely to vary with each condition but are likely to include promoting autoimmunity through molecular mimicry; disrupting immune homeostasis; modulating brain function via bacterial metabolites that travel in the circulation and cross the blood-brain barrier; influencing neural activity through signals generated in the enteric nervous system; or even the possibility that prion-like aggregates are formed in the gut and passage to the CNS via the vagus nerve. Although no proven benefit of modulating the microbiome exists for any brain disease today, this situation is likely to change as information about specific disease-associated microbial communities rapidly increases, along with improved methods to fine-tune their proportions and overall diversity in humans.

PATHOLOGIC PROTEINS, PRIONS, AND NEURODEGENERATION (FIG. 435-3)

PROTEIN AGGREGATION AND CELL DEATH

The term *protein aggregation* has become widely used to describe easily recognizable hallmarks of neurodegeneration. While such neuropathologic hallmarks including plaques, neurofibrillary tangles (NFTs), and inclusion bodies are often thought to cause neurologic dysfunction, numerous new discoveries over the past several decades have rendered this view increasingly unlikely. Instead, protein aggregates represent

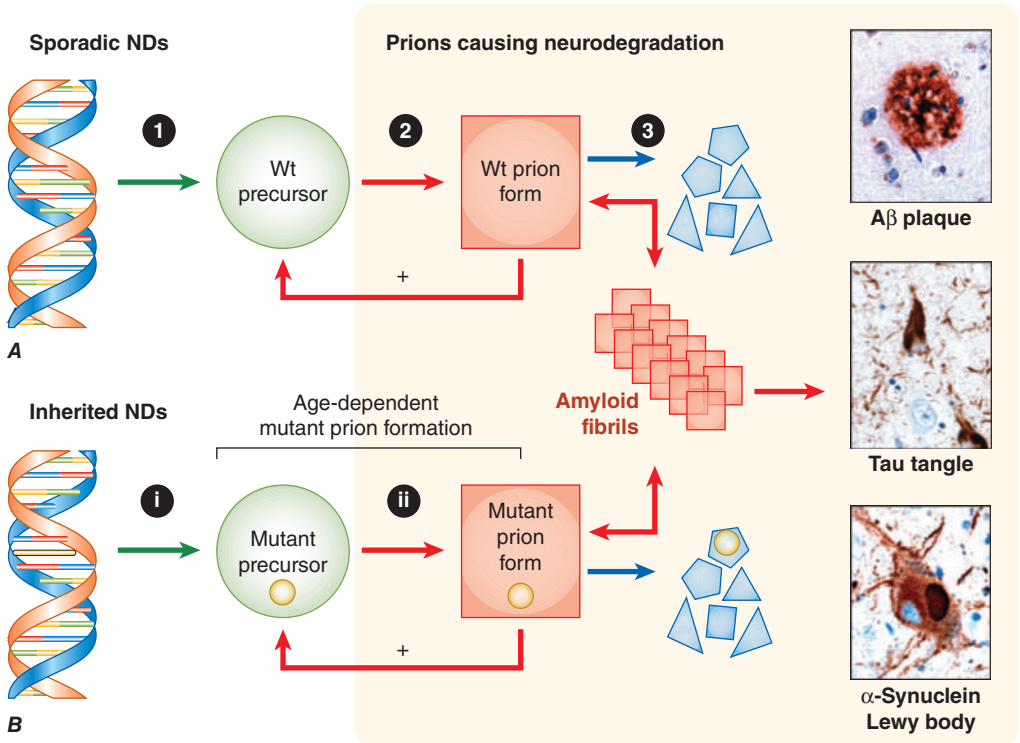

FIGURE 435-3 Neurodegeneration caused by prions. ***A.*** In sporadic neurodegenerative diseases (NDs), wild-type (Wt) prions multiply through self-propagating cycles of posttranslational modification, during which the precursor protein (*green circle*) is converted into the prion form (*red square*), which generally is high in β-sheet content. Pathogenic prions are most toxic as oligomers and less toxic after polymerization into amyloid fibrils. The small polygons (*blue*) represent proteolytic cleavage products of the prion. Depending on the protein, the fibrils coalesce into Aβ amyloid plaques in Alzheimer's disease (AD), neurofibrillary tangles in AD and other tauopathies, or Lewy bodies in Parkinson's disease (PD) and dementia with Lewy bodies. Drug targets for the development of therapeutics include: (1) lowering the precursor protein, (2) inhibiting prion formation, and (3) enhancing prion clearance. ***B.*** Late-onset heritable neurodegeneration argues for two discrete events: The (*i*) first event is the synthesis of mutant precursor protein (*green circle*), and the (*ii*) second event is the age-dependent formation of mutant prions (*red square*). The *highlighted yellow bar* in the DNA structure represents mutation of a base pair within an exon, and the *small yellow circles* signify the corresponding mutant amino acid substitution. *Green arrows* represent a normal process; *red arrows*, a pathogenic process; and *blue arrows*, a process that is known to occur but unknown whether it is normal or pathogenic. *(Used with permission of Annual Reviews, from [Biology and genetics of prions causing neurodegeneration, SB Prusiner, 47:601, 2013 permission conveyed through Copyright Clearance Center, Inc.)*

accumulations of toxic proteins that may become less harmful when they are sequestered into plaques, NFTs, and inclusion bodies.

Most mutations in the amyloid precursor protein (APP) gene causing familial AD are concentrated within the Aβ peptide. Many of these mutations increase production of the Aβ42 peptide composed of β-amyloid with 42 amino acids, which has an increased propensity to adopt a prion conformation, as compared to β-amyloid with 40 amino acids. In contrast, mutations in the APP that reduce the production of β-amyloid protect against the development of AD and are associated with preserved cognition in the elderly. The most common cause of NFTs is AD, but the precise molecular events that produce tangles are unknown. Mutations in the *MAPT* gene encoding tau stimulate NFT formation in familial frontotemporal dementia, inherited progressive supranuclear palsy, and other familial tauopathies. Like AD, the majority of most tauopathies as well as PD are sporadic.

The second most common neurodegenerative disease is PD. The saga of α-synuclein and PD begins in 1996 with the identification of a mutation in a family of Greek descent. With this family and others, there were sufficient patients to establish genetic linkage. Soon thereafter, immunostaining showed that α-synuclein was present in Lewy bodies, and the following year staining of glial cytoplasmic inclusions (GCIs) was identified in the brains of deceased multiple-system atrophy (MSA) patients. Subsequently, brains from deceased MSA patients transmitted the disease to transgenic mice, establishing that the α-synucleinopathies are prion diseases. Before the α-synuclein (*SCNA*) gene was found to cause familial PD, other genes such as the leucine-rich repeat kinase 2 (*LRRK2*) were found to modify the onset of PD; other similar PD modifier genes include *parkin, PINK1,* and *DJ-1*. PINK1 is a mitochondrial kinase (see below), and DJ-1 is a protein involved in protection from oxidative stress. Parkin, which causes autosomal recessive early-onset PD-like illness, is a ubiquitin ligase. The characteristic histopathologic feature of PD is the Lewy body, an eosinophilic cytoplasmic inclusion that contains both neurofilaments and α-synuclein. Huntington's disease (HD) and cerebellar degenerations are associated with expansions of polyglutamine repeats in proteins, which aggregate to produce neuronal intranuclear inclusions. Familial ALS is associated with superoxide dismutase (SOD1) mutations and cytoplasmic inclusions containing superoxide dismutase. An important finding was the discovery that ubiquitinated inclusions observed in most cases of ALS and the most common form of frontotemporal dementia are composed of TAR DNA-binding protein 43 (*TDP-43*). Subsequently, mutations in the *TDP-43* gene, and in the fused in sarcoma gene (*FUS*), were found in familial ALS. Both of these proteins are involved in transcription regulation as well as RNA metabolism.

Another key mechanism linked to cell death is mitochondrial dynamics, which refers to the processes involved in movement of mitochondria, as well as in mitochondrial fission and fusion, which play a critical role in mitochondrial turnover and in replenishment of damaged mitochondria. Mitochondrial dysfunction is strongly linked to the pathogenesis of a number of neurodegenerative diseases such as Friedreich's ataxia, which is caused by mutations in an iron-binding protein that plays an important role in transferring iron to iron-sulfur clusters in aconitase and complex I and II of the electron transport chain. Mitochondrial fission is dependent on the dynamin-related proteins (Drp1), which bind to its receptor Fis, whereas mitofusins 1 and 2 (MFN 1/2) and optic atrophy protein 1 (OPA1) are responsible for fusion of the outer and inner mitochondrial membrane, respectively. Mutations in *MFN2* cause Charcot-Marie-Tooth neuropathy type 2A, and mutations in *OPA1* cause autosomal dominant optic atrophy. Both β-amyloid and mutant huntingtin protein induce mitochondrial fragmentation and neuronal cell death associated with increased activity of Drp1. In addition, mutations in genes causing autosomal recessive PD, *parkin* and *PINK1*, cause abnormal mitochondrial morphology and result in impairment of the ability of the cell to remove damaged mitochondria by autophagy.

As noted above, one major scientific question is whether protein aggregates directly contribute to neuronal death or whether they are merely secondary bystanders. A focus in all the neurodegenerative diseases is on small-protein aggregates termed *oligomers*. How many monomers polymerize into a particular disease-specific oligomer has been elusive. Whether oligomers are the toxic species of β-amyloid, α-synuclein, or proteins with expanded polyglutamines such as the one causing HD remains to be established. Protein aggregates are usually ubiquitinated, which targets them for degradation by the 26S component of the proteasome. An inability to degrade protein aggregates could lead to cellular dysfunction, impaired axonal transport, and cell death by apoptotic mechanisms.

Autophagy is the degradation of cystolic components in lysosomes. There is increasing evidence that autophagy plays an important role in degradation of protein aggregates in the neurodegenerative diseases, and it is impaired in AD, PD, FTD, and HD. Autophagy is particularly important to the health of neurons, and failure of autophagy contributes to cell death. In HD, a failure of cargo recognition occurs, contributing to protein aggregates and cell death.

There is other evidence for lysosomal dysfunction and impaired autophagy in PD. Mutations in glucocerebrosidase (*GBA*) are associated with 5% of all PD cases as well as 8–9% of patients with dementia with Lewy bodies. Notably, glucocerebrosidase and enzymatic activity are reduced in the substantia nigra of sporadic PD patients. α-Synuclein is degraded by chaperone-mediated and macro autophagy. The degradation of α-synuclein has been shown to be impaired in transgenic mice deficient in glucocerebrosidase, and α-synuclein inhibits the activity of glucocerebrosidase; thus, there appears to be bidirectional feedback between α-synuclein and glucocerebrosidase.

The retromer complex is a conserved membrane-associated protein complex that functions in endosome to Golgi transport. The retromer complex contains a cargo selective complex consisting of VPS35, VPS26, and VPS29, along with a sorting nexin dimer. Mutations in VPS35 were shown to be a cause of late-onset autosomal dominant PD. The retromer also traffics APP away from endosomes, where it is cleaved to generate β-amyloid. Deficiencies of VPS35 and VPS26 were also identified in hippocampal brain tissue from AD. A potential therapeutic approach to these diseases might therefore be to use chaperones to stabilize the retromer and reduce the generation of β-amyloid and α-synuclein.

PRIONS AND NEURODEGENERATIVE DISEASES

As we have learned more about the etiology and pathogenesis of the neurodegenerative diseases, it has become clear that the histologic abnormalities that were once curiosities, in fact, are likely to reflect the etiologies. For example, the amyloid plaques in kuru and Creutzfeldt-Jakob disease (CJD) are filled with the PrP^{Sc} prions that have assembled into fibrils. The past three decades have witnessed an explosion of new knowledge about prions. For many years, kuru, CJD, and scrapie of sheep were thought to be caused by slow-acting viruses, but a large body of experimental evidence argues that the infectious pathogens causing these diseases are devoid of nucleic acid. Such pathogens are called prions, which are composed of host-encoded proteins that adopt alternative conformations that undergo self-propagation. Prions impose their conformations on the normal, precursor proteins, which in turn become self-templating, resulting in faithful copies; most prions are enriched for β-sheet and can assemble into amyloid fibrils.

Similar to the plaques in kuru and CJD that are composed of PrP prions, the amyloid plaques in AD are filled with Aβ prions that have polymerized into fibrils. This relationship between the neuropathologic findings and the etiologic prion was strengthened by the genetic linkage between familial CJD and mutations in the PrP gene, as well as (as noted above) between familial AD and mutations in the *APP* gene. Moreover, a mutation in the *APP* gene that prevents Aβ peptide formation was correlated with a decreased incidence of AD in Iceland.

The heritable neurodegenerative diseases offer an important insight into the pathogenesis of the more common sporadic ones. Although the mutant proteins that cause these disorders are expressed in the brains of people early in life, the diseases do not occur for many decades. Many explanations for the late onset of familial neurodegenerative diseases have been offered, but none is supported by substantial experimental evidence. The late onset might be due to a second event

TABLE 435-1 Prion-Based Classification of Neurodegenerative Diseases

NEURODEGENERATIVE DISEASE	CAUSATIVE PRION PROTEINS
Creutzfeldt-Jakob disease (CJD)	PrP^{Sc}
Kuru	PrP^{Sc}
Gerstmann-Sträussler-Scheinker disease (GSS)	PrP^{Sc}
Fatal insomnia	PrP^{Sc}
Bovine spongiform encephalopathy (BSE)	PrP^{Sc}
Scrapie	PrP^{Sc}
Chronic wasting disease (CWD)	PrP^{Sc}
Feline spongiform encephalopathy	PrP^{Sc}
Transmissible mink encephalopathy	PrP^{Sc}
Alzheimer's disease (AD)	Aβ → tau
Down syndrome	Aβ → tau
ALS-parkinsonism dementia complex (PDC) of Guam	Aβ → tau
Parkinson's disease (PD)	α-Synuclein
Dementia with Lewy bodies	α-Synuclein
Multiple-system atrophy	α-Synuclein
Frontotemporal dementias (FTDs)	Tau, TDP43, FUS (C9orf72, progranulin)
Posttraumatic FTD	Tau
Chronic traumatic encephalopathy (CTE)	
Amyotrophic lateral sclerosis (ALS)	SOD1, TDP43, FUS (C9orf72)
Huntington's disease (HD)	Huntingtin

in which a mutant protein, after its conversion into a prion, begins to accumulate at some rather advanced age. Such a formulation is also consistent with data showing that the protein quality-control mechanisms diminish in efficiency with age. Thus, the prion forms of both wild-type and mutant proteins are likely to be efficiently degraded in younger people but are less well handled in older individuals. This explanation is consistent with the view that neurodegenerative diseases are disorders of the aging nervous system.

A new classification for neurodegenerative diseases can be proposed based on not only the traditional phenotypic presentation and neuropathology but also the prion etiology **(Table 435-1)**. An expanding body of experimental data has accumulated connecting prions in each of these illnesses. In addition to kuru and CJD, Gerstmann-Sträussler-Scheinker disease (GSS) and fatal insomnia in humans are caused by PrP^{Sc} prions. In animals, PrP^{Sc} prions cause scrapie of sheep and goats, bovine spongiform encephalopathy (BSE), chronic wasting disease (CWD) of deer and elk, feline spongiform encephalopathy, and transmissible mink encephalopathy (TME). Similar to PrP, Aβ, tau, α-synuclein, superoxide dismutase 1 (SOD1), and possibly huntingtin all adopt alternative conformations that become self-propagating, and thus, each protein can become a prion and be transferred to synaptically connected neurons. Moreover, each of these prions causes a distinct constellation of neurodegenerative diseases.

Evidence for a prion etiology of AD comes from a series of transmission experiments initially performed in marmosets and subsequently in transgenic mice expressing the mutant APP from which the Aβ peptide is derived (Table 435-1). Synthetic mutant Aβ peptides folded into a β-sheet-rich conformation exhibited prion infectivity in cultured cells. Studies of the tau protein have shown that it not only features in the pathogenesis of AD but also causes the frontotemporal dementias including chronic traumatic encephalopathy, which has been reported in both contact sport athletes and military personnel who have suffered traumatic brain injuries. A series of incisive studies using cultured cells and Tg mice have demonstrated that both tau and Aβ prions are found together in the brains of AD patients. These findings indicated that AD is a double-prion disease (Table 435-1); unexpectedly, two more double-prion diseases have been identified recently. Patients with Down syndrome, from 6–72 years of age, all had both Aβ and tau prions in their brains with the frequent diagnosis of AD. The third double-prion disease has been found in the Chamorro people on Guam as well as Japanese living on the Kii peninsula: both groups of people develop ALS with dementia and both have Aβ and tau prions in their brains.

In contrast to Aβ and tau prions, α-synuclein prions cause very different illnesses, i.e., PD, dementia with Lewy bodies (DLB), and MSA. Brains from MSA patients inoculated into Tg(*SCNA**A53T) mice died ~90 days after intracerebral inoculation, whereas mutant α-synuclein (A53T) prions formed spontaneously in Tg mouse brains that killed recipient Tg mice in ~200 days (Table 435-1).

For many years, the most frequently cited argument against prions was the existence of strains that produced distinct clinical presentations and different patterns of neuropathologic lesions. Some investigators argued that the biologic information carried in different prion strains could be encoded only within a nucleic acid. Subsequently, many studies demonstrated that strain-specified variation is enciphered in the conformation of PrP^{Sc}, but the molecular mechanisms responsible for the storage of this biologic information remains enigmatic. The neuroanatomical patterns of prion deposition have been shown to be dependent on the particular strain of prion. Convincing evidence in support of this proposition has been accumulated for PrP, Aβ, tau, and α-synuclein prions. The most persuasive information on prion strains comes from studies in yeast where the tools of yeast genetics allowed inciteful investigations to be performed in ways that could not be accomplished in mammals.

Although the number of prions identified in mammals and in fungi continues to expand, the existence of prions in other phylogeny remains undetermined. Some mammalian prions perform vital functions and do not cause disease; such nonpathogenic prions include the cytoplasmic polyadenylation element-binding (CPEB) protein, the mitochondrial antiviral-signaling (MAVS) protein, and T cell–restricted intracellular antigen 1 (TIA-1).

Many but not all prion proteins adopt a β-sheet-rich conformation and appear to readily oligomerize as this process becomes self-propagating. Control of the self-propagating state of benign mammalian prions is less well understood than that of pathogenic mammalian prions, which appear to multiply exponentially. We do not know if prions multiply as monomers or as oligomers; notably, the ionizing radiation target size of PrP^{Sc} prions suggests it is a trimer. The oligomeric states of pathogenic mammalian prions are thought to be toxic; larger polymers, such as amyloid fibrils, seem to be a mechanism for minimizing toxicity.

The development of drugs designed to inhibit the conversion of the normal precursor proteins into prions or to enhance the degradation of prions focuses on the initial step in prion accumulation. Although a dozen drugs that cross the blood-brain barrier have been identified that prolong the lives of mice infected with scrapie prions, none has been identified that extends the lives of Tg mice that replicate human CJD prions. Despite doubling or tripling the length of incubation times in mice inoculated with scrapie prions, all of the mice eventually succumb to illness. Because all of the treated mice develop neurologic dysfunction at the same time, the mutation rate as judged by drug resistance is likely to approach 100%, which is much higher than mutation rates recorded for bacteria and viruses. Mutations in prions seem likely to represent conformational variants that are selected for in mammals where survival becomes limited by the fastest-replicating prions. The results of these studies make it likely that cocktails of drugs that attack a variety of prion conformers will be required for the development of effective therapeutics.

NEURAL STEM CELL BIOLOGY

Normal and genetically modified ("transgenic") mice are the most widely used model systems to study features of human nervous system diseases. However, modeling genetic diseases in rodents is limited to the relatively small number of monogenic human diseases where the specific gene mutations are known and is further limited by species differences. The latter can be particularly important in brain regions such as the cerebral cortex that have undergone significant evolutionary expansion in humans. These shortcomings, which likely contribute to the low probability that therapeutic efficacy translates from animal models to humans, can potentially be overcome through stem cell models that enable the use of human cells and tissues to model human diseases. The advent of new stem cell technologies

is transforming our understanding of the pathobiology of human neurologic diseases. Stem cell platforms are being used to screen for therapeutic agents, to uncover adverse drug effects, and to discover novel therapeutic targets.

Among the most exciting recent advances in stem cell technology is the ability to convert somatic cells, either skin fibroblasts or blood cells, into pluripotent stem cells known as induced pluripotent stem cells (iPSCs). This technology has introduced an entirely new and powerful approach to study the pathobiology of heritable diseases. Pluripotent stem cells can be easily obtained through minimally invasive procedures such as a skin biopsy or blood sample and converted to pluripotency through application of a cocktail of reprogramming factors to create iPSCs. Initially, a set of four programming factors, Oct3/4, Klf-4, Sox2, and c-Myc, was delivered to cells using lentiviruses that stably integrated the reprogramming factor genes into the iPSC genome, potentially altering disease phenotypes and also abrogating expression of native genes at the DNA sites where the factors integrated. Newer techniques have been developed that use nonintegrating approaches such as through the use of Sendai virus, messenger RNA (mRNA), or episomal vectors that circumvent these problems. Once created, iPSC lines can be expanded indefinitely to produce a limitless supply of stem cells. These cells are the starting material for the derivation of specific cell types based on protocols that use small molecules, proteins, or direct gene induction to recapitulate developmental programs. Most current protocols derive neuronal progenitors through dual-SMAD inhibition, a step that involves the use of small-molecule inhibitors to block endoderm and mesodermal cell fates, thereby creating neural cells by default. Multiple protocols have been developed over the last decade for creating large numbers of human neuron progenitor cell types and directing them toward specific nervous system cell fates, including neuron subtypes from multiple regions of brain and spinal cord as well as retinal cells, glial cells including astrocytes and oligodendrocytes, immune cells, and peripheral nervous system cells.

The primary medical benefit of iPSC technology is that it enables the creation of patient-specific cells or tissues that are genetically matched to individual subjects. This approach enables the study of not only monogenetic disorders but also sporadic forms of disease and complex polygenic disorders including those with unidentified risk loci. Furthermore, by deriving iPSC cell lines from multiple patients, it is possible to explore how disease phenotypes may vary according to genetic background. Another approach that has been used to generate specific neuron and glial cell types from somatic cells such as fibroblasts is through direct reprogramming. This approach relies on a cocktail of specific transcription factors to directly convert somatic cells into the alternate desired cell type. This approach bypasses the epigenetic reset that accompanies cells as they are reprogrammed to a pluripotent state. The advantage of this approach is that age-related epigenetic signatures are not erased, so that derived neurons may more readily reflect diseases that manifest in older cells.

Despite the advantages of using in vitro models of nervous system diseases derived from patient-specific iPSCs, several potential roadblocks remain. There are no standard reprogramming or derivation protocols, and the different methods can result in considerable variability in the disease phenotypes reported by different laboratories. Confidence in the specificity of a particular phenotype is therefore increased if it has been validated across multiple laboratories. There is also the problem of inherent variability between patient lines that may result from their different genetic backgrounds. One solution, available only in the case of monogenic disorders, is to use isogenic controls generated using gene editing, such as with CRISPR-Cas9 technology, to create disease and control lines on an identical genetic background. However, because differences in genetic background can influence the penetrance of a particular trait, it will still be necessary to compare disease lines from multiple patients to discern a true disease phenotype. For polygenic disorders where the causative mutations are unknown, it will not be possible to create isogenic controls, and in these situations, the best strategy for improving reliability and sensitivity is to compare lines from multiple patients.

ORGANOIDS

Most nervous system disorders, including ASD, schizophrenia, PD, AD, and ALS, are complex disorders, resulting from an unknown combination of gene mutations, and manifest not only in specific cell types but also in alterations of the local tissue environment. These disorders are difficult to model in animals, but they are approachable using three-dimensional human iPSC stem cell models, often referred to as "organoids." Organoids are derived from pluripotent stem cells that are directed along a tissue-specific lineage through the timed application of growth factors, genes, or small-molecule activators or inhibitors, and allowed to aggregate into three-dimensional structures. With time, cell intrinsic programs are spontaneously engaged and the cellular aggregates begin to self-organize and develop into structures that recapitulate the complex topographical and cellular diversity of normal organ development. In this way, it has been possible to create, at least in part, in vitro brainlike organoids that resemble parts of the human brain at early stages of development. When allowed to develop from an anterior neural tube stage, these structures can become heterogeneous, containing regions with forebrain, midbrain, and/or hindbrain identity and can often include retina-like structures. The high degree of variability in such "whole-brain organoids" can be a liability for controlled studies and can be reduced by the use of directed protocols that restrict outcomes to more defined brain regions, such as forebrain, cortex, or ganglionic eminence. A variety of protocols have now been developed to generate organoids with specific regional identity, and fusing organoids of different regional identity with each other has been used to reproduce cellular interactions such as neuronal migration across regions. Many protocols are focused on modeling cortical development, and they can reproduce developmental features including a diversity of progenitor and neuronal cell types topographically distributed within ventricular and subventricular progenitor regions and rudimentary cortical layers. However, the organoids follow a human developmental timetable and still remain at stages roughly comparable to late fetal development even after 6–9 months of culture. Moreover, they lack key cell types such as endothelial cells, pericytes, and microglia, and have few if any astrocytes or oligodendrocytes. Recently, it has become possible to derive these cell types independently from stem cells and then combine them with brain organoids to create tissue-diverse brain organoids that also contain, for example, vascular or immune cells. Nonetheless, while still only reflecting rudimentary organizational and compositional features, organoids have become attractive models to study human brain development and the pathophysiology of human nervous system diseases in the context of a partially organized brainlike structure.

BRAIN DEVELOPMENT AND DEVELOPMENTAL DISORDERS: MICROCEPHALY AND LISSENCEPHALY

Transcriptional analysis has suggested that the neurons produced by most stem cell protocols resemble early- to mid-gestational stages of human brain development. The immaturity of stem cell–derived human neurons may limit their utility for modeling adult diseases, but it does make them ideally suited for the study of brain development and the pathophysiology of neurodevelopmental disorders.

Primary autosomal recessive microcephaly (MCPH) is a rare neurodevelopmental disorder producing severe microcephaly with simplified cortical gyration and intellectual disability. MCPH was one of the first disorders to be studied using cerebral organoids. Mutations in genes encoding microtubule spindle components and spindle-associated proteins are the most frequent causes of congenital microcephaly. Among them is cyclin-dependent kinase 5 related activator protein 2 (CDK5RAP2). Skin fibroblasts derived from a single microcephalic patient carrying a mutation in CDK5RAP2 were used to generate four iPSC lines. Cerebral organoids grown from these cell lines contained fewer proliferating progenitor cells and showed premature neural differentiation compared to wild-type controls. Introducing functional CDK5RAP2 by electroporation partially rescued the disease phenotype, supporting the notion that failure of the founder population of neural progenitors to properly expand underlies the smaller brain. This study demonstrated that brain organoids derived from patients with microcephaly can be used to reproduce features of the disease but

did not reveal new insights or disease features of CDK5RAP2 microcephaly that had not already been described in mouse models.

Organoids, however, are well-suited to model human microcephaly because the phenotype manifests at early prenatal ages and can be assessed by organoid size, which can serve as a proxy for a microcephaly phenotype. For example, a loss-of-function screen of candidate microcephaly human genes was carried out in organoids using CRISPR-lineage tracing; 173 potential microcephaly genes were tested, and novel mechanisms involved in brain size control were discovered including a pathway involved in endoplasmic reticulum function and extracellular matrix production.

Cortical organoids have also been used to model lissencephaly or "smooth brain." Miller-Dieker syndrome (MDS), a severe congenital form of lissencephaly, was modeled in organoids and features of the human disease were observed that had not been noted in murine models. Classical lissencephaly is a genetic neurologic disorder associated with intellectual disability and intractable epilepsy, and MDS is a severe form of the disorder. Cortical folding in humans begins toward the end of the second trimester, but gyrencephaly depends upon earlier events such as neural progenitor cell proliferation and neuronal migration, which can be modeled in organoids. The human organoid model of MDS exhibited several neural progenitor cell phenotypes that had already been reported in mouse models, including altered mitotic spindle orientation and neuronal migration defects. But the organoids also displayed a mitotic defect in a specific neural stem cell subtype, the outer radial glia cell (oRG), that had not been observed in mice. oRG cells are enriched in the outer subventricular zone, a proliferative region that is large in primates and not present in rodents. These cells are particularly numerous in the developing human cortex and are thought to underlie the developmental and evolutionary expansion of the human cortex. oRG cells from MDS patients behaved abnormally and had arrested or delayed mitoses. MDS organoids also identified noncell autonomous defects in *Wnt* signaling as an underlying mechanism. These insights into mechanistic and cell-type-specific features of human disease highlight how organoid technology can provide new and valuable perspectives on the pathophysiology of disorders of in utero development.

ACQUIRED NEURODEVELOPMENTAL DISORDERS: ZIKA

The outbreak of Zika virus (ZIKV) and associated microcephaly cases in the Americas provided a test case for the utility of brain organoids to model acquired human microcephaly. Despite a correlation between Zika infection rates and the incidence of congenital microcephaly, compelling evidence that ZIKV caused microcephaly was lacking in the early phases of the epidemic. The causal link between ZIKV and congenital microcephaly was buttressed by two studies in 2016 that used human iPSC-derived neural progenitor cells and organoids to demonstrate ZIKV tropism for human neural progenitor cells. Neural progenitor cells (radial glia) were readily infected in vitro with subsequent progenitor cell death and involution of organoid size. Forebrain organoids were further used to highlight the role of the flavivirus entry factor, AXL, in determining viral tropism, and were also used to explore the disease mechanism by demonstrating upregulation of the innate immune receptor toll-like receptor 3 (TLR) in response to ZIKV infection. Stem cell–derived models of human brain development have also demonstrated centrosomal abnormalities in radial glia and alteration in the cleavage plane of mitotic radial glia associated with premature neural differentiation. Mouse models are also being used to study the pathophysiology of congenital ZIKV syndrome, but the availability of unlimited numbers of human neural cells produced using stem cell technology has enabled high-throughput screening assays to test libraries of clinically approved compounds for potential therapeutic agents. This strategy has already highlighted several compounds that could potentially help protect against ZIKV microcephaly.

NEURODEVELOPMENTAL DISORDERS: AUTISM AND SCHIZOPHRENIA

ASDs are complex and heterogeneous neurodevelopmental disorders usually manifesting in childhood with difficulties in social interaction, verbal and nonverbal communication, and repetitive behaviors. The cellular and molecular mechanisms underlying ASD are thought to arise at stages of fetal brain development, making them well-suited for exploration using human iPSC-derived disease models. iPSC-derived neurons have been used to study the pathophysiology of disorders associated with ASD that are caused by monogenic mutations, including fragile X, Rett, and Timothy syndromes.

Fragile X is the most common heritable cause of intellectual disability, affecting 1 in 4000 males and 1 in 8000 females, and is a leading genetic cause of ASD. Patients also have speech delay, growth and motor abnormalities, hyperactivity, and anxiety. The causative mutation lies in the *FMR1* gene and produces a CGG triplet repeat expansion from a normal number of 5–20 to >200, leading to epigenetic silencing of the *FMR1* gene and loss of the fragile X mental retardation protein. The epigenetic mechanism means that unlike a simple gene deletion that would lead to ubiquitous loss of expression, the FMR1 locus becomes hypermethylated and epigenetically silenced during differentiation; thus, FMR1 protein is expressed by the early embryo and becomes absent only around the beginning of the second trimester. Interestingly, this expression pattern is recapitulated during cellular differentiation in stem cell models. Pluripotent fragile X stem cell lines have been derived from embryos identified through preimplantation genetic diagnosis and by reprogramming skin fibroblasts from fragile X patients to create iPSC lines. In both cases, *FMR1* was expressed by the pluripotent stem cells but underwent transcriptional silencing following differentiation. Fragile X stem cell lines can therefore be used to study the mechanism of FMR1 silencing, an effort that is ongoing. Neurons generated from fragile X iPSC cells reproduce features observed in neurons from transgenic *FMR1* mouse models and patients, including stunted neurites with decreased branching, increasing confidence in the iPSC model. In addition to providing a model that can be used to study disease pathogenesis, fragile X iPSC-derived neurons could be used to screen for potential therapeutic agents or gene-editing strategies to remove the repressive epigenetic marks induced by the mutation and rescue the phenotype.

Rett syndrome is an X-linked neurodevelopmental disorder with dominant inheritance caused by a mutation in the *MECP2* gene. Because males carrying one copy of the defective gene usually die in infancy, most patients are girls. Random inactivation of the X chromosome in girls results in mosaic cellular expression of the mutation that circumvents fatality and produces a variable phenotype. The symptoms are present in early childhood and include microcephaly associated with developmental delay, autistic-like behaviors and cognitive dysfunction, seizures, and repetitive motor actions; these then progress to include difficulties with gait, swallowing, and breathing before usually stabilizing with patients surviving to adulthood. The pathophysiology of Rett syndrome is presumed to involve abnormal epigenetic regulation leading to decreased transcriptional repression of genes whose overexpression produces the disease phenotype, although this concept has been contested. In one of the first studies to use iPSC modeling to study Rett syndrome, it was discovered that when fibroblasts from patients were reprogrammed to pluripotent stem cells, X inactivation was erased. In apparent recapitulation of endogenous events, X chromosome inactivation re-occurred during neuronal differentiation, producing a mosaic of cells carrying the mutant gene intermingled with normal cells. Rett neurons had fewer dendritic spines and synapses, smaller cell bodies, and reduced network activity. Another iPSC model of Rett syndrome highlighted the potential role of altered inhibitory function. Rett neurons were found to have a deficit of potassium/chloride cotransporter (KCC2) that is developmentally regulated and normally leads to a switch in GABA signaling from excitatory at embryonic ages to inhibitory by birth. In Rett neurons, KCC2 expression level was low, and the functional switch in GABA effects was delayed, contributing to some of the disease features and possibly accounting for the developmental onset of the disease. One curious feature of some iPSC Rett lines was that despite the mosaic expression of the mutation, disease phenotypes were observed in all cells. Possibly, this could reflect a noncell autonomous effect, but as in all iPSC disease models, confidence in disease-specific features will be increased when similar phenotypes are seen across multiple independent studies.

Timothy syndrome, another severe neurodevelopmental disease associated with ASD, has been modeled using iPSC-derived organoids. Timothy syndrome is caused by a mutation in the *CACNA1C* gene coding for a voltage-gated calcium channel, and neuron defects in Timothy syndrome organoids were rescued by selectively altering calcium channel activity. In one study, two separate organoids were produced with different regional identity, one represented neocortex and one a more ventral structure known as the medial ganglionic eminence, which is the source of most cortical interneurons. The two organoids were then fused together to allow the interneurons to migrate into the cortex, mimicking their endogenous behavior. The ability to model interneuron migration led to the discovery of a cell-autonomous migration defect in the disease-carrying neurons.

The majority of nervous system diseases, including ASD, are polygenic and cannot be modeled in animals but can be modeled using patient-derived iPSCs. For example, a subset of patients with ASD have large head size, and a cohort of patients with this phenotype was used to generate iPSCs that were converted to neural progenitor cells and forebrain neurons. The progenitors had an accelerated cell cycle and produced an excess of inhibitory interneurons and had exuberant cellular overgrowth of neurites and synapses. This last feature is in contrast to the decrease in spines and synapses observed in other iPSC models of ASD such as fragile X and Rett syndrome and underscores the need for replication and validation of purported disease phenotypes given the high variability based on differences between stem cell lines, protocols, patient genetic background, and other factors. Moreover, the clinical features of most neuropsychiatric diseases reflect disorders in processes such as circuit formation and refinement that occur after birth and may be difficult to capture at the fetal stage of development reflected in stem cell models.

Patient stem cells have also been used by multiple groups to study the pathophysiology of schizophrenia, producing a variety of diverse and sometimes contradictory results. Reports claim obvious phenotypes such as disruptions in the adherens junctions of forebrain radial glia or aberrant neuronal migration, although such gross abnormalities observed at the equivalent of in utero stages of development seem very unlikely to underlie a disease that usually manifests at adolescence or young adulthood. Other studies report abnormalities related to abnormal microRNA expression, disordered cyclic AMP and *Wnt* signaling, abnormal stress responses, diminished neuronal connectivity, fewer neuronal processes, problems with neuronal differentiation, and mitochondrial abnormalities, among others. While the pathophysiology of as complex a neurodevelopmental disorder as schizophrenia may be multidimensional, it is unclear which, if any, of the reported findings in iPSC models reflect the true pathology of schizophrenia. Progress will likely depend on the adoption of more standard and reproducible protocols, more rigorous identification of cell types, markers of regional identity, and indicators of maturity.

ALZHEIMER'S DISEASE

As noted above, the leading concept of AD pathogenesis, the amyloid hypothesis, suggests that an imbalance between production and clearance of β-amyloid leads to excessive accumulation of β-amyloid peptide and the formation of NFTs within neurons, composed of aggregated hyperphosphorylated tau proteins. Additionally, aggregates of amyloid fibrils are deposited outside neurons in the form of neuritic plaques. Among the causes of familial AD are mutations in genes involved in β-amyloid production, including amyloid precursor protein (APP) and presenilin 1 and 2. Shortly after the introduction of iPSC technology, human stem cell–derived neurons were generated from patients carrying mutations in AD-causative genes as well as from sporadic AD cases. The disease neurons developed hallmarks of AD including intracellular accumulation of β-amyloid and phosphorylated tau, as well as secretion of APP cleavage products, features that could be reduced by adding β- or γ-secretase inhibitors or β-amyloid-specific antibodies. The neurons also demonstrated other disease features observed in postmortem AD tissues. However, extracellular β-amyloid aggregation and NFTs were not robustly modeled in these two-dimensional systems, presumably because secreted factors were able to readily diffuse away. The use of three-dimensional organoids to model AD overcame this limitation, presumably by recreating a more faithful extracellular matrix. Organoid models promoted the aggregation of β-amyloid, and more readily recapitulated the pathologic features of AD, including the formation of NFTs and neuritic plaques.

It is hoped that the new stem cell models, particularly organoid models, will accelerate our understanding of AD by enabling the study of human disease-carrying cells in a quasi in situ setting. These new models may lead to discovery of novel druggable targets and new diagnostic and prognostic biomarkers. One concern is that the pathogenic features of AD usually appear in the sixth or seventh decade of life and progress slowly over years, while most protocols for the derivation of human cortical neurons generate cells over weeks or months and most remain comparable to immature neurons at fetal stages of development. Nonetheless, these young cells have been used to model neurodegenerative diseases such as AD and HD that strike patients in middle to late adulthood. Possibly the onset of disease phenotype is accelerated in stem cell models due to increased cellular stress, which appears to be a feature of stem cell culture, or disease features may actually have a subtle onset at earlier stages than generally suspected. Indeed, 3-year-old children at genetic risk of developing early-onset AD appear to have smaller hippocampal size and lower scores on memory tests than children in a nonrisk group. The phenotypes of adult neurodegenerative diseases that are visible at fetal stages may or may not correspond to those manifest at later, adult stages, but they may offer the possibility of devising preventative strategies effective at very early stages of the disease.

CELL TYPE DISORDERS: ALS AND HUNTINGTON'S DISEASE

In diseases such as ALS, PD, and HD, that mostly target specific neuron subtypes, stem cells provide an ideal means to study the vulnerable human cell populations. By enabling the production of unlimited numbers of normal and diseased human midbrain dopaminergic neurons for the study of PD, medium spiny striatal neurons for HD, and spinal and cortical motor neurons for ALS, iPSC approaches have the potential to transform our understanding and management of these diseases. Stem cell–derived neurons serve as platforms to explore mechanisms of cell vulnerability, to screen drugs for neural protection, and potentially to derive neurons for replacement therapy.

AMYOTROPHIC LATERAL SCLEROSIS

One of the first protocols for producing neurons of a specific subtype from embryonic stem cells recapitulated normal developmental programs to generate mouse spinal motor neurons. Pluripotent mouse stem cells underwent neural induction and adopted a caudal identity through the application of retinoic acid, and subsequently adopted motor neuron fate through the action of Sonic hedgehog (Shh), a ventralizing factor. Generating human motor neurons proved more complex, requiring additional steps, such as early exposure to the growth factor, FGF2. The first application of stem cell–derived motor neurons to study ALS involved the use of mouse motor neurons generated from transgenic mice expressing a mutation in the superoxide dismutase 1 (*SOD1*) gene, the most common mutation responsible for familial ALS. Only 5–10% of ALS cases are familial, but the known mutations provide a useful entry point to tease apart the causative pathophysiology. Mutations in *SOD1* produce ALS through a toxic gain of function for which the mechanism remains unclear, despite the use of multiple transgenic animal and iPSC models. The use of mouse embryonic stem cell–derived motor neurons, however, demonstrated that toxic factors secreted by SOD1 astrocytes contribute to the death of motor neurons. Interestingly, stem cell–derived interneurons were spared, indicating a specific vulnerability of motor neurons. These findings helped establish the notion that a non-cell-autonomous toxic mechanism contributes to ALS pathogenesis and may ultimately lead to novel treatment strategies. These findings also highlight that modeling the full pathophysiology of ALS may require the reproduction of a complex environment including motor neurons, astrocytes, and possibly additional cell types such as microglia. A variety of approaches including

co-culture of specific cell types, three-dimensional spinal cord organoids, and microfluidic organ-on-chip models are being explored to achieve a more complete facsimile of spinal cord organization. Similar to other neurologic disorders where a clearly defined phenotype has been observed in human stem cell–derived models, there is hope that drug screening using human disease-expressing cells will identify a potential therapeutic compound.

HUNTINGTON'S DISEASE

HD is caused by an expansion in CAG triplet repeats in the huntingtin gene, which leads to an expanded polyglutamine tract in the huntingtin protein. HD is dominantly inherited, with symptoms of cognitive decline and uncontrollable gait and limb motions beginning in the third to fifth decade of life with progression to dementia and death approximately 20 years later. Mutant huntingtin causes a toxic gain of function, with the degree of effect related to the CAG repeat length. For example, a CAG length of 40–60 repeats produces adult-onset HD, whereas repeats of 60 or more produce juvenile-onset disease. Although it has been 25 years since the discovery of this causative mutation, the disease mechanism remains poorly understood. Excess huntingtin protein and protein fragments accumulate in specific subtypes of neurons where they misfold and form aggregates that are visible as cellular inclusions. Affected cells eventually die, possibly as a result of metabolic toxicity. The medium spiny neurons of the striatum are the most vulnerable neurons, spurring ongoing attempts to produce replacement cells derived from stem cells, but neuron loss is widespread including in the cortex, complicating a cell replacement approach for this disease. HD iPSCs have been generated from patients with various CAG repeat lengths, but those from juvenile-onset disease with the longest repeat lengths have been favored as being most likely to express robust disease phenotypes at an early stage. This is particularly important given the immature stage of maturation of stem cell–derived human neurons. This approach has been able to produce disease phenotypes observed in patients including huntingtin protein aggregation, decreased metabolic capacity, increased oxidative stress with mitochondrial fragmentation, and apoptosis enhanced by withdrawal of growth factor support. However, many of these phenotypes were observed in pluripotent cells prior to neural differentiation and in neural progenitors and a broad array of CNS neurons in contrast to the cell type–specific features of the disease. Nonetheless, neurons that assumed striatal fate appear to be more vulnerable to stress and apoptosis than other cell types. As with other iPSC models of nervous system diseases, there have so far been few efforts to validate results in multiple iPSC lines having different genetic backgrounds but with similar CAG repeat lengths. An HD consortium has been formed to address this problem by generating a series of iPSC lines from multiple patients. An alternative strategy to validate disease phenotypes has been to use gene editing to create isogenic iPSC lines that are corrected to produce wild-type control and HD iPSC lines against the same genetic background.

FUTURE PERSPECTIVES

Despite early successes, it may prove difficult to reconstitute neurodegenerative disease conditions in human cells in vitro over a short course of time because the pathogenic changes of degenerative diseases progress slowly and commence in the later stages of life. The differentiation and maturation of human neurons from stem cell lines occur over a span of months, which may not be long enough to establish the aged-brain conditions under which patients develop robust neurodegenerative pathology. Possible manipulation through gene editing or by application of aging-associated stresses, such as DNA-damaging agents or proteasome inhibitors, may accelerate the expression of degenerative phenotypes in human iPSC-derived cellular models. Stem cell–derived organoid models are also ideal platforms to apply methods for cellular-level visualization such as CLARITY and multielectrode recording techniques to better evaluate three-dimensional organoid structures and explore early-forming circuits. These applications are only just beginning.

Two-dimensional cell cultures are ideal for production and evaluation of large numbers of specific cells of a particular identity but may not provide the complex extracellular environment necessary to model certain disease processes, such as extracellular protein aggregation. These features can be best modeled using three-dimensional organoids, but current methods do not reproduce all the relevant features of brain tissue. Optimization will be needed to better reproduce the cellular composition of brain, including endothelial cells, astrocytes, microglia, and oligodendrocytes. It may also be necessary to combine different brain regions generated separately, possibly by fusion of tissues such as dorsal cortex, subpallium, thalamus, retina, and others in so-called "assembloids." One roadblock has been the limited ability to recreate tissues or neurons with regional brain identity, such as hippocampus, thalamus, or cerebellum. However, recently regionalized organoids have been created using innovative microfluidic chambers and the imposition of morphogen gradients such as bone morphogenetic proteins (BMPs) and WNTs. More faithful organoid models could also emerge through the application of bioengineered scaffolds, matrices, or perfusion systems that might allow the growth of larger structures, a feature currently limited due to the emergence of a necrotic core when nonperfused organoids exceed a certain size. Of course, not all aspects of mature brain architecture and function will be modeled by these tissue structures, particularly as they generally represent prenatal stages of development, but perhaps the most precocious events in disease etiology can be captured and investigated, and these may share mechanistic pathways with disease features that manifest at later stages.

The current excitement surrounding human stem cells has more to do with their promise to improve on animal models of disease, for which their potential appears unlimited, rather than on their use as a source for cell-based therapies, where the potential has thus far been relatively limited. Even without new insights into disease pathogenesis, it is likely that iPSC models such as brain organoids will serve as drug-screening platforms for discovery of novel therapeutics and for detection of off-target and toxic effects. The failure of many neurotherapeutic approaches to translate from animal models to clinical practice underscores the need for better predictive models, and stem cell models and brain organoids based on human cells may be ideally suited to bridge this divide.

A CURRENT PERSPECTIVE ON NEURAL STEM CELLS IN THE CLINIC

The prospect of stem cell therapies to treat diseases or injuries of the nervous system has captured the attention of researchers, clinicians, and the public. The pace of research is usually slow and deliberate, but in the stem cell arena, there has been enormous pressure to accelerate the pace of progress in order to bring cell-based therapies to the clinic. Expectations have been raised, and clinics have already begun offering unproven or dangerous treatments to a public that can be, in some situations, ill-informed and vulnerable to exploitation. Nonetheless, there has been remarkable progress over the past few years toward legitimate stem cell–based therapies for a number of nervous system disorders. There are multiple clinical trials underway fueling cautious optimism that stem cells will eventually realize the promise of regenerative therapy for at least some currently untreatable or incurable nervous system diseases.

PARKINSON'S DISEASE

Pursuit of a cell-based therapy for PD using fetal-derived midbrain cells has been ongoing for many decades but with disappointing results. Following anecdotal success in a handful of patients who appeared to improve following striatal grafts of fetal midbrain dopaminergic cells, two National Institutes of Health (NIH)-sponsored double-blind control studies were launched in the 1990s. However, only a small number of younger patients showed some benefit, and several patients developed spontaneous dyskinetic movements related to the therapy. These efforts constituted a failed trial as the treated patients who did not experience side effects failed to improve significantly. However, techniques to extract dopaminergic cells from fetal tissue have improved, and on the basis of encouraging results in individual transplanted patients, some of whom have managed to go off their Parkinson's

medication, a new trial of fetal cell transplantation for PD was conducted in Europe. Unfortunately, enrollment was unexpectedly slow and the trial was terminated after several years without reaching the anticipated number of patients. There was no clear clinical improvement among the treated patients, possibly due to difficulty harvesting sufficient fetal cells to reach the targeted number per patient. Despite the disappointing clinical outcome, enthusiasm remains high for a better outcome with stem cell–derived dopamine neurons where, among other differences, cell number is not a limitation.

The dyskinesias that curtailed the NIH trials in the 1990s were eventually ascribed to an abundance of serotonergic neurons that were inadvertently included in some of the cell grafts. Protocols for deriving dopaminergic neurons from stem cells would presumably avoid this complication by providing a more purified cell population, and several groups around the world have been aggressively pursuing a stem cell–based approach to PD. In 2018, researchers from Kyoto University in Japan started a phase 1/2 clinical trial to treat PD using stem cells. The investigators chose to use iPSCs derived from a healthy person who had the most common HLA haplotype in Japan. The iPSCs were used to make dopamine-secreting neurons. Seven patients have had the reprogrammed stem cells surgically delivered into the brain and have been followed for two years postinjection to assess safety and possible efficacy. The U.S. Food and Drug Administration (FDA) recently approved the first clinical trial of a stem cell–derived dopamine neuron for the treatment of PD in the United States. These cells, derived from an embryonic stem cell line, have been delivered to 10 patients in a phase 1 clinical trial to assess safety, tolerability, and preliminary efficacy. A European trial of embryonic stem cell–derived dopaminergic neurons led by scientists in Sweden and the United Kingdom began in 2023. Four patients given a low dose experienced no acute adverse effects, and four more will be treated with a higher dose, and all will be followed for 36 months to evaluate safety and tolerability.

A clinical trial using iPSC-generated dopaminergic neurons to treat patients with PD was begun in 2018 in Japan. The cell line was derived from a healthy individual with the most common HLA haplotype in the Japanese population. The clinical product consisted of 80% dopamine neuron progenitor cells and a population of glial cells. Because the cell line was genetically altered, the karyotype, plasmid survival, and genomic and epigenomic abnormalities were evaluated and known carcinogenic gene mutations were screened. A single-arm, nonrandomized and open-phase 1/2 study was begun in 2018 with ~5 million cells transplanted stereotactically to the putamen bilaterally. Seven patients have been treated thus far.

BATTEN'S DISEASE AND PELIZAEUS-MERZBACHER DISEASE

One of the first cell-based clinical trials for a neurologic disease targeted patients suffering from an untreatable childhood disorder, Batten disease. Batten disease is an autosomal recessive metabolic disorder resulting from an inability to synthesize a lysosomal enzyme critical to brain function. The phase 1 trial involved six patients with infantile and late-infantile forms of the disease who received neural stem cells rather than any specific postmitotic cell type. Neural stem cells derived from donated fetal tissue were expanded in vitro prior to surgical grafting into the brain. This approach was not without risk, as the neural stem cells were proliferating and could potentially form an abnormal growth. The rationale was that the cells would be capable of synthesizing and secreting the missing lysosomal enzyme and would therefore serve as a delivery device. Animal studies using a transgenic mouse model of Batten disease demonstrated rescue, and this promising result led to a small phase 1 trial. The phase 1 study was considered a success as no adverse events were reported and the cells appeared to be safe, though there was no clinical improvement and no clear evidence of whether the cells had dispersed, transformed into neurons or glia, or indeed survived at all. Despite clearing the phase 1 trial, the company did not pursue further trials for Batten disease, but instead initiated clinical trials using the same cell product for several other indications, including an inherited fatal dysmyelination syndrome known as Pelizaeus-Merzbacher disease (PMD). The human neural stem cells have both neurogenic and gliogenic potential, and when delivered to white matter regions in experimental animals, most persisting cells had become oligodendrocytes. This supported use of the cells to promote myelin formation in conditions such as PMD. The company also initiated trials in spinal cord injury. However, the spinal cord trial failed to achieve sufficient benefit in phase 2 and the company ceased its work on stem cell therapies.

SPINAL CORD INJURY

There is a pressing need for novel therapies for spinal cord injury, with >1 million patients worldwide suffering from spinal cord injuries and no effective treatment options. Not surprisingly, there has been intense interest in achieving a stem cell treatment for this condition and dozens of early-stage clinical trials, and anecdotal treatment results have been reported by investigators around the globe. The vast majority have not been blinded controlled trials, but rather individual reports treating a handful of patients, and somewhat surprisingly, most are using mesenchymal stem cells (MSCs) or hematopoietic stem cells that normally generate either bone, cartilage, fat, or blood cells. As described below, the rationale for the use of MSCs for neurologic conditions is based on vague and poorly understood mechanisms of action.

A series of stem cell trials designed to treat subacute spinal cord injury is underway in the United States and Europe using neural stem cells or their derivatives as potential therapeutic agents. The first to enter clinical trials in the United States was based on a protocol designed to generate oligodendrocytes from pluripotent embryonic stem cells. Evidence of efficacy was obtained in animal models following surgical grafting of cells to sites of spinal cord injury. However, evidence of myelination of host axons was minimal, and other mechanisms were invoked for improvement in gait, including trophic support and immune modulation. Regulatory permission for a phase 1 trial for subacute midthoracic injury was initially stalled by concern over abnormal growths at sites of cell deposit in some animals, but this was satisfactorily addressed and patient trials commenced. However, following a change in leadership, the stem cell program was terminated. The program was acquired by another company that has resumed the spinal cord injury trial and received regulatory approval to advance to include cervical-level injuries. The current phase 1/2a multicenter clinical trial is an open-label, single-arm trial testing three sequential escalating doses administered 21–42 days after injury in 25 patients with subacute severe cervical spinal cord injuries. No adverse events have been reported for 21 patients at 2 years posttreatment. A later-stage comparative clinical trial is now planned to probe for possible efficacy.

In 2020, an open-label, single-arm clinical trial for subacute spinal cord injury patients was begun in Japan using iPSC-derived neural stem and progenitor cells injected directly into the damaged spinal cord. The rationale for injecting neuronal precursor cells into the injured spinal cord is not clear as no specific mechanism of action has been demonstrated. Trophic support and neuroimmune modulation have been proposed, and while studies in mice show that newborn neurons can form synapses onto host spinal neurons, how this could lead to improved locomotor or sensory function remains unclear. Results of the trial have yet to be reported.

Initial clinical trials for stem cell therapies that address grave medical conditions such as spinal cord injury often involve small numbers of patients, and larger pivotal trials that can confirm clinical benefit can take a long time to conduct. In a controversial move designed to accelerate the regulatory approval process, in 2014 the Ministry of Health of Japan authorized the use of conditional and time-limited (CTL) approval for regenerative medical products. This designation can be applied when safety has been demonstrated but efficacy has not yet been fully established and enables the manufacturer to market and sell the product. CTL approval converts to full approval if postmarketing clinical data demonstrate clinical benefit, but if no convincing clinical benefit can be demonstrated within 7 years, the product must be withdrawn.

The effort to bring MSC treatments to patients with currently untreatable neurologic conditions has consequently had a recent boost

in Japan. Autologous bone marrow–derived stem cells were evaluated in an open-label trial involving 13 patients who had experienced severe spinal cord injury 1 month prior to treatment. Mesenchymal stem cells were taken from the patient's own bone marrow, expanded in number, and delivered back to the patient by intravenous infusion. Six months after treatment, 12 of the patients improved by at least one level on the American Spinal Injury Association impairment scale that ranks muscle contraction and touch, although patients with the same or even greater degree of injury can show spontaneous improvement. As is the case for most MSC therapies, the proposed mechanism of action was quite vague, including reducing inflammation, protecting existing neurons, or replacing damaged neurons. It is also unclear how intravenous delivery could accomplish any of the proposed actions. In 2018, on the basis of the results, unpublished at the time, Japan's health ministry gave conditional (CTL) approval for the treatment, called Stemirac. This became the first stem cell therapy for spinal cord injury to receive government approval for sale to patients. But the approval of a therapy that may carry risk following a small, unblinded, and uncontrolled study without actual proof of efficacy raised considerable concern among scientists in the stem cell community. Charging patients for such an unproven therapy raises even more ethical concerns. Patients in Japan can now be charged for their treatment while trials to test efficacy are still proceeding.

AMYOTROPHIC LATERAL SCLEROSIS

The possibility of treating ALS by replacing dying motor neurons with stem cell–derived substitutes has excited interest, but this prospect seems very remote. Even if new neurons are able to integrate into spinal cord circuits and become properly innervated, they would have to grow long axons that would take many months to years to project to appropriate targets and attract myelinating Schwann cells. Furthermore, cells would need to be grafted at multiple spinal cord and brainstem levels, and the upper motor neuron deficit would need to be treated by replacing projecting neurons in the motor cortex. An additional complication is the recent finding that spinal motor neurons have unique segmental identity, and replacement cells might need to be generated with a range of molecular identities in order to integrate at multiple spinal levels. This would still leave unaddressed the toxic effects recently shown to be produced in ALS by diseased astrocytes and microglia that could attack the replacement cells. A more tractable near-term solution would be to graft support cells that could rescue or protect endogenous motor neurons from damage. This approach was tried in a mouse model of ALS. Human fetal stem cell–derived neural progenitor cells engineered to express glial cell line–derived neurotrophic factor (GDNF), a growth factor known to provide trophic support for neurons, were grafted to the spinal cord of young ALS mice. The cells dispersed and were able to rescue motor neurons, a very promising result, but disappointingly, the animals became weak and died at the same rate as untreated control animals. ALS is a deadly disease with no known treatment; thus in the hope that patients will respond differently from mice, a phase 1/2a clinical trial based on this approach was approved by the FDA in 2016 and completed in 2019. Patients had the GDNF-producing progenitor cells surgically grafted unilaterally into the lumbar spinal cord. Although disease progression appeared to slow in some treated patients, this was not statistically significant. Of note, several patients developed painful schwannomas, a result of off-targeting deposit of the GDNF-secreting cells close to the dorsal horn root entry zone. Autopsy study of 13 of the 18 treated patients who died within 2 years of treatment showed that the grafted cells had survived. Based on these results, a new trial has begun. With the notion that rescuing lower motor neurons alone may not be sufficient to arrest progression of a disease that affects both upper and lower motor neurons, this trial aims to enroll 16 patients who will have the GDNF-secreting progenitor cells grafted to the motor cortex in an area controlling hand movement. The goal is to try to slow the progression of the upper motor deficit associated with ALS.

Among the many MSC-based clinical trials for ALS, two are particularly notable. Corestem, a stem cell company in South Korea, launched a phase 1 open-label study demonstrating the safety and feasibility of intrathecal injections of autologous bone marrow–derived MSCs in seven patients with ALS. This was followed by a phase 2 trial that demonstrated safety and efficacy for slowing disease progression. On the basis of these results, Corestem received conditional approval in South Korea in 2014 to market the first stem cell therapy for ALS. By 2021, >300 patients had received this cell treatment. However, full approval is contingent on the results of a randomized, double-blind, placebo-controlled, multicenter phase 3 study, which began in 2021. The trial aims to enroll 115 patients who will receive repeated intrathecal injections of the autologous cells. The goal is to slow or prevent ALS progression and delay death for up to 3 years.

The importance of conducting proper phase 3 clinical trials to determine therapeutic efficacy in ALS is underscored by the recent experience of BrainStorm Cell Therapeutics. In 2016, the company reported preliminary positive results for its bone marrow MSC cell therapy in an uncontrolled study of nearly 50 ALS patients. Based on those results, the company launched a phase 3, multicenter, placebo-controlled, randomized, double-blind trial of 189 ALS patients. In 2020, the company reported that there was no significant clinical improvement in the treatment group. Interestingly, despite the failed clinical trial, a public campaign led by ALS patients and advocates called on the FDA to approve the stem cell treatment. The social media response prompted the FDA to take the unusual step of releasing a public statement underscoring the lack of efficacy, and in 2023, an FDA advisory committee voted against approval. The company responded by withdrawing its Biologics License Application and announcing a phase 3b trial that will focus on early-stage patients.

EPILEPSY

A phase 1/2 clinical trial was launched in 2022 using stem cell–derived inhibitory interneurons to treat medically intractable temporal lobe epilepsy. Somatostatin (SST)-expressing inhibitory interneurons, matching the predominant cortical interneuron subtype, were derived from an embryonic stem cell line. Following demonstration of efficacy in a mouse model of temporal lobe epilepsy, 10 patients who had been determined to have a seizure focus in the hippocampus had stem cell–derived interneurons surgically delivered to the epileptic hippocampus. The first five patients received a low dose followed by five patients who received a higher dose. All 10 patients will be followed for 2 years after treatment. As in the PD clinical trials, all patients received antirejection therapy for the first 12 months. The current standard of care for patients with intractable temporal lobe epilepsy is surgical ablation or resection of the epileptic hippocampus. Surgically treated patients can have seizure remission but often have cognitive decline, particularly if the focus is in the dominant hemisphere. Early indications are that the cell-based therapy can not only reduce seizures but also spare or improve cognitive function.

MACULAR DEGENERATION

Because iPSC technology enables the generation of pluripotent stem cells from adult somatic cells, it has enabled the production of patient-specific autologous cells for cell replacement therapy. Following Shinya Yamanaka's discovery of iPSCs, the Japanese government has invested in bringing iPSC-derived cell therapy to the clinic. Banks of iPSC lines selected to capture the diversity of HLA haplotypes found in the Japanese population have been produced in the hope that these will allow cell therapies to be matched to individual patient haplotypes in order to avoid immune rejection. While these stem cell banks were still being produced, the first Japanese study to use stem cells was approved in 2013 and involved patients who were to receive customized therapy using cells derived from their own skin fibroblasts. The targeted disease was age-related macular degeneration, a common cause of blindness in the elderly that results from loss of retinal pigment epithelial (RPE) cells. RPE cells are relatively easy to generate from pluripotent stem cells, making replacement therapy an attractive target in this condition. A challenge is to coax the replacement cells to recreate an epithelium in the subretinal space. The Japanese approach involves surgical insertion of a biofilm seeded with RPE cells into the retina. One patient was treated with their own stem cell–derived RPE cells, but prior to treating

a second patient, the genome of the RPE cell line was sequenced, and a mutation was discovered in a known oncogene. The trial was halted and a decision made to discontinue the effort for customized cell therapy in favor of using RPE cells derived from the national repository of banked iPSC lines which undergo extensive gene sequencing and quality controls. This outcome serves as a caution for the challenges involved in bringing a customized cell therapy to the clinic.

MESENCHYMAL STEM CELLS

By far the largest number of human trials have been performed using MSCs sourced from a variety of sites including bone marrow, peripheral blood, adipose tissue, umbilical cord, and other sites. Interest in the potential utility of MSCs for regenerative therapy began with the optimistic report that bone marrow stem cells were pluripotent and capable of generating nerve and heart muscle as well as blood cells. The possibility that easily obtainable MSCs could be used to regenerate injured or diseased cells or organs to treat diseases ranging from stroke, neurodegenerative disease, myocardial infarct, and even diabetes, generated enormous enthusiasm. The enthusiasm proved irresistible to many, and even after the initial reports were discredited—MSCs turned out not to be pluripotent stem cells as initially thought—a veritable flood of papers began to appear claiming disease-modifying activity of MSCs in mouse models of a wide range of degenerative disease and injury models. But when it became clear that the MSCs were not transforming into or generating new neurons or cardiac myocytes, alternative mechanisms of action were invoked, including the release of trophic factors, cytokines, or inflammatory modulators that were credited with producing their remarkable restorative effects. The relative ease with which blood or adipose tissue can be harvested from patients or donors and MSCs extracted has led to a rapidly expanding number of clinical trials for conditions ranging from stroke and MS to AD, ALS, and PD. Furthermore, a loophole in the regulatory framework of the FDA allows autologous cell therapy to escape regulation provided that the cells have not been significantly processed. This lax regulation has spawned a veritable industry of stem cell clinics making unsubstantiated claims of success in treating nervous system diseases. Patients have died from treatments in unregulated clinics operating in countries around the world, and three patients became blind in a well-publicized incident following stem cell treatments delivered by a Florida clinic. The "stem cells" were derived from the patients' own fat tissue and blood. These activities represent the dark side of the stem cell revolution perpetrated by practitioners who exploit the desperation of patients and their families. Legitimate and effective stem cell therapies will emerge over time, but given the prevalence and abundance of misleading information available on the Internet and elsewhere, a trusted and well-informed physician can play a key role in helping patients navigate the current cell therapy minefield.

MSCS FOR TRAUMATIC BRAIN INJURY

An allogeneic bone marrow–derived MSC line received conditional marketing approval in Japan in 2024 for the indication of improving chronic motor paralysis resulting from traumatic brain injury. The MSCs were transiently transfecting with the human Notch-1 intracellular domain gene to promote FDF-2 secretion in order to "enhance their ability to regenerate nerve cells" according to the pharmaceutical company that developed the cell-based therapy. The approval followed results of a phase 2 clinical trial conducted in Japan and the United States. Forty-six patients with moderate to severe traumatic brain injury and chronic motor deficits had MSCs stereotactically infused into an area of encephalomalacia identified on MRI scan while a sham group of 15 patients had burr holes only. The trial met the primary endpoint showing significant improvement in motor function at 24 weeks on the Fugle-Meyer Motor Scale (FMMS) (p = .04). Interestingly, a small improvement was noted in the sham-treated group as well, indicating the presence of a placebo effect. A larger, double-blind, randomized, sham-controlled study is now planned.

PERSPECTIVE

The premise that stem cell biology would herald an era of regenerative medicine has fueled exaggerated claims, false starts, and a proliferation of bogus clinics. But now we may be on the threshold of a new era of stem cell-based therapies for neurologic diseases and disorders including PD, spinal cord injury, ALS, and epilepsy. Whether this promise becomes reality will depend on the outcome of the first wave of pivotal double-blind controlled trials that are now being conducted or planned.

Section 2 Diseases of the Central Nervous System

436 Seizures and Epilepsy

Patricia Dugan, Vikram R. Rao

A *seizure* (from the Latin *sacire*, "to take possession of") is a transient occurrence of signs or symptoms due to abnormal excessive or synchronous neuronal activity in the brain. Depending on the distribution of discharges, this abnormal brain activity can have various manifestations, ranging from dramatic convulsive activity to experiential phenomena not readily discernible by an observer. Although a variety of factors influence the incidence and prevalence of seizures, ~5–10% of the population will have at least one seizure, with the highest incidence occurring in early childhood and late adulthood.

The meaning of the term *seizure* needs to be carefully distinguished from that of epilepsy. *Epilepsy* describes a condition in which a person has a risk of *recurrent* seizures due to a chronic, underlying process. This definition implies that a person with a single seizure, or recurrent

seizures due to correctable or avoidable circumstances, does not necessarily have epilepsy (although a single seizure associated with clinical or electroencephalographic features portending high risk of recurrence may establish the diagnosis of epilepsy). Epilepsy refers to a clinical phenomenon rather than a single disease entity because many forms and causes exist. However, among the many causes of epilepsy, there are various *epilepsy syndromes* in which the clinical and pathologic characteristics are distinctive and suggest a specific underlying etiology.

Using the definition of epilepsy as two or more unprovoked seizures, the incidence of epilepsy is ~0.3–0.5% in different populations throughout the world, and the prevalence of epilepsy has been estimated at 5–30 persons per 1000.

CLASSIFICATION OF SEIZURES

Determining the type of seizure that has occurred is essential for focusing the diagnostic approach on particular etiologies, selecting appropriate therapy, and providing information regarding prognosis. The International League Against Epilepsy (ILAE) Commission on Classification and Terminology updated their approach to classification of seizures in 2017 **(Table 436-1)**. This system is based on the clinical features of seizures and associated electroencephalographic findings. Other potentially distinctive features such as etiology or cellular substrate are not considered in this classification system, although this will undoubtedly change in the future as more is learned about the pathophysiologic mechanisms that underlie specific seizure types.

A fundamental principle is that seizures may be either focal or generalized. *Focal seizures* originate within networks limited to one brain region (note that the term *partial seizures* is no longer used). *Generalized seizures* arise within and rapidly engage networks distributed across both cerebral hemispheres. Focal seizures are often associated with structural abnormalities of the brain. In contrast, generalized seizures may result from cellular, biochemical, or structural abnormalities with a more widespread distribution. There are exceptions in both cases, however.

FOCAL ONSET SEIZURES

Focal seizures arise from a neuronal network either discretely localized within one brain region or more broadly distributed but still within a cerebral hemisphere. With the new classification system, the subcategories of "simple focal seizures" and "complex focal seizures" have been eliminated. Instead, the classification emphasizes the effect on awareness (intact or impaired) and nature of the onset (motor or nonmotor). Focal seizures can also evolve into generalized seizures. In the past, this was referred to as *focal seizures with secondary generalization*, but the new system relies on descriptions of the type of generalized seizures that evolve from the focal seizure.

The routine interictal (i.e., between seizures) electroencephalogram (EEG) in patients with focal seizures is often normal or may show brief discharges termed *epileptiform spikes*, or *sharp waves*. Because focal seizures can arise from the medial temporal lobe or inferior frontal lobe (i.e., regions distant from the scalp), the EEG recorded during the seizure may be nonlocalizing. However, the region of seizure onset may be defined using surgically placed intracranial electrodes.

TABLE 436-1 Classification of Seizures[a]

1. **Focal Onset**
   (Can be further described as having intact or impaired awareness, motor or nonmotor onset, or evolve from focal to bilateral tonic clonic)
2. **Generalized Onset**
   a. Motor
      Tonic-clonic
      Other motor (e.g., atonic, myoclonic)
   b. Nonmotor (absence)
3. **Unknown Onset**
   Motor, nonmotor, or unclassified

[a]Based on the 2017 International League Against Epilepsy classification of seizure types. (Data from RS Fisher et al: Operational classification of seizure types by the International League Against Epilepsy: Position Paper of the ILAE Commission for Classification and Terminology. Epilepsia 58:522, 2017.)

Focal Seizures with Intact Awareness Focal seizures can have motor manifestations (such as tonic, clonic, or myoclonic movements) or nonmotor manifestations (such as sensory, autonomic, or emotional symptoms) without impairment of awareness. For example, a patient having a focal motor seizure arising from the right primary motor cortex near the area controlling hand movement will experience involuntary movements of the contralateral left hand. Since the cortical region controlling hand movement is immediately adjacent to the region for facial expression, the seizure may also cause abnormal movements of the face synchronous with the movements of the hand. The EEG recorded with scalp electrodes during the seizure (i.e., an ictal EEG) may show abnormal focal discharges over the corresponding area of cerebral cortex.

Three additional features of focal motor seizures are worth noting. First, in some patients, the abnormal motor movements may begin in a very restricted region, such as the fingers, and gradually progress (over seconds to minutes) to include a larger portion of the extremity. This phenomenon, described by Hughlings Jackson and known as a "Jacksonian march," represents the spread of seizure activity over a progressively larger region of motor cortex. Second, patients may experience a localized paresis (Todd's paralysis) for minutes to many hours in the involved region following the seizure. Third, in rare instances, the seizure may continue for hours or days. This condition, termed *epilepsia partialis continua*, is often refractory to medical therapy.

Focal seizures may also manifest as changes in somatic sensation (e.g., paresthesias), vision (flashing lights or formed hallucinations), equilibrium (sensation of falling or vertigo), or autonomic function (flushing, sweating, piloerection). Focal seizures arising from the temporal lobe may also cause the sensation of acrid odors (e.g., bleach or burning rubber) or tastes (e.g., bitter or metallic), or hearing sounds (simple noise or complex sounds), or an epigastric sensation that rises to the head. Some patients describe intense internal feelings such as fear, a dreamlike sense, depersonalization, déjá vu, or illusions that objects are growing smaller (micropsia) or larger (macropsia). These subjective, "experiential" events that are not directly observable by someone else are referred to as *auras*.

Focal Seizures with Impaired Awareness Focal seizures may also be accompanied by a transient impairment of the patient's ability to maintain normal contact with the environment. The patient is unable to respond appropriately to visual or verbal commands during the seizure and has impaired recollection or awareness of the ictal phase. The seizures frequently begin with an aura (i.e., a focal seizure without cognitive disturbance) that is stereotypic for the patient. The start of the ictal phase is often a motionless stare, which marks the onset of the period of impaired awareness. The impaired awareness may be accompanied by *automatisms*, involuntary movements that can involve basic behaviors, such as chewing, lip smacking, swallowing, or "picking" hand movements, or more elaborate behaviors, such as a display of emotion or running. The patient is typically disoriented following the seizure, and the transition to full recovery of consciousness may range from seconds to hours. Examination immediately following the seizure may show an anterograde amnesia or transient neurologic deficits (such as aphasia, hemi-neglect, or visual loss) caused by postictal inhibition of the cortical regions most involved in the seizure.

The range of potential clinical behaviors linked to focal seizures is so broad that extreme caution is advised before concluding that paroxysmal, stereotypic episodes of bizarre or atypical behavior are not due to seizure activity. In such cases, additional detailed EEG studies may be helpful.

EVOLUTION OF FOCAL SEIZURES TO GENERALIZED SEIZURES

Focal seizures can spread to involve both cerebral hemispheres and produce a generalized seizure, usually of the tonic-clonic variety (discussed below). This evolution is observed frequently following focal seizures arising from a region in the frontal lobe but may also be associated with focal seizures occurring elsewhere in the brain. A focal seizure that evolves into a generalized seizure is often difficult

to distinguish from a primary generalized onset tonic-clonic seizure because bystanders tend to emphasize the more dramatic, generalized convulsive phase of the seizure and overlook the more subtle, focal symptoms present at onset. In some cases, the focal onset of the seizure becomes apparent only when a careful history identifies a preceding aura. Often, however, the focal onset is not clinically evident and may be established only through careful EEG analysis. Nonetheless, distinguishing between these two entities is extremely important, because there are substantial differences in the evaluation and treatment of epilepsies characterized by focal versus generalized onset seizures.

GENERALIZED ONSET SEIZURES

Generalized seizures arise at some point in the brain but immediately and rapidly engage neuronal networks in both cerebral hemispheres. Several types of generalized seizures have features that place them in distinctive categories and facilitate clinical diagnosis.

Typical Absence Seizures Typical absence seizures are characterized by sudden, brief lapses of consciousness without loss of postural control. The seizure usually lasts for only seconds, consciousness returns as suddenly as it was lost, and there is no postictal confusion. Although the brief loss of consciousness may be clinically inapparent or the sole manifestation of the seizure, absence seizures are usually accompanied by subtle, bilateral motor signs such as rapid blinking, chewing movements, or small-amplitude, clonic movements of the hands.

Typical absence seizures are associated with a group of genetically determined epilepsies with onset usually in childhood (ages 4–10 years) or early adolescence and are the main seizure type in 15–20% of children with epilepsy. The seizures can occur hundreds of times per day, but the child may be unaware of or unable to convey their existence. Because the clinical signs of the seizures are subtle, especially to parents who may not have had previous experience with seizures, it is not surprising that the first clue to absence epilepsy is often unexplained "daydreaming" and a decline in school performance recognized by a teacher. Indeed, absence epilepsy is often misdiagnosed as an attention deficit disorder.

The electrophysiologic hallmark of typical absence seizures is a burst of generalized, symmetric, 3-Hz, spike-and-slow-wave discharges that begins and ends suddenly, superimposed on a normal EEG background. Periods of spike-and-slow-wave discharges lasting more than a few seconds usually correlate with clinical signs, but the EEG often shows many more brief bursts of abnormal cortical activity than suspected clinically. Hyperventilation tends to provoke these electrographic discharges and even the seizures themselves and is routinely used when recording the EEG.

Atypical Absence Seizures Atypical absence seizures have features that deviate both clinically and electrophysiologically from typical absence seizures. For example, the lapse of consciousness is usually longer and less abrupt in onset and cessation, and the seizure is accompanied by more obvious motor signs that may include focal or lateralizing features. The EEG shows a generalized, slow spike-and-slow-wave pattern with a frequency of ≤2.5 Hz, as well as other abnormal activity. Atypical absence seizures are usually associated with diffuse or multifocal structural abnormalities of the brain and therefore may accompany other signs of neurologic dysfunction, such as developmental delay. Furthermore, the seizures are less responsive to anticonvulsants compared to typical absence seizures.

Generalized, Tonic-Clonic Seizures Generalized onset tonic-clonic seizures are the main seizure type in ~10% of all persons with epilepsy. They are also the most common seizure type resulting from metabolic derangements and are therefore frequently encountered in many different clinical settings. The seizure usually begins abruptly without warning, although some patients describe vague premonitory symptoms in the hours leading up to the seizure. This prodrome is distinct from the stereotypic auras associated with focal seizures that generalize. The initial phase of the seizure is usually tonic contraction of muscles throughout the body, accounting for several classic features of the event. Tonic contraction of the muscles of expiration and the larynx at the onset will produce a loud moan or "ictal cry." Respirations are impaired, secretions pool in the oropharynx, and cyanosis develops. Contraction of the jaw muscles may cause biting of the tongue. A marked enhancement of sympathetic tone leads to increases in heart rate, blood pressure, and pupillary size. After 10–20 s, the tonic phase of the seizure typically evolves into the clonic phase, produced by the superimposition of periods of muscle relaxation on the tonic muscle contraction. The periods of relaxation progressively increase until the end of the ictal phase, which usually lasts no more than 1 min. The postictal phase is characterized by unresponsiveness, muscular flaccidity, and excessive salivation that can cause stridorous breathing and partial airway obstruction. Bladder or bowel incontinence may occur at this point. Patients gradually regain consciousness over minutes to hours, and, during this transition, there is typically a period of postictal confusion. Patients subsequently complain of headache, fatigue, and muscle ache that can last for many hours. The duration of impaired consciousness in the postictal phase can be extremely long (i.e., many hours) in patients with prolonged seizures or underlying central nervous system (CNS) disease.

The EEG during the tonic phase of the seizure shows a progressive increase in generalized low-voltage fast activity, followed by generalized high-amplitude, polyspike discharges. In the clonic phase, the high-amplitude activity is typically interrupted by slow waves to create a spike-and-slow-wave pattern. Generalized seizures tend to terminate synchronously over widespread brain regions. The postictal EEG shows diffuse suppression of all cerebral activity, followed by slowing that gradually recovers as the patient awakens.

There are several variants of generalized motor seizures, including pure tonic and pure clonic seizures. Brief tonic seizures lasting only a few seconds are especially noteworthy since they are usually associated with specific epilepsy syndromes having mixed seizure phenotypes, such as the Lennox-Gastaut syndrome (discussed below).

Atonic Seizures Atonic seizures are characterized by sudden loss of postural muscle tone lasting 1–2 s. Consciousness is briefly impaired, but there is usually no postictal confusion. A very brief seizure may cause only a quick head drop or nodding movement, whereas a longer seizure will cause the patient to collapse (hence, the less formal term, *drop attacks*). This can be extremely dangerous because there is a substantial risk of direct head injury with the fall. The EEG shows brief, generalized spike-and-wave discharges followed immediately by diffuse slow waves that correlate with the loss of muscle tone. Like pure tonic seizures, atonic seizures are usually seen in association with known epilepsy syndromes.

Myoclonic Seizures Myoclonus is a sudden and brief muscle contraction that may involve one part of the body or the entire body. A normal, common physiologic form of myoclonus is the sudden jerking movement observed while falling asleep. Pathologic myoclonus is most often seen in association with metabolic disorders, degenerative CNS diseases, or anoxic brain injury **(Chap. 318)**. Although the distinction from other forms of myoclonus is imprecise, myoclonic seizures are true epileptic events because they are caused by cortical (vs subcortical or spinal) dysfunction. The EEG shows bilaterally synchronous spike-and-slow-wave discharges immediately prior to the movement and muscle artifact associated with the myoclonus. Myoclonic seizures usually coexist with other forms of generalized seizures but are the predominant feature of juvenile myoclonic epilepsy (JME) (discussed below).

Epileptic Spasms Epileptic spasms are characterized by a briefly sustained flexion or extension of predominantly proximal muscles, including truncal muscles. The EEG usually shows *hypsarrhythmia*, a chaotic background of diffuse, large-amplitude slow waves and irregular, multifocal spikes and sharp waves. During the clinical spasm, there is a marked suppression of the EEG background (the "electrodecremental response"). The electromyogram (EMG) also reveals a characteristic rhomboid pattern that may help distinguish spasms from brief tonic and myoclonic seizures. Epileptic spasms occur predominantly

in infants and likely result from differences in neuronal function and connectivity in the immature versus mature CNS.

EPILEPSY SYNDROMES

Epilepsy syndromes are disorders in which epilepsy is a predominant feature, and there is sufficient evidence (e.g., through clinical, EEG, radiologic, or genetic observations) to suggest a common underlying mechanism. Three important epilepsy syndromes are listed below; additional examples with a known genetic basis are shown in **Table 436-2**.

JUVENILE MYOCLONIC EPILEPSY

JME is a generalized seizure disorder of unknown cause that appears in early adolescence and is usually characterized by bilateral myoclonic jerks that may be single or repetitive. The myoclonic seizures are most frequent in the morning after awakening and can be provoked by sleep deprivation. Awareness is preserved unless the myoclonus is especially severe. Many patients also experience generalized tonic-clonic seizures, and up to one-third have absence seizures. Although complete remission is uncommon, the seizures usually respond well to appropriate antiseizure medication. There is often a family history of epilepsy, and genetic studies suggest a polygenic cause.

LENNOX-GASTAUT SYNDROME

Lennox-Gastaut syndrome occurs in children and is defined by the following triad: (1) multiple seizure types (usually including generalized tonic-clonic, atonic, and atypical absence seizures); (2) an EEG with slow (<3 Hz) spike-and-wave discharges and a variety of other abnormalities; and (3) developmental delay. Lennox-Gastaut syndrome is associated with CNS disease or dysfunction from a variety of causes, including de novo mutations, developmental abnormalities, perinatal hypoxia/ischemia, trauma, infection, and other acquired lesions. The multifactorial nature of this syndrome suggests that it is a nonspecific response of the brain to diffuse neuronal dysfunction. Unfortunately, many patients have a poor prognosis due to the underlying CNS disease and the physical and psychosocial consequences of severe, poorly controlled epilepsy. Implanted neurostimulation devices (discussed below) are now being investigated for treatment of seizures in Lennox-Gastaut syndrome and other generalized epilepsies.

MESIAL TEMPORAL LOBE EPILEPSY SYNDROME

Mesial temporal lobe epilepsy (MTLE) is the most common syndrome associated with focal seizures with impairment of consciousness and is an example of an epilepsy syndrome with distinctive clinical, EEG, and pathologic features **(Table 436-3)**. High-resolution magnetic resonance imaging (MRI) can detect the characteristic hippocampal sclerosis that appears to be essential in the pathophysiology of MTLE for many patients **(Fig. 436-1)**. Recognition of this syndrome is especially important because it tends to be refractory to treatment with anticonvulsants but responds well to surgical intervention. Advances in the understanding of basic mechanisms of epilepsy have come through studies of experimental models of MTLE, discussed below.

THE CAUSES OF SEIZURES AND EPILEPSY

Seizures are a result of a shift in the normal balance of excitation and inhibition within the CNS. Given the numerous properties that control neuronal excitability, it is not surprising that there are many ways to perturb this normal balance and, therefore, many different causes of both seizures and epilepsy. Three clinical observations emphasize how a variety of factors determine why certain conditions may cause seizures or epilepsy in a given patient.

1. *The normal brain can have a seizure under the appropriate circumstances, and there are differences between individuals in the susceptibility or threshold for seizures*. For example, seizures may be induced by high fever in children who are otherwise normal and who never develop other neurologic problems, including epilepsy. However, febrile seizures occur only in a relatively small proportion of children. This implies there are various underlying *endogenous factors* that influence the threshold for having a seizure. Some of these factors are genetic, as a family history of epilepsy has a clear influence on the likelihood of seizures occurring in otherwise normal individuals. Normal development also plays an important role, because the brain appears to have different seizure thresholds at different maturational stages.
2. *There are a variety of conditions that have an extremely high likelihood of resulting in a chronic seizure disorder*. One of the best examples of this is severe, penetrating head trauma, which is associated with up to a 45% risk of subsequent epilepsy. The high propensity for severe traumatic brain injury to lead to epilepsy suggests that the injury results in a long-lasting pathologic change in the CNS that transforms a presumably normal neuronal network into one that is abnormally hyperexcitable. This process is known as *epileptogenesis*, and the specific changes that result in a lowered seizure threshold can be considered *epileptogenic factors*. Other processes associated with epileptogenesis include stroke, infection, neurodegeneration, and abnormalities of CNS development.
3. *Seizures are episodic*. Seizures occur intermittently, and, depending on the underlying cause, people with epilepsy may feel completely normal for months or years between seizures. This implies there are important provocative or *precipitating factors* that induce seizures in people with epilepsy. Similarly, precipitating factors are responsible for causing the single seizure in someone without epilepsy. Precipitants include those due to intrinsic physiologic processes, such as psychological or physical stress, sleep deprivation, or hormonal changes. They also include exogenous factors such as exposure to toxic substances, certain medications, and intermittent photic stimulation from strobe lights or some video games.

These observations emphasize the concept that the many causes of seizures and epilepsy result from a dynamic interplay between endogenous factors, epileptogenic factors, and precipitating factors. The potential role of each needs to be considered when determining the appropriate management of a patient with seizures. For example, the identification of predisposing factors (e.g., family history of epilepsy) in a patient with febrile seizures may increase the necessity for closer follow-up and a more aggressive diagnostic evaluation. Finding an epileptogenic lesion may help in the estimation of seizure recurrence and duration of therapy. Removal or modification of a precipitating factor may be an effective and safer method for preventing further seizures than the prophylactic use of anticonvulsant drugs. An emerging concept holds that underlying seizure risk itself fluctuates cyclically, potentially explaining why the same precipitating factor (e.g., sleep deprivation) can be well tolerated on some occasions but result in a seizure on others.

CAUSES ACCORDING TO AGE

In practice, it is useful to consider the etiologies of seizures based on the age of the patient, because age is one of the most important factors determining both the incidence and the likely causes of seizures or epilepsy **(Table 436-4)**. During the *neonatal period and early infancy*, potential causes include hypoxic-ischemic encephalopathy, trauma, CNS infection, congenital CNS abnormalities, and metabolic disorders. Babies born to mothers using neurotoxic drugs such as cocaine, heroin, or ethanol are susceptible to drug-withdrawal seizures in the first few days after delivery. Hypoglycemia and hypocalcemia, which can occur as secondary complications of perinatal injury, are also causes of early postnatal seizures. Seizures due to inborn errors of metabolism usually present once regular feeding begins, typically 2–3 days after birth. Pyridoxine (vitamin B_6) deficiency, an important cause of neonatal seizures, is treated with pyridoxine replacement. Idiopathic or familial forms of benign neonatal seizures are also seen during this time.

The most common seizures arising in *late infancy and early childhood* are febrile seizures, which are seizures associated with fevers but without evidence of CNS infection or other defined causes. The overall prevalence is 3–5% and even higher in some parts of the world such as Asia. Patients often have a family history of febrile seizures or epilepsy. Febrile seizures usually occur between 3 months and 5 years of age and have a peak incidence between 18 and 24 months. The typical scenario is a child who has a generalized, tonic-clonic seizure during a febrile illness in the setting of a common childhood infection such as otitis

TABLE 436-2 Examples of Genes Associated with Epilepsy Syndromes[a]

GENE (LOCUS)	FUNCTION OF GENE	CLINICAL SYNDROME	COMMENTS
CHRNA4 (20q13.2)	Nicotinic acetylcholine receptor subunit; mutations cause alterations in Ca^{2+} flux through the receptor; this may reduce the amount of GABA release in presynaptic terminals	Sleep-related hypermotor epilepsy (SHE); childhood onset; brief, nighttime seizures with prominent motor movements; often misdiagnosed as primary sleep disorder	Rare; first identified in a large Australian family; other families found to have mutations in *CHRNA2* or *CHRNB2*, and some families appear to have mutations at other loci
KCNQ2 (20q13.3)	Voltage-gated potassium channel subunits; mutation in pore regions may cause a 20–40% reduction of potassium currents, which will lead to impaired repolarization	Self-limited familial neonatal epilepsy; autosomal dominant inheritance; onset in first week of life in infants who are otherwise normal; remission usually within weeks to months; long-term epilepsy in 10–15%	Rare; other families found to have mutations in *KCNQ3*; sequence and functional homology to *KCNQ1*, mutations of which cause long QT syndrome and a cardiac-auditory syndrome
SCN1A (2q24.3)	α-Subunit of a voltage-gated sodium channel; numerous mutations affecting sodium currents that cause either gain or loss of function; network effects appear related to expression in excitatory or inhibitory cells	Very common cause of Dravet syndrome (severe myoclonic epilepsy of infancy) and some cases of Lennox-Gastaut syndrome. Also found in other syndromes, including genetic epilepsy with febrile seizures plus (GEFS+); autosomal dominant inheritance; presents with febrile seizures at median 1 year, which may persist >6 years, then variable seizure types not associated with fever	Incidence of Dravet syndrome is 1 in 20,000 births, and de novo *SCN1A* mutation is found in ~80% of cases. Incidence in GEFS+ uncertain; identified in other families with mutations in other sodium channel subunits (*SCN2B* and *SCN2A*) and $GABA_A$ receptor subunit (*GABRG2* and *GABRA1*); significant phenotypic heterogeneity within same family, including members with febrile seizures only. Avoid sodium channel–blocking antiseizure medications
LGI1 (10q24)	Leucine-rich glioma-inactivated 1 gene; previous evidence for role in glial tumor progression; recent studies suggest an influence in the postnatal development of glutamatergic circuits in the hippocampus	Autosomal dominant epilepsy with auditory features (ADEAF); a form of lateral temporal lobe epilepsy with auditory symptoms or aphasia as a major focal seizure manifestation; age of onset usually between 10 and 25 years	Mutations found in up to 50% of families containing two or more subjects with focal epilepsy with ictal auditory symptoms, suggesting that at least one other gene may underlie this syndrome
DEPDC5 (22q12.2)	Disheveled, Egl-10, and pleckstrin domain containing protein 5; exerts an inhibitory effect on mammalian target of rapamycin (mTOR)–mediated processes, such as cell growth and proliferation	Autosomal dominant familial focal epilepsy with variable foci (FFEVF); family members have seizures originating from different cortical regions; neuroimaging usually normal but may harbor subtle malformations; recent studies also suggest association with benign epilepsy with centrotemporal spikes	Study of families with the limited number of affected members revealed mutations in ~12% of families; thus, may be a relatively common cause of lesion-negative focal epilepsies with suspected genetic basis. Also associated with mutations in the GATOR1 genes *NPRL2* and *NPRL3*
GRIN2A (16p13.2)	Encodes NMDA receptor (NMDAR) subunit GluN2A	Spectrum of phenotypes ranging from benign childhood epilepsy with centrotemporal spikes (BECTS) to epilepsy-aphasia syndromes such as Landau-Kleffner syndrome (LKS) and other epileptic encephalopathies	Complex inheritance is implicated, and studies have shown considerable inter- and intrafamilial phenotypic variability and incomplete penetrance
CDKL-5 (Xp22.13)	Encodes cyclin-dependent kinase-like 5 (CDKL-5), a serine-threonine kinase involved in neural maturation and synaptogenesis	CDKL-5 deficiency disorder (CDD) results from pathogenic mutation in the *CDKL5* gene that causes absence or nonfunctional CDKL-5 protein. CDD is a severe developmental epileptic encephalopathy characterized by very-early-onset seizures. X-linked, affects females more than males	Ganaxolone is a recently approved antiseizure drug that has been shown to significantly reduce CDD-associated seizures
SLC2A1 (1p34.2)	Glucose transporter protein type 1 (GLUT1); transports glucose across the blood-brain barrier	Loss of function of one allele leads to GLUT1 deficiency, a severe metabolic encephalopathy including intractable epilepsy, complex motor dysfunction, and intellectual disability. Milder GLUT1 deficiency causes a combination of movement disorder (paroxysmal exertional dyskinesia) and epilepsy with prominent absence seizures, though intellect is often normal	Milder forms of epilepsy due to GLUT1 deficiency may respond to standard antiseizure medications, but the gold standard treatment for refractory forms is the ketogenic diet, which bypasses defective glucose transport to provide an alternative energy supply to the brain
CSTB (21q22.3)	Cystatin B, a noncaspase cysteine protease inhibitor; normal protein may block neuronal apoptosis by inhibiting caspases directly or indirectly (via cathepsins), or controlling proteolysis	Progressive myoclonus epilepsy (PME) (Unverricht-Lundborg disease); autosomal recessive inheritance; age of onset between 6 and 15 years, myoclonic seizures, ataxia, and progressive cognitive decline; brain shows neuronal degeneration	Overall rare, but relatively common in Finland and western Mediterranean (>1 in 20,000); precise role of cystatin B in human disease unknown, although mice with null mutations of cystatin B have similar syndrome
EPM2A (6q24)	Laforin, a protein tyrosine phosphatase (PTP); involved in glycogen metabolism and may have antiapoptotic activity	Progressive myoclonus epilepsy (Lafora's disease); autosomal recessive inheritance; age of onset 6–19 years, death within 10 years; brain degeneration associated with polyglucosan intracellular inclusion bodies in numerous organs	Most common PME in southern Europe, Middle East, northern Africa, and Indian subcontinent; genetic heterogeneity; unknown whether seizure phenotype due to degeneration or direct effects of abnormal laforin expression
Doublecortin (Xq21-24)	Doublecortin, expressed primarily in frontal lobes; directly regulates microtubule polymerization and bundling	Classic lissencephaly associated with severe mental retardation and seizures in males; subcortical band heterotopia with more subtle findings in females (presumably due to random X inactivation); X-linked dominant	Relatively rare but of uncertain incidence; recent increased ascertainment due to improved imaging techniques; relationship between migration defect and seizure phenotype unknown

[a]The first seven syndromes listed in the table (SHE, benign familial neonatal convulsions, GEFS+, ADEAF, FFEVF, BECTS, LKS, CDD) are examples of genetic epilepsies associated with identified gene mutations. The last three syndromes are examples of the numerous Mendelian disorders in which seizures are one part of the phenotype.

Abbreviation: GABA, γ-aminobutyric acid.

TABLE 436-3 Characteristics of the Mesial Temporal Lobe Epilepsy Syndrome	
History	
History of febrile seizures	Rare generalized seizures
Family history of epilepsy	Seizures may remit and reappear
Early onset	Seizures often intractable
Clinical Observations	
Aura common	Postictal disorientation
Behavioral arrest/stare	Memory loss
Complex automatisms	Dysphasia (with focus in dominant hemisphere)
Unilateral posturing	
Laboratory Studies	
Unilateral or bilateral anterior temporal spikes on EEG	
Hypometabolism on interictal PET	
Hyperperfusion on ictal SPECT	
Material-specific memory deficits on intracarotid amobarbital (Wada) test	
MRI Findings	
Small hippocampus with increased signal on T2-weighted sequences and loss of trilaminar hippocampal internal architecture	
Small temporal lobe	
Enlarged temporal horn	
Pathologic Findings	
Highly selective loss of specific cell populations within hippocampus in most cases, granule cell layer dispersion, gliosis	

Abbreviations: EEG, electroencephalogram; MRI, magnetic resonance imaging; PET, positron emission tomography; SPECT, single-photon emission computed tomography.

media, respiratory infection, or gastroenteritis. The seizure is likely to occur during the rising phase of the temperature curve (i.e., during the first day) rather than well into the course of the illness. A *simple* febrile seizure is a single, isolated event, brief, and symmetric in appearance. *Complex* febrile seizures are characterized by repeated seizure activity, a duration >15 minutes, or by focal features. Approximately one-third

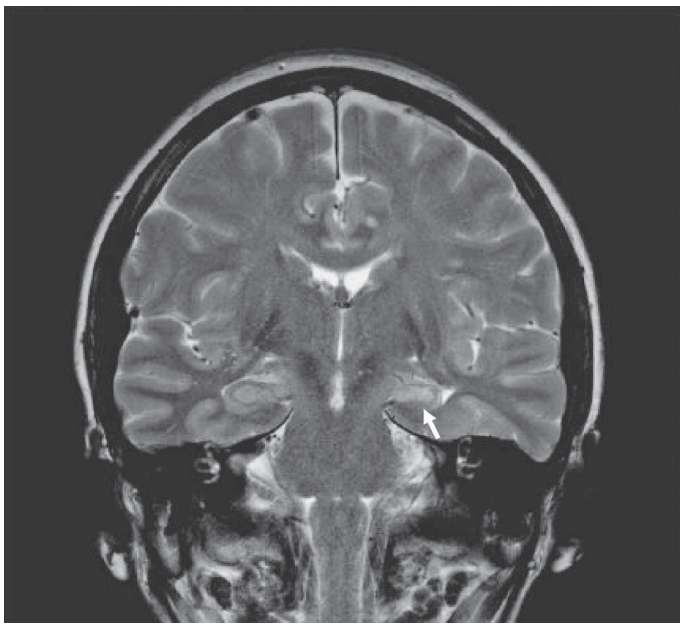

FIGURE 436-1 Mesial temporal lobe epilepsy. The electroencephalogram and seizure semiology were consistent with a left temporal lobe focus. This coronal high-resolution T2-weighted fast spin echo magnetic resonance image obtained at 3 Tesla is at the level of the hippocampal bodies and shows abnormal high signal intensity, blurring of internal laminar architecture, and reduced size of the left hippocampus (arrow) relative to the right. This triad of imaging findings is consistent with hippocampal sclerosis.

TABLE 436-4 Causes of Seizures	
Neonates (<1 month)	Perinatal hypoxia and ischemia Intracranial hemorrhage and trauma CNS infection Metabolic disturbances (hypoglycemia, hypocalcemia, hypomagnesemia, pyridoxine deficiency) Drug withdrawal Developmental disorders Genetic disorders
Infants and children (>1 month and <12 years)	Febrile seizures Genetic disorders (metabolic, degenerative, primary epilepsy syndromes) CNS infection Developmental disorders Trauma
Adolescents (12–18 years)	Trauma Genetic disorders Infection Illicit drug use Brain tumor
Young adults (18–35 years)	Trauma Alcohol withdrawal Illicit drug use Brain tumor Autoantibodies
Older adults (>35 years)	Cerebrovascular disease Brain tumor Alcohol withdrawal Metabolic disorders (uremia, hepatic failure, electrolyte abnormalities, hypoglycemia, hyperglycemia) Alzheimer's disease and other degenerative CNS diseases Autoantibodies

Abbreviation: CNS, central nervous system.

of patients with febrile seizures will have a recurrence, but <10% have three or more episodes. Recurrences are much more likely when the febrile seizure occurs in the first year of life. Simple febrile seizures are not associated with increased risk of developing epilepsy, while complex febrile seizures have a risk of 2–5%; other risk factors include the presence of preexisting neurologic deficits and a family history of nonfebrile seizures.

Childhood marks the age at which many of the well-defined epilepsy syndromes present. Some children who are otherwise normal develop idiopathic, generalized tonic-clonic seizures without other features that fit into specific syndromes. Temporal lobe epilepsy usually presents in childhood and may be related to mesial temporal lobe sclerosis (as part of the MTLE syndrome) or other focal abnormalities, such as cortical dysgenesis. Other types of focal seizures, including those that evolve into generalized seizures, may be late manifestations of a developmental disorder, an acquired lesion such as head trauma, CNS infection (e.g., viral encephalitis), or a CNS tumor.

The period of *adolescence and early adulthood* is one of transition during which the idiopathic or genetically based epilepsy syndromes, including JME and juvenile absence epilepsy, become less common, while epilepsies secondary to acquired CNS lesions begin to predominate. Seizures that arise in patients in this age range may be associated with head trauma, CNS infections (including parasitic infections such as cysticercosis), brain tumors, congenital CNS abnormalities, illicit drug use, or alcohol withdrawal. Autoantibodies directed against CNS antigens such as potassium channels or glutamate receptors are a cause of epilepsy that also begins to appear in this age group (although cases of autoimmunity are being increasingly described in the pediatric population), including patients without an identifiable cancer. This etiology should be suspected when a previously normal individual presents

with fulminant seizures, especially when combined with psychiatric symptoms and changes in cognitive function.

Head trauma is a common cause of epilepsy in adolescents and adults. The head injury can be caused by a variety of mechanisms, and the likelihood of developing epilepsy is strongly correlated with the severity of the injury. A patient with a penetrating head wound, depressed skull fracture, intracranial hemorrhage, or prolonged posttraumatic coma or amnesia has a 30–50% risk of developing epilepsy, whereas a patient with a closed head injury and cerebral contusion has a 5–25% risk. Recurrent seizures usually develop within 1 year after head trauma, although intervals of >10 years are well known. In controlled studies, mild head injury, defined as a concussion with amnesia or loss of consciousness of <30 min, was found to be associated with only a slightly increased likelihood of epilepsy. Nonetheless, some patients experience focal seizures within hours or days of a mild head injury and subsequently develop chronic seizures of the same type; such cases may represent rare examples of epilepsy resulting from mild head injury.

The causes of seizures in *older adults* include cerebrovascular disease, trauma (including subdural hematoma), CNS tumors, and degenerative diseases. Cerebrovascular disease may account for ~50% of new cases of epilepsy in patients >65 years. Acute poststroke seizures (i.e., occurring within the first 24 h after acute stroke) are more common after hemorrhagic strokes compared to ischemic strokes. Chronic seizures typically appear months to years after the initial event and are associated with all forms of stroke.

Metabolic disturbances such as electrolyte imbalance, hypo- or hyperglycemia, renal failure, and hepatic failure may cause seizures at any age. Similarly, endocrine disorders, hematologic disorders, vasculitides, and many other systemic diseases may cause seizures over a broad age range. Many medications and abused substances can precipitate seizures as well **(Table 436-5)**.

TABLE 436-5 Drugs and Other Substances That Can Cause Seizures

Alkylating agents (e.g., busulfan, chlorambucil)
Antimalarials (chloroquine, mefloquine)
Antimicrobials/antivirals
β-Lactam and related compounds
Quinolones
Acyclovir
Isoniazid
Ganciclovir
Anesthetics and analgesics
Meperidine
Fentanyl
Tramadol
Local anesthetics
Dietary supplements
Ephedra (ma huang)
Gingko
Immunomodulatory drugs
Cyclosporine
OKT3 (monoclonal antibodies to T cells)
Tacrolimus
Interferons
Psychotropics
Antidepressants (e.g., bupropion)
Antipsychotics (e.g., clozapine)
Lithium
Radiographic contrast agents
Drug withdrawal
Alcohol
Baclofen
Barbiturates (short-acting)
Benzodiazepines (short-acting)
Zolpidem
Drugs of abuse
Amphetamine
Cocaine
Phencyclidine
Methylphenidate
Flumazenil[a]

[a]In benzodiazepine-dependent patients.

BASIC MECHANISMS

MECHANISMS OF SEIZURE INITIATION AND PROPAGATION

Focal seizure activity can begin in a discrete region of cortex and then slowly invade the surrounding regions. The hallmark of an established seizure is typically an electrographic "spike" due to intense near-simultaneous firing of many local excitatory neurons, resulting in an apparent hypersynchronization of the excitatory bursts across a relatively large cortical region. The bursting activity in individual neurons (the "paroxysmal depolarization shift") is caused by a relatively long-lasting depolarization of the neuronal membrane due to influx of extracellular calcium (Ca^{2+}), which leads to the opening of voltage-dependent sodium (Na^+) channels, influx of Na^+, and generation of repetitive action potentials. This is followed by a hyperpolarizing afterpotential mediated by γ-aminobutyric acid (GABA) receptors or potassium (K^+) channels, depending on the cell type. The synchronized bursts from enough neurons result in summation of field potentials producing a spike discharge on the EEG.

The spreading seizure wavefront is thought to slow and ultimately halt by intact hyperpolarization and a "surround" inhibition created by feedforward activation of inhibitory neurons. With sufficient activation, there is a recruitment of surrounding neurons via a number of synaptic and nonsynaptic mechanisms, including (1) an increase in extracellular K^+, which blunts hyperpolarization and depolarizes neighboring neurons; (2) accumulation of Ca^{2+} in presynaptic terminals, leading to enhanced neurotransmitter release; (3) depolarization-induced activation of the *N*-methyl-D-aspartate (NMDA) subtype of the excitatory amino acid receptor, which causes additional Ca^{2+} influx and neuronal activation; and (4) ephaptic interactions related to changes in tissue osmolarity and cell swelling. The recruitment of a sufficient number of neurons leads to the propagation of excitatory currents into contiguous areas via local cortical connections and to more distant areas via long commissural pathways such as the corpus callosum.

Many factors control neuronal excitability, and thus, there are many potential mechanisms for altering a neuron's propensity to have bursting activity. Mechanisms *intrinsic* to the neuron include changes in the conductance of ion channels, response characteristics of membrane receptors, cytoplasmic buffering, second-messenger systems, and protein expression as determined by gene transcription, translation, and posttranslational modification. Mechanisms *extrinsic* to the neuron include changes in the amount or type of neurotransmitters present at the synapse, modulation of receptors by extracellular ions and other molecules, and temporal and spatial properties of synaptic and nonsynaptic input. Glial cells, such as astrocytes and oligodendrocytes, have an important role in many of these mechanisms as well.

Certain recognized causes of seizures are explained by these mechanisms. For example, accidental ingestion of domoic acid, an analogue of glutamate (the principal excitatory neurotransmitter in the brain) produced by naturally occurring microscopic algae, causes profound seizures via direct activation of excitatory amino acid receptors throughout the CNS. Penicillin, which can lower the seizure threshold in humans and is a potent convulsant in experimental models, reduces inhibition by antagonizing the effects of GABA at its receptor. The basic mechanisms of other precipitating factors of seizures, such as sleep deprivation, fever, alcohol withdrawal, hypoxia, and infection, are not as well understood but presumably involve analogous perturbations in

neuronal excitability. Similarly, the endogenous factors that determine an individual's seizure threshold may relate to these properties as well.

Knowledge of the mechanisms responsible for initiation and propagation of most generalized seizures (including tonic-clonic, myoclonic, and atonic types) remains rudimentary and reflects the limited understanding of the connectivity of the brain at a systems level. Much more is understood about the origin of generalized spike-and-wave discharges in absence seizures. These appear to be related to oscillatory rhythms normally generated during sleep by circuits connecting the thalamus and cortex. This oscillatory behavior involves an interaction between $GABA_B$ receptors, T-type Ca^{2+} channels, and K^+ channels located within the thalamus. Pharmacologic studies indicate that modulation of these receptors and channels can induce absence seizures, and there is good evidence that the genetic forms of absence epilepsy may be associated with mutations of components of this system.

MECHANISMS OF EPILEPTOGENESIS

Epileptogenesis refers to the transformation of a normal neuronal network into one that is chronically hyperexcitable. There is often a delay of months to years between an initial CNS injury such as trauma, stroke, or infection and the first clinically evident seizure. The injury appears to initiate a process that gradually lowers the seizure threshold in the affected region until a spontaneous seizure occurs. In many genetic and idiopathic forms of epilepsy, epileptogenesis is presumably determined by developmentally regulated events.

Pathologic studies of the hippocampus from patients with temporal lobe epilepsy suggest that some forms of epileptogenesis are related to *structural changes in neuronal networks*. For example, many patients with MTLE have a highly selective loss of neurons that normally contribute to inhibition of the main excitatory neurons within the dentate gyrus. There is also evidence that, in response to the loss of neurons, there is reorganization of surviving neurons in a way that affects the excitability of the network. Some of these changes can be seen in experimental models of prolonged electrical seizures or traumatic brain injury. Thus, an initial injury such as head injury may lead to a focal region of structural change that causes local hyperexcitability. The local hyperexcitability leads to further structural changes that evolve over time until the focal lesion produces clinically evident seizures. Similar models have provided strong evidence for long-term alterations in *intrinsic, biochemical properties of cells* within the network such as chronic changes in glutamate or GABA receptor function. Induction of inflammatory cascades may be a critical factor in these processes as well.

GENETIC CAUSES OF EPILEPSY

An area of ongoing progress in epilepsy research has been the identification of genetic mutations associated with a variety of epilepsy syndromes (Table 436-2). Although most of the mutations identified to date cause rare forms of epilepsy, their discovery has led to extremely important conceptual advances. For example, it appears that many of the inherited epilepsies are due to mutations affecting ion channel function. These syndromes are therefore part of the larger group of channelopathies causing paroxysmal disorders such as cardiac arrhythmias, episodic ataxia, periodic weakness, and familial hemiplegic migraine. Other gene mutations are proving to be associated with pathways influencing CNS development, synaptic physiology, or neuronal homeostasis. De novo and somatic mutations may explain a significant proportion of these syndromes, especially those with onset in early childhood. A current challenge is to identify the multiple susceptibility genes that underlie the more common forms of idiopathic epilepsies. Ion channel mutations and copy number variants may be pathogenic in a subset of these patients.

MECHANISMS OF ACTION OF ANTISEIZURE DRUGS

Antiseizure drugs appear to act primarily by blocking the initiation or spread of seizures. This occurs through a variety of mechanisms that modify the activity of ion channels or neurotransmitters, and in most cases, the drugs have pleiotropic effects. The mechanisms include inhibition of Na^+-dependent action potentials in a frequency-dependent manner (e.g., phenytoin, carbamazepine, lamotrigine, topiramate, zonisamide, lacosamide, rufinamide, cenobamate), inhibition of voltage-gated Ca^{2+} channels (phenytoin, gabapentin, pregabalin), facilitating the opening of potassium channels (ezogabine), attenuation of glutamate activity (lamotrigine, topiramate, felbamate, perampanel), potentiation of GABA receptor function (benzodiazepines, barbiturates), increase in the availability of GABA (valproic acid, gabapentin, tiagabine), and modulation of release of synaptic vesicles (levetiracetam, brivaracetam). Two of the effective drugs for absence seizures, ethosuximide and valproic acid, probably act by inhibiting T-type Ca^{2+} channels in thalamic neurons. Cannabidiol (CBD), a derivative of cannabis plants, is effective for reducing seizures in children with Dravet syndrome, Lennox-Gastaut syndrome, and tuberous sclerosis but does not act through endogenous cannabinoid receptors. Rather, CBD has a multimodal mechanism of action involving modulation of intracellular calcium via G protein–coupled receptor 55, extracellular calcium influx via transient receptor potential vanilloid type 1 (TRPV1) channels, and adenosine-mediated signaling. Fenfluramine is an amphetamine derivative that probably exerts its antiseizure effect by inhibiting serotonin reuptake and increasing extracellular levels. Ganaxolone is a synthetic analogue of allopregnanolone and an allosteric modulator of $GABA_A$ receptors that reduces seizures associated with cyclin-dependent kinase-like 5 (CDKL-5) deficiency disorder.

In contrast to the relatively large number of antiseizure drugs that can attenuate seizure activity, there are currently no drugs known to prevent the formation of a seizure focus following CNS injury. Eventual development of such "antiepileptogenic" drugs will provide means of preventing the emergence of epilepsy following injuries such as head trauma, stroke, and CNS infection.

APPROACH TO THE PATIENT

Seizure

When a patient presents shortly after a seizure, the first priorities are attention to vital signs, respiratory and cardiovascular support, and treatment of seizures if they resume (see "Treatment: Seizures and Epilepsy"). Life-threatening conditions such as CNS infection, metabolic derangement, or drug toxicity must be recognized and managed appropriately.

When the patient is not acutely ill, the evaluation will initially focus on whether there is a history of earlier seizures **(Fig. 436-2)**. If this is the first seizure, then the emphasis will be to (1) establish whether the reported episode was a seizure rather than another paroxysmal event, (2) determine the cause of the seizure by identifying risk factors and precipitating events, and (3) decide whether antiseizure drug therapy is required in addition to treatment for any underlying illness.

In the patient with prior seizures or a known history of epilepsy, the evaluation is directed toward (1) identification of the underlying cause and precipitating factors, and (2) determination of the adequacy of the patient's current therapy.

HISTORY AND EXAMINATION

The first goal is to determine whether the event was truly a seizure. A detailed history is essential, because *in many cases the diagnosis of a seizure is based solely on clinical grounds—the examination and laboratory studies are often normal*. Questions should focus on the symptoms before, during, and after the episode to differentiate a seizure from other paroxysmal events (see "Differential Diagnosis of Seizures" below). Seizures frequently occur out-of-hospital, and the patient may be unaware of the ictal and immediate postictal phases; thus, witnesses to the event should be interviewed carefully.

The history should also focus on risk factors and predisposing events. Clues for a predisposition to seizures include a history of febrile seizures, a family history of seizures, and, of particular importance, earlier auras or brief seizures not recognized as such. Epileptogenic factors such as prior head trauma, stroke, tumor, or CNS infection should be identified. In children, a careful assessment of developmental

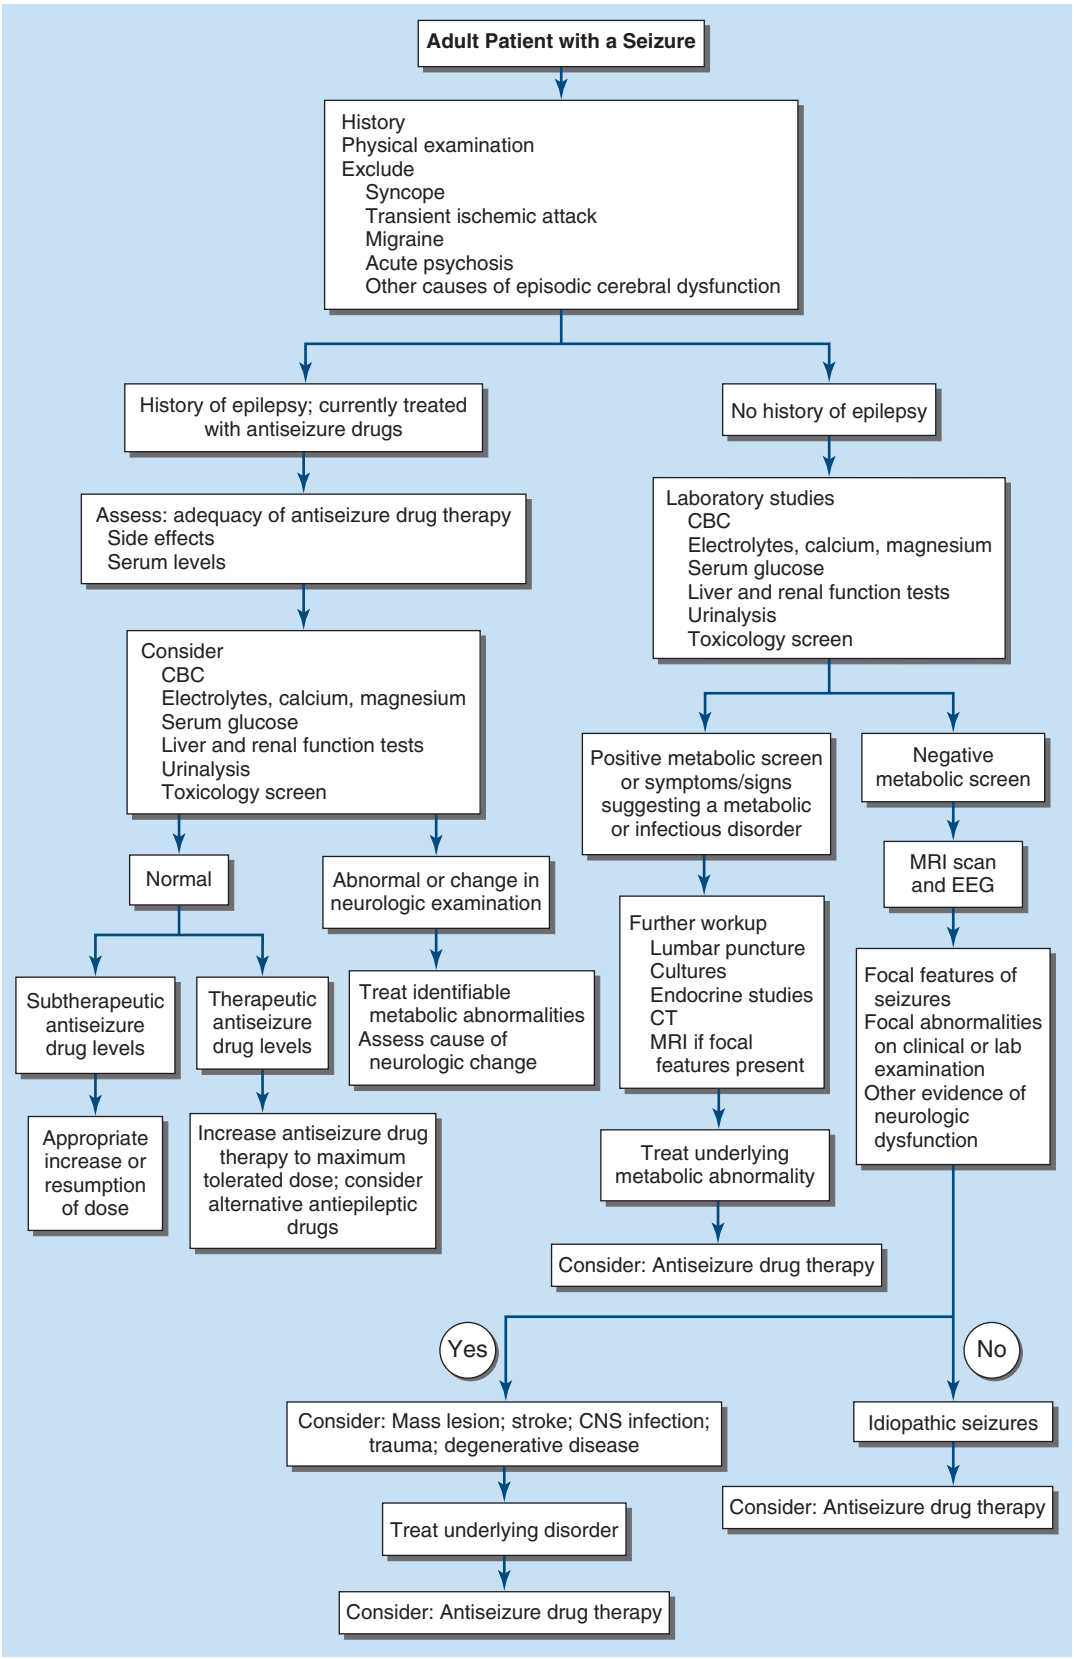

FIGURE 436-2 Evaluation of the adult patient with a seizure. CBC, complete blood count; CNS, central nervous system; CT, computed tomography; EEG, electroencephalogram; MRI, magnetic resonance imaging.

milestones may provide evidence for underlying CNS disease. Precipitating factors such as sleep deprivation, systemic diseases, electrolyte or metabolic derangements, acute infection, drugs that lower the seizure threshold (Table 436-5), or alcohol or illicit drug use should also be identified.

The general physical examination includes a search for signs of infection or systemic illness. Careful examination of the skin may reveal signs of neurocutaneous disorders, such as tuberous sclerosis or neurofibromatosis, or chronic liver or renal disease. A finding of organomegaly may indicate a metabolic storage disease, and limb asymmetry may provide a clue to brain injury early in development. Signs of head trauma and use of alcohol or illicit drugs should be sought. Auscultation of the heart and carotid arteries may identify an abnormality that predisposes to cerebrovascular disease.

All patients require a complete neurologic examination, with particular emphasis on eliciting signs of cerebral hemispheric disease (Chap. 433). Careful assessment of mental status (including memory, language function, and abstract thinking) may suggest lesions in the anterior frontal, parietal, or temporal lobes. Testing of visual fields will help screen for lesions in the optic pathways and occipital lobes. Screening tests of motor function such as pronator drift, deep tendon reflexes, gait, and coordination may suggest lesions in motor (frontal) cortex, and cortical sensory testing (e.g., double simultaneous stimulation) may detect lesions in the parietal cortex.

LABORATORY STUDIES

Routine blood studies are indicated to identify the more common metabolic causes of seizures such as abnormalities in electrolytes, glucose, calcium, or magnesium, and hepatic or renal disease. A screen for toxins in blood and urine should also be obtained from all patients in appropriate risk groups, especially when no clear precipitating factor has been identified. A lumbar puncture is indicated if there is any suspicion of meningitis or encephalitis, and it is mandatory in all patients infected with HIV, even in the absence of symptoms or signs suggesting infection. Testing for autoantibodies in the serum and cerebrospinal fluid (CSF) should be considered in patients presenting with fulminant onset of epilepsy associated with other abnormalities such as psychiatric symptoms or cognitive disturbances (Chap. 99).

ELECTROPHYSIOLOGIC STUDIES

The electrical activity of the brain (the EEG) is easily recorded from electrodes placed on the scalp. The potential difference between pairs of electrodes on the scalp (bipolar derivation) or between individual scalp electrodes and a relatively inactive common reference point (referential derivation) is amplified and displayed on a computer monitor. Digital systems allow the EEG to be displayed with any desired format and to be manipulated for more detailed analysis, and they also enable computational algorithms that can automatically detect certain abnormalities. The characteristics of the normal EEG depend on the patient's age and level of arousal. The rhythmic activity normally recorded represents the postsynaptic potentials of vertically oriented pyramidal cells of the cerebral cortex and is characterized by its frequency. In normal awake adults lying quietly with the eyes closed, an 8- to 13-Hz alpha rhythm is seen posteriorly in the EEG, intermixed with a variable amount of generalized faster (beta) activity (>13 Hz); the alpha rhythm is attenuated when the eyes are opened (Fig. 436-3). During drowsiness and light sleep, slower activity in the theta (4–7 Hz) and delta (<4 Hz) ranges becomes more conspicuous.

All patients who have a possible seizure disorder should be evaluated with an EEG as soon as possible. In the evaluation of a patient with suspected epilepsy, the presence of *electrographic seizure activity* during the clinical event (i.e., abnormal, repetitive, rhythmic activity having a discrete onset and termination) clearly establishes the diagnosis. The EEG is always abnormal during generalized tonic-clonic seizures. The absence of electrographic seizure activity does not exclude a seizure disorder, however, because focal seizures may originate from a region of the cortex that cannot be detected by standard scalp electrodes. Because seizures are typically infrequent and unpredictable, it is often not possible to obtain the EEG during a clinical event. In such situations, activating procedures are generally undertaken to provoke abnormalities while the EEG is recorded. These procedures commonly include hyperventilation, photic stimulation, sleep, and sleep deprivation on the night prior to the recording. Continuous monitoring for prolonged periods in video-EEG telemetry units for hospitalized patients or the use of portable equipment to record the EEG continuously for ≥24 h in ambulatory patients has made it easier to capture the electrophysiologic correlates of clinical events. Video-EEG telemetry is now a routine approach for the accurate diagnosis of epilepsy in patients with poorly characterized events or seizures that are difficult to control. A variety of technologies, including sub-scalp EEG devices, are being developed to enable ultra-long-term ambulatory recordings of brain activity, analogous to implanted loop recorders used to capture infrequent cardiac arrhythmias.

The EEG may also be helpful in the interictal period by showing certain abnormalities that are highly supportive of the diagnosis of epilepsy. Such *epileptiform activity* consists of bursts of abnormal discharges containing spikes or sharp waves. The presence of epileptiform activity is not entirely specific for epilepsy, but it has a much greater prevalence in patients with epilepsy than in other individuals. However, even in an individual who is known to have epilepsy, the initial routine interictal EEG may be normal 50–80% of the time. Thus, the EEG has limited sensitivity and cannot establish the diagnosis of epilepsy in many cases.

The EEG is also used for classifying seizure disorders and aiding in the selection of antiseizure medications (Fig. 436-4). For example, episodic generalized spike-wave activity is usually seen in patients with typical absence epilepsy and may be seen with other generalized epilepsy syndromes. Focal interictal epileptiform discharges would support the diagnosis of a focal seizure disorder such as temporal lobe epilepsy or frontal lobe seizures, depending on the location of the discharges.

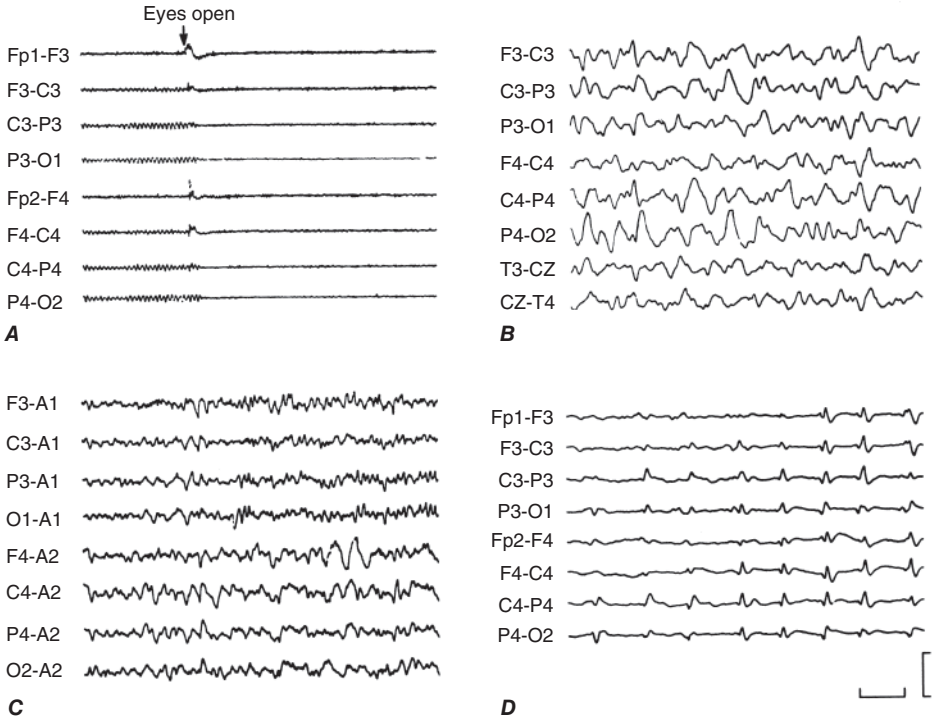

FIGURE 436-3 Electroencephalograms. ***A.*** Normal electroencephalogram (EEG) showing a posteriorly situated 9-Hz alpha rhythm that attenuates with eye opening. ***B.*** Abnormal EEG showing irregular diffuse slow activity in an obtunded patient with encephalitis. ***C.*** Irregular slow activity in the right central region, on a diffusely slowed background, in a patient with a right parietal glioma. ***D.*** Periodic complexes occurring once every second in a patient with Creutzfeldt-Jakob disease. Horizontal calibration: 1 s; vertical calibration: 200 μV in A, 300 μV in other panels. In this and the following figure, electrode placements are indicated at the left of each panel and accord with the international 10–20 system. A, earlobe; C, central; F, frontal; Fp, frontal polar; O, occipital; P, parietal; T, temporal. Right-sided placements are indicated by even numbers, left-sided placements by odd numbers, and midline placements by Z. *(Reproduced with permission from MJ Aminoff: Aminoff's Electrodiagnosis in Clinical Neurology, 6th ed. Oxford: Elsevier Saunders, 2012.)*

Horizontal calibration: 1 s; vertical calibration: 400 μV in *A*, 200 μV in *B*, and 750 μV in *C*. *(Reproduced with permission from MJ Aminoff: Aminoff's Electrodiagnosis in Clinical Neurology, 6th ed. Oxford: Elsevier Saunders, 2012.)*

The routine scalp EEG may also be used to assess the prognosis of seizure disorders; in general, a normal EEG implies a better prognosis, whereas an abnormal background or frequent epileptiform activity suggests a worse outcome. Unfortunately, the EEG has not proved to be useful in predicting which patients with predisposing conditions such as head injury or brain tumor will go on to develop epilepsy, because in such circumstances, epileptiform activity is commonly encountered regardless of whether seizures occur.

High-density EEG provides higher resolution localization by utilizing up to 257 scalp electrodes, as opposed to the 21 electrodes used in a standard EEG recording. This makes use of scalp voltage field data to determine dipole location, orientation, and propagation. EEG source imaging (ESI) permits visualization of these dipoles by mapping them onto a three-dimensional model that is co-registered on brain MRI.

Magnetoencephalography (MEG) provides another way of looking noninvasively at cortical activity. Instead of measuring electrical activity of the brain, it measures the small magnetic fields that are generated by this activity. The epileptiform activity seen on MEG can be analyzed, and its source in the brain can be estimated using a variety of mathematical techniques. These source estimates can then be plotted on an anatomic image of the brain such as an MRI (discussed below) to generate a magnetic source image (MSI). MSI can be useful to localize potential seizure foci.

BRAIN IMAGING

Almost all patients with new-onset seizures should have a brain imaging study to determine whether there is an underlying structural abnormality that is responsible. The only potential exception to this rule is children who have an unambiguous history and examination suggestive of a benign, generalized seizure disorder such as absence epilepsy. MRI has been shown to be superior to computed tomography (CT) for the detection of cerebral lesions associated with epilepsy. In some cases, MRI will identify lesions such as tumors, vascular malformations, or other pathologies that need urgent therapy. The availability of newer MRI methods, such as three-dimensional structural imaging at submillimeter resolution, has increased the sensitivity for detection of abnormalities of cortical architecture, including hippocampal atrophy associated with mesial temporal sclerosis, as well as abnormalities of neuronal migration. In such cases, the findings provide an explanation for the patient's seizures and point to the need for chronic antiseizure drug therapy or possible surgical resection.

In the patient with a suspected CNS infection or mass lesion, CT scanning should be performed emergently when MRI is not immediately available. Otherwise, it is usually appropriate to obtain an MRI study within a few days of the initial evaluation. Functional imaging procedures such as positron emission tomography (PET) and single-photon emission computed tomography (SPECT) are also used to evaluate certain patients with medically refractory seizures (Table 436-3).

GENETIC TESTING

With the increasing recognition of specific gene mutations causing epilepsy (Table 436-2), genetic testing is beginning to emerge as part of the diagnostic evaluation of patients with epilepsy. In addition to providing a definitive diagnosis (which may be of great benefit to the patient and family members and curtail the pursuit of additional, unrevealing laboratory testing), genetic testing may offer a guide for therapeutic options (see section "Selection of Antiseizure Drugs" below). Genetic testing is currently being done mainly in infants and children with epilepsy syndromes thought to have a genetic cause but should also be considered in older patients with a history suggesting an undiagnosed genetic epilepsy syndrome that began early in life.

DIFFERENTIAL DIAGNOSIS OF SEIZURES

Disorders that may mimic seizures are listed in Table 436-6. In most cases, seizures can be distinguished from other conditions by meticulous attention to the history and relevant laboratory studies. On occasion, additional studies such as video-EEG monitoring, sleep studies, tilt-table analysis, or cardiac electrophysiology may be required to reach a correct diagnosis. Two of the more common nonepileptic syndromes in the differential diagnosis are discussed below.

SYNCOPE

The diagnostic dilemma encountered most frequently is the distinction between a generalized seizure and syncope. Observations by the patient and bystanders that can help differentiate between the two are listed in Table 436-7. Characteristics of a seizure include the presence of an aura, cyanosis, unconsciousness, motor manifestations lasting >15 s, postictal disorientation, muscle soreness, and sleepiness. In contrast, a syncopal episode is more likely if the event was provoked by acute pain or emotional stress or occurred immediately after arising from the lying or sitting position. Patients with syncope often describe a stereotyped transition from consciousness to unconsciousness that includes tiredness, sweating, nausea, and tunneling of vision, and they experience a relatively brief loss of consciousness with rapid recovery of normal mentation. Headache and incontinence are unreliable

TABLE 436-6 Differential Diagnosis of Seizures

Syncope	**Transient ischemic attack (TIA)**
Vasovagal syncope	Basilar artery TIA
Cardiac arrhythmia	**Sleep disorders**
Valvular heart disease	Narcolepsy/cataplexy
Cardiac failure	Benign sleep myoclonus
Orthostatic hypotension	**Movement disorders**
Psychological disorders	Tics
Psychogenic seizure	Nonepileptic myoclonus
Hyperventilation	Paroxysmal choreoathetosis
Panic attack	**Special considerations in children**
Metabolic disturbances	Breath-holding spells
Alcoholic blackouts	Migraine with recurrent abdominal pain and cyclic vomiting
Delirium tremens	Benign paroxysmal vertigo
Hypoglycemia	Apnea
Hypoxia	Night terrors
Psychoactive drugs (e.g., hallucinogens)	Sleepwalking
Migraine	
Confusional migraine	
Basilar migraine	

features in differentiating between syncope and seizure. A brief period (i.e., 1–10 s) of convulsive motor activity is frequently seen immediately at the onset of a syncopal episode, especially if the patient remains in an upright posture after fainting (e.g., in a dentist's chair) and therefore has a sustained decrease in cerebral perfusion. Rarely, a syncopal episode can induce a full tonic-clonic seizure. In such cases, the evaluation must focus on both the cause of the syncopal event as well as the possibility that the patient has a propensity for recurrent seizures. Postictal symptoms can be helpful when differentiating convulsive syncope from seizure, as confusion and disorientation are typically much less prominent following syncope.

PSYCHOGENIC SEIZURES

Psychogenic seizures are nonepileptic behaviors that resemble seizures. They are often part of a conversion reaction precipitated by underlying psychological distress. Certain behaviors such as side-to-side turning of the head, ictal eye closure, asynchronous and large-amplitude shaking movements of the limbs, twitching of all four extremities without loss of consciousness, and pelvic thrusting are more commonly associated with psychogenic rather than epileptic seizures. Psychogenic seizures often last longer than epileptic seizures and may wax and wane over minutes to hours. However, the distinction is sometimes difficult on clinical grounds alone, and there are many examples of diagnostic errors made by experienced epileptologists. This is especially true for psychogenic seizures that resemble focal seizures, because the behavioral manifestations of focal seizures (especially of frontal lobe origin) can be extremely unusual, and, in both cases, the routine surface EEG may be normal. Video-EEG monitoring is very useful when historic features are nondiagnostic. Generalized tonic-clonic seizures always produce marked EEG abnormalities during and after the seizure. For suspected focal seizures, the use of additional electrodes may help to localize a seizure focus. Most generalized seizures and some focal seizures are accompanied by a rise in serum prolactin during the immediate 30-min postictal period, whereas psychogenic seizures are not, though this is not always reliable because baseline prolactin levels are rarely available and certain medications can elevate prolactin levels. The diagnosis of psychogenic seizures also does not exclude a concurrent diagnosis of epilepsy, because the two often coexist.

TABLE 436-7 Features That Distinguish Generalized Tonic-Clonic Seizure from Syncope

FEATURES	SEIZURE	SYNCOPE
Immediate precipitating factors	Usually none	Emotional stress, Valsalva, orthostatic hypotension, cardiac etiologies
Premonitory symptoms	None or aura (e.g., odd odor)	Tiredness, nausea, diaphoresis, tunneling of vision
Posture at onset	Variable	Usually erect
Transition to unconsciousness	Often immediate	Gradual over seconds[a]
Duration of unconsciousness	Minutes	Seconds
Duration of tonic or clonic movements	30–60 s	Never >15 s
Facial appearance during event	Cyanosis, frothing at mouth	Pallor
Disorientation and sleepiness after event	Many minutes to hours	<5 min
Aching of muscles after event	Often	Sometimes
Biting of tongue	Sometimes	Rarely
Incontinence	Sometimes	Sometimes
Headache	Sometimes	Rarely

[a]May be sudden with certain cardiac arrhythmias.

TREATMENT

Seizures and Epilepsy

Therapy for a patient with a seizure disorder is almost always multimodal and includes treatment of underlying conditions that cause or contribute to the seizures, avoidance of precipitating factors, suppression of recurrent seizures by prophylactic therapy with antiseizure medications or surgery, and addressing a variety of psychological and social issues. Treatment plans must be individualized, given the many different types and causes of seizures as well as the differences in efficacy and toxicity of antiseizure medications for each patient. In almost all cases, a neurologist with experience in the treatment of epilepsy should design and oversee implementation of the treatment strategy. Furthermore, patients with refractory epilepsy or those who require polypharmacy with antiseizure drugs should remain under the regular care of a neurologist.

TREATMENT OF UNDERLYING CONDITIONS

If the sole cause of a seizure is a metabolic disturbance such as an abnormality of serum electrolytes or glucose, then treatment is aimed at reversing the metabolic problem and preventing its recurrence. Therapy with antiseizure drugs is usually unnecessary unless the metabolic disorder cannot be corrected promptly and the patient is at risk of having further seizures. If the apparent cause of a seizure was a medication (e.g., bupropion) or illicit drug use (e.g., cocaine), then appropriate therapy is avoidance of the drug; there is usually no need for antiseizure medications unless subsequent seizures occur in the absence of these precipitants.

Seizures caused by a structural CNS lesion such as a brain tumor, vascular malformation, or brain abscess may not recur after appropriate treatment of the underlying lesion. However, despite removal of the structural lesion, there is a risk that the seizure focus will remain in the surrounding tissue or develop de novo as a result of gliosis and other processes induced by surgery, radiation, or other therapies. Most patients are therefore maintained on an antiseizure medication for 6–12 months, and an attempt is made to withdraw medications only if the patient has been completely seizure free. If seizures are refractory to medication, the patient may benefit from surgical removal of the seizure-producing brain tissue (see below).

AVOIDANCE OF PRECIPITATING FACTORS

Unfortunately, little is known about the specific factors that determine precisely when a seizure will occur in a patient with epilepsy. An almost universal precipitating factor for seizures is sleep deprivation, so patients should do everything possible to optimize their sleep quality. Many patients can identify other avoidable situations that appear to lower their seizure threshold. For example, patients may note an association between alcohol intake and seizures, and

they should be encouraged to modify their drinking habits accordingly. There are also relatively rare cases of patients with seizures that are induced by highly specific stimuli such as a video game monitor, music, startling sounds, or an individual's voice ("reflex epilepsy"). Because there is often an association between stress and seizures, stress reduction techniques such as physical exercise, meditation, or counseling may be helpful.

ANTISEIZURE DRUG THERAPY

Antiseizure drug therapy is the mainstay of treatment for most people with epilepsy. The overall goal is to completely prevent seizures without causing any untoward side effects, preferably with a single medication and a dosing schedule that is easy for the patient to follow. Seizure classification is an important element in designing the treatment plan, because some antiseizure drugs have different activities against various seizure types. However, there is considerable overlap between antiseizure drugs, and choice of therapy is often determined by anticipated side effects, drug-drug interactions, medical comorbidities, dosing frequency, and cost.

When to Initiate Antiseizure Drug Therapy Antiseizure drug therapy should be started in any patient with recurrent seizures of unknown etiology or a known cause that cannot be reversed. Whether to initiate therapy in a patient with a single seizure is controversial. Patients with a single seizure due to an identified lesion such as a CNS tumor, infection, or trauma, in which there is strong evidence that the lesion is epileptogenic, should be treated. The risk of seizure recurrence in a patient with an apparently unprovoked seizure is uncertain, with estimates ranging from 31 to 71% in the first 12 months after the initial seizure. This uncertainty arises from differences in the underlying seizure types and etiologies in various published epidemiologic studies. Generally accepted risk factors associated with recurrent seizures include the following: (1) prior brain insult such as a stroke or trauma, (2) an EEG with epileptiform abnormalities, (3) a significant brain imaging abnormality, or (4) a nocturnal seizure. Most patients with one or more of these risk factors should be treated. Issues such as employment or driving may influence the decision regarding whether to start medications as well. For example, a patient with a single unprovoked seizure whose job depends on driving may prefer taking an antiseizure drug to reduce risk of seizure recurrence and the potential loss of driving privileges.

Selection of Antiseizure Drugs Antiseizure drugs available in the United States are shown in **Table 436-8**, and the main pharmacologic characteristics of commonly used drugs are listed in **Table 436-9**. Worldwide, older medications such as phenytoin, valproic acid, carbamazepine, phenobarbital, and ethosuximide are generally used as first-line therapy for most seizure disorders because, overall, they are as effective as more recent drugs and significantly less expensive overall. Most of the new drugs that have become available in the past decade are used as adjunctive therapy, although many are now also being used as first-line monotherapy.

In addition to efficacy, factors influencing the choice of an initial medication include the convenience of dosing (e.g., once daily vs three times daily) and potential side effects. In this regard, many of the newer drugs have the advantage of reduced drug-drug interactions and easier dosing. Almost all the commonly used antiseizure drugs can cause similar, dose-related side effects such as sedation, ataxia, dizziness, and diplopia. Long-term use of some agents in adults, especially the elderly, can lead to osteoporosis. Close follow-up is required to ensure these side effects are promptly recognized and reversed. Most of the older drugs and some of the newer ones can also cause idiosyncratic toxicity such as rash, bone marrow suppression, or hepatotoxicity. Although rare, these side effects should be considered during drug selection, and patients must be instructed about symptoms or signs that should signal the need to alert their health care provider. For some drugs, laboratory tests (e.g., complete blood count and liver function tests) are recommended prior to the institution of therapy (to establish baseline values) and during initial dosing and titration of the agent. Monitoring serum concentrations of antiseizure medications can help determine when a therapeutic dose has been reached, though clinical response is paramount (see below).

TABLE 436-8 Selection of Antiseizure Drugs

GENERALIZED-ONSET TONIC-CLONIC	FOCAL	TYPICAL ABSENCE	ATYPICAL ABSENCE, MYOCLONIC, ATONIC
First-Line

[a]As adjunctive therapy.

An important advance in the care of people with epilepsy has been the application of genetic testing to help guide the choice of therapy (as well as establishing the underlying cause of a patient's syndrome; Table 436-2). For example, the identification of a mutation in the *SLC2A1* gene, which encodes the glucose type 1 transporter (GLUT-1) and is a cause of GLUT-1 deficiency, should prompt immediate treatment with the ketogenic diet. Mutations of the *ALDH7A1* gene, which encodes antiquitin, can cause alterations in pyridoxine metabolism that are reversed by treatment with pyridoxine. There is also mounting evidence that certain gene mutations may indicate better or worse response to specific antiseizure drugs. For example, patients with mutations in the sodium channel subunit *SCN1A* should generally avoid taking phenytoin or lamotrigine, whereas patients with mutations in the *SCN2A* or *SCN8A* sodium channel subunits appear to respond favorably to high-dose phenytoin. Genetic testing may also help predict antiseizure drug toxicity. Studies have shown that individuals of Asian descent who carry the human leukocyte antigen (HLA) allele HLA-B*1502 are at particularly high risk of developing serious skin reactions from carbamazepine, phenytoin, oxcarbazepine, and lamotrigine. HLA-A*31:01 has also been found to be associated with carbamazepine-induced hypersensitivity reactions in patients of European or Japanese ancestry.

Antiseizure Drug Selection for Focal Seizures Carbamazepine (or related drugs, oxcarbazepine and eslicarbazepine), lamotrigine, phenytoin, and levetiracetam are currently the drugs of choice approved for the initial treatment of focal seizures, including those that evolve into generalized seizures. Overall, they have very similar efficacy, but differences in pharmacokinetics and toxicity are the main determinants for use in a given patient. For example, an advantage of carbamazepine (which is also available in an extended-release form) is that its metabolism follows first-order pharmacokinetics, which allows for a linear relationship between drug dose, serum levels, and toxicity. Carbamazepine can cause leukopenia, aplastic anemia, or hepatotoxicity and would therefore be

TABLE 436-9 Dosage and Adverse Effects of Commonly Used Antiepileptic Drugs

GENERIC NAME	TRADE NAME	PRINCIPAL USES	TYPICAL DOSE; DOSE INTERVAL	HALF-LIFE	THERAPEUTIC RANGE	ADVERSE EFFECTS		DRUG INTERACTIONS[a]
						NEUROLOGIC	SYSTEMIC	
Brivaracetam	Briviact	Focal onset	100–200 mg/d; bid	7–10 h	Not established	Fatigue Dizziness Weakness Ataxia Mood changes	Gastrointestinal irritation	May increase carbamazepine-epoxide causing decreased tolerability May increase phenytoin
Cannabidiol	Epidiolex	Dravet and Lennox-Gastaut syndromes Tuberous sclerosis complex-associated seizures	10–20 mg/kg per d; bid	18–32 h	Not established	Sedation	Elevated transaminases Anorexia Weight loss Diarrhea	Increases clobazam causing somnolence
Carbamazepine	Tegretol[c]	Tonic-clonic Focal onset	600–1800 mg/d (15–35 mg/kg, child); bid (capsules or tablets), tid-qid (oral suspension)	10–17 h (variable due to autoinduction: complete 3–5 wk after initiation)	4–12 µg/mL	Ataxia Dizziness Diplopia Vertigo	Aplastic anemia Leukopenia Gastrointestinal irritation Hepatotoxicity Hyponatremia Rash	Level decreased by enzyme-inducing drugs[b] Level increased by erythromycin, propoxyphene, isoniazid, cimetidine, fluoxetine
Cenobamate	Xcopri	Focal onset	100–400 mg/d; daily (tablets)	50–60 h	Not established	Cognitive dysfunction Dizziness Disequilibrium Gait disturbance Headache	Anorexia Constipation Diarrhea Dyspepsia Nausea	Major CYP3A4 inducer; moderate CYP2C19 inhibitor
Clobazam	Onfi	Lennox-Gastaut syndrome	10–40 mg/d (5–20 mg/d for patients <30 kg body weight); bid	36–42 h (71–82 h for less active metabolite)	Not established	Fatigue Sedation Ataxia Aggression Insomnia	Constipation Anorexia Skin rash	Level increased by CYP2C19 inhibitors
Clonazepam	Klonopin	Absence Atypical absence Myoclonic	1–12 mg/d; qd-tid	24–48 h	10–70 ng/mL	Ataxia Sedation Lethargy	Anorexia	Level decreased by enzyme-inducing drugs[b]
Eslicarbazepine	Aptiom	Focal onset	400–1600 mg/d; qd	20–24 h	10–35 µg/mL (as oxcarbazepine mono-hydroxy derivative)	Sedation Ataxia Dizziness Diplopia Vertigo	See carbamazepine	Level decreased by enzyme-inducing drugs[b]
Ethosuximide	Zarontin	Absence	750–1250 mg/d (20–40 mg/kg); qd-bid	60 h, adult 30 h, child	40–100 µg/mL	Ataxia Lethargy Headache	Gastrointestinal irritation Skin rash Bone marrow suppression	Level decreased by enzyme-inducing drugs[b] Level increased by valproic acid
Felbamate	Felbatol	Focal onset Lennox-Gastaut syndrome Tonic-clonic	2400–3600 mg/d, tid-qid	16–22 h	30–60 µg/mL	Insomnia Dizziness Sedation Headache	Aplastic anemia Hepatic failure Weight loss Gastrointestinal irritation	Increases phenytoin, valproic acid, active carbamazepine metabolite
Fenfluramine	Fintepla	Dravet and Lennox-Gastaut syndromes	0.1–0.35 mg/kg/dose bid (oral solution); dosage depends on coadministration with stiripentol and/or clobazam	20 h	Not established	Ataxia Behavioral disturbance Headache Somnolence	Anorexia Constipation Hypertension Serotonin syndrome Weight loss	CYP1A2, CYP2B6, CYP2D6, CYPDA4 substrate

[a]Examples only; please refer to other sources for comprehensive listings of all potential drug-drug interactions. [b]Phenytoin, carbamazepine, phenobarbital. [c]Extended-release product available.

contraindicated in patients with predispositions to these problems. Oxcarbazepine has the advantage of being metabolized in a way that avoids an intermediate metabolite ("toxic epoxide") associated with some of the side effects of carbamazepine. Oxcarbazepine also has fewer drug interactions than carbamazepine. Eslicarbazepine has a long serum half-life and is dosed once daily.

Lamotrigine tends to be well tolerated in terms of side effects and has mood-stabilizing properties that can be beneficial. However, patients need to be particularly vigilant about the possibility of a skin rash during the initiation of therapy. This can be extremely severe and lead to Stevens-Johnson syndrome if unrecognized and if the medication is not discontinued immediately. This risk can be reduced by using low initial doses and slow titration. Lamotrigine must be started at even lower initial doses when used as add-on therapy with valproic acid, because valproic acid inhibits lamotrigine metabolism and substantially prolongs its half-life.

Phenytoin has a relatively long half-life and offers the advantage of once- or twice-daily dosing compared to twice- or thrice-daily dosing for many of the other drugs. However, phenytoin shows properties of nonlinear kinetics, such that small increases in phenytoin doses above a standard maintenance dose can precipitate marked side effects. This is one of the main causes of acute phenytoin toxicity (dizziness, diplopia, ataxia). Long-term use of phenytoin is associated with untoward cosmetic effects (e.g., hirsutism, coarsening of facial features, gingival hypertrophy) and osteoporosis. Due to these side effects, phenytoin is often avoided in young patients who are likely to require the drug for many years.

Levetiracetam has the advantage of having no known clinically relevant drug-drug interactions, making it especially useful in the elderly and patients on other medications. However, a significant number of patients taking levetiracetam complain of irritability, anxiety, and other psychiatric symptoms.

Topiramate can be used for both focal and generalized seizures. Like some of the other antiseizure drugs, topiramate can cause significant psychomotor slowing and other cognitive problems. Additionally, it should not be used in patients at risk for renal stones.

Valproic acid is an effective alternative for some patients with focal seizures, especially when the seizures generalize. Gastrointestinal side effects are fewer when using the delayed-release formulation. Laboratory testing is required to monitor toxicity because valproic acid can rarely cause reversible bone marrow suppression and hepatotoxicity. This drug should generally be avoided in patients with preexisting bone marrow or liver disease. Valproic acid also has relatively high risks of unacceptable adverse effects for women of childbearing age, including hyperandrogenism, that may affect fertility and teratogenesis (e.g., neural tube defects) in offspring. Irreversible, fatal hepatic failure appearing as an idiosyncratic rather than dose-related side effect is a relatively

rare complication; its risk is highest in children <2 years old, especially those taking other antiseizure drugs or with inborn errors of metabolism.

Zonisamide, brivaracetam, tiagabine, gabapentin, perampanel, and lacosamide are additional drugs currently used for the treatment of focal seizures with or without evolution into generalized seizures. Phenobarbital and other barbiturate compounds were commonly used in the past as first-line therapy for many forms of epilepsy. However, the barbiturates frequently cause sedation in adults, hyperactivity in children, and other more subtle cognitive changes; thus, their use should be limited to situations in which no other suitable treatment alternatives exist. Cenobamate is a recently approved antiseizure drug that has been shown to significantly improve seizure control in patients with focal epilepsy who were not adequately treated with up to three medications.

Antiseizure Drug Selection for Generalized Seizures

Lamotrigine, valproic acid, and levetiracetam are currently considered the best initial choice for the treatment of primary generalized, tonic-clonic seizures. Topiramate, zonisamide, perampanel, phenytoin, carbamazepine, and oxcarbazepine are suitable alternatives, although carbamazepine, oxcarbazepine, and phenytoin can worsen certain types of generalized seizures. Valproic acid is particularly effective in absence, myoclonic, and atonic seizures. It is therefore commonly used in patients with generalized epilepsy syndromes having mixed seizure types. However, levetiracetam, rather than valproic acid, is increasingly considered the initial drug of choice for women with epilepsies having mixed seizure types given the adverse effects of valproic acid for women of childbearing age (discussed below). Lamotrigine is also an alternative to valproate, especially for absence epilepsies. Ethosuximide is a particularly effective drug for the treatment of absence seizures, but it is not useful for tonic-clonic or focal seizures. Periodic monitoring of blood cell counts is required since ethosuximide rarely causes bone marrow suppression.

INITIATION AND MONITORING OF THERAPY

Because the response to any antiseizure drug is unpredictable, patients should be carefully educated about the approach to therapy. The goal is to prevent seizures and minimize the side effects of treatment; determination of the optimal medication and the optimal dose typically involves trial and error. This process may take months or longer if the baseline seizure frequency is low. Most antiseizure drugs need to be introduced relatively slowly to minimize side effects. Patients should expect that minor side effects such as mild sedation, slight changes in cognition, or imbalance will typically resolve within a few days. Starting doses are usually the lowest value listed under the dosage column in Table 436-9. Subsequent increases should be made only after achieving a steady state with the previous dose (i.e., after an interval of five or more half-lives).

Monitoring of serum antiseizure drug levels can be very useful for establishing the initial dosing schedule. However, the published therapeutic ranges of serum drug concentrations are only an approximate guide for determining the proper dose for a given patient. The key determinants are the clinical measures of seizure frequency and presence of side effects, not the laboratory values. Conventional assays of serum drug levels measure the total drug (i.e., both free and protein bound). However, it is the concentration of free drug that reflects extracellular levels in the brain and correlates best with efficacy. Thus, patients with decreased levels of serum proteins (e.g., decreased serum albumin due to impaired liver or renal function) may have an increased ratio of free to bound drug, yet the concentration of free drug may be adequate for seizure control. These patients may have a "subtherapeutic" drug level, but the dose should be changed only if seizures remain uncontrolled, not just to achieve a "therapeutic" level. It is also useful to monitor free drug levels in such patients. In practice, other than during the initiation or modification of therapy, monitoring of antiseizure drug levels is most useful for documenting adherence, assessing clinical suspicion of toxicity, or establishing baseline serum concentrations prior to pregnancy, when clearance of many antiseizure drugs increases significantly.

If seizures continue despite gradual increases to the maximum tolerated dose and documented compliance, then it becomes necessary to switch to another antiseizure drug. This is usually done by maintaining the patient on the first drug while a second drug is added. The dose of the second drug should be adjusted to decrease seizure frequency without causing toxicity. Once this is achieved, the first drug can be gradually withdrawn (usually over weeks unless there is significant toxicity). The dose of the second drug is then further optimized based on seizure response and side effects. Monotherapy should be the goal whenever possible.

WHEN TO DISCONTINUE THERAPY

Some patients who have their seizures completely controlled with antiseizure drugs can eventually discontinue therapy. The following patient profile yields the greatest chance of remaining seizure free after drug withdrawal: (1) complete medical control of seizures for 1–5 years; (2) single seizure type, with generalized seizures having a better prognosis than focal seizures; (3) normal neurologic examination, including intelligence; (4) no family history of epilepsy; and (5) normal EEG. The appropriate seizure-free interval is unknown and depends on the form of epilepsy and whether or not the causal factor is still present (e.g., resection of a brain tumor causing seizures). However, it seems reasonable to attempt withdrawal of therapy after 2 years in a patient who meets all the above criteria, is motivated to discontinue the medication, and clearly understands the potential risks and benefits. In most cases, it is preferable to reduce the dose of the drug gradually over 2–3 months. Most recurrences occur in the first 3 months after discontinuing therapy, and patients should be advised to avoid potentially dangerous situations such as driving or swimming during this period. Rarely, seizure-free patients who discontinue antiseizure medications but then have a recurrent seizure may not regain full control when these medications are resumed.

TREATMENT OF REFRACTORY EPILEPSY

Approximately half of people with epilepsy do not respond to treatment with the first antiseizure drug, and it becomes necessary to try additional drugs alone or in combination. Patients who have focal epilepsy related to an underlying structural lesion or those with multiple seizure types and developmental delay are particularly likely to require multiple drugs. There are currently no clear guidelines for rational polypharmacy, although in theory, a combination of drugs with different mechanisms of action may be most useful. In most cases, the initial combination therapy combines first-line drugs (i.e., carbamazepine, oxcarbazepine, lamotrigine, valproic acid, levetiracetam, and phenytoin). If these drugs are unsuccessful, then the addition of other drugs such as cenobamate, zonisamide, brivaracetam, topiramate, or lacosamide is indicated. Patients with myoclonic seizures resistant to valproic acid may benefit from the addition of levetiracetam, zonisamide, clonazepam, or clobazam, and those with absence seizures may respond to a combination of valproic acid and ethosuximide. The same principles concerning the monitoring of therapeutic response, toxicity, and serum levels for monotherapy apply to polypharmacy, and potential drug interactions need to be recognized. If there is no improvement, a third drug can be added while the first two are maintained. If there is a response, the less effective or less well tolerated of the first two drugs should be gradually withdrawn.

SURGICAL TREATMENT OF REFRACTORY EPILEPSY

Approximately 30% of patients with epilepsy continue to have seizures despite efforts to find an effective combination of antiseizure drugs. For some patients with focal epilepsy, surgery can be extremely effective in substantially reducing seizure frequency and even providing complete seizure control. Understanding the potential value of surgery is especially important when a patient's seizures are not controlled with initial treatment, as such patients

often do not respond to subsequent medication trials. Rather than submitting the patient to years of unsuccessful medical therapy and the psychosocial trauma and increased mortality associated with ongoing seizures, the patient should have an efficient but relatively brief attempt at medical therapy and then be referred for surgical evaluation.

The most common surgical procedure for patients with temporal lobe epilepsy involves resection of the anteromedial temporal lobe (temporal lobectomy) or a more limited removal of the underlying hippocampus and amygdala (amygdalohippocampectomy). Focal seizures arising from extratemporal regions may be abolished by a focal neocortical resection with precise removal of an identified lesion (lesionectomy). Localized neocortical resection without a clear lesion identified on MRI is also possible when other tests (e.g., MEG, PET, SPECT) implicate a focal cortical region as a seizure onset zone. When the cortical region cannot be removed, multiple subpial transection, which disrupts intracortical connections, is sometimes used to prevent seizure spread. Hemispherectomy or multilobar resection is useful for some patients with severe seizures due to hemispheric abnormalities such as hemimegalencephaly or other dysplastic abnormalities, and corpus callosotomy has been shown to be effective for disabling tonic or atonic seizures, usually when they are part of a mixed-seizure syndrome (e.g., Lennox-Gastaut syndrome).

Presurgical evaluation is designed to identify the functional and structural basis of the patient's seizure disorder. Inpatient video-EEG monitoring is used to localize the seizure focus and to correlate the abnormal electrophysiologic activity with neuroimaging and behavioral manifestations of the seizure. Routine scalp EEG recordings and a high-resolution MRI scan are often sufficient for localization of the epileptogenic focus, especially when the findings are concordant. Functional imaging studies such as SPECT, PET, and MEG are adjunctive tests that may help to reveal or verify the localization of an apparent epileptogenic region. Once the presumed location of the seizure onset is identified, additional studies, including neuropsychological testing, the intracarotid amobarbital (Wada) test, and functional MRI may be used to assess language and memory localization and to determine the possible functional consequences of surgical removal of the epileptogenic region. In some cases, standard noninvasive evaluation is not sufficient to localize the seizure onset zone, and invasive electrophysiologic monitoring is required for more definitive localization. Traditionally, this required open craniotomy and subdural electrode placement. Robot-assisted stereotactic EEG (stereo-EEG) has surged in use as a less invasive surgical option that involves placing depth electrodes through burr holes in the skull and into the brain parenchyma to record from regions suspected of generating seizures. Although subdural electrodes provide extensive cortical sampling, they are unable to record from deep structures; depth electrodes permit sampling of both cortical and subcortical tissue, albeit with more restricted spatial resolution. Stereo-EEG studies are typically associated with shorter hospital stays and lower complication rates than subdural electrode studies.

The exact extent of the resection to be undertaken can also be determined by performing cortical mapping at the time of the surgical procedure, allowing for a tailored resection. This involves electrocorticographic recordings made with electrodes on the surface of the brain to identify the extent of epileptiform disturbances. If the region to be resected is within or near brain regions suspected of having sensorimotor or language function, electrical cortical stimulation mapping is performed on the awake patient to determine the function of cortical regions in question to avoid resection of so-called eloquent cortex and thereby minimize postsurgical deficits.

Advances in presurgical evaluation and microsurgical techniques have led to a steady increase in the success of epilepsy surgery. Clinically significant complications of surgery are <5%, and the use of functional mapping procedures has markedly reduced the neurologic sequelae due to removal or sectioning of brain tissue. For example, ~70% of well-selected patients treated with temporal lobectomy will become seizure free, and another 15–25% will have at least a 90% reduction in seizure frequency. Marked improvement is also usually seen in patients treated with hemispherectomy for catastrophic seizure disorders due to large hemispheric abnormalities. Postoperatively, patients generally need to remain on antiseizure drug therapy, but the marked reduction of seizures following resective surgery can have a very beneficial effect on quality of life. Recently, catheter-based stereotactic laser thermal ablation has been developed as a less invasive means for destroying the seizure focus in select patients.

Not all medically refractory patients are suitable candidates for resective surgery or laser ablation. For example, some patients have seizures arising from more than one brain region or from a single "eloquent" region that mediates a critical function (e.g., vision, movement, language), such that the potential harm from removal is unacceptably high. In these patients, implanted neurostimulation devices that deliver electrical energy to the brain to reduce seizures represent palliative treatment options. Vagus nerve stimulation (VNS) involves an extracranial device that works through scheduled intermittent ("open loop") stimulation of the left vagus nerve. Efficacy of VNS is limited, and side effects related to recurrent laryngeal nerve activation (e.g., hoarseness, throat pain, dyspnea) can be significant and dose-limiting. By contrast, responsive neurostimulation (RNS) involves an implanted device connected to two lead wires that are placed intracranially at the site(s) from where seizures arise. The neurostimulator detects the onset of a seizure (often before the seizure becomes clinically apparent) and delivers electrical stimulation—typically imperceptible—directly to the brain to reduce seizures over time, a form of "closed loop" neurostimulation. RNS is the only device that provides chronic EEG, which has a growing number of clinical applications, such as quantifying the lateralization of seizures arising from both sides of the brain, characterizing clinical spells, assessing effects of medications and other therapeutic interventions, and revealing cyclical patterns of epileptic brain activity that may help anticipate future events. A third modality, thalamic deep brain stimulation (DBS), involves open loop stimulation of deep, bilateral cerebral structures, the anterior thalamic nuclei, which are key nodes in limbic circuits mediating certain types of seizures. Whereas precise seizure localization is necessary for RNS, it is not required for VNS or DBS. Stimulation of thalamic nuclei, which project broadly to different cortical regions, with RNS or DBS is an appealing approach to treating poorly localized, spatially extensive, or multifocal seizure foci.

Long-term clinical trials of all three neurostimulation devices demonstrate significant reductions in frequency with outcomes improving over time, but only a minority of patients treated with these devices achieve seizure freedom (e.g., ~15% with RNS). Furthermore, no head-to-head device trials exist to establish relative superiority, so choice of a device is guided by patient-specific factors and by the strengths and limitations of each technology.

STATUS EPILEPTICUS

Status epilepticus refers to continuous seizures or repetitive, discrete seizures with impaired consciousness in the interictal period. Status epilepticus has numerous subtypes, including generalized convulsive status epilepticus (GCSE) (e.g., persistent, generalized electrographic seizures, coma, and tonic-clonic movements) and nonconvulsive status epilepticus (NCSE; e.g., persistent absence seizures or focal seizures with confusion or partially impaired consciousness, and minimal motor abnormalities). The duration of seizure activity sufficient to meet the definition of status epilepticus has traditionally been specified as 15–30 min. However, a more practical definition is to consider status epilepticus as a situation in which the duration of seizures prompts the acute use of anticonvulsant therapy. For GCSE, this is typically when seizures last beyond 5 min.

GCSE is an emergency and must be treated immediately, because cardiorespiratory dysfunction, hyperthermia, and metabolic derangements can develop as a consequence of prolonged seizures, and these

can lead to irreversible CNS injury. Furthermore, CNS injury can occur even when the patient is paralyzed with neuromuscular blockade but continues to have electrographic seizures. The most common causes of GCSE are anticonvulsant withdrawal or noncompliance, metabolic disturbances, drug toxicity, CNS infection, CNS tumors, refractory epilepsy, and head trauma.

GCSE is obvious when the patient is having overt seizures. However, after 30–45 min of uninterrupted seizures, the signs may become increasingly subtle. Patients may have mild clonic movements of only the fingers or fine, rapid movements of the eyes. There may be paroxysmal episodes of tachycardia, hypertension, and pupillary dilation. In such cases, the EEG may be the only method of establishing the diagnosis. Thus, if the patient stops having overt seizures, yet remains comatose, an EEG should be performed to rule out ongoing status epilepticus. This is obviously also essential when a patient with GCSE has been paralyzed with neuromuscular blockade in the process of protecting the airway.

The first steps in the management of a patient in GCSE are to attend to any acute cardiorespiratory problems or hyperthermia, perform a brief medical and neurologic examination, establish venous access, and send samples for laboratory studies to identify metabolic abnormalities. Anticonvulsant therapy should then begin without delay **(Fig. 436-5)**.

The treatment of NCSE is thought to be less urgent than GCSE, because the ongoing seizures are not accompanied by the severe metabolic disturbances seen with GCSE. However, evidence suggests that NCSE, especially that caused by ongoing, focal seizure activity, is associated with cellular injury in the region of the seizure focus; therefore, this condition should be treated as promptly as possible using the general approach described for GCSE. Portable headband devices that provide a limited form of EEG can be rapidly applied without skilled technicians to help rule out NCSE in acute care settings.

BEYOND SEIZURES: OTHER MANAGEMENT ISSUES

EPILEPSY COMORBIDITIES

The adverse effects of epilepsy often go beyond clinical seizures. Many people with epilepsy feel completely normal between seizures and live highly successful and productive lives. However, a significant proportion of patients suffer from varying degrees of cognitive dysfunction, including psychiatric disease, and it has become increasingly clear that the network dysfunction underlying epilepsy can have effects well beyond the occurrence of seizures. For example, patients with seizures secondary to developmental abnormalities or acquired brain injury may have impaired cognitive function and other neurologic deficits due to abnormal brain structure. Frequent interictal EEG abnormalities are associated with subtle dysfunction of memory and attention. Patients with many seizures, especially those emanating from the temporal lobe, often note an impairment of short-term memory that may progress over time.

The psychiatric problems associated with epilepsy include depression, anxiety, and psychosis. This risk varies considerably depending on many factors, including the etiology, frequency, and severity of seizures and the patient's age and previous personal or family history of psychiatric disorder. Depression occurs in ~20–30% of patients, and the incidence of suicide is higher in people with epilepsy than in the general population. Depression should be treated through counseling and/or medication. The selective serotonin reuptake inhibitors (SSRIs) typically have minimal effect on seizures, whereas tricyclic antidepressants may lower the seizure threshold. Anxiety can be a seizure symptom, and anxious or psychotic behavior can occur during a postictal delirium. Postictal psychosis is a rare phenomenon that typically occurs after a period of increased seizure frequency. There is

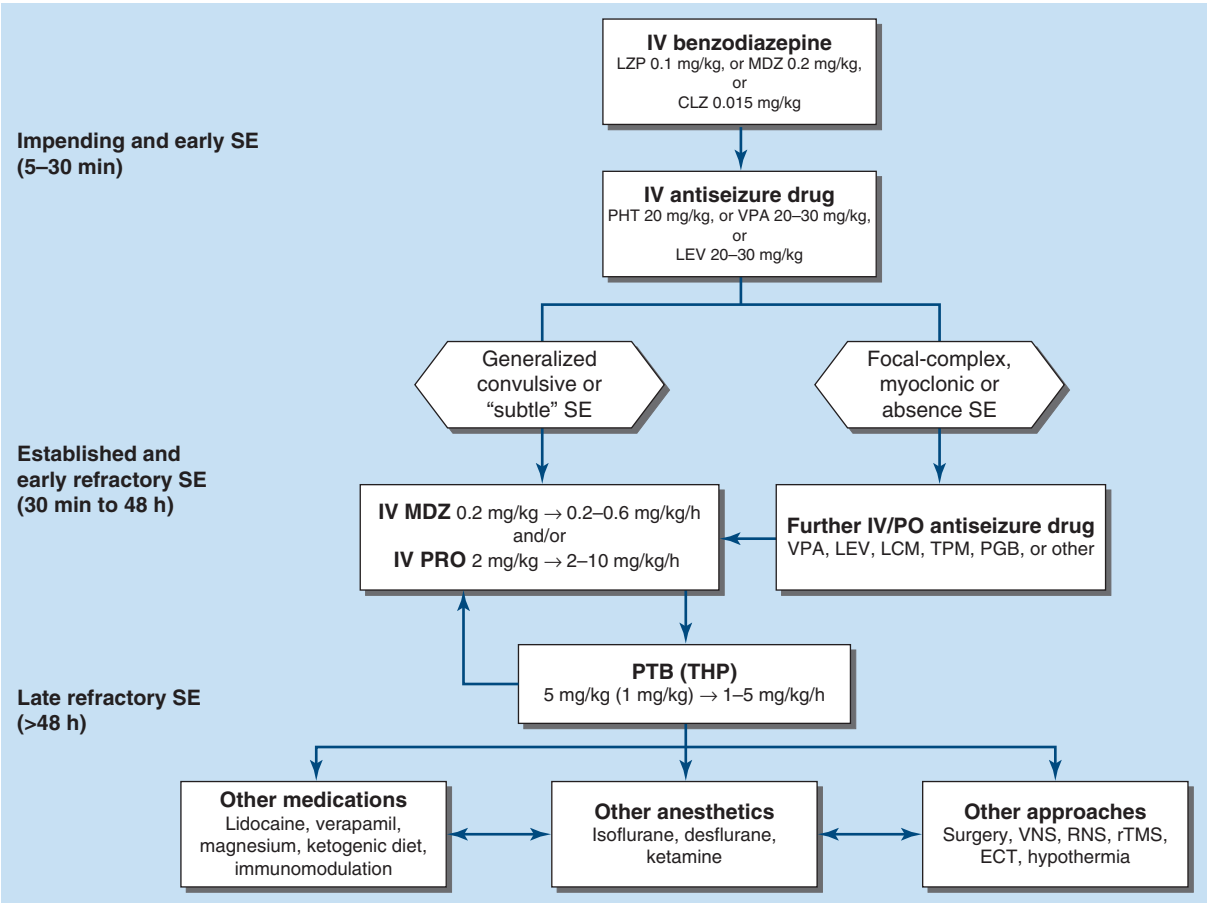

FIGURE 436-5 Pharmacologic treatment of generalized tonic-clonic status epilepticus (SE) in adults. CLZ, clonazepam; ECT, electroconvulsive therapy; LCM, lacosamide; LEV, levetiracetam; LZP, lorazepam; MDZ, midazolam; PGB, pregabalin; PHT, phenytoin or fosphenytoin; PRO, propofol; PTB, pentobarbital; RNS, responsive neurostimulation; rTMS, repetitive transcranial magnetic stimulation; THP, thiopental; TPM, topiramate; VNS, vagus nerve stimulation; VPA, valproic acid. *(Data from AO Rossetti, DH Lowenstein: Management of refractory status epilepticus in adults: still more questions than answers. Lancet Neurol 10:922, 2011.)*

usually a brief lucid interval lasting up to a week, followed by days to weeks of agitated, psychotic behavior. The psychosis usually resolves spontaneously but frequently will require short-term treatment with antipsychotic or anxiolytic medications.

MORTALITY OF EPILEPSY

People with epilepsy have a risk of death that is roughly two to three times greater than expected in a matched population without epilepsy. Most of the increased mortality is due to the underlying etiology of epilepsy (e.g., tumors or strokes in older adults). However, a significant number of patients die from accidents, status epilepticus, and a syndrome known as *sudden unexpected death in epilepsy* (SUDEP), which usually affects young people with convulsive seizures and tends to occur at night. The cause of SUDEP is unknown; it may result from brainstem-mediated effects of seizures on pulmonary, cardiac, and arousal functions. Genetic mutations may be the cause of both epilepsy and a cardiac conduction defect that gives rise to sudden death.

PSYCHOSOCIAL ISSUES

There continues to be a cultural stigma about epilepsy, although it is slowly declining in societies with effective health education programs. Many people with epilepsy harbor fear of progressive cognitive decline or dying during a seizure. These issues need to be carefully addressed by educating the patient about epilepsy and by ensuring that family members, teachers, fellow employees, and other associates are equally well informed. A useful source of educational material is the website *www.epilepsy.com*.

EMPLOYMENT, DRIVING, AND OTHER ACTIVITIES

Many patients with epilepsy face difficulty in obtaining or maintaining employment, even when their seizures are well controlled. Federal and state legislation is designed to prevent employers from discriminating against people with epilepsy, and patients should be encouraged to understand and claim their legal rights. Patients in these circumstances also benefit greatly from the assistance of health providers who act as strong patient advocates.

Loss of driving privileges is one of the most disruptive social consequences of epilepsy. Physicians should be very clear about local regulations concerning driving and epilepsy because the laws vary considerably among states and countries. In all cases, it is the physician's responsibility to warn patients of the danger imposed on themselves and others while driving if their seizures are uncontrolled (unless the seizures are not associated with impairment of consciousness or motor control). In general, most states in the United States allow patients to drive after a seizure-free interval (on or off medications) of 3–18 months.

Patients with incompletely controlled seizures must also contend with the risk of being in other situations where an impairment of consciousness or loss of motor control could lead to major injury or death. Thus, depending on the type and frequency of seizures, many patients need to be instructed to avoid working at heights or with machinery or to have someone close by for activities such as bathing and swimming.

The importance of quantifying seizures in people living with epilepsy has catalyzed a burgeoning industry of wearable sensors, such as wristwatches, that can detect seizures through noninvasive measurement of physiologic variables. Generally, non-EEG devices either have low sensitivity or high false alarm rate, but reliability is highest for detection of tonic-clonic seizures.

SPECIAL ISSUES RELATED TO WOMEN AND EPILEPSY

CATAMENIAL EPILEPSY

Some women experience a marked increase in seizure frequency around the time of menses. This is believed to be mediated by either the effects of estrogen and progesterone on neuronal excitability or changes in antiseizure drug levels due to altered protein binding or metabolism. Vulnerability to seizures is typically highest just before and during menses and during ovulation due to relatively high estrogen and low progesterone levels. Some women with epilepsy may benefit from increases in antiseizure drug dosages during menses. Natural progestins or intramuscular medroxyprogesterone may be of benefit to a subset of women.

PREGNANCY

Most women with epilepsy who become pregnant will have an uncomplicated gestation and deliver a normal baby. However, epilepsy poses some important risks to a pregnancy. Seizure frequency during pregnancy will remain unchanged in ~50% of women, increase in ~30%, and decrease in ~20%. Changes in seizure frequency are attributed to endocrine effects on the CNS, variations in antiseizure drug pharmacokinetics (such as acceleration of hepatic drug metabolism, increased renal blood flow, increased volume of distribution, or effects on plasma protein binding), or decreased antiseizure medication absorption due to nausea and vomiting. It is useful to see patients at frequent intervals during pregnancy and monitor serum antiseizure drug levels monthly; the risk of seizure exacerbation increases when serum levels decrease >35% from prepregnancy levels. Measurement of the unbound drug concentrations may be useful if there is an increase in seizure frequency or worsening of side effects of antiseizure drugs.

The overall incidence of fetal abnormalities in children born to mothers with epilepsy is 5–6%, compared to 2–3% in healthy women. Part of the higher incidence is due to teratogenic effects of antiseizure drugs, and the risk increases with the number of medications used (e.g., 10–20% risk of malformations with three drugs) and possibly with higher doses. A meta-analysis of published pregnancy registries and cohorts found that the most common malformations were defects in the cardiovascular and musculoskeletal system (1.4–1.8%). Valproic acid is strongly associated with an increased risk of adverse fetal outcomes (7–20%). Findings from a large pregnancy registry suggest that the newer antiseizure drugs are far safer than valproic acid.

Because the potential harm of uncontrolled convulsive seizures on the mother and fetus is considered greater than the teratogenic effects of antiseizure drugs, it is currently recommended that pregnant women be maintained on effective drug therapy. When possible, it seems prudent to have the patient on monotherapy at the lowest effective dose, especially during the first trimester. For some women, however, the type and frequency of their seizures may allow for them to safely wean off antiseizure drugs prior to conception. Patients should also take folate (1–4 mg/d), because the antifolate effects of anticonvulsants are thought to play a role in the development of neural tube defects, although the benefits of this treatment remain unproven in this setting.

Enzyme-inducing drugs such as phenytoin, carbamazepine, oxcarbazepine, topiramate, phenobarbital, and primidone cause a transient and reversible deficiency of vitamin K–dependent clotting factors in ~50% of newborn infants. Although neonatal hemorrhage is uncommon, the mother should be treated with oral vitamin K (20 mg/d, phylloquinone) in the last 2 weeks of pregnancy, and the infant should receive intramuscular vitamin K (1 mg) at birth.

CONTRACEPTION

Special care should be taken when prescribing antiseizure medications for women who are taking oral contraceptive agents. Drugs such as carbamazepine, phenytoin, phenobarbital, and topiramate can significantly decrease the efficacy of oral contraceptives via enzyme induction and other mechanisms. Patients should be advised to consider alternative forms of contraception, including intrauterine devices and other long-acting reversible contraceptives, or their oral contraceptive medications should be modified to offset the effects of the antiseizure medications. Estrogen-containing oral contraceptive agents induce glucuronidation of lamotrigine and can decrease lamotrigine serum levels by >50%.

BREAST-FEEDING

Antiseizure medications are excreted into breast milk, and the ratio of drug concentration in breast milk relative to serum ranges from ~5% (valproic acid) to 300% (levetiracetam). Given the overall benefits of breast-feeding and the lack of evidence for long-term harm to the infant by being exposed to antiseizure drugs, mothers with epilepsy should be encouraged to breast-feed unless there is evidence of drug effects on the infant, such as lethargy or poor feeding.

SPECIAL ISSUES RELATED TO EPILEPSY IN THE ELDERLY

Epilepsy has a bimodal distribution according to age, with the highest incidence in the very young and in the elderly. The increased incidence in the elderly may be attributed to age- and aging-related epileptogenic factors. The most common cause is stroke, followed by neoplasm, and dementia, resulting in a preponderance of extratemporal epilepsy. Antiseizure medication selection requires careful consideration of medical and psychiatric comorbidities, side effect profiles, effects on mood and cognition, and drug-drug interactions.

437 Introduction to Cerebrovascular Diseases

Wade S. Smith, J. Claude Hemphill, III

Cerebrovascular diseases include some of the most common and devastating disorders: ischemic stroke and hemorrhagic stroke. Stroke is the second leading cause of death worldwide, with 7.1 million dying from stroke in 2020. Nearly 7 million Americans age 20 or older report having had a stroke, and the prevalence is estimated to rise by 3.4 million adults in the next decade, representing 4% of the entire adult population. Although mortality is increased from 6.2 million in 2010, the age standardized death rate has fallen by 15% in this decade, likely due to better prevention and treatment. However, overall disease burden will continue to climb as the population ages, and stroke is likely to remain the second most common disabling condition in individuals aged 50 or older worldwide.

A stroke, or cerebrovascular accident, is defined as an abrupt onset of a neurologic deficit that is attributable to a vascular cause. Thus, the definition of stroke is clinical, and laboratory studies including brain imaging are used to support the diagnosis. The clinical manifestations of stroke are highly variable because of the complex anatomy of the brain and its vasculature. *Cerebral ischemia* is caused by a reduction in blood flow that lasts longer than several seconds. Neurologic symptoms are manifest within seconds because neurons lack glycogen, so energy failure is rapid. If the cessation of flow lasts for more than a few minutes, *infarction* or death of brain tissue results. When blood flow is quickly restored, brain tissue can recover fully and the patient's symptoms are only transient: this is called a *transient ischemic attack* (TIA). The definition of TIA requires that all neurologic signs and symptoms resolve within 24 h without evidence of brain infarction on brain imaging. Stroke has occurred if the neurologic signs and symptoms last for >24 h or brain infarction is demonstrated. A generalized reduction in cerebral blood flow due to systemic hypotension (e.g., cardiac arrhythmia, sepsis, or hemorrhagic shock) usually produces syncope **(Chap. 23)**. If low cerebral blood flow persists for a longer duration, then infarction in the border zones between the major cerebral artery distributions may develop. In more severe instances as in cardiac arrest, *global hypoxia-ischemia* causes widespread brain injury; the constellation of cognitive sequelae that ensues is called *hypoxic-ischemic encephalopathy* **(Chap. 318)**. *Focal ischemia* or infarction, conversely, is usually caused by thrombosis of the cerebral vessels themselves or by emboli from a proximal arterial source or the heart **(Chap. 438)**. *Intracranial hemorrhage* is caused by bleeding directly into or around the brain; it produces neurologic symptoms by producing a mass effect on neural structures, from the toxic effects of blood itself, or by increasing intracranial pressure **(Chap. 439)**.

APPROACH TO THE PATIENT

Cerebrovascular Disease

Rapid evaluation is essential for use of acute treatments such as thrombolysis or thrombectomy. However, patients with acute stroke often do not seek medical assistance on their own because they may lose the appreciation that something is wrong (anosognosia) or lack the knowledge that acute treatment is beneficial; it is often a family member or a bystander who calls for help. Therefore, patients and their family members should be counseled to call emergency medical services immediately if they experience or witness the sudden onset of any of the following: loss of sensory and/or motor function on one side of the body (nearly 85% of ischemic stroke patients have hemiparesis); change in vision, gait, or ability to speak or understand; or a sudden, severe headache. The acronym FAST (*f*acial weakness, *a*rm weakness, *s*peech abnormality, and *t*ime) is simple and helpful to teach to the lay public about the common physical symptoms of stroke and to underscore that treatments are highly time sensitive.

Other causes of sudden-onset neurologic symptoms that may mimic stroke include seizure, intracranial tumor, migraine, and metabolic encephalopathy. An adequate history from an observer that no convulsive activity occurred at the onset usually excludes seizure **(Chap. 436)**, although ongoing complex partial seizures without tonic-clonic activity can on occasion mimic stroke. Tumors **(Chap. 95)** may present with acute neurologic symptoms due to hemorrhage, seizure, or hydrocephalus. Surprisingly, migraine **(Chap. 441)** can mimic stroke, even in patients without a significant migraine history. When migraine develops without head pain (*acephalgic migraine*), the diagnosis can be especially difficult. Patients without any prior history of migraine may develop acephalgic migraine even after age 65. A sensory disturbance is often prominent, and the sensory deficit, as well as any motor deficits, tends to migrate slowly across a limb, over minutes rather than seconds as with stroke. The diagnosis of migraine becomes more secure as the cortical disturbance begins to cross vascular boundaries or if classic visual symptoms are present such as scintillating scotomata. At times, it may be impossible to make the diagnosis of migraine until there have been multiple episodes with no residual symptoms or signs and no changes on brain magnetic resonance imaging (MRI). Metabolic encephalopathies typically produce fluctuating mental status changes without focal neurologic findings. However, in the setting of prior stroke or brain injury, a patient with

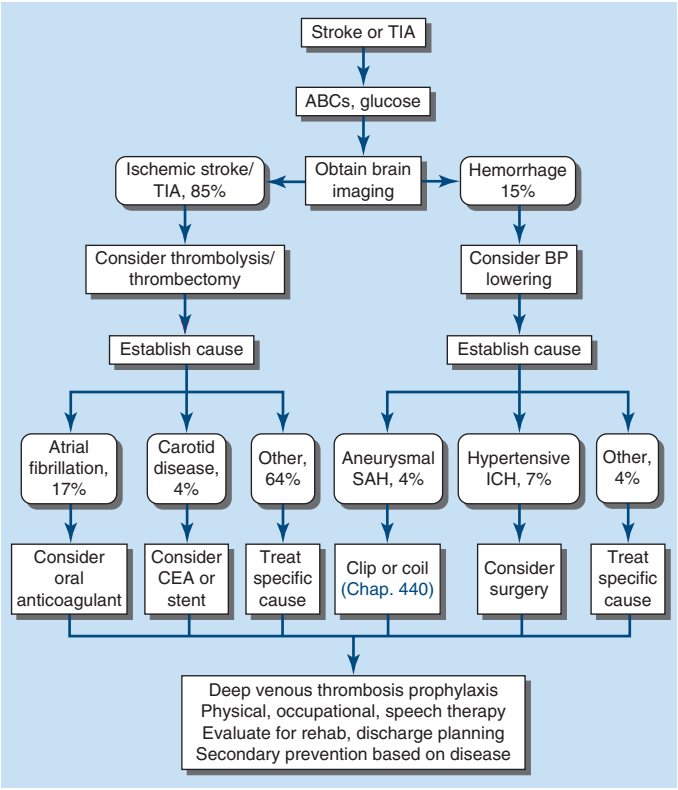

FIGURE 437-1 Medical management of stroke and TIA. *Rounded boxes* are diagnoses; *rectangles* are interventions. Numbers are percentages of stroke overall. ABCs, airway, breathing, circulation; BP, blood pressure; CEA, carotid endarterectomy; ICH, intracerebral hemorrhage; SAH, subarachnoid hemorrhage; TIA, transient ischemic attack.

fever or sepsis may manifest a recurrent hemiparesis, which clears rapidly when the infection is treated. The metabolic process serves to "unmask" a prior deficit and is termed "stroke recrudescence."

Once the diagnosis of stroke is made, a brain imaging study is necessary to determine if the cause of stroke is ischemia or hemorrhage **(Fig. 437-1)**. Computed tomography (CT) imaging of the brain is the standard imaging modality to detect the presence or absence of intracranial hemorrhage (see "Imaging Studies," below). If the stroke is ischemic, administration of recombinant tissue plasminogen activator (rtPA) or endovascular mechanical thrombectomy may be beneficial in restoring cerebral perfusion **(Chap. 438)**. Medical management to reduce the risk of complications becomes the next priority, followed by plans for secondary prevention. For ischemic stroke, several strategies can reduce the risk of subsequent stroke in all patients, while other strategies are effective for patients with specific causes of stroke such as cardiac embolus and carotid atherosclerosis. For hemorrhagic stroke, aneurysmal subarachnoid hemorrhage (SAH) and hypertensive intracerebral hemorrhage are two important causes. **The treatment and prevention of hypertensive intracerebral hemorrhage are discussed in Chap. 439. SAH is discussed in Chap. 440.**

STROKE SYNDROMES

A careful history and neurologic examination can often localize the region of brain dysfunction; if this region corresponds to an arterial distribution, the possible causes responsible for the syndrome can be narrowed. This is of particular importance when the patient presents with a TIA and a normal examination. For example, if a patient develops language loss and a right homonymous hemianopia, a search for causes of left middle cerebral emboli should be performed. A finding of an isolated stenosis of the right internal carotid artery in that patient, for example, suggests an asymptomatic carotid stenosis, and the search for other causes of stroke should continue. The following sections describe the clinical findings of cerebral ischemia associated with cerebral vascular territories depicted in **Figs. 437-2 through 437-11**. Stroke syndromes are divided into (1) large-vessel stroke within the anterior circulation, (2) large-vessel stroke within the posterior circulation, and (3) small-vessel disease of either vascular bed.

Stroke within the Anterior Circulation The internal carotid artery and its branches compose the anterior circulation of the brain. These vessels can be occluded by intrinsic disease of the vessel (e.g., atherosclerosis or dissection) or by embolic occlusion from a proximal source as discussed above. Occlusion of each major intracranial vessel has distinct clinical manifestations.

MIDDLE CEREBRAL ARTERY Occlusion of the proximal middle cerebral artery (MCA) or one of its major branches is most often due to an embolus (artery-to-artery, cardiac, or of unknown source) rather than intracranial atherothrombosis. Atherosclerosis of the proximal MCA may cause distal emboli to the middle cerebral territory or, less commonly, may produce low-flow TIAs. Collateral formation via leptomeningeal vessels often prevents MCA stenosis from becoming symptomatic.

The cortical branches of the MCA supply the lateral surface of the hemisphere except for (1) the frontal pole and a strip along the superomedial border of the frontal and parietal lobes supplied by the anterior cerebral artery (ACA) and (2) the lower temporal and occipital pole convolutions supplied by the posterior cerebral artery (PCA) (Figs. 437-2–437-5).

The proximal MCA (M1 segment) gives rise to penetrating branches (termed *lenticulostriate arteries*) that supply the putamen, outer globus pallidus, posterior limb of the internal capsule, adjacent corona radiata, and most of the caudate nucleus (Fig. 437-2). In the sylvian fissure, the MCA in most patients divides into *superior* and *inferior* divisions (M2 branches). Branches of the inferior division supply the inferior parietal and temporal cortex, and those from the superior division supply the frontal and superior parietal cortex (Fig. 437-3).

If the entire MCA is occluded at its origin (blocking both its penetrating and cortical branches) and the distal collaterals are limited, the clinical findings are contralateral hemiplegia, hemianesthesia, homonymous hemianopia, and a day or two of gaze preference to the ipsilateral side. Dysarthria is common because of facial weakness. When the dominant hemisphere is involved, global aphasia is present also, and when the nondominant hemisphere is affected, anosognosia, constructional apraxia, and neglect are found **(Chap. 32)**.

Complete MCA syndromes occur most often when an embolus occludes the stem of the artery. Cortical collateral blood flow and differing arterial configurations are probably responsible for the development of many partial syndromes. Partial syndromes may also be due to emboli that enter the proximal MCA without complete occlusion, occlude distal MCA branches, or fragment and move distally.

Partial syndromes due to embolic occlusion of a single branch include hand, or arm and hand, weakness alone (brachial syndrome) or facial weakness with nonfluent (Broca) aphasia **(Chap. 32)**, with or without arm weakness (frontal opercular syndrome). A combination of sensory disturbance, motor weakness, and nonfluent aphasia suggests that an embolus has occluded the proximal superior division and infarcted large portions of the frontal and parietal cortices (Fig. 437-3). If a fluent (Wernicke's) aphasia occurs without weakness, the inferior division of the MCA supplying the posterior part (temporal cortex) of the dominant hemisphere is probably involved. Jargon speech and an inability to comprehend written and spoken language are prominent features, often accompanied by a contralateral, homonymous superior quadrantanopia. Hemineglect or spatial agnosia without weakness indicates that the inferior division of the MCA in the nondominant hemisphere is involved.

Occlusion of a lenticulostriate vessel produces small-vessel (lacunar) stroke within the internal capsule (Fig. 437-2). This produces pure motor stroke or sensory-motor stroke contralateral to the lesion. Ischemia within the genu of the internal capsule causes primarily facial weakness followed by arm and then leg weakness as the ischemia moves posterior within the capsule. Alternatively, the contralateral hand may become ataxic, and dysarthria will be prominent (clumsy hand, dysarthria lacunar syndrome). Lacunar infarction affecting the globus pallidus and putamen often has few clinical signs, but parkinsonism and hemiballismus have been reported.

ANTERIOR CEREBRAL ARTERY The ACA is divided into two segments: the precommunal (A1) circle of Willis, or stem, which connects

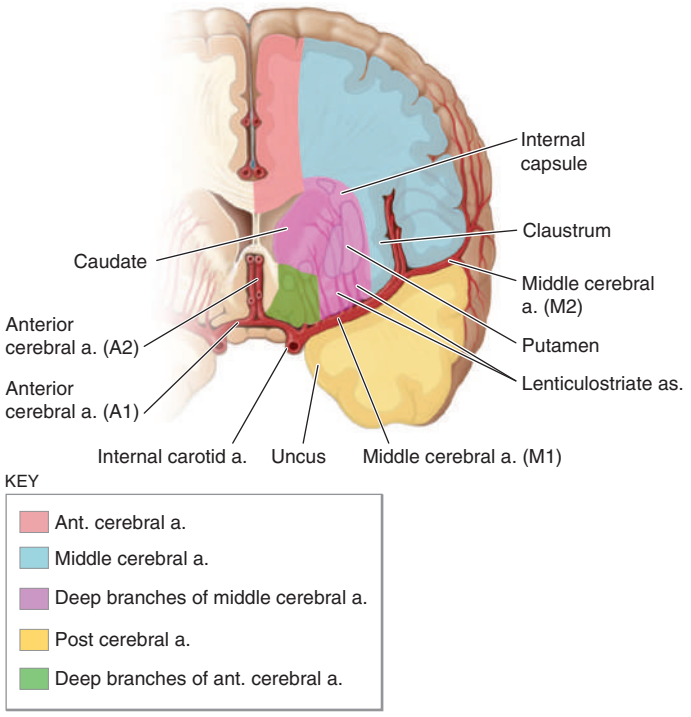

FIGURE 437-2 Diagram of a cerebral hemisphere in coronal section showing the territories of the major cerebral vessels that branch from the internal carotid arteries.

the internal carotid artery to the anterior communicating artery, and the postcommunal (A2) segment distal to the anterior communicating artery (Figs. 437-2 and 437-4). The A1 segment gives rise to several deep penetrating branches that supply the anterior limb of the internal capsule, the anterior perforate substance, amygdala, anterior hypothalamus, and the inferior part of the head of the caudate nucleus.

Occlusion of the proximal ACA is usually well tolerated because of collateral flow through the anterior communicating artery and collaterals through the MCA and PCA. Occlusion of a single A2 segment results in the contralateral symptoms noted in Fig. 437-4. If both A2 segments arise from a single anterior cerebral stem (contralateral A1 segment atresia), the occlusion may affect both hemispheres. Profound abulia (a delay in verbal and motor response) and bilateral pyramidal signs with paraparesis or quadriparesis and urinary incontinence result.

ANTERIOR CHOROIDAL ARTERY This artery arises from the internal carotid artery and supplies the posterior limb of the internal capsule and the white matter posterolateral to it, through which pass some of the geniculocalcarine fibers (Fig. 437-5). The complete syndrome of anterior choroidal artery occlusion consists of contralateral hemiplegia, hemianesthesia (hypesthesia), and homonymous hemianopia. However, because this territory is also supplied by penetrating vessels of the proximal MCA and the posterior communicating and posterior choroidal arteries, minimal deficits may occur, and patients frequently recover substantially. Anterior choroidal strokes are usually the result of in situ thrombosis of the vessel, and the vessel is particularly vulnerable to iatrogenic occlusion during surgical clipping of aneurysms arising from the internal carotid artery.

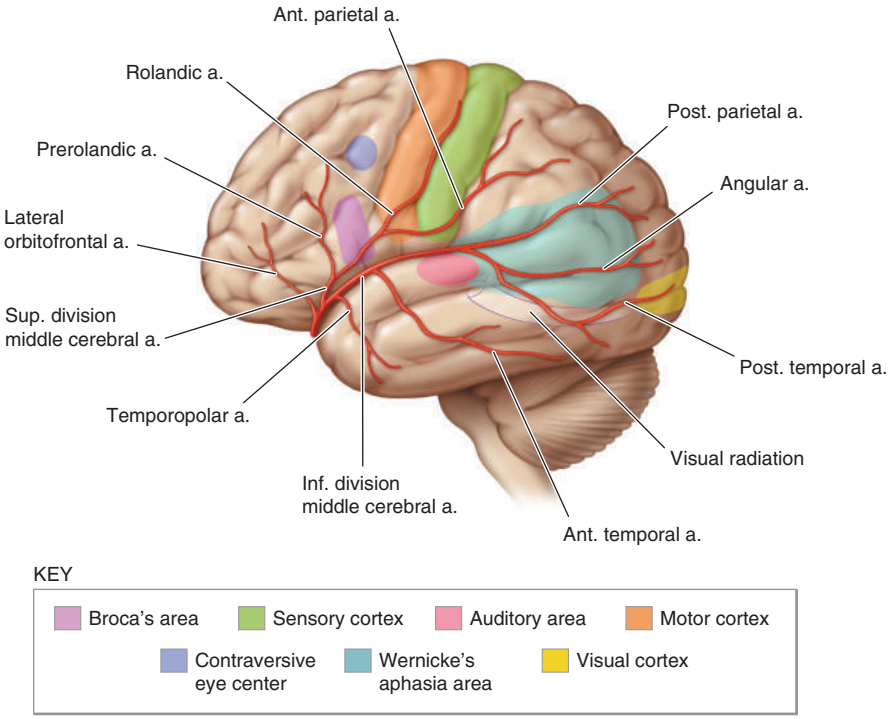

FIGURE 437-3 Diagram of a cerebral hemisphere, lateral aspect, showing the branches and distribution of the middle cerebral artery (MCA) and the principal regions of cerebral localization. Note the bifurcation of the MCA into a superior and inferior division.

Signs and symptoms: *Structures involved*

Paralysis of the contralateral face, arm, and leg; sensory impairment over the same area (pinprick, cotton touch, vibration, position, two-point discrimination, stereognosis, tactile localization, barognosis, cutaneographia): *Somatic motor area for face and arm and the fibers descending from the leg area to enter the corona radiata and corresponding somatic sensory system*

Motor aphasia: Motor speech area of the dominant hemisphere

Central aphasia, word deafness, anomia, jargon speech, sensory agraphia, acalculia, alexia, finger agnosia, right-left confusion (the last four comprise the Gerstmann syndrome): Central, suprasylvian speech area and parietooccipital cortex of the dominant hemisphere

Conduction aphasia: Central speech area (parietal operculum)

Apractagnosia of the nondominant hemisphere, anosognosia, hemiasomatognosia, unilateral neglect, agnosia for the left half of external space, dressing "apraxia," constructional "apraxia," distortion of visual coordinates, inaccurate localization in the half field, impaired ability to judge distance, upside-down reading, visual illusions (e.g., it may appear that another person walks through a table): *Nondominant parietal lobe (area corresponding to speech area in dominant hemisphere); loss of topographic memory is usually due to a nondominant lesion, occasionally to a dominant one*

Homonymous hemianopsia (or less frequently a superior quadrantanopsia due to isolated anterior temporal lobe infarction or inferior quadrantanopsia due to isolated parietal lobe infarction)

Paralysis of conjugate gaze to the opposite side: *Frontal contraversive eye field or projecting fibers.*

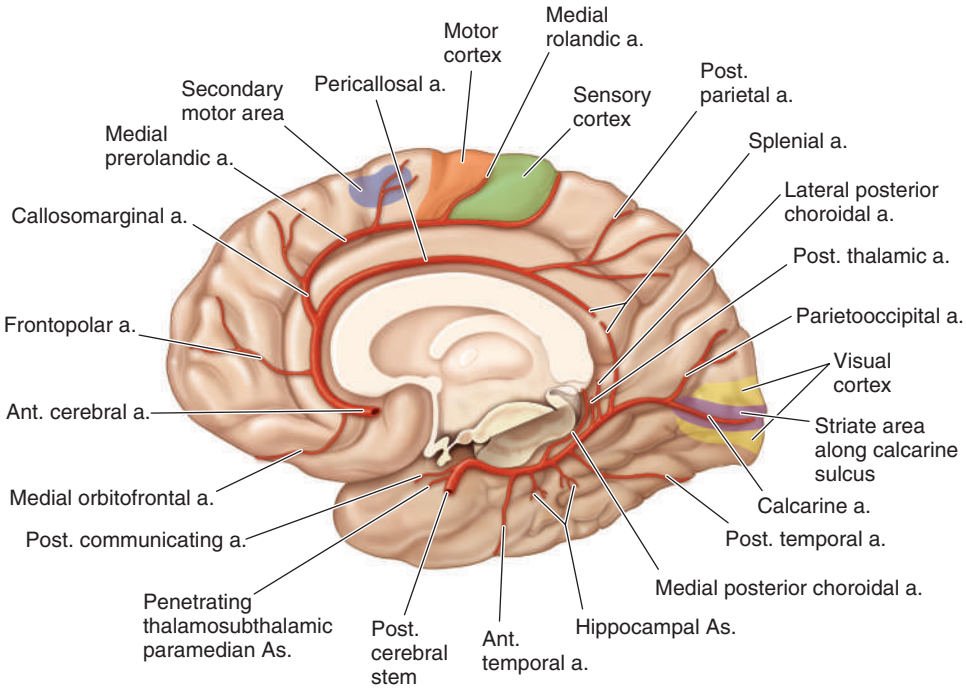

FIGURE 437-4 Diagram of a cerebral hemisphere, medial aspect, showing the branches and distribution of the anterior cerebral artery and the principal regions of cerebral localization.

Signs and symptoms: *Structures involved*
Paralysis of opposite foot and leg: *Motor leg area*
A lesser degree of paresis of opposite arm: *Arm area of cortex or fibers descending to corona radiata.*
Cortical sensory loss over toes, foot, and leg: *Sensory area for foot and leg*
Urinary incontinence: *Sensorimotor area in paracentral lobule*
Contralateral grasp reflex, sucking reflex, gegenhalten (paratonic rigidity): *Medial surface of the posterior frontal lobe; likely supplemental motor area*
Abulia (akinetic mutism), slowness, delay, intermittent interruption, lack of spontaneity, whispering, reflex distraction to sights and sounds: *Uncertain localization—probably cingulate gyrus and medial inferior portion of frontal, parietal, and temporal lobes*
Impairment of gait and stance (gait apraxia): *Frontal cortex near leg motor area*
Dyspraxia of left limbs, tactile aphasia in left limbs: *Corpus callosum*

INTERNAL CAROTID ARTERY The clinical picture of internal carotid occlusion varies depending on whether the cause of ischemia is propagated thrombus, embolism, or low flow. The cortex supplied by the MCA territory is affected most often. With a competent circle of Willis, occlusion may go unnoticed. If the thrombus propagates up the internal carotid artery into the MCA or embolizes it, symptoms are identical to proximal MCA occlusion (see above). Sometimes there is massive infarction of the entire deep white matter and cortical surface. When the origins of both the ACA and MCA are occluded at the top of the carotid artery, abulia or stupor occurs with hemiplegia, hemianesthesia, and aphasia or anosognosia. When the PCA arises from the internal carotid artery (a configuration called a *fetal PCA*), it may also become occluded and give rise to symptoms referable to its peripheral territory (Figs. 437-4 and 437-5).

In addition to supplying the ipsilateral brain, the internal carotid artery perfuses the optic nerve and retina via the ophthalmic artery. In ~25% of symptomatic internal carotid disease, recurrent transient monocular blindness (amaurosis fugax) warns of the lesion. Patients typically describe a horizontal shade that sweeps down or up across the field of vision. They may also complain that their vision was blurred in that eye or that the upper or lower half of vision disappeared. In most cases, these symptoms last only a few minutes. Rarely, ischemia or infarction of the ophthalmic artery or central retinal arteries occurs at the time of cerebral TIA or infarction.

A high-pitched prolonged carotid bruit fading into diastole is often associated with tightly stenotic lesions. As the stenosis grows tighter and flow distal to the stenosis becomes reduced, the bruit becomes fainter and may disappear when occlusion is imminent.

COMMON CAROTID ARTERY All symptoms and signs of internal carotid occlusion may also be present with occlusion of the common carotid artery. Jaw claudication may result from low flow in the external carotid branches. Bilateral common carotid artery occlusions at their origin may occur in Takayasu's arteritis **(Chap. 375)**.

Stroke within the Posterior Circulation

The posterior circulation is composed of the paired vertebral arteries, the basilar artery, and the paired PCAs. The vertebral arteries join to form the basilar artery at the pontomedullary junction. The basilar artery divides into two PCAs in the interpeduncular fossa (Figs. 437-4–437-6). These major arteries give rise to long and short circumferential branches and to smaller deep penetrating branches that supply the cerebellum, medulla, pons, midbrain, subthalamus, thalamus, hippocampus, and medial temporal and occipital lobes. Occlusion of each vessel produces its own distinctive syndrome.

POSTERIOR CEREBRAL ARTERY In 75% of cases, both PCAs arise from the bifurcation of the basilar artery; in 20%, one has its origin from the ipsilateral internal carotid artery via the posterior communicating artery; in 5%, both originate from the respective ipsilateral internal carotid arteries (Figs. 437-4–437-6). The precommunal, or P1, segment of the true PCA is atretic in such cases.

PCA syndromes usually result from atheroma formation or emboli that lodge at the top of the basilar artery; posterior circulation disease may also be caused by dissection of either vertebral artery or fibromuscular dysplasia.

Two clinical syndromes are commonly observed with occlusion of the PCA: (1) *P1 syndrome*: midbrain, subthalamic, and thalamic signs, which are due to disease of the proximal P1 segment of the PCA or its penetrating branches (thalamogeniculate, Percheron, and posterior choroidal arteries); and (2) *P2 syndrome*: cortical temporal and occipital lobe signs, due to occlusion of the P2 segment distal to the junction of the PCA with the posterior communicating artery.

P1 SYNDROMES Infarction usually occurs in the ipsilateral subthalamus and medial thalamus and in the ipsilateral cerebral peduncle and midbrain (Figs. 437-5 and 437-11). A third nerve palsy with contralateral ataxia (Claude's syndrome) or with contralateral hemiplegia (Weber's syndrome) may result. The ataxia indicates involvement of

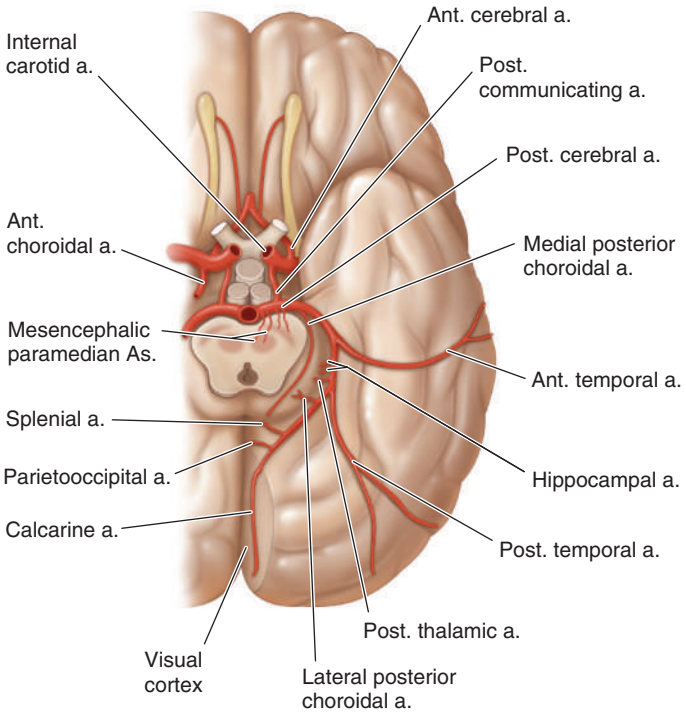

FIGURE 437-5 Inferior aspect of the brain with the branches and distribution of the posterior cerebral artery and the principal anatomic structures shown.

Signs and symptoms: *Structures involved*

Peripheral territory (see also Fig. 437-9). Homonymous hemianopia (often upper quadrantic): *Calcarine cortex or optic radiation nearby.* Bilateral homonymous hemianopia, cortical blindness, awareness or denial of blindness; tactile naming, achromatopia (color blindness), failure to see to-and-fro movements, inability to perceive objects not centrally located, apraxia of ocular movements, inability to count or enumerate objects, tendency to run into things that the patient sees and tries to avoid: *Bilateral occipital lobe with possibly the parietal lobe involved.* Verbal dyslexia without agraphia, color anomia: *Dominant calcarine lesion and posterior part of corpus callosum.* Memory defect: *Hippocampal lesion bilaterally or on the dominant side only.* Topographic disorientation and prosopagnosia: *Usually with lesions of nondominant, calcarine, and lingual gyrus.* Simultanagnosia, hemivisual neglect: *Dominant visual cortex, contralateral hemisphere.* Unformed visual hallucinations, peduncular hallucinosis, metamorphopsia, teleopsia, illusory visual spread, palinopsia, distortion of outlines, central photophobia: *Calcarine cortex.* Complex hallucinations: *Usually nondominant hemisphere.*

Central territory. Thalamic syndrome: sensory loss (all modalities), spontaneous pain and dysesthesias, choreoathetosis, intention tremor, spasms of hand, mild hemiparesis: *Posteroventral nucleus of thalamus; involvement of the adjacent subthalamus body or its afferent tracts.* Thalamoperforate syndrome: crossed cerebellar ataxia with ipsilateral third nerve palsy (Claude's syndrome): *Dentatothalamic tract and issuing third nerve.* Weber's syndrome: third nerve palsy and contralateral hemiplegia: *Third nerve and cerebral peduncle.* Contralateral hemiplegia: *Cerebral peduncle.* Paralysis or paresis of vertical eye movement, skew deviation, sluggish pupillary responses to light, slight miosis and ptosis (retraction nystagmus and "tucking" of the eyelids may be associated): *Supranuclear fibers to third nerve, interstitial nucleus of Cajal, nucleus of Darkschewitsch, and posterior commissure.* Contralateral rhythmic, ataxic action tremor; rhythmic postural or "holding" tremor (rubral tremor): *Dentatothalamic tract.*

the red nucleus or dentatorubrothalamic tract; the hemiplegia is localized to the cerebral peduncle (Fig. 437-11). If the subthalamic nucleus is involved, contralateral hemiballismus may occur. Occlusion of the artery of Percheron produces paresis of upward gaze and drowsiness and often abulia. Extensive infarction in the midbrain and subthalamus occurring with bilateral proximal PCA occlusion presents as coma, unreactive pupils, bilateral pyramidal signs, and decerebrate rigidity.

Occlusion of the penetrating branches of thalamic and thalamogeniculate arteries produces less extensive thalamic and thalamocapsular lacunar syndromes. The *thalamic Déjérine-Roussy syndrome* consists of contralateral hemisensory loss followed later by an agonizing, searing, or burning pain in the affected areas. It is persistent and responds poorly to analgesics. Anticonvulsants (carbamazepine or gabapentin) or tricyclic antidepressants may be beneficial.

P2 SYNDROMES (Figs. 437-4 and 437-5) Occlusion of the distal PCA causes infarction of the medial temporal and occipital lobes.

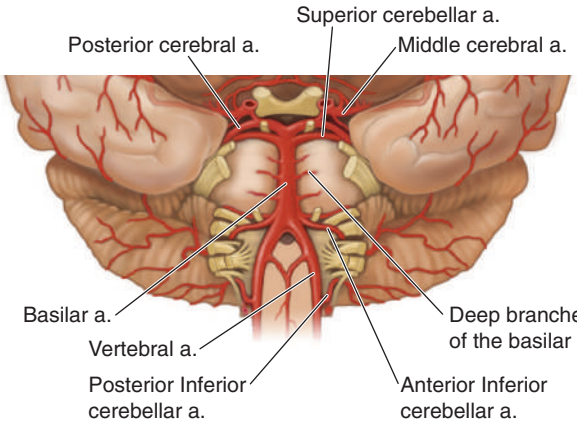

FIGURE 437-6 Diagram of the posterior circulation, showing the intracranial vertebral arteries forming the basilar artery that gives off the anterior inferior cerebellar, superior cerebellar, and posterior cerebral arteries. The posterior inferior cerebellar artery arises from each of the vertebral segments. The majority of brainstem blood flow arises from numerous deep branches of the basilar artery that penetrate directly into the brainstem.

Contralateral homonymous hemianopia without macula sparing is the usual manifestation. (MCA strokes often produce hemianopia but typically spare the macula as calcarine cortex is perfused by the P2 segment.) Occasionally, only the upper quadrant of visual field is involved or the macula vision is spared. If the visual association areas are spared and only the calcarine cortex is involved, the patient may be aware of visual defects. Medial temporal lobe and hippocampal involvement may cause an acute disturbance in memory, particularly if it occurs in the dominant hemisphere. The defect usually clears because memory has bilateral representation. If the dominant hemisphere is affected and the infarct extends to involve the splenium of the corpus callosum, the patient may demonstrate alexia without agraphia. Visual agnosia for faces, objects, mathematical symbols, and colors and anomia with paraphasic errors (amnestic aphasia) may also occur, even without callosal involvement. Occlusion of the PCA can produce *peduncular hallucinosis* (visual hallucinations of brightly colored scenes and objects).

Bilateral infarction in the distal PCAs produces cortical blindness (blindness with preserved pupillary light reaction). The patient is often unaware of the blindness or may even deny it (*Anton's syndrome*). Tiny islands of vision may persist, and the patient may report that vision fluctuates as images are captured in the preserved portions. Rarely, only peripheral vision is lost and central vision is spared, resulting in "gun-barrel" vision. Bilateral visual association area lesions may result in *Balint's syndrome*, a disorder of the orderly visual scanning of the environment (Chap. 32), usually resulting from infarctions secondary to low flow in the "watershed" between the distal PCA and MCA territories, as occurs after cardiac arrest. Patients may experience persistence of a visual image for several minutes despite gazing at another scene (*palinopsia*) or an inability to synthesize the whole of an image (*asimultanagnosia*). Embolic occlusion of the top of the basilar artery can produce any or all the central or peripheral territory symptoms. The hallmark is the sudden onset of bilateral signs, including ptosis, pupillary asymmetry or lack of reaction to light, and somnolence. Patients will often have posturing and myoclonic jerking that simulates seizure. Interrogation of the noncontrast CT scan for a hyperdense basilar artery sign (indicating thrombus in the basilar artery) or CT angiography (CTA) establishes this diagnosis. Physicians should be suspicious of this rare but potentially treatable stroke syndrome in the setting of presumed new-onset seizure and cranial nerve deficits.

VERTEBRAL AND POSTERIOR INFERIOR CEREBELLAR ARTERIES The vertebral artery, which arises from the innominate artery on the right and the subclavian artery on the left, consists of four segments. The first (V1) extends from its origin to its entrance into the sixth or fifth transverse vertebral foramen. The second segment (V2) traverses the vertebral foramina from C6 to C2. The third (V3) passes through the transverse foramen and circles around the arch of the atlas to pierce the dura at the foramen magnum. The fourth (V4) segment courses

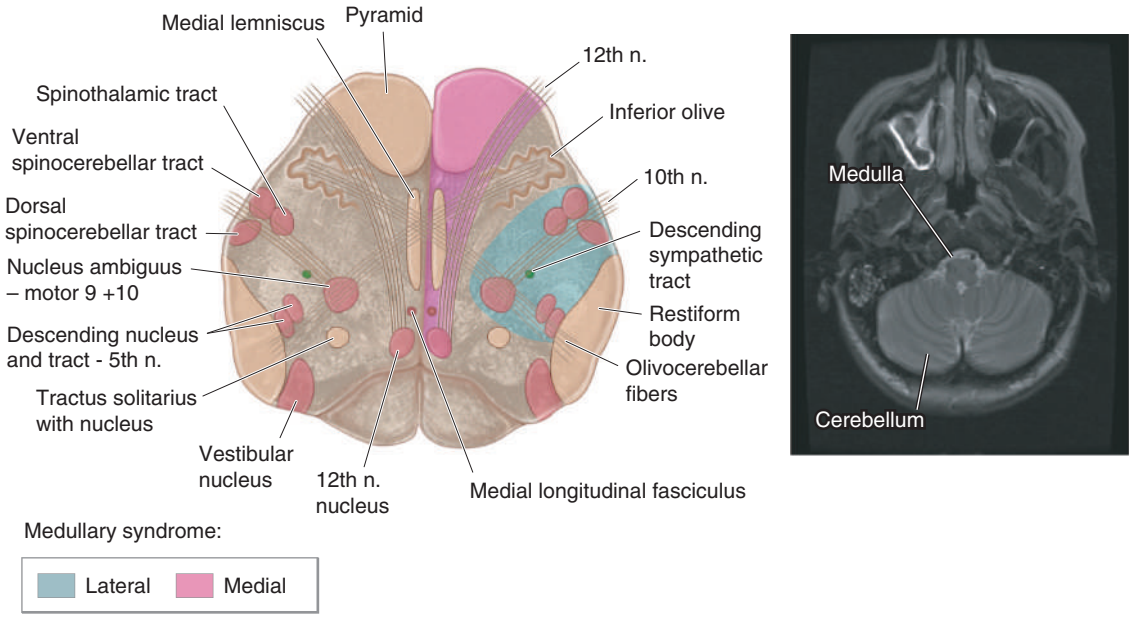

FIGURE 437-7 Axial section at the level of the medulla, depicted schematically on the left, with a corresponding magnetic resonance image on the right. Note that in Figs. 437-7 through 437-11, all drawings are oriented with the dorsal surface at the bottom, matching the orientation of the brainstem that is commonly seen in all modern neuroimaging studies. Approximate regions involved in medial and lateral medullary stroke syndromes are shown.

Signs and symptoms: *Structures involved*

1. Medial medullary syndrome (occlusion of vertebral artery or of branch of vertebral or lower basilar artery)

On side of lesion

Paralysis with atrophy of one-half half the tongue: *Ipsilateral twelfth nerve*

Paralysis of arm and leg, sparing face; impaired tactile and proprioceptive sense over one-half the body: *Contralateral pyramidal tract and medial lemniscus*

Pain, numbness, impaired sensation over one-half the face: *Descending tract and nucleus fifth nerve*

Ataxia of limbs, falling to side of lesion: *Uncertain—restiform body, cerebellar hemisphere, cerebellar fibers, spinocerebellar tract (?)*

Nystagmus, diplopia, oscillopsia, vertigo, nausea, vomiting: *Vestibular nucleus*

Horner's syndrome (miosis, ptosis, decreased sweating): *Descending sympathetic tract*

Dysphagia, hoarseness, paralysis of palate, paralysis of vocal cord, diminished gag reflex: *Issuing fibers ninth and tenth nerves*

Loss of taste: *Nucleus and tractus solitarius*

Numbness of ipsilateral arm, trunk, or leg: *Cuneate and gracile nuclei*

Weakness of lower face: *Genuflected upper motor neuron fibers to ipsilateral facial nucleus*

Impaired pain and thermal sense over half the body, sometimes face: *Spinothalamic tract*

5. Basilar artery syndrome (the syndrome of the lone vertebral artery is equivalent): A combination of the various brainstem syndromes plus those arising in the posterior cerebral artery distribution.

Bilateral long tract signs (sensory and motor; cerebellar and peripheral cranial nerve abnormalities): *Bilateral long tract; cerebellar and peripheral cranial nerves*

Paralysis or weakness of all extremities, plus all bulbar musculature: *Corticobulbar and corticospinal tracts bilaterally*

upward to join the other vertebral artery to form the basilar artery (Fig. 437-6); only the fourth segment gives rise to branches that supply the brainstem and cerebellum. The posterior inferior cerebellar artery (PICA) in its proximal segment supplies the lateral medulla and, in its distal branches, the inferior surface of the cerebellum.

Atherothrombotic lesions have a predilection for V1 and V4 segments of the vertebral artery. The first segment may become diseased at the origin of the vessel and may produce posterior circulation emboli; collateral flow from the contralateral vertebral artery or the ascending cervical, thyrocervical, or occipital arteries is usually sufficient to prevent low-flow TIAs or stroke. When one vertebral artery is atretic and an atherothrombotic lesion threatens the origin of the other, the collateral circulation, which may also include retrograde flow down the basilar artery, is often insufficient (Figs. 437-5 and 437-6). In this setting, low-flow TIAs may occur, consisting of syncope, vertigo, and alternating hemiplegia; this state also sets the stage for thrombosis. Disease of the distal fourth segment of the vertebral artery can promote thrombus formation manifest as embolism or with propagation as basilar artery thrombosis. Stenosis proximal to the origin of the PICA can threaten the lateral medulla and posterior inferior surface of the cerebellum.

If the subclavian artery is occluded proximal to the origin of the vertebral artery, there is a reversal in the direction of blood flow in the ipsilateral vertebral artery. Exercise of the ipsilateral arm may increase demand on vertebral flow, producing posterior circulation TIAs, or "subclavian steal."

Although atheromatous disease rarely narrows the second and third segments of the vertebral artery, this region is subject to dissection, fibromuscular dysplasia, and, rarely, encroachment by osteophytic spurs within the vertebral foramina.

Embolic occlusion or thrombosis of a V4 segment causes ischemia of the lateral medulla. The constellation of vertigo, numbness of the ipsilateral face and contralateral limbs, diplopia, hoarseness, dysarthria, dysphagia, and ipsilateral Horner's syndrome is called the *lateral medullary (or Wallenberg's) syndrome* (Fig. 437-7). Ipsilateral upper motor neuron facial weakness can also occur. Most cases result from ipsilateral vertebral artery occlusion; in the remainder, PICA occlusion is responsible. Occlusion of the medullary penetrating branches of the vertebral artery or PICA results in partial syndromes. *Hemiparesis is not a typical feature of vertebral artery occlusion; however, quadriparesis may result from occlusion of the anterior spinal artery.*

Rarely, a *medial medullary syndrome* occurs with infarction of the pyramid and contralateral hemiparesis of the arm and leg, sparing the face. If the medial lemniscus and emerging hypoglossal nerve fibers are involved, contralateral loss of joint position sense and ipsilateral tongue weakness occur.

Cerebellar infarction can lead to *respiratory arrest* due to brainstem herniation from cerebellar swelling, closure of the aqueduct of Silvius or fourth ventricle, followed by hydrocephalus and central herniation. This added downward displacement of the brainstem from hydrocephalus will exacerbate respiratory and hemodynamic instability. Drowsiness, Babinski signs, dysarthria, and bifacial weakness may be absent, or present only briefly, before respiratory arrest ensues. Gait unsteadiness, headache, dizziness, nausea, and vomiting may be the only early symptoms and signs and should arouse suspicion of this impending complication, which may require neurosurgical decompression, often with an excellent outcome. Separating these symptoms from those of

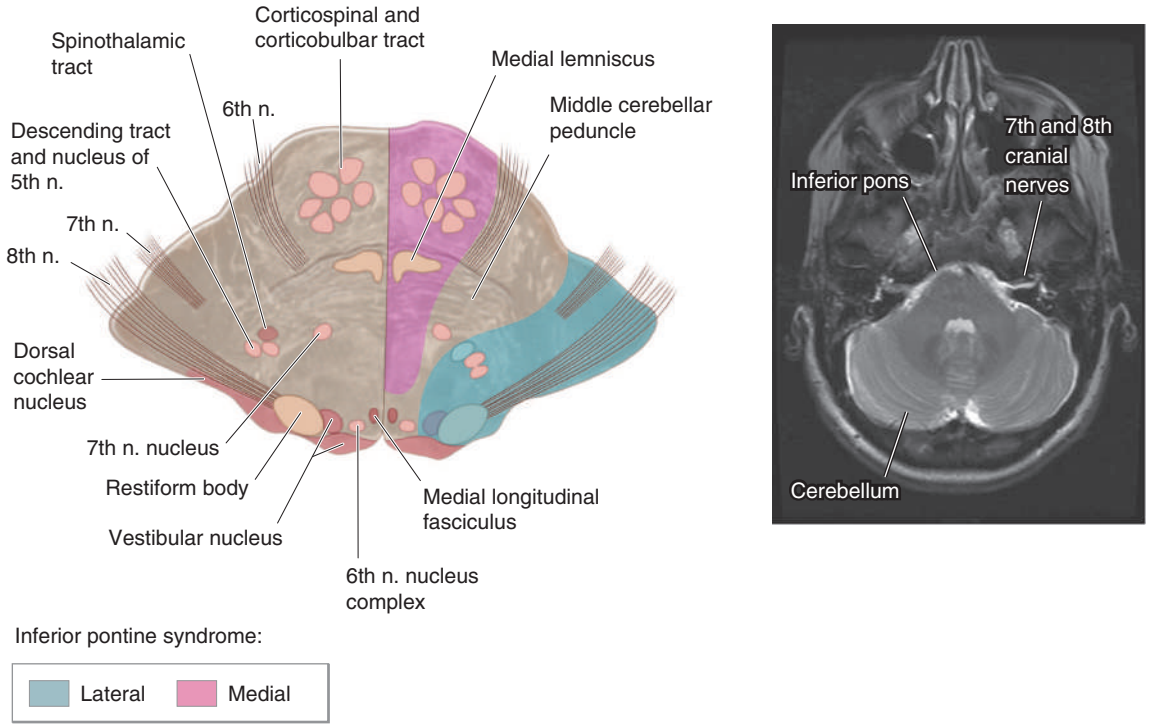

FIGURE 437-8 Axial section at the level of the inferior pons, depicted schematically on the left, with a corresponding magnetic resonance image on the right. Approximate regions involved in medial and lateral inferior pontine stroke syndromes are shown.

Signs and symptoms: *Structures involved*
Paralysis of conjugate gaze to side of lesion (preservation of convergence): *Center for conjugate lateral gaze*
Nystagmus: *Vestibular nucleus*
Ataxia of limbs and gait: Likely *middle cerebellar peduncle*
Diplopia on lateral gaze: *Abducens nerve*
Paralysis of face, arm, and leg: *Corticobulbar and corticospinal tract in lower pons*
Impaired tactile and proprioceptive sense over one-half of the body: *Medial lemniscus*
Horizontal and vertical nystagmus, vertigo, nausea, vomiting, oscillopsia: *Vestibular nerve or nucleus*
Facial paralysis: *Seventh nerve*
Paralysis of conjugate gaze to side of lesion: *Center for conjugate lateral gaze*
Deafness, tinnitus: *Auditory nerve or cochlear nucleus*
Ataxia: *Middle cerebellar peduncle and cerebellar hemisphere*
Impaired sensation over face: *Descending tract and nucleus fifth nerve*
Impaired pain and thermal sense over one-half the body (may include face): *Spinothalamic tract*

viral labyrinthitis can be a challenge, but headache, neck stiffness, and unilateral dysmetria favor stroke.

BASILAR ARTERY Branches of the basilar artery (Fig. 437-6) supply the base of the pons and superior cerebellum and fall into three groups: (1) paramedian, 7–10 in number, which supply a wedge of pons on either side of the midline; (2) short circumferential, 5–7 in number, that supply the lateral two-thirds of the pons and middle and superior cerebellar peduncles; and (3) bilateral long circumferential (superior cerebellar and anterior inferior cerebellar arteries), which course around the pons to supply the cerebellar hemispheres.

Atheromatous lesions can occur anywhere along the basilar trunk but are most frequent in the proximal basilar and distal vertebral segments. Typically, lesions occlude either the proximal basilar and one or both vertebral arteries. The clinical picture varies depending on the availability of retrograde collateral flow from the posterior communicating arteries. Rarely, dissection of a vertebral artery may involve the basilar artery and, depending on the location of true and false lumen, may produce multiple penetrating artery strokes.

Although atherothrombosis occasionally occludes the distal portion of the basilar artery, emboli from the heart or proximal vertebral or basilar segments are more commonly responsible for "top of the basilar" syndromes.

Because the brainstem contains many structures in close apposition, a diversity of clinical syndromes may emerge with ischemia, reflecting involvement of the corticospinal and corticobulbar tracts, ascending sensory tracts, and cranial nerve nuclei (Figs. 437-7 to 437-11).

The symptoms of transient ischemia or infarction in the territory of the basilar artery often do not indicate whether the basilar artery itself or one of its branches is diseased, yet this distinction has important implications for therapy. *The picture of complete basilar occlusion, however, is easy to recognize as a constellation of bilateral long tract signs (sensory and motor) with signs of cranial nerve and cerebellar dysfunction.* Patients may have spontaneous posturing movements that are myoclonic in nature and simulate seizure activity. These movements are brief, repetitive, and multifocal and often confused with status epilepticus. CT or magnetic resonance angiography can rapidly detect basilar thrombosis, and rapid treatment (thrombectomy) can be lifesaving. A "locked-in" state of preserved consciousness with quadriplegia and cranial nerve signs suggests complete pontine and lower midbrain infarction. The therapeutic goal is to identify *impending* basilar occlusion before devastating infarction occurs. A series of TIAs and a slowly progressive, fluctuating stroke are extremely significant, because they often herald an atherothrombotic occlusion of the distal vertebral or proximal basilar artery.

TIAs in the proximal basilar distribution may produce vertigo (often described by patients as "swimming," "swaying," "moving," "unsteadiness," or "light-headedness"). Other symptoms that warn of basilar thrombosis include diplopia, dysarthria, facial or circumoral numbness, and hemisensory symptoms. In general, symptoms of basilar branch TIAs affect one side of the brainstem, whereas symptoms of basilar artery TIAs usually affect both sides, although a "herald" hemiparesis has been emphasized as an initial symptom of basilar occlusion. Most often, TIAs, whether due to impending occlusion of the basilar artery or a basilar branch, are short lived (5–30 min) and repetitive, occurring several times a day. The pattern suggests intermittent reduction of flow. Although treatment with intravenous heparin or various

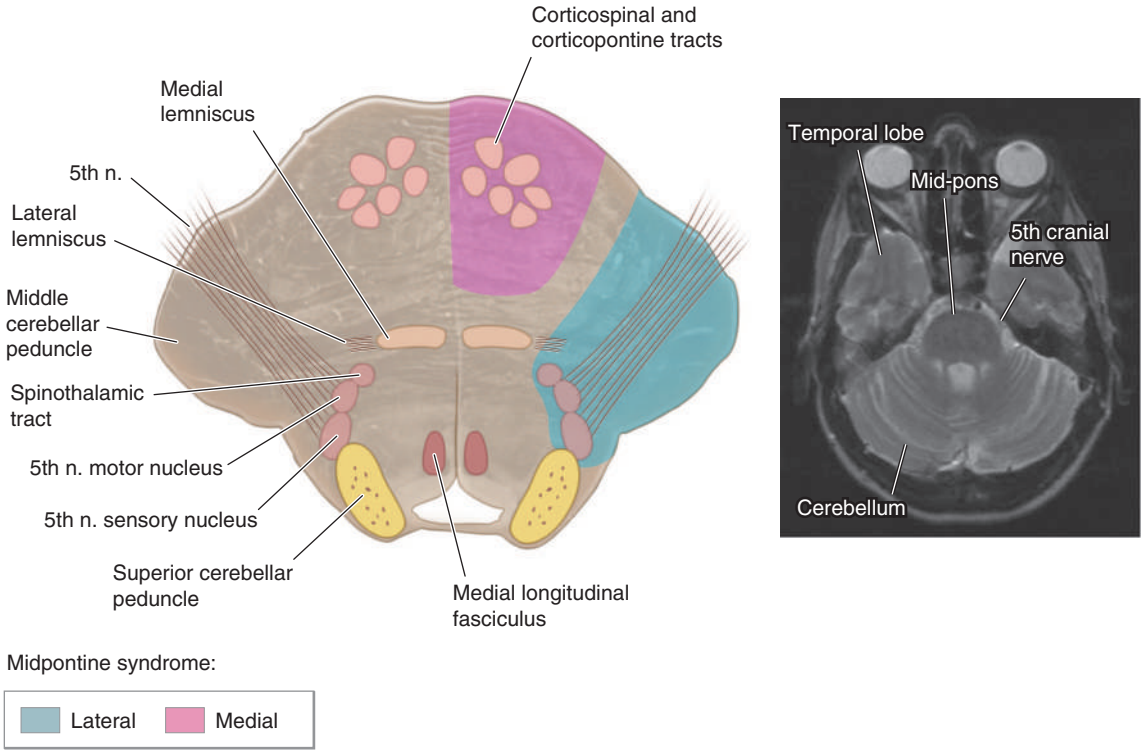

FIGURE 437-9 Axial section at the level of the midpons, depicted schematically on the left, with a corresponding magnetic resonance image on the right. Approximate regions involved in medial and lateral midpontine stroke syndromes are shown.

Signs and symptoms: *Structures involved*
Ataxia of limbs and gait (more prominent in bilateral involvement): *Pontine nuclei*
Paralysis of face, arm, and leg: *Corticobulbar and corticospinal tract*
Variable impaired touch and proprioception when lesion extends posteriorly: *Medial lemniscus*
Ataxia of limbs: *Middle cerebellar peduncle*
Paralysis of muscles of mastication: *Motor fibers or nucleus of fifth nerve*
Impaired sensation over side of face: *Sensory fibers or nucleus of fifth nerve*
Impaired pain and thermal sense on limbs and trunk: *Spinothalamic tract*

combinations of antiplatelet agents has been used to prevent clot propagation, there is no specific evidence to support any one approach, and endovascular intervention is also an option.

Atherothrombotic occlusion of the basilar artery with infarction usually causes *bilateral* brainstem signs. A gaze paresis or internuclear ophthalmoplegia associated with ipsilateral hemiparesis may be the only manifestation of bilateral brainstem ischemia. More often, unequivocal signs of bilateral pontine disease are present. Complete basilar thrombosis carries a high mortality.

Occlusion of a branch of the basilar artery usually causes *unilateral* symptoms and signs involving motor, sensory, and cranial nerves. If symptoms remain unilateral, concern over pending basilar occlusion should be reduced.

Occlusion of the superior cerebellar artery results in severe ipsilateral cerebellar ataxia, nausea and vomiting, dysarthria, and contralateral loss of pain and temperature sensation over the extremities, body, and face (spino- and trigeminothalamic tract). Partial deafness, ataxic tremor of the ipsilateral upper extremity, Horner's syndrome, and palatal myoclonus may occur rarely. Partial syndromes occur frequently (Fig. 437-10). With large strokes, swelling and mass effects may compress the midbrain or produce hydrocephalus; these symptoms may evolve rapidly. Neurosurgical intervention may be lifesaving in such cases.

Occlusion of the anterior inferior cerebellar artery produces variable degrees of infarction because the size of this artery and the territory it supplies vary inversely with those of the PICA. The principal symptoms include (1) ipsilateral deafness, facial weakness, vertigo, nausea and vomiting, nystagmus, tinnitus, cerebellar ataxia, Horner's syndrome, and paresis of conjugate lateral gaze; and (2) contralateral loss of pain and temperature sensation. An occlusion close to the origin of the artery may cause corticospinal tract signs (Fig. 437-8).

Occlusion of one of the short circumferential branches of the basilar artery affects the lateral two-thirds of the pons and middle or superior cerebellar peduncle, whereas occlusion of one of the paramedian branches affects a wedge-shaped area on either side of the medial pons (Figs. 437-8–437-10).

IMAGING STUDIES

See also Chap. 434.

CT Scans CT radiographic images identify or exclude hemorrhage as the cause of stroke, and they identify extraparenchymal hemorrhages, neoplasms, abscesses, and other conditions masquerading as stroke. Brain CT scans obtained in the first several hours after an infarction generally show no abnormality (Fig. 437-12*A*), and the infarct may not be seen reliably for 24–48 h. The decision to treat patients with IV plasminogen activators is based on the clinical diagnosis of stroke and a CT scan showing no hemorrhage. CT may fail to show small ischemic strokes in the posterior fossa because of bone artifact; small infarcts on the cortical surface may also be missed.

Contrast-enhanced CT scans add specificity by showing contrast enhancement of subacute infarcts and allow visualization of venous structures. Coupled with multidetector scanners, CT angiography can be performed with administration of IV iodinated contrast allowing visualization of the cervical and intracranial arteries, intracranial veins, and aortic arch in one imaging session. Carotid disease and intracranial vascular occlusions are readily identified with this method (see Fig. 438-2). After an IV bolus of contrast, deficits in brain perfusion produced by vascular occlusion can also be demonstrated (Fig. 437-12*D*) and used to predict the region of infarcted brain and the brain at risk of further infarction (i.e., the ischemic penumbra, see "Pathophysiology of Ischemic Stroke" in Chap. 438). CT imaging is also sensitive for detecting SAH (although by itself does not rule it out), and CTA can readily

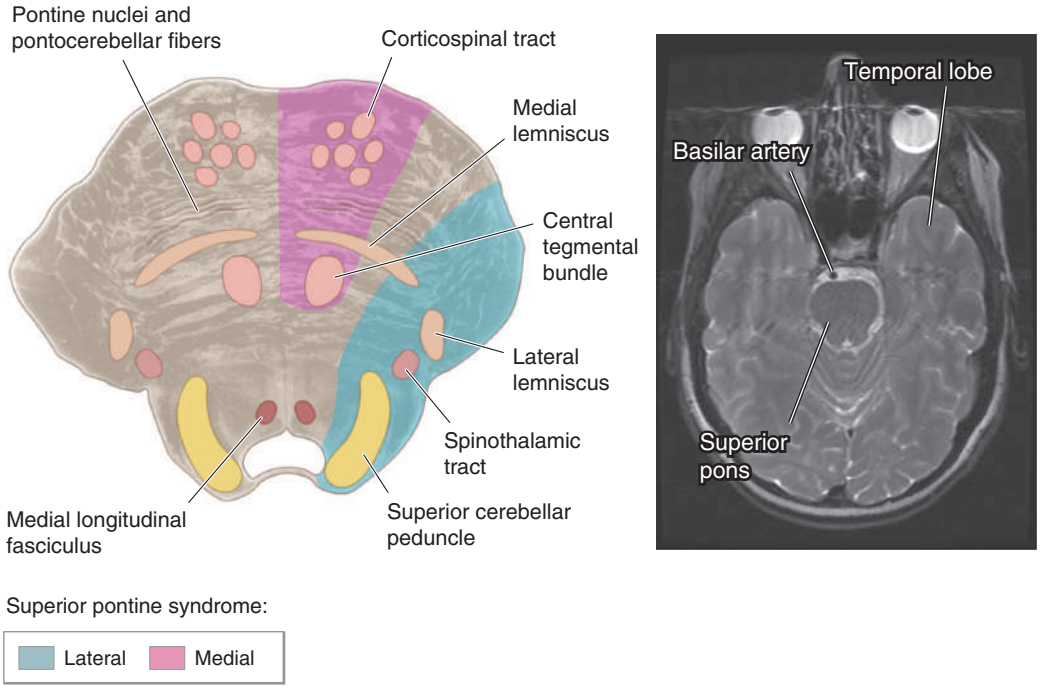

FIGURE 437-10 Axial section at the level of the superior pons, depicted schematically on the left, with a corresponding magnetic resonance image on the right. Approximate regions involved in medial and lateral superior pontine stroke syndromes are shown.

Signs and symptoms: *Structures involved*
Cerebellar ataxia (probably): *Superior and/or middle cerebellar peduncle*
Internuclear ophthalmoplegia: *Medial longitudinal fasciculus*
Myoclonic syndrome, palate, pharynx, vocal cords, respiratory apparatus, face, oculomotor apparatus, etc.: *Localization uncertain—central tegmental bundle, dentate projection, inferior olivary nucleus*
Paralysis of face, arm, and leg: *Corticobulbar and corticospinal tract*
Rarely touch, vibration, and position are affected: *Medial lemniscus*
Ataxia of limbs and gait, falling to side of lesion: *Middle and superior cerebellar peduncles, superior surface of cerebellum, dentate nucleus*
Dizziness, nausea, vomiting; horizontal nystagmus: *Vestibular nucleus*
Paresis of conjugate gaze (ipsilateral): *Pontine contralateral gaze*
Skew deviation: *Uncertain*
Miosis, ptosis, decreased sweating over face (Horner's syndrome): *Descending sympathetic fibers*
Tremor: Localization unclear—*Dentate nucleus, superior cerebellar peduncle*
Impaired pain and thermal sense on face, limbs, and trunk: *Spinothalamic tract*
Impaired touch, vibration, and position sense, more in leg than arm (there is a tendency to incongruity of pain and touch deficits): *Medial lemniscus (lateral portion)*

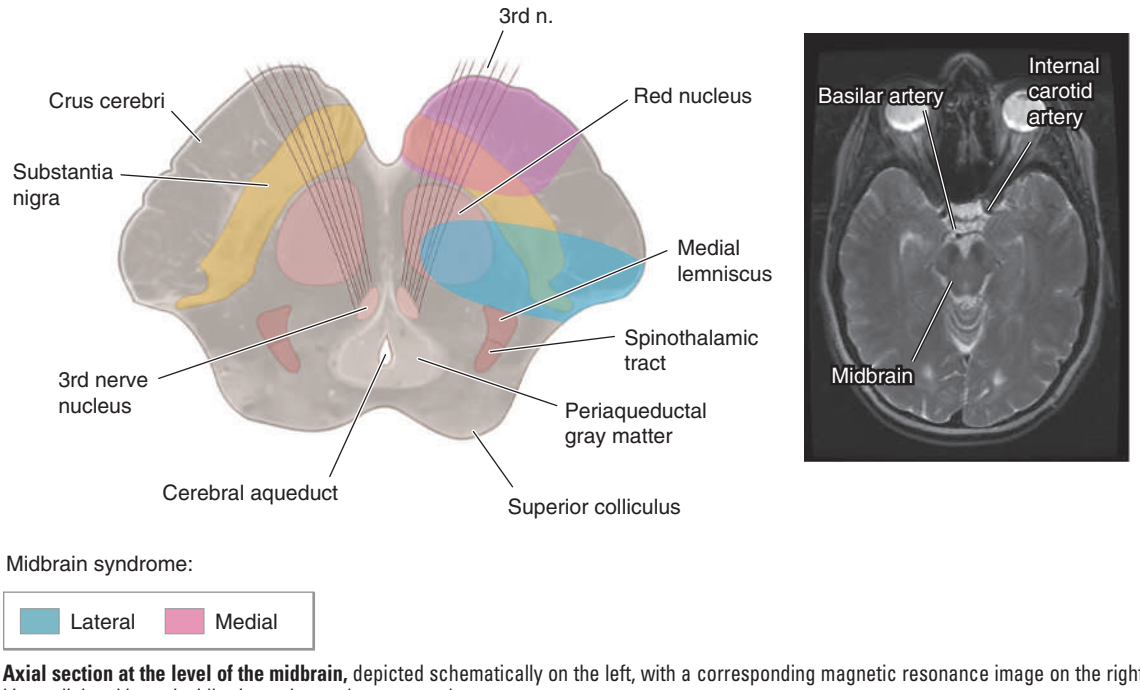

FIGURE 437-11 Axial section at the level of the midbrain, depicted schematically on the left, with a corresponding magnetic resonance image on the right. Approximate regions involved in medial and lateral midbrain stroke syndromes are shown.

Signs and symptoms: *Structures involved*
Eye "down and out" secondary to unopposed action of fourth and sixth cranial nerves, with dilated and unresponsive pupil: *Third nerve fibers*
Paralysis of face, arm, and leg: *Corticobulbar and corticospinal tract descending in crus cerebri*
Eye "down and out" secondary to unopposed action of fourth and sixth cranial nerves, with dilated and unresponsive pupil: *Third nerve fibers and/or third nerve nucleus*
Hemiataxia, hyperkinesias, tremor: *Red nucleus, dentatorubrothalamic pathway*

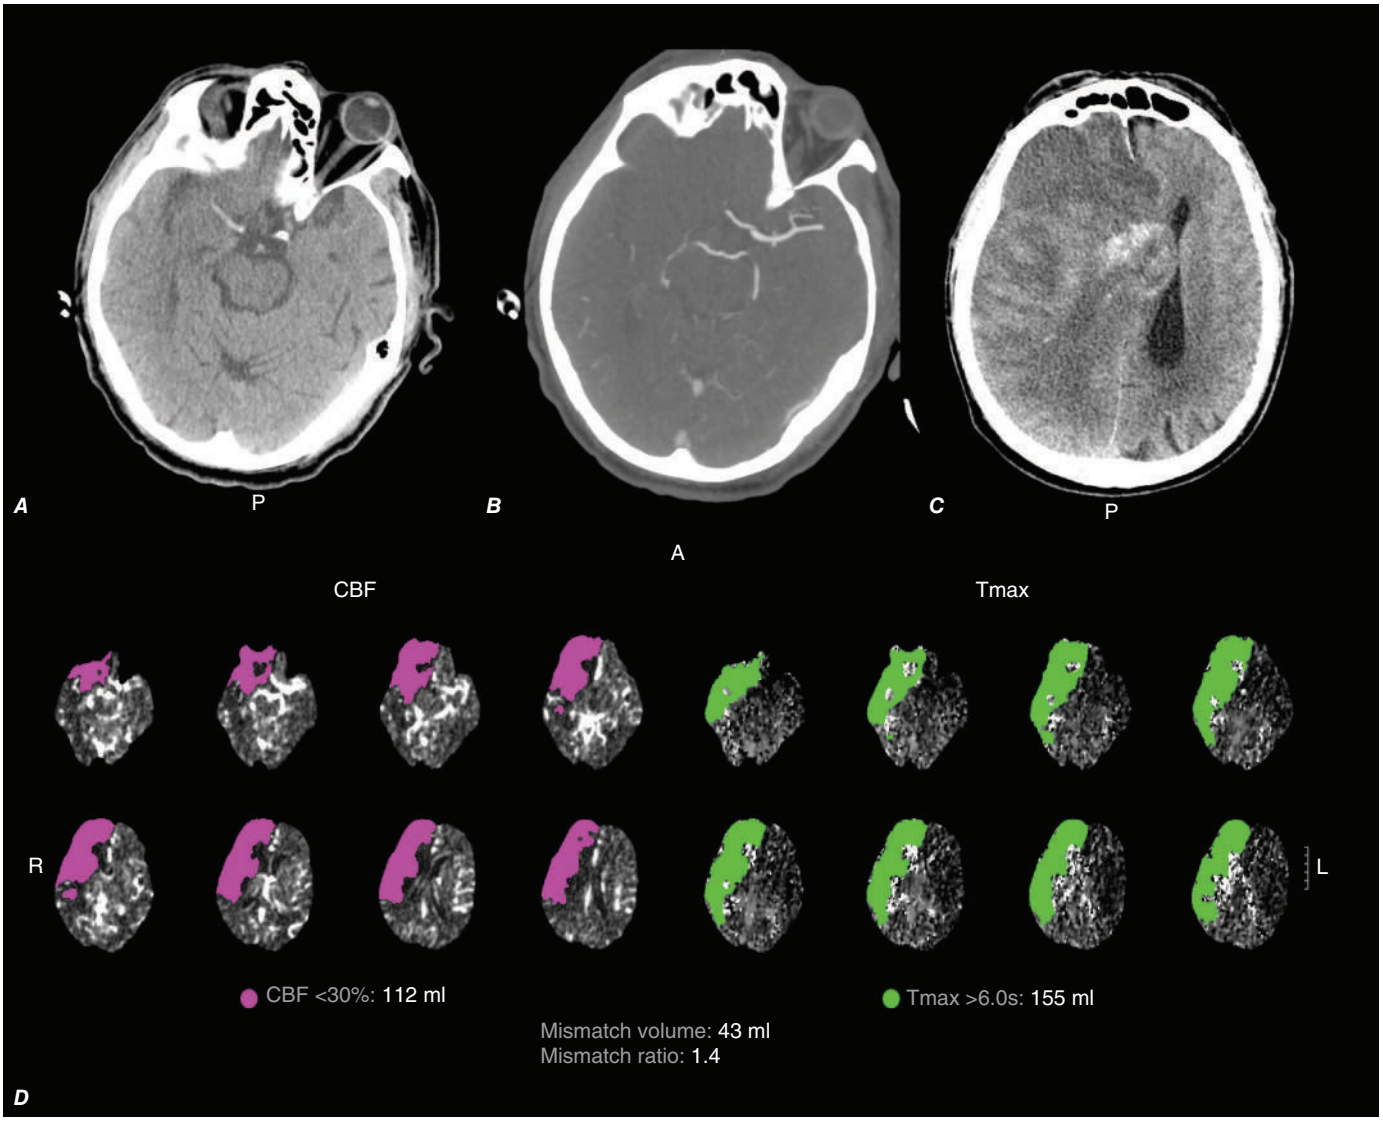

FIGURE 437-12 ***(A)*** Noncontrast head computed tomography (CT) image of an 83-year-old man with sudden onset left hemiplegia, left homonymous hemianopia, rightward gaze deviation and left hemineglect showing no clear brain infarction and hyperdensity within the right middle cerebral artery (MCA) suggestive of clot. ***(B)*** CT angiography performed at the same time as the CT showing absence of the right MCA and anterior cerebral artery (ACA) vessels consistent with occlusion of the bifurcation of the right intracranial internal carotid artery. ***(C)*** Follow-up head CT 1 day later showing extensive infarction of the right frontal lobe with brain herniation. ***(D)*** CT perfusion performed with studies shown in ***A*** and ***B***. This predicts a large core infarction (pink regions) despite attempts at revascularization with thrombectomy. CBF, cerebral blood flow.

identify intracranial aneurysms (Chap. 440). Because of its speed and wide availability, noncontrast head CT is the imaging modality of choice in patients with acute stroke (Fig. 437-1), and CTA and CT perfusion imaging may also be useful and convenient adjuncts.

MRI

MRI reliably documents the extent and location of infarction in all areas of the brain, including the posterior fossa and cortical surface. Diffusion-weighted imaging (DWI) identifies regions of brain infarction within minutes of the stroke onset (Fig. 437-13*A, B*), while fluid-attenuated inversion recovery (FLAIR) imaging reliably reveals areas of prior brain infarction from a few days to years later (Fig. 437-13*C*). CT is poorly sensitive to brain infarction in the posterior fossae compared to MRI DWI images (Fig. 437-13*D, E*). MRI also identifies intracranial hemorrhage and other abnormalities and, using special sequences, can be as sensitive as CT for detecting acute intracerebral hemorrhage. MRI scanners with magnets of higher field strength produce more reliable and precise images. Using IV administration of gadolinium contrast, magnetic resonance (MR) perfusion studies can be performed. Brain regions showing poor perfusion but no abnormality on diffusion provide, compared to CT, an equivalent measure of the ischemic penumbra. MR angiography is highly sensitive for stenosis of extracranial internal carotid arteries and of large intracranial vessels. With higher degrees of stenosis, MR angiography tends to overestimate the degree of stenosis when compared to conventional x-ray angiography. MRI with fat saturation is an imaging sequence used to visualize extra- or intracranial arterial dissection. This sensitive technique images clotted blood within the dissected vessel wall. Iron-sensitive imaging (ISI) is helpful to detect cerebral microbleeds that may be present in cerebral amyloid angiopathy and other hemorrhagic disorders.

MRI is more expensive and time consuming than CT and less readily available. Claustrophobia and the logistics of imaging acutely critically ill patients also limit its application. Most acute stroke protocols use CT because of these limitations. However, MRI is useful outside the acute period by more clearly defining the extent of tissue injury and discriminating new from old regions of brain infarction. MRI may have utility in patients with TIA, because it is also more likely to identify new infarction, which is a strong predictor of subsequent stroke.

Cerebral Angiography Conventional x-ray cerebral angiography is the gold standard for identifying and quantifying atherosclerotic stenoses of the cerebral arteries and for identifying and characterizing other pathologies, including aneurysms, vasospasm, intraluminal thrombi, fibromuscular dysplasia, arteriovenous fistulae, vasculitis, and collateral channels of blood flow. Conventional angiography carries risks of arterial damage, groin hemorrhage, embolic stroke, and

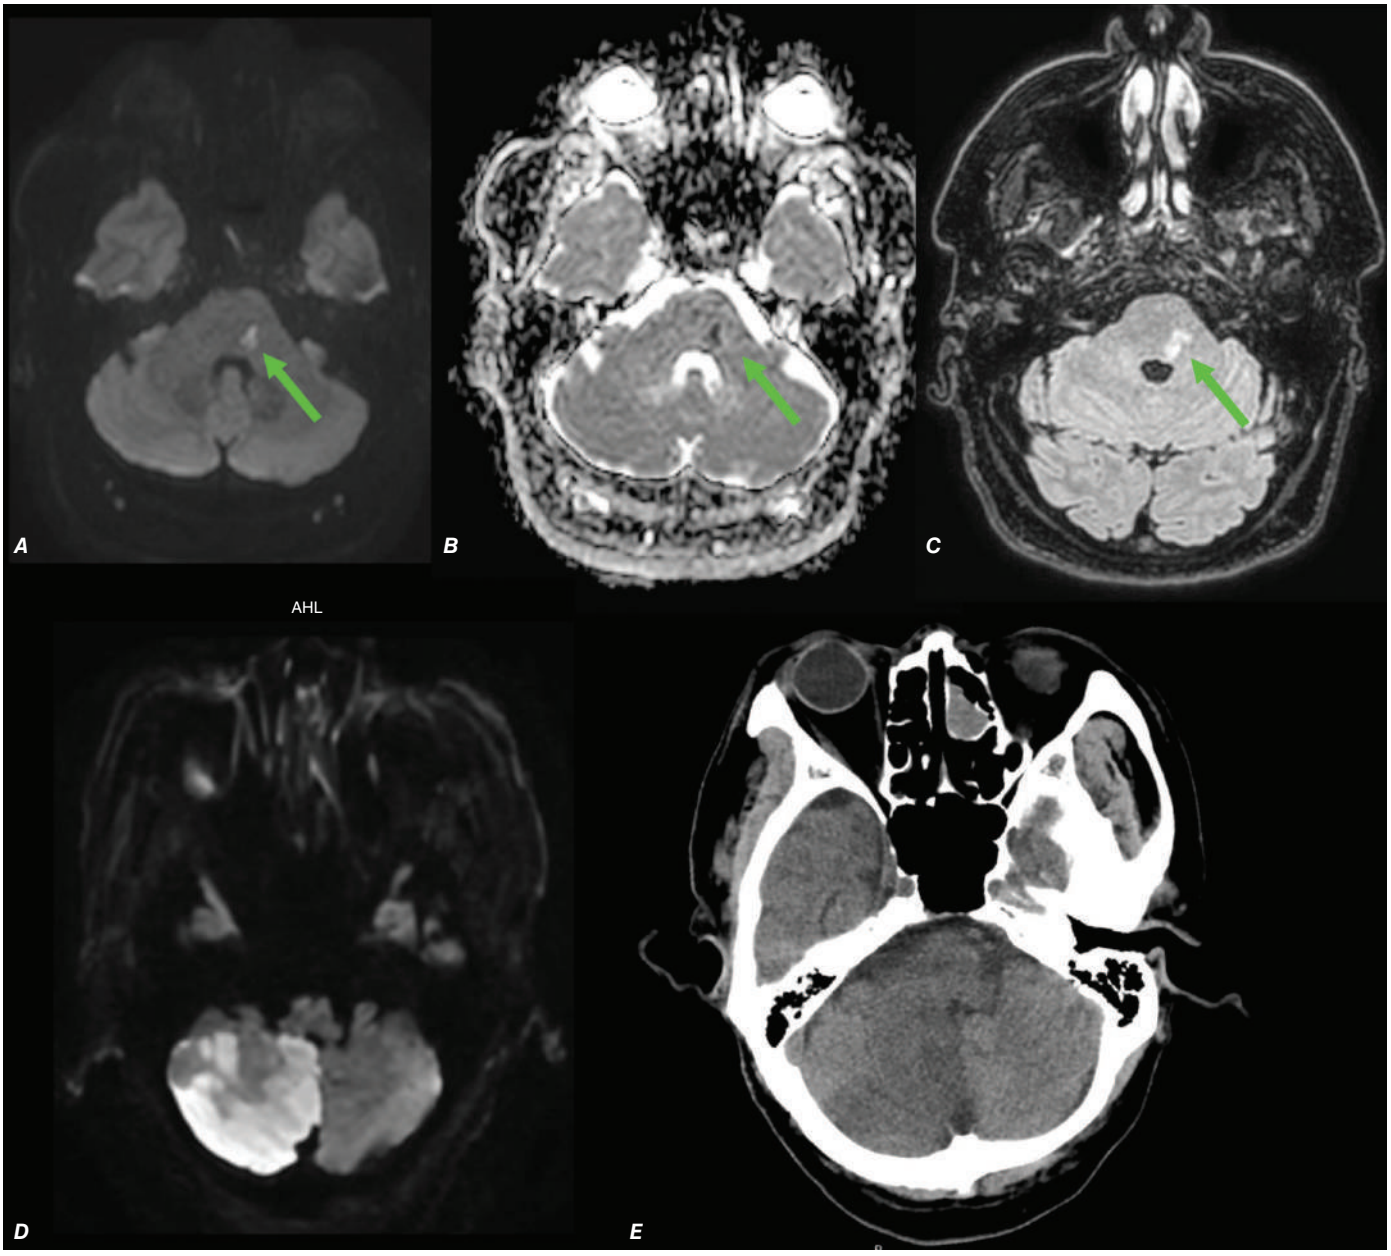

FIGURE 437-13 Examples of magnetic resonance imaging (MRI) imaging of acute ischemic infarcts. ***(A)*** Diffusion-weighted image (DWI) revealing bright region in the left pons (*arrow*), and ***(B)*** dark region on apparent diffusion coefficient (ADC) in the same region. Bright regions on DWI and corresponding dark regions on ADC are consistent with acute brain ischemia (within minutes to hours of stroke onset). (***C***) Same region of the brain 2 days later showing bright region in the infarcted tissue on fluid-attenuated inversion recovery (FLAIR) images. The DWI and ADC values will return to normal after 10–14 days while the FLAIR abnormality will persist long term. ***(D)*** DWI MRI and ***(E)*** computed tomography (CT) images of a patient with acute-onset vertigo. The DWI image shows an acute ischemic infarction of the right posterior inferior cerebellar artery territory within the cerebellum, whereas the CT scan is only subtly hypodense in the same region. MRI is superior to CT imaging for identifying ischemic infarction especially within the posterior fossa.

renal failure from contrast nephropathy, so it should be reserved for situations where less invasive means are inadequate. Acute stroke treatment with endovascular thrombectomy has proven effective in ischemic strokes caused by internal carotid terminus or MCA occlusions and is now part of routine clinical practice at centers that have this capability **(see Chap. 438)**.

Ultrasound Techniques Stenosis at the origin of the internal carotid artery can be identified and quantified reliably by ultrasonography that combines a B-mode ultrasound image with a Doppler ultrasound assessment of flow velocity ("duplex" ultrasound). Transcranial Doppler (TCD) assessment of MCA, ACA, and PCA flow and of vertebrobasilar flow is also useful. This latter technique can detect stenotic lesions in the large intracranial arteries because such lesions increase systolic flow velocity. TCD can also detect microemboli from otherwise asymptomatic carotid plaques. In many cases, MR angiography combined with carotid and transcranial ultrasound studies eliminates the need for conventional x-ray angiography in evaluating vascular stenosis. Alternatively, CTA of the entire head and neck can be performed during the initial imaging of acute stroke. Because this images the entire arterial system relevant to stroke, with the exception of the heart, much of the clinician's stroke workup can be completed with this single imaging study.

Radionuclide Perfusion Techniques Both xenon techniques (principally xenon-CT) and positron emission tomography (PET) can quantify cerebral blood flow. These tools are generally used for research **(Chap. 434)** but can be useful for determining the significance of arterial stenosis and planning for revascularization surgery. Single-photon emission computed tomography (SPECT) and CT or MR perfusion techniques report relative cerebral blood flow. As noted above, CT imaging is used as the initial imaging modality for acute stroke, and

some centers combine both CTA and CT perfusion imaging together with the noncontrast CT scan. CT perfusion imaging increases the sensitivity for detecting ischemia and can measure the ischemic penumbra (Fig. 437-12). Alternatively, MR perfusion can be combined with MR diffusion imaging to identify the ischemic penumbra as the mismatch between these two imaging sequences.

438 Ischemic Stroke

Wade S. Smith, Anthony S. Kim, J. Claude Hemphill, III

The clinical diagnosis of stroke is discussed in **Chap. 437**. Once this diagnosis is made and either a noncontrast computed tomography (CT) scan or magnetic resonance imaging (MRI) scan has been performed, rapid reversal of ischemia is paramount. This chapter will focus on the stroke treatment timeline and subsequent secondary stroke prevention.

PATHOPHYSIOLOGY OF ISCHEMIC STROKE

Acute occlusion of an intracranial vessel causes reduction in blood flow to the brain region it supplies **(Fig. 438-1)**. The magnitude of flow reduction is a function of collateral blood flow, and this depends on an individual's vascular anatomy (which may be altered by disease), the site of occlusion, and systemic blood pressure. A decrease in cerebral blood flow to zero causes death of brain tissue (neuron cell bodies, dendrites, axons, and glial cells) within 4–10 min; values <16–18 mL/100 g tissue per minute cause infarction within an hour; and values <20 mL/100 g tissue per minute cause ischemia without infarction unless prolonged for several hours or days. If blood flow is restored to ischemic tissue before significant infarction develops, the patient may experience only transient symptoms, and the clinical syndrome is called a transient ischemic attack (TIA). Another important concept is the *ischemic penumbra*, defined as the ischemic but reversibly dysfunctional tissue surrounding a core area of infarction. The penumbra can be imaged by perfusion imaging using MRI or CT (see Fig. 438-3 and **Figs. 437-12** and **437-13**). The ischemic penumbra will eventually progress to infarction if no change in flow occurs, and hence, saving the ischemic penumbra is the goal of revascularization therapy. Restoration of blood flow provides oxygen and glucose to the penumbral tissue, preventing infarction not only by supplying fuel for metabolism but by reversing tissue acidosis, clearing glutamate and toxic oxygen species, and halting waves of cortical spreading depression emanating from the ischemic core that add metabolic stress to the tissue.

Ischemia causes a reduction in glucose and oxygen delivery, which in turn results in reduced capacity of cells to generate ATP. Without ATP, membrane ion pumps stop functioning and cells depolarize, allowing intracellular sodium and calcium to rise. Cellular depolarization also causes glutamate release from synaptic terminals and a failure of glutamate uptake by glial cells. The resulting sustained elevation in extracellular glutamate produces neurotoxicity by activating postsynaptic glutamate receptors that increase neuronal calcium influx and the production of reactive oxygen species. Reactive oxygen species damage DNA, lipid membranes, and likely other vital functions of cells. An innate immune response becomes apparent within a few hours after stroke, consisting of activation of proinflammatory microglia (the resident immune cells in brain) and infiltration of immune cells from the circulation. While important in repairing stroke damage, this acute inflammatory response may also contribute to tissue injury after stroke by release of proteases and reactive oxygen species. Ischemia and the postischemic inflammatory response also injure or destroy axons and dendrites at some distance from the infarct itself. Fever dramatically worsens brain injury during ischemia, as does hyperglycemia (glucose >11.1 mmol/L [200 mg/dL]), so it is reasonable to suppress fever and prevent hyperglycemia during and after brain ischemia. The value of induced mild hypothermia to improve stroke outcomes has not been clearly demonstrated and remains the subject of continuing clinical research.

TREATMENT

Acute Ischemic Stroke (Fig. 438-2)

After the clinical diagnosis of stroke is made **(Chap. 437)**, an orderly and prompt process of evaluation and treatment should follow. The first goal is to prevent or reverse brain injury. Attend to the patient's airway, breathing, and circulation (ABCs), and treat hypoglycemia or hyperglycemia if identified by finger stick testing. Perform an emergency noncontrast head CT scan to differentiate between ischemic stroke and hemorrhagic stroke **(Chap. 439)**; there are no reliable clinical findings that conclusively separate ischemia from hemorrhage, although a more depressed level of consciousness, higher initial blood pressure, or worsening of symptoms after onset favor hemorrhage, and a deficit that is maximal at onset, or remits, suggests ischemia. Treatments designed to reverse or lessen the amount of tissue infarction and improve clinical outcome fall within six categories: (1) medical support, (2) IV thrombolysis, (3) endovascular revascularization, (4) antithrombotic treatment, (5) neuroprotection, and (6) stroke centers and rehabilitation.

MEDICAL SUPPORT

When ischemic stroke occurs, the immediate goal is to optimize cerebral perfusion in the surrounding ischemic penumbra. Attention is also directed toward preventing the common complications of bedridden patients—infections (pneumonia, urinary, and skin) and deep-venous thrombosis (DVT) with pulmonary embolism. Subcutaneous heparin (unfractionated and low-molecular-weight) is safe and can be used concomitantly. Use of pneumatic compression stockings is of proven benefit in reducing risk of DVT and is a safe alternative to heparin.

Because collateral blood flow within the ischemic brain may be blood pressure dependent, there is controversy about whether blood pressure should be lowered acutely. Blood pressure should be reduced if it exceeds 220/120 mmHg, if there is malignant hypertension **(Chap. 288)** or concomitant myocardial ischemia, or if blood pressure is >185/110 mmHg and thrombolytic therapy is anticipated. When faced with the competing demands of myocardium and brain, lowering the heart rate with a β_1-adrenergic blocker (such as esmolol) can be a first step to decrease cardiac work and maintain blood pressure. Routine lowering of blood pressure below the limits listed above has the potential to worsen outcomes. Fever is detrimental and should be treated with antipyretics and surface cooling. Serum glucose should be monitored and kept <10.0 mmol/L (180 mg/dL), and above at least 3.3 mmol/L (60 mg/dL); a more intensive glucose control strategy does not improve outcome.

Between 5 and 10% of patients develop enough cerebral edema to cause obtundation and brain herniation. Edema peaks on the second or third day but can cause mass effect for ~10 days. The larger the infarct, the greater the likelihood that clinically significant edema will develop. Water restriction and IV mannitol

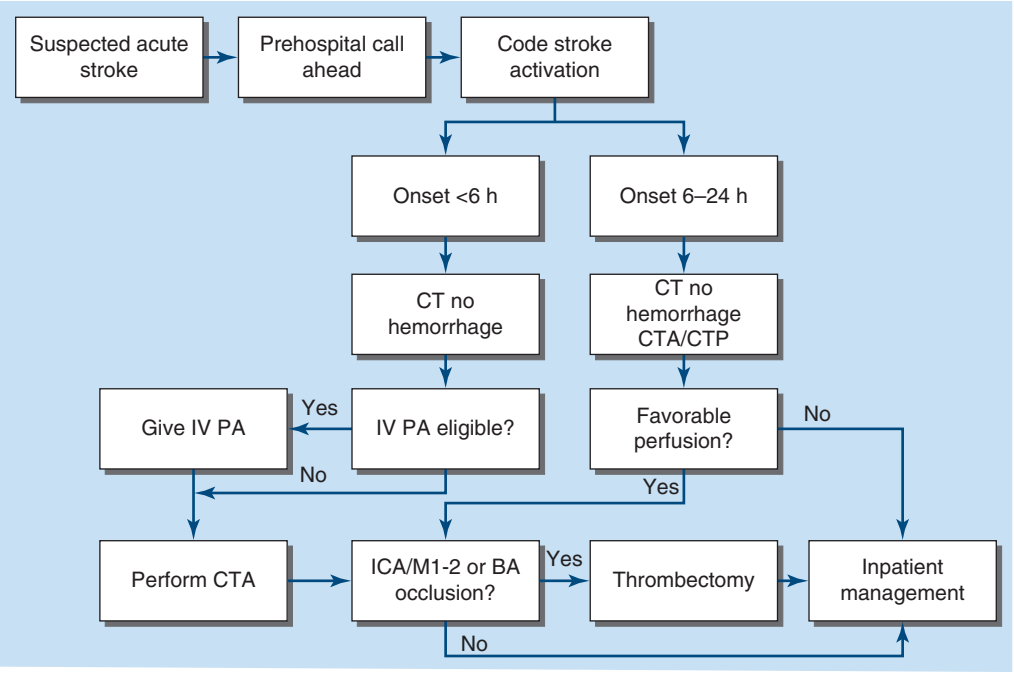

FIGURE 438-2 Management of acute stroke (pathway followed by the authors). For suspected stroke identified by prehospital professionals, we encourage calling ahead to the destination hospital. This allows early "stroke code" activation to prepare for an emergent computed tomography (CT) on arrival. For patients with onset <6 h from last time seen normal, we expedite a noncontrast head CT scan, and if free of hemorrhage and the patient is IV thrombolysis eligible (typically <4.5 h of last seen well time), this is administered in the CT scanner. (For IV tissue PA [tPA], the bolus is given and infusion initiated; for tenecteplase, the full dose is given as a bolus.) Then CT angiography (CTA) from left atrium to skull vertex is performed to identify an eligible target lesion for thrombectomy. For a patient presenting in the 6- to 24-h time window, thrombolysis is not considered, and the decision to perform thrombectomy is based on perfusion imaging.

Priorities of Acute Stroke Consultation: Once stroke is suspected, the first priorities are to assess airway and blood pressure, followed by establishing the time last seen normal. Patients with disabling neurologic deficits (particularly with National Institutes of Health Stroke Scale >5) may be eligible for thrombolytic and/or endovascular therapy. Based on the onset time, we follow the protocol shown in the figure. Following acute treatments, if any, we proceed with establishing the cause of the ischemic stroke. If atrial fibrillation is established or newly discovered, we favor use of apixaban 5 mg twice daily (or a reduced dose of 2.5 mg twice daily for impaired glomerular filtration rate) lifelong. If atrial fibrillation is not detected during the hospital encounter, we obtain an ambulatory electrocardiogram monitor to surveil for intermittent atrial fibrillation while treating with antiplatelet agents, then convert to oral anticoagulation if intermittent atrial fibrillation is detected. If we identify significant internal carotid stenosis, we refer for carotid endarterectomy during the same hospitalization regardless of infarct size. For all else, we use the dual antiplatelet agents aspirin (81 mg) and either clopidogrel (600 mg-load, followed by 75 mg daily) or ticagrelor (180-mg load, followed by 90 mg twice daily) daily for 21–30 days then continue aspirin at 81 mg daily. Ticagrelor has the advantage of not being affected by common polymorphisms of CYP2C19 that limit efficacy of clopidogrel in significant proportions of patients, particularly those of Asian descent. If the CTA revealed significant intracranial atherosclerosis or other precranial vessel stenosis within the vascular territory of the infarct (lumen caliber reduced by >50%), we continue dual antiplatelet agents for at least 3 months and then convert to a single agent. Unless contraindicated, all patients receive a high-intensity statin such as atorvastatin 80 mg or rosuvastatin 40 mg, with goal low-density lipoprotein level of <70 mg/dL unless the stroke has a nonatherothrombotic cause. Patients who are statin intolerant can receive PCSK9 inhibitors. Blood pressure control should target systolic blood pressure <120 mmHg long term, but we allow permissive hypertension for the first few days or weeks to help with collateral flow to the brain. BA, basilar artery; CTP, computed tomography perfusion; ICA, internal carotid artery; IV, intravenous; M1, middle cerebral artery first division; M2, middle cerebral artery second division; PA, plasminogen activator (tissue plasminogen activator or tenecteplase).

or hypertonic saline may be used to raise the serum osmolarity, but hypovolemia should be avoided because this may contribute to hypotension and worsening infarction. Combined analysis of three randomized European trials of hemicraniectomy (craniotomy and temporary removal of part of the skull) shows that hemicraniectomy reduces mortality by 50%, and the clinical outcomes of survivors are significantly improved. Older patients (age >60 years) benefit less but still significantly. The size of the diffusion-weighted imaging volume of brain infarction during the acute stroke is a predictor of future deterioration requiring hemicraniectomy.

Special vigilance is warranted for patients with cerebellar infarction. These strokes may mimic labyrinthitis because of prominent vertigo and vomiting; the presence of head or neck pain should alert the physician to consider cerebellar stroke due to vertebral artery dissection. Even small amounts of cerebellar edema can acutely increase intracranial pressure (ICP) by obstructing cerebrospinal fluid (CSF) flow leading to hydrocephalus or by directly compressing the brainstem. The resulting brainstem compression can manifest as coma and respiratory arrest and require emergency surgical decompression. Suboccipital decompression is recommended in patients with cerebellar infarcts who demonstrate neurologic deterioration and should be performed before significant brainstem compression occurs.

INTRAVENOUS THROMBOLYSIS

The National Institute of Neurological Disorders and Stroke (NINDS) Recombinant Tissue Plasminogen Activator (rtPA) Stroke Study showed a clear benefit for IV rtPA in selected patients with acute stroke. The NINDS study used IV rtPA (0.9 mg/kg to a 90-mg maximum; 10% as a bolus, then the remainder over 60 min) versus placebo in ischemic stroke within 3 h of onset. One-half of the patients were treated within 90 min. Symptomatic intracranial hemorrhage occurred in 6.4% of patients on rtPA and 0.6% on placebo. In the rtPA group, there was a significant 12% absolute increase in the number of patients with only minimal disability (32% on placebo and 44% on rtPA) and a nonsignificant 4% reduction in mortality (21% on placebo and 17% on rtPA). Thus, despite an increased incidence of symptomatic intracranial hemorrhage, treatment with IV rtPA within 3 h of the onset of ischemic stroke improved clinical outcome.

Three subsequent trials of IV rtPA did not confirm this benefit, perhaps because of the dose of rtPA used, the timing of its delivery, and small sample size. When data from all randomized IV rtPA trials were combined, however, efficacy was confirmed in the <3-h time window, and efficacy likely extended to 4.5 h and possibly to 6 h. Based on these combined results, the European Cooperative Acute Stroke Study (ECASS) III explored the safety and efficacy of rtPA in the 3- to 4.5-h time window. Unlike the NINDS study, patients aged >80 years and diabetic patients with a previous stroke were excluded. In this 821-patient randomized study, efficacy was again confirmed, although the treatment effect was less robust than in the 0- to 3-h time window. In the rtPA group, 52.4% of patients achieved a good outcome at 90 days, compared to 45.2% of the placebo group (odds ratio [OR] 1.34, $p = .04$). The symptomatic intracranial hemorrhage rate was 2.4% in the rtPA group and 0.2% in the placebo group ($p = .008$).

Based on these data, rtPA is approved in the 3- to 4.5-h window in Europe and Canada but is only approved for 0–3 h in the United States. A dose of 0.6 mg/kg is typically used in Japan and other Asian countries based on observation of >600 patients given this lower dose and observing similar outcomes to historical controls and a lower rate of intracranial hemorrhage. This dose also mitigates concerns that patients of Asian descent have a higher propensity to bleed from most antithrombotic and thrombolytic medications. The infrastructure to efficiently administer IV rtPA to eligible patients is a central component of primary stroke centers (see below). It represents the first treatment proven to improve clinical outcomes in ischemic stroke and is cost-effective and cost-saving. The time of stroke onset is defined as the time the patient's symptoms were witnessed to begin or the time the patient was last seen as normal. Patients who awaken with stroke have the onset defined as when they went to bed. Advanced neuroimaging techniques **(see Chap. 437)** may help to select patients beyond the 4.5-h window who will benefit from thrombolysis. Two trials using MRI selection beyond 4.5 h have shown clinical benefit from IV rtPA. Patients with minor stroke (nondisabling deficit and National Institutes of Health Stroke Scale [NIHSS] 0–5) appear to respond to acute aspirin or short-term dual antiplatelet therapy using the combination of aspirin and clopidogrel as well as IV rtPA. **Table 438-1** summarizes eligibility criteria and instructions for administration of IV rtPA.

TABLE 438-1 Administration of Intravenous Recombinant Tissue Plasminogen Activator (rtPA) or Tenecteplase for Acute Ischemic Stroke (AIS)[a]

INDICATION	CONTRAINDICATION
Clinical diagnosis of stroke	Sustained BP >185/110 mmHg despite treatment
Onset of symptoms to time of drug administration ≤4.5 h[b]	Bleeding diathesis
CT scan showing no hemorrhage, and no edema > 1/3 of the MCA territory	Recent head injury or intracerebral hemorrhage
Age ≥18 years	Major surgery in preceding 14 days
	Gastrointestinal bleeding in preceding 21 days
	Recent myocardial infarction
Administration of stroke thrombolysis	
IV access with two peripheral IV lines (avoid arterial or central line placement)	
Review eligibility for stroke thrombolysis	
Administer 0.9 mg/kg IV (maximum 90 mg) rtPA IV as 10% of total dose by bolus, followed by remainder of total dose over 1 h[c]	
Or Administer 0.25 mg/kg IV (maximum 25 mg) tenecteplase IV push over 5 s[d]	
Frequent cuff BP monitoring	
No other antithrombotic treatment for 24 h	
For decline in neurologic status or uncontrolled BP, stop infusion, give cryoprecipitate, and reimage brain emergently	
Avoid urethral catheterization for ≥2 h	

[a]See Activase (tissue plasminogen activator) package insert for complete list of contraindications and dosing. [b]Depending on the country, IV rtPA may be approved for up to 4.5 h with additional restrictions. [c]An rtPA dose of 0.6 mg/kg is commonly used in Asia (Japan and China) based on randomized data indicating less hemorrhage and similar efficacy using this lower dose. [d]Use of tenecteplase for acute ischemic stroke is off-label.

Abbreviations: BP, blood pressure; CT, computed tomography; MCA, middle cerebral artery.

The plasminogen activator tenecteplase (0.25 mg/kg IV bolus over 5 s with a maximum dose of 25 mg) has been directly compared to rtPA and is being adopted by many centers because it is given without need for a 1-h infusion. This improves the efficiency of transferring patients to comprehensive stroke centers for thrombectomy because the IV infusion required for IV rtPA is not required for tenecteplase, thus obviating need for critical care transport. Several trials using tenecteplase prior to endovascular therapy have found it to be safe.

ENDOVASCULAR REVASCULARIZATION

Ischemic stroke from large-vessel intracranial occlusion results in high rates of mortality and morbidity. Occlusions in such large vessels (middle cerebral artery [MCA], intracranial internal carotid artery, and the basilar artery) generally involve a large clot burden and often fail to open with IV thrombolysis alone.

Endovascular mechanical thrombectomy has been studied as an alternative or adjunctive treatment of acute stroke in patients who are ineligible for, or have contraindications to, thrombolytics or in those who failed to achieve vascular recanalization with IV thrombolytics **(Fig. 438-3)**. In 2015, the results of six randomized trials were published, all demonstrating that endovascular therapy improved clinical outcomes for internal carotid and MCA occlusions proven by CT angiography (CTA), under 6 h from stroke

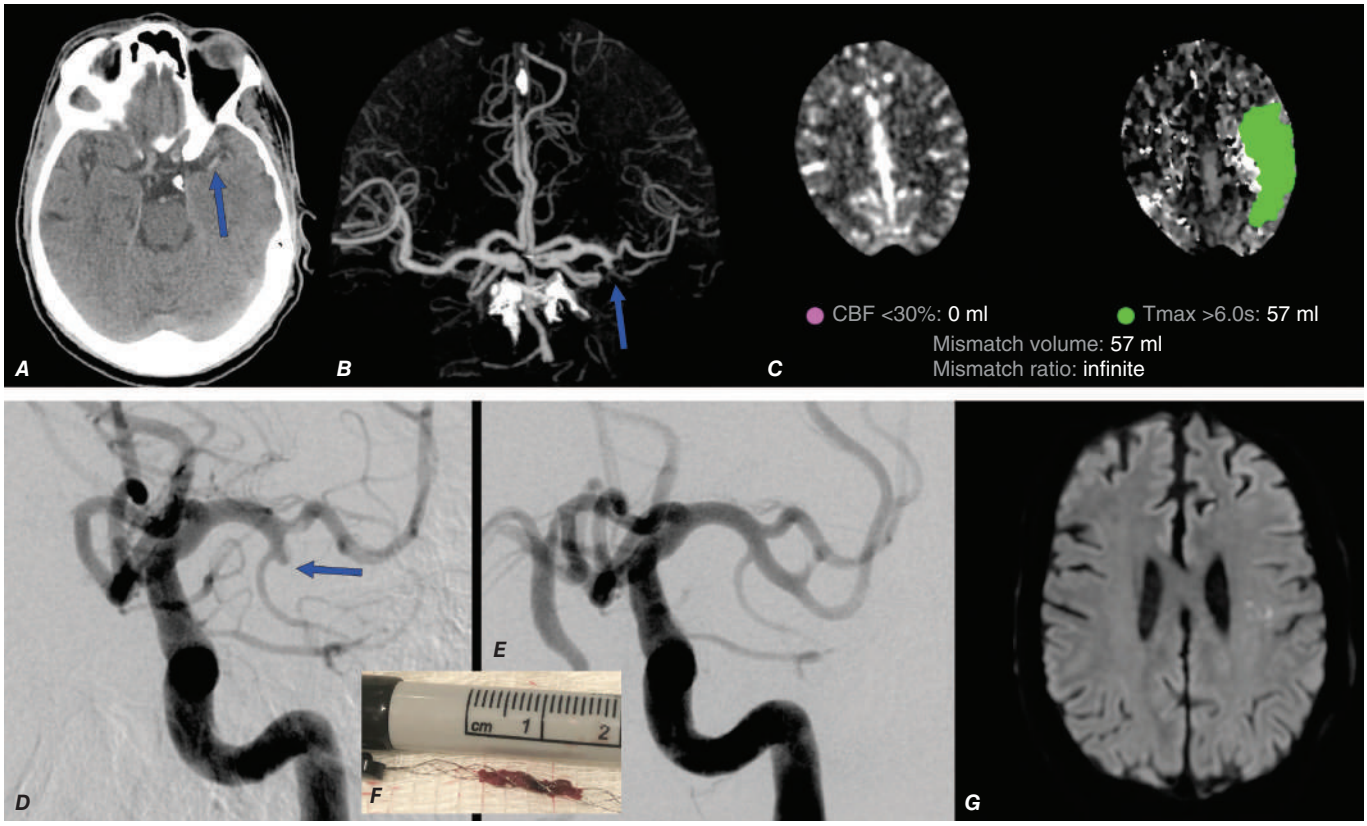

FIGURE 438-3 (***A***) Noncontrast head computed tomography (CT) scan of a 78-year-old man with atrial fibrillation and hypertension who was not taking oral anticoagulants and awoke with right hemiparesis and expressive aphasia. The head CT shows no intracerebral hemorrhage. He was not treated with plasminogen activators because his last seen normal time was 8 h prior. Head CT also shows hyperdensity in the left middle cerebral artery (MCA, *arrow*); this finding is highly specific for MCA occlusion but is poorly sensitive, as only 20% of patients with MCA occlusion show hyperdensity. (***B***) To confirm a large-vessel occlusion, CT angiography (CTA) performed in the same session reveals an occlusion of a secondary branch of the left MCA (*arrow*). (***C***) CT perfusion performed immediately following the CTA shows no core infarct (no pink signal in the left image) but a large region (green shading in the right image) of ischemic tissue that will die if revascularization is not achieved. (***D***) Catheter angiography shows the occluded branch of the left MCA (*arrow*) and (***E***) restored flow after successful clot removal (***F***). (***G***) A subsequent diffusion-weighted imaging scan shows a very small residual brain infarction. CBF, cerebral blood flow.

onset, with or without pretreatment with IV tissue plasminogen activator (tPA). One study concluded that patients were home nearly 2 months earlier if they received endovascular therapy. A combined meta-analysis of all patients in these trials confirmed a large benefit with endovascular therapy (OR, 2.49; 95% confidence interval [CI], 1.76–3.53; p <.001). The percentage of patients who achieved modified Rankin scores of 0–2 (normal or symptomatic but independent) was 46% in the endovascular group and 26.5% in the medical arm. A more recent meta-analysis reveals a mortality benefit with thrombectomy as well. As with IV rtPA treatment, clinical outcome is dependent on time to effective therapy. The odds of a good outcome exceed 3 if groin puncture occurs within 2 h of symptom onset but is only 2 if 8 h elapse. Over 80% of patients who had vessel opening within 1 h of arrival to the emergency department had a good outcome, whereas only one-third had a good outcome if 6 h elapsed.

The outcomes from endovascular therapy are likely improved with IV rtPA treatment prior to thrombectomy if the patient is eligible for rtPA and it is safe to administer. Recent data support replacing IV rtPA with IV tenecteplase because its simple bolus administration makes transporting the patient to an endovascular center less cumbersome.

Extending the time window beyond 6 h appears to be effective if the patient has specific imaging findings demonstrating good vascular collaterals (CT perfusion or magnetic resonance [MR] perfusion techniques, see Chap. 437) and can be treated within 24 h. The Clinical Mismatch in the Triage of Wake Up and Late Presenting Strokes Undergoing Neurointervention with Trevo (DAWN) trial reported good outcomes more frequently with endovascular therapy than with medical care alone (47 vs 13%, p <.0001). The Endovascular Therapy Following Imaging Evaluation for Ischemic Stroke 3 (DEFUSE-3) trial confirmed these results (45 vs 17%, p <.001) if treated up to 16 h from stroke onset. Nonrandomized data of thrombectomy for basilar occlusion have found this treatment to be safe up to 24 h from symptom onset and associated with lower 3-month Rankin scores. An example of how advanced imaging techniques (CT, CTA, CT perfusion, catheter-based angiography), endovascular thrombectomy with clot removal, and follow-up MRI can lead to a better than predicted stroke outcome is shown in Fig 438-3.

Now that endovascular stroke therapy is proven to be effective, the creation of comprehensive stroke centers designed to rapidly identify and treat patients with large-vessel cerebral ischemia has been a major focus internationally. Creating regional systems of care whereby stroke patients are first evaluated at acute stroke ready hospitals or primary stroke centers (which can administer IV rtPA or tenecteplase) then transferred to thrombectomy-capable or comprehensive stroke centers if needed, or directly triaged to thrombectomy-capable or comprehensive centers based on field assessment, appears to be an effective strategy to improve outcomes.

ANTITHROMBOTIC TREATMENT

Platelet Inhibition Aspirin is the only antiplatelet agent that has been proven to be effective for the acute treatment of ischemic stroke; there are several antiplatelet agents proven for the secondary prevention of stroke (see below). Two large trials, the International Stroke Trial (IST) and the Chinese Acute Stroke Trial (CAST), found that the use of aspirin within 48 h of stroke onset reduced both stroke recurrence risk and mortality minimally. Among 19,435 patients in IST, those allocated to aspirin, 300 mg/d, had slightly fewer deaths within 14 days (9.0 vs 9.4%), significantly fewer recurrent ischemic strokes (2.8 vs 3.9%), no excess of hemorrhagic strokes (0.9 vs 0.8%), and a trend toward a reduction in death or dependence at 6 months (61.2 vs 63.5%). In CAST, 21,106 patients

with ischemic stroke received 160 mg/d of aspirin or a placebo for up to 4 weeks. In the aspirin group, there were very small reductions in early mortality (3.3 vs 3.9%), recurrent ischemic strokes (1.6 vs 2.1%), and dependency at discharge or death (30.5 vs 31.6%). These trials demonstrate that the use of aspirin in the treatment of acute ischemic stroke is safe and produces a small net benefit. For every 1000 acute strokes treated with aspirin, ~9 deaths or nonfatal stroke recurrences will be prevented in the first few weeks, and ~13 fewer patients will be dead or dependent at 6 months. The short-term combination of aspirin with clopidogrel or with ticagrelor following minor stroke or TIA is effective at preventing early second stroke (see below).

Anticoagulation Numerous clinical trials have failed to demonstrate any benefit of routine anticoagulation in the primary treatment of atherothrombotic cerebral ischemia and have also shown an increase in the risk of brain and systemic hemorrhage. Therefore, the routine use of heparin or other anticoagulants for patients with atherothrombotic stroke is not warranted. Heparin and oral anticoagulation are likely no more effective than aspirin for stroke associated with arterial dissection. However, there may be benefit of anticoagulation for halting progression of dural sinus thrombosis.

NEUROPROTECTION

Neuroprotection is the concept of providing a treatment that prolongs the brain's tolerance to ischemia. Drugs that block the excitatory amino acid pathways have been shown to protect neurons and glia in animals, but despite multiple clinical trials, they have not yet been proven to be beneficial in humans. Hypothermia is a powerful neuroprotective treatment in patients with cardiac arrest **(Chap. 318)** and is neuroprotective in animal models of stroke, but it has not been adequately studied in patients with ischemic stroke and is associated with an increase in pneumonia rates that could adversely impact stroke outcomes. Hypothermia combined with hemicraniectomy is no more effective than hemicraniectomy with euthermia.

STROKE CENTERS AND REHABILITATION

Patient care in stroke units followed by rehabilitation services improves neurologic outcomes and reduces mortality. Use of clinical pathways and staff dedicated to the stroke patient can improve care. This includes use of standardized stroke order sets. Stroke teams that provide emergency 24-h evaluation of acute stroke patients for acute medical management and consideration of thrombolysis or endovascular treatments, potentially provided using telemedicine/telestroke services, are essential components of primary and comprehensive stroke centers, respectively.

Proper rehabilitation of the stroke patient includes early physical, occupational, and speech therapy. It is directed toward educating the patient and family about the patient's neurologic deficit, preventing the complications of immobility (e.g., pneumonia, DVT and pulmonary embolism, pressure sores of the skin, and muscle contractures), and providing encouragement and instruction in overcoming the deficit. Use of pneumatic compression stockings is of proven benefit in reducing risk of DVT and is a safe alternative to heparin. The goal of rehabilitation is to return the patient home and to maximize recovery by providing a safe, progressive regimen suited to the individual patient. Additionally, the use of constrained movement therapy (immobilizing the unaffected side) has been shown to improve hemiparesis following stroke, even years after the stroke, suggesting that physical therapy can recruit unused neural pathways. Controversy exists regarding whether selective serotonin uptake inhibitors improve motor recovery, but they may be helpful in preventing poststroke depression. Newer robotic therapies and neuromodulation approaches using transcranial magnetic stimulation or transcranial direct current stimulation are under active investigation **(Chap. 500)**. The human nervous system is more adaptable than previously thought, and developing physical and pharmacologic strategies to enhance long-term neural recovery are the subject of ongoing research.

ETIOLOGY OF ISCHEMIC STROKE

(Fig. 438-4 and Table 438-2) Although the initial management of acute ischemic stroke often does not depend on the etiology, establishing a cause is essential to reduce the risk of recurrence. Focus should be on atrial fibrillation and carotid atherosclerosis, because these etiologies

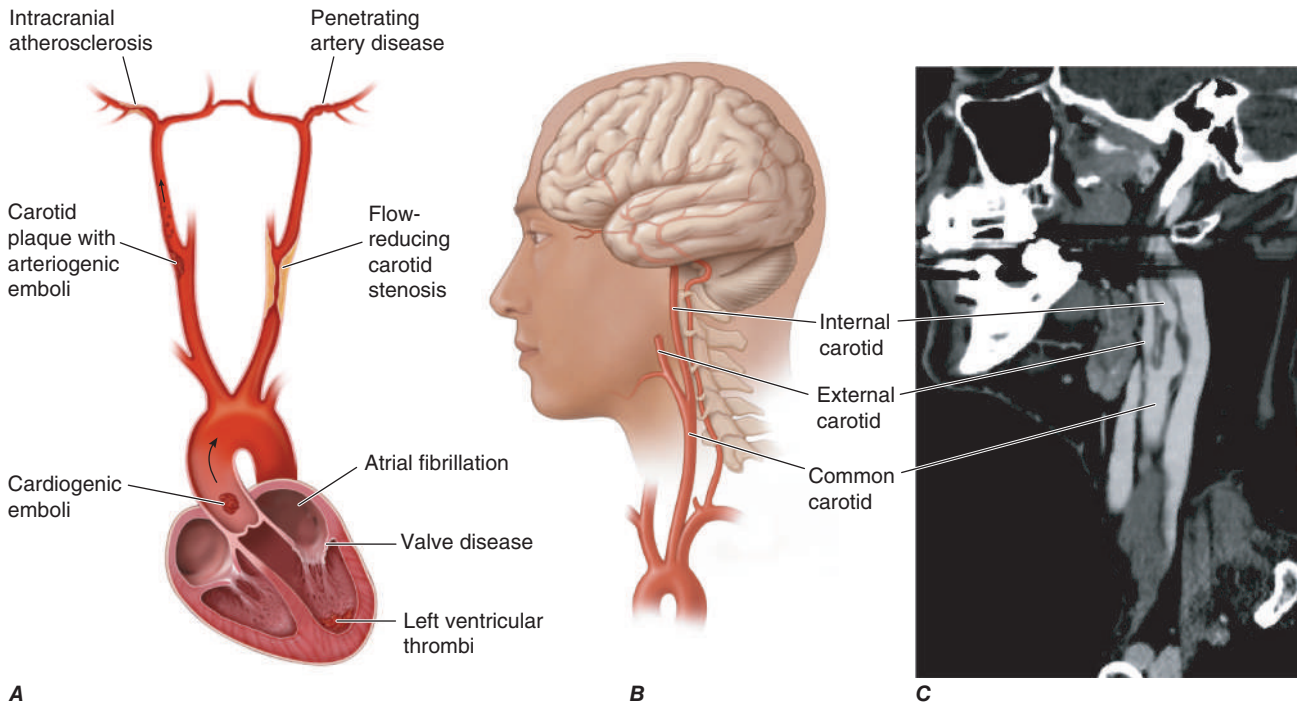

FIGURE 438-4 Pathophysiology of ischemic stroke. ***A.*** Diagram illustrating the three major mechanisms that underlie ischemic stroke: (1) occlusion of an intracranial vessel by an embolus (e.g., cardiogenic sources such as atrial fibrillation or artery-to-artery emboli from carotid atherosclerotic plaque), often affecting the large intracranial vessels; (2) in situ thrombosis of an intracranial vessel, typically affecting the small penetrating arteries that arise from the major intracranial arteries; and (3) hypoperfusion caused by flow-limiting stenosis of a major extracranial (e.g., internal carotid) or intracranial vessel, often producing "watershed" ischemia. ***B.*** and ***C.*** Diagram and reformatted computed tomography angiogram of the common, internal, and external carotid arteries. High-grade stenosis of the internal carotid artery, which may be associated with either cerebral emboli or flow-limiting ischemia, was identified in this patient.

TABLE 438-2 Causes of Ischemic Stroke

COMMON CAUSES	UNCOMMON CAUSES
Thrombosis	Hypercoagulable disorders
Lacunar stroke (small vessel)	Protein C deficiency[a]
Large-vessel thrombosis	Protein S deficiency[a]
Dehydration	Antithrombin III deficiency[a]
Embolic occlusion	Antiphospholipid syndrome
Artery-to-artery	Factor V Leiden mutation[a]
Carotid bifurcation	Prothrombin G20210A mutation[a]
Aortic arch	Systemic malignancy
Arterial dissection	Sickle cell anemia
Cardioembolic	β Thalassemia
Atrial fibrillation	Polycythemia vera
Mural thrombus	Systemic lupus erythematosus
Myocardial infarction	Homocysteinemia
Dilated cardiomyopathy	Thrombotic thrombocytopenic purpura
Valvular lesions	Disseminated intravascular coagulation
Mitral stenosis	Dysproteinemias[a]
Mechanical valve	Nephrotic syndrome[a]
Bacterial endocarditis	Inflammatory bowel disease[a]
Paradoxical embolus	Oral contraceptives
Atrial septal defect	COVID-19 infection
Patent foramen ovale	Venous sinus thrombosis[b]
Atrial septal aneurysm	Fibromuscular dysplasia
Spontaneous echo contrast	Vasculitis
Stimulant drugs: cocaine, amphetamine	Systemic vasculitis (PAN, granulomatosis with polyangiitis, Takayasu's, giant cell arteritis)
	Primary CNS vasculitis
	Meningitis (syphilis, tuberculosis, fungal, bacterial, zoster)
	Noninflammatory vasculopathy
	Reversible vasoconstriction syndrome
	Fabry's disease
	Angiocentric lymphoma
	Cardiogenic
	Mitral valve calcification
	Atrial myxoma
	Intracardiac tumor
	Marantic endocarditis
	Libman-Sacks endocarditis
	Subarachnoid hemorrhage vasospasm
	Moyamoya disease
	Eclampsia

[a]Chiefly cause venous sinus thrombosis. [b]May be associated with any hypercoagulable disorder.

Abbreviations: CNS, central nervous system; PAN, polyarteritis nodosa.

have proven secondary prevention strategies. The clinical presentation and examination findings often establish the cause of stroke or narrow the possibilities to a few. Judicious use of laboratory testing and imaging studies completes the initial evaluation. Nevertheless, nearly 30% of strokes remain unexplained despite extensive evaluation.

Clinical examination should focus on the peripheral and cervical vascular system (measuring blood pressure), the heart (dysrhythmia, murmurs), extremities (peripheral emboli), and retina (effects of hypertension and cholesterol emboli [Hollenhorst plaques]). A complete neurologic examination is performed to localize the anatomic site of stroke **(Chap. 437)**. An imaging study of the brain is nearly always indicated and is required for patients being considered for thrombolysis; it may be combined with CT- or MRI-based angiography to visualize the vasculature of the neck and intracranial vessels **(see "Imaging Studies," Chap. 437)**. A chest x-ray, electrocardiogram (ECG), urinalysis, complete blood count, erythrocyte sedimentation rate (ESR), serum electrolytes, blood urea nitrogen (BUN), creatinine, blood glucose, serum lipid profile, prothrombin time (PT), and partial thromboplastin time (PTT) are often useful and should be considered in all patients. An ECG, and subsequent cardiac telemetry, may demonstrate arrhythmias or reveal evidence of recent myocardial infarction (MI). Of all these studies, only brain imaging and finger stick blood glucose are necessary prior to IV thrombolysis; the results of other studies should not delay the rapid administration of IV thrombolysis if the patient is eligible.

Cardioembolic Stroke Cardioembolism is responsible for ~20% of all ischemic strokes. Stroke caused by heart disease is primarily due to embolism of thrombotic material forming on the atrial or ventricular wall or the left heart valves. These thrombi then detach and embolize into the arterial circulation. The thrombus may fragment or lyse quickly, producing only a TIA. Alternatively, the arterial occlusion may last longer, producing stroke. Embolic strokes tend to occur suddenly with maximum neurologic deficit present at onset. With reperfusion following more prolonged ischemia, petechial hemorrhages can occur within the ischemic territory. These are usually of no clinical significance and should be distinguished from frank intracranial hemorrhage into a region of ischemic stroke where the mass effect from the hemorrhage can cause a significant decline in neurologic function.

Emboli from the heart most often lodge in the intracranial internal carotid artery, the MCA, the posterior cerebral artery (PCA), or one of their branches; infrequently, the anterior cerebral artery (ACA) is involved. Emboli large enough to occlude the stem of the MCA (3–4 mm) or internal carotid terminus lead to large infarcts that involve both deep gray and white matter and some portions of the cortical surface and its underlying white matter. A smaller embolus may occlude a small cortical or penetrating arterial branch. The location and size of an infarct within a vascular territory depend on the extent of the collateral circulation.

The most significant cause of cardioembolic stroke in most of the world is nonrheumatic (often called nonvalvular) atrial fibrillation. MI, prosthetic valves, rheumatic heart disease, and ischemic cardiomyopathy are other considerations (Table 438-2). Cardiac disorders causing brain embolism are discussed in the chapters on heart diseases, but a few pertinent aspects are highlighted here.

Nonrheumatic atrial fibrillation is the most common cause of cerebral embolism overall. The presumed stroke mechanism is thrombus formation in the fibrillating atrium or atrial appendage, with subsequent embolization. Patients with atrial fibrillation have an average annual risk of stroke of ~5%. The risk of stroke can be estimated by calculating the CHA_2DS_2-VASc score **(Table 438-3)**. Left atrial enlargement is an additional risk factor for formation of atrial thrombi. Rheumatic heart disease usually causes ischemic stroke when there is prominent mitral stenosis or atrial fibrillation. Recent MI may be a source of emboli, especially when transmural and involving the anteroapical ventricular wall, and prophylactic anticoagulation following MI with left ventricular thrombus has been shown to reduce ischemic stroke risk. Mitral valve prolapse is not usually a source of emboli unless the prolapse is severe.

Paradoxical embolization occurs when venous thrombi migrate to the arterial circulation, usually via a patent foramen ovale (PFO) or atrial septal defect. Bubble-contrast echocardiography (IV injection of agitated saline coupled with either transthoracic or transesophageal echocardiography) can demonstrate a right-to-left cardiac shunt, revealing the conduit for paradoxical embolization. Alternatively, a right-to-left shunt is implied if immediately following IV injection of agitated saline, the ultrasound signature of bubbles is observed during transcranial Doppler insonation of the MCA; pulmonary arteriovenous malformations should be considered if this test is positive yet an echocardiogram fails to reveal an intracardiac shunt. Both techniques are highly sensitive for detection of right-to-left shunts. Besides venous clot, fat and tumor emboli, bacterial endocarditis, IV air, and amniotic fluid emboli at childbirth may occasionally be responsible for paradoxical embolization. The importance of a PFO as a cause of stroke is debated, particularly because they are present in ~15% of the general population. The presence of a venous source of embolus,

TABLE 438-3 Recommendations on Chronic Use of Antithrombotics for Various Cardiac Conditions

CONDITION	RECOMMENDATION
Nonvalvular atrial fibrillation	Calculate CHA_2DS_2-VASc score[a]
• CHA_2DS_2-VASc score of 0	Aspirin or no antithrombotic
• CHA_2DS_2-VASc score of 1	Aspirin or OAC
• CHA_2DS_2-VASc score of ≥2	OAC
Rheumatic mitral valve disease	
• With atrial fibrillation, previous embolization, or atrial appendage thrombus, or left atrial diameter >55 mm	OAC
• Embolization or appendage clot despite OAC	OAC plus aspirin
• Mitral valve prolapse	
• Asymptomatic	No therapy
• With otherwise cryptogenic stroke or TIA	Aspirin
• Atrial fibrillation	OAC
Mitral annular calcification	
• Without atrial fibrillation but systemic embolization, or otherwise cryptogenic stroke or TIA	Aspirin
• Recurrent embolization despite aspirin	OAC
• With atrial fibrillation	OAC
Aortic valve calcification	
• Asymptomatic	No therapy
• Otherwise cryptogenic stroke or TIA	Aspirin
Aortic arch mobile atheroma	
• Otherwise cryptogenic stroke or TIA	Aspirin or OAC
Patent foramen ovale	
• Otherwise cryptogenic ischemic stroke or TIA	Aspirin or closure with device
• Indication for OAC (deep-venous thrombosis or hypercoagulable state)	OAC
Mechanical heart value	
• Aortic position, bileaflet or Medtronic Hall tilting disk with normal left atrial size and sinus rhythm	VKA INR 2.5, range 2–3
• Mitral position tilting disk or bileaflet valve	VKA INR 3.0, range 2.5–3.5
• Mitral or aortic position, anterior-apical myocardial infarct or left atrial enlargement	VKA INR 3.0, range 2.5–3.5
• Mitral or aortic position, with atrial fibrillation, or hypercoagulable state, or low ejection fraction, or atherosclerotic vascular disease	Aspirin plus VKA INR 3.0, range 2.5–3.5
• Systemic embolization despite target INR	Add aspirin and/or increase INR: prior target was 2.5, increase to 3.0, range 2.5–3.5; prior target was 3.0, increase to 3.5, range 3–4
Bioprosthetic valve	
• No other indication for VKA therapy	Aspirin
Infective endocarditis	Avoid antithrombotic agents
Nonbacterial thrombotic endocarditis	
• With systemic embolization	Full-dose, unfractionated heparin or SC LMWH, or Xa inhibitor

[a]CHA_2DS_2-VASc score is calculated as follows: 1 point for congestive heart failure, 1 point for hypertension, 2 points for age ≥75 years, 1 point for diabetes mellitus, 2 points for stroke or TIA, 1 point for vascular disease (prior myocardial infarction, peripheral vascular disease, or aortic plaque), 1 point for age 65–74 years, 1 point for female sex category; sum of points is the total CHA_2DS_2-VASc score.

Note: Dose of aspirin is 50–325 mg/d; target INR for VKA is between 2 and 3 unless otherwise specified.

Abbreviations: INR, international normalized ratio; LMWH, low-molecular-weight heparin; OAC, oral anticoagulant (VKA, thrombin inhibitor, or oral factor Xa inhibitors); TIA, transient ischemic attack; VKA, vitamin K antagonist.

Sources: Data from DE Singer et al: Chest 133:546S, 2008; DN Salem et al: Chest 133:593S, 2008; CT January et al: JACC 64:2246, 2014.

most commonly a deep-venous thrombus, may provide confirmation of the importance of a PFO with an accompanying right-to-left shunt in a particular case. Meta-analysis of three recent randomized trials reported a hazard ratio of 0.41 for recurrent stroke (about a 1% per year absolute reduction) using percutaneous occlusion devices in patients with larger PFOs and no other explanation for their stroke. Guidelines now endorse PFO closure with percutaneous devices after consultation with a neurologist and a cardiologist.

Bacterial endocarditis can be a source of valvular vegetations that give rise to septic emboli. The appearance of multifocal symptoms and signs in a patient with stroke makes bacterial endocarditis more likely. Infarcts of microscopic size occur, and large septic infarcts may evolve into brain abscesses or cause hemorrhage into the infarct, which generally precludes use of anticoagulation or thrombolytics. Mycotic aneurysms caused by septic emboli may also present as subarachnoid hemorrhage (SAH) or intracerebral hemorrhage.

Artery-to-Artery Embolic Stroke Thrombus formation on atherosclerotic plaques may embolize to intracranial arteries producing an artery-to-artery embolic stroke. Less commonly, a diseased vessel may acutely thrombose. Unlike the myocardial vessels, artery-to-artery embolism, rather than local thrombosis, appears to be the dominant vascular mechanism causing large-vessel brain ischemia. Any diseased vessel may be an embolic source, including the aortic arch, common carotid, internal carotid, vertebral, and basilar arteries.

CAROTID ATHEROSCLEROSIS Atherosclerosis within the carotid artery occurs most frequently within the common carotid bifurcation and proximal internal carotid artery; the carotid siphon (portion within the cavernous sinus) is also vulnerable to atherosclerosis. Male gender, older age, smoking, hypertension, diabetes, and hypercholesterolemia are risk factors for carotid disease, as they are for stroke in general **(Table 438-4)**. Carotid atherosclerosis produces an estimated 10% of ischemic stroke. **For further discussion of the pathogenesis of atherosclerosis, see Chap. 244.**

Carotid disease can be classified by whether the stenosis is symptomatic or asymptomatic and by the degree of stenosis (percent narrowing of the narrowest segment compared to a nondiseased segment). Symptomatic carotid disease implies that the patient has experienced a recent (within 6 months) stroke or TIA within the vascular distribution of the artery, and it is associated with a greater risk of subsequent stroke than asymptomatic stenosis, in which the patient is symptom free and the stenosis is detected through screening. Greater degrees of arterial narrowing are generally associated with a higher risk of stroke, except that those with near occlusions are at lower risk of stroke.

OTHER CAUSES OF ARTERY-TO-ARTERY EMBOLIC STROKE *Intracranial atherosclerosis* produces stroke either by an embolic mechanism or by in situ thrombosis of a diseased vessel. It is more common in patients of Asian and African-American descent. Recurrent stroke risk is ~15% per year, similar to untreated symptomatic carotid atherosclerosis.

Dissection of the internal carotid or vertebral arteries or even vessels beyond the circle of Willis is a common source of embolic stroke in young (age <60 years) patients. The dissection is usually painful and precedes the stroke by several hours or days. Extracranial dissections do not cause hemorrhage, presumably because of the tough adventitia of these vessels. Intracranial dissections, conversely, may produce SAH because the adventitia of intracranial vessels is thin and pseudoaneurysms may form, requiring urgent treatment to prevent rerupture. Treating asymptomatic pseudoaneurysms following extracranial dissection is likely not necessary. The cause of dissection is usually unknown, and recurrence is rare. Ehlers-Danlos type IV, Marfan's disease and related disorders of connective tissue **(Chap. 425)**, and fibromuscular dysplasia **(Chap. 292)** are associated with dissections. Trauma (usually a motor vehicle accident or a sports injury) can cause carotid and vertebral artery dissections. Spinal manipulative therapy is associated with vertebral artery dissection and stroke. Most dissections heal spontaneously, and stroke or TIA is uncommon beyond 2 weeks. One trial showed no difference in stroke prevention with antiplatelet regimens compared to anticoagulation, with a low recurrent stroke rate of 2%.

TABLE 438-4 Risk Factors for Stroke

RISK FACTOR	RELATIVE RISK	RELATIVE RISK REDUCTION WITH TREATMENT	NUMBER NEEDED TO TREAT[a]	
			PRIMARY PREVENTION	SECONDARY PREVENTION
Hypertension	2–5	38%	100–300	50–100
Atrial fibrillation	1.8–2.9	68% warfarin, 21% aspirin	20–83	13
Diabetes	1.8–6	No proven effect		
Smoking	1.8	50% at 1 year, baseline risk at 5 years postcessation		
Hyperlipidemia	1.8–2.6	16–30%	560	230
Asymptomatic carotid stenosis	2.0	53%	85	N/A
Symptomatic carotid stenosis (70–99%)		65% at 2 years	N/A	12
Symptomatic carotid stenosis (50–69%)		29% at 5 years	N/A	77

[a]Number needed to treat to prevent one stroke annually. Prevention of other cardiovascular outcomes is not considered here.

Abbreviation: N/A, not applicable.

SMALL-VESSEL STROKE

The term *lacunar infarction* refers to infarction following atherothrombotic or lipohyalinotic occlusion of a small artery in the brain. The term *small-vessel stroke* denotes occlusion of such a small penetrating artery and is now the preferred term. Small-vessel strokes account for ~20% of all strokes.

Pathophysiology The MCA stem, the arteries comprising the circle of Willis (A1 segment, anterior and posterior communicating arteries, and P1 segment), and the basilar and vertebral arteries all give rise to 30- to 300-μm branches that penetrate the deep gray and white matter of the cerebrum or brainstem (Fig. 438-5). Each of these small branches can occlude either by atherothrombotic disease at its origin or by the development of lipohyalinotic thickening. Thrombosis of these vessels causes small infarcts that are referred to as *lacunes* (Latin for "lake" of fluid noted at autopsy). These infarcts range in size from 3 mm to 2 cm in diameter. Hypertension and age are the principal risk factors.

Clinical Manifestations The most common small-vessel stroke syndromes are the following: (1) *pure motor hemiparesis* from an infarct in the posterior limb of the internal capsule or the pons; the face, arm, and leg are almost always involved; (2) *pure sensory stroke* from an infarct in the ventral thalamus; (3) *ataxic hemiparesis* from an infarct in the ventral pons or internal capsule; (4) and *dysarthria and a clumsy hand* or arm due to infarction in the ventral pons or in the genu of the internal capsule.

Transient symptoms (small-vessel TIAs) may herald a small-vessel infarct; they may occur several times a day and last only a few minutes. Recovery from small-vessel strokes tends to be more rapid and complete than recovery from large-vessel strokes; in some cases, however, there is early worsening of symptoms or a stuttering course and severe permanent disability may result.

A large-vessel source (either thrombosis or embolism) may manifest initially as a small-vessel infarction. Therefore, the search for embolic sources (carotid and heart) should not be completely abandoned in the evaluation of these patients. Secondary prevention of small-vessel stroke involves risk factor modification, specifically reduction in blood pressure (see "Treatment: Primary and Secondary Prevention of Stroke and TIA," below).

LESS COMMON CAUSES OF STROKE

(Table 438-2) *Hypercoagulable disorders* (Chap. 69) primarily increase the risk of cortical vein or cerebral venous sinus thrombosis. Systemic

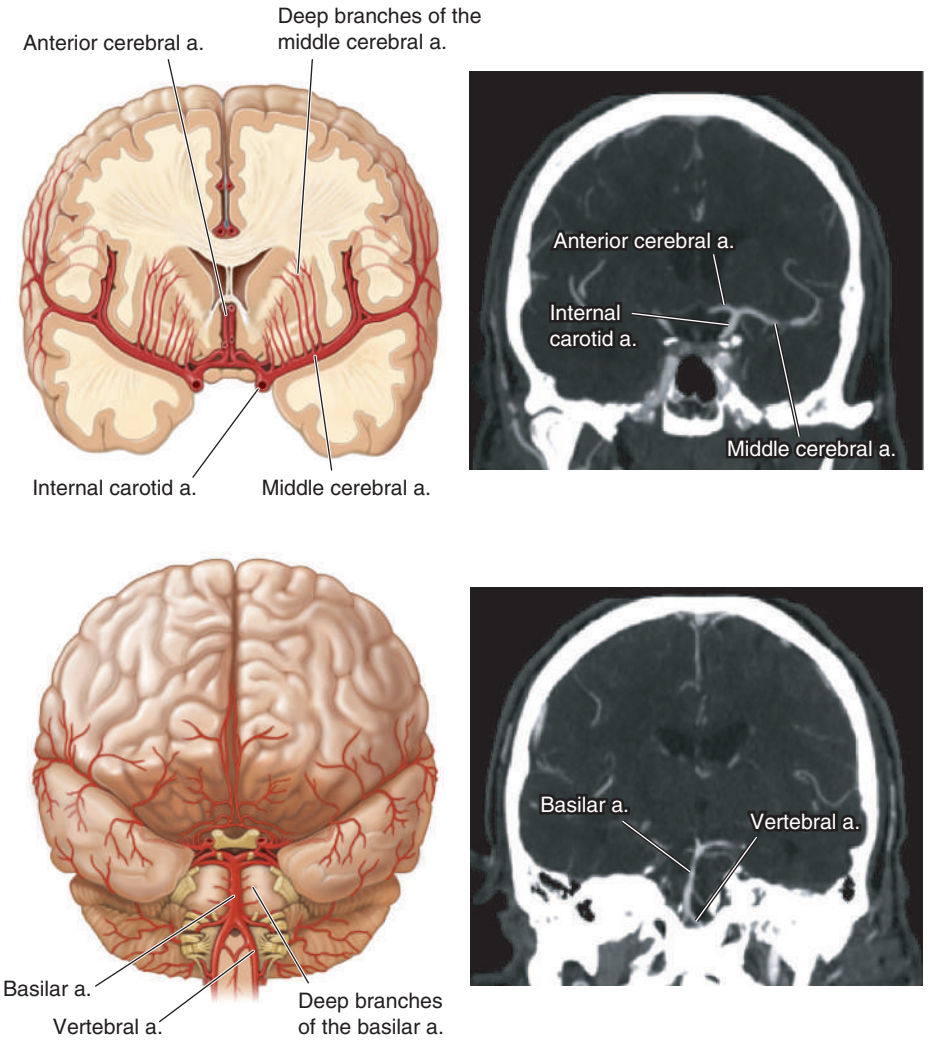

FIGURE 438-5 Diagrams and reformatted computed tomography (CT) angiograms in the coronal section illustrating the deep penetrating arteries involved in small-vessel strokes. In the anterior circulation, small penetrating arteries called *lenticulostriates* arise from the proximal portion of the anterior and middle cerebral arteries and supply deep subcortical structures (***upper panels***). In the posterior circulation, similar arteries arise directly from the vertebral and basilar arteries to supply the brainstem (***lower panels***). Occlusion of a single penetrating artery gives rise to a discrete area of infarct (pathologically termed a "lacune," or lake). Note that these vessels are too small to be visualized on CT angiography.

lupus erythematosus **(Chap. 368)** with Libman-Sacks endocarditis can be a cause of embolic stroke. These conditions overlap with the antiphospholipid syndrome **(Chap. 369)**, which probably requires long-term anticoagulation to prevent further stroke. Homocysteinemia may cause arterial thromboses as well; this disorder is caused by various mutations in the homocysteine pathways and responds to different forms of cobalamin depending on the mutation. Disseminated intravascular coagulopathy can cause both venous and arterial occlusive events; COVID-19 infection may predispose for acute ischemic stroke due to large-vessel occlusion.

Venous sinus thrombosis of the lateral or sagittal sinus or of small cortical veins (cortical vein thrombosis) occurs as a complication of oral contraceptive use, pregnancy and the postpartum period, inflammatory bowel disease, intracranial infections (meningitis), and dehydration. It is also seen in patients with laboratory-confirmed thrombophilia including antiphospholipid syndrome, polycythemia, sickle cell anemia, deficiencies of proteins C and S, factor V Leiden mutation (resistance to activated protein C), antithrombin III deficiency, homocysteinemia, and the prothrombin G20210A mutation. Women who take oral contraceptives and have the prothrombin G20210A mutation may be at particularly high risk for sinus thrombosis. Patients present with headache and may also have focal neurologic signs (especially paraparesis) and seizures. Often, CT imaging is normal unless an intracranial venous hemorrhage has occurred, but the venous sinus occlusion is readily visualized using MR or CT venography or conventional x-ray angiography. With greater degrees of sinus thrombosis, the patient may develop signs of increased ICP and coma. Intravenous heparin, regardless of the presence of intracranial hemorrhage, reduces morbidity and mortality, and the long-term outcome is generally good. Heparin prevents further thrombosis and reduces venous hypertension and ischemia. If an underlying hypercoagulable state is not found, many physicians treat with oral anticoagulants for 3–6 months and then convert to aspirin, depending on the degree of resolution of the venous sinus thrombus. Anticoagulation is often continued indefinitely if thrombophilia is diagnosed.

Sickle cell anemia (SS disease) is a common cause of stroke in children. A subset of homozygous carriers of this hemoglobin mutation develop stroke in childhood, and this may be predicted by documenting high-velocity blood flow within the MCAs using transcranial Doppler ultrasonography. In children who are identified to have high velocities, treatment with aggressive exchange transfusion dramatically reduces risk of stroke, and if exchange transfusion is ceased, their stroke rate increases again along with MCA velocities.

Fibromuscular dysplasia **(Chap. 292)** affects the cervical arteries and occurs mainly in women. The carotid or vertebral arteries show multiple rings of segmental narrowing alternating with dilatation. Vascular occlusion is usually incomplete. The process is often asymptomatic but occasionally is associated with an audible bruit, TIAs, or stroke. Involvement of the renal arteries is common and may cause hypertension. The cause and natural history of fibromuscular dysplasia are unknown. TIA or stroke generally occurs only when the artery is severely narrowed or dissects. Anticoagulation or antiplatelet therapy may be helpful.

Temporal (giant cell) arteritis **(Chap. 375)** is a relatively common affliction of elderly individuals in which the external carotid system, particularly the temporal arteries, undergoes subacute granulomatous inflammation with giant cells. Occlusion of posterior ciliary arteries derived from the ophthalmic artery results in blindness in one or both eyes and can be prevented with glucocorticoids. It rarely causes stroke because the internal carotid artery is usually not inflamed. Idiopathic giant cell arteritis involving the great vessels arising from the aortic arch (*Takayasu's arteritis*) may cause carotid or vertebral thrombosis; it is rare in the Western Hemisphere.

Necrotizing (or granulomatous) arteritis **(Chap. 375)**, occurring alone or in association with generalized polyarteritis nodosa or granulomatosis with polyangiitis, involves the distal small branches (<2 mm diameter) of the main intracranial arteries and produces small ischemic infarcts in the brain, optic nerve, and spinal cord. The CSF often shows pleocytosis, and the protein level is elevated. *Primary central nervous system vasculitis* is rare; small or medium-sized vessels are usually affected, without apparent systemic vasculitis. The differential diagnosis includes other inflammatory vasculopathies including infection (tuberculous, fungal), sarcoidosis, angiocentric lymphoma, carcinomatous meningitis, and noninflammatory causes such as atherosclerosis, emboli, connective tissue disease, vasospasm, migraine-associated vasculopathy, and drug-associated causes. Some cases develop in the postpartum period and are self-limited.

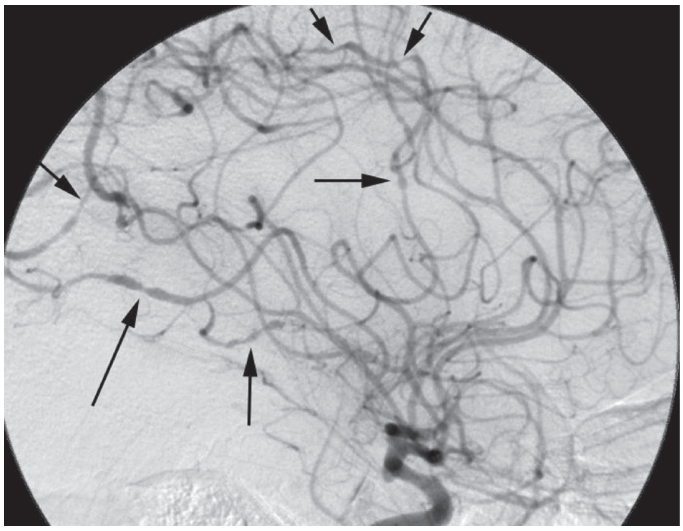

FIGURE 438-6 Cerebral angiogram from a 32-year-old male with central nervous system vasculopathy. Dramatic beading (*arrows*) typical of vasculopathy is shown.

Patients with any form of vasculopathy may present with insidious progression of combined white and gray matter infarctions, prominent headache, and cognitive decline. Brain biopsy or high-resolution conventional x-ray angiography is usually required to make the diagnosis **(Fig. 438-6)**. A lumbar puncture (elevated white blood cells, elevated IgG index, bands on electrophoresis) can provide support for an inflammatory etiology of a neurovascular problem. When inflammation is confirmed, aggressive immunosuppression with glucocorticoids, and often cyclophosphamide, is usually necessary to prevent progression; a diligent investigation for infectious causes such as tuberculosis is essential prior to immunosuppression. With prompt recognition and treatment, many patients can make an excellent recovery.

Drugs, in particular amphetamines and perhaps cocaine, may cause stroke on the basis of acute hypertension or drug-induced vasculopathy. This vasculopathy is commonly due to vasospasm or atherosclerosis, but cases of inflammatory vasculitis have also been reported. No data exist on the value of any treatment, but cessation of stimulants is prudent. Phenylpropanolamine has been linked with intracranial hemorrhage, as has cocaine and methamphetamine, perhaps related to a vasculopathy. *Moyamoya disease* is a poorly understood occlusive disease involving large intracranial arteries, especially the distal internal carotid artery and the stem of the MCA and ACA. Vascular inflammation is absent. The lenticulostriate arteries develop a rich collateral circulation around the occlusive lesion, which gives the impression of a "puff of smoke" (*moyamoya* in Japanese) on conventional x-ray angiography. Other collaterals include transdural anastomoses between the cortical surface branches of the meningeal and scalp arteries. The disease occurs mainly in Asian children or young adults, but the appearance may be identical in adults who have atherosclerosis, particularly in association with diabetes. Intracranial hemorrhage may result from rupture of the moyamoya collaterals; thus, anticoagulation is risky. Progressive occlusion of large surface arteries can occur, producing large-artery distribution strokes. Surgical bypass of extracranial carotid arteries to the dura or MCAs may prevent stroke and hemorrhage.

Posterior reversible encephalopathy syndrome (PRES) can occur with head injury, seizure, migraine, sympathomimetic drug use, and eclampsia and in the postpartum period. The pathophysiology is uncertain but likely involves a hyperperfusion state where blood pressure exceeds the upper limit of cerebral autoregulation resulting

in cerebral edema (Chap. 318). Patients complain of headache and manifest fluctuating neurologic symptoms and signs, especially visual symptoms. Sometimes cerebral infarction ensues, but typically, the clinical and imaging findings reverse completely. MRI findings are characteristic with edema present within the occipital lobes but also can be generalized and do not respect any single vascular territory. A closely related *reversible cerebral vasoconstriction syndrome* (RCVS) typically presents with sudden, severe headache closely mimicking SAH. Patients may experience ischemic infarction and intracerebral hemorrhage and typically have new-onset, severe hypertension. Conventional x-ray angiography reveals changes in the vascular caliber throughout the hemispheres resembling vasculitis, but the process is noninflammatory. Oral calcium channel blockers may be effective in producing remission, and recurrence is rare.

Leukoaraiosis, or *periventricular white matter disease*, is the result of multiple small-vessel infarcts within the subcortical white matter. It is readily seen on CT or MRI scans as areas of white matter injury surrounding the ventricles and within the corona radiata. The pathophysiologic basis of the disease is lipohyalinosis of small penetrating arteries within the white matter, likely produced by chronic hypertension. Patients with periventricular white matter disease may develop a subcortical dementia syndrome, and it is likely that this common form of dementia may be delayed or prevented with antihypertensive medications (Chap. 444).

CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy) is an inherited disorder that presents as small-vessel strokes, progressive dementia, and extensive symmetric white matter changes often including the anterior temporal lobes visualized by MRI. Approximately 40% of patients have migraine with aura, often manifest as transient motor or sensory deficits. Onset is usually in the fourth or fifth decade of life. This autosomal dominant condition is caused by one of several mutations in *Notch-3*, a member of a highly conserved gene family characterized by epidermal growth factor repeats in its extracellular domain. Other monogenic ischemic stroke syndromes include cerebral autosomal recessive arteriopathy with subcortical infarcts and leukoencephalopathy (CARASIL) and hereditary endotheliopathy, retinopathy, nephropathy, and stroke (HERNS). Fabry's disease also produces both a large-vessel arteriopathy and small-vessel infarctions. The *COL4A1* mutation is associated with multiple small-vessel strokes with hemorrhagic transformation.

TRANSIENT ISCHEMIC ATTACKS

TIAs are episodes of stroke symptoms that last only briefly; the standard definition of duration is <24 h, but most TIAs last <1 h. If a relevant brain infarction is identified on brain imaging, the clinical entity is now classified as stroke regardless of the duration of symptoms. A normal brain imaging study following a TIA does not rule out TIA; rather, the clinical syndrome is diagnostic. The causes of TIA are similar to those of ischemic stroke, but because TIAs may herald stroke, they are an important risk factor that should be considered urgently. TIAs may arise from emboli to the brain or from in situ thrombosis of an intracranial vessel. With a TIA, the occluded blood vessel reopens and neurologic function is restored.

The risk of stroke after a TIA is ~10–15% in the first 3 months, with most events occurring in the first 2 days. This risk can be directly estimated using the well-validated ABCD^2 score (Table 438-5). Therefore, urgent evaluation and treatment are justified. Because etiologies for stroke and TIA are identical, evaluation for TIA should parallel that of stroke.

TABLE 438-5 Risk of Stroke Following Transient Ischemic Attack: The ABCD^2 Score

CLINICAL FACTOR	SCORE
A: Age ≥60 years	1
B: SBP >140 mmHg or DBP >90 mmHg	1
C: Clinical symptoms	
Unilateral weakness	2
Speech disturbance without weakness	1
D: Duration	
>60 min	2
10–59 min	1
D: Diabetes (oral medications or insulin)	1
TOTAL SCORE	**SUM EACH CATEGORY**

TREATMENT

Transient Ischemic Attack

The improvement characteristic of TIA is a contraindication to thrombolysis. However, because the risk of subsequent stroke in the first few hours and days following TIA is high, some physicians admit the patient to the hospital so a plasminogen activator can be rapidly administered if symptoms return. The combination of aspirin and clopidogrel was found to prevent stroke following TIA better than aspirin alone in a large Chinese randomized trial and the National Institutes of Health (NIH)–sponsored POINT trial. Failure to respond to the combination of aspirin and clopidogrel is linked to carriage of a common CYP2C19 polymorphism that leads to poor metabolism of clopidogrel into its active form. This mutation is common, particularly in Asians. Recently, ticagrelor, 180-mg loading dose and then 90 mg twice daily, was tested in combination with aspirin compared to aspirin alone, and this also showed benefit in preventing stroke; this dual antiplatelet regimen may be favored because of the lack of genetic heterogeneity in platelet inhibition.

Primary and Secondary Prevention of Stroke and TIA

GENERAL PRINCIPLES

Many medical and surgical interventions, as well as lifestyle modifications, are available for preventing stroke. Some of these can be widely applied because of their low cost and minimal risk; others are expensive and carry substantial risk but may be valuable for selected high-risk patients. Identification and control of modifiable risk factors, and especially hypertension, is the best strategy to reduce the burden of stroke, and the total number of strokes could be reduced substantially by these means (Table 438-4).

ATHEROSCLEROSIS RISK FACTORS

The relationship of various factors to the risk of atherosclerosis is described in Chaps. 244 and 245. Older age, diabetes mellitus, hypertension, tobacco smoking, abnormal blood cholesterol (particularly, low high-density lipoprotein [HDL] and/or elevated low-density lipoprotein [LDL]), lipoprotein (a) excess, and other factors are either proven or probable risk factors for ischemic stroke, largely by their link to atherosclerosis. Risk of stroke is much greater in those with prior stroke or TIA. Many cardiac conditions predispose to stroke, including atrial fibrillation and recent MI. Oral contraceptives and hormone replacement therapy increase stroke risk, and although rare, certain inherited and acquired hypercoagulable states predispose to stroke.

Hypertension is the most significant of the risk factors; in general, all hypertension should be treated to a target of <130/80 mmHg. Recent data (the Systolic Blood Pressure Intervention

Trial—SPRINT) suggest that lowering systolic blood pressure <120 mmHg reduces stroke and heart attack by 43% compared to systolic blood pressure <140 mmHg, without an increased risk of syncope or falls, although patients with a history of stroke were specifically excluded from this study. The presence of known cerebrovascular disease is not a contraindication to treatment aimed at achieving normotension. Data are particularly strong in support of thiazide diuretics and angiotensin-converting enzyme inhibitors.

Several trials have confirmed that statin drugs reduce the risk of stroke even in patients without elevated LDL or low HDL. The Stroke Prevention by Aggressive Reduction in Cholesterol Levels (SPARCL) trial showed benefit in secondary stroke reduction for patients with recent stroke or TIA who were prescribed atorvastatin, 80 mg/d. The primary prevention trial, Justification for the Use of Statins in Prevention: An Intervention Trial Evaluating Rosuvastatin (JUPITER), found that patients with an elevated C-reactive protein benefitted by daily use of this statin, despite LDL <130 mg/dL. Primary stroke occurrence was reduced by 51% (hazard ratio, 0.49; $p = .004$), and there was no increase in the rates of intracranial hemorrhage. Meta-analysis has also supported a primary treatment effect for statins given acutely for ischemic stroke. A serum LDL <70 mg/dL lowers recurrent stroke risk better than an LDL of 90–110 mg/dL. Therefore, a statin should be considered in all patients with prior ischemic stroke. Tobacco smoking should be discouraged in all patients **(Chap. 465)**. The use of pioglitazone (an agonist of peroxisome proliferator-activated receptor gamma) in patients with type 2 diabetes and previous stroke does not lower stroke, MI, or vascular death rates but is effective in lowering vascular events in patients with stroke and prediabetes or insulin resistance alone. Diabetes prevention is likely the most effective strategy for primary and secondary stroke prevention.

ANTIPLATELET AGENTS FOR STROKE PREVENTION

Platelet antiaggregation agents can prevent atherothrombotic events, including TIA and stroke, by inhibiting the formation of intra-arterial platelet aggregates. These can form on diseased arteries, induce thrombus formation, and occlude or embolize into the distal circulation. Aspirin, clopidogrel, the combination of aspirin plus extended-release dipyridamole, and recently ticagrelor are the antiplatelet agents most commonly used for this purpose. Ticagrelor has not been found to be better than aspirin for stroke prevention except in combination with aspirin following TIA.

Aspirin is the most widely studied antiplatelet agent. Aspirin acetylates platelet cyclooxygenase, which irreversibly inhibits the formation in platelets of thromboxane A_2, a platelet aggregating and vasoconstricting prostaglandin. This effect is permanent and lasts for the usual 8-day life of the platelet. Paradoxically, aspirin also inhibits the formation in endothelial cells of prostacyclin, an antiaggregating and vasodilating prostaglandin. This effect is transient. As soon as aspirin is cleared from the blood, the nucleated endothelial cells again produce prostacyclin. Aspirin in low doses given once daily inhibits the production of thromboxane A_2 in platelets without substantially inhibiting prostacyclin formation. Higher doses of aspirin have not been proven to be more effective than lower doses.

Clopidogrel and ticagrelor block the adenosine diphosphate (ADP) receptor on platelets and thus prevent the cascade resulting in activation of the glycoprotein IIb/IIIa receptor that leads to fibrinogen binding to the platelet and consequent platelet aggregation. Clopidogrel can cause rash and, in rare instances, thrombotic thrombocytopenic purpura. The Clopidogrel versus Aspirin in Patients at Risk of Ischemic Events (CAPRIE) trial, which led to U.S. Food and Drug Administration (FDA) approval, found that it was only marginally more effective than aspirin in reducing risk of stroke. The Management of Atherothrombosis with Clopidogrel in High-Risk Patients (MATCH) trial was a large multicenter, randomized, double-blind study that compared clopidogrel in combination with aspirin to clopidogrel alone in the secondary prevention of TIA or stroke. The MATCH trial found no difference in TIA or stroke prevention with this combination but did show a small but significant increase in major bleeding complications (3 vs 1%). In the Clopidogrel for High Atherothrombotic Risk and Ischemic Stabilization, Management, and Avoidance (CHARISMA) trial, which included a subgroup of patients with prior stroke or TIA along with other groups at high risk of cardiovascular events, there was no benefit of clopidogrel combined with aspirin compared to aspirin alone. Lastly, the SPS3 trial looked at the long-term combination of clopidogrel and aspirin versus clopidogrel alone in small-vessel stroke and found no improvement in stroke prevention and a significant increase in both hemorrhage and death. Thus, the long-term use of clopidogrel in combination with aspirin is not recommended for stroke prevention.

The short-term combination of clopidogrel with aspirin may be effective in preventing second stroke, however. A large trial of Chinese patients enrolled within 24 h of TIA or minor ischemic stroke found that a clopidogrel-aspirin regimen (clopidogrel 300 mg load then 75 mg/d with aspirin 75 mg for the first 21 days) was superior to aspirin (75 mg/d) alone, with 90-day stroke risk decreased from 11.7 to 8.2% ($p <.001$) and no increase in major hemorrhage. This benefit was limited to those not carrying the CYP2C19 polymorphism associated with clopidogrel hypometabolism. An international NIH-sponsored trial demonstrated similar results; therefore, the combination of aspirin and clopidogrel should be administered for TIA or minor ischemic stroke for the first 21 days before switching to monotherapy.

A recent study of oral ticagrelor plus aspirin versus aspirin alone has shown similar benefits in secondary stroke reduction and carries the likely advantage that ticagrelor's antiplatelet effect is not genetically variable, as is the case with clopidogrel.

Dipyridamole is an antiplatelet agent that inhibits the uptake of adenosine by a variety of cells, including those of the vascular endothelium. The accumulated adenosine is an inhibitor of aggregation. At least in part through its effects on platelet and vessel wall phosphodiesterases, dipyridamole also potentiates the antiaggregatory effects of prostacyclin and nitric oxide produced by the endothelium and acts by inhibiting platelet phosphodiesterase, which is responsible for the breakdown of cyclic AMP. The resulting elevation in cyclic AMP inhibits aggregation of platelets. Dipyridamole is erratically absorbed depending on stomach pH, but a newer formulation combines timed-release dipyridamole, 200 mg, with aspirin, 25 mg, and has better oral bioavailability. This combination drug was studied in three trials. The European Stroke Prevention Study (ESPS) II showed efficacy of both 50 mg/d of aspirin and extended-release dipyridamole in preventing stroke and a significantly better risk reduction when the two agents were combined. The open-label ESPRIT (European/Australasian Stroke Prevention in Reversible Ischaemia Trial) trial confirmed the ESPS-II results. After 3.5 years of follow-up, 13% of patients on aspirin and dipyridamole and 16% on aspirin alone (hazard ratio, 0.80; 95% CI, 0.66–0.98) met the primary outcome of death from all vascular causes. In the Prevention Regimen for Effectively Avoiding Second Strokes (PRoFESS) trial, the combination of extended-release dipyridamole and aspirin was compared directly with clopidogrel with and without the angiotensin receptor blocker telmisartan; there were no differences in the rates of second stroke (9% each) or degree of disability in patients with median follow-up of 2.4 years. Telmisartan also had no effect on these outcomes. This suggests that these antiplatelet regimens are similar and raises questions about default prescription of agents to block the angiotensin pathway in all stroke patients. The principal side effect of dipyridamole is headache. The combination capsule of extended-release dipyridamole and aspirin is approved for prevention of stroke.

Many large clinical trials have demonstrated clearly that most antiplatelet agents reduce the risk of all important vascular atherothrombotic events (i.e., ischemic stroke, MI, and death due to all vascular causes) in patients at risk for these events. The overall *relative* reduction in risk of nonfatal stroke is ~25–30% and of all vascular events is ~25%. The *absolute* reduction varies considerably, depending on the patient's risk. Individuals at very low risk

for stroke seem to experience the same relative reduction, but their risks may be so low that the "benefit" is meaningless. Conversely, individuals with a 10–15% risk of vascular events per year experience a reduction to ~7.5–11%.

Aspirin is inexpensive, can be given in low doses, and could be recommended for all adults to prevent both stroke and MI. However, it causes epigastric discomfort, gastric ulceration, and gastrointestinal hemorrhage, which may be asymptomatic or life threatening. Consequently, not every 40- or 50-year-old should be advised to take aspirin regularly because the risk of atherothrombotic stroke is extremely low and is outweighed by the risk of adverse side effects. Conversely, every patient who has experienced an atherothrombotic stroke or TIA and has no contraindication to antiplatelet therapy (or indication for anticoagulation) should be taking an antiplatelet agent regularly because the average annual risk of another stroke is 8–10%; another few percent will experience an MI or vascular death. Clearly, the likelihood of benefit far outweighs the risks of treatment.

The choice of antiplatelet agent and dose must balance the risk of stroke, the expected benefit, and the risk and cost of treatment. However, there are no definitive data, and opinions vary. Many authorities believe low-dose (30–75 mg/d) and high-dose (650–1300 mg/d) aspirin are about equally effective. Some advocate very low doses to avoid adverse effects, and still others advocate very high doses to be sure the benefit is maximal. Most physicians in North America recommend 81–325 mg/d, whereas most Europeans recommend 50–100 mg. Clopidogrel and extended-release dipyridamole plus aspirin are being increasingly recommended as first-line drugs for secondary prevention. Similarly, the choice of aspirin, clopidogrel, or dipyridamole plus aspirin must balance the fact that the latter are more effective than aspirin but the cost is higher, and this is likely to affect long-term patient adherence. The use of platelet aggregation studies in individual patients taking aspirin is controversial because of limited data.

In our practices, when considering antithrombotic therapy for secondary stroke prevention for noncardioembolic strokes and TIAs, we prescribe aspirin 81 mg/d in aspirin-I patients after an initial load of 325 mg. We add either clopidogrel (600-mg load, then 75 mg daily) or ticagrelor (180-mg load, then 90 mg twice daily) for TIA or minor stroke (NIHSS <5) for 21–30 days, followed by monotherapy with aspirin alone at 81 mg daily. We treat stroke due to intracranial atherosclerosis with aspirin 81 mg plus clopidogrel 75 mg daily for 3 months, after which time treatment is continued with aspirin alone.

ANTICOAGULATION THERAPY AND EMBOLIC STROKE PREVENTION

Several trials have shown that anticoagulation (international normalized ratio [INR] range, 2–3) in patients with chronic nonvalvular (nonrheumatic) atrial fibrillation (NVAF) prevents cerebral embolism and stroke and is safe. For primary prevention and for patients who have experienced stroke or TIA, anticoagulation with a vitamin K antagonist (VKA) reduces the risk by ~67%, which clearly outweighs the 1–3% risk per year of a major bleeding complication. VKAs are difficult to dose, their effects vary with dietary intake of vitamin K, and they require frequent blood monitoring of the PTT/INR. Several direct oral anticoagulants (DOACs) have recently been shown to be more convenient and efficacious for stroke prevention in NVAF. A randomized trial compared the oral thrombin inhibitor dabigatran to VKAs in a noninferiority trial to prevent stroke or systemic embolization in NVAF. Two doses of dabigatran were used: 110 mg/d and 150 mg/d. Both dose tiers of dabigatran were noninferior to VKAs in preventing second stroke and systemic embolization, and the higher dose tier was superior (relative risk, 0.66; 95% CI, 0.53–0.82; p <.001) and the rate of major bleeding was lower in the lower dose tier of dabigatran compared to VKAs. Dabigatran requires no blood monitoring to titrate the dose, and its effect is independent of oral intake of vitamin K. Newer oral factor Xa inhibitors have also been found to be equivalent or safer and more effective than VKAs in NVAF stroke prevention. In the Apixaban for Reduction in Stroke and Other Thromboembolic Events in Atrial Fibrillation (ARISTOTLE) trial, patients were randomized between apixaban, 5 mg twice daily, and dose-adjusted warfarin (INR 2–3). The combined endpoint of ischemic or hemorrhagic stroke or system embolism occurred in 1.27% of patients in the apixaban group and in 1.6% in the warfarin group (p <.001 for noninferiority and p <.01 for superiority). Major bleeding was 1% less, favoring apixaban (p <.001). Similar results were obtained in the Rivaroxaban Once Daily Oral Direct Factor Xa Inhibition Compared with Vitamin K Antagonism for Prevention of Stroke and Embolism Trial in Atrial Fibrillation (ROCKET-AF). In this trial, patients with NVAF were randomized to rivaroxaban versus warfarin: 1.7% of the factor Xa group and 2.2% of the warfarin group reached the endpoint of stroke and systemic embolism (p <.001 for noninferiority); intracranial hemorrhage was also lower with rivaroxaban. Finally, the factor Xa inhibitor edoxaban was also found to be noninferior to warfarin. Thus, oral factor Xa inhibitors are at least a suitable alternative to VKAs, for both primary and secondary prevention, and likely are superior both in efficacy and perhaps compliance. Recent FDA approval of a reversal agent for the Xa inhibitors apixaban and rivaroxaban (andexanet alfa) provides an antidote in the case of major bleeding. Idarucizumab has been available for reversal of dabigatran. Randomized trials have not demonstrated the superiority of anticoagulants over antiplatelet medications for strokes that appear embolic without a clear source, even when limited to the subset with evidence of an atrial cardiopathy.

For patients who cannot take anticoagulant medications, clopidogrel plus aspirin was compared to aspirin alone in the Atrial Fibrillation Clopidogrel Trial with Irbesartan for Prevention of Vascular Events (ACTIVE-A). Clopidogrel combined with aspirin was more effective than aspirin alone in preventing vascular events, principally stroke, but increased the risk of major bleeding (relative risk, 1.57; p <.001). Left atrial appendage occlusion followed by antiplatelet therapy was found to be noninferior to oral Xa inhibitors in patients at moderate to high risk of bleeding in a single trial. If confirmed, this may be a safer strategy than management with aspirin alone for these patients at high risk of atrial fibrillation–related stroke.

The decision to use anticoagulation for primary prevention is based primarily on risk factors (Table 438-3). The history of a TIA or stroke tips the balance in favor of anticoagulation regardless of other risk factors. Intermittent atrial fibrillation carries the same risk of stroke as chronic atrial fibrillation, and several ambulatory studies of seemingly "cryptogenic" stroke have found evidence of intermittent atrial fibrillation in nearly 20% of patients monitored for a few weeks. Interrogation of implanted pacemakers also confirms an association between subclinical atrial fibrillation and stroke risk. Therefore, for patients with otherwise cryptogenic embolic stroke (no evidence of any other cause for stroke), ambulatory monitoring for at least 30 days is a reasonable strategy to determine the best prophylactic therapy, and some patients may benefit from placement of longer-term implantable loop recorders.

Because of the high annual stroke risk in untreated rheumatic heart disease with atrial fibrillation, primary prophylaxis against stroke has not been studied in a double-blind fashion. These patients generally should receive long-term anticoagulation. Dabigatran and the oral Xa inhibitors have not been studied in this population.

Anticoagulation also reduces the risk of embolism in acute MI. Most clinicians recommend a 3-month course of anticoagulation when there is anterior Q-wave infarction, substantial left ventricular dysfunction, congestive heart failure, mural thrombosis, or atrial fibrillation. Oral anticoagulants are recommended long term if atrial fibrillation persists.

Stroke secondary to thromboembolism is one of the most serious complications of prosthetic heart valve implantation. The intensity of anticoagulation and/or antiplatelet therapy is dictated by the type

of prosthetic valve and its location. Dabigatran may be less effective than warfarin, and the oral Xa inhibitors have not been studied in this population.

If the embolic source cannot be eliminated, anticoagulation should in most cases be continued indefinitely. Many neurologists recommend combining antiplatelet agents with anticoagulants for patients who "fail" anticoagulation (i.e., have another stroke or TIA), but the evidence basis for this is lacking.

It is our practice to prescribe apixaban 5 mg twice daily (adjusted to 2.5 mg twice daily if age, weight, and renal function criteria are met) for nonvalvular atrial fibrillation with CHA_2DS_2-VASc score of ≥2, aspirin 81 mg plus clopidogrel 75 mg daily for patients who cannot take oral anticoagulation, and VKAs for valvular atrial fibrillation or mechanical heart valve.

ANTICOAGULATION THERAPY AND NONCARDIOGENIC STROKE

Data do not support the use of long-term VKAs for preventing atherothrombotic stroke for either intracranial or extracranial cerebrovascular disease. The Warfarin-Aspirin Recurrent Stroke Study (WARSS) found no benefit of warfarin sodium (INR 1.4–2.8) over aspirin, 325 mg, for secondary prevention of stroke but did find a slightly higher bleeding rate in the warfarin group; a European study confirmed this finding. The Warfarin and Aspirin for Symptomatic Intracranial Disease (WASID) study (see below) demonstrated no benefit of warfarin (INR 2–3) over aspirin in patients with symptomatic intracranial atherosclerosis and found a higher rate of bleeding complications. Two trials testing factor Xa medications for prevention of embolic stroke of undetermined source (ESUS) failed to show benefit compared to treatment with antiplatelet medications and a third trial limited to ESUS patients with atrial cardiopathy had similar results. The oral factor Xa inhibitor apixaban was found to be noninferior to subcutaneous dalteparin for patients with cancer and venous thromboembolism; many oncologists are using Xa inhibitors to prevent second stroke in patients with malignancy.

It is our practice to prescribe aspirin for secondary stroke prevention in noncardiogenic cerebral embolism except for stroke associated with cancer (apixaban 5 mg twice daily) and the antiphospholipid syndrome (warfarin with target INR 2–3).

TREATMENT

Carotid Atherosclerosis

Carotid atherosclerosis can be removed surgically (endarterectomy), mitigated with endovascular stenting with or without balloon angioplasty, or using the transcarotid artery revascularization (TCAR) approach. Anticoagulation has not been directly compared with antiplatelet therapy for carotid disease.

SURGICAL THERAPY

Symptomatic carotid stenosis was studied in the North American Symptomatic Carotid Endarterectomy Trial (NASCET) and the European Carotid Surgery Trial (ECST). Both showed a substantial benefit for surgery in patients with stenosis of ≥70%. In NASCET, the average cumulative ipsilateral stroke risk at 2 years was 26% for patients treated medically and 9% for those receiving the same medical treatment plus a carotid endarterectomy. This 17% *absolute* reduction in the surgical group is a 65% *relative* risk reduction favoring surgery (Table 438-4). NASCET also showed a significant, although less robust, benefit for patients with 50–70% stenosis. ECST found harm for patients with stenosis <30% treated surgically.

A patient's risk of stroke and possible benefit from surgery are related to the presence of retinal versus hemispheric symptoms, degree of arterial stenosis, extent of associated medical conditions (of note, NASCET and ECST excluded "high-risk" patients with significant cardiac, pulmonary, or renal disease), institutional surgical morbidity and mortality, timing of surgery relative to symptoms, and other factors. A recent meta-analysis of the NASCET and ECST trials demonstrated that endarterectomy is most beneficial when performed within 2 weeks of symptom onset. In addition, benefit is more pronounced in patients >75 years, and men appear to benefit more than women.

In summary, a patient with recent symptomatic hemispheric ischemia, high-grade stenosis in the appropriate internal carotid artery, and an institutional perioperative morbidity and mortality rate of ≤6% generally should undergo carotid endarterectomy. If the perioperative stroke rate is >6% for any particular surgeon, however, the benefits of carotid endarterectomy are questionable.

The indications for surgical treatment of *asymptomatic carotid disease* have been clarified by the results of the Asymptomatic Carotid Atherosclerosis Study (ACAS) and the Asymptomatic Carotid Surgery Trial (ACST). ACAS randomized asymptomatic patients with ≥60% stenosis to medical treatment with aspirin or the same medical treatment plus carotid endarterectomy. The surgical group had a risk over 5 years for ipsilateral stroke (and any perioperative stroke or death) of 5.1%, compared to a risk in the medical group of 11%. Although this demonstrates a 53% *relative* risk reduction, the *absolute* risk reduction is only 5.9% over 5 years, or 1.2% annually (Table 438-4). Nearly one-half of the strokes in the surgery group were caused by preoperative angiograms. ACST randomized asymptomatic patients with >60% carotid stenosis to endarterectomy or medical therapy. The 5-year risk of stroke in the surgical group (including perioperative stroke or death) was 6.4%, compared to 11.8% in the medically treated group (46% relative risk reduction and 5.4% absolute risk reduction).

In both ACAS and ACST, the perioperative complication rate was higher in women, perhaps negating any benefit in the reduction of stroke risk within 5 years. It is possible that with longer follow-up, a clear benefit in women will emerge. At present, carotid endarterectomy in asymptomatic women remains particularly controversial.

In summary, the natural history of asymptomatic stenosis is an ~2% per year stroke rate, whereas symptomatic patients experience a 13% per year risk of stroke. Whether to recommend carotid revascularization for an asymptomatic patient is somewhat controversial and depends on many factors, including patient preference, degree of stenosis, age, gender, and comorbidities. Medical therapy for reduction of atherosclerosis risk factors, including cholesterol-lowering agents and antiplatelet medications, is generally recommended for patients with asymptomatic carotid stenosis. As with atrial fibrillation, it is imperative to counsel the patient about TIAs so that therapy can be revised if symptoms develop.

ENDOVASCULAR THERAPY

Balloon angioplasty coupled with stenting is one option to open stenotic carotid arteries and maintain their patency. These techniques can treat carotid stenosis not only at the bifurcation but also near the skull base and in the intracranial segments. The Stenting and Angioplasty with Protection in Patients at High Risk for Endarterectomy (SAPPHIRE) trial randomized high-risk patients (defined as patients with clinically significant coronary or pulmonary disease, contralateral carotid occlusion, restenosis after endarterectomy, contralateral laryngeal-nerve palsy, prior radical neck surgery or radiation, or age >80) with symptomatic carotid stenosis >50% or asymptomatic stenosis >80% to either stenting combined with a distal emboli-protection device or endarterectomy. The risk of death, stroke, or MI within 30 days and ipsilateral stroke or death within 1 year was 12.2% in the stenting group and 20.1% in the endarterectomy group (p = .055), suggesting that stenting is at the very least comparable to endarterectomy as a treatment option for this patient group at high risk of surgery. However, the outcomes with both interventions may not have been better than leaving the carotid stenoses untreated, particularly for the asymptomatic patients, and much of the benefit seen in the stenting group was due to a reduction in periprocedure MI. Two randomized trials comparing stents to endarterectomy in lower-risk patients have been published. The Carotid Revascularization Endarterectomy versus Stenting Trial (CREST) enrolled patients with either asymptomatic

or symptomatic stenosis. The 30-day risk of stroke was 4.1% in the stent group and 2.3% in the surgical group, but the 30-day risk of MI was 1.1% in the stent group and 2.3% in the surgery group, suggesting relative equivalence of risk between the procedures. At median follow-up of 2.5 years, the combined endpoint of stroke, MI, and death was the same (7.2% stent vs 6.8% surgery) and remained so at 10-year follow-up. The rate of restenosis at 2 years was also similar in both groups. The International Carotid Stenting Study (ICSS) randomized symptomatic patients to stents versus endarterectomy and found a different result: at 120 days, the incidence of stroke, MI, or death was 8.5% in the stenting group versus 5.2% in the endarterectomy group (p = .006). At median follow-up of 5 years, these differences were no longer significant except a small increase in nondisabling stroke in the stenting group but no change in the average disability. In meta-analysis, carotid endarterectomy (CEA) is less morbid in older patients (aged ≥70) than is stenting. Recently, transcarotid artery revascularization (TCAR), which involves the reversal of blood flow during an angioplasty and stenting procedure, has been offered as an alternative to transfemoral carotid artery stenting or when CEA presents high risks. Investigation is ongoing in asymptomatic patients to compare medical therapy to stenting and CEA. This will likely answer how well medical patients do with more modern medical therapy (statins, close blood pressure control, and lifestyle modification).

BYPASS SURGERY

Extracranial-to-intracranial (EC-IC) bypass surgery has been proven ineffective for atherosclerotic stenoses that are inaccessible to conventional CEA. In patients with recent stroke, an associated carotid occlusion, and evidence of inadequate perfusion of the brain as measured with positron emission tomography, no benefit from EC-IC bypass was found in a trial stopped for futility.

PATENT FORAMEN OVALE

In patients with PFO and/or atrial septal aneurysm with an embolic stroke and no other cause identified, three randomized trials using various endovascular closure devices individually and in meta-analysis reported a significant (1% per year) reduction in second stroke compared to antiplatelet agents. If the neurologic opinion is that no other source of stroke is identified and consultation with a cardiologist knowledgeable about PFO closure supports intervention, we recommend endovascular PFO closure.

INTRACRANIAL ATHEROSCLEROSIS

The WASID trial randomized patients with symptomatic stenosis (50–99%) of a major intracranial vessel to either high-dose aspirin (1300 mg/d) or warfarin (target INR, 2.0–3.0), with a combined primary endpoint of ischemic stroke, brain hemorrhage, or death from vascular cause other than stroke. The trial was terminated early because of an increased risk of adverse events related to warfarin anticoagulation. With a mean follow-up of 1.8 years, the primary endpoint was seen in 22.1% of patients in the aspirin group and 21.8% of the warfarin group. Death from any cause was seen in 4.3% of the aspirin group and 9.7% of the warfarin group; 3.2% of patients on aspirin experienced major hemorrhage, compared to 8.3% of patients taking warfarin.

Intracranial stenting of intracranial atherosclerosis was found to be dramatically harmful compared to aspirin in the Stenting and Aggressive Medical Management for Preventing Recurrent Stroke in Intracranial Stenosis (SAMMPRIS) trial. This trial enrolled newly symptomatic TIA or minor stroke patients with associated 70–99% intracranial stenosis to primary stenting with a self-expanding stent or to medical management. Both groups received clopidogrel, aspirin, statin, and aggressive control of blood pressure. The endpoint of stroke or death occurred in 14.7% of the stented group and 5.8% of the medically treated groups (p = .002). This low rate of second stroke was significantly lower than in the WASID trial and suggests that aggressive medical management had a marked influence on secondary stroke risk. A concomitant study of balloon-expandable stenting was halted early at 125 patients because of the negative SAMMPRIS results and due to harm. Therefore, routine use of intracranial stenting is harmful, and medical therapy is superior for intracranial atherosclerosis.

Dural Sinus Thrombosis Limited evidence exists to support short-term use of anticoagulants, regardless of the presence of intracranial hemorrhage, for venous infarction following sinus thrombosis. The long-term outcome for most patients, even those with intracerebral hemorrhage, is excellent.

439 Intracerebral Hemorrhage

J. Claude Hemphill, III, Edilberto Amorim, Wade S. Smith

Intracerebral hemorrhage (ICH) is a form of stroke **(see Chap. 437)**. Compared to ischemic stroke, patients with ICH are more likely to present with headache; however, brain imaging is required to distinguish these entities. CT imaging of the head is highly sensitive and specific for intracranial hemorrhage and determines the location(s) of bleeding. Hemorrhages are classified by their location and the underlying vascular pathology. ICH is defined as spontaneous hemorrhage directly into the brain parenchyma and will be considered here along with intracranial vascular anomalies such as arteriovenous malformations (AVMs) of the brain. Other categories of intracranial hemorrhage include bleeding into subarachnoid, subdural, or epidural spaces, usually caused by trauma **(Chap. 454)**, and subarachnoid hemorrhage due to trauma or the rupture of an intracranial aneurysm **(Chap. 440)**.

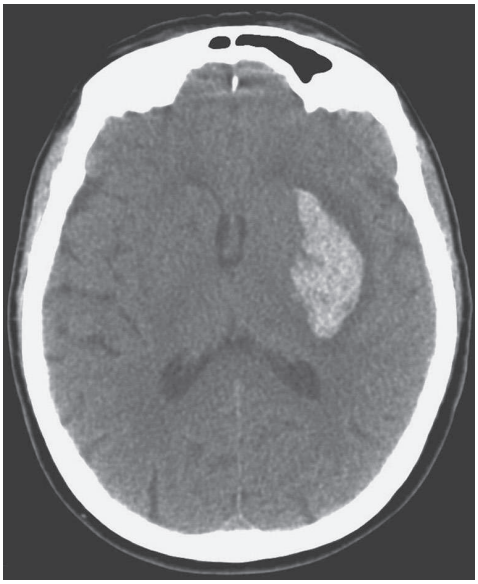

FIGURE 439-1 Hypertensive intracerebral hemorrhage. Transaxial noncontrast computed tomography scan through the region of the basal ganglia reveals a hematoma involving the left putamen in a patient with rapidly progressive onset of right hemiparesis.

CAUSE	LOCATION	COMMENTS
Primary ICH		
Cerebral amyloid angiopathy	Lobar	Degenerative disease of intracranial vessels; associated with dementia, rare in patients <60 years
Coagulopathy	Any	Risk for hematoma expansion
Drug	Any, lobar, subarachnoid	Cocaine, amphetamine
Hypertension	Putamen, globus pallidus, thalamus, cerebellar hemisphere, pons	Chronic hypertension produces hemorrhage from small (~30–100 μm) vessels in these regions
Secondary ICH		
Aneurysm	Subarachnoid, intraparenchymal, rarely subdural	Mycotic and nonmycotic forms of aneurysms
Arteriovenous malformation	Lobar, intraventricular, subarachnoid	Risk is ~2–4% per year for bleeding if previously unruptured
Capillary telangiectasias	Usually brainstem	Rare cause of hemorrhage
Cavernous angioma	Intraparenchymal	Multiple cavernous angiomas linked to mutations in *KRIT1*, *CCM2*, and *PDCD10* genes
Dural arteriovenous fistula	Lobar, subarachnoid	Produces bleeding from venous hypertension
Dural sinus thrombosis	Along sagittal sinus, posterior temporal/ inferior parietal	Sagittal sinus thrombosis can cause hemispheric parasagittal hemorrhage with edema; vein of Labbé occlusion from transverse sinus occlusion produces posterior temporal and/or inferior parietal hemorrhage
Metastatic or primary brain tumors	Lobar	Lung, choriocarcinoma, melanoma, renal cell carcinoma, thyroid, hepatocellular carcinoma, and pilocytic astrocytoma are more commonly associated with bleeding complications
Transformation of prior ischemic infarction	Basal ganglion, subcortical regions, lobar	Occurs in a significant proportion of ischemic strokes, more commonly in large hemispheric infarctions; is symptomatic in 3–9% of patients undergoing acute intervention

DIAGNOSIS

Intracranial hemorrhage is often identified on noncontrast computed tomography (CT) imaging of the head during the acute evaluation of stroke. Because CT is more widely available and may be logistically easier to perform than magnetic resonance imaging (MRI), CT imaging is generally the preferred method for acute stroke evaluation (Fig. 439-1). The location of the hemorrhage narrows the differential diagnosis to a few entities. Table 439-1 lists the causes and anatomic spaces involved in intracranial hemorrhages.

EMERGENCY MANAGEMENT

Close attention should be paid to airway management because deterioration in the level of consciousness is common and often progressive. The initial blood pressure should be maintained until the results of the CT scan are reviewed and demonstrate ICH. A higher blood pressure may promote hematoma expansion, but it remains unclear if lowering of blood pressure reduces hematoma growth. Recent clinical trials have shown that systolic blood pressure (SBP) can be safely lowered acutely and rapidly to <140 mmHg in patients with spontaneous ICH whose initial SBP was 150–220 mmHg. The INTERACT2 trial was a large phase 3 clinical trial to address the effect of acute blood pressure lowering on ICH functional outcome. INTERACT2 randomized patients with spontaneous ICH within 6 h of onset and a baseline SBP of 150–220 mmHg to two different SBP targets (<140 and <180 mmHg). In those with the target SBP <140 mmHg, 52% had an outcome of death or major disability at 90 days compared with 55.6% of those with a target SBP <180 mmHg (p = .06). There was a significant shift to improved outcomes in the lower blood pressure arm, whereas both groups had a similar mortality. ATACH2 was a similarly designed clinical trial that assessed the same blood pressure targets but demonstrated no difference in outcome between groups; however, aggressive blood pressure lowering did increase renal adverse events. Current U.S. and European guidelines emphasize that blood pressure lowering to a target SBP is likely safe and possibly beneficial. While the specific optimal target remains a point of debate, the most recent American Heart Association/American Stroke Association guidelines for the management of spontaneous ICH endorse achieving and maintaining a target SBP of 130–150 mmHg in these patients to avoid unintended hypoperfusion. It is unclear whether these clinical trial results apply to patients who have higher SBP on presentation or who are deeply comatose with possible elevated intracranial pressure (ICP). In patients who have ICP monitors in place, maintaining the cerebral perfusion pressure (mean arterial pressure [MAP] minus ICP) of 60 to ≥70 mmHg is reasonable, depending on the individual patient's cerebral autoregulation status (Chap. 318). Blood pressure should be lowered using IV drugs with less cerebral vasodilating action such as nicardipine, clevidipine, labetalol, or esmolol. Patients with radiographic evidence of hydrocephalus or cerebellar ICH with depressed mental status should undergo urgent neurosurgical evaluation; these patients require close monitoring because they can deteriorate rapidly. Based on the clinical examination and CT findings, further imaging studies may be necessary, including MRI or conventional x-ray angiography. Stuporous or comatose patients with clinical and imaging signs of herniation can be presumptively treated for elevated ICP with tracheal intubation and sedation, administration of osmotic diuretics such as mannitol or hypertonic saline, and elevation of the head of the bed while surgical consultation is obtained (Chap. 318). Rapid reversal of coagulopathy ideally within 1 h of presentation and consideration of surgical evacuation of the hematoma (detailed below) are two other principal aspects of initial emergency management.

INTRACEREBRAL HEMORRHAGE

ICH accounts for ~10% of all strokes, and ~35–45% of patients die within the first month. Incidence rates are particularly high in Asian and Black patient groups. Hypertension, coagulopathy, sympathomimetic

drugs (cocaine, methamphetamine), and cerebral amyloid angiopathy (CAA) cause most of these hemorrhages. Advanced age, heavy alcohol, and low-dose aspirin use in those without symptomatic cardiovascular disease increase ICH risk, and cocaine or methamphetamine use is one of the most important causes in the young.

Hypertensive ICH • **PATHOPHYSIOLOGY** Hypertensive ICH usually results from spontaneous rupture of a small penetrating artery deep in the brain. The most common sites are the basal ganglia (especially the putamen), thalamus, cerebellum, and pons. The small arteries in these areas seem most prone to hypertension-induced vascular injury. When hemorrhages occur in other brain areas or in nonhypertensive patients, greater consideration should be given to other causes such as hemorrhagic disorders, neoplasms, vascular malformations, vasculitis, and CAA. The hemorrhage may be small, or a large clot may form and compress adjacent tissue, causing herniation and death. Blood may also dissect into the ventricular space, which substantially increases morbidity and may cause hydrocephalus.

Most hypertensive ICHs initially develop over 30–90 min, whereas those associated with anticoagulant therapy may evolve for as long as 24–48 h. It is now recognized that about a third of patients even with no coagulopathy may have significant hematoma expansion within the first day. Within 48 h, macrophages begin to phagocytize the hemorrhage at its outer surface. After 1–6 months, the hemorrhage is generally resolved to a slitlike cavity lined with a glial scar and hemosiderin-laden macrophages.

CLINICAL MANIFESTATIONS ICH generally presents as the abrupt onset of a focal neurologic deficit. Seizures are uncommon on presentation but may occur in 6–15% of patients within the first 3 days. Although clinical symptoms may be maximal at onset, more commonly, the focal deficit worsens over 30–90 min and is associated with a diminishing level of consciousness and signs of increased ICP such as headache and vomiting.

The putamen is the most common site for hypertensive hemorrhage, and the adjacent internal capsule is usually damaged (Fig. 439-1). Contralateral hemiparesis is therefore the sentinel sign. When mild, the face sags on one side over 5–30 min, speech becomes slurred, the arm and leg gradually weaken, and the eyes deviate away from the side of the hemiparesis. The paralysis may worsen until the affected limbs become flaccid or extend rigidly. When hemorrhages are large, drowsiness gives way to stupor as signs of upper brainstem compression appear. Coma ensues, accompanied by deep, irregular, or intermittent respiration, a dilated and fixed ipsilateral pupil, and decerebrate rigidity. Edema in adjacent brain tissue may cause progressive deterioration over 24–96 h.

Thalamic hemorrhages may also produce a contralateral hemiplegia or hemiparesis from pressure on, or dissection into, the adjacent internal capsule. A prominent sensory deficit involving all modalities is usually present. Aphasia, often with preserved verbal repetition, may occur after hemorrhage into the dominant thalamus, and constructional apraxia or mutism occurs in some cases of nondominant hemorrhage. There may also be a homonymous visual field defect. Thalamic hemorrhages cause several typical ocular disturbances by extension inferiorly into the upper midbrain. These include deviation of the eyes downward and inward so that they appear to be looking at the nose, unequal pupils with absence of light reaction, skew deviation with the eye opposite the hemorrhage displaced downward and medially, ipsilateral Horner's syndrome, absence of convergence, paralysis of vertical gaze, and retraction nystagmus. Patients may later develop a chronic, contralateral pain syndrome (Déjérine-Roussy syndrome).

In pontine hemorrhages, deep coma with quadriplegia often occurs over a few minutes. Typically, there is prominent decerebrate rigidity and "pinpoint" (1 mm) pupils that react to light. There is impairment of reflex horizontal eye movements evoked by head turning (doll's-head or oculocephalic maneuver) or by irrigation of the ears with ice water **(Chap. 30)**. Hyperpnea, severe hypertension, and hyperhidrosis are common. Most patients with deep coma from pontine hemorrhage ultimately die or develop a locked-in state, but small hemorrhages are compatible with survival and significant recovery.

Cerebellar hemorrhages usually develop over several hours and are characterized by occipital headache, repeated vomiting, and ataxia of gait. In mild cases, there may be no other neurologic signs except for gait ataxia. Dizziness or vertigo may be prominent. There is often paresis of conjugate lateral gaze toward the side of the hemorrhage, forced deviation of the eyes to the opposite side, or an ipsilateral sixth nerve palsy. Less frequent ocular signs include blepharospasm, involuntary closure of one eye, ocular bobbing, and skew deviation. Dysarthria and dysphagia may occur. As the hours pass, the patient often becomes stuporous and then comatose from brainstem compression or obstructive hydrocephalus; immediate surgical evacuation before severe brainstem compression occurs may be lifesaving. Hydrocephalus from fourth ventricle compression can be relieved by external ventricular drainage; however, in this situation, definitive hematoma evacuation is recommended rather than treatment with ventricular drainage alone. If the deep cerebellar nuclei are spared, full recovery is common.

Lobar hemorrhages usually present with symptoms related to the specific site of origin. The major neurologic deficit with an occipital hemorrhage is hemianopsia; with a left temporal hemorrhage, aphasia and confusion; with a parietal hemorrhage, hemisensory loss; and with frontal hemorrhage, arm weakness. Large hemorrhages may be associated with stupor or coma if they compress the thalamus or midbrain. Most patients with lobar hemorrhages have focal headaches, and more than one-half vomit or are drowsy. Seizures may occur.

Other Causes of ICH and Intracranial Hemorrhage CAA is a disease of the elderly in which arteriolar degeneration occurs and amyloid is deposited in the walls of the cerebral arteries. Amyloid angiopathy causes both single and recurrent lobar hemorrhages and is probably the most common cause of lobar hemorrhage in the elderly. It accounts for some intracranial hemorrhages associated with IV thrombolysis given for myocardial infarction. This disorder can be suspected in patients who present with multiple hemorrhages (and infarcts) over several months or years or in patients with "microbleeds" in the cortex, seen on brain MRI sequences sensitive for hemosiderin (susceptibility weighted imaging), but it is definitively diagnosed by pathologic demonstration of Congo red staining of amyloid in cerebral vessels. The ε2 and ε4 allelic variations of the apolipoprotein E gene are associated with increased risk of recurrent lobar hemorrhage and may therefore be markers of amyloid angiopathy. Positron emission tomography imaging can image amyloid-beta deposits in CAA using specific antibody labels and may be helpful in diagnosing CAA noninvasively. Although cerebral biopsy is the most definitive method of diagnosis, evidence of inflammation on lumbar puncture should prompt consideration of CAA-associated vasculitis as an underlying cause, and oral glucocorticoids may be beneficial. Noninflammatory CAA has no specific treatment. Oral anticoagulants are typically avoided.

Cocaine and *methamphetamine* are frequent causes of stroke in young (age <45 years) patients. ICH, ischemic stroke, and subarachnoid hemorrhage (SAH) are all associated with stimulant use. Angiographic findings vary from completely normal arteries to large-vessel occlusion or stenosis, vasospasm, or changes consistent with vasculopathy. The mechanism of sympathomimetic-related stroke is not known, but cocaine enhances sympathetic activity causing acute, sometimes severe, hypertension, and this may lead to hemorrhage. Slightly more than one-half of stimulant-related intracranial hemorrhages are intracerebral and the rest are subarachnoid. In cases of SAH, a saccular aneurysm is usually identified. Presumably, acute hypertension causes aneurysmal rupture.

Head injury often causes intracranial hemorrhage. The common sites are intraparenchymal (especially temporal and inferior frontal lobes) and into the subarachnoid, subdural, and epidural spaces. Trauma must be considered in any patient with an unexplained acute neurologic deficit (hemiparesis, stupor, or confusion), particularly if the deficit occurred in the context of a fall **(Chap. 454)**.

Intracranial hemorrhages associated with *anticoagulant therapy* can occur at any location; they are often lobar or subdural. Anticoagulant-related ICHs may continue to evolve over 24–48 h, especially if coagulopathy is insufficiently reversed. Coagulopathy and thrombocytopenia

should be reversed rapidly, as discussed below. ICH associated with *hematologic disorders* (leukemia, aplastic anemia, thrombocytopenic purpura) can occur at any site and may present as multiple ICHs. Skin and mucous membrane bleeding may be evident and offers a diagnostic clue.

Hemorrhage into a *brain tumor* may be the first manifestation of neoplasm. Choriocarcinoma, malignant melanoma, renal cell carcinoma, and thyroid, lung, and hepatocellular carcinoma are among the most common metastatic tumors associated with ICH. Pilocytic astrocytoma and glioblastoma multiforme in adults and medulloblastoma in children may also have areas of ICH.

Hypertensive encephalopathy is a complication of malignant hypertension. In this acute syndrome, severe hypertension is associated with headache, nausea, vomiting, convulsions, confusion, stupor, and coma. Focal or lateralizing neurologic signs, either transitory or permanent, may occur but are infrequent and therefore suggest some other vascular disease (hemorrhage, embolism, or atherosclerotic thrombosis). There may be retinal hemorrhages, exudates, papilledema (hypertensive retinopathy), and evidence of renal and cardiac disease. MRI brain imaging shows a pattern of typically posterior (occipital > frontal) brain edema. The hypertension may be essential or due to chronic renal disease, acute glomerulonephritis, acute toxemia of pregnancy, pheochromocytoma, or other causes. Lowering the blood pressure reverses the process, but stroke can occur, especially if blood pressure is lowered too rapidly. Neuropathologic examination reveals multifocal to diffuse cerebral edema and hemorrhages of various sizes from petechial to massive. Microscopically, there is necrosis of arterioles, minute cerebral infarcts, and hemorrhages. The terms *hypertensive encephalopathy* and *posterior reversible encephalopathy syndrome* **(Chap. 318)** should be reserved for this syndrome and not for chronic recurrent headaches, dizziness, recurrent transient ischemic attacks, or small strokes that often occur in association with high blood pressure. Distinguishing hypertensive encephalopathy with ICH from hypertensive ICH is important since aggressive lowering of SBP to 130–150 mmHg acutely is often considered in hypertensive ICH, but less aggressive measures should be used in hypertensive encephalopathy. Having no alteration in mental status or other prodrome prior to the ICH favors hypertensive ICH as the disease.

Primary intraventricular hemorrhage is rare and should prompt investigation for an underlying vascular anomaly. Sometimes bleeding begins within the periventricular substance of the brain and dissects into the ventricular system without leaving signs of intraparenchymal hemorrhage. Alternatively, bleeding can arise from periependymal veins. Vasculitis, usually polyarteritis nodosa or lupus erythematosus, can produce hemorrhage in any region of the central nervous system; most hemorrhages are associated with hypertension, but the arteritis itself may cause bleeding by disrupting the vessel wall. Nearly one-half of patients with primary intraventricular hemorrhage have identifiable bleeding sources seen using conventional angiography.

Venous sinus thrombosis **(Chap. 438)** causes cortical vein hypertension, cerebral edema, and venous infarction. This may progress to cause intracranial hemorrhage surrounding the region of the occluded cerebral venous sinus or within the drainage region of the vein of Labbé, producing a posterior temporal or inferior parietal hematoma. Despite the presence of hemorrhage, IV anticoagulation is indicated to reduce the venous hypertension and limit venous ischemia and further bleeding.

Sepsis can cause small petechial hemorrhages throughout the cerebral white matter. *Moyamoya disease* **(Chap. 438)**, mainly an occlusive arterial disease that causes ischemic symptoms, may on occasion produce ICH. Hemorrhages into the spinal cord are usually the result of an AVM, cavernous malformation, or metastatic tumor. *Epidural spinal hemorrhage* produces a rapidly evolving syndrome of spinal cord or nerve root compression **(Chap. 453)**. Spinal hemorrhages usually present with sudden back pain and some manifestation of myelopathy.

Laboratory and Imaging Evaluation Patients should have routine blood chemistries and hematologic studies. Specific attention to the platelet count, prothrombin time, partial thromboplastin time, and international normalized ratio is important to identify coagulopathy. CT imaging reliably detects acute focal hemorrhages in the supratentorial space. Rarely, very small pontine or medullary hemorrhages may not be well delineated because of motion and bone-induced artifact that obscure structures in the posterior fossa. After the first 2 weeks, x-ray attenuation values of clotted blood diminish until they become isodense with surrounding brain. Mass effect and edema may remain. In some cases, a surrounding rim of contrast enhancement appears after 2–4 weeks and may persist for months. MRI, although more sensitive for delineating posterior fossa lesions, is generally not necessary for primary diagnosis. MR angiography (MRA), CT angiography (CTA), and conventional x-ray angiography are used when the cause of intracranial hemorrhage is uncertain, particularly if the patient is young or not hypertensive and the hematoma is not in one of the usual sites for hypertensive hemorrhage. CTA or postcontrast CT imaging may reveal one or more small areas of enhancement within a hematoma; this "spot sign" is thought to represent ongoing bleeding. The presence of a spot sign is associated with an increased risk of hematoma expansion, increased mortality, and lower likelihood of favorable functional outcome. Because patients typically have focal neurologic signs and obtundation and often show signs of increased ICP, a lumbar puncture is generally unnecessary and should usually be avoided because it may induce cerebral herniation.

TREATMENT

Intracerebral Hemorrhage

ACUTE MANAGEMENT

After immediate attention to blood pressure and airway protection (see above), focus can switch to medical and surgical management. Approximately 40% of patients with a hypertensive ICH die, but survivors can have a good to complete recovery. The ICH Score **(Table 439-2)** is a validated clinical grading scale that is useful for stratification of mortality risk and clinical outcome. However, a specific ICH clinical grading scale should not be used to precisely prognosticate outcome because of the concern of creating a self-fulfilling prophecy of poor outcome if early aggressive care is withheld. Any identified coagulopathy should be corrected as soon as possible. For patients taking vitamin K antagonists (VKAs), rapid correction of coagulopathy can be achieved by infusing prothrombin complex concentrates (PCCs), which can be administered quickly, with

vitamin K administered concurrently. Fresh frozen plasma (FFP) is an alternative, but since it requires larger fluid volumes and longer time to achieve adequate reversal than PCC, it is not recommended if PCC is available. Idarucizumab is a monoclonal antibody to dabigatran, and the administration of two doses reverses the anticoagulation effect of dabigatran quickly. The oral Xa inhibitors apixaban and rivaroxaban can be reversed with andexanet alfa. PCC may partially reverse the effects of oral factor Xa inhibitors and are reasonable to administer if andexanet alfa is not available. When ICH is associated with thrombocytopenia (platelet count <50,000/μL), transfusion of fresh platelets is indicated. A clinical trial of platelet transfusions in patients with ICH and without thrombocytopenia who were taking antiplatelet drugs showed no benefit and possible harm.

Hematomas may expand for several hours following the initial hemorrhage, even in patients without coagulopathy. The precise mechanism is unclear. A phase 3 trial of treatment with recombinant factor VIIa reduced hematoma expansion; however, clinical outcomes were not improved, so use of this drug is not recommended. The administration of tranexamic acid was not found to alter outcome in a large randomized trial. Blood pressure lowering has been considered due to the theoretical risk of acutely elevated blood pressure on hematoma expansion, although clinical trials did not find a difference in hematoma expansion between the SBP targets of 140–180 mmHg. In deep hemorrhages that involve the basal ganglia, more intensive blood pressure lowering reduced hematoma expansion but had no effect on functional outcome.

Initial clinical trials of evacuation of supratentorial hematomas, primarily via standard craniotomy, did not demonstrate clear benefit; however, recent focus on minimally-invasive surgical techniques holds promise. The International Surgical Trial in Intracerebral Haemorrhage (STICH) randomized patients with supratentorial ICH to either early surgical evacuation or initial medical management. No benefit was found in the early surgery arm, although analysis was complicated by the fact that 26% of patients in the initial medical management group ultimately had surgery for neurologic deterioration. The follow-up study, STICH-II, found that craniotomy and hematoma evacuation within 24 h of lobar supratentorial hemorrhage did not improve overall outcome but might have a role in select severely affected patients. However, many centers still consider surgery for patients deemed salvageable and who are experiencing progressive neurologic deterioration due to herniation. Surgical techniques continue to evolve. In a clinical trial of minimally invasive hematoma evacuation using instillation of the thrombolytic agent alteplase into the clot, mortality was decreased but there was not an improvement in functional outcome. In 2024, the first randomized trial demonstrating improvement in functional outcome after surgical hematoma evacuation was published. The Early MiNimally-invasive Removal of IntraCerebral Hemorrhage (ENRICH) trial found that surgical removal of lobar hematomas within 24 hours of onset in selected patients (hematoma volume 30–80 mL; Glasgow Coma Score 5–14 [Table 454-1]; pre-ICH functionally independent) was beneficial compared with medical management alone. Several clinical trials testing other minimally invasive surgical hematoma evacuation techniques are ongoing.

For cerebellar hemorrhages in patients with decreased level of consciousness or obstructive hydrocephalus, a neurosurgeon should be consulted immediately to assist with the evaluation. If the patient is alert without focal brainstem signs and the hematoma is small, surgical removal is usually unnecessary. Patients with hematomas >1 cm in diameter require careful observation for signs of impaired consciousness, progressive hydrocephalus, and precipitous respiratory failure. Hydrocephalus due to cerebellar hematoma generally requires surgical evacuation and should usually not be treated solely with ventricular drainage.

Tissue surrounding hematomas is displaced and compressed but not necessarily infarcted. Hence, major functional improvement often occurs as the hematoma is reabsorbed and the adjacent tissue regains its function over several months following acute injury. Careful management of the patient during the acute phase of the hemorrhage can lead to considerable recovery.

Bundles of care that incorporate multiple interventions may provide more value in the management of ICH patients than separating out different singular interventions. A hospital in the United Kingdom found that an ICH care bundle consisting of coagulopathy reversal, blood pressure lowering, and neurosurgical referral decreased patient mortality when implemented as a quality assurance project. In the INTERACT-3 randomized clinical trial performed in low- to middle-income countries, a bundle of care that included vitamin K coagulopathy reversal, acute blood pressure lowering, glucose control, and temperature control was associated with improved functional outcome and fewer adverse events.

Surprisingly, ICP is often normal even with large ICHs. However, if the hematoma causes marked midline shift of structures with consequent obtundation, coma, or hydrocephalus, osmotic agents can be instituted in preparation for placement of a ventriculostomy or parenchymal ICP monitor **(Chap. 318)**. Once ICP is recorded, CSF drainage (if available), osmotic therapy, and blood pressure management can be tailored to maintain cerebral perfusion pressure (MAP minus ICP) of 60 to ≥70 mmHg. For example, if ICP is found to be high, CSF can be drained from the ventricular space and osmotic therapy continued; persistent or progressive elevation in ICP may prompt surgical evacuation of the clot. Alternately, if ICP is normal, interventions such as osmotic therapy may be tapered. Because hyperventilation may produce ischemia due to cerebral vasoconstriction, induced hyperventilation should be limited to acute resuscitation of the patient with presumptive high ICP and eliminated once osmotic therapy or surgical treatments have been instituted. Glucocorticoids are not recommended for the treatment of intracerebral hemorrhage.

PREVENTION

Hypertension is the leading cause of primary ICH. Prevention is aimed at reducing chronic hypertension, eliminating excessive alcohol use, and discontinuing use of illicit drugs such as cocaine and amphetamines. Oral anticoagulant medications should generally be avoided in patients with high-risk features for CAA, but antiplatelet agents may be administered if there is an indication based on atherothrombotic vascular disease. Ongoing studies are investigating the risk-benefit ratio of reinitiation of anticoagulation in patients with recent ICH who have atrial fibrillation.

VASCULAR ANOMALIES

ARTERIOVENOUS MALFORMATIONS

True AVMs are shunts between the arterial and venous systems that may present with headache, seizures, and intracranial hemorrhage. AVMs consist of a tangle of abnormal vessels across the cortical surface or deep within the brain substance. AVMs vary in size from a small blemish a few millimeters in diameter to a large mass of tortuous channels composing an arteriovenous shunt of sufficient magnitude to raise cardiac output and precipitate heart failure. Blood vessels forming the tangle interposed between arteries and veins are usually abnormally thin and histologically resemble both arteries and veins. AVMs occur in all parts of the cerebral hemispheres, brainstem, and spinal cord, but the largest ones are most frequently located in the posterior half of the hemispheres, commonly forming a wedge-shaped lesion extending from the cortex to the ventricle. Most AVMs are congenital, but cases of acquired lesions have been reported.

Bleeding, headache, and seizures are most common between the ages of 10 and 30, occasionally as late as the fifties. AVMs are more frequent in men, and rare familial cases have been described. Familial AVM may be a part of the autosomal dominant syndrome of hereditary hemorrhagic telangiectasia (Osler-Rendu-Weber) syndrome due to mutations in either endoglin or activin receptor-like kinase 1, both involved in transforming growth factor (TGF) signaling and angiogenesis.

Headache (without bleeding) may be hemicranial and throbbing, like migraine, or diffuse. Focal seizures, with or without generalization,

occur in ~30% of cases. One-half of AVMs become evident as ICHs. In most, the hemorrhage is mainly intraparenchymal with extension into the subarachnoid space in some cases. Unlike primary SAHs **(Chap. 440)**, blood from a ruptured AVM is usually not deposited in the basal cisterns, and symptomatic cerebral vasospasm is rare. The risk of AVM rupture is strongly influenced by a history of prior rupture. Although unruptured AVMs have a hemorrhage rate of ~2–4% per year, previously ruptured AVMs may have a rate as high as 17% a year, at least for the first year. Hemorrhages may be massive, leading to death, or may be as small as 1 cm in diameter, leading to minor focal symptoms or no deficit. The AVM may be large enough to steal blood away from adjacent normal brain tissue or to increase venous pressure significantly to produce venous ischemia locally and in remote areas of the brain. This is seen most often with large AVMs in the territory of the middle cerebral artery.

Large AVMs of the anterior circulation may be associated with a systolic and diastolic bruit (sometimes self-audible) over the eye, forehead, or neck and a bounding carotid pulse. Headache at the onset of AVM rupture is generally not as explosive as with aneurysmal rupture. MRI is better than CT for diagnosis, although noncontrast CT scanning sometimes detects calcification of the AVM and contrast may demonstrate the abnormal blood vessels. Once identified, conventional x-ray angiography is the gold standard for evaluating the precise anatomy of the AVM.

Surgical treatment of AVMs presenting with hemorrhage, often done in conjunction with preoperative embolization to reduce operative bleeding, is usually indicated for accessible lesions. Stereotactic radiosurgery, an alternative to conventional surgery, can produce a slow sclerosis of the AVM over 2–3 years.

Several angiographic features can be used to help predict future bleeding risk. Paradoxically, smaller lesions seem to have a higher hemorrhage rate. The presence of deep venous drainage, venous outflow stenosis, and intranidal aneurysms may increase rupture risk. Because of the relatively low annual rate of hemorrhage and the risk of complications due to surgical or endovascular treatment, the indications for surgery in asymptomatic AVMs are uncertain. The ARUBA (A Randomized Trial of Unruptured Brain Arteriovenous Malformations) trial randomized patients to medical management versus intervention (surgery, endovascular embolization, combination embolization and surgery, or gamma-knife). The trial was stopped prematurely for harm, with the medical arm achieving the combined endpoint of death or symptomatic stroke in 10% of patients compared to 31% in the intervention group at a mean follow-up time of 33 months. This highly significant finding argues against routine intervention for patients presenting without hemorrhage, although debate ensues regarding the generalizability of these results.

CAVERNOUS ANGIOMAS

Cavernous angiomas (cavernous malformations) are tufts of capillary sinusoids that form within the deep hemispheric white matter and brainstem with no normal intervening neural structures. The pathogenesis is unclear. Most cavernous angiomas are congenital, but they may occur during life as well. Familial cavernous angiomas have been mapped to several different genes: *KRIT1, CCM2*, and *PDCD10*. Both *KRIT1* and *CCM2* have roles in blood vessel formation, whereas *PDCD10* is an apoptotic gene. Cavernous angiomas are typically <1 cm in diameter and are often associated with a venous anomaly. Bleeding is usually of small volume, causing slight mass effect only. The bleeding risk for single cavernous malformations is 0.7–1.5% per year and may be higher for patients with prior clinical hemorrhage or multiple malformations. Seizures may occur if the malformation is located near the cerebral cortex. Surgical resection eliminates bleeding risk and may reduce seizure risk but is usually reserved for those malformations that form near the brain surface in patients with prior clinical episodes of bleeding or with medically refractory seizures. Stereotactic radiosurgery has been considered as a secondary treatment, but risks may outweigh benefits. Retrospective data show that intracranial hemorrhage from cavernous malformations is likely not increased with administration of antiplatelet and anticoagulant medications prescribed for other medical conditions.

Developmental venous anomalies are the result of development of anomalous cerebral, cerebellar, or brainstem venous drainage. These structures, unlike AVMs, are functional venous channels. They are of little clinical significance and should be ignored if found incidentally on brain imaging studies. Surgical resection of these anomalies may result in venous infarction and hemorrhage. Venous anomalies may be associated with cavernous malformations, which do carry some bleeding risk.

Capillary telangiectasias are true capillary malformations that often form extensive vascular networks through an otherwise normal brain structure. The pons and deep cerebral white matter are typical locations, and these capillary malformations can be seen in patients with hereditary hemorrhagic telangiectasia (Osler-Rendu-Weber) syndrome. If bleeding does occur, it rarely produces mass effect or significant symptoms. No treatment options exist.

Dural arteriovenous fistulas are acquired connections usually from a dural artery to a dural sinus. Patients may complain of a pulse-synchronous cephalic bruit ("pulsatile tinnitus") and headache. Depending on the magnitude of the shunt, venous pressures may rise high enough to cause cortical ischemia or venous hypertension and hemorrhage, particularly SAH. Surgical and endovascular techniques are usually curative. These fistulas may form because of trauma, but most are idiopathic. There is an association between fistulas and dural sinus thrombosis. Fistulas have been observed to appear months to years following venous sinus thrombosis, suggesting that angiogenesis factors elaborated from the thrombotic process may cause these anomalous connections to form. Alternatively, dural arteriovenous fistulas can produce venous sinus occlusion over time, perhaps from the high pressure and high flow through a venous structure.

440 Subarachnoid Hemorrhage

Wade S. Smith, Nerissa U. Ko, J. Claude Hemphill, III

Subarachnoid hemorrhage (SAH) renders the brain critically ill from both primary and secondary brain insults. Excluding head trauma, the most common cause of SAH is rupture of a saccular aneurysm. Other causes include bleeding from a vascular malformation (arteriovenous malformation or dural arteriovenous fistula) and extension into the

subarachnoid space from a primary intracerebral hemorrhage. Some idiopathic SAHs are localized to the perimesencephalic cisterns and are benign; they probably have a venous or capillary source, and angiography is unrevealing.

SACCULAR ("BERRY") ANEURYSM

Autopsy and angiography studies have found that ~2% of adults harbor intracranial aneurysms, for a prevalence of 4 million persons in the United States. The incidence of SAH from aneurysmal rupture is estimated at between 6 and 11 per 100,000 person-years, resulting in 25,000–30,000 cases annually in the United States, with a 1.3 relative risk in women. Although most affected patients are under age 55, there is also an increasing incidence with age. The overall mortality rate for aneurysmal SAH is ~35%, with approximately one-third of patients dying immediately and prior to hospital admission. Of those who survive, more than half are left with clinically significant neurologic deficits because of the initial hemorrhage, delayed cerebral ischemia, or hydrocephalus. If the patient survives but the aneurysm is not obliterated, the rate of rebleeding is ~20% in the first 2 weeks, 30% in the first month, and ~3% per year afterward. Given these alarming figures, the major therapeutic emphasis is on preventing the predictable early complications of the SAH.

Unruptured, asymptomatic aneurysms are much less dangerous than recently ruptured ones. A large international observational study found that the annual risk of rupture for unruptured aneurysms <7 mm in size was 0% over 5 years. However, subsequent studies from Japan and Finland found that the majority of ruptured aneurysms were <6 mm in size. Aneurysms of <3 mm in size rarely, if ever, bleed. As the size of an aneurysm increases, so does the risk for rupture, but growth is not linear and appears to occur in phases, making surveillance for growing aneurysms problematic. The location of an unruptured aneurysm is also important in assessment, as basilar bifurcation and origin posterior communicating artery aneurysms appear to have a higher risk for rupture than other sites. Because of their longer length of exposure to risk of rupture, younger patients with aneurysms >10 mm in size may benefit from prophylactic treatment (see below). As with the treatment of asymptomatic carotid stenosis **(Chap. 438)**, this risk-benefit ratio strongly depends on the rate of procedural complications.

Giant aneurysms, those >25 mm in diameter, occur at the same sites (see below) as small aneurysms, and account for 5% of cases. The three most common locations are the terminal internal carotid artery, middle cerebral artery (MCA) bifurcation, and top of the basilar artery. Their risk of rupture is ~8–10% annually after identification and may remain high indefinitely. They often cause symptoms by compressing the adjacent brain or cranial nerves.

Mycotic aneurysms are usually located distal to the first bifurcation of major arteries of the circle of Willis. Most result from infected emboli due to bacterial endocarditis causing septic degeneration of arteries and subsequent dilation and rupture. Whether these lesions should be sought and repaired prior to rupture or left to heal spontaneously with antibiotic treatment remains controversial.

Pathophysiology Saccular aneurysms occur at the bifurcations of the large- to medium-sized intracranial arteries; rupture is into the subarachnoid space in the basal cisterns and sometimes into the parenchyma of the adjacent brain.

Approximately 89% of aneurysms occur in the anterior circulation, mostly on the circle of Willis **(Fig. 440-1)**. About 20% of patients have multiple aneurysms, many at mirror sites bilaterally. As an aneurysm develops, it typically forms a neck with a dome. The length of the neck and the size of the dome vary greatly and are important factors in planning neurosurgical obliteration or endovascular embolization. The arterial internal elastic lamina disappears at the base of the neck. The media thins, and connective tissue replaces smooth-muscle cells. At the site of rupture (most often the dome), the wall thins, and the tear that allows bleeding is often ≤0.5 mm long. Fusiform aneurysms, where the locations of inflow and outflow are different, typically occur in the basilar artery and are very challenging to treat.

Clinical Manifestations Most unruptured intracranial aneurysms are completely asymptomatic. Symptoms are usually due to rupture and resultant SAH, although some unruptured aneurysms present with mass effect on cranial nerves or brain parenchyma. At the moment of aneurysmal rupture with a major SAH, the intracranial pressure (ICP) suddenly rises. This may account for the sudden transient loss of consciousness that occurs in nearly half of patients. Sudden loss of consciousness may be preceded by a brief moment of excruciating headache, but most patients first complain of headache upon regaining consciousness. In 10% of cases, aneurysmal bleeding is severe enough to cause loss of consciousness for several days. In ~45% of cases, severe headache associated with exertion is the presenting complaint. The patient often calls the headache "the worst headache of my life"; however, the most important characteristic is sudden onset. Occasionally, these ruptures may present as headache of only moderate intensity or as a change in the patient's usual headache pattern. The headache is usually generalized, often with neck stiffness, and vomiting is common.

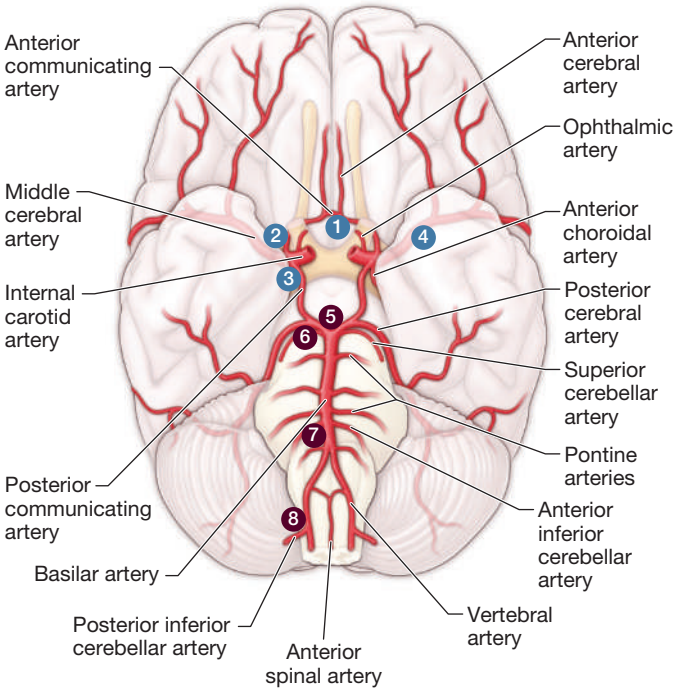

FIGURE 440-1 View of the major blood vessels supplying the brain and common locations of saccular aneurysms: (1) Anterior communicating (12%), (2) internal carotid (30%), (3) posterior communicating (12%), (4) middle cerebral (34%), (5) basilar terminus, (6) superior cerebellar, (7) anterior inferior cerebellar, and (8) posterior inferior cerebellar aneurysm. Locations 1–4 are considered anterior circulation aneurysms totaling 89% overall, while locations 5–8 total 11%.

Although sudden headache in the absence of focal neurologic symptoms is the hallmark of aneurysmal rupture, focal neurologic deficits may occur. Anterior communicating artery or MCA bifurcation aneurysms may rupture into the adjacent brain or subdural space and form a hematoma large enough to produce mass effect. The deficits that result can include hemiparesis, aphasia, and mental slowness (abulia).

Occasionally, prodromal symptoms suggest the location of a progressively enlarging unruptured aneurysm. A third cranial nerve palsy, particularly when associated with pupillary dilation, loss of ipsilateral (but retained contralateral) light reflex, and focal pain above or behind the eye, may occur with an expanding aneurysm at the junction of the posterior communicating artery and the internal carotid artery. A sixth nerve palsy may indicate an aneurysm in the cavernous sinus, and visual field defects can occur with an expanding supraclinoid carotid or anterior cerebral artery (ACA) aneurysm. Occipital and posterior cervical pain may signal a posterior inferior cerebellar artery or anterior inferior cerebellar artery aneurysm **(Chap. 438)**. Pain in or behind the eye and in the low temple can occur with an expanding MCA aneurysm. Thunderclap headache is a variant of migraine that simulates an SAH. Before concluding that a patient with sudden, severe headache has thunderclap migraine, a definitive workup for aneurysm or other intracranial pathology is required.

TABLE 440-1 Grading Scales for Subarachnoid Hemorrhage

GRADE	HUNT-HESS SCALE	WORLD FEDERATION OF NEUROSURGICAL SOCIETIES (WFNS) SCALE
1	Asymptomatic, or minimal headache and slight nuchal rigidity. Normal mental status, no cranial nerve or motor findings	GCSa score 15, no motor deficits
2	Moderate to severe headache, nuchal rigidity, normal mental status and motor function, may have cranial nerve deficit	GCS score 13–14, no motor deficits
3	Somnolent, confused, may have cranial nerve or mild motor deficit	GCS score 13–14, with motor deficits
4	Stupor, moderate to severe motor deficit, may have intermittent reflex posturing	GCS score 7–12, with or without motor deficits
5	Coma, reflex posturing or flaccid	GCS score 3–6, with or without motor deficits

[a]Glasgow Coma Scale; see **Table 454-1**.

Aneurysms can undergo small ruptures and leaks of blood into the subarachnoid space, so-called *sentinel bleeds*. Sudden unexplained headache at any location should raise suspicion of SAH and be investigated because a major hemorrhage may be imminent.

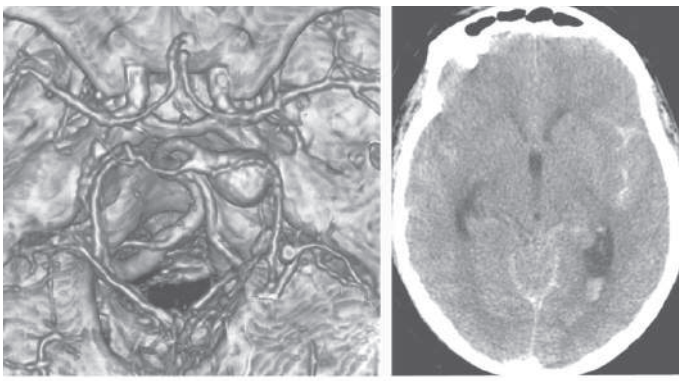
The initial clinical manifestations of SAH can be graded using the Hunt-Hess or World Federation of Neurosurgical Societies classification schemes **(Table 440-1)**. For ruptured aneurysms, prognosis for a good outcome falls as the grade increases. For example, it is unusual for a Hunt-Hess grade 1 patient to die if the aneurysm is treated, but the mortality rate for grade 4 and 5 patients may be as high as 60%.

Delayed Neurologic Deficits There are four major causes of delayed neurologic deficits: rerupture, hydrocephalus, delayed cerebral ischemia, and hyponatremia.

1. *Rerupture*. The incidence of rerupture of an untreated aneurysm in the first month following SAH is ~30%, with the peak in the first 7 days. Rerupture is associated with a 50% mortality rate and poor outcome. Early treatment eliminates this risk, and advances in endovascular and surgical techniques contribute to better outcomes.
2. *Hydrocephalus*. Acute hydrocephalus can cause stupor and coma and can be mitigated by placement of an external ventricular drain. More often, subacute hydrocephalus may develop over a few days or weeks and cause progressive drowsiness or slowed mentation with incontinence. Hydrocephalus may clear spontaneously, require temporary ventricular drainage, or in some cases require placement of a ventriculoperitoneal shunt. Chronic hydrocephalus may develop weeks to months after SAH and manifest as gait difficulty, incontinence, or impaired mentation. Subtle signs may be a lack of initiative in conversation or a failure to recover independence.
3. *Delayed cerebral ischemia*. Vasospasm is the narrowing of the arteries at the base of the brain following SAH and has been associated with delayed cerebral ischemia and infarction. Delayed cerebral ischemia occurs in ~30% of patients and is the major cause of delayed morbidity and death. Signs first appear 4–14 days after the hemorrhage, most often at 7 days. While therapies can be targeted for vasospasm, there are other complex mechanisms associated with delayed cerebral ischemia and progression to infarction independent of vasospasm alone.

   Narrowing of the arteries causing vasospasm and thickening of the vessel wall is believed to result from direct effects of clotted blood and its breakdown products on the arteries within the subarachnoid space. In general, the more blood that surrounds the arteries, the greater is the chance of symptomatic vasospasm. Focal narrowing of major arteries produces symptoms referable to the appropriate vascular territory **(Chap. 437)**. All of these focal symptoms may present abruptly, fluctuate, or develop over a few days. The clinical syndrome often manifests as a decline in mental status and worsening headache.

   Vasospasm of the large arteries can be detected reliably with conventional x-ray angiography, but this procedure is invasive and carries the risk of stroke and other complications. Transcutaneous Doppler ultrasound is based on the principle that the velocity of blood flow within an artery will rise as the lumen diameter is narrowed. By directing the probe along the MCA and proximal ACA, carotid terminus, and vertebral and basilar arteries on a daily or every-other-day basis, vasospasm can be reliably detected and treatments initiated to prevent cerebral ischemia (see below). Computed tomography (CT) angiography is another method that can detect vasospasm. The addition of CT perfusion imaging may help identify reversible ischemic deficits. In high-grade patients, invasive neuromonitoring techniques can also be considered.
4. *Hyponatremia*. Hyponatremia may be profound and can develop quickly in the first 2 weeks following SAH. There is both natriuresis and volume depletion with SAH, so that patients become both hyponatremic and hypovolemic. Both atrial natriuretic peptide and brain natriuretic peptide have a role in producing this "cerebral salt-wasting syndrome." Typically, it clears over the course of 1–2 weeks and, in the setting of SAH, should not be treated with free-water restriction as this may increase the risk of stroke (see below).



Laboratory Evaluation and Imaging (Fig. 440-2) The hallmark of aneurysmal rupture is blood in the CSF. More than 95% of cases have enough blood to be visualized on a high-quality noncontrast CT scan obtained within 72 h. If the scan fails to establish the diagnosis of SAH and no mass lesion or obstructive hydrocephalus is found, a lumbar puncture should be performed to establish the presence of subarachnoid blood. Lysis of the red blood cells and subsequent conversion of hemoglobin to bilirubin stains the spinal fluid yellow within 6–12 h. This xanthochromic spinal fluid peaks in intensity at 48 h and lasts for 1–4 weeks, depending on the amount of subarachnoid blood present.

The extent and location of subarachnoid blood on a noncontrast CT scan help locate the underlying aneurysm, identify the cause of any neurologic deficit, and predict the occurrence of vasospasm. The likelihood of symptomatic vasospasm in the MCA and ACA can be predicted based on the size and location of clotted blood **(Table 440-2)**. CT scans less reliably predict vasospasm in the vertebral, basilar, or posterior cerebral arteries.

Lumbar puncture prior to an imaging procedure is indicated only if a CT scan is not available at the time of the suspected SAH. Once the diagnosis of hemorrhage from a ruptured saccular aneurysm is confirmed, four-vessel conventional x-ray angiography (both carotids and both vertebrals) is generally performed to localize and define the anatomic details of the aneurysm and to determine if other unruptured aneurysms exist **(Fig. 440-2*C*)**. The ruptured aneurysm can be treated using endovascular techniques at the time of the initial angiogram to expedite treatment and minimize the number of invasive procedures. CT angiography is an alternative method for locating the aneurysm and may be sufficient for planning definitive therapy.

Close monitoring (daily or twice daily) of electrolytes is important because hyponatremia can occur precipitously during the first 2 weeks following SAH (see above).

The electrocardiogram (ECG) frequently shows ST-segment and T-wave changes similar to those associated with cardiac ischemia. A prolonged QRS complex, increased QT interval, and prominent "peaked" or deeply inverted symmetric T waves are usually secondary to the intracranial hemorrhage. Structural myocardial lesions produced by circulating catecholamines and excessive discharge of sympathetic neurons may occur after SAH, causing these ECG changes and a reversible cardiomyopathy sufficient to cause shock. Echocardiography often reveals a pattern of regional wall motion abnormalities that follow the distribution of sympathetic nerves rather than the major coronary arteries, with relative sparing of the ventricular wall apex. The sympathetic nerves themselves appear to be injured by direct toxicity

from the excessive catecholamine release. An asymptomatic troponin elevation is common. While arrythmias can occur after SAH, serious ventricular dysrhythmias occurring in-hospital are unusual.

TREATMENT

Subarachnoid Hemorrhage

Early aneurysm repair prevents rerupture and allows the safe application of techniques to improve blood flow (e.g., induced hypertension) should vasospasm and delayed cerebral ischemia develop. At many centers, definitive repair is carried out within 24 h of the bleed in all patients who are stable enough to tolerate the procedure.

TABLE 440-2 Modified Fisher Grading System for Prediction of Vasospasm Risk

GRADE	CT SCAN FINDINGS	RISK OF SYMPTOMATIC VASOSPASM
0	No subarachnoid or intraventicular blood	0%
1	Focal or diffuse thin subarachnoid blood without intraventricular blood	24%
2	Focal or diffuse thin subarachnoid blood with intraventricular blood	33%
3	Focal or diffuse thick subarachnoid blood without intraventricular blood	33%
4	Focal or diffuse thick subarachnoid blood with intraventricular blood	40%

Note: "Thin" is <1 mm, whereas "thick" is ≥1 mm.

Abbreviation: CT, computed tomography.

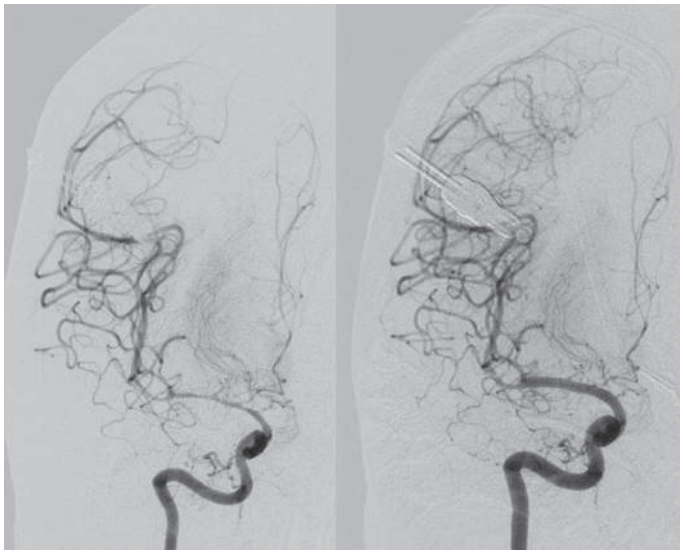
An aneurysm can be "clipped" by a neurosurgeon or "coiled" by an endovascular surgeon. Surgical repair involves placing a metal clip across the aneurysm neck, thereby immediately eliminating the risk of rebleeding. This approach requires craniotomy and brain retraction, which is associated with neurologic morbidity. Endovascular techniques involve placing coils, or other embolic material, within the aneurysm via a catheter that is passed from the femoral or radial artery. The aneurysm is packed tightly to enhance thrombosis and over time is walled off from the circulation **(Fig. 440-2*D*)**. There have been two prospective randomized trials of surgery versus endovascular treatment for ruptured aneurysms: the first was the International Subarachnoid Aneurysm Trial (ISAT), which was terminated early when 24% of patients treated with endovascular therapy were dead or dependent at 1 year compared to 31% treated with surgery, a significant 23% relative reduction. After 5 years, the risk of death was still lower in the coiling group, although the proportion of survivors who were independent was the same in both groups. The risk of rebleeding was generally low, but was more common in the coiling group. These results favoring coiling at 1 year were confirmed in a second trial, although the differences in functional outcome of survivors were no longer significant at 3 years. Because some aneurysms have a morphology that is not amenable to endovascular treatment, surgery remains an important treatment option, especially in cases where evacuation of a parenchymal hematoma could be beneficial. Newer endovascular devices and techniques using balloon-assisted coiling or placement of flow-diverting stents are increasing the types of aneurysms amenable to endovascular intervention. Centers that combine both endovascular and neurosurgical expertise likely offer the best outcomes for patients, and transfer to centers that specialize in aneurysm treatment are associated with improved outcomes and lower mortality rates.

The early medical management of SAH focuses on protecting the airway, managing blood pressure before and after repair of the aneurysm, preventing rebleeding prior to the intervention, and treating hydrocephalus. Subsequent management is focused on preventing late neurologic injury, including managing vasospasm and delayed cerebral ischemia, treating hyponatremia, limiting secondary brain insults from medical comorbidities, and preventing pulmonary emboli.

Intracranial hypertension following aneurysmal rupture occurs secondary to subarachnoid blood, parenchymal hematoma, acute hydrocephalus, and/or loss of vascular autoregulation. Patients who are stuporous should undergo emergent ventriculostomy to measure and treat high ICP in order to prevent cerebral herniation and ischemia. Medical therapies designed to combat raised ICP (e.g., osmotic therapy and sedation) can also be used as needed. High ICP refractory to treatment is a poor prognostic sign. Drainage of CSF via a lumbar route has been shown to decrease the rate of delayed cerebral injury, vasospasm, and mortality but confounds measurement of true ICP.

Prior to definitive treatment of the ruptured aneurysm, care is required to maintain adequate cerebral perfusion pressure while avoiding excessive elevation of arterial pressure. If the patient is alert, it is reasonable to lower the systolic blood pressure to below 160 mmHg using agents such as nicardipine, clevidipine, or labetalol to limit blood pressure variability. If the patient has a depressed level of consciousness, ICP should be measured and the cerebral perfusion pressure targeted to 60–70 mmHg. If headache or neck pain is severe, mild sedation and analgesia are prescribed. Extreme sedation is avoided if possible because it can obscure the ability to clinically detect changes in neurologic status. Goal-directed therapy to target euvolemia is recommended, while avoiding hypervolemia, which has been associated with a greater risk for complications.

Seizures are uncommon at the onset of aneurysmal rupture, but in patients who present with seizures, treatment with a 7-day course of an anticonvulsant such as levetiracetam is reasonable. The quivering, jerking, and extensor posturing that often accompany loss of consciousness with SAH are probably related to the sharp rise in ICP rather than seizures. Monitoring with electroencephalogram



(EEG) can help detect seizures in patients with poor mental status or fluctuating exam findings. Anticonvulsants are sometimes administered as prophylactic therapy in high-risk patients, but if used, the treatment course should also not exceed >7 days. Phenytoin should be avoided because of its association with increased morbidity and mortality in this setting.

Glucocorticoids may reduce the headache and neckache caused by the irritative effect of the subarachnoid blood; however, there is no good evidence that steroids reduce cerebral edema, are neuroprotective, or reduce vascular injury, and their routine use therefore is not recommended.

Antifibrinolytic agents are not routinely prescribed but have been considered in patients in whom aneurysm repair cannot proceed immediately. They are associated with a reduced incidence of aneurysmal rerupture but may also increase the risk of delayed cerebral ischemia and deep-vein thrombosis (DVT). More recent studies showed no improvement in functional outcomes, and use of these agents is not currently recommended.

Delayed cerebral ischemia remains the leading cause of morbidity and mortality following aneurysmal SAH in patients who survive the initial hemorrhage. Treatment with the calcium channel antagonist nimodipine (60 mg PO every 4 h) has been shown to improve outcomes, perhaps by preventing ischemic injury rather than reducing the risk of vasospasm. Nimodipine can cause significant hypotension in some patients, which may worsen cerebral ischemia in patients with vasospasm. Symptomatic cerebral vasospasm can also be treated by increasing the cerebral perfusion pressure by raising mean arterial pressure through plasma volume expansion and the judicious use of IV vasopressor agents, usually phenylephrine or norepinephrine. Increasing perfusion pressure has been associated with clinical improvement in many patients, but high arterial pressure may also promote rebleeding in unrepaired aneurysms. Treatment with induced hypertension in symptomatic patients requires close monitoring of arterial pressures. Prophylactic use of induced hypertension is not recommended, as it is associated with worse outcomes. Euvolemia should be targeted as significant hypervolemia may lead to cardiopulmonary complications. Hypovolemia should be strictly avoided.

If delayed cerebral ischemia due to vasospasm persists despite optimal medical therapy, endovascular rescue therapies with intra-arterial vasodilators and percutaneous transluminal angioplasty can be considered **(Fig. 440-3)**. Vasodilatation by direct angioplasty appears to be permanent, allowing hypertensive therapy to be tapered sooner. In contrast, the pharmacologic vasodilators (verapamil and nicardipine) do not last more than about 24 h, and therefore, multiple treatments may be required until the subarachnoid blood is reabsorbed. Newer therapies including milrinone, neural ganglia blocks, antithrombotic agents, and intrathecal and cisternal agents are currently under investigation.

A ***B***

FIGURE 440-3 Vasospasm of the right middle cerebral artery. ***A.*** Catheter angiography demonstrates significant narrowing of the right middle cerebral artery (MCA). ***B.*** Because of symptomatic delayed cerebral ischemia, soft-balloon angioplasty was used to dilate the proximal portion of the main MCA stem.

Severe cerebral edema in patients with infarction from vasospasm may increase the ICP to levels that reduce cerebral perfusion pressure. Treatment may include cerebrospinal fluid (CSF) drainage, mannitol, or hypertonic saline; for intractable cases, hemicraniectomy, deep sedation, paralysis, and moderate hypothermia may be considered.

Delayed cerebral ischemia may also occur in the absence of significant large-vessel vasospasm. Potential mechanisms include microthrombosis, activation of the inflammatory cascade, microvascular dysregulation and constriction, and cortical spreading depolarization. Targeted treatments for these mechanisms are under investigation.

Acute hydrocephalus can cause stupor or coma. It may clear spontaneously or require temporary ventricular drainage. When chronic hydrocephalus develops, ventricular shunting is the treatment of choice.

Free-water restriction is contraindicated in patients with SAH at risk for delayed cerebral ischemia because hypovolemia and hypotension may occur and precipitate cerebral ischemia. Many patients continue to experience a decline in serum sodium due to cerebral salt wasting despite receiving parenteral fluids containing normal saline. Frequently, supplemental oral salt coupled with normal saline will mitigate hyponatremia, but often patients also require intravenous hypertonic (3%) saline. Care must be taken not to correct serum sodium too quickly in patients with marked hyponatremia of several days' duration, as the osmotic demyelination syndrome **(Chap. 318)** may occur.

All patients should have pneumatic compression stockings applied to prevent pulmonary emboli. Unfractionated heparin and low-molecular-weight heparinoids administered subcutaneously for DVT prophylaxis can be initiated within 1–2 days following endovascular treatment or craniotomy with surgical clipping; this approach is more effective than use of pneumatic compression stockings alone. Treatment of pulmonary emboli depends on whether the aneurysm has been treated and whether or not the patient has had a craniotomy. Continuous systemic anticoagulation with heparin is contraindicated in patients with ruptured and untreated aneurysms. It is a relative contraindication following craniotomy for several days, and it may delay thrombosis of a coiled aneurysm. If DVT or pulmonary emboli occur within the first days following craniotomy, use of an inferior vena cava filter may be considered to prevent additional emboli, whereas systemic anticoagulation with heparin is preferred following successful endovascular treatment.

In patients who survive their acute hospitalization, follow-up care is important to address the high prevalence of cognitive and behavioral deficits that greatly impact quality of life. Efficient recognition and treatment of these disorders can improve both short-term and long-term outcomes. In addition, some patients require ongoing follow-up to manage unruptured aneurysms that may require further care.

441 Migraine and Other Primary Headache Disorders

Peter J. Goadsby

The general approach to headache as a cardinal symptom is covered elsewhere (Chap. 17); here, disorders in which headache and associated features occur in the absence of any exogenous cause are discussed. The most common are migraine, tension-type headache (TTH), and the trigeminal autonomic cephalalgias (TACs), notably cluster headache; the complete list is summarized in Table 441-1.

MIGRAINE

Migraine, the second most common cause of headache, and the most common headache-related, and indeed neurologic, cause of disability in the world, afflicts ~15% of women and 6% of men over a 1-year period. It is usually an episodic headache associated with certain features, such as sensitivity to light, sound, or movement; nausea and vomiting often accompany the headache. A useful description of migraine is a recurring syndrome of headache associated with other symptoms of neurologic dysfunction in varying admixtures (Table 441-2). A migraine attack has three phases: premonitory (prodrome), headache phase, and postdrome; each has distinct and sometimes disabling symptoms, which may overlap. About 20–25% of migraine patients have a fourth phase: aura. Migraine can often be recognized by its activators, referred to as *triggers*.

Migraineurs are particularly sensitive to environmental and sensory stimuli; migraine-prone patients do not habituate easily to sensory stimuli. This sensitivity is amplified in women during the menstrual cycle. Headache can be initiated or amplified by various triggers, including altered sleep patterns; hunger; let-down from stress; physical exertion; stormy weather or barometric pressure changes; hormonal fluctuations during menses; and alcohol or other chemical stimulation, such as with nitrates. Knowledge of a patient's susceptibility to specific triggers can be useful in management strategies involving lifestyle adjustments, although it is becoming recognized that some apparent triggers, such as light sensitivity, may be part of the initial phase of the attack; i.e., the premonitory phase or prodrome.

Pathogenesis The sensory sensitivity that is characteristic of migraine is probably due to dysfunction of monoaminergic and other sensory control systems located in the brainstem and hypothalamus (Fig. 441-1).

Activation of cells in the trigeminal nucleus results in the release of vasoactive neuropeptides, notably calcitonin gene–related peptide (CGRP) and pituitary adenylate cyclase activating polypeptide (PACAP), at vascular terminals of the trigeminal nerve and within the trigeminal nucleus. CGRP receptor antagonists, *gepants*, have now been shown to be effective in the acute and preventive treatment of migraine, and four monoclonal antibodies to CGRP, or its receptor, have been shown to be effective in migraine prevention, as has one PACAP monoclonal antibody in a phase 2 study. Centrally, the second-order trigeminal neurons cross the midline and project to ventrobasal and posterior nuclei of the thalamus for further processing. Additionally, there are projections to the periaqueductal gray and hypothalamus, from which reciprocal descending systems have established antinociceptive effects. Other brainstem regions likely to be involved in descending modulation of trigeminal pain include the locus coeruleus and parabrachial nucleus in the pons and the rostroventromedial medulla.

Pharmacologic and other data point to the involvement of the neurotransmitter 5-hydroxytryptamine (5-HT; also known as *serotonin*) in migraine. In the late 1950s, methysergide was suggested to antagonize certain peripheral actions of 5-HT and was introduced, based on its anti-inflammatory properties, as a migraine preventive. The *triptans* were designed to stimulate selectively subpopulations of 5-HT receptors; at least 14 different 5-HT receptors exist in humans. The triptans are potent agonists of 5-HT_{1B} and 5-HT_{1D} receptors, and some are active at the 5-HT_{1F} receptor; the latter's exclusive agonists are called *ditans*. Triptans arrest nerve signaling in the nociceptive pathways of the trigeminovascular system, at least in the trigeminal nucleus caudalis and trigeminal sensory thalamus, in addition to promoting cranial vasoconstriction, whereas *ditans*, which are also effective in acute migraine, act only at neural targets. A range of other neural targets are currently under investigation for the acute and preventive management of migraine.

Data also support a role for dopamine in the pathophysiology of migraine. Many migraine premonitory symptoms can be induced by dopaminergic stimulation. Moreover, there is dopamine receptor hypersensitivity in migraineurs, as demonstrated by the induction of yawning, nausea, vomiting, hypotension, and other symptoms of a migraine attack by dopaminergic agonists at doses that do not affect nonmigraineurs. Dopamine receptor antagonists are effective therapeutic agents in migraine, especially when given parenterally or concurrently with other antimigraine agents. Moreover, hypothalamic activation, anterior to that seen in cluster headache, has been shown in the premonitory (prodromal) phase of migraine using functional imaging, and this may hold a key to understanding some part of the role of dopamine in the disorder.

Migraine genes identified by studying families with familial hemiplegic migraine (FHM) reveal involvement of ion channels, suggesting that alterations in membrane excitability can predispose to migraine aura. Mutations involving the $Ca_v2.1$ (P/Q)–type voltage-gated calcium channel *CACNA1A* gene are now known to cause FHM 1; this mutation is responsible for about 50% of FHM cases. Mutations in the Na^+-K^+ ATPase *ATP1A2* gene, designated FHM 2, are responsible for about 20% of FHMs. Mutations in the neuronal voltage-gated sodium channel *SCN1A* cause FHM 3. Functional neuroimaging has suggested that brainstem regions in migraine (Fig. 441-2) and the posterior hypothalamic gray matter region close to the human circadian pacemaker cells of the suprachiasmatic nucleus in cluster headache (Fig. 441-3) are good candidates for specific involvement in these primary headache disorders.

Diagnosis and Clinical Features Classic diagnostic criteria for migraine headache are listed in Table 441-3 and should be considered together with the extended features in Table 441-2. A high index of suspicion is required to diagnose migraine: the migraine aura, consisting of visual disturbances with flashing lights or zigzag lines moving across the visual field or of other neurologic symptoms, is reported in only 20–25% of patients. It should be distinguished from the pan-field television static-like disturbance now recognized as *visual snow*. The first phase of a migraine attack for most patients is the premonitory (prodromal) phase consisting of some or all of the following: yawning, sleepiness, fatigue, cognitive dysfunction, mood change, neck discomfort, polyuria, and food cravings; this can last from a few hours to days. Typically, the headache phase follows with its associated features, such as nausea, photophobia, and phonophobia as well as allodynia or vertigo. When questioned, these typical migraine symptoms also emerge in the premonitory phase, and typical premonitory symptoms also continue into the headache phase. As the headache lessens, many patients enter a postdrome, most commonly feeling tired/weary, having problems concentrating, and experiencing mild neck discomfort that can last for hours and sometimes up to a day. A headache diary can often be helpful in making the diagnosis and in assessing disability and the frequency of acute attacks. Patients with episodes of migraine on 8 or more days per month and with at least 15 total days of headache per month are considered to have chronic migraine (see "Chronic Daily Headache" in Chap. 17). Migraine must be differentiated from TTH (discussed below), which is reported to be the most common primary headache disorder. Migraine has several forms that have been defined (Table 441-1): migraine with and without aura and chronic migraine are the most important. *Migraine at its most*

TABLE 441-1 Primary Headache Disorders, Modified from International Classification of Headache Disorders-III (Headache Classification Committee of the International Headache Society, 2018)

1. Migraine	1.1 Migraine without aura 1.2 Migraine with aura 1.2.1 Migraine with typical aura 1.2.1.1 Typical aura with headache 1.2.1.2 Typical aura without headache 1.2.2 Migraine with brainstem aura 1.2.3 Hemiplegic migraine 1.2.3.1 Familial hemiplegic migraine (FHM) 1.2.3.1.1 Familial hemiplegic migraine type 1 1.2.3.1.2 Familial hemiplegic migraine type 2 1.2.3.1.3 Familial hemiplegic migraine type 3 1.2.3.1.4 Familial hemiplegic migraine, other loci 1.2.3.2 Sporadic hemiplegic migraine 1.2.4 Retinal migraine 1.3 Chronic migraine 1.4 Complications of migraine 1.4.1 Status migrainosus 1.4.2 Persistent aura without infarction 1.4.3 Migrainous infarction 1.4.4 Migraine aura-triggered seizure 1.5 Probable migraine 1.5.1 Probable migraine without aura 1.5.2 Probable migraine with aura 1.6 Episodic syndromes that may be associated with migraine 1.6.1 Recurrent gastrointestinal disturbance 1.6.1.1 Cyclical vomiting syndrome 1.6.1.2 Abdominal migraine 1.6.2 Benign paroxysmal vertigo 1.6.3 Benign paroxysmal torticollis A 1.6.4 Infantile colic A 1.6.6 Vestibular migraine
2. Tension-type headache	2.1 Infrequent episodic tension-type headache 2.2 Frequent episodic tension-type headache 2.3 Chronic tension-type headache 2.4 Probable tension-type headache
3. Trigeminal autonomic cephalalgias	3.1 Cluster headache 3.1.1 Episodic cluster headache 3.1.2 Chronic cluster headache 3.2 Paroxysmal hemicrania 3.2.1 Episodic paroxysmal hemicrania 3.2.2 Chronic paroxysmal hemicrania 3.3 Short-lasting unilateral neuralgiform headache attacks 3.3.1 Short-lasting unilateral neuralgiform headache attacks with conjunctival injection and tearing (SUNCT) 3.3.1.1 Episodic SUNCT 3.3.1.2 Chronic SUNCT 3.3.2 Short-lasting unilateral neuralgiform headache attacks with cranial autonomic symptoms (SUNA) 3.3.2.1 Episodic SUNA 3.3.2.2 Chronic SUNA 3.4 Hemicrania continua 3.5 Probable trigeminal autonomic cephalalgia
4. Other primary headache disorders	4.1 Primary cough headache 4.2 Primary exercise headache 4.3 Primary headache associated with sexual activity 4.4 Primary thunderclap headache 4.5 Cold-stimulus headache 4.5.1 Headache attributed to external application of a cold stimulus 4.5.2 Headache attributed to ingestion or inhalation of a cold stimulus 4.6 External-pressure headache 4.6.1 External-compression headache 4.6.2 External-traction headache 4.7 Primary stabbing headache 4.8 Nummular headache 4.9 Hypnic headache 4.10 New daily persistent headache (NDPH)

TABLE 441-2 Migraine Symptoms by Attack Phase

Premonitory (prodromal)
- Neck discomfort
- Higher center
• Cognitive impairment (brain "fog")
• Mood change
• Fatigue
- Homeostatic
• Yawning/sleepiness
• Polyuria/polydipsia
• Food cravings
Aura
- Neurologic disturbance, such as scintillating scotoma
Headache phase
- Pain
- Nausea/vomiting
- Sensory sensitivity
• Photophobia
• Phonophobia
• Osmophobia
• Allodynia
• Vertigo
Postdrome
- Tiredness
- Weariness
- Concentration impairment

basic level is headache with associated features, and TTH is headache that is featureless. Most patients with disabling headache probably have migraine.

Patients with acephalgic migraine (typical aura without headache, 1.2.1.2 in Table 441-1) experience recurrent neurologic symptoms, often with nausea or vomiting, but with little or no headache. Vertigo can be prominent; it has been estimated that one-third of patients referred for vertigo or dizziness have a primary diagnosis of migraine; the term vestibular migraine is often used in this setting (Table 441-1 A1.6.6). Migraine aura can have prominent brainstem symptoms, and the terms *basilar artery* and *basilar-type migraine* have now been replaced by *migraine with brainstem aura* (Table 441-1).

TREATMENT

Migraine Headache

Once a diagnosis of migraine has been established, it is important to assess the extent of a patient's disease and disability. The Migraine Disability Assessment Score (MIDAS) is a well-validated, easy-to-use tool **(Fig. 441-4)**.

Patient education is an important aspect of migraine management. Information for patients is available at websites such as the American Migraine Foundation (*www.americanmigrainefoundation.org*) and the Migraine Trust (*www.migrainetrust.org*). It is helpful for patients to understand that migraine is an inherited tendency to headache; that migraine can be modified and controlled by lifestyle adjustments and medications, but it cannot be eradicated; and that, except on some occasions in women on oral estrogens or contraceptives, migraine is not associated with serious or life-threatening illnesses.

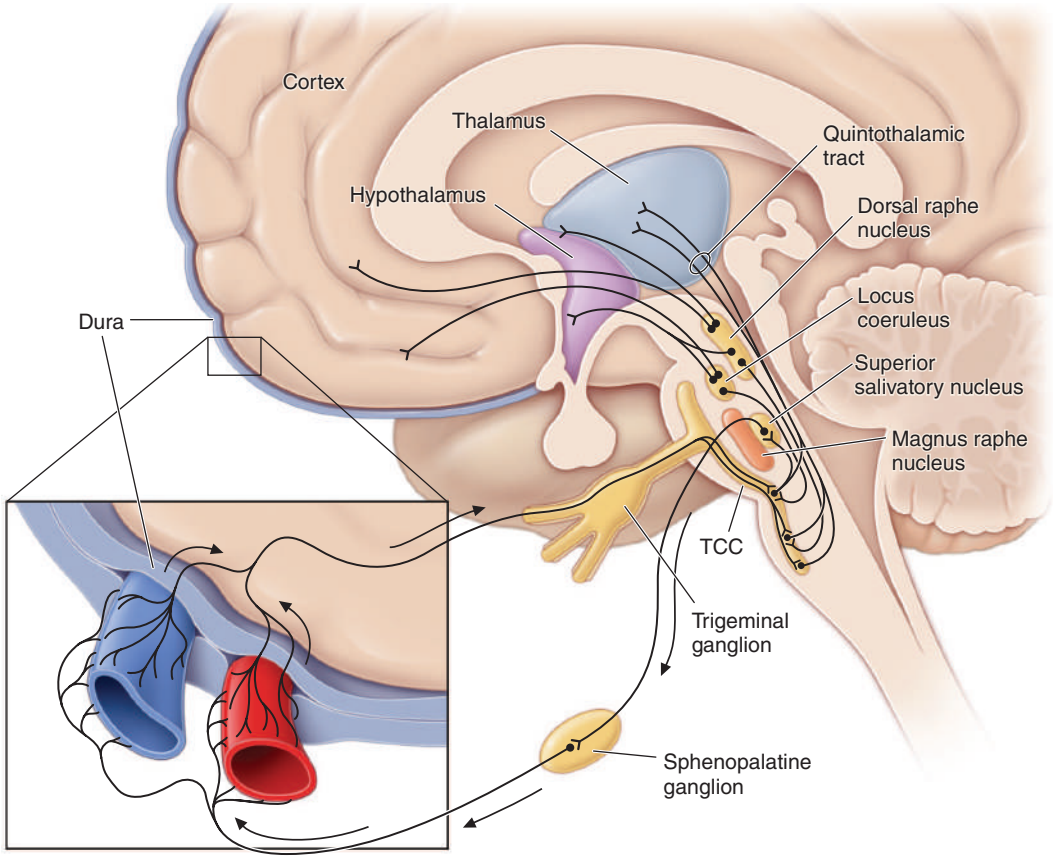

FIGURE 441-1 Brainstem pathways that modulate sensory input. The key pathway for pain in migraine is the trigeminovascular input from the meningeal vessels, which passes through the trigeminal ganglion and synapses on second-order neurons in the trigeminocervical complex (TCC). These neurons in turn project in the quintothalamic tract and, after decussating in the brainstem, synapse on neurons in the thalamus. Important modulation of the trigeminovascular nociceptive input comes from the dorsal raphe nucleus, locus coeruleus, and nucleus raphe magnus.

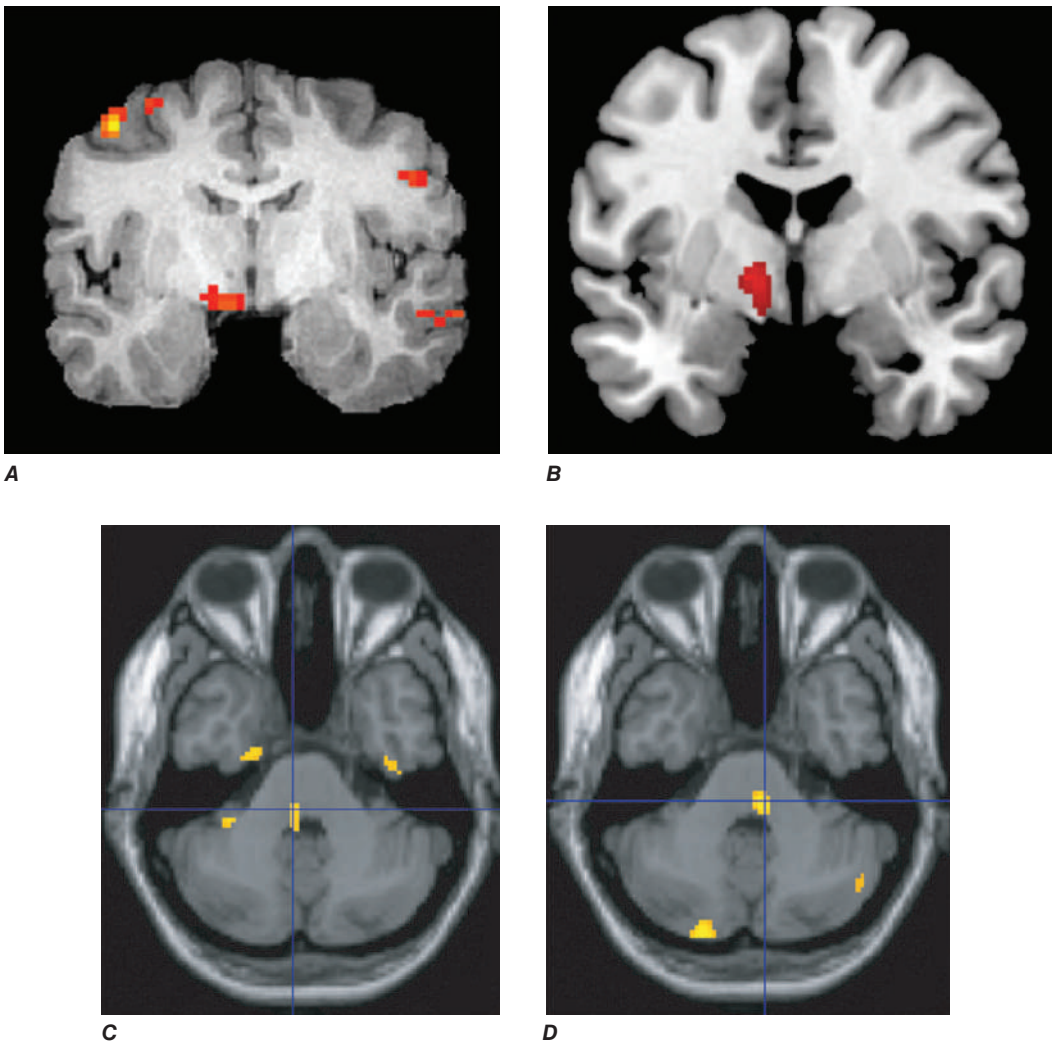

FIGURE 441-2 Positron emission tomography (PET) and arterial spin labelled activations in migraine. Hypothalamic, dorsal midbrain, and dorsolateral pontine activation are seen in triggered attacks in the premonitory phase before pain, whereas in migraine attacks, dorsolateral pontine activation persists, as it does in chronic migraine (not shown). The dorsolateral pontine area, which includes the noradrenergic locus coeruleus, is fundamental to the expression of migraine. Moreover, lateralization of changes in this region of the brainstem correlates with lateralization of the head pain in hemicranial migraine; the scans shown in panels ***C*** and ***D*** are of patients with acute migraine headache on the right and left side, respectively. *(Panel A from FH Maniyar et al: Brain activations in the premonitory phase of nitroglycerin-triggered migraine attacks. Brain 137:232, 2014. Panel B from unpublished data, Karsan and Goadsby. Panels C and D from SK Afridi et al: A PET study exploring the laterality of brainstem activation in migraine using glyceryl trinitrate. Brain 128:932, 2005.)*

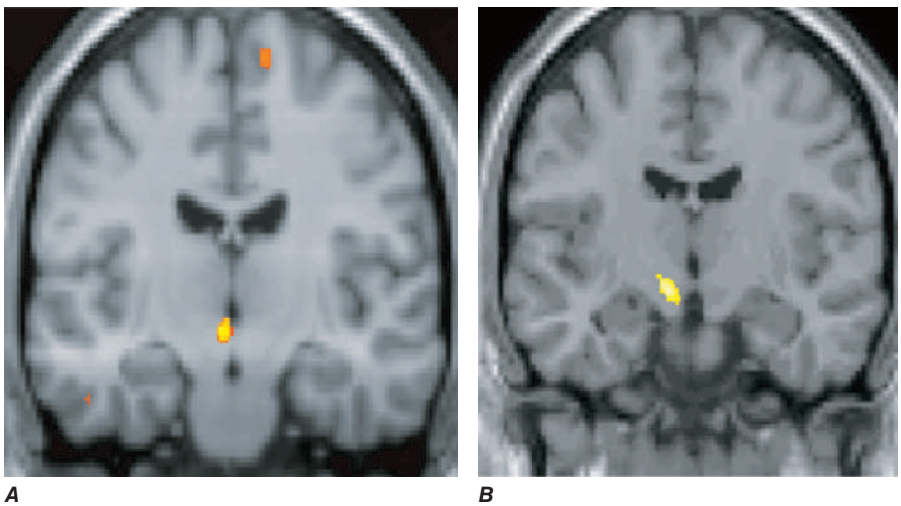

FIGURE 441-3 ***A.*** Posterior hypothalamic gray matter region activation demonstrated by positron emission tomography in a patient with acute cluster headache. ***B.*** High-resolution T1-weighted magnetic resonance image obtained using voxel-based morphometry demonstrates increased gray matter activity, lateralized to the side of pain in a patient with cluster headache. *(Panel A from A May et al: Hypothalamic activation in cluster headache attacks. Lancet 352:275, 1998. Panel B from A May et al: Correlation between structural and functional changes in brain in an idiopathic headache syndrome. Nat Med 5:836, 1999.)*

TABLE 441-3 Simplified Diagnostic Criteria for Migraine

REPEATED ATTACKS OF HEADACHE LASTING 4–72 H IN PATIENTS WITH A NORMAL PHYSICAL EXAMINATION, NO OTHER REASONABLE CAUSE FOR THE HEADACHE, AND:	
AT LEAST 2 OF THE FOLLOWING FEATURES:	**PLUS AT LEAST 1 OF THE FOLLOWING FEATURES:**
Unilateral pain	Nausea/vomiting
Throbbing pain	Photophobia and phonophobia
Aggravation by movement	
Moderate or severe intensity

NONPHARMACOLOGIC MANAGEMENT

Migraine can often be managed to some degree by a variety of nonpharmacologic approaches. When patients can identify reliable triggers, their avoidance can be useful. A regulated lifestyle is helpful, including a healthy diet, regular exercise, regular sleep patterns, avoidance of excess caffeine and alcohol, and avoidance of acute changes in stress levels, being particularly wary of the let-down effect.

The measures that benefit a given individual should be used routinely because they provide a simple, cost-effective approach to migraine management. Patients with migraine do not encounter more stress than headache-free individuals; overresponsiveness to changes in stress appears to be the issue. Because the stresses of everyday living cannot be eliminated, lessening one's response to stress by various techniques is helpful for many patients. These may include yoga, transcendental meditation, hypnosis, and conditioning techniques such as biofeedback. For most patients seen in clinical practice, this approach is, at best, an adjunct to pharmacotherapy. Nonpharmacologic measures are unlikely to prevent all migraine attacks, and pharmacologic approaches are often needed.

ACUTE ATTACK THERAPIES FOR MIGRAINE

The mainstay of pharmacologic therapy is the judicious use of one or more of the many medicines that are effective in migraine **(Table 441-4)**. The selection of the optimal regimen for a given patient depends on a number of factors, the most important of which is the severity of the attack. Mild migraine attacks can usually be managed by oral agents; the average efficacy (pain relief) rate is 50–70%. Severe migraine attacks may require parenteral therapy. Most drugs effective in the treatment of migraine are members of one of five major pharmacologic classes: nonsteroidal anti-inflammatory drugs; 5-$HT_{1B/1D}$ receptor agonists—triptans; CGRP receptor antagonists—gepants; 5-HT_{1F} receptor agonists—ditans; and dopamine receptor antagonists.

In general, an adequate dose of whichever agent is chosen should be used as soon as possible after the onset of an attack. If additional medication is required within 60 min because symptoms return or have not abated, the initial dose should be increased for subsequent attacks or a different class of drug tried as first-line treatment. Repeat dosing of the same medicine at 2 h, while safe, is ineffective for triptans, and in contrast effective for gepants. Migraine therapy must be individualized; a standard approach for all patients is not possible. A therapeutic regimen may need to be refined until one is identified that provides the patient with rapid, complete, and consistent relief with minimal side effects **(Table 441-5)**.

Nonsteroidal Anti-Inflammatory Drugs (NSAIDs) Both the severity and duration of a migraine attack can be reduced significantly by NSAIDs (Table 441-4). Indeed, many undiagnosed migraineurs self-treat with nonprescription NSAIDs. A general consensus is that NSAIDs are most effective when taken early in the migraine attack. However, the effectiveness of these agents in migraine is usually less than optimal in moderate or severe migraine attacks. The combination of acetaminophen (paracetamol), aspirin, and caffeine has been approved for use by the U.S. Food and Drug Administration (FDA) for the treatment of mild to moderate migraine. The combination of aspirin and metoclopramide has been shown to be

***MIDAS Questionnaire**

INSTRUCTIONS: Please answer the following questions about ALL headaches you have had over the last 3 months. Write zero if you did not do the activity in the last 3 months.
