Patients who have lcSSc coexisting with features of SLE, polymyositis, and rheumatoid arthritis may have mixed connective tissue disease (MCTD), generally associated with high titers of autoantibodies to U1-RNP. The characteristic initial presentation is Raynaud's phenomenon associated with puffy fingers and myalgia. Over time, sclerodactyly, soft tissue calcinosis, and cutaneous telangiectasia may appear. Skin rash suggestive of SLE (malar erythema, photosensitivity) or

dermatomyositis (heliotrope rash on the eyelids, erythematous rash on knuckles) may occur. Arthralgia is common, and some patients develop erosive polyarthritis. Pulmonary fibrosis and isolated or secondary PAH may develop. Other manifestations include esophageal dysmotility, pericarditis, Sjögren's syndrome, and renal disease, especially membranous glomerulonephritis. Laboratory evaluation shows elevated ESR and hypergammaglobulinemia. In contrast to SSc, MCTD often responds to glucocorticoids, and the long-term prognosis is better than that of SSc. Whether MCTD is truly a distinct entity or is a subset of SLE or SSc remains controversial.

EOSINOPHILIC FASCIITIS (DIFFUSE FASCIITIS WITH EOSINOPHILIA)

Eosinophilic fasciitis is a rare idiopathic disorder of adults associated with abrupt skin induration. The skin characteristically shows a coarse cobblestone "peau d'orange" appearance. In contrast to SSc, Raynaud's phenomenon and SSc-associated internal organ involvement and autoantibodies are absent. Furthermore, skin involvement spares the fingers. Full-thickness biopsy of the lesional skin reveals fibrosis of the subcutaneous fascia, with variable inflammation and eosinophil infiltration. In the acute phase of the illness, peripheral blood eosinophilia may be prominent. MRI appears to be a sensitive tool for the diagnosis of eosinophilic fasciitis. Eosinophilic fasciitis can occur in association with, or preceding, various myelodysplastic syndromes or multiple myeloma. Although glucocorticoids cause prompt resolution of eosinophilia, the skin shows slow and variable improvement. The prognosis of patients with eosinophilic fasciitis is generally good.

373 Sjögren's Disease

Haralampos M. Moutsopoulos, Clio P. Mavragani

DEFINITION, INCIDENCE, AND PREVALENCE

Sjögren's disease is a prototype autoimmune disease characterized by lymphocytic infiltration of the exocrine glands resulting in xerostomia, dry eyes (keratoconjunctivitis sicca), and profound B-cell hyperactivity. The disease has unique features since it presents with a wide clinical spectrum from organ-specific to systemic disease; can occur alone or in association with other systemic rheumatic diseases, more commonly rheumatoid arthritis, limited scleroderma, and systemic lupus erythematosus; and displays high probability of the development of lymphoma. Because of all these characteristics, it is an ideal model to study not only autoimmunity but also lymphoid malignancy.

Middle-aged women (female-to-male ratio 10–20:1) are primarily affected, although Sjögren's disease may occur at any age, including childhood. Patients with earlier disease onset express a more aggressive disease phenotype manifested by a high occurrence of systemic manifestations and serum autoantibodies. The prevalence of Sjögren's disease is ~0.5–1%, while 5–20% of patients with other autoimmune diseases can express sicca manifestations.

PATHOGENESIS

The autoimmune phenomena observed in Sjögren's disease include lymphocytic infiltration of the exocrine glands (primarily salivary and lachrymal glands) and B lymphocyte hyperreactivity. The latter is mainly manifested by hypergammaglobulinemia and the presence of serum autoantibodies toward non-organ-specific antigens such as immunoglobulins (rheumatoid factors) and extractable cellular antigens (Ro52, Ro60, and La). The major infiltrating cells in the affected exocrine glands are activated T lymphocytes. In labial minor salivary gland tissues with extensive lymphocytic infiltrations, B-cell populations prevail. Other cellular subsets detected in the labial minor salivary gland histopathologic lesion of Sjogren's disease include follicular, myeloid, and plasmacytoid dendritic cells, as well as macrophages. The latter along with inflammasome activation have been shown to be associated with increased risk for lymphoma development.

The interplay of endogenous (e.g., intracellular stress, inappropriate overexpression of endogenous nucleic acids) and exogenous triggers (e.g., viruses, hormonal triggers, stressful life events) in a background of a genetically determined hyperactive immune response seems to be crucial for the initiation and perpetuation of the disease. Ductal and acinar epithelial cells appear to play a significant role in the initiation and perpetuation of autoimmune injury. These cells (1) express inappropriately costimulatory molecules and the intracellular autoantigens Ro and La on their cell surfaces, acquiring the capacity to provide signals essential for lymphocytic activation; (2) produce proinflammatory cytokines and lymphocyte-attracting chemokines necessary for sustaining the autoimmune lesion and allowing the formation of ectopic germinal centers; (3) express functional receptors of innate immunity, particularly Toll-like receptors (TLRs) 3, 7, and 9 molecules, which may account for the initiation of the autoimmune reactivity; and (4) display immunoregulatory molecules such as ICAM and CD40. Glandular epithelial cells also seem to have an active role in the production of B cell–activating factor (BAFF), which is induced after stimulation with type I and II interferons. Circulating BAFF has been found to be elevated also in the serum of Sjögren's disease patients, especially those with hypergammaglobulinemia and serum autoantibodies, and probably accounts for the antiapoptotic effect on B lymphocytes.

In contrast to B and T lymphocytes, glandular epithelial cells display increased rates of apoptotic death. Established risk genetic loci implicated in Sjögren's disease include the human leukocyte antigen DQA1*0501 allele, variations involved in the interferon/BAFF axis (*IRF5, STAT4, BAFF*) and B-cell function (*EBF1, BLK*), as well as combined genetic deficiencies in the classical complement pathway.

CLINICAL MANIFESTATIONS

Most patients with Sjögren's disease have symptoms related to impaired exocrine gland, particularly lacrimal and salivary gland, function. The disease evolution is slow and, in the majority of patients, runs a benign course. Studies have shown that prior to disease onset, patients with Sjögren's disease experience major stressful life events with which they cannot cope adequately.

The principal oral symptom of Sjögren's disease is dryness (xerostomia). Patients report difficulty in swallowing dry food, a burning mouth sensation, an increase in dental caries, and problems in wearing complete dentures. Physical examination shows a dry, erythematous sticky oral mucosa. In patients with severe oral dryness, the filiform papillae on the tongue dorsum are atrophic, and the tongue is deeply fissured **(Fig. 373-1)**. Furthermore, saliva from the major glands is either not expressible or cloudy. Intermittent or persistent enlargement of the parotid or other major salivary glands occurs in two-thirds of patients with Sjögren's disease. Diagnostic tests include sialometry and several imaging techniques, including ultrasound, magnetic resonance

FIGURE 373-1 A dry deeply fissured tongue from a patient with Sjögren's disease.

TABLE 373-1 Prevalence of Extraglandular Manifestations in Primary Sjögren's disease

CLINICAL MANIFESTATION	PERCENT	REMARKS
Nonspecific		
Fatigability/myalgias	25	Fibromyalgia
Arthralgias/arthritis	60	Usually nonerosive, leading to Jaccoud's arthropathy
Raynaud's phenomenon	37	In one-third of patients, precedes sicca manifestations
Periepithelial		
Lung involvement	14	Small airway disease/lymphocyte interstitial pneumonitis
Kidney involvement	9	Interstitial kidney disease is usually asymptomatic
Liver involvement	6	Primary biliary cirrhosis stage I
Immune complex–mediated		
Small vessel vasculitis	9	Purpura, urticarial lesions
Peripheral neuropathy	2	Polyneuropathy, either sensory or sensorimotor
Glomerulonephritis	2	Membranoproliferative
Lymphoma		
Lymphoma	6	Glandular MALT[a] lymphoma is most common

[a]Mucosa-associated lymphoid tissue.

imaging (MRI), and magnetic resonance sialography of the major salivary glands. In particular, salivary gland ultrasound is an emerging tool of both diagnostic and prognostic utility. Biopsy of the labial minor salivary gland allows histopathologic confirmation of focal lymphocytic infiltrates.

Ocular involvement is the other major manifestation of Sjögren's disease. Patients usually report a sandy or gritty feeling under the eyelids. Other ocular symptoms include burning, accumulation of secretions in thick strands at the inner canthi, decreased tearing, redness, itching, eye fatigue, and increased photosensitivity. These symptoms are attributed to the destruction of corneal and bulbar conjunctival epithelium, a pathology termed *keratoconjunctivitis sicca*. Diagnostic evaluation of keratoconjunctivitis sicca includes measurement of tear flow by Schirmer's I test, determination of tear composition by tear breakup time or tear lysozyme content, and slit-lamp examination of the cornea and conjunctiva after lissamine green or Rose Bengal staining that reveals punctuate corneal and bulbar conjunctival ulcerations and attached filaments.

Involvement of other exocrine glands, which occurs less frequently, includes a decrease in mucous gland secretions of the upper and lower respiratory tree, resulting in dry nose, throat, and trachea (xerotrachea). In addition, diminished secretion of the exocrine glands of the gastrointestinal tract leads to esophageal mucosal dysmotility and atrophic gastritis. Dyspareunia, in premenopausal women, due to dryness of the external genitalia and dry skin also may occur.

Extraglandular (systemic) manifestations are seen in one-third of patients with Sjögren's disease **(Table 373-1)** and can be classified as follows: *nonspecific, periepithelial* (surrounding of epithelial tissues by lymphocytes), *immune complex–mediated*, and *lymphoma*. *Nonspecific* manifestations include fatigability, low-grade fever, Raynaud's phenomenon, myalgias, arthralgias, and arthritis. Arthritis in patients with primary Sjögren's disease is nonerosive. *Periepithelial* pathology due to periepithelial accumulation of lymphocytes results from the involvement of parenchymal organs such as the lungs, kidneys, and liver. On the basis of this observation, one of the authors (H.M.M.) has coined the term *autoimmune epithelitis*. Lung involvement is usually manifested with dry cough and rarely with dyspnea. The underlying lung pathology includes peribronchial infiltrates (bronchitis sicca) and interstitial pneumonitis. Renal involvement includes interstitial nephritis, clinically manifested by hyposthenuria and renal tubular dysfunction with or without acidosis. Untreated acidosis may lead to nephrocalcinosis. *Immune complex–mediated* disease is expressed with vasculitis affecting primarily small-sized vessels, mainly manifested with purpura and rarely with urticarial rash, skin ulcerations, mononeuritis multiplex, and membranoproliferative glomerulonephritis associated with mixed type II or III cryoglobulinemia. Central nervous system involvement is rarely recognized. A few cases of myelitis associated with antibodies to aquaporin 4 have been described.

Sjögren's disease is characterized by the highest risk for lymphoma development among all autoimmune diseases with clinical, laboratory, and histopathologic features being designated as risk factors **(Fig. 373-2)**. Despite that the pathogenesis of lymphoma in the setting of Sjögren's disease remains to be elucidated, genetic alterations involved in chronic inflammatory, B-cell activation, and the type I and II interferon pathways, as well as epigenetic abnormalities, have been shown to be significant contributors. Of interest, B cells producing cryoglobulins were shown to harbor mutations in genes recurrently mutated in B-cell malignancies. Most lymphomas are extranodal, low-grade, marginal zone B-cell lymphomas and are usually detected incidentally during evaluation of the labial minor salivary gland biopsy. The affected lymph nodes are usually peripheral. Survival rates are decreased in patients with B symptoms, lymph node mass >7 cm in diameter, and high or intermediate histologic grade. Fluorodeoxyglucose positron emission tomography (FDG-PET)/computed tomography (CT) can be a useful tool to exclude lymphoma when suspected. In line with observations in rheumatoid arthritis and systemic lupus erythematosus, patients with Sjögren's disease also display an increased risk of cardiovascular disease.

Routine laboratory tests in Sjögren's disease can reveal leukopenia and infrequently lymphopenia. In two-thirds of patients, elevated erythrocyte sedimentation rate, hypergammaglobulinemia, antinuclear antibodies, rheumatoid factors, and antibodies against Ro52/Ro60 and La autoantigens are detected. Anticentromere autoantibodies are present in Sjögren's patients with a clinical picture similar to that of limited scleroderma **(Chap. 372)**, while the presence of antimitochondrial antibodies may connote liver involvement in the form of autoimmune cholangitis **(Chap. 357)**. Autoantibodies to 21-hydroxylase are found in patients with a blunted adrenal response, while autoantibodies to citrullinated peptides are seen in Sjögren's patients with

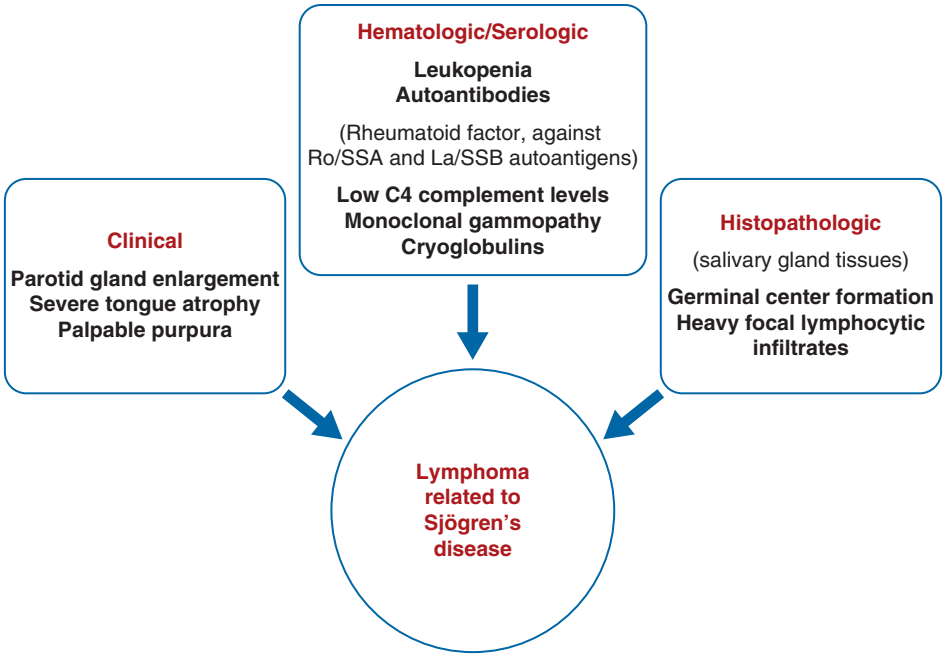

FIGURE 373-2 Sjögren's disease risk factors for lymphoma development.

arthritis. Anticalponin-3 antibodies have been recently associated with the occurrence of peripheral neuropathies.

DIAGNOSIS AND DIFFERENTIAL DIAGNOSIS

Sjögren's disease should be suspected if a patient presents with eye and/or mouth dryness, major salivary gland enlargement, or systemic manifestations such as Raynaud's phenomenon, palpable purpura, or symptomatology of renal tubular acidosis. A careful history of medications causing dryness should be obtained. Recently, cases of Sjögren's disease were triggered by PD-1/PD-L1 checkpoint inhibitors.

The workup should include eye tests that might reveal keratoconjunctivitis sicca, salivary flow tests or ultrasonography, and serum evaluation for specific autoantibodies. Testing for chronic viral infections (hepatitis C virus, HIV), chest x-ray to rule out sarcoidosis, protein electrophoresis, IgG4 serum levels, and autoantibodies to thyroid antigens can be also offered. Labial biopsy is valuable to rule out conditions that may cause dry mouth, dry eyes, or parotid gland enlargement (Tables 373-2 and 373-3). A diagnostic algorithm based on recent classification criteria (2016 American College of Rheumatology–European League Against Rheumatism [EULAR] Classification Criteria) is presented in Fig. 373-3.

TABLE 373-2 Differential Diagnosis of Sicca Symptoms

XEROSTOMIA	DRY EYE	BILATERAL PAROTID GLAND ENLARGEMENT
Viral infections (HCV, HIV)	Inflammation	Viral infections
Drugs	Stevens-Johnson syndrome	Mumps
Psychotherapeutic	Pemphigoid	Influenza
Parasympatholytic	Chronic conjunctivitis	Epstein-Barr virus
Antihypertensive	Chronic blepharitis	Coxsackievirus A
Psychogenic origin	Sjögren's Disease	Cytomegalovirus
Irradiation	Toxicity	HIV, HCV
Diabetes mellitus	Burns	Sarcoidosis, tuberculosis
Trauma	Drugs	IgG4-related disease
Sjögren's disease	Neurologic conditions	Sjögren's disease
Amyloidosis	Impaired lacrimal gland function	Metabolic disorders
Autoimmune thyroid disease	Impaired eyelid function	Diabetes mellitus
	Miscellaneous	Hyperlipoproteinemias (types IV and V)
	Trauma	Chronic pancreatitis
	Hypovitaminosis A	Hepatic cirrhosis
	Blink abnormality	Endocrine
	Anesthetic cornea	Acromegaly
	Lid scarring	Gonadal hypofunction
	Epithelial irregularity	Eosinophilic sialodochitis
	Autoimmune thyroid disease	Lymphoma

Abbreviation: HCV, hepatitis C virus.

TREATMENT

Sjögren's Disease

Treatment of Sjögren's disease aims to relieve symptoms and limit the damage from chronic xerostomia and keratoconjunctivitis sicca through substitution or stimulation of impaired secretions.

To replace deficient tears, several ophthalmic preparations are readily available (hydroxypropyl methylcellulose; polyvinyl alcohol; 0.5% methylcellulose; Hypo Tears). If corneal ulcerations are present, eye patching and boric acid ointments are recommended, as well as cyclosporine eye drops. Certain drugs that may decrease lacrimal and salivary secretions, such as diuretics, antihypertensive drugs, anticholinergics, and antidepressants, should be avoided.

For xerostomia, the best replacement is water. Propionic acid gels may be used to treat vaginal dryness. To stimulate secretions, orally administered pilocarpine (5 mg thrice daily) or cevimeline (30 mg

TABLE 373-3 Differential Diagnosis of Sjögren's disease

HIV INFECTION AND SICCA SYNDROME	SJÖGREN'S DISEASE	SARCOIDOSIS
Predominant in young males	Predominant in middle-aged women	No age or sex preference
Lack of autoantibodies to Ro and/or La	Presence of autoantibodies	Lack of autoantibodies to Ro and/or La
Lymphoid infiltrates of salivary glands by CD8+ T lymphocytes	Lymphoid infiltrates of salivary glands by CD4+ T lymphocytes	Granulomas in salivary glands
Association with HLA-DR5	Association with HLA-DR3 and DRw52	Unknown

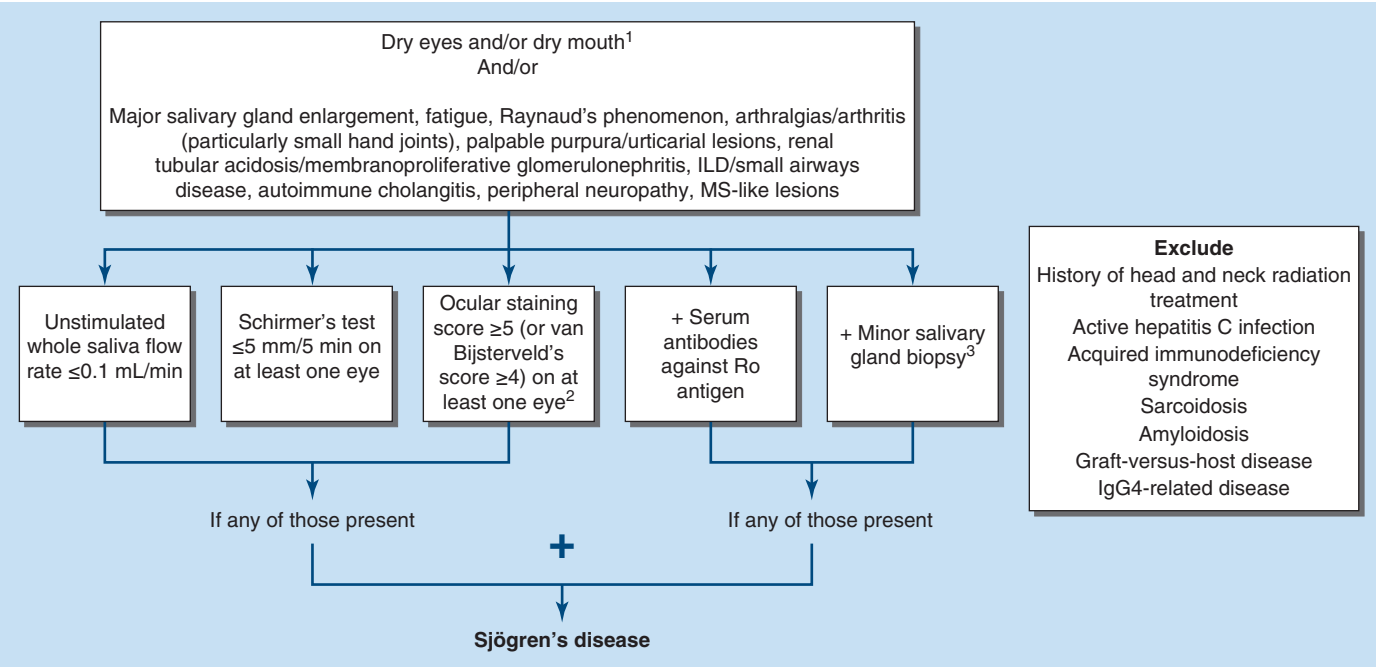

FIGURE 373-3 Diagnostic algorithm for Sjögren's disease. [1]Defined as a positive response to at least one of the following questions: (a) Have you had daily, persistent, troublesome dry eyes for more than 3 months? (b) Do you have a recurrent sensation of sand or gravel in the eyes? (c) Do you use tear substitutes more than three times a day? (d) Have you had a daily feeling of dry mouth for more than 3 months? (e) Do you frequently drink liquids to aid in swallowing dry food? [2]Ocular staining score described in Whitcher et al. van Bijsterveld score described in van Bijsterveld et al. [3]Focus score count ≥1 (based on the number of foci per 4 mm^2 of salivary gland tissue) following a protocol described in Daniels et al. ILD, interstitial lung disease; MS, multiple sclerosis.

thrice daily) appears to improve sicca manifestations, and both are well tolerated. Hydroxychloroquine (200 to 400 mg daily) and/or methotrexate (0.2–0.3 mg/kg body weight/weekly) are helpful for arthralgias and mild arthritis.

Patients with renal tubular acidosis should receive sodium bicarbonate by mouth (0.5–2 mmol/kg in four divided doses). Glucocorticoids and monoclonal antibody to CD20 (rituximab) appear to be effective in patients with systemic disease, particularly in those with purpura and persistent arthritis. Novel monoclonal antibodies targeting the CD40L/CD40 costimulatory pathway or the BAFF receptor or sequential treatment of belimumab and rituximab seem to be promising therapeutic strategies. Data for a beneficial role of other conventional immunosuppressants are limited. Treatment of lymphoma in the setting of Sjögren's disease follows the general guidelines for lymphoma management in the general population. Detailed recommendations on Sjögren's disease management have been issued by EULAR and British Society of Rheumatology.

374 Spondyloarthritis

Atul Deodhar, Dirk Elewaut

Spondyloarthritis (SpA) refers to a family of immune-mediated inflammatory arthritis disorders that share many clinical, genetic, and pathologic characteristics. Moll and Wright are credited in recognizing these diseases in 1974 as distinct from rheumatoid arthritis (RA), a well-recognized inflammatory arthritis at that time. While axial skeletal involvement is hinted at in the word "spondyloarthritis," it is not mandatory. The musculoskeletal manifestations of SpA include sacroiliitis, inflammatory spinal lesions, peripheral inflammatory arthritis, enthesitis (inflammation at the attachment of tendons and ligaments to the bones), tendonitis, tenosynovitis, and dactylitis ("sausage digits"). Other clinical manifestations include uveitis, skin psoriasis, inflammatory bowel disease (IBD, Crohn's, or ulcerative colitis), absence of rheumatoid factor (RF) and nodules (to differentiate from RA), familial correlation, and association with the gene human leukocyte antigen *(HLA)-B27*. The 2009 Assessment of Spondyloarthritis International Society (ASAS) classification criteria divided SpA under "axial" (axSpA) and "peripheral" (pSpA). "Peripheral" SpA may seem a misnomer, but it simply indicates that peripheral musculoskeletal

TABLE 374-1 Spectrum of Spondyloarthritis

SPONDYLOARTHRITIS (SPA)			
AXIAL SPONDYLOARTHRITIS (axSpA)		**PERIPHERAL SPONDYLOARTHRITIS (pSpA)**	
CONDITION	**CLINICAL FEATURES**	**CONDITION**	**CLINICAL FEATURES**
		Conditions commonly included under pSpA	
Radiographic axSpA (r-axSpA, also called ankylosing spondylitis [AS])	Sacroiliitis grade 2 (bilateral), grade 3 or 4 (unilateral or bilateral)	Psoriatic arthritis	Skin psoriasis and nail involvement usually preceding arthritis, enthesitis, dactylitis
Nonradiographic axSpA (nr-axSpA)	Sacroiliitis grade 1 (unilateral or bilateral) or grade 2 (unilateral)	Inflammatory bowel disease–associated arthritis	Crohn's disease or ulcerative colitis with inflammatory arthritis
		Reactive arthritis	Urethritis, history of preceding infection with *Salmonella, Shigella, Yersinia, Campylobacter,* and *Chlamydia,* mucosal ulcers, conjunctivitis, keratoderma blennorrhagica
		Undifferentiated peripheral SpA	Enthesitis, dactylitis, family history of SpA, *HLA-B27,* acute anterior uveitis, and not fitting in any of the other conditions mentioned above
		Conditions sometimes included under pSpA	
		SAPHO syndrome	Synovitis, acne, pustulosis, hyperostosis, and osteitis; typical involvement of anterior chest wall joints
		Acne-associated arthritis	Acne conglobata, peripheral arthritis
		Hidradenitis suppurativa–associated arthritis	Hidradenitis suppurativa, peripheral arthritis, rarely asymmetric sacroiliitis

manifestations are predominant and more troublesome to the patient than the spinal involvement.

AxSpA is further divided into radiographic (r-axSpA, also known as ankylosing spondylitis [AS]), and nonradiographic (nr-axSpA). The conditions included under pSpA are psoriatic arthritis (PsA), reactive arthritis (ReA), arthritis associated with IBD, and undifferentiated SpA, where patients cannot be classified under any known categories. Patients with axSpA can have peripheral musculoskeletal manifestations, and patients with pSpA may have additional axial skeletal involvement at presentation or may develop it later in the course of their disease. Other conditions sometimes included under pSpA are SAPHO (synovitis, acne, pustulosis, hyperostosis, and osteitis) syndrome, acne-associated arthritis, and arthritis associated with hidradenitis suppurativa. **Table 374-1** shows the full spectrum of conditions included under "spondyloarthritis."

Pattern recognition is important for the diagnosis of SpA. Typical patterns include asymmetric, mono- or oligoarticular (four or less joints) inflammatory arthritis of large joints in the lower limb (usually knee), with enthesitis, tendonitis, and dactylitis. This contrasts with RA, where polyarticular symmetric involvement of metacarpophalangeal (MCP)/proximal interphalangeal (PIP) joints predominates. The cumulative prevalence of all conditions under SpA is 2–3% of the population, much more common than RA.

PATHOLOGY OF SPONDYLOARTHRITIS

SpA is a prototypic chronic immune-mediated inflammatory disease that couples inflammation to structural damage. A unique feature of SpA is that inflammation-induced bone loss coexists with pathologic new bone formation, which occurs at specific sites in the skeleton. These sites include not only the sacroiliac joint but also the anterior spinal ligaments or at entheses in the peripheral skeleton. If uncontrolled, axSpA may ultimately lead to a complete ankylosis of the sacroiliac joints and the spine, termed "bamboo spine." With increasing awareness of SpA resulting from early diagnosis and treatment, there has been a steady decrease in the amount of structural damage observed over the past decades with a gradual shift of higher prevalence from r-AxSpA to nr-AxSpA.

While histopathologic studies have led to an increased understanding of local inflammatory and structural changes, the accessibility to target tissue particularly in the axial skeleton and tendons/entheses has been hampered by technical issues. Most of the information to date comes from surgically derived specimens from patients with longstanding disease. Accordingly, many of the described features represent disease under treatment, which inevitably impacts histopathology. Obtaining synovial tissue from an array of joints such as knees, wrists, and small joints in fingers has become much more readily accessible through ultrasound-guided synovial tissue biopsy, which permits study of synovial tissue alterations in an early treatment-naïve stage.

PATHOGENESIS OF SPONDYLOARTHRITIS

Although the exact mechanisms that initiate the disease are not fully delineated, genetic and environmental risk factors and molecular and cellular alterations at key disease sites have been implicated in the pathophysiology of SpA **(Fig. 374-1)**. At these sites, which include the axial and peripheral joints, entheses, skin, and gut, variation is seen in the disease mechanisms and perturbations of the key cytokine pathways. These tissue-based variations are most likely associated with the dissimilar clinical responses observed between the spine, peripheral joints, and gut during treatment with cytokine inhibitors.

GENETIC ASSOCIATIONS IN AXIAL SPONDYLOARTHRITIS AND OTHER SPONDYLOARTHRITIS: *HLA-B27* AND BEYOND

HLA-B27 is a major histocompatibility complex (MHC) class I allele that forms the strongest genetic risk factor for SpA and specifically axSpA. MHC class I molecules are expressed on the surface of nucleate cells and can present peptides to CD8+ T cells. *HLA-B27* is present in 85–90% of the patients with r-axSpA and 50–90% in nr-axSpA, in contrast to about 5% of the healthy Caucasian population.

Besides *HLA-B27*, other MHC class I genes and non-MHC coding genes have been identified in large genome-wide association studies (GWAS) in axSpA. Within the group of non-MHC coding genes, genes linked to innate immune processes, interleukin (IL)-23/IL-17 immunity, joint and bone remodeling, epithelial function, and antigen presentation are seen, which are processes relevant in the immunopathogenesis of axSpA. Whether all of these represent independent risk factors is still not clear, although some appear to be interconnected. For example, genetic epistatic interaction has been suggested between ERAP1, a peptide-trimming enzyme, of which single nucleotide polymorphisms (SNPs) are associated with AS and *HLA-B27*. How *HLA-B27* fosters development of SpA remains unclear despite the discovery of this strong genetic association 50 years ago. At present, several theories exist with limitations to each of them.

The "arthritogenic peptide" theory proposes that *HLA-B27* presents pathological microbial peptides to CD8+ cytotoxic T cells that

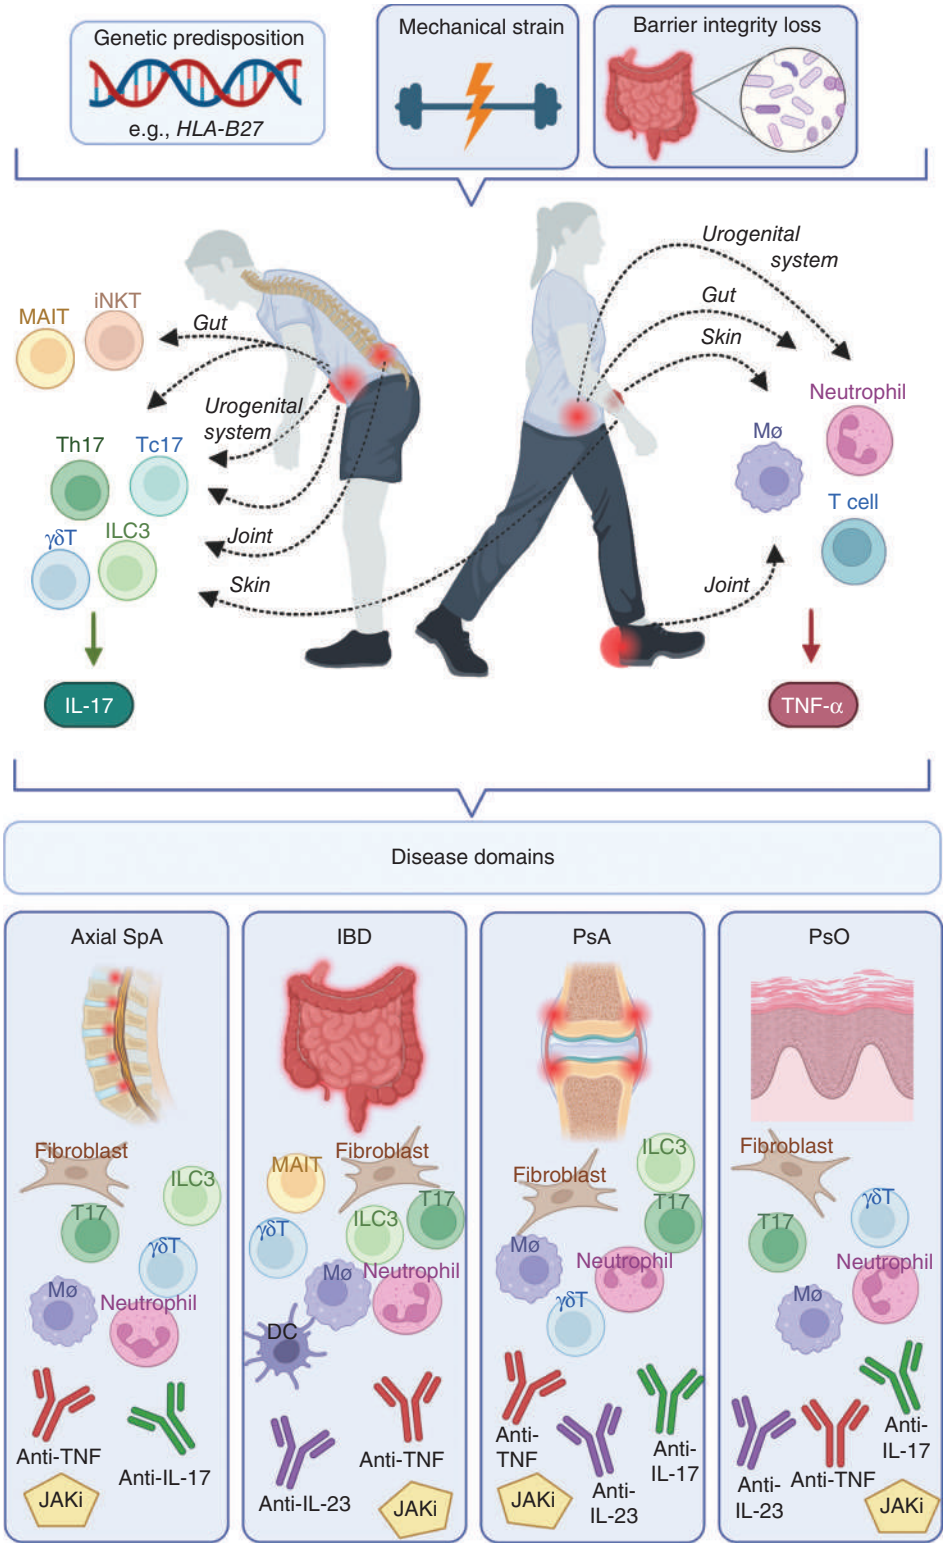

FIGURE 374-1 Pathogenesis and signature cytokines across different disease domains in spondyloarthritis (SpA). In genetically predisposed individuals, SpA may arise from mechanical stress, a well-known disease precipitator in psoriatic arthritis and axial SpA, or by altered host-microbial interplay at inner (gut, urogenital tract) or outer (skin) surfaces culminating in a cytokine crosstalk characterized by both tumor necrosis factor (TNF)- and interleukin (IL)-17-driven immune responses. Drivers of disease include cells of both innate and adaptive immune system, along with tissue-resident stromal cells. Different disease domains (gut, spin, peripheral joints, and skin) harbor overlapping (e.g., TNF-α) but also distinct (e.g., IL-17, IL-23) signature cytokines, which has major therapeutic implications. Janus kinase (JAK) inhibitors, which interfere with signaling of several cytokines, are effective across all domains.

then target cross-reactive human peptides leading to inflammation and resulting in molecular mimicry. Presumably, this first antigenic exposure could take place in the gut or at the urogenital tract. Several allotypes of *HLA-B27* exist, but not all of them represent risk factors for axSpA. For example, HLA-B*2704 and HLA-B*2705 subtypes confer a genetic risk, whereas the HLA-B*2706 and HLA-B*2709 allotypes are not associated with axSpA even though they only differ in one peptide residue or amino acid. This would suggest that there could be specific peptides that can only be presented by the pathogenic *HLA-B27* subtypes to induce the "arthritogenic" response. In the arthritogenic peptide hypothesis, inflammation is driven by antigen presentation to CD8+ T cells. Existence of *HLA-B27*-restricted CD8+ T cells in the synovial fluid of AS patients was shown three decades ago, whereas more recent next-generation sequencing T-cell receptor (TCR) studies

showed expansion of both CD4+ and CD8+ TCR clonotypes in blood and synovium of *HLA-B27*-positive SpA. Expansion of CD8+ TCR clonotypes with the CAS **STDTQYF CDR3 motif were found in AS patients versus *HLA-B27*-positive controls in blood and synovium, which was recently suggested as a target for therapeutic intervention.

The second theory relates to the ability of *HLA-B27* to homodimerize. These *HLA-B27* homodimers can be expressed at the cell surface and interact with innate immune receptors, such as the KIR3DL2 receptor, on T and natural killer (NK) cells resulting in IL-17 production, one of the key pathogenic cytokines in axSpA. However, there is still some controversy regarding whether various allotypes of *HLA-B27* differ in their ability to form homodimers.

A third theory links *HLA-B27* to unfolded protein responses (UPR) and autophagy, which may promote type 17 immune responses through release of IL-23. Support comes from the *HLA-B27* transgenic rat model, while no evidence for an increase in UPR in synovial tissue or blood of *HLA-B27*-positive AS patients was found in steady state, which questions its role in humans.

Although *HLA-B27* has the strongest genetic link, other MHC class I associations have also been found, for example (HLA-Cw6) in PsA. IL-23R gene polymorphisms are shared across most forms of SpA. This suggests overlapping yet distinct features across different disease domains.

FACTORS INSTIGATING THE ONSET OF SPONDYLOARTHRITIS IN GENETICALLY PREDISPOSED INDIVIDUALS

Despite the strong genetic association between *HLA-B27* and AS, only a minority of *HLA-B27*-positive subjects develop disease. In addition, the risk of developing AS in *HLA-B27*-positive first-degree relatives of AS patients is only 20%. This indicates that additional factors are needed to induce disease. Because SpA affects seemingly distinct tissues (spine, peripheral joints, enthesis, anterior eye chamber, intestine, skin), it has been a challenge to seek a common denominator between these different organs. Two main mechanisms are currently under consideration: the role of intestinal microbiota following a loss of barrier integrity and an aberrant response to mechanical stress.

Barrier Integrity Loss and the Intestinal Microbiota in SpA In view of the link between gut inflammation and SpA, much attention has been focused on barrier integrity loss in the intestine and the role of the intestinal microbiota. Evidence supporting this mechanism has been the development of ReA following an infectious gastroenteritis with *Salmonella typhimurium, Shigella enteritidis, Yersinia enterocolitica*, or *Campylobacter enteritidis*. Studies have highlighted the loss of barrier integrity, which may facilitate translocation of bacteria and microbial peptides that can elicit an immune response. The human microbiome is shaped by genetic and environmental factors. Changes in diversity and composition of the gut microbiome have been identified in SpA, pinpointing an intestinal dysbiosis that is similar to patients with IBD. While most information on host-microbial interplay in SpA relates to the intestine, other mucosal surfaces and particularly the urogenital tract (e.g., *Chlamydia*) may serve as an entry route for pathogens to instigate the onset of SpA.

Germ-free *HLA-B27* transgenic rats fail to develop SpA, suggesting a crucial pathogenic role for intestinal microbiota. In humans, microbiome profiling in stool and biopsy samples of *HLA-B27*–positive individuals found that *HLA-B27* affects the gut microbiome even in the absence of disease. This supports the concept that in *HLA-B27*–positive individuals, intestinal dysbiosis occurs prior to the onset of clinical manifestations and may contribute to the risk of disease. Earlier research suggested that *HLA-B27* may promote intracellular survival and persistence of pathogens such as *Chlamydia trachomatis* in monocytes, which could travel to joints and promote synovial inflammation. More recent studies indicate that not all preclinical models of combined gut and joint disease mimicking SpA impact these sites similarly: in a tumor necrosis factor (TNF) cytokine-dependent model with Crohn's-like ileitis and peripheral arthritis, gut inflammation was found to be microbiota dependent but not joint inflammation. This suggests that intestinal microbiota may play a role in some, but not all, SpA patients or disease features.

The skin, as the outer barrier of the body, is also vulnerable to the development of immune-mediated inflammatory disease. Like the inner barriers of the intestines and joints, the skin plays a key role in preserving tissue homeostasis at a site exposed to microbial, chemical, and mechanical challenges. Alterations in the cutaneous microbiome of patients with psoriasis and PsA have been described with striking similarities between nonlesional and lesional skin. However, the functional impact of skin microbiota on the disease trajectory is still ill defined.

Mechanical Stress as Gateway to Joint Disease in SpA The entheses in SpA and PsA are key inflammatory target tissues, and patients can present with both axial and peripheral entheseal inflammation. In both SpA patients and in individuals without inflammatory conditions, mechanical stress in entheses may lead to microdamage that leads to immune activation and tissue repair. The importance of mechanical strain in the pathophysiology of enthesitis in SpA is supported by observations in patients and animal models. Enthesitis occurs more often in the lower limbs, which are subject to higher mechanical strain. In patients with AS, exposure to physical labor was related to more structural damage. In mouse models, mechanical strain was shown to be causally related to development of enthesitis and SpA-related new bone formation through mechanisms that support chronicity of inflammation.

Responses to mechanical stress are physiologic and self-limited, but they appear to be enhanced and prolonged in SpA. The reason for this is unclear, but this may be influenced by genetic factors and/or impaired intestinal barrier function.

Chronic entheseal inflammation in axSpA also leads to excessive local bone responses. This is associated with osteoblast differentiation initiated by prostaglandin E_2, IL-17-A and -F, and IL-22 followed by activation of downstream bone morphogenic proteins and Wnt proteins, which are thought to play a role in pathological new bone formation. This culminates in the generation of bony spurs at vertebral bodies and sacroiliac joints, eventually leading to ankylosis.

Common Versus Private Cytokine Hubs in Disease Domains in SpA Regardless of the route of disease initiation, several common effector pathways have emerged, with TNF and IL-17 representing signature cytokines in the immunologic basis of axSpA.

The impact of TNF-α as a common effector pathway that acts downstream in the inflammatory process has been long recognized given its broad therapeutic efficacy across all disease domains (gut, enthesis, skin, eye, spine, and joints). TNF-α is an important activator and product of macrophages that stimulates cytokine production in immune cells and activates fibroblasts. TNF-α can also be made by neutrophils and activated T cells in the inflamed synovium, enthesis, and intestine. By activating osteoclasts, it promotes inflammation-induced bone loss and bone erosions in SpA.

Even though axSpA and IBD share a similar genetic predisposition in IL-23R polymorphisms, the two disorders differ substantially in their cytokine dependency. IL-17A blockade is effective in axSpA, whereas IL-23 inhibition does not provide benefit. Conversely, IL-23 blockers are approved in IBD, but agents targeting IL-17A are contraindicated in active IBD, due to the barrier protective roles of IL-17. In PsA, IL-23 and IL-17 inhibitors both appear to be effective.

These observations instigated a search into cellular sources of IL-17 in SpA and their dependency on IL-23. Several IL-17A–producing cell types, including T17 cells (consisting of both CD4+ T_H17 and CD8+ cytotoxic T17 [Tc17] cells), γ/δ T cells, and ILC3, are present at entheseal sites in steady-state conditions. In synovial fluid of SpA patients, innate-like T cells such as γδ T cells were found to be the major T-cell source of IL-17 in the presence or absence of IL-23. This is of particular interest as these γδ T cells also survey epithelial sites such as skin or intestine. Thus, entheses, synovium, and mucosal sites appear to harbor cells that may boost IL-17A responses in the absence of IL-23.

Janus kinase (JAK) inhibitors, which block signaling of several cytokines, are effective in a wide range of SpA including all clinical domains (Fig. 374-1).

AXIAL SPONDYLOARTHRITIS

AxSpA is a chronic, immune-mediated inflammatory disorder predominantly involving the axial skeleton (sacroiliac joints and the spine) and also the peripheral skeleton. The axial skeleton is always involved, and involvement of the peripheral joints occurs in ~30–40% of patients. The hips, historically considered "root joints," are the most common nonspinal joints affected. Enthesitis in the axial and peripheral skeleton is a common feature, but dactylitis is relatively rare. Extraarticular manifestations include psoriasis, acute anterior uveitis, and IBD. Some patients with axSpA experience gradual spinal bony fusion over several years, which leads to reduced spine and neck flexibility. Despite these osteoproliferative changes in the skeleton, osteoporosis is a common morbidity. AxSpA significantly affects patients' well-being, function, productivity, and health-related quality of life.

DEFINITIONS AND NOMENCLATURE

AxSpA is divided into r-axSpA (also called AS) and nr-axSpA, the difference based on the presence or absence of definitive sacroiliitis on plain radiographs. "Definitive sacroiliitis" is defined by the modified New York criteria **(Table 374-2)** as grade 2 bilateral or grade 3 or 4 unilateral or bilateral **(Table 374-3)**. Patients with sacroiliitis of lower grade are classified as nr-axSpA. Since the differentiation between r-axSpA and nr-axSpA is based on the degree of sacroiliitis, it is open to disagreements even between trained musculoskeletal radiologists. The interreader reliability as measured by the kappa statistic is between 0.35 and 0.45. nr-axSpA and r-axSpA have the same clinical features and share similar disease burden, though in late-stage r-axSpA, fusion of spine and hip involvement can add to functional loss.

EPIDEMIOLOGY

The male-to-female ratio is 2:1 for r-axSpA and 1:1 for nr-axSpA. The population prevalence of axSpA depends on the prevalence of *HLA-B27* in that geographic region. In Europe, *HLA-B27* frequency in the population increases from south to north, and so does the prevalence of axSpA. For example, the prevalence of *HLA-B27* in Spain and Norway is 7 and 9%, respectively, and the prevalence of AS and axSpA in these two countries is 0.1 and 0.56%. The 2009–2010 National Health and Nutritional Examination Survey (NHANES) estimated that in the United States, the population prevalence of *HLA-B27* is 6% and that of axSpA is between 0.9 and 1.4%, of which 0.5% were reported to have AS. The population prevalence of axSpA in the rest of the world is not well studied and is believed to be between 0.02 and 1.5%. Diagnostic prevalence of axSpA in the United States, which includes only the diagnosed cases in a population, is one-tenth that of population prevalence, suggesting a large undiagnosed population. Based on insurance claims databases in the United States, the diagnostic prevalence of axSpA increased between 2006 to 2019, which could be attributed to increased disease awareness. The incidence rates of AS are 0.005–0.01 per 100 patient-years globally and are not available for nr-axSpA.

The risk of axSpA is 5% in *HLA-B27*-positive people but increases to 20% in *HLA-B27*-positive first-degree relatives of affected individuals with axSpA.

TABLE 374-2 Modified New York Classification Criteria for Ankylosing Spondylitis (AS)

Clinical Criteria
1. Low back pain >3 months
Improved with exercise
Not relieved by rest
2. Limited lumbar motion in fontal and lateral planes
3. Reduced chest expansion
Radiographic Criteria
1. Bilateral grade >2 sacroiliitis on x-ray
2. Unilateral or bilateral grade 3 or 4 on x-ray
Definite AS requires ≥1 clinical criterion plus 1 radiographic criterion

TABLE 374-3 Grading of Sacroiliitis

GRADE	DESCRIPTION
Grade 0	Normal
Grade 1	Suspicious change
Grade 2	Minimum abnormality (small, localized areas with erosions or sclerosis, without alterations in the joint width)
Grade 3	Unequivocal abnormality (moderate or advanced sacroiliitis with erosions, evidence of sclerosis, widening, narrowing, or partial ankylosis)
Grade 4	Severe abnormality (total ankylosis)

CLINICAL MANIFESTATIONS

The most common first manifestation of axSpA is low back, hip, or buttock pain, which starts before the age of 40–45 years, usually in the 20s to 30s. The typical characteristics of this back pain include any combination of the following: insidious onset, chronicity (>3 months' duration), age of onset <45 years, improvement with exercise or activity and no improvement with rest, worse back pain in the second half of the night with improvement after getting out of bed and walking around, and prolonged (>30 min) morning stiffness. Back pain with these characteristics is termed "inflammatory back pain" (IBP) to differentiate it from the common "mechanical back pain" **(Table 374-4)**, but the term is a misnomer because only 15% of patients with IBP have demonstrable inflammation in their axial skeleton. Rarely, thoracic or neck pain can be a presenting feature, and when present, it is more commonly seen in women. Fatigue and stiffness are the two most bothersome symptoms after back pain in axSpA. Fatigue is multifactorial, secondary to sleep disturbance, active inflammation, and anemia, and may also indicate underlying depression and anxiety of chronic disease.

Peripheral arthritis is seen in 30–40% of patients with axSpA. Typically, this is an asymmetric, oligoarticular inflammatory arthritis involving the large joints of the lower extremities and rarely the small joints of hands and feet. Hip involvement, presenting as pain in the groin with radiation to medial thigh or the knee, is common and is associated with significant functional impairment. Enthesitis is a common manifestation of axSpA. Enthesitis may present as heel pain (plantar fasciitis, Achilles tendon insertion pain), chest wall pain, intercostal muscle insertions, medial or lateral epicondylitis, quadriceps or patellar tendon insertion pain around knees, or pelvic rim pain. Dactylitis is an uncommon manifestation of axSpA. Persistent axial inflammation may lead to bony fusion of sacroiliac joints, apophyseal joints, and development of syndesmophytes by osteoproliferation in the outer fibers of the annulus fibrosus of the intervertebral disks. These bony changes lead to limitation of spinal, including neck, mobility in all directions and are a major cause of significant functional impairment in late stages of the disease.

Extramusculoskeletal manifestations of axSpA, such as psoriasis, IBD, and acute anterior uveitis, can also be the presenting symptom of axSpA in some patients, and such patients may first present to a dermatologist, gastroenterologist, or an ophthalmologist. Uveitis, the most

TABLE 374-4 Clinical Features of Inflammatory Versus Mechanical Back Pain

FEATURE	INFLAMMATORY BACK PAIN	MECHANICAL BACK PAIN
Age at onset	Before 40–45 years	20–65 years
Onset	Insidious	Acute or insidious
Morning stiffness	Prolonged (more than 30 min)	Less than 30 min
Pain at night	Yes, usually after midnight	No, usually late in the day
Exercise/activity	Improves pain and stiffness	Worsens pain
Rest/inactivity	Worsens pain and stiffness	Improves pain
Duration	Chronic	Acute or chronic
Response to full-dose NSAIDs	More than 50% relief in 48 hours	Limited relief

Note: Not all features are required for diagnosis of inflammatory back pain, nor are they present in every patient.

Abbreviation: NSAIDs: nonsteroidal anti-inflammatory drugs.

common extramusculoskeletal manifestation, is seen in 40% of patients with axSpA and presents as eye discomfort followed by redness, pain, photophobia, and miosis. The typical phenotype of uveitis associated with axSpA is acute, anterior, unilateral, and episodic. While frank IBD is seen in 10%, histologic evidence of subclinical gut inflammation is seen in up to 50% of patients. Psoriasis is seen in 10%, and osteoporosis can be present in 40%.

AxSpA can affect multiple organ systems. The two renal manifestations of axSpA are IgA nephropathy, which can present at any time in the disease course as microscopic hematuria, and nephrotic syndrome secondary to renal (AA) amyloidosis, which is a late complication only seen after prolonged uncontrolled inflammation. Conduction abnormalities (heart blocks) can be seen at any stage of the disease, whereas aortic valve insufficiency and cauda equina syndrome presenting as urinary hesitancy and/or saddle anesthesia are late complications. Pulmonary manifestations of axSpA include apical fibrosis, cavitary lung lesion, or fibrotic parenchymal lesions. Sleep apnea syndrome and restrictive lung disease seen in late-stage axSpA are mostly related to osteoproliferative structural changes of the cervical spine and rib cage.

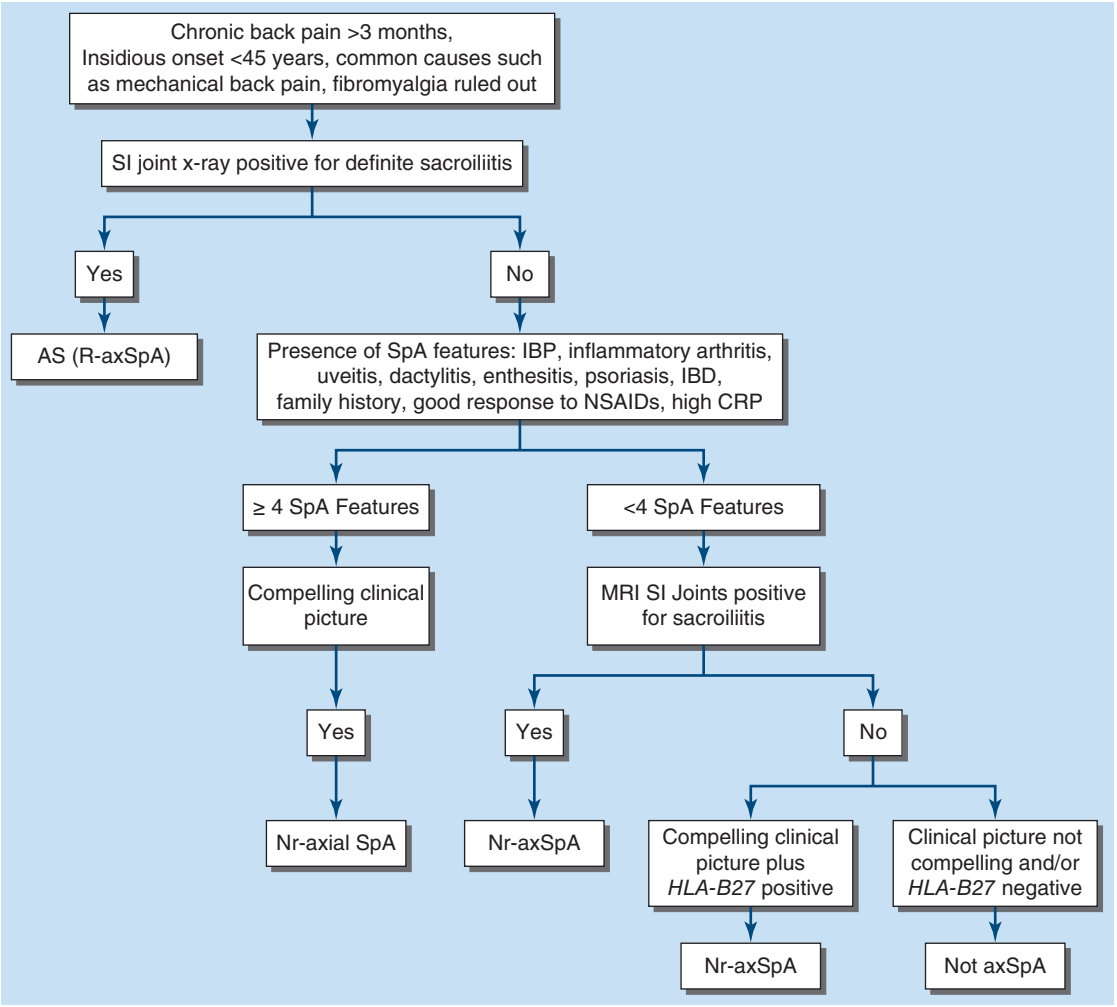
The course of axSpA can be variable, with close to 50% of patients progressing from nonradiographic to radiographic stage over 20 years and <10% progressing to significant spinal involvement with bamboo spine. Risk factors for osteoproliferation include male sex, persistent inflammation (seen on magnetic resonance imaging [MRI] of sacroiliac joints and spine, high C-reactive protein [CRP]), syndesmophytes, presence of *HLA-B27*, and smoking.

DIAGNOSIS

A diagnostic delay of 5–14 years from symptom onset of axSpA reported in various parts of the world is mostly related to the commonality of mechanical back pain in the general population. Traditionally, AS is thought to be a disease of males, and back pain and enthesitis in women are commonly mistaken for fibromyalgia. This delays the diagnosis in females even further. Lower prevalence of *HLA-B27* in nonwhite populations also adds to the delay in diagnosis.

The diagnosis of axSpA is based on pattern recognition, ruling out common causes for the symptoms, and clinical reasoning. **Figure 374-2** shows a schema for the diagnosis of axSpA in a patient complaining of chronic (>3 months) back pain. While elevated inflammatory markers, erythrocyte sedimentation rate (ESR), and CRP help in making the diagnosis of axSpA, these tests are neither sensitive (seen in only 30–40% of patients with active axSpA) nor specific for axSpA.

Imaging plays a very important role in the diagnosis of axSpA. A single anteroposterior (AP) view or a Ferguson view x-ray of the pelvis is sufficient to image sacroiliac joints. Multiple views (e.g., oblique) of the sacroiliac joints add little in making the diagnosis; in addition, they increase radiation risk to gonads. Radiographic features of sacroiliitis include marginal sclerosis, erosions, narrowing and widening of the joints, and in late stages, fusion (**Fig. 374-3*A*** and Table 374-3). As a general rule, plain radiographs of the spine should be avoided in patients with chronic back pain. However, there are some characteristic changes of axSpA seen in the lateral radiograph of the spine, and they include Romanus lesions or the shiny corner sign and squaring of the vertebral body seen as a result of erosions at the attachments of the spinal ligaments at the vertebral corners. Andersson lesion is an uncommon finding and is characterized by vertebral body erosion and sclerosis at the intervertebral disk level. In the late stages, ossification of the outer layer of annulus fibrosus leads to syndesmophyte formation **(Fig. 374-3*B*)**. Typical syndesmophyte orientation is vertical, differentiating it from the horizontal orientation of osteophytes, which is commonly seen with osteoarthritis (OA) of the spine. Bamboo spine, or ankylosis of the entire spine, is seen in a very small percentage of late-stage AS patients.



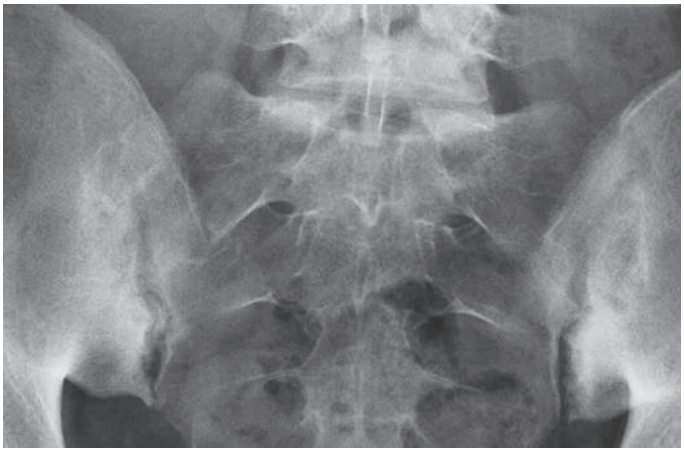


FIGURE 374-2 Schema for the diagnosis of axial spondyloarthritis in a patient complaining of chronic back pain (back pain lasting >3 months).

A

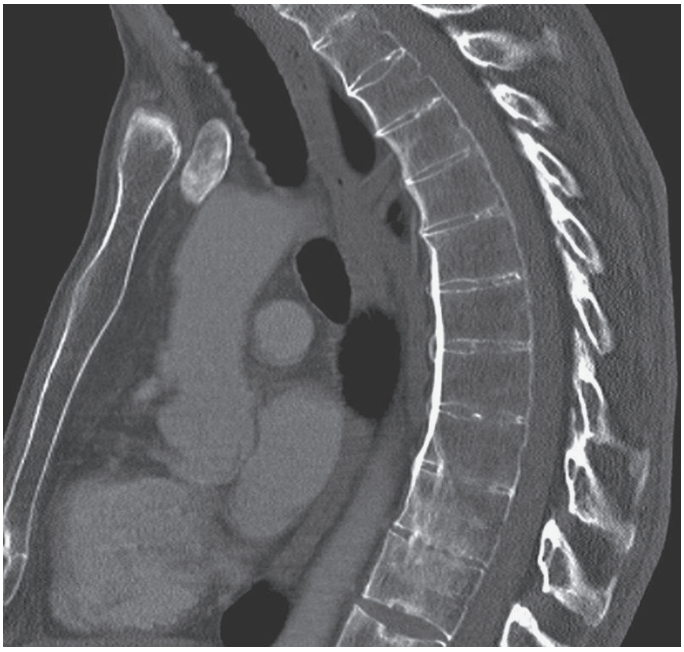
B

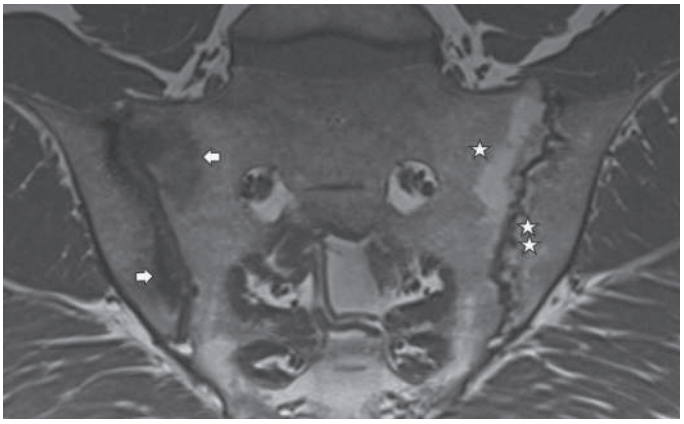
FIGURE 374-3 Radiographic axial spondyloarthritis. ***A.*** Bilateral sacroiliitis (modified New York grade 3) with sclerosis and erosions. ***B.*** Lateral view cervical spine in advanced radiographic axial spondyloarthritis showing anterior syndesmophytes and fused facet joints.

Low-dose computed tomography (CT) of the sacroiliac joints and spine in the diagnosis of axSpA is emerging as an alternative to plain radiography for diagnosis and assessing progression **(Fig. 374-4)**.

Magnetic resonance imaging (MRI) of the sacroiliac joints and spine has evolved as an important tool in making the diagnosis of axSpA. During the early stage of disease, MRI of the sacroiliac joints may show evidence of active inflammation, or "osteitis," and that may be the only abnormality. As time passes, the active inflammatory changes transition to fatty metaplasia, and this may further transform to new bone formation. The structural changes of sclerosis, fat metaplasia, erosions, fat metaplasia in an erosion cavity (backfill), and new bone formation, in addition to the inflammatory changes seen on MRI, aid in making the diagnosis of axSpA **(Fig. 374-5)**. Sole presence of inflammatory lesions in early stages or sole presence of ankylosis in very late stage may be enough for the diagnosis of axSpA, but as a general rule, multiple types of inflammatory and structural lesions increase the suspicion of axSpA. In the spine, multiple corner inflammatory lesions and/or multiple corner fatty lesions increase the confidence of axSpA diagnosis.

MRI is a very sensitive imaging technique, and mechanical stress on the sacroiliac joints in professional athletes, postpartum women, and even in normal individuals, especially above the age of 40, may show changes of osteitis. Fat metaplasia-type changes in the sacroiliac joints are also seen in degenerative arthritis as well as in normal individuals. Inappropriate utilization of MRI can lead to overdiagnosis.





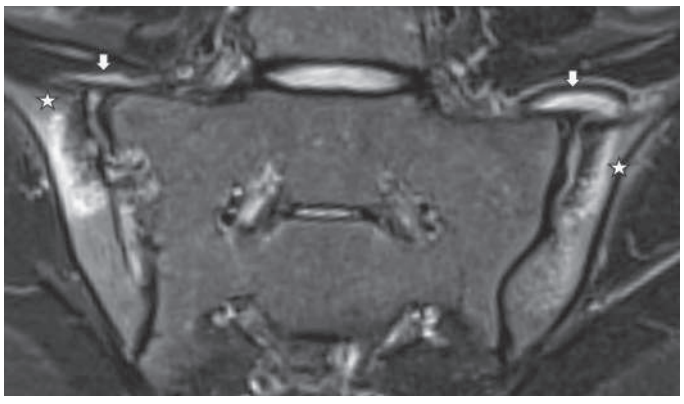


FIGURE 374-4 Computed tomography of the thoracic spine sagittal view in radiographic axial spondyloarthritis showing anterior and posterior syndesmophytes.

DIFFERENTIAL DIAGNOSIS

Chronic nonspecific "mechanical" back pain is common in the general population, and axSpA is the etiology in only 4–5% of such patients. Mechanical causes of back pain therefore should be considered first in a patient presenting with chronic back pain. The so-called "red flag"

A

B

FIGURE 374-5 Magnetic resonance images of spondyloarthritis. ***A.*** T1-weighted image of sacroiliac joints with bilateral erosions (left-sided erosions marked by **), left fatty metaplasia (single *), and right bone marrow edema (marked with *white arrows*). ***B.*** Short tau inversion recovery (STIR) image with bilateral bone marrow edema suggestive of joint space inflammation (shown by *) and anterior capsulitis (shown by a *white arrow*).

signs of fever, weight loss, advanced age, and past history of malignancy should alert the examiner to look for osteomyelitis, osteoporotic fracture, or metastatic disease. In young patients with generalized body pain, fibromyalgia, central sensitization, hypermobility, hypothyroidism, and hypovitaminosis D may be considered.

Abnormalities on incidental imaging in a patient with or even without chronic back pain lead to other differential diagnoses such as diffuse idiopathic skeletal hyperostosis (DISH) or osteitis condensans ilii (OCI). DISH is a noninflammatory, degenerative condition affecting the spine, with exuberant new bone formation in the form of anterior and posterior longitudinal ligament ossification of at least four contiguous vertebral bodies and bulky "flowing" osteophytes typically on the right side of the thoracic spine, but normal sacroiliac joints. It is generally seen in obese, diabetic males, often older than 50 years of age. DISH is sometimes mistaken for bamboo spine of AS. OCI is usually an asymptomatic condition of multiparous women characterized by radiographic findings of a triangular area of dense sclerosis on the lower and inferior part of the iliac side of the sacroiliac joints. This can be mistaken for sacroiliitis, and in early stages, MRI of the sacroiliac joints may be indistinguishable from that of axSpA. Lack of erosions should help distinguish OCI from axSpA. OCI can be seen in nulliparous women and even men. While DISH and OCI are generally asymptomatic, some patients with either condition may present with chronic back pain.

Inflammatory back pain with sclerotic changes on sacroiliac joint radiographs can also be seen in conditions such as postpartum insufficiency fracture of the sacrum; septic sacroiliitis from tuberculosis, brucellosis, fungi, and other infectious agents; and rarely, malignancies such as acute lymphoblastic leukemia.

MONITORING

AxSpA patients should be monitored at every visit for disease activity, function, and medication safety. The frequency of monitoring is individualized. Assessment of disease activity can be performed by using the Bath Ankylosing Spondylitis Disease Activity Index (BASDAI) or the Ankylosing Spondylitis Disease Activity Score (ASDAS). Functional impairment can be measured by the Bath Ankylosing Spondylitis Functional Index (BASFI). This is a patient-administered questionnaire that includes 10 activities of daily living. The Bath Ankylosing Spondylitis Metrology Index is an index of spinal and hip mobility in patients with AS.

The ESR and CRP may be useful in monitoring disease activity. MRI of the sacroiliac joints or spine is expensive and is not indicated to monitor disease activity of AxSpA. Spine radiographs and MRI are not used for monitoring purposes in daily practice, although they may be used if back pain persists or relapses to rule out active inflammation despite therapy or complications such as spinal fractures.

TREATMENT

Axial Spondyloarthritis

Principles of treatment of nr-axSpA and r-axSpA are identical and are described as one disease. Some agents are approved to treat only AS (r-axSpA) and are mentioned below.

The targets for treatment include low disease activity or remission. Traditionally, the treatment of axSpA was limited to exercise, physical therapy, and nonsteroidal anti-inflammatory drugs (NSAIDs), but with the advent of biologics and targeted synthetic disease-modifying antirheumatic drugs (tsDMARDs), great strides have been made in in the last two decades. Shared decision-making regarding all modes of therapy is the key to success.

Treatment of axSpA can be divided into nonpharmacologic, pharmacologic, and surgical.

NONPHARMACOLOGIC INTERVENTIONS

Physical exercise in the form of active physical therapy (on land or aquatic) and self-directed physical exercise are strongly recommended by all international guidelines and should be promoted. Physical therapy improves fatigue, mobility, and posture. Smoking cessation is encouraged in all patients.

PHARMACOLOGIC INTERVENTIONS

The American College of Rheumatology (ACR), Spondylitis Association of America (SAA), Spondyloarthritis Research and Treatment Network (SPARTAN) treatment guidelines, and ASAS-EULAR (European Alliance of Associations for Rheumatology) treatment recommendations have many commonalities regarding the order of treatments, choices of agents, and precautions. **Table 374-5** outlines pharmacologic interventions for the treatment of axSpA.

The use of immunosuppressive biologics and tsDMARDs has been associated with an increased risk of serious infections. While bacterial infections are seen in both classes, herpes zoster is mostly seen with JAK inhibitors (JAKis), and reactivation of latent tuberculosis is mostly seen with TNF inhibitors (TNFis). Mucosal and skin *Candida* infections are associated with IL-17 inhibitor (IL-17i) use.

Other side effects of biologic therapy include injection-site reactions with subcutaneous injections or infusion reactions with intravenous (IV) medication. TNFi adverse effects include development of demyelinating disease, worsening of congestive heart failure, and paradoxical development of psoriasis-like skin lesions. Adverse events associated with IL-17i therapy include leukopenia and development or worsening of IBD. JAKis have a higher risk of major cardiovascular adverse events and cancers (lymphoma and lung cancers), especially in patients aged 65 years or older and in those with current or past history of smoking, with history of cardiovascular disease, or with malignancy. As a result, the U.S. Food and Drug Administration (FDA) suggests reserving these medicines for patients who have had an inadequate response or intolerance to one or more TNFi.

SURGICAL INTERVENTIONS

Hip involvement in axSpA leads to significant functional impairment, and total hip arthroplasty should be considered in patients with refractory hip pain or functional decline in the presence of radiographic evidence of structural damage. Spinal osteotomies should be reserved for severe fixed kyphotic deformities in advanced AS that affect horizontal vision and should be performed in centers of expertise.

COMPLICATIONS

The prevalence of osteoporosis is ~25% after 10 years of axSpA. Vertebral fractures are seen in ~10% of patients with AS. The lower cervical spine is the most commonly involved area, where there is often also neurologic compromise. One should consider vertebral fractures in patients with neck and back pain that has changed in intensity or character from baseline. Another rare complication is the cauda equina syndrome from long-standing AS resulting from inflammation of the lumbosacral nerve roots caused by arachnoiditis. Cardiac manifestations include aortic valve insufficiency and conduction abnormalities. Pulmonary manifestations are rare and include chest expansion restriction from ossification of costovertebral joints and upper lobe–predominant interstitial lung disease. Patients with AS can have IgA nephropathy or, in late stages, renal amyloidosis if the disease is left untreated. Cardiovascular disease is being recognized as a common comorbidity in patients with AS and is linked to chronic inflammation. All patients with AS should be counseled about the traditional risk factors for cardiovascular disease, and appropriate treatment should be instituted if necessary.

PSORIATIC ARTHRITIS

PsA is a relatively common immune-mediated inflammatory condition that may lead to progressive joint damage. If left untreated, it is associated with poor quality of life, loss of function, and increased morbidity and mortality. PsA, associated with cutaneous and nail psoriasis, involves peripheral joints, axial skeleton (sacroiliac joints and spine), entheses, and tendon sheaths. In addition, uveitis and inflammatory bowel disease may coexist with PsA. Common comorbidities of PsA

TABLE 374-5 Pharmacologic Management of Axial Spondyloarthritis (axSpA)

- Nonsteroidal anti-inflammatory drugs (NSAIDs) should be used in highest tolerable doses continuously in active disease and on an as-needed basis if the disease is stable. No particular NSAID is preferred over any other. Side effects to monitor are gastric ulcer disease, hypertension, renal insufficiency, and cardiovascular disease.
- Conventional synthetic DMARDs like sulfasalazine, up to 3 g/d, and methotrexate, up to 25 mg/wk, are useful for the treatment of peripheral joint and entheses involvement, but not for axial disease in axSpA.
- If the disease remains active despite a 4-week trial of full-dose NSAIDs, treatment should be escalated to start a biologic from either the TNFi or IL-17i class.
- Before initiating therapy with biologics or JAKi, screening for latent tuberculosis, hepatitis B, and hepatitis C should be performed.
- All five TNFi agents are approved for the treatment of AS, while selective TNFis are approved for nr-axSpA in various countries.
  - Soluble receptor of TNF–etanercept 50 mg subcutaneous (SC) injection once weekly.
  - TNFi monoclonal antibodies:
    - Adalimumab 40 mg SC every 2 weeks.
    - Certolizumab pegol 200 mg SC twice a month or 400 mg SC once a month.
    - Golimumab 50 mg SC once a month or golimumab 2 mg/kg intravenous (IV) at weeks 0, 4, and then every 8 weeks thereafter.
    - Infliximab 5 mg/kg IV infusion at weeks 0, 2, 6, and then every 6 weeks.
  - No TNFi is preferred, except in patients with concomitant uveitis or IBD in whom TNF monoclonal antibodies are preferred over soluble receptor TNFi therapy.
  - In the case of primary failure of TNFi, treatment can be switched to IL-17i or JAKi. In the case of secondary failure of TNFi therapy (failing after initial benefit), an alternative TNFi can be used.
- Two IL-17Ais are approved for the treatment of nr-axSpA and AS.
  - Secukinumab 150 mg SC at weeks 0, 1, 2, 3, and 4, followed by 150 or 300 mg every 4 weeks.
  - Ixekizumab 160 mg SC once, followed by 80 mg every 4 weeks.
  - In case of primary failure of IL-17Ai, treatment can be switched to TNFi or JAKi. In the case of secondary failure of IL-17Ai therapy, an alternative IL-17i can be used.
- Two JAKis are approved for the treatment of AS, while only one is approved for nr-axSpA. JAKi should be used in patients who have failed TNFi.
  - Tofacitinib 5 mg orally two times a day is approved for the treatment of AS only.
  - Upadacitinib 15 mg once a day is approved for the treatment of AS and nr-axSpA.
- One IL-17A and IL-17F inhibitor is approved in certain parts of the world to treat both nr-axSpA and radiographic axSpA.
  - Bimekizumab 160 mg SC every 4 weeks.
- Local glucocorticoid injections for upper extremity enthesitis or intraarticular injections for peripheral arthritis are indicated. Injections around lower limb weight-bearing entheses are not recommended because of the risk of rupture.
- Systemic glucocorticoids do not have any efficacy in axSpA and should be avoided.

Abbreviations: AS, ankylosing spondylitis; DMARDs, disease-modifying antirheumatic drugs; IBD, inflammatory bowel disease; IL-17i, interleukin 17 inhibitor; JAKi, Janus kinase inhibitor; nr-axSpA, nonradiographic axial spondyloarthritis; TNFi, tumor necrosis factor inhibitor.

include depression, metabolic syndrome, diabetes mellitus, and cardiovascular disease. Sometimes the term "psoriatic disease" is used to emphasize these varied manifestations.

In 1973 Moll and Wright defined PsA as an inflammatory arthritis (peripheral arthritis and/or sacroiliitis or spondylitis), with presence of cutaneous psoriasis and absence of RF. They demonstrated the association between PsA and the gene *HLA-B*27* and described five phenotypes of PsA, namely asymmetric oligoarticular inflammatory arthritis, symmetric polyarticular arthritis, distal interphalangeal joint arthritis, spondylitis, and arthritis mutilans. Over the years, enthesitis and dactylitis have been added to these musculoskeletal manifestations. It is important to remember that these clinical phenotypes are not exclusive and frequently coexist.

EPIDEMIOLOGY

With a prevalence of 2–3%, skin psoriasis is one of the most common immune-mediated diseases. The prevalence of PsA in patients with psoriasis is 30% (range, 6–42%). The incidence of PsA in patients with psoriasis is 3 per 100 patient-years (range 2–10) and depends on the severity of skin psoriasis. The likelihood of developing PsA in psoriasis patients does not change over time.

CLINICAL FEATURES

Clinical features of PsA include peripheral arthritis, axial arthritis (spondylitis), enthesitis, dactylitis, and tenosynovitis. Inflammatory arthritis presents with joint pain, swelling, prolonged stiffness, and reduced mobility. Typically, early PsA is oligoarticular (<4 joints) and often asymmetric, and as the number of affected joints increases, the disease becomes polyarticular and the distribution becomes more symmetric. Distal interphalangeal joint involvement is typical of PsA and is associated with psoriatic nail changes since the nail bed is closely linked to the distal interphalangeal (DIP) joints.

Inflammatory arthritis of the axial skeleton occurs in 5% of PsA patients in early stage and can be seen in 50% of patients after 20 years of disease. Axial inflammatory arthritis presents with inflammatory back and/or neck pain and stiffness, which is typically worse after periods of prolonged inactivity and improves with activity. However, axial arthritis can be asymptomatic or overshadowed by patients' peripheral arthritis symptoms. Most patients with axial involvement have sacroiliitis, although axial involvement without sacroiliitis may distinguish axial PsA from axial SpA. While many of the radiographic features may resemble AS, presence of asymmetric sacroiliitis, nonmarginal and asymmetric bulky syndesmophytes, and frequent involvement of cervical spine have been more often assigned to axial PsA then AS. These phenotypic differences have led to the suggestion that this may reflect potential pathogenic distinctions. Whether axial PsA pathogenesis differs substantially from axSpA and especially whether this has therapeutic consequences are the subjects of investigations by several international consortia.

Other important musculoskeletal manifestations of PsA include dactylitis, enthesitis, and tenosynovitis. Dactylitis is defined as inflammatory swelling of an entire finger or toe. Dactylitis is due to inflammation of the joints, tendons, bones, and soft tissues within the digit. Dactylitis is a marker of severity of PsA, and persistent dactylitis leads to structural damage to the joints within that digit. Arthritis mutilans is an end manifestation of a severe arthritis process.

Enthesitis is another important manifestation of PsA. The most common sites affected by enthesitis are the plantar fascia and Achilles tendon insertion on the calcaneum (plantar fasciitis and Achilles enthesitis). Other common sites for enthesitis include quadriceps tendon insertion on the patella, patellar tendon insertion on tibia, medial and lateral epicondyle, pelvic rim, spinous processes, and intercostal muscle insertion on ribs. Tenosynovitis, or inflammation of the tendon sheath, may affect tendons in the hands, wrists, and around the ankles.

Most patients with PsA have psoriasis vulgaris. In ~80% of people with PsA, psoriasis develops first, and the musculoskeletal manifestations develop after a variable duration. In ~10%, both arthritis

and psoriasis develop simultaneously. While patients with PsA have psoriasis by definition, in 10% of patients, the arthritis develops first and cutaneous psoriasis manifests a few years later. Diagnosis of PsA is challenging in such patients, and family history of psoriasis, with typical musculoskeletal involvement, can help make the diagnosis. Although 40% of patients with psoriasis without PsA have nail lesions, nail involvement is much more frequent in patients with PsA, affecting close to 90% of patients. Psoriatic nail manifestations may be classified into nail matrix disease and nail bed disease. Nail pitting, leukonychia, crumbling, and red spots in the lunula are manifestations of nail matrix disease, whereas onycholysis, subungual hyperkeratosis, oil drop change, and splinter hemorrhages are manifestations of nail bed disease.

Patients with PsA may also have involvement of the eye and gastrointestinal tract. Uveitis may occur in 5% of patients, and conjunctivitis is rarely seen. While unilateral acute anterior uveitis is the commonest form, posterior uveitis and bilateral eye involvement are also reported. IBD (Crohn's disease or rarely ulcerative colitis) may coexist in patients with PsA. Mucous membrane inflammation presents with painful mouth ulcers and rarely urethritis.

The disease course of PsA is variable. Whereas some patients do well with few joints involved and no significant damage, others progress very quickly to develop marked joint damage within a few months. Patients with PsA have a worse quality of life and function compared with the general population as well as to patients with psoriasis without PsA.

Patients with psoriasis and PsA have an increased risk of cardiovascular disease, as high as the risk in people with diabetes mellitus. The increased risk is independent of cardiovascular risk factors and correlates with more severe skin disease, disease duration, and increased inflammatory markers. Patients with PsA have more severe subclinical atherosclerosis compared with psoriasis patients without PsA. The prevalence of hypertension, type 2 diabetes, obesity, metabolic syndrome, fatty liver disease, angina, and myocardial infarction is higher among patients with PsA compared with the general population. Obesity has an additional adverse impact on PsA disease activity and treatment response. Patients with psoriasis and PsA have increased rates of depression and suicidality compared to the general population. The prevalence of malignancy in PsA is not increased, and mortality studies have shown conflicting results.

DIAGNOSIS

The diagnosis of PsA is based on clinical features of cutaneous psoriasis with inflammatory musculoskeletal disease such as arthritis, dactylitis, enthesitis, or spondylitis. Presence of dactylitis is an important sign, and careful examination of feet is important since dactylitis of a single toe or enthesitis around the heel may be the only musculoskeletal manifestation of PsA in a patient with psoriasis. Psoriasis may be hidden in areas such as the scalp, umbilicus, below breasts, or in the natal cleft, or it may be present in the nail only and should be looked for carefully. Typical involvement of the joints of the fingers or toes is in a "ray" distribution (involvement of all joints in a finger or toe), with one finger showing dactylitis, another with bony ankylosis, and the neighboring finger showing arthritis mutilans. The pattern of involvement in PsA is often asymmetric compared with RA, in which the pattern tends to be symmetric. The presence of spondylitis with asymmetric oligoarticular peripheral arthritis would virtually rule out RA and would make the diagnosis of PsA more likely. The diagnosis of PsA may sometimes be made even in the absence of psoriasis if the above characteristic features are present and if there is a family history of psoriasis or PsA.

Laboratory tests only play a minor role in the diagnosis of PsA. Tests for acute-phase reactants such as ESR or CRP are abnormal in ~50% of patients despite clinically active disease. High levels of ESR or CRP are markers of severe disease and are predictors of radiographic damage and mortality. RF is typically negative, but low titer RF or low titer anticyclic citrullinated peptide antibody may be positive in <10% of patients. *HLA-B27* is positive in 20% of all patients with PsA and 50% of patients with axial PsA. A patient with PsA may present with monoarticular arthritis of knee or ankle, and in this situation, synovial fluid analysis will differentiate between infection ("septic arthritis"), crystal-induced arthritis, OA, or immune-mediated inflammatory arthritis such as PsA. White blood cell counts of >2000/mL of synovial fluid with no crystals and negative Gram stain and culture are diagnostic of inflammatory arthritis and, in this clinical scenario, should raise the suspicion of SpA such as PsA, reactive arthritis, or IBD-associated arthritis. Routine laboratory tests such as complete blood counts or kidney or liver function tests do not help in making the diagnosis of PsA but can be useful for monitoring treatment or assessing comorbidities.

IMAGING FEATURES

Imaging is an important modality in the assessment of PsA and may help in confirming the diagnosis and determining disease severity. Radiographs of the hands, feet, pelvis, spine, and other affected joints should be performed to look for changes suggestive of PsA. In early disease, x-rays of the hands and feet show soft tissue swelling around the involved joints. Periarticular osteopenia is generally absent. Marginal erosions are markers of disease severity and predict further radiographic progression, deformity, and disability. In PsA, erosions are often accompanied by "fluffy" new bone formation. The combination of erosions at joint margins with new bone formation is characteristic of PsA **(Fig. 374-6)**. New bone formation may also cause ankylosis of the joints. There also may be joint space narrowing, "pencil-in-cup" deformity, and in late stages, such as arthritis mutilans, total joint destruction or joint lysis and acro-osteolysis (resorption of the terminal phalanx) are seen.

Certain characteristic radiographic features such as "pencil-in-cup" deformity, bony ankylosis in a ray distribution, or "fluffy" new bone formation close to sites of erosions can be pathognomonic of PsA.

X-ray of the pelvis (anteroposterior view) may show changes of sacroiliitis. Sacroiliitis in PsA is more likely to be unilateral compared to axSpA, where it is usually bilateral. Axial involvement in PsA may show changes of shiny vertebral corners, erosions, squaring of vertebrae, and syndesmophyte formation on the lateral view of the spine. While this may mimic radiographic axSpA, often in PsA, the syndesmophytes are chunky and "nonmarginal" and develop from sites away from the vertebral corners **(Fig. 374-7)**. The presence of such syndesmophytes is characteristic of PsA. Cervical and lumbar vertebrae are frequently involved. Rarely, atlantoaxial subluxation develops with potentially serious consequences.

Ultrasound combined with Doppler evaluation can help in differentiating enthesitis from fibromyalgia tender points or in differentiating mechanical versus inflammatory etiology. Ultrasound can also detect erosions before they appear on x-rays, especially in the hand joints. Some of the findings in inflammatory enthesitis in PsA include thickening of the tendon with loss of the regular fibrillar architecture, hypoechoic lesion, and neovascularization around insertions of tendons, ligaments, and joint capsules at the bone. Bony irregularities and erosions would distinguish inflammatory from mechanical enthesitis. Ultrasound, however, is highly operator dependent and is useful in expert hands only, which remains a limitation. MRI with IV contrast of the peripheral joints can detect synovitis, and MRI without contrast in axial joints may show bone marrow edema (on the short tau inversion recovery [STIR] image) suggestive of active inflammation before any abnormality is visualized on x-rays. MRI can also show erosions in the joints even before they are seen on plain x-rays. MRI is also very useful in visualizing enthesitis. CT scans are useful when an MRI is unavailable or contraindicated, although the risk of considerable radiation exposure needs to be balanced with the benefits. Nuclear medicine bone scans are neither specific nor sensitive to diagnose PsA. Use of fluorodeoxyglucose positron emission tomography scans to assess inflammatory burden in PsA is experimental.

CLASSIFICATION CRITERIA

The Classification of Psoriatic Arthritis (CASPAR) criteria **(Table 374-6)** have a specificity of 98.7% and sensitivity of 91.4%. To meet the CASPAR criteria for PsA, individuals must first have inflammatory articular disease (joint, spine, or entheseal) and must have at least three points from the five categories described in Table 374-6.

FIGURE 374-6 ***A.*** X-ray of the feet in psoriatic arthritis. These images show erosions, loss of cartilage in bilateral first metatarsophalangeal (MTP) joints, bilateral interphalangeal joint of great toes, and right fifth MTP joint. There are changes of secondary osteoarthritis with sclerosis and osteophyte formation in these joints and early pencil-in-cup deformity in the left fifth MTP joint. ***B.*** X-ray of the hands in psoriatic arthritis. Left thumb interphalangeal joint showing early pencil-in-cup deformity (marked with **). Right third finger has dactylitis and shows periosteal new bone formation in the third proximal phalanx (*white arrow*), along with erosions in the proximal (marked with *) and distal interphalangeal joints (marked with *). This combination of periosteal new bone formation and erosions in "ray" distribution is typical of psoriatic arthritis.

DIFFERENTIAL DIAGNOSIS

OA, the most common form of arthritis, occurs in ~5% of the population, and it may coexist with psoriasis especially in the DIP joints. Thus, the presence of Heberden nodules in the context of patients with hand OA with concomitant psoriasis is an important differential diagnosis to be made. Psoriatic nail involvement would differentiate PsA from inflammatory OA of the DIP joints, along with imaging abnormalities such as on ultrasonography. Patients with "seronegative RA" should be carefully examined for presence of psoriasis in hidden areas (scalp, umbilicus, gluteal cleft, genitals, below breasts, and nails) and questioned about family history of psoriasis. Many patients with seronegative RA may have pSpA such as PsA, ReA, or IBD-associated arthritis. The high skin turnover in psoriasis can lead to hyperuricemia, and gout can coexist with PsA. Flare of monoarticular PsA should be assessed with synovial fluid analysis to rule out gout or septic arthritis. PsA shares several clinical, laboratory, and imaging features with other SpA conditions such as ReA, IBD-associated arthritis, and axSpA, and patients may fulfill classification criteria of multiple SpAs simultaneously. Calcium pyrophosphate deposition disease (CPPD) arthritis affecting the MCP joints may coexist in the elderly with skin psoriasis. Chondrocalcinosis of the triangular fibrocartilage in the wrist, "hook-like" osteophytes in the MCP joints, and absence of erosions or fluffy new bone formation should rule out PsA. Synovitis, acne, pustulosis, SAPHO, and rarely hidradenitis suppurativa may mimic palmer plantar psoriasis and PsA.

ASSESSING DISEASE ACTIVITY IN PSORIATIC ARTHRITIS

Disease Activity in Psoriatic Arthritis (DAPSA) and Minimal Disease Activity (MDA) are the most common instruments used to assess disease activity in clinical practice. A simple scale used to assess plaque psoriasis is to ask the patient, "How many palms will be covered by the current psoriasis on your body?" With one palm of the patient counted as 1% body surface area (BSA), the total BSA involved by active psoriasis can be assessed. Nail psoriasis and dactylitis can be

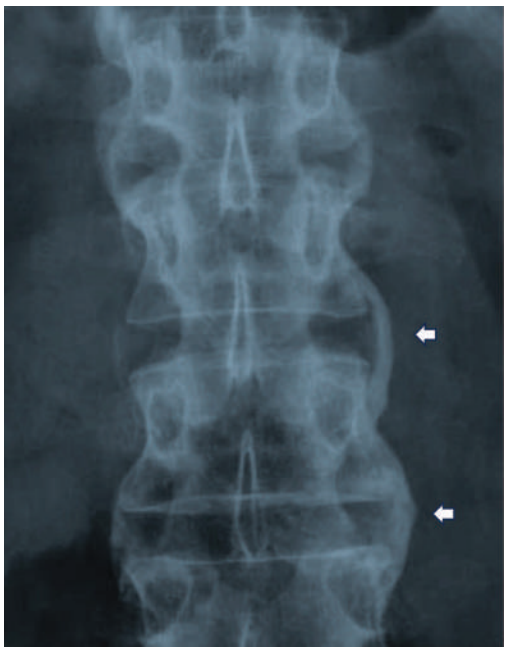

FIGURE 374-7 X-ray of the lumbar spine anteroposterior view in psoriatic arthritis. The images show nonmarginal "chunky" syndesmophytes (marked with *white arrows*).

TABLE 374-6 Classification Criteria for Psoriatic Arthritis (CASPAR)
Patients with Inflammatory Articular Disease (Joint, Spine, or Entheseal) Plus ≥3 Points Meet CASPAR Criteria for Psoriatic Arthritis

CATEGORY	DESCRIPTION	POINT VALUE
Psoriasis[a]	Current psoriasis as determined by a rheumatologist or dermatologist	2
	Personal history of psoriasis obtained from patient or qualified health care provider	1
	A family history of psoriasis as reported by patient in a first- or second-degree relative	1
Nail changes	Typical psoriatic nail dystrophy (onycholysis, pitting, and hyperkeratosis) present at assessment	1
Rheumatoid factor	Rheumatoid factor negative	1
Dactylitis (swelling of entire digit)	Current dactylitis or history of dactylitis recorded by a rheumatologist	1
Radiographic evidence	Juxtaarticular new bone formation (excluding osteophyte formation) on plain radiograph of hand or foot; appears as ill-defined ossification near joint margins	1

[a]Psoriasis should account for only one of the three descriptors.

Source: Adapted from WJ Taylor et al: Arthritis Rheum 54: 2665, 2006.

assessed by simply counting the digits with affected fingernails or with dactylitis. A number of enthesitis indices have been developed, such as the Spondyloarthritis Research Consortium of Canada Index and the Leeds Enthesitis Index. Axial arthritis is assessed using tools borrowed from axSpA assessment.

TREATMENT

Psoriatic Arthritis

The treatment target is remission or low disease activity. This is achieved by nonpharmacologic and pharmacologic interventions including novel advanced therapies. A multidisciplinary team consisting of rheumatologists, physical and occupational therapists, dermatologists, and depending upon the domains involved, gastroenterologists, ophthalmologists, psychologists/psychiatrists, dieticians, endocrinologists, and cardiologists may be needed to manage common comorbidities. All pharmacologic interventions need to be based on shared decision-making between the patient and their provider.

The four main classes of pharmacotherapy used in the management of PsA include NSAIDs, conventional synthetic disease-modifying antirheumatic drugs (csDMARDs), biologic DMARDs, and tsDMARDs. Biologic and tsDMARDs have revolutionized the management of PsA by effectively controlling signs and symptoms, decreasing joint damage progression, and improving health-related quality of life. Biologic DMARDs used in the management of PsA include TNFi (etanercept, adalimumab, infliximab, certolizumab, or golimumab), antibodies against IL-12/23 (ustekinumab), IL-17A (secukinumab, ixekizumab), IL-17A and IL-17F (bimekizumab), IL-23 (guselkumab, risankizumab), and costimulatory blockade agent (abatacept). tsDMARDs include the phosphodiesterase-4 (PDE4) inhibitor apremilast; JAKis such as tofacitinib, baricitinib, and upadacitinib; and the tyrosine kinase 2 (TYK2) inhibitor deucravacitinib. The IL-17A and IL-17A+F inhibitor nanobodies izokibep and sonelokimab are currently undergoing clinical trials.

TREATMENT RECOMMENDATIONS

The ACR along with National Psoriasis Foundation (ACR-NPF), EULAR, and Group for the Research and Assessment of Psoriasis and Psoriatic Arthritis (GRAPPA) have published separate recommendations for the pharmacologic management of PsA, though there are many similarities. They all recommend that the treatment should be tailored according to the disease activity assessed by level of symptoms and clinical findings in peripheral joints, skin, nails, axial skeleton, entheses, and presence of dactylitis. Individual clinical features (age, gender, concomitant medications, and psychosocial factors), comorbidities (especially IBD, uveitis, metabolic syndrome, and heart disease), prognostic indicators, and patient preferences, values, and cultural background need to be considered in this shared decision-making process. Patients should be monitored at regular intervals and treatment adjusted as appropriate. Treatment is generally continued indefinitely for this lifelong disease since there is high risk of flare once treatment is discontinued.

Principles and recommendations for PsA management from these recommendations are summarized in **Table 374-7**.

For musculoskeletal manifestations of PsA, TNFi and IL-17i have demonstrated comparable efficacy, whereas IL-17i, IL-12/23i, and IL-23i have shown superior efficacy in clearing skin psoriasis compared to TNFi in head-to-head studies. JAKis have comparable efficacy to TNFis for musculoskeletal manifestations of PsA. All biologics except abatacept, and JAKis have shown efficacy in reducing radiographic progression in PsA, but none of the csDMARDs, PDE-4 inhibitors, or TYK2 inhibitors have shown this. While there are no comparative studies on safety, IL-17i, IL-12/23i, IL-23i, PDE-4 inhibitors, and TYK2 inhibitors are perceived to be safer than TNFis in clinical practice.

REACTIVE ARTHRITIS

The interrelation between infection and arthritic disease has been established for many decades. ReA refers to the development of arthritis following urogenital or gastrointestinal infection involving well-defined triggering microorganisms that are normally not cultivable from the joints affected. Prototypical inducers of reactive arthritis include *Yersinia, Campylobacter, Salmonella, Shigella,* and *Chlamydia*.

CLINICAL FEATURES

A crucial factor in the diagnosis relates to recognition of the clinical picture and the identification of causative organisms. A hallmark feature is the time delay between initial infection and onset of arthritis: the interval ranges between 1 day and 4 weeks after infection. Inflammatory musculoskeletal disease (joint, spine, or entheseal) is essential for the diagnosis of ReA. The clinical spectrum may include a typical asymmetrical oligoarticular arthritis preferentially involving lower limbs, enthesitis, tendonitis, bursitis, dactylitis, inflammatory back pain, and sacroiliitis. Mucocutaneous lesions may also occur in addition to the musculoskeletal manifestations and include uveitis/conjunctivitis, erythema nodosum, oral ulcers, circinate balanitis, and keratoderma blenorrhagica.

ReA is strongly associated with the presence of *HLA-B27*, with up to 50–80% of all reactive arthritis patients carrying *HLA-B27*. Accordingly, prevalence of ReA matches the prevalence of *HLA-B27*, which has a clear North-South gradient; e.g., the highest prevalence of *HLA-B27* is observed in the Northern Hemisphere, which was reflected by historical large outbreaks of ReA in, for example, Scandinavian regions. However, over the past decades, there has been a steady decline in the number of such outbreaks with improved hygiene and changes in microbiota. Recent updates on incidence of reactive arthritis point to an overall incidence rate estimate of 3.4 cases per 100,000 person-years. Overall, the estimated percentage of cases to develop ReA following an enteric infection with *Campylobacter, Salmonella, Shigella,* or *Yersinia* is estimated around 2.6%.

Expert consensus refers to ReA only if clinical picture and causative microbes are *HLA-B27* and SpA related. Hence many other infections that trigger onset of arthritis fall outside of the SpA construct. These "infection-related arthritides" constitute all forms of arthritis associated with infections except septic arthritis. They include, among others, acute rheumatic fever, meningococcus, *Mycoplasma genitalium*, *Ureaplasma urealyticum*, *Chlamydia pneumoniae*, beta-hemolytic streptococci, and some live vaccines and COVID. These should not be described as ReA since the clinical pattern does not fit the SpA spectrum and is unrelated to *HLA-B27*. Thus, the term ReA should be restricted to an *acute SpA* that is linked to an acute genitourinary or gastrointestinal infection. The other forms should be referred to as postinfectious arthritides and will not be discussed further in this chapter.

DIAGNOSIS

ReA is diagnosed based on clinical features and identification of an antecedent infection from medical history and laboratory tests and exclusion of other different diagnosis. While diagnostic procedures are focused around *HLA-B27* and molecular testing for *Chlamydia trachomatis* infection, additional individualized diagnostic tests must also be considered to rule out other causes (e.g., postinfectious arthritides). Laboratory tests such as stool cultures to test for *Salmonella, Shigella*, *Campylobacter,* and *Yersinia* can sometimes confirm a preceding or concomitant infection with a causative pathogen, but since gastrointestinal symptoms often have resolved when rheumatic features develop, pathogens may no longer be retrievable. Serology for enteric pathogens is used primarily in epidemiologic studies to test for preceding infections, but there are some questions on its utility in daily clinical practice given the overall low yield of positive results. All patients should be offered screening for *Chlamydia*.

TREATMENT

Reactive Arthritis

Treatment of ReA is oriented to management of SpA features, but treatment guidelines for ReA do not exist currently. While antibiotics are not used in the routine care of ReA, one study demonstrated

TABLE 374-7 Pharmacologic Management of Psoriatic Arthritis (PsA)

PRINCIPLES AND RECOMMENDATIONS

1. The primary goal of treating patients with PsA is to maximize long-term health-related quality of life through control of symptoms, abrogation of inflammation, prevention of structural damage, normalization of function, and social participation.
2. PsA requires multidisciplinary treatment (rheumatologist, dermatologist, psychiatrist, gastroenterologist, ophthalmologist, dietician, endocrinologist, cardiologist, and physical/occupational therapists), and it should be based on a shared decision-making between the patient and the rheumatologist.
3. "Treat to target" is recommended, with the target being minimal disease activity or remission. Patients should be regularly monitored, and treatment should be adjusted appropriately to reach the target.
4. NSAIDs may be used as an initial short-term treatment to relieve symptoms related to peripheral arthritis, enthesitis, dactylitis, and axial disease. NSAIDs alone are very rarely sufficient to treat PsA but can be combined with cs-, b-, or tsDMARDs.
5. Local injections of glucocorticoids should be considered for active arthritis, enthesitis, and/or dactylitis. Glucocorticoid injections around lower extremity weight-bearing entheses should be avoided due to the risk of tendon rupture.
6. Systemic glucocorticoids should be avoided. In rare circumstances such as acute flares of arthritis, they may be used with caution at the lowest effective dose for the shortest period.
7. In patients with active disease with peripheral arthritis, enthesitis, and/or dactylitis, treatment with csDMARDs, such as methotrexate, sulfasalazine, or leflunomide, should be considered at an early stage. Methotrexate is preferred if clinically relevant psoriasis is present.
8. PDE-4 inhibitor or TYK-2 inhibitor may be considered as the initial treatment instead of csDMARD for active musculoskeletal disease (except axial disease) or active skin disease.
9. In patients with predominant axial disease, csDMARDs should be avoided, and either bDMARDs or JAKi should be considered after inadequate response to NSAIDs.
10. In rare circumstances, in patients with very active musculoskeletal disease (multiple swollen joints, structural damage in the presence of active inflammation, and/or clinically relevant extraarticular manifestations such as IBD or uveitis) or extensive skin involvement, treatment with bDMARDs can be started before csDMARDs at the discretion of the treating provider.
11. The choice of initial biologic for active musculoskeletal disease (TNF, IL-12/23, IL-17, or IL-23 inhibitors) should be based on pros and cons of each therapy class, patients' comorbidities, and their comfort with risks/benefit.
12. For patients with predominant skin disease along with musculoskeletal disease, IL-12/23, IL-17, or IL-23 inhibitors are preferred over TNF inhibitors.
13. For PsA patients with comorbid IBD, monoclonal antibodies against TNF, IL-12/23 inhibitors, IL-23 inhibitors, or JAKi therapy is preferred. IL-17 inhibitors should be avoided in patients with active IBD but can be used in patients with history of IBD.
14. For PsA patients with comorbid uveitis, therapy with monoclonal antibodies against TNF is preferred.
15. JAKi should be used after failure of TNF inhibitors according to the black-box warning issued by regulatory authorities based on their CV risk. Comorbidities of metabolic syndrome and CV disease should be considered before JAKi treatment.
16. Combination of methotrexate with bDMARDs such as TNF inhibitors has not been shown to improve efficacy compared to bDMARDs alone.
17. Abatacept has no efficacy against the disease domains of skin, nail, and the axial skeleton. Its efficacy against peripheral arthritis is modest.
18. Agents that effectively treat skin and nail involvement (but with minimal efficacy on the musculoskeletal domains) include topical glucocorticoids such as clobetasol, retinoic acid derivatives, PUVA, and cyclosporin.
19. Biosimilars may be used in place of the original biologics.
20. Tapering of DMARDs in a PsA patient with long-term minimal disease activity or remission should be a shared decision. Stopping DMARD therapy is not recommended.

that a 6-month course of combination antibiotics (doxycycline or azithromycin, combined with rifampicin) yielded higher response rates then placebo in chronic *Chlamydia*-induced ReA. However, these results have not been replicated, and the routine use of long-term antibiotics to treat chronic ReA is not recommended.

In acute ReA, management of joint symptoms include NSAIDs, intraarticular glucocorticoids for monoarthritis or oligoarthritis, and short-term low-dose systemic glucocorticoids for polyarticular joint involvement. While ReA is thought to be self-limiting and resolving in a large proportion of patients, ReA may also evolve into a chronic phase. The presence of *HLA-B27* has been linked to the evolution into chronicity in part because *HLA-B27* has been suggested to promote intracellular survival of causative microorganisms in infected macrophages, providing a roadmap to chronicity. In chronic forms of ReA (e.g., lasting longer than 6 months and with inadequate response to management outline in acute ReA), DMARDs such as sulfasalazine and methotrexate and even TNFis can be considered. Overall, the management of chronic forms of ReA follows treatment principles of peripheral SpA.

IBD-ASSOCIATED ARTHRITIS

An intriguing relationship between bowel and joint inflammation has emanated for >50 years that points to a prominent role of barrier integrity loss and dysbiosis in SpA, initially recognized by uncovering the occurrence of arthritis in IBD patients. The link between gut and joint inflammation, however, is reciprocal. Hence, patients with a diagnosis of SpA but without associated gastrointestinal symptoms were also found to display histologic signs of inflammation in ileocolonoscopic studies, primarily in the terminal ileum. Here, two types of lesions were described: an acute type of inflammation resembling an infectious enterocolitis and a chronic type of inflammation with many features of Crohn's disease. Overall, the frequency of microscopic inflammatory lesions mounts up to 50% of new-onset treatment-naïve SpA patients and is associated with higher degrees of bone marrow edema in MRI of sacroiliac joints. Furthermore, the presence of chronic lesions represents a risk factor for evolution into full-blown Crohn's disease and progression to AS. These microscopic lesions are accompanied by elevated fecal calprotectin and CRP levels.

Both ulcerative colitis and Crohn's disease are associated with SpA. AxSpA as well as pSpA commonly occur in both of them, with pSpA being the most prevalent form. R-axSpA develops in up to 10% of IBD patients, whereas prevalence of pSpA varies largely according to various studies, ranging from 10 to 30%.

Conversely, patients with axSpA have a substantially higher risk of developing IBD, with a prevalence varying between 5 and 10% and with an observed increase with disease duration. This reciprocal relationship between IBD and AS is reflected by a considerable overlap in the genetic predisposition between these diseases, including polymorphisms in genes linked to type 3 immunity (e.g., IL-23R, IL-12p40,

RORc), innate immunity (TNFAIP3, TLR4), and epithelial integrity (GPR35, PTGER4). However, *HLA-B27* is not a risk factor for IBD.

CLINICAL FEATURES

Axial skeletal involvement associated with IBD is clinically similar to idiopathic axSpA. There may be, however, a disconnect in time in the occurrence of both. Thus, axSpA may develop after diagnosis of IBD but, in other cases, precedes onset of IBD. Peripheral involvement in IBD resembles the clinical picture of peripheral SpA, which may include more acute forms of oligoarthritis that co-occur with relapses of IBD. More chronic forms of SpA may also occur that may cause substantial structural damage if not appropriately treated. A rare symmetric polyarticular arthritis that runs an independent course has also been described.

In addition to IBD patients with a firm diagnosis of SpA, a comparable fraction of IBD patients have arthralgias or fibromyalgia symptoms.

DIAGNOSIS

IBD-related arthritis is diagnosed based on clinical and imaging features in patients with a history of IBD and follows the same diagnostic principles as other forms of SpA. It is important to note, however, that most patients with IBD-related arthritis are seen while being treated for IBD. Thus, special caution should be taken in interpretation of imaging in patients treated with biologics, immune suppressive drugs, and glucocorticoids.

TREATMENT

IBD-Associated Arthritis

Management of IBD-related arthritis follows the general principles of axSpA and pSpA treatment with some special considerations, given the observed disconnect that may occur between gut and joint symptoms with some targeted therapies. Within the targeted therapies, the monoclonal antibodies, but not the soluble receptor, blocking TNF-α are effective in IBD as well as in both axial and peripheral SpA. Other biologics with efficacy in IBD that may have proven efficacy in peripheral SpA include ustekinumab (anti-IL12/23p40), guselkumab, and risankizumab (anti-IL23p19), but anti-IL17 therapy is contraindicated. The JAKi tofacitinib and upadacitinib are approved in ulcerative colitis and upadacitinib in Crohn's disease and are also effective in axSpA and pSpA. Other treatments for IBD include sulfasalazine and related drugs as well as systemic and local glucocorticoids. NSAIDs, especially COX2-selective formulations, are helpful for arthritis and generally well tolerated but may induce IBD flares, so they should be considered only for temporary use. Vedolizumab is a gut-selective integrin inhibitor approved for both Crohn's disease and ulcerative colitis. However, up to 15% of IBD patients treated with vedolizumab may develop new-onset disease or flare of axSpA or pSpA.

UNDIFFERENTIATED PERIPHERAL SPONDYLOARTHRITIS

The term "undifferentiated pSpA" is used to describe patients who do not fit into any of the above well-defined conditions such as axSpA, PsA, ReA, or IBD-associated arthritis but have the typical SpA phenotype (oligoarticular inflammatory arthritis, usually involving lower limbs, asymmetric, or peripheral enthesitis or dactylitis). The ASAS group developed classification criteria for pSpA in 2011 **(Table 374-8)**. These criteria allow the classification of a patient with peripheral enthesitis or dactylitis but without peripheral arthritis. The prevalence and incidence of undifferentiated pSpA are not known since there are no epidemiologic studies available. Some of these patients are likely to have ReA, where the inciting infection is silent, and in some patients, features of psoriasis and/or IBD may develop later. Treatment of pSpA should be individualized based on the predominant musculoskeletal manifestation.

TABLE 374-8 Assessment of Spondyloarthritis International Society (ASAS) Criteria for Peripheral Spondyloarthritis (SpA)

Arthritis or **enthesitis** or **dactylitis**	
Plus ≥1 of:	**Plus ≥2 of the remaining:**
- Psoriasis	- Arthritis
- Inflammatory bowel disease	- Enthesitis
- Preceding infection	- Dactylitis
- *HLA-B27*	- IBP in the past
- Uveitis	- Positive family history for SpA
- Sacroiliitis on imaging (radiographs or MRI)	

Note: Peripheral arthritis: usually lower limb, asymmetric arthritis; enthesitis: clinically assessed; dactylitis: clinically assessed.

Abbreviations: IBP, Inflammatory back pain; MRI, magnetic resonance imaging.

SPONDYLOARTHRITIS ASSOCIATED WITH SAPHO SYNDROME AND HIDRADENITIS SUPPURATIVA

SAPHO is a clinical entity that is sometimes associated with *Propionibacterium acne* infection on bone biopsies. It is included under SpA since some patients have asymmetric inflammatory arthritis (typically sternoclavicular joints and chest wall costochondral junctions), sacroiliitis, and spinal hyperostosis. The skin manifestations include acne conglobate and palmoplantar pustular lesions that are pathologically identical to psoriasis. Some consider SAPHO as the adult phenotype of juvenile chronic recurrent multifocal osteomyelitis (CRMO), where the osteomyelitis is sterile. Apart from TNFi, IL-17i, and JAKi, there are case reports of pamidronate, a bisphosphonate, being effective in treatment. Hidradenitis suppurativa patients may develop a SpA phenotype of musculoskeletal involvement, including asymmetric sacroiliitis.

375 The Vasculitis Syndromes

Carol A. Langford, Anthony S. Fauci

DEFINITION

Vasculitis is a clinicopathologic process characterized by inflammation of and damage to blood vessels. The vessel lumen is usually compromised, and this is associated with ischemia of the tissues supplied by the involved vessel. A broad and heterogeneous group of syndromes may result from this process, since any type, size, and location of blood vessel may be involved. Vasculitis and its consequences may be the primary or sole manifestation of a disease; alternatively, vasculitis may be a secondary component of another disease. Vasculitis may be confined to a single organ, such as the skin, or it may simultaneously involve several organ systems.

CLASSIFICATION

The vasculitic syndromes as a group have a great deal of heterogeneity while also possessing a considerable degree of overlap. Table 375-1 lists the major vasculitis syndromes. The distinguishing and overlapping features of these syndromes are discussed below.

PATHOPHYSIOLOGY AND PATHOGENESIS

Generally, most of the vasculitic syndromes are assumed to be mediated at least in part by immunopathogenic mechanisms that occur in response to certain antigenic stimuli. However, evidence supporting this hypothesis is for the most part indirect and may reflect epiphenomena as opposed to true causality. Furthermore, it is unknown why some individuals might develop vasculitis in response to certain antigenic stimuli, whereas others do not. It is likely that a number of factors are involved in the ultimate expression of a vasculitic syndrome. These include the genetic predisposition, environmental exposures, and the regulatory mechanisms associated with immune response to certain antigens. Although immune complex formation, antineutrophil cytoplasmic antibodies (ANCA), and pathogenic T lymphocyte responses (Table 375-2) have been among the prominent hypothesized mechanisms, the pathogenesis of individual forms of vasculitis remains complex and varied.

TABLE 375-1 Vasculitis Syndromes

PRIMARY VASCULITIS SYNDROMES	SECONDARY VASCULITIS SYNDROMES
Granulomatosis with polyangiitis	Vasculitis associated with probable etiology
Microscopic polyangiitis	Drug-induced vasculitis
Eosinophilic granulomatosis with polyangiitis (Churg-Strauss)	Hepatitis C virus–associated cryoglobulinemic vasculitis
IgA vasculitis (Henoch-Schönlein)	Hepatitis B virus–associated vasculitis
Cryoglobulinemic vasculitis	Cancer-associated vasculitis
Polyarteritis nodosa	Vasculitis associated with systemic disease
Kawasaki disease	Lupus vasculitis

PATHOGENIC IMMUNE-COMPLEX FORMATION

Deposition of immune complexes was the first and most widely accepted pathogenic mechanism of vasculitis. However, the causal role of immune complexes has not been clearly established in most of the vasculitic syndromes. Circulating immune complexes need not result in deposition of the complexes in blood vessels with ensuing vasculitis, and many patients with active vasculitis do not have demonstrable circulating or deposited immune complexes. The actual antigen contained in the immune complex has only rarely been identified in vasculitic syndromes. In this regard, hepatitis B antigen has been identified in both the circulating and deposited immune complexes in a subset of patients who have features of a systemic vasculitis clinically similar to polyarteritis nodosa (see "Polyarteritis Nodosa"). Cryoglobulinemic vasculitis is strongly associated with hepatitis C virus infection; hepatitis C virions and hepatitis C virus antigen-antibody complexes have been identified in the cryoprecipitates of these patients (see "Cryoglobulinemic Vasculitis").

The mechanisms of tissue damage in immune complex–mediated vasculitis resemble those described for serum sickness. In this model, antigen-antibody complexes are formed in antigen excess and are deposited in vessel walls whose permeability has been increased by vasoactive amines such as histamine, bradykinin, and leukotrienes released from platelets or from mast cells as a result of IgE-triggered mechanisms. The deposition of complexes results in activation of complement components, particularly C5a, which is strongly chemotactic for neutrophils. These cells then infiltrate the vessel wall, phagocytose the immune complexes, and release their intracytoplasmic enzymes, which damage the vessel wall. As the process becomes subacute or chronic, mononuclear cells infiltrate the vessel wall resulting in compromise of the vessel lumen with ischemic changes in the tissues supplied by the involved vessel. Several variables may explain why only certain types of immune complexes cause vasculitis and why only certain vessels are affected in individual patients. These include the ability of the reticuloendothelial system to clear circulating complexes from the blood, the size and physicochemical properties of immune complexes, the relative degree of turbulence of blood flow, the intravascular hydrostatic pressure in different vessels, and the preexisting integrity of the vessel endothelium.

ANTINEUTROPHIL CYTOPLASMIC ANTIBODIES

ANCA are antibodies directed against certain proteins in the cytoplasmic granules of neutrophils and monocytes. These autoantibodies are present in a high percentage of patients with active granulomatosis with polyangiitis and microscopic polyangiitis and in a lower percentage of patients with eosinophilic granulomatosis with polyangiitis. Because these diseases share the presence of ANCA

and small-vessel vasculitis, they have been grouped collectively as "ANCA-associated vasculitis." However, since these diseases possess unique clinical phenotypes, they should continue to be viewed as separate entities.

There are two major categories of ANCA based on different targets for the antibodies. The terminology of *cytoplasmic ANCA* (cANCA) refers to the diffuse, granular cytoplasmic staining pattern observed by immunofluorescence microscopy when serum antibodies bind to indicator neutrophils. Proteinase-3, a 29-kDa neutral serine proteinase present in neutrophil azurophilic granules, is the major cANCA antigen. More than 90% of patients with active granulomatosis with polyangiitis have detectable antibodies to proteinase-3 (see below). The terminology of *perinuclear ANCA* (pANCA) refers to the more localized perinuclear or nuclear staining pattern of the indicator neutrophils. The major target for pANCA is the enzyme myeloperoxidase; other targets that can produce a pANCA pattern include elastase, cathepsin G, lactoferrin, lysozyme, and bactericidal/permeability-increasing protein. However, only antibodies to myeloperoxidase have been convincingly associated with vasculitis. Antimyeloperoxidase antibodies have been reported in a variable percentage of patients with microscopic polyangiitis, eosinophilic granulomatosis with polyangiitis, isolated necrotizing crescentic glomerulonephritis, and granulomatosis with polyangiitis (see below). A pANCA pattern that is not due to antimyeloperoxidase antibodies has been associated with nonvasculitic entities such as rheumatic and nonrheumatic autoimmune diseases, inflammatory bowel disease, certain drugs, and infections such as endocarditis and bacterial airway infections in patients with cystic fibrosis.

It is unclear why patients with these vasculitis syndromes develop antibodies to myeloperoxidase or proteinase-3 or what role these antibodies play in disease pathogenesis. There are a number of in vitro observations that suggest possible mechanisms whereby these antibodies can contribute to the pathogenesis of the vasculitis syndromes. Proteinase-3 and myeloperoxidase reside in the azurophilic granules and lysosomes of resting neutrophils and monocytes, where they are apparently inaccessible to serum antibodies. However, when neutrophils or monocytes are primed by tumor necrosis factor α (TNF-α) or interleukin 1 (IL-1), or activation of the alternative complement cascade, proteinase-3 and myeloperoxidase translocate to the cell membrane, where they can interact with extracellular ANCA. The neutrophils then degranulate and produce reactive oxygen species that can cause tissue damage. Furthermore, ANCA-activated neutrophils can adhere to and kill endothelial cells in vitro. Activation of neutrophils and monocytes by ANCA also induces the release of proinflammatory cytokines such as IL-1 and IL-8. Adoptive transfer experiments in genetically engineered mice provide further evidence for a direct pathogenic role of ANCA in vivo. In contradiction, however, a number of clinical and laboratory observations argue against a primary pathogenic role for ANCA. Patients may have active granulomatosis with polyangiitis in the absence of ANCA; the absolute height of the antibody titers does not correlate well with disease activity; and patients with granulomatosis with polyangiitis in remission may continue to have high ANCA levels for years (see below).

PATHOGENIC T LYMPHOCYTE RESPONSES AND GRANULOMA FORMATION

The histopathologic feature of granulomatous vasculitis has provided evidence to support a role of pathogenic T lymphocyte responses and cell-mediated immune injury. Vascular endothelial cells can express human leukocyte antigen (HLA) class II molecules following activation by cytokines such as interferon (IFN) γ. This allows these cells to participate in immunologic reactions such as interaction with CD4+ T lymphocytes in a manner similar to antigen-presenting macrophages. Endothelial cells can secrete IL-1, which may activate T lymphocytes and initiate or propagate in situ immunologic processes within the blood vessel. In addition, IL-1 and TNF-α are potent inducers of endothelial-leukocyte adhesion molecule 1 (ELAM-1) and vascular cell adhesion molecule 1 (VCAM-1), which may enhance the adhesion of leukocytes to endothelial cells in the blood vessel wall.

APPROACH TO THE PATIENT

General Principles of Diagnosis

The diagnosis of vasculitis should be considered in any patient with an unexplained systemic illness. However, there are certain clinical features that should suggest a diagnosis of vasculitis. These include palpable purpura, pulmonary infiltrates and microscopic hematuria, chronic sinusitis, mononeuritis multiplex, unexplained ischemic events, and glomerulonephritis with evidence of multisystem disease. As a number of nonvasculitic diseases may also produce these abnormalities, the first step in the workup of a patient with suspected vasculitis is to exclude other diseases that can mimic vasculitis **(Table 375-3)**. It is particularly important to exclude infectious diseases with features that overlap those of vasculitis, especially if the patient's clinical condition is deteriorating rapidly and empirical immunosuppressive treatment is being contemplated.

Once diseases that mimic vasculitis have been excluded, the workup should follow a series of progressive steps that establish the diagnosis of vasculitis and determine, where possible, the category of the vasculitis syndrome **(Fig. 375-1)**. This approach is of considerable importance since several of the vasculitis syndromes require aggressive therapy with glucocorticoids and other immunosuppressive agents, whereas other syndromes usually resolve spontaneously and require symptomatic treatment only. The definitive diagnosis of vasculitis is usually made based on biopsy of involved tissue. The yield of "blind" biopsies of organs with no subjective or objective evidence of involvement is very low and should be avoided.

TABLE 375-3 Conditions That Can Mimic Vasculitis

Infectious Diseases
Bacterial endocarditis
Disseminated gonococcal infection
Pulmonary histoplasmosis
Coccidioidomycosis
Syphilis
Lyme disease
Rocky Mountain spotted fever
Whipple's disease
Coagulopathies/Thrombotic Microangiopathies
Antiphospholipid syndrome
Thrombotic thrombocytopenic purpura
Neoplasms
Atrial myxoma
Lymphoma
Carcinomatosis
Drug Toxicity
Cocaine
Levamisole
Amphetamines
Ergot alkaloids
Methysergide
Arsenic
Other
Sarcoidosis
Atheroembolic disease
Antiglomerular basement membrane disease (Goodpasture's syndrome)
Amyloidosis
Migraine
Fibromuscular dysplasia
Heritable disorders of connective tissue
Segmental arterial mediolysis (SAM)
Reversible cerebral vasoconstrictive syndrome

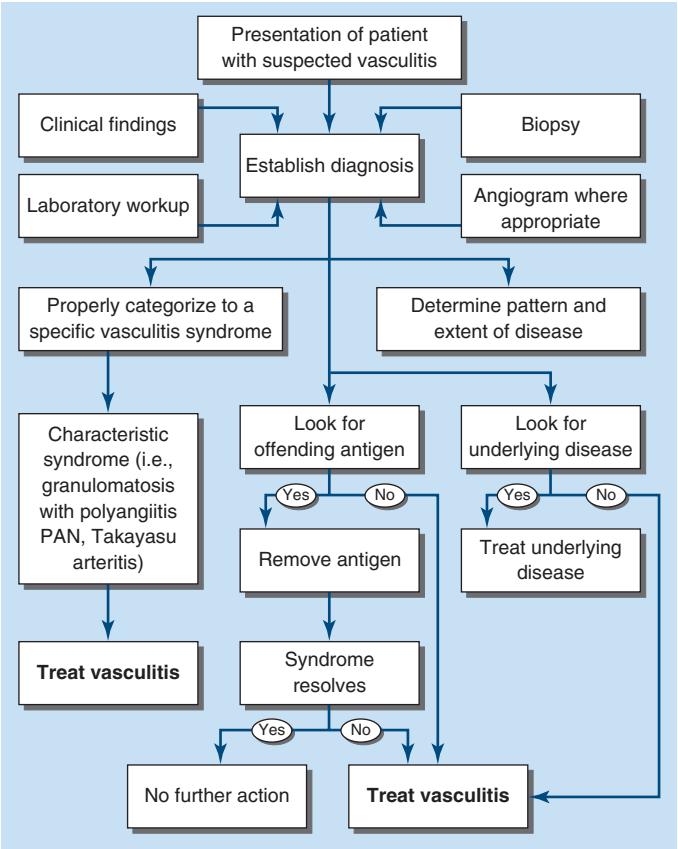

FIGURE 375-1 Algorithm for the approach to a patient with suspected diagnosis of vasculitis. PAN, polyarteritis nodosa.

When syndromes such as polyarteritis nodosa, Takayasu arteritis, or primary central nervous system (CNS) vasculitis are suspected, arteriogram of organs with suspected involvement should be performed.

GENERAL PRINCIPLES OF TREATMENT

Once a diagnosis of vasculitis has been established, a decision regarding therapeutic strategy must be made (Fig. 375-1). If an offending antigen that precipitates the vasculitis is recognized, the antigen should be removed where possible. If the vasculitis is associated with an underlying disease such as an infection, neoplasm, or connective tissue disease, the underlying disease should be treated. If the syndrome represents a primary vasculitic disease, treatment should be initiated according to the category of the vasculitis syndrome. Specific therapeutic regimens are discussed below for the individual vasculitis syndromes; however, certain general principles regarding therapy should be considered. Decisions regarding treatment should be based on the use of regimens for which there has been published literature supporting efficacy for that particular vasculitic disease. Since the potential toxic side effects of certain therapeutic regimens may be substantial, the risk-versus-benefit ratio of any therapeutic approach should be weighed carefully. Glucocorticoids and/or other immunosuppressive agents should be instituted immediately in diseases where irreversible organ system dysfunction and high morbidity and mortality rates have been clearly established. Granulomatosis with polyangiitis is the prototype of a severe systemic vasculitis requiring such a therapeutic approach (see below). Conversely, aggressive therapy should be avoided for vasculitic manifestations that rarely result in irreversible organ system dysfunction such as isolated idiopathic cutaneous vasculitis. Glucocorticoids should be initiated in those systemic vasculitides that cannot be specifically categorized or for which there is no established standard therapy, with other immunosuppressive agents being added if an adequate response does not result or if remission can only be achieved and maintained with an unacceptably toxic regimen of glucocorticoids. Following improvement, one should continually attempt to taper glucocorticoids and discontinue when possible. When using other immunosuppressive regimens, one should base the choice of agent upon the available therapeutic data supporting efficacy in that disease, the site and severity of organ involvement, and the toxicity profile of the drug.

Most forms of vasculitis carry the potential for relapse such that treatment planning needs to include assessment of relapse risk for that vasculitis and the medication regimen being used.

Physicians should be thoroughly aware of the acute and long-term side effects associated with the agents that are commonly used to treat different forms of vasculitis **(Table 375-4)**.

Morbidity and mortality can occur as a result of treatment, and strategies to monitor for and prevent toxicity represent an essential part of patient care.

Addressing the risk of bone loss is important in all patients receiving glucocorticoids. Daily cyclophosphamide should be taken all at once in the morning with a large amount of fluid throughout the day to reduce the risk of bladder injury, and monitoring for bladder cancer should continue indefinitely.

Maintaining the white blood cell (WBC) count at >3000/μL and the neutrophil count at >1500/μL is essential to reduce the risk of life-threatening infections. Monitoring of the complete blood count every 1–2 weeks for as long as the patient receives cyclophosphamide can effectively prevent cytopenias. Methotrexate, azathioprine, and mycophenolate mofetil are also associated with bone marrow suppression, and complete blood counts should be obtained every 1–2 weeks for the first 1–2 months after their initiation and once a month thereafter. To lessen toxicity, methotrexate is often given together with folic acid, 1 mg daily, or folinic acid, 5–10 mg once a week 24 h following methotrexate. Methotrexate is eliminated by the kidney and contraindicated in renal insufficiency as this increases the risk for toxicity. Prior to initiation of azathioprine, thiopurine methyltransferase (TPMT), an enzyme involved in the metabolism of azathioprine, should be assayed because inadequate levels may result in severe cytopenia.

Rituximab can be associated with infusion reactions. In addition to administering this within a skilled infusion center, these reactions can be lessened by the use of premedications. There is a risk of hepatitis B reactivation with rituximab such that all patients should be screened for this infection prior to its use. Immunoglobulins should be monitored with rituximab use.

Tocilizumab and sarilumab are associated with cytopenias, hepatotoxicity, and hyperlipidemia. Laboratory monitoring for drug toxicity should be performed 4–8 weeks after start of therapy and every 3 months thereafter.

Infection represents a significant toxicity for all vasculitis patients treated with immunosuppressive therapy. Infections with *Pneumocystis jirovecii* and certain fungi can be seen even when the WBC count is within normal limits, particularly in patients receiving glucocorticoids. Use of prophylactic therapy to prevent *P. jirovecii* infection should be based on the treatment regimen being used. Patients with granulomatosis with polyangiitis or microscopic polyangiitis who are receiving induction treatment with glucocorticoids in combination with another immunosuppressive agent should receive trimethoprim-sulfamethoxazole (TMP-SMX) or a different preventive medication. Continuation of *Pneumocystis* prophylaxis during maintenance therapy should be strongly considered in most patients, particularly for those receiving rituximab or who have persistent lymphopenia.

In recent years, national and regional organizations have published treatment guidelines that can provide additional direction to clinicians. It should be emphasized that each patient is unique and requires individual decision-making. Information from guidelines as well as this chapter should serve as a framework for the application of evidence-based approaches with incorporation of patient-specific goals to provide maximal therapeutic efficacy with minimal toxic side effects.

TABLE 375-4 Major Toxic Side Effects of Drugs Used in the Treatment of Vasculitis[a]

CONVENTIONAL IMMUNOSUPPRESSIVE AGENTS	
Glucocorticoids	
Osteoporosis	Growth suppression in children
Cataracts	Hypertension
Glaucoma	Avascular necrosis of bone
Diabetes mellitus	Myopathy
Electrolyte abnormalities	Alterations in mood
Metabolic abnormalities	Psychosis
Severe and opportunistic infections	Pseudotumor cerebri
Cushingoid features	Peptic ulcer diathesis
	Pancreatitis
Cyclophosphamide	
Bone marrow suppression	Hypogammaglobulinemia
Cystitis	Pulmonary fibrosis
Bladder carcinoma	Myelodysplasia
Gonadal suppression	Oncogenesis
Gastrointestinal intolerance	Teratogenicity
	Severe and opportunistic infections
Methotrexate	
Gastrointestinal intolerance	Pneumonitis
Stomatitis	Teratogenicity
Bone marrow suppression	Severe and opportunistic infections
Hepatotoxicity (may lead to fibrosis or cirrhosis)	
Azathioprine	
Gastrointestinal intolerance	Severe and opportunistic infections
Bone marrow suppression	Hypersensitivity
Hepatotoxicity	
Mycophenolate mofetil	
Bone marrow suppression	Severe and opportunistic infections
Gastrointestinal intolerance	Teratogenicity
BIOLOGIC AGENTS AND SMALL-MOLECULE INHIBITORS	
Rituximab (granulomatosis with polyangiitis and microscopic polyangiitis)	
Infusion reactions	Severe and opportunistic infections
Progressive multifocal leukoencephalopathy	Hepatitis B reactivation
Mucocutaneous reactions	Tumor lysis syndrome
Hypogammaglobulinemia	Late-onset neutropenia
Impaired vaccine response	
Tocilizumab (giant cell arteritis)	
Sarilumab (polymyalgia rheumatica)	
Bone marrow suppression	Severe and opportunistic infections
Hepatotoxicity	Gastrointestinal perforation
Hyperlipidemia	Hypersensitivity reactions
Mepolizumab (eosinophilic granulomatosis with polyangiitis [Churg-Strauss])	
Hypersensitivity reactions	Opportunistic infections: herpes zoster
Apremilast (Behçet's syndrome; see Chap. 376)	
Diarrhea, nausea, and vomiting	Weight decrease
Depression	
Avacopan (severe granulomatosis with polyangiitis and microscopic polyangiitis)	
Hepatotoxicity	Hepatitis B reactivation
Hypersensitivity reactions	Serious infections

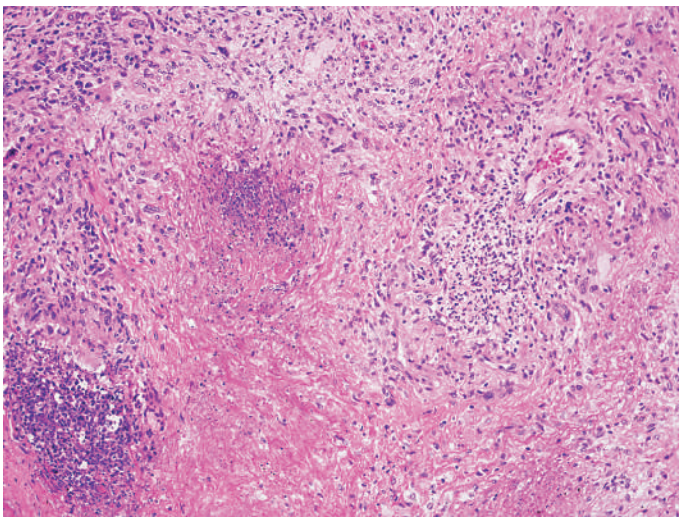

FIGURE 375-2 Lung histology in granulomatosis with polyangiitis. This area of geographic necrosis has a serpiginous border of histiocytes and giant cells surrounding a central necrotic zone. Vasculitis is also present with neutrophils and lymphocytes infiltrating the wall of a small arteriole (*upper right*). *(Courtesy of William D. Travis, MD; with permission.)*

GRANULOMATOSIS WITH POLYANGIITIS

DEFINITION

Granulomatosis with polyangiitis is a distinct clinicopathologic entity characterized by granulomatous vasculitis of the upper and lower respiratory tracts together with glomerulonephritis. In addition, variable degrees of disseminated vasculitis involving both small arteries and veins may occur.

INCIDENCE AND PREVALENCE

Granulomatosis with polyangiitis has an estimated prevalence of 3 per 100,000. It is extremely rare in blacks compared with whites; the male-to-female ratio is 1:1. The disease can be seen at any age; ~15% of patients are <19 years of age, but only rarely does the disease occur before adolescence; the mean age of onset is 40–60 years.

PATHOLOGY AND PATHOGENESIS

The histopathologic hallmarks of granulomatosis with polyangiitis are necrotizing vasculitis of small arteries and veins together with granuloma formation, which may be either intravascular or extravascular (Fig. 375-2). Lung involvement typically appears as multiple, bilateral, nodular or cavitary infiltrates (Fig. 375-3), which on biopsy can reveal necrotizing granulomatous vasculitis. Upper airway lesions, particularly those in the sinuses and nasopharynx, typically reveal inflammation, necrosis, and granuloma formation, with or without vasculitis.

In its earliest form, renal involvement is characterized by a focal and segmental glomerulitis that may evolve into a rapidly progressive crescentic glomerulonephritis. Granuloma formation is only rarely seen on

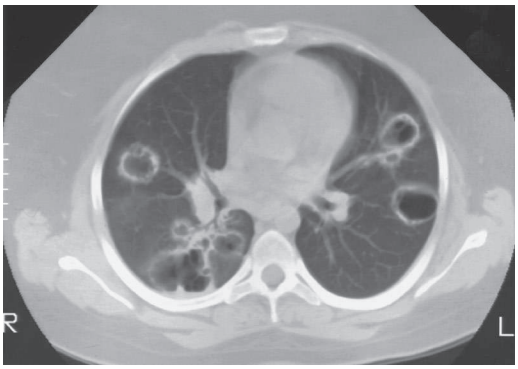

FIGURE 375-3 Computed tomography scan of a patient with granulomatosis with polyangiitis. The patient developed multiple, bilateral, and cavitary infiltrates.

renal biopsy. In contrast to other forms of glomerulonephritis, immune complex deposition is not found in the renal lesion of granulomatosis with polyangiitis (pauci-immune glomerulonephritis). In addition to the classic triad of disease of the upper and lower respiratory tracts and kidney, virtually any organ can be involved with vasculitis, granuloma, or both.

The immunopathogenesis of this disease is unclear, although the involvement of upper airways and lungs with granulomatous vasculitis suggests an aberrant cell-mediated immune response to an exogenous or even endogenous antigen that enters through or resides in the upper airway. Chronic nasal carriage of *Staphylococcus aureus* has been reported to be associated with a higher relapse rate of granulomatosis with polyangiitis; however, there is no evidence for a role of this organism in the pathogenesis of the disease.

Peripheral blood mononuclear cells obtained from patients with granulomatosis with polyangiitis manifest increased secretion of IFN-γ but not of IL-4, IL-5, or IL-10 compared to healthy controls. In addition, TNF-α production from peripheral blood mononuclear cells and CD4+ T cells is elevated and monocytes from patients with granulomatosis with polyangiitis produce increased amounts of IL-12. These findings indicate an unbalanced T_H1-type T-cell cytokine pattern in this disease that may have pathogenic and perhaps therapeutic implications.

A high percentage of patients with granulomatosis with polyangiitis develop ANCA, and these autoantibodies may play a role in the pathogenesis of this disease (see above).

CLINICAL AND LABORATORY MANIFESTATIONS

Involvement of the upper airways occurs in 95% of patients with granulomatosis with polyangiitis. Patients often present with severe upper respiratory tract findings such as paranasal sinus pain and drainage and purulent or bloody nasal discharge, with or without nasal mucosal ulceration **(Table 375-5)**. Nasal septal perforation may follow, leading to saddle nose deformity. Serous otitis media may occur as a result of eustachian tube blockage. Subglottic stenosis resulting from active disease or scarring occurs in ~16% of patients and may result in severe airway obstruction.

Pulmonary involvement (85–90% of patients) may be clinically expressed as cough, hemoptysis, dyspnea, and chest discomfort, or active disease may be asymptomatic in up to 30% of cases. Endobronchial disease, either in its active form or as a result of fibrous scarring, may lead to obstruction with atelectasis.

Eye involvement (52% of patients) may range from a mild conjunctivitis to dacryocystitis, episcleritis, scleritis, granulomatous sclerouveitis, ciliary vessel vasculitis, and retroorbital mass lesions leading to proptosis.

Skin lesions (46% of patients) appear as papules, vesicles, palpable purpura, ulcers, or subcutaneous nodules; biopsy reveals vasculitis, granuloma, or both. Cardiac involvement (8% of patients) manifests as pericarditis, coronary vasculitis, or, rarely, cardiomyopathy. Nervous system manifestations (23% of patients) include cranial neuritis, mononeuritis multiplex, or, rarely, cerebral vasculitis and/or granuloma.

Renal disease (77% of patients) generally dominates the clinical picture and, if left untreated, accounts directly or indirectly for most of the mortality in this disease. Although it may smolder in some cases as a mild glomerulitis with proteinuria, hematuria, and red blood cell casts, once clinically detectable renal functional impairment occurs, rapidly progressive renal failure usually ensues unless appropriate treatment is instituted.

While the disease is active, most patients have nonspecific symptoms and signs such as malaise, weakness, arthralgias, anorexia, and weight loss. Fever may indicate activity of the underlying disease but more often reflects secondary infection, usually of the upper airway.

Characteristic laboratory findings include an elevated erythrocyte sedimentation rate (ESR) and/or C-reactive protein (CRP), anemia and leukocytosis, and mild hypergammaglobulinemia. Thrombocytosis may be seen as an acute-phase reactant. Approximately 90% of patients with active granulomatosis with polyangiitis have a positive antiproteinase-3 ANCA. However, in the absence of active disease, the sensitivity drops to ~60–70%. A small percentage of patients with granulomatosis with polyangiitis may have antimyeloperoxidase rather than antiproteinase-3 antibodies, and up to 20% may lack ANCA.

Patients with granulomatosis with polyangiitis have been found to have an increased incidence of venous thrombotic events. Although routine anticoagulation for all patients is not recommended, a heightened awareness for any clinical features suggestive of deep-vein thrombosis or pulmonary emboli is warranted.

TABLE 375-5 Granulomatosis with Polyangiitis: Frequency of Clinical Manifestations in 158 Patients Studied at the National Institutes of Health

MANIFESTATION	PERCENTAGE AT DISEASE ONSET	PERCENTAGE THROUGHOUT COURSE OF DISEASE
Kidney		
Glomerulonephritis	18	77
Ear/Nose/Throat	**73**	**92**
Sinusitis	51	85
Nasal disease	36	68
Otitis media	25	44
Hearing loss	14	42
Subglottic stenosis	1	16
Ear pain	9	14
Oral lesions	3	10
Lung	**45**	**85**
Pulmonary infiltrates	25	66
Pulmonary nodules	24	58
Hemoptysis	12	30
Pleuritis	10	28
Eyes		
Conjunctivitis	5	18
Dacryocystitis	1	18
Scleritis	6	16
Proptosis	2	15
Eye pain	3	11
Visual loss	0	8
Retinal lesions	0	4
Corneal lesions	0	1
Iritis	0	2

DIAGNOSIS

The diagnosis of granulomatosis with polyangiitis can be established by the demonstration of necrotizing granulomatous vasculitis on tissue biopsy in a patient with compatible clinical features. Pulmonary tissue offers the highest diagnostic yield, almost invariably revealing granulomatous vasculitis. Biopsy of upper airway tissue usually reveals acute and chronic inflammation but can show granulomas and/or vasculitis. Renal biopsy can confirm a pauci-immune glomerulonephritis

(Chaps. A4 and A14), which differentiates this from other causes of glomerular disease (Chap. 326).

The utility of ANCA in diagnosis varies based on the clinical presentation. The predictive value of a positive ANCA is 90% in patients with active glomerulonephritis. However, in patients who present with sinus and/or lung disease where renal disease is absent, this decreases to 30–60%. Tissue biopsy is typically necessary in these settings to rule out infection or malignancy, which can have a similar presentation and be associated with a false-positive ANCA. Biopsy should also be pursued when clinically inconsistent features are present or when ANCA is absent.

In its typical presentation, the clinicopathologic complex of granulomatosis with polyangiitis usually provides ready differentiation from other disorders. However, if all the typical features are not present at once, it needs to be differentiated from the other vasculitides, antiglomerular basement membrane disease (Goodpasture's syndrome) (Chap. 326), relapsing polychondritis (Chap. 378), tumors of the upper airway or lung, and infectious diseases such as histoplasmosis (Chap. 218), endocarditis (Chap. 133), mucocutaneous leishmaniasis (Chap. 233), and rhinoscleroma (Chap. 166) as well as noninfectious granulomatous diseases.

Of particular note is the differentiation from other *midline destructive diseases*. These diseases lead to extreme tissue destruction and mutilation localized to the midline upper airway structures including the sinuses; erosion through the skin of the face commonly occurs, a feature that is extremely rare in granulomatosis with polyangiitis. Although blood vessels may be involved in the intense inflammatory reaction and necrosis, primary vasculitis is not seen. *Upper airway neoplasms* and specifically *extranodal natural killer (NK)/T-cell lymphoma (nasal type)* are important causes of midline destructive disease. These lesions are diagnosed based on histology, which reveals polymorphous atypical lymphoid cells with an NK cell immunophenotype, typically Epstein-Barr virus (Chap. 199). Such cases are treated based on their degree of dissemination, and localized lesions have responded to irradiation. Upper airway lesions should never be irradiated in granulomatosis with polyangiitis. Cocaine-induced tissue injury can be another important mimic of granulomatosis with polyangiitis in patients who present with isolated midline destructive disease. ANCA that target human neutrophil elastase can be found in patients with cocaine-induced midline destructive lesions and can complicate the differentiation from granulomatosis with polyangiitis. This has been further confounded by the high frequency of levamisole adulteration of cocaine, which can result in cutaneous infarction and serologic changes that may mimic vasculitis. Granulocytopenia is a common finding in levamisole-induced disease that is not associated with granulomatosis with polyangiitis.

Granulomatosis with polyangiitis must also be differentiated from *lymphomatoid granulomatosis*, which is an Epstein-Barr virus–positive B-cell proliferation that is associated with an exuberant T-cell reaction. Lymphomatoid granulomatosis is characterized by lung, skin, CNS, and kidney involvement in which atypical lymphocytoid and plasmacytoid cells infiltrate nonlymphoid tissue in an angioinvasive manner. In this regard, it clearly differs from granulomatosis with polyangiitis in that it is not an inflammatory vasculitis in the classic sense but an angiocentric perivascular infiltration of atypical mononuclear cells. Up to 50% of patients may develop a true malignant lymphoma.

TREATMENT

Granulomatosis with Polyangiitis

Prior to the introduction of effective therapy, granulomatosis with polyangiitis was universally fatal within a few months of diagnosis. Glucocorticoids alone led to some symptomatic improvement, with little effect on the ultimate course of the disease. The development of treatment with cyclophosphamide dramatically changed patient outcome such that marked improvement was seen in >90% of patients, complete remission was seen in 75% of patients, and 5-year patient survival was seen in >80%.

Despite the ability to successfully induce remission, 50–70% of remissions are later associated with one or more relapses. The determination of relapse should be based on objective evidence of disease activity, taking care to rule out other features that may have a similar appearance such as infection, medication toxicity, or chronic disease sequelae. Many patients who achieve remission continue to have a positive ANCA for years, and changes in ANCA should not be used as a measure of disease activity. Results from a large prospective study found that only 43% of patients relapsed within 1 year of an increase in ANCA levels. Thus, a rise in ANCA by itself is not a harbinger of immediate disease relapse and should not lead to reinstitution or increase in immunosuppressive therapy. Reinduction of remission after relapse is almost always achieved; however, a high percentage of patients ultimately have some degree of damage from irreversible features of their disease, such as varying degrees of renal insufficiency, neurologic impairment, hearing loss, subglottic stenosis, saddle nose deformity, and chronic sinus dysfunction. Patients who developed irreversible renal failure but who achieved subsequent remission have undergone successful renal transplantation.

Treatment of granulomatosis with polyangiitis is viewed as having two phases: *induction*, where active disease is put into remission, followed by *maintenance*. Decisions regarding induction and maintenance agents are guided by published data, individual patient factors that include contraindications, relapse history, and comorbidities, and stratification based on disease severity. Severe disease is associated with life- or organ-threatening manifestations and is based not only on the degree of involvement but also the organ affected. Pulmonary involvement can be nonsevere when presenting as nodular disease without respiratory compromise or severe in the setting of alveolar hemorrhage. In contrast, active glomerulonephritis is always considered to be severe disease even when renal function remains normal.

REMISSION INDUCTION OF SEVERE DISEASE

Regimens to induce remission of severe active disease consist of either cyclophosphamide or rituximab given in combination with glucocorticoids and consideration of adjunctive avacopan. Glucocorticoids were historically given as prednisone 1 mg/kg per day for the first month, followed by tapering. In a randomized trial, use of a reduced-dose glucocorticoid regimen was noninferior to a standard-dose regimen and was associated with a lower rate of serious infection.

Avacopan (a C5a receptor inhibitor) was investigated in a randomized trial as an alternative to glucocorticoids in patients receiving induction with either cyclophosphamide or rituximab. At 52 weeks, sustained remission was higher in those who received avacopan as compared to prednisone with a similar rate of serious adverse events. Although glucocorticoids were given within the first few weeks to most patients receiving avacopan, glucocorticoid exposure in the avacopan group remained markedly less than those randomized to the prednisone treatment arm. This supported that glucocorticoids can be rapidly withdrawn in patients with severe active disease receiving avacopan together with either rituximab or cyclophosphamide.

In patients presenting with disease that is life-threatening, methylprednisolone 1000 mg daily for 3 days has been used. Adjunctive plasma exchange was found to provide no added benefit in reducing the composite outcome of end-stage renal disease or death in a large, randomized trial. Whether it may still play a role in selected patients with the most fulminant disease remains controversial. Although a low number of patients in this trial were enrolled with alveolar hemorrhage requiring mechanical ventilation, a retrospective study also showed no benefit. From a meta-analysis, patients with active glomerulonephritis and serum creatinine >5.7 mg/dL who received plasma exchange had improvement in renal function but an increased risk of serious infection. Plasma exchange should be used in patients with granulomatosis with polyangiitis or microscopic polyangiitis who are also positive for antiglomerular basement membrane autoantibody (Chap. 326). When plasma

exchange is used concurrently with rituximab, these treatments must be separated by at least 48 h to avoid removal of rituximab.

CYCLOPHOSPHAMIDE INDUCTION FOR SEVERE DISEASE

Daily cyclophosphamide combined with glucocorticoids was the first regimen proven to effectively induce remission and prolong survival. Cyclophosphamide is given in doses of 2 mg/kg per day orally, but because it is renally eliminated, dosage reduction should be considered in patients with renal insufficiency. Although we continue to favor the use of daily cyclophosphamide, a randomized trial found IV cyclophosphamide 15 mg/kg, three infusions given every 2 weeks, then every 3 weeks thereafter, to have a similar rate of remission but higher frequency of relapse compared to cyclophosphamide 2 mg/kg daily given for 3 months followed by 1.5 mg/kg daily. Although leukopenia occurred more often with daily cyclophosphamide, this was likely related to a reduced frequency of blood count monitoring after the first month.

RITUXIMAB INDUCTION FOR SEVERE DISEASE

Rituximab (anti-CD20) has been of proven effectiveness for the treatment of granulomatosis with polyangiitis and microscopic polyangiitis. In two randomized trials that enrolled patients with severe active granulomatosis with polyangiitis or microscopic polyangiitis, rituximab 375 mg/m^2 once a week for 4 weeks in combination with glucocorticoids was found to be as effective as cyclophosphamide with glucocorticoids for inducing disease remission. In the trial that also enrolled patients with relapsing disease, rituximab was found to be statistically superior to cyclophosphamide. Although rituximab does not have the bladder toxicity or infertility risks of cyclophosphamide, in both randomized trials, the rate of adverse events was similar in the rituximab and cyclophosphamide arms.

The decision about whether to utilize cyclophosphamide or rituximab for remission induction must be individually based. Factors to consider include disease severity, whether the patient has newly diagnosed or relapsing disease, medication contraindications, and individual patient factors particularly fertility concerns and risk factors for toxicity. In patients with rapidly progressive glomerulonephritis with a creatinine >4.0 mg/dL or pulmonary hemorrhage requiring mechanical ventilation, daily cyclophosphamide and glucocorticoids may be favored.

There has been no evidence to date that using cyclophosphamide and rituximab together for induction is more efficacious, and combined use raises concern for additive toxicity, particularly infection. However, in instances of toxicity or rare occurrences of inefficacy, there may be a need to switch from cyclophosphamide to rituximab or vice versa.

REMISSION MAINTENANCE OF SEVERE DISEASE

When cyclophosphamide is given for induction, it should be stopped after 3–6 months and switched to another agent for remission maintenance. Medications used in this setting with which there has been published experience from randomized trials are rituximab, azathioprine, methotrexate, and mycophenolate mofetil. A lower rate of relapse was seen with rituximab given at 500 mg for two doses followed by 500 mg every 6 months when compared to azathioprine 2 mg/kg per day. In a randomized trial comparing methotrexate to azathioprine for remission maintenance, similar rates of toxicity and relapse were seen. Methotrexate is administered orally or subcutaneously at a starting dose of 15 mg/week, which is increased by 2.5 mg every 2 weeks up to a dosage of 20–25 mg/week. In patients who are unable to receive methotrexate or azathioprine or who have experienced relapse on such treatment, mycophenolate mofetil 1000 mg twice a day may also sustain remission, but it is associated with a higher rate of relapse compared to azathioprine.

For patients who receive rituximab for remission induction, a randomized trial found that rituximab had a lower rate of relapse compared to azathioprine. Although rituximab maintenance doses have not been directly compared, use of 1000 mg every 4 months in this trial was not found to be associated with a longer length of sustained remission after discontinuation.

The optimal duration of maintenance therapy is uncertain. With regard to glucocorticoids, it has been unclear whether maintaining patients on prednisone 5 mg/d has greater risks or benefits. Maintenance therapy with azathioprine, methotrexate, or mycophenolate mofetil is usually given for a minimum of 2 years. Because there is evidence that the risk of relapse is higher once maintenance medication has been stopped, the decision is individualized regarding whether to continue treatment or taper these agents over a 6- to 12-month period until discontinuation. Patients with significant organ damage or a history of relapse may benefit from longer-term maintenance therapy. Although rituximab has been found to have a lower relapse rate, studies have similarly shown that relapses occur once treatment is discontinued. Longer term use of rituximab can be associated with hypogammaglobulinemia such that the decision for how long to continue this agent beyond 2 years must be weighed in each patient.

REMISSION INDUCTION AND MAINTENANCE OF NONSEVERE DISEASE

For patients whose disease is not immediately organ- or life-threatening, methotrexate or mycophenolate mofetil together with glucocorticoids, often initiated at a lower dose, may be given to induce and then maintain remission. Rituximab can also be used in this setting weighing the risks and benefits. Treatment with cyclophosphamide is rarely, if ever, justified for the treatment of nonsevere granulomatosis with polyangiitis. There have been no published studies to date with the use of avacopan in nonsevere disease.

OTHER BIOLOGIC AGENTS

Etanercept (TNF inhibitor) was not found to sustain remission when used adjunctively to standard therapy and should not be used in granulomatosis with polyangiitis. Belimumab (anti-B lymphocyte stimulator) was examined as an adjunctive therapy to azathioprine for remission maintenance but showed no added benefit in reducing the risk of relapse. Abatacept (CTLA4-Ig) was examined in a randomized trial in patients with nonsevere relapsing disease where it did not reduce the risk of relapse, disease worsening, or failure to achieve remission.

ORGAN-SPECIFIC TREATMENT

Not all manifestations of granulomatosis with polyangiitis require or respond to immunosuppressive therapy, and differentiation of active disease from damage is necessary. As sinus disease can disrupt the mucociliary barrier, patients should be instructed on the use of local care with moisturization and humidification. Although certain reports have indicated that TMP-SMX may be of benefit in the treatment of granulomatosis with polyangiitis isolated to the sinonasal tissues, it should never be used alone to treat active granulomatosis with polyangiitis involving other organs. Subglottic stenosis can often scar and responds optimally to nonmedical intervention with dilation and glucocorticoid injection.

MICROSCOPIC POLYANGIITIS

DEFINITION

The term *microscopic polyarteritis* was introduced into the literature by Davson in 1948 in recognition of the presence of glomerulonephritis in patients with polyarteritis nodosa. In 1992, the Chapel Hill Consensus Conference on the Nomenclature of Systemic Vasculitis adopted the term *microscopic polyangiitis* to connote a necrotizing vasculitis with few or no immune complexes affecting small vessels (capillaries, venules, or arterioles). Glomerulonephritis is very common in microscopic polyangiitis, and pulmonary capillaritis often occurs. The absence of granulomatous inflammation in microscopic polyangiitis is said to differentiate it from granulomatosis with polyangiitis.

INCIDENCE AND PREVALENCE

The incidence of microscopic polyangiitis is estimated to be 3–5/100,000. The mean age of onset is ~57 years, and males are slightly more frequently affected than females.

PATHOLOGY AND PATHOGENESIS

Microscopic polyangiitis has a predilection to involve capillaries and venules in addition to small- and medium-sized arteries. Immunohistochemical staining reveals a paucity of immunoglobulin deposition in the vascular lesion of microscopic polyangiitis, suggesting that immune-complex formation does not play a role in the pathogenesis of this syndrome. The renal lesion seen in microscopic polyangiitis is histologically identical to that of granulomatosis with polyangiitis. Like granulomatosis with polyangiitis, microscopic polyangiitis is highly associated with ANCA, which may play a role in pathogenesis of this syndrome (see above).

CLINICAL AND LABORATORY MANIFESTATIONS

Because of its predilection to involve the small vessels, microscopic polyangiitis and granulomatosis with polyangiitis share similar clinical features. Disease onset may be gradual, with initial symptoms of fever, weight loss, and musculoskeletal pain; however, it is often acute. Glomerulonephritis occurs in at least 79% of patients and can be rapidly progressive, leading to renal failure. Hemoptysis may be the first symptom of alveolar hemorrhage, which occurs in 12% of patients. Other manifestations include mononeuritis multiplex and gastrointestinal tract and cutaneous vasculitis. Upper airway disease and pulmonary nodules are not typically found in microscopic polyangiitis and, if present, suggest granulomatosis with polyangiitis.

Features of inflammation may be seen, including an elevated ESR and/or CRP, anemia, leukocytosis, and thrombocytosis. ANCA are present in 75% of patients with microscopic polyangiitis, with antimyeloperoxidase antibodies being the predominant antigen association.

DIAGNOSIS

The diagnosis is based on histologic evidence of vasculitis or pauci-immune glomerulonephritis in a patient with compatible clinical features of multisystem disease. Although microscopic polyangiitis is strongly ANCA-associated, tissue biopsy should continue to be pursued in patients who do not have a clinically compatible picture.

TREATMENT

Microscopic Polyangiitis

The 5-year survival rate for patients with treated microscopic polyangiitis is 74%, with disease-related mortality occurring from alveolar hemorrhage or gastrointestinal, cardiac, or renal disease. Studies on treatment have come from trials that have included patients with granulomatosis with polyangiitis or microscopic polyangiitis. Currently, the treatment approach for microscopic polyangiitis is the same as is used for granulomatosis with polyangiitis (see "Granulomatosis with Polyangiitis" for a detailed description of this therapeutic regimen). Disease relapse has been observed in at least 34% of patients. Treatment for such relapses would be based on site and severity of disease.

EOSINOPHILIC GRANULOMATOSIS WITH POLYANGIITIS (CHURG-STRAUSS)

DEFINITION

Eosinophilic granulomatosis with polyangiitis was described in 1951 by Churg and Strauss and is characterized by asthma, peripheral and tissue eosinophilia, extravascular granuloma formation, and vasculitis of multiple organ systems.

INCIDENCE AND PREVALENCE

Eosinophilic granulomatosis with polyangiitis is an uncommon disease with an estimated annual incidence of 1–3 per million. The disease can occur at any age with the possible exception of infants. The mean age of onset is 48 years, with a female-to-male ratio of 1.2:1.

PATHOLOGY AND PATHOGENESIS

The necrotizing vasculitis of eosinophilic granulomatosis with polyangiitis involves small- and medium-sized muscular arteries, capillaries, veins, and venules. A characteristic histopathologic feature of eosinophilic granulomatosis with polyangiitis is granuloma that may be present in the tissues or even within the walls of the vessels themselves. These are usually associated with infiltration of the tissues with eosinophils. This process can occur in any organ in the body; lung involvement is predominant, with skin, cardiovascular system, kidney, peripheral nervous system, and gastrointestinal tract also commonly involved. Although the precise pathogenesis of this disease is uncertain, its strong association with asthma and its clinicopathologic manifestations, including eosinophilia, granuloma, and vasculitis, point to aberrant immunologic phenomena.

CLINICAL AND LABORATORY MANIFESTATIONS

Patients with eosinophilic granulomatosis with polyangiitis often exhibit nonspecific manifestations such as fever, malaise, anorexia, and weight loss, which are characteristic of a multisystem disease. The pulmonary findings in eosinophilic granulomatosis with polyangiitis dominate the clinical picture with asthmatic attacks and the presence of pulmonary infiltrates. Mononeuritis multiplex is the second most common manifestation and occurs in up to 72% of patients. Allergic rhinitis and sinusitis develop in up to 61% of patients and are often observed early in the course of disease. Clinically recognizable heart disease with myocarditis, pericarditis, endocarditis, or coronary vasculitis occurs in ~14% of patients and is an important cause of mortality. Skin lesions occur in ~51% of patients and include purpura in addition to cutaneous and subcutaneous nodules. Renal disease in eosinophilic granulomatosis with polyangiitis is less common than that of granulomatosis with polyangiitis and microscopic polyangiitis.

The characteristic laboratory finding in virtually all patients with eosinophilic granulomatosis with polyangiitis is a striking eosinophilia, which reaches levels >1000 cells/μL in >80% of patients. Evidence of inflammation as evidenced by elevated ESR and/or CRP, fibrinogen, or α_2-globulins can be found in 81% of patients. The other laboratory findings reflect the organ systems involved. Approximately 48% of patients with eosinophilic granulomatosis with polyangiitis have circulating ANCA that is usually antimyeloperoxidase.

DIAGNOSIS

Although the diagnosis of eosinophilic granulomatosis with polyangiitis is optimally made by biopsy in a patient with the characteristic clinical manifestations (see above), histologic confirmation can be challenging because the pathognomonic features often do not occur simultaneously. In order to be diagnosed with eosinophilic granulomatosis with polyangiitis, a patient should have evidence of asthma, peripheral blood eosinophilia, and clinical features consistent with vasculitis.

TREATMENT

Eosinophilic Granulomatosis with Polyangiitis

The prognosis of untreated eosinophilic granulomatosis with polyangiitis is poor, with a reported 5-year survival of 25%. With treatment, prognosis is favorable, with one study finding a 78-month actuarial survival rate of 72%. Myocardial involvement is the most frequent cause of death and is responsible for 39% of patient mortality. Echocardiography should be performed in all newly diagnosed patients because this may influence therapeutic decisions.

Glucocorticoids alone appear to be effective in many patients. Dosage tapering is often limited by asthma, with asthma often persisting after clinical recovery from vasculitis. In patients who present with fulminant multisystem disease, particularly cardiac involvement, the treatment of choice is daily cyclophosphamide and prednisone followed by azathioprine or methotrexate (see "Granulomatosis with Polyangiitis" for a detailed description of this therapeutic regimen). Use of rituximab and prednisone can be considered, particularly in ANCA-positive patients who have glomerulonephritis or other features of severe small-vessel vasculitis.

Mepolizumab (anti-IL-5 antibody) 300 mg given subcutaneously once a month was studied in a randomized trial and found

to be more effective than placebo, with a higher number of weeks in remission (28% vs 3%) and a higher proportion of patients in remission (32% vs 3%). Patients with life-threatening eosinophilic granulomatosis with polyangiitis were excluded from this trial, and mepolizumab should not be used for the treatment of severe disease. Mepolizumab may have a particularly beneficial role in the setting of relapsing or resistant asthma requiring glucocorticoids, sinus disease, mild to moderate eosinophilic disease features, or mild vasculitis. In a recent study, benralizumab, which also inhibits IL-5, demonstrated noninferior rates of remission compared to mepolizumab in patients with relapsing or refractory, non-life-threatening eosinophilic granulomatosis with polyangiitis.

POLYARTERITIS NODOSA

DEFINITION

Polyarteritis nodosa was described in 1866 by Kussmaul and Maier. It is a multisystem, necrotizing vasculitis of small- and medium-sized muscular arteries characteristically involving the renal and visceral arteries. Polyarteritis nodosa does not involve pulmonary arteries, although bronchial vessels may be involved; glomerulonephritis, granuloma, and significant eosinophilia are not seen.

INCIDENCE AND PREVALENCE

It is difficult to establish an accurate incidence of polyarteritis nodosa because previous reports have included microscopic polyangiitis as well as other related vasculitides. Polyarteritis nodosa, as currently defined, is felt to be a very uncommon disease.

PATHOLOGY AND PATHOGENESIS

The vascular lesion in polyarteritis nodosa is a necrotizing inflammation of small- and medium-sized muscular arteries. The lesions are segmental and tend to involve bifurcations and branchings of arteries. They may spread circumferentially to involve adjacent veins. However, involvement of venules is not seen in polyarteritis nodosa and, if present, suggests microscopic polyangiitis (see below). In the acute stages of disease, polymorphonuclear neutrophils infiltrate all layers of the vessel wall and perivascular areas, which results in intimal proliferation and degeneration of the vessel wall. Mononuclear cells infiltrate the area as the lesions progress to the subacute and chronic stages. Fibrinoid necrosis of the vessels ensues with compromise of the lumen, thrombosis, infarction of the tissues supplied by the involved vessel, and, in some cases, hemorrhage. As the lesions heal, there is collagen deposition, which may lead to further occlusion of the vessel lumen. Aneurysmal dilations up to 1 cm in size along the involved arteries are characteristic.

Multiple organ systems are involved, and the clinicopathologic findings reflect the degree and location of vessel involvement and the resulting ischemic changes. As mentioned above, pulmonary arteries are not involved, and bronchial artery involvement is uncommon. The pathology in the kidney is that of arteritis without glomerulonephritis. In patients with significant hypertension, typical pathologic features of glomerulosclerosis may be seen. In addition, pathologic sequelae of hypertension may be found elsewhere in the body.

The presence of a polyarteritis nodosa–like vasculitis in patients with hepatitis B together with the isolation of circulating immune complexes composed of hepatitis B antigen and immunoglobulin and the demonstration by immunofluorescence of hepatitis B antigen, IgM, and complement in the blood vessel walls strongly suggest the role of immunologic phenomena in the pathogenesis of this disease. A polyarteritis nodosa–like vasculitis has also been reported in patients with hepatitis C. Hairy cell leukemia can be associated with polyarteritis nodosa; the pathogenic mechanisms of this association are unclear.

A polyarteritis nodosa–like vasculitis has been described in conjunction with deficiency of adenosine deaminase type 2 (DADA2). Patients with DADA2 usually present in childhood with a variable pattern of clinical features and vascular pathology that is responsive to TNF inhibitors. As this differs from the usual treatment for polyarteritis nodosa, DADA2 should be considered in patients with suggestive clinical features, particularly those with early-onset disease.

TABLE 375-6 Clinical Manifestations Related to Organ System Involvement in Polyarteritis Nodosa

ORGAN SYSTEM	PERCENT INCIDENCE	CLINICAL MANIFESTATIONS
Renal	60	Renal failure, hypertension
Musculoskeletal	64	Arthritis, arthralgia, myalgia
Peripheral nervous system	51	Peripheral neuropathy, mononeuritis multiplex
Gastrointestinal tract	44	Abdominal pain, nausea and vomiting, bleeding, bowel infarction and perforation, cholecystitis, hepatic infarction, pancreatic infarction
Skin	43	Rash, purpura, nodules, cutaneous infarcts, livedo reticularis, Raynaud's phenomenon
Cardiac	36	Congestive heart failure, myocardial infarction, pericarditis
Genitourinary	25	Testicular, ovarian, or epididymal pain
Central nervous system	23	Cerebral vascular accident, altered mental status, seizure

CLINICAL AND LABORATORY MANIFESTATIONS

Nonspecific signs and symptoms are the hallmarks of polyarteritis nodosa. Fever, weight loss, and malaise are present in over one-half of cases. Patients usually present with vague symptoms such as weakness, malaise, headache, abdominal pain, and myalgias that can rapidly progress to a fulminant illness. Specific complaints related to the vascular involvement within a particular organ system may also dominate the presenting clinical picture as well as the entire course of the illness (Table 375-6). Renal involvement most commonly manifests as hypertension, renal insufficiency, or hemorrhage due to microaneurysms.

There are no diagnostic serologic tests for polyarteritis nodosa. In >75% of patients, the leukocyte count is elevated with a predominance of neutrophils. Eosinophilia is rare and, when present at high levels, suggests the diagnosis of eosinophilic granulomatosis with polyangiitis. The anemia of chronic disease may be seen, and an elevated ESR and/or CRP is almost always present. Other laboratory findings reflect the particular organ involved. Hypergammaglobulinemia may be present, and all patients should be screened for hepatitis B and C. ANCA are rarely found.

DIAGNOSIS

The diagnosis of polyarteritis nodosa is based on the demonstration of characteristic findings of vasculitis on biopsy material of involved organs. Biopsy of symptomatic organs such as nodular skin lesions, painful testes, and nerve/muscle provides the highest diagnostic yields. In the absence of easily accessible tissue for biopsy, the arteriographic demonstration of involved vessels, particularly in the form of aneurysms of small- and medium-sized arteries in the renal, hepatic, and visceral vasculature, is sufficient to make the diagnosis. This should consist of a catheter-directed dye arteriogram because magnetic resonance and computed tomography arteriograms do not have sufficient resolution at the current time to visualize the affected vessels. Aneurysms of vessels are not pathognomonic of polyarteritis nodosa; furthermore, aneurysms may not always be present, and arteriographic findings may be limited to stenotic segments and obliteration of vessels.

TREATMENT

Polyarteritis Nodosa

The prognosis of untreated polyarteritis nodosa is extremely poor, with a reported 5-year survival rate between 10 and 20%. Death usually results from gastrointestinal complications, particularly bowel infarcts and perforation, and cardiovascular causes. Intractable

hypertension often compounds dysfunction in other organ systems, such as the kidneys, heart, and CNS, leading to additional late morbidity and mortality. The combination of prednisone and cyclophosphamide has been found to significantly improve the survival rate (see "Granulomatosis with Polyangiitis" for a description of this therapeutic regimen). In less severe cases, glucocorticoids alone have resulted in disease remission. Treatment of hypertension can lessen vascular complications. Following remission, relapse has been estimated to occur in 10–20% of patients. In patients with hepatitis B or C who have a polyarteritis nodosa–like vasculitis, antiviral therapy is an essential part of management, with immunosuppression being given concurrently for severe vasculitis and then withdrawn once the vasculitis is controlled. Plasma exchange has been used in some series of hepatitis virus-associated polyarteritis nodosa.

GIANT CELL ARTERITIS AND POLYMYALGIA RHEUMATICA

DEFINITION

Giant cell arteritis, historically referred to as *temporal arteritis*, is an inflammation of medium- and large-sized arteries. It characteristically involves one or more branches of the carotid artery, particularly the temporal artery. However, it is a systemic disease that can involve arteries in multiple locations, particularly the aorta and its main branches.

Giant cell arteritis is closely associated with *polymyalgia rheumatica*, which is characterized by stiffness, aching, and pain in the muscles of the neck, shoulders, lower back, hips, and thighs. Most commonly, polymyalgia rheumatica occurs in isolation, but it may be seen in 40–50% of patients with giant cell arteritis. In addition, ~10–20% of patients who initially present with features of isolated polymyalgia rheumatica later go on to develop giant cell arteritis. A careful history and physical examination at initial and subsequent visits should be performed in patients with polymyalgia rheumatica to look for features suggestive of giant cell arteritis. This strong clinical association together with data from pathophysiologic studies has supported that giant cell arteritis and polymyalgia rheumatica represent differing clinical spectrums of a single disease process.

INCIDENCE AND PREVALENCE

Giant cell arteritis occurs almost exclusively in individuals aged >50 years. It is more common in women than in men and is rare in blacks. The incidence of giant cell arteritis varies widely in different studies and in different geographic regions. A high incidence has been found in Scandinavia and in regions of the United States with large Scandinavian populations, compared to a lower incidence in southern Europe. The annual incidence rates in individuals aged ≥50 years range from 6.9 to 32.8 per 100,000 population. Familial aggregation has been reported, as has an association with HLA-DR4. In addition, genetic linkage studies have demonstrated an association of giant cell arteritis with alleles at the HLA-DRB1 locus, particularly HLA-DRB1*04 variants. In Olmsted County, Minnesota, the annual incidence of polymyalgia rheumatica in individuals aged ≥50 years is 58.7 per 100,000 population.

PATHOLOGY AND PATHOGENESIS

Although the temporal artery is most frequently involved in giant cell arteritis, patients often have a systemic vasculitis of multiple medium- and large-sized arteries, which may go undetected. Histopathologically, the disease is a panarteritis with inflammatory mononuclear cell infiltrates within the vessel wall with frequent giant cell formation. There is proliferation of the intima and fragmentation of the internal elastic lamina. Pathophysiologic findings in organs result from the ischemia related to the involved vessels.

Experimental data support that giant cell arteritis is an antigen-driven disease in which activated T lymphocytes, macrophages, and dendritic cells play a critical role in pathogenesis. Sequence analysis of the T-cell receptor of tissue-infiltrating T cells in lesions of giant cell arteritis indicates restricted clonal expansion, suggesting the presence of an antigen residing in the arterial wall. Giant cell arteritis is believed to be initiated in the adventitia where CD4+ T cells enter through the vasa vasorum, become activated, and orchestrate macrophage differentiation. T cells recruited to vasculitic lesions in patients with giant cell arteritis produce predominantly IL-2 and IFN-γ, and the latter has been suggested to be involved in the progression to arteritis. Laboratory-based data demonstrate that at least two separate lineages of CD4 T cells—IFN-γ-producing T_H1 cells and IL-17-producing T_H17 cells—participate in vascular inflammation and may have differing levels of responsiveness to glucocorticoids.

CLINICAL AND LABORATORY MANIFESTATIONS

Giant cell arteritis is most commonly characterized clinically by the complex of fever, anemia, high ESR and/or CRP, and headaches in a patient aged >50 years. Four phenotypic manifestations can be seen including cranial arteritis, polymyalgia rheumatica, large-vessel disease, and features of systemic inflammation. These can occur together, in isolation, or at different times.

In patients with involvement of the cranial arteries, headache is the predominant symptom and may be associated with a tender, thickened, or nodular artery, which may pulsate early in the disease but may become occluded later. Scalp pain and claudication of the jaw and tongue may occur. A well-recognized and dreaded complication of giant cell arteritis, particularly in untreated patients, is ischemic optic neuropathy, which may lead to serious visual symptoms, including sudden blindness in some patients. However, most patients have complaints relating to the head or eyes before visual loss. Attention to such symptoms with institution of appropriate therapy (see below) lessens the risk of this complication. Other cranial ischemic complications include strokes and scalp or tongue infarction.

Up to one-third of patients can have large-vessel disease that can be the primary presentation of giant cell arteritis or can emerge at a later point in patients who have had previous cranial arteritis features or polymyalgia rheumatica. Manifestations of large-vessel disease can include subclavian artery stenosis that can present as arm claudication or aortic aneurysms involving the thoracic and to a lesser degree the abdominal aorta, which carry risks of rupture or dissection.

Clinical features of systemic inflammation can include malaise, fatigue, anorexia, weight loss, and sweats. Laboratory findings can also support an inflammatory process. An elevated ESR and/or CRP will be seen in most patients. Therapeutic blockade of IL-6 signaling prevents the hepatic production of CRP and other acute-phase proteins like ESR. These values will therefore normalize in patients who are treated with an IL-6 inhibitor, eliminating the ability to utilize CRP and ESR in monitoring disease activity or infection assessment in this setting. Other laboratory features include a normochromic or slightly hypochromic anemia. Liver function abnormalities are common, particularly increased alkaline phosphatase levels. Increased levels of IgG and complement have been reported.

DIAGNOSIS

The diagnosis of giant cell arteritis can often be suggested clinically by the demonstration of the complex of fever, anemia, and high ESR and/or CRP with or without symptoms of polymyalgia rheumatica in a patient >50 years old. The diagnosis can be confirmed by biopsy of the temporal artery but may not be positive in all patients due to patchy histologic findings. Since involvement of the vessel may be segmental, positive yield is increased by obtaining a biopsy segment of 3–5 cm together with serial sectioning of biopsy specimens. Ultrasonography of the temporal arteries alone or in combination with the axillary arteries demonstrating a noncompressible "halo" sign has been used in supporting the diagnosis. Therapy should not be delayed pending the performance of diagnostic studies. In this regard, it has been reported that temporal artery biopsies may show vasculitis even after ~14 days of glucocorticoid therapy. A dramatic clinical response to a trial of glucocorticoid therapy can further support the diagnosis.

Large-vessel disease may be suggested by symptoms and findings on physical examination such as diminished pulses or bruits. It is confirmed by vascular imaging, most commonly through magnetic

resonance or computed tomography. Positron emission tomography has become increasingly investigated, although its role in diagnosis and monitoring remains unclear.

Isolated polymyalgia rheumatica is a clinical diagnosis made by the presence of typical symptoms of stiffness, aching, and pain in the muscles of the hip and shoulder girdle, an increased ESR and/or CRP, the absence of clinical features suggestive of giant cell arteritis, and a prompt therapeutic response to low-dose prednisone. Polymyalgia rheumatica can be associated with a peripheral arthritis that can mimic rheumatoid arthritis **(Chap. 370)**. Rheumatoid factor and anti–cyclic citrullinated peptide (CCP) should be negative. In patients who develop a worsening pattern of peripheral arthritis, the potential for a seronegative rheumatoid arthritis or other inflammatory arthropathy should be considered. Levels of enzymes indicative of muscle damage such as serum creatine kinase are not elevated.

TREATMENT

Giant Cell Arteritis

Acute disease–related mortality directly from giant cell arteritis is uncommon, with fatalities occurring from cerebrovascular events or myocardial infarction. However, patients are at risk of late mortality from aortic aneurysm rupture or dissection as patients with giant cell arteritis are 18 times more likely to develop thoracic aortic aneurysms than the general population.

The goals of treatment in giant cell arteritis are to reduce symptoms and, most importantly, to prevent visual loss. The treatment approach for cranial arteritis and large-vessel disease in giant cell arteritis is currently the same.

Giant cell arteritis and its associated symptoms are responsive to glucocorticoid therapy. Treatment should begin with prednisone 40–60 mg/d for ~1 month, followed by a gradual tapering. When ocular signs and symptoms occur, consideration should be given for the use of methylprednisolone 1000 mg daily for 3 days to protect remaining vision. Although the optimal duration of glucocorticoid therapy has not been established, most series have found that patients require treatment for ≥2 years. Symptom recurrence during prednisone tapering develops in 60–85% of patients with giant cell arteritis, requiring a dosage increase. For patients treated with prednisone alone, the ESR and/or CRP can serve as an indicator of inflammatory disease activity in monitoring and tapering therapy and can be used to guide the tapering schedule. However, minor increases in the ESR and/or CRP can occur as glucocorticoids are being tapered and do not necessarily reflect an exacerbation of arteritis, particularly if the patient remains symptom-free. Under these circumstances, the tapering should continue with caution. An increase in ESR and/or CRP can also occur for other reasons, including infection. Glucocorticoid toxicity occurs in 35–65% of patients and represents an important cause of patient morbidity.

Tocilizumab (anti-IL-6 receptor) 162 mg given subcutaneously once every week or once every other week combined with a 26-week prednisone taper was found to be superior to prednisone alone in sustaining glucocorticoid-free remission in a randomized trial. The decision about when to use tocilizumab in giant cell arteritis is individually based, taking into account comorbidities, glucocorticoid toxicity, and the side effects of tocilizumab. Pharmacokinetic studies supported that tocilizumab 6 mg/kg given intravenously every 4 weeks could also be used as a treatment option in giant cell arteritis.

The use of methotrexate as a glucocorticoid-sparing agent was examined in two randomized placebo-controlled trials that reached conflicting conclusions. It may be considered in select patients with glucocorticoid toxicity who are unable to take or are intolerant of tocilizumab.

Abatacept (CTLA4-Ig) was examined in a small randomized trial in giant cell arteritis and demonstrated greater efficacy than glucocorticoids alone. Infliximab, a monoclonal antibody to TNF, was studied in a randomized trial and was not found to provide benefit.

Aspirin 81 mg daily has been found in retrospective studies to reduce the occurrence of cranial ischemic complications in giant cell arteritis, and adjunctive use should be considered in patients who do not have contraindications.

Polymyalgia Rheumatica

Patients with isolated polymyalgia rheumatica respond promptly to prednisone given at a dose of 10–20 mg/d. Similar to giant cell arteritis, the ESR and/or CRP can serve as a useful indicator in monitoring prednisone reduction in those treated with glucocorticoids alone. Recurrent polymyalgia symptoms develop in the majority of patients during prednisone tapering.

Sarilumab (anti-IL-6 receptor) was found to be effective in a randomized trial of patients with glucocorticoid-resistant polymyalgia rheumatica who relapsed on prednisone ≥7.5 mg/d. In this trial, sarilumab 200 mg given subcutaneously every 2 weeks plus a 14-week glucocorticoid taper was associated with a higher rate of sustained remission compared to glucocorticoids alone. As most patients with polymyalgia rheumatica can be successfully treated with glucocorticoids alone, use of sarilumab should be restricted to those who have had an inadequate response to glucocorticoids or who relapse with a glucocorticoid taper.

One study of methotrexate found that this reduced the prednisone dose on average by only 1 mg and did not decrease prednisone-related side effects. A randomized trial in polymyalgia rheumatica did not find infliximab to lessen relapse or glucocorticoid requirements.

TAKAYASU ARTERITIS

DEFINITION

Takayasu arteritis is an inflammatory disease of large-sized arteries characterized by a strong predilection for the aortic arch and its branches.

INCIDENCE AND PREVALENCE

Takayasu arteritis is an uncommon disease with an estimated annual incidence rate of 1.2–2.6 cases per million. It is most prevalent in adolescent girls and young women. Although it is more common in Asia, it is neither racially nor geographically restricted.

PATHOLOGY AND PATHOGENESIS

The disease involves large-sized arteries, with a strong predilection for the aortic arch and its branches; the pulmonary artery may also be involved. The most commonly affected arteries seen by arteriography are listed in **Table 375-7**. The involvement of the major branches of

TABLE 375-7 Frequency of Arteriographic Abnormalities and Potential Clinical Manifestations of Arterial Involvement in Takayasu Arteritis

ARTERY	PERCENTAGE OF ARTERIOGRAPHIC ABNORMALITIES	POTENTIAL CLINICAL MANIFESTATIONS
Subclavian	93	Arm claudication, Raynaud's phenomenon
Common carotid	58	Visual changes, syncope, transient ischemic attacks, stroke
Abdominal aorta[a]	47	Abdominal pain, nausea, vomiting
Renal	38	Hypertension, renal failure
Aortic arch or root	35	Aortic insufficiency, congestive heart failure
Vertebral	35	Visual changes, dizziness
Coeliac axis[a]	18	Abdominal pain, nausea, vomiting
Superior mesenteric[a]	18	Abdominal pain, nausea, vomiting
Iliac	17	Leg claudication
Pulmonary	10–40	Atypical chest pain, dyspnea
Coronary	<10	Chest pain, myocardial infarction

[a]Arteriographic lesions at these locations are usually asymptomatic but may potentially cause these symptoms.

Source: G Kerr et al: Ann Intern Med 120:919, 1994.

the aorta is much more marked at their origin than distally. The disease is a panarteritis with inflammatory mononuclear cell infiltrates and occasionally giant cells. There are marked intimal proliferation and fibrosis, scarring and vascularization of the media, and disruption and degeneration of the elastic lamina. The vasa vasorum are frequently involved. Narrowing of the lumen occurs with or without thrombosis. Pathologic changes in various organs typically reflect reduced blood flow through these vascular stenoses. Aneurysms can also occur due to weakening of the vessel wall.

Immunopathogenic mechanisms, the precise nature of which is uncertain, are suspected in this disease. As with several of the vasculitis syndromes, circulating immune complexes have been demonstrated, but their pathogenic significance is unclear.

CLINICAL AND LABORATORY MANIFESTATIONS

Takayasu arteritis is a systemic disease with generalized as well as vascular symptoms. The generalized symptoms include malaise, fever, night sweats, arthralgias, anorexia, and weight loss, which may occur months before vessel involvement is apparent. These symptoms may merge into those related to vascular compromise and organ ischemia. Pulses are commonly absent in the involved vessels, particularly the subclavian artery. The frequency of arteriographic abnormalities and the potentially associated clinical manifestations are listed in Table 375-7. Hypertension occurs in 32–93% of patients and contributes to renal, cardiac, and cerebral injury.

Characteristic laboratory findings include an elevated ESR and/or CRP, mild anemia, and elevated immunoglobulin levels.

DIAGNOSIS

The diagnosis of Takayasu arteritis should be suspected strongly in a young woman who develops a decrease or absence of peripheral pulses, a discrepancy in blood pressure between arms, or arterial bruits. The diagnosis is confirmed by the characteristic pattern on arteriography, which includes irregular vessel walls, stenosis, poststenotic dilation, aneurysm formation, occlusion, and evidence of increased collateral circulation. Complete imaging of the aorta and its major branches by magnetic resonance or computed tomography arteriography should be obtained to fully delineate the distribution and degree of arterial disease. Because of the involvement of the large vessels, tissue is rarely available or necessary as a means of diagnosis and obtained only if vascular surgery is necessary. IgG4-related disease **(Chap. 380)** is a potential cause of aortitis and periaortitis that is histologically differentiated from Takayasu arteritis by a dense lymphoplasmacytic infiltrate rich in IgG4-positive plasma cells, a storiform pattern of fibrosis, and obliterative phlebitis.

TREATMENT

Takayasu Arteritis

The long-term outcome of patients with Takayasu arteritis has varied widely between studies. Although two North American reports found overall survival to be ≥94%, the 5-year mortality rate from other studies has ranged from 0 to 35%. Disease-related mortality most often occurs from congestive heart failure, cerebrovascular events, myocardial infarction, aneurysm rupture, or renal failure. Even in the absence of life-threatening disease, Takayasu arteritis can be associated with significant morbidity. The course of the disease is variable, and although spontaneous remissions may occur, Takayasu arteritis is most often chronic and relapsing. Although glucocorticoids, given as prednisone 40–60 mg/d followed by a taper, alleviate symptoms, there are no convincing studies that indicate that it increases survival. The combination of glucocorticoid therapy for acute signs and symptoms and an aggressive surgical and/or arterioplastic approach to stenosed vessels has markedly improved outcome and decreased morbidity by lessening the risk of stroke, correcting hypertension due to renal artery stenosis, and improving blood flow to ischemic viscera and limbs. Unless it is urgently required, surgical correction of stenosed arteries should be undertaken only when the vascular inflammatory process is well controlled with medical therapy.

In individuals who are refractory to or unable to taper glucocorticoids, methotrexate in doses up to 25 mg per week has been used with positive results. Retrospective series with anti-TNF therapies have shown benefit, but these agents have not been studied through randomized trials to determine efficacy.

Tocilizumab has been investigated in a randomized trial where it did not reach its primary efficacy endpoint, although it was found to be associated with glucocorticoid-sparing effects and improvements in well-being. Encouraging results have also been seen in retrospective studies such that the utility of this agent remains an active question. Abatacept was examined in a randomized trial in Takayasu arteritis but did not demonstrate efficacy beyond glucocorticoids alone.

IGA VASCULITIS (HENOCH-SCHÖNLEIN)

DEFINITION

IgA vasculitis (Henoch-Schönlein) is a small-vessel vasculitis characterized by palpable purpura (most commonly distributed over the buttocks and lower extremities), arthralgias, gastrointestinal signs and symptoms, and glomerulonephritis.

INCIDENCE AND PREVALENCE

IgA vasculitis is usually seen in children ages 4–7 years; however, the disease may also be seen in infants and adults. It is not a rare disease; in one series, it accounted for between 5 and 24 admissions per year at a pediatric hospital. The male-to-female ratio is 1.5:1. A seasonal variation with a peak incidence in spring has been noted.

PATHOLOGY AND PATHOGENESIS

The presumptive pathogenic mechanism for IgA vasculitis is immune-complex deposition. A number of inciting antigens have been suggested including upper respiratory tract infections, various drugs, foods, insect bites, and immunizations. IgA is the antibody class most often seen in the immune complexes and has been demonstrated in the renal biopsies of these patients.

CLINICAL AND LABORATORY MANIFESTATIONS

In pediatric patients, palpable purpura is seen in virtually all patients; most patients develop polyarthralgias in the absence of frank arthritis. Gastrointestinal involvement, which is seen in almost 70% of pediatric patients, is characterized by colicky abdominal pain usually associated with nausea, vomiting, diarrhea, or constipation, and is frequently accompanied by the passage of blood and mucus per rectum; bowel intussusception may occur. Renal involvement occurs in 10–50% of patients and is usually characterized by mild glomerulonephritis leading to proteinuria and microscopic hematuria, with red blood cell casts in the majority of patients; it usually resolves spontaneously without therapy. Progressive glomerulonephritis rarely develops. In adults, presenting symptoms are most frequently related to the skin and joints, while initial complaints related to the gut are less common. Although certain studies have found that renal disease is more frequent and more severe in adults, this has not been a consistent finding. However, the course of renal disease in adults may be more insidious and thus requires close follow-up. Myocardial involvement can occur in adults but is rare in children.

Laboratory studies generally show a mild leukocytosis, a normal platelet count, and occasionally eosinophilia. Serum complement components are normal, and IgA levels are elevated in about one-half of patients.

DIAGNOSIS

The diagnosis of IgA vasculitis is based on clinical signs and symptoms. Skin biopsy specimen can be useful in confirming leukocytoclastic vasculitis with IgA and C3 deposition by immunofluorescence. Renal biopsy is rarely needed for diagnosis but may provide prognostic information in some patients.

TREATMENT

IgA Vasculitis

The prognosis of IgA vasculitis is excellent. Mortality is exceedingly rare, and 1–5% of children progress to end-stage renal disease, although renal failure may be more common in adults. Most patients recover completely, and some do not require therapy. When glucocorticoids are required, prednisone, 1 mg/kg per day and tapered according to clinical response, has been shown to be useful in decreasing tissue edema, arthralgias, and abdominal discomfort; however, it has not proved beneficial in the treatment of skin or renal disease and does not appear to shorten the duration of active disease or lessen the chance of recurrence. Patients with rapidly progressive glomerulonephritis have been anecdotally reported to benefit from glucocorticoids used in combination with another immunosuppressive agent. Disease recurrences have been reported in 10–40% of patients.

CRYOGLOBULINEMIC VASCULITIS

DEFINITION

Cryoglobulins are cold-precipitable monoclonal or polyclonal immunoglobulins. Cryoglobulinemia may be associated with a systemic vasculitis characterized by palpable purpura, arthralgias, weakness, neuropathy, and glomerulonephritis. The most common association has been with hepatitis C, although cryoglobulinemia can be observed in association with a variety of underlying disorders including multiple myeloma, lymphoproliferative disorders, connective tissue diseases, infection, and liver disease and can be idiopathic.

INCIDENCE AND PREVALENCE

The incidence of cryoglobulinemic vasculitis has not been established. It has been estimated that 5% of patients with chronic hepatitis C will develop cryoglobulinemic vasculitis.

PATHOLOGY AND PATHOGENESIS

Skin biopsies in cryoglobulinemic vasculitis reveal an inflammatory infiltrate surrounding and involving blood vessel walls, with fibrinoid necrosis, endothelial cell hyperplasia, and hemorrhage. Deposition of immunoglobulin and complement is common. Abnormalities of uninvolved skin including basement membrane alterations and deposits in vessel walls may be found. Membranoproliferative glomerulonephritis is responsible for 80% of all renal lesions in cryoglobulinemic vasculitis.

The association between hepatitis C and cryoglobulinemic vasculitis has been supported by the high frequency of documented hepatitis C infection, the presence of hepatitis C RNA and anti–hepatitis C antibodies in serum cryoprecipitates, evidence of hepatitis C antigens in vasculitic skin lesions, and the effectiveness of antiviral therapy. Current evidence suggests that in the majority of cases, cryoglobulinemic vasculitis occurs when an aberrant immune response to hepatitis C infection leads to the formation of immune complexes consisting of hepatitis C antigens, polyclonal hepatitis C–specific IgG, and monoclonal IgM rheumatoid factor. The deposition of these immune complexes in blood vessel walls triggers an inflammatory cascade that results in cryoglobulinemic vasculitis.

CLINICAL AND LABORATORY MANIFESTATIONS

The most common clinical manifestations of cryoglobulinemic vasculitis are cutaneous vasculitis, arthritis, peripheral neuropathy, and glomerulonephritis. Renal disease develops in 10–30% of patients. Life-threatening rapidly progressive glomerulonephritis or vasculitis of the CNS, gastrointestinal tract, or heart occurs infrequently.

The presence of circulating cryoprecipitates is the fundamental finding in cryoglobulinemic vasculitis. Rheumatoid factor is almost always found and may be a useful clue to the disease when cryoglobulins are not detected. Hypocomplementemia occurs in 90% of patients. An elevated ESR and/or CRP and anemia occur frequently. Evidence for hepatitis C infection must be sought in all patients by testing for hepatitis C antibodies and hepatitis C RNA.

TREATMENT

Cryoglobulinemic Vasculitis

Acute mortality directly from cryoglobulinemic vasculitis is uncommon, but the presence of glomerulonephritis is a poor prognostic sign for overall outcome. In such patients, 15% progress to end-stage renal disease, with 40% later experiencing fatal cardiovascular disease, infection, or liver failure. As indicated above, the majority of cases are associated with hepatitis C infection. In such patients, treatment with antiviral therapy (Chap. 352) is first-line therapy for hepatitis C–associated cryoglobulinemic vasculitis, particularly given the efficacy of current hepatitis C therapies. Clinical improvement with antiviral therapy is dependent on the virologic response. Patients who clear hepatitis C from the blood have objective improvement in their vasculitis along with significant reductions in levels of circulating cryoglobulins, IgM, and rheumatoid factor. While transient improvement can be observed with glucocorticoids, a complete response is seen in only 7% of patients. Plasma exchange and cytotoxic agents have been used in anecdotal reports. These observations have not been confirmed, and such therapies carry significant risks. Randomized trials with rituximab in hepatitis C–associated cryoglobulinemic vasculitis showed evidence of benefit such that this should be considered in patients with active vasculitis either in combination with antiviral therapy or alone in patients who have relapsed through, are intolerant to, or have contraindications to antiviral agents.

SINGLE-ORGAN VASCULITIS

Single-organ vasculitis has been defined as vasculitis in arteries or veins of any size in a single organ that has no features that indicate that it is a limited expression of a systemic vasculitis. Examples include isolated aortitis, testicular vasculitis, vasculitis of the breast, isolated cutaneous vasculitis, and primary CNS vasculitis. In some instances, this may be discovered at the time of surgery such as orchiectomy for a testicular mass where there is concern for neoplasm that is found instead to be vasculitis. Some patients originally diagnosed with single-organ vasculitis may later develop additional manifestations of a more systemic disease. In instances where there is no evidence of systemic vasculitis and the affected organ has been removed in its entirety, the patient may be followed closely without immunosuppressive therapy. In other instances, such as primary CNS vasculitis, medical intervention is necessary.

IDIOPATHIC CUTANEOUS VASCULITIS

DEFINITION

The term *cutaneous vasculitis* is defined broadly as inflammation of the blood vessels of the dermis. Because of its heterogeneity, cutaneous vasculitis has been described by a variety of terms including *hypersensitivity vasculitis* and *cutaneous leukocytoclastic angiitis*. However, cutaneous vasculitis is not one specific disease but a manifestation that can be seen in a variety of settings. In >70% of cases, cutaneous vasculitis occurs either as part of a primary systemic vasculitis or as a secondary vasculitis related to an inciting agent or an underlying disease (see "Secondary Vasculitis," below). In the remaining 30% of cases, cutaneous vasculitis occurs idiopathically.

INCIDENCE AND PREVALENCE

Cutaneous vasculitis represents the most commonly encountered vasculitis in clinical practice. The exact incidence of idiopathic cutaneous vasculitis has not been determined due to the predilection for cutaneous vasculitis to be associated with an underlying process and the variability of its clinical course.

PATHOLOGY AND PATHOGENESIS

The typical histopathologic feature of cutaneous vasculitis is the presence of vasculitis of small vessels. Postcapillary venules are the most commonly involved vessels; capillaries and arterioles may be involved less frequently. This vasculitis is characterized by a *leukocytoclasis*, a

term that refers to the nuclear debris remaining from the neutrophils that have infiltrated in and around the vessels during the acute stages. In the subacute or chronic stages, mononuclear cells predominate; in certain subgroups, eosinophilic infiltration is seen. Erythrocytes often extravasate from the involved vessels, leading to palpable purpura. *Cutaneous arteritis* can also occur, which involves slightly larger-sized vessels within the dermis.

CLINICAL AND LABORATORY MANIFESTATIONS

The hallmark of idiopathic cutaneous vasculitis is the predominance of skin involvement. Skin lesions may appear typically as palpable purpura; however, other cutaneous manifestations of the vasculitis may occur, including macules, papules, vesicles, bullae, subcutaneous nodules, ulcers, and recurrent or chronic urticaria. The skin lesions may be pruritic or painful, with a burning or stinging sensation. Lesions most commonly occur in the lower extremities in ambulatory patients or in the sacral area in bedridden patients due to the effects of hydrostatic forces on the postcapillary venules. Edema may accompany certain lesions, and hyperpigmentation often occurs in areas of recurrent or chronic lesions.

There are no specific laboratory tests diagnostic of idiopathic cutaneous vasculitis. A mild leukocytosis with or without eosinophilia is characteristic, as is an elevated ESR and/or CRP. Laboratory studies should be aimed toward ruling out features to suggest an underlying disease or a systemic vasculitis.

DIAGNOSIS

The diagnosis of cutaneous vasculitis is made by the demonstration of vasculitis on biopsy. An important diagnostic principle in patients with cutaneous vasculitis is to search for an etiology of the vasculitis—be it an exogenous agent, such as a drug or an infection, or an endogenous underlying disease (Fig. 375-1). In addition, a careful history, physical, and laboratory examination should be performed to rule out the possibility of coexisting systemic vasculitis.

TREATMENT

Idiopathic Cutaneous Vasculitis

When an antigenic stimulus is recognized as the precipitating factor in the cutaneous vasculitis, it should be removed; if this is a microbe, appropriate antimicrobial therapy should be instituted. If the vasculitis is associated with another underlying disease, treatment of the latter often results in resolution of the former. In situations where disease is apparently self-limited, no therapy, except possibly symptomatic therapy, is indicated. When cutaneous vasculitis persists and when there is no evidence of an inciting agent, an associated disease, or an underlying systemic vasculitis, the decision to treat should be based on weighing the balance between the degree of symptoms and the risk of treatment. Some cases of idiopathic cutaneous vasculitis resolve spontaneously, whereas others remit and relapse. In patients with persistent vasculitis, a variety of therapeutic regimens have been tried with variable results. In general, the treatment of idiopathic cutaneous vasculitis has not been satisfactory. Fortunately, since the disease is generally limited to the skin, this lack of consistent response to therapy usually does not lead to a life-threatening situation. Agents with which there have been anecdotal reports of success include dapsone, colchicine, hydroxychloroquine, and nonsteroidal anti-inflammatory agents. Glucocorticoids are often used in the treatment of idiopathic cutaneous vasculitis. Therapy is usually instituted with the lowest effective dose of prednisone with rapid tapering to discontinuation. In cases that prove refractory to glucocorticoids, a trial of another immunosuppressive agent may be indicated. Patients with chronic vasculitis isolated to cutaneous venules rarely respond dramatically to any therapeutic regimen, and other immunosuppressive agents should be used only as a last resort in these patients. Methotrexate and azathioprine have been used in such situations in anecdotal reports. Cyclophosphamide should almost never be used for idiopathic cutaneous vasculitis because of the potential toxicity.

PRIMARY CENTRAL NERVOUS SYSTEM VASCULITIS

Primary CNS vasculitis is an uncommon clinicopathologic entity characterized by vasculitis restricted to the vessels of the CNS without other apparent systemic vasculitis. The inflammatory process is usually composed of mononuclear cell infiltrates with or without granuloma formation.

Patients may present with headaches, altered mental function, and focal neurologic defects. Systemic symptoms are generally absent. Devastating neurologic abnormalities may occur depending on the extent of vessel involvement. The diagnosis can be suggested by abnormal magnetic resonance imaging of the brain, an abnormal lumbar puncture, and/or demonstration of characteristic vessel abnormalities on arteriography **(Fig. 375-4)**, but it is confirmed by biopsy of the brain parenchyma and leptomeninges. In the absence of a brain biopsy, care should be taken not to misinterpret as true primary vasculitis arteriographic abnormalities that might actually be related to another cause. An important entity in the differential diagnosis is reversible cerebral vasoconstrictive syndrome, which typically presents with "thunderclap" headache and is associated with reversible arteriographic abnormalities that mimic primary CNS vasculitis. Other diagnostic considerations include infection, atherosclerosis, emboli, connective tissue disease, sarcoidosis, malignancy, and drug-associated causes. The prognosis of granulomatous primary CNS vasculitis is poor; however, some reports indicate that glucocorticoid therapy, alone or together with cyclophosphamide administered as described above, has induced clinical remissions. Following disease remission, cyclophosphamide should be switched to azathioprine or mycophenolate mofetil as these have good penetration into the CNS.

BEHÇET'S DISEASE

Behçet's disease is a clinicopathologic entity characterized by recurrent episodes of oral and genital ulcers, iritis, and cutaneous lesions. The underlying pathologic process is a leukocytoclastic venulitis, although vessels of any size and in any organ can be involved. **This disorder is described in detail in Chap. 376.**

COGAN'S SYNDROME

Cogan's syndrome is characterized by interstitial keratitis together with vestibuloauditory symptoms. It may be associated with a systemic vasculitis, particularly aortitis with involvement of the aortic valve.

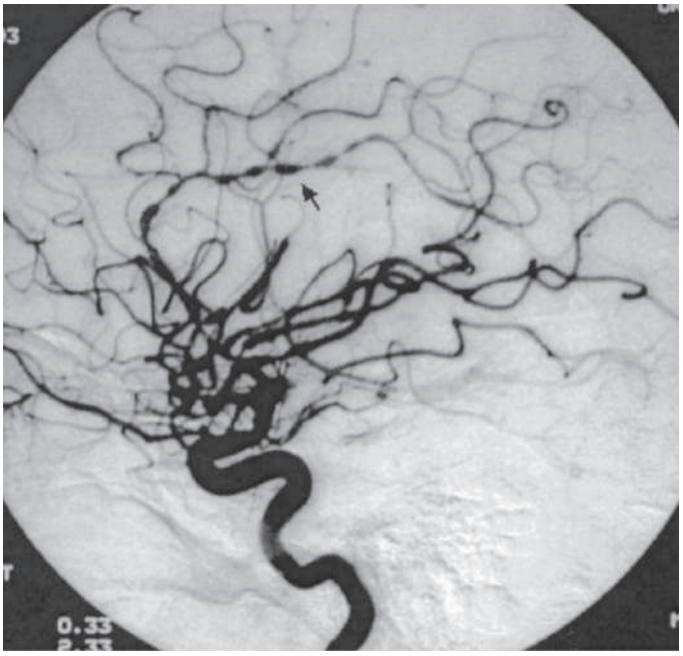

FIGURE 375-4 Cerebral arteriogram from a 32-year-old man with primary central nervous system vasculitis. Dramatic beading (*arrow*) typical of vasculitis is seen.

Glucocorticoids are the mainstay of treatment. Initiation of treatment as early as possible after the onset of hearing loss improves the likelihood of a favorable outcome.

KAWASAKI'S DISEASE

Kawasaki's disease is an acute, febrile, multisystem disease of children. Some 80% of cases occur prior to the age of 5, with the peak incidence occurring at ≤2 years. It is characterized by nonsuppurative cervical adenitis and changes in the skin and mucous membranes such as edema; congested conjunctivae; erythema of the oral cavity, lips, and palms; and desquamation of the skin of the fingertips. Although the disease is generally benign and self-limited, it is associated with coronary artery aneurysms in ~25% of cases, with an overall case-fatality rate of 0.5–2.8%. These complications usually occur between the third and fourth weeks of illness during the convalescent stage. Vasculitis of the coronary arteries is seen in almost all the fatal cases that have been autopsied and can cause complications into adulthood. There is typical intimal proliferation and infiltration of the vessel wall with mononuclear cells. Beadlike aneurysms and thromboses may be seen along the artery. Other manifestations include pericarditis, myocarditis, myocardial ischemia and infarction, and cardiomegaly.

Apart from the up to 2.8% of patients who develop fatal complications, the prognosis of this disease for uneventful recovery is excellent. High-dose IV γ-globulin (2 g/kg as a single infusion over 10 h) together with aspirin (100 mg/kg per day for 14 days followed by 3–5 mg/kg per day for several weeks) has been shown to be effective in reducing the prevalence of coronary artery abnormalities when administered early in the course of the disease. Surgery may be necessary for Kawasaki disease patients who have giant coronary artery aneurysms or other coronary complications. Surgical treatment most commonly includes thromboendarterectomy, thrombus clearing, aneurysmal reconstruction, and coronary artery bypass grafting.

Multisystem inflammatory syndrome (MIS-C), a serious condition that may resemble Kawasaki's disease, has been observed with infections due to SARS-CoV-2 **(Chap. 205)**. Although clinical features consistent with Kawasaki's disease have been observed, these patients can also have manifestations atypical for Kawasaki's disease, including gastrointestinal symptoms, myocarditis, neurocognitive symptoms, and shock. Any patient who presents with a clinical picture suggestive of Kawasaki's disease should be tested for SARS-CoV-2 to guide management.

POLYANGIITIS OVERLAP SYNDROMES

Some patients with systemic vasculitis manifest clinicopathologic characteristics that do not fit into a specific disease but have overlapping features of different vasculitides. The diagnostic and therapeutic considerations as well as the prognosis for these patients depend on the sites and severity of active vasculitis. Patients with vasculitis that could cause irreversible damage to a major organ system should be treated as described under "Granulomatosis with Polyangiitis."

SECONDARY VASCULITIS

DRUG-INDUCED VASCULITIS

Vasculitis associated with drug reactions usually presents as palpable purpura that may be generalized or limited to the lower extremities or other dependent areas; however, urticarial lesions, ulcers, and hemorrhagic blisters may also occur **(Chap. 63)**. Signs and symptoms may be limited to the skin, although systemic manifestations such as fever, malaise, and polyarthralgias may occur. Although the skin is the predominant organ involved, systemic vasculitis may result from drug reactions. Drugs that have been implicated in vasculitis include allopurinol, thiazides, gold, sulfonamides, phenytoin, and penicillin **(Chap. 63)**.

An increasing number of drugs have been reported to cause vasculitis associated with ANCA. Of these, the best evidence of causality exists for hydralazine and propylthiouracil. The clinical manifestations in ANCA-positive drug-induced vasculitis can range from cutaneous lesions to glomerulonephritis and pulmonary hemorrhage. Outside of drug discontinuation, treatment should be based on the severity of the vasculitis. Patients with immediately life-threatening small-vessel vasculitis should initially be treated with glucocorticoids and cyclophosphamide as described for granulomatosis with polyangiitis. Following clinical improvement, consideration may be given for tapering such agents along a more rapid schedule.

SERUM SICKNESS AND SERUM SICKNESS–LIKE REACTIONS

These reactions are characterized by the occurrence of fever, urticaria, polyarthralgias, and lymphadenopathy 7–10 days after primary exposure and 2–4 days after secondary exposure to a heterologous protein (classic serum sickness) or a nonprotein drug such as penicillin or sulfa (serum sickness–like reaction). Most manifestations are not due to vasculitis; however, occasional patients will have typical cutaneous venulitis that may progress rarely to a systemic vasculitis.

VASCULITIS ASSOCIATED WITH OTHER UNDERLYING DISEASES

Certain *infections* may directly trigger an inflammatory vasculitic process. For example, rickettsias can invade and proliferate in the endothelial cells of small blood vessels causing a vasculitis **(Chap. 192)**. In addition, the inflammatory response around blood vessels associated with certain systemic fungal diseases such as histoplasmosis **(Chap. 218)** may mimic a primary vasculitic process. A cutaneous leukocytoclastic vasculitis with occasional involvement of other organs may be a component of some infections. These include *subacute bacterial endocarditis*, *Epstein-Barr virus infection*, *HIV infection*, and a number of other infections.

Vasculitis can be associated with certain *malignancies*, particularly leukemic, lymphoid, or reticuloendothelial neoplasms. Leukocytoclastic venulitis confined to the skin is the most common finding; however, systemic vasculitis may occur.

A number of *connective tissue diseases* have vasculitis as a secondary manifestation of the underlying primary process. Foremost among these are *systemic lupus erythematosus* **(Chap. 368)**, *rheumatoid arthritis* **(Chap. 370)**, *inflammatory myositis* **(Chap. 377)**, *relapsing polychondritis* **(Chap. 378)**, and *Sjögren's syndrome* **(Chap. 373)**. The most common form of vasculitis in these conditions is the small-vessel venulitis isolated to the skin. However, certain patients may develop a fulminant systemic necrotizing vasculitis.

Secondary vasculitis has also been observed in association with *ulcerative colitis*, *congenital deficiencies of various complement components*, *sarcoidosis*, *primary biliary cirrhosis*, α_1*-antitrypsin deficiency*, and *intestinal bypass surgery*.

376 Behçet Syndrome

Yusuf Yazici

Behçet syndrome is a systemic vasculitis, first described by Hulusi Behçet, a Turkish dermatologist. It can present with oral and genital ulcers, skin lesions, uveitis, arthritis, major arterial and venous vessel disease, and gastrointestinal and neurologic manifestations. These manifestations can be present in various combinations and sequences over time. Patients are most commonly from the Middle East, the Mediterranean region, and the Far East; it is most prevalent in Turkey, with a prevalence of 1 in 250 adults. It is relatively rare before the late teens and after age 50. Males and females are equally affected; however, males frequently have more severe disease and poorer outcomes. Some manifestations may show regional differences; for example, gastrointestinal involvement, rare in Turkey, is more common in Japan and is seen in ~30% of patients in the United States.

DIAGNOSIS

Behçet syndrome is diagnosed clinically. There are no specific laboratory, imaging, or histologic features that can help in the diagnosis of a patient with suggestive symptoms. However, these can be used in ruling out conditions that may mimic Behçet syndrome and the diagnosis is based on a combination of clinical features in the setting of ruling out other potential causes. In this regard, some patients may require months to years to develop the array of symptoms that would lead to a definitive diagnosis, although a tentative diagnosis may be made well before. The most commonly used and best performing diagnostic criteria are the International Study Group (ISG) criteria (sensitivity ~95%, specificity ~96%); patients need to have recurrent oral ulcers plus two of the following four clinical manifestations: recurrent genital ulcers, skin lesions, eye lesions, or a positive pathergy test (Table 376-1). Additional clinical manifestations may involve various organ systems, including the gastrointestinal, vascular, pulmonary, and central nervous systems. Up to 50–60% of patients, depending on where they are from, can be positive for HLA B*51; however, it is not used as a diagnostic test because it is also found in around 20% of the normal population.

PATHOGENESIS

The pathogenesis and etiology of Behçet syndrome are unknown. Family studies show a possible genetic predisposition, and increased inflammation and immunologic mechanisms play a role. Both innate and adaptive immune systems may be involved. Unlike other autoimmune diseases, however, Behçet syndrome is not typically associated with autoantibodies, Raynaud's phenomenon, Sjögren's syndrome, thrombocytopenia, hemolytic anemia, sun hypersensitivity, serosal involvement, or an increased risk for other autoimmune diseases. On the other hand, features that separate it from autoinflammatory conditions include tendency to abate with time, absence of mutations associated with autoinflammatory diseases, and higher prevalence than typical autoinflammatory diseases such as familial Mediterranean fever (Chap. 381). There is neutrophil hyperreactivity; however, it is not clear whether this is primary or secondary to cytokine-directed activation. There is also evidence from retrospective patient cohort analyses that there may be different clusters of disease presentation; for example, acne lesions are more commonly seen with arthritis and associated with enthesitis, and each of these clusters may have a different pathogenesis.

TABLE 376-1 International Study Group Criteria for the Diagnosis of Behçet Syndrome

CRITERIA	FREQUENCY	COMMENTS
Oral ulcers	~98%	At least 3 times in a 12-month period
Plus 2 out of 4 from below:		
Recurrent genital ulcers	~80%	Usually scarring
Skin lesions	~80%	Erythema nodosum, pseudofolliculitis, papulopastular or acneiform nodules (postadolescent, not receiving corticosteroids)
Eye lesions	~50%	Anterior or posterior uveitis, cells in vitreous or retinal vasculitis
Pathergy	~50%	Evaluated in 24–48 h, after dermal insertion of a 20-gauge needle

CLINICAL PRESENTATION

The most common symptoms are associated with mucocutaneous tissues. Oral ulcers are seen in virtually all patients and are commonly the first manifestation (Fig. 376-1). Commonly, like ordinary canker sores, they are usually multiple. They last around 10 days but recur unless treated. Only the uncommon, major ulcers tend to scar. Beneficial effects of dental and periodontal therapies suggest that decreased oral health is associated with disease severity.

Genital ulcers are the most specific lesions, most commonly occurring on the scrotum or labia (Fig. 376-1). They are larger and deeper and take longer to heal than oral ulcers and tend to form scars.

Acne-like or papulopustular lesions are indistinguishable from acne vulgaris in appearance and pathology. They are seen both at the usual acne sites as well as at uncommon sites such as lower extremities. Other skin findings are the nodular lesions, which are of two types: erythema nodosum lesions due to panniculitis and superficial vein thromboses. Superficial thrombophlebitis often occurs in men and is associated with deep-vein thrombosis; it should trigger workup for other vascular involvement, including pulmonary artery aneurysms.

Pathergy reaction is a nonspecific hyperreactivity of the skin to trauma. Typically, a papule or pustule forms in 24–48 h after a

A

B

20–21-gauge needle prick. It is rather unique for Behçet syndrome and is part of the ISG diagnostic criteria.

Arthralgia or arthritis is seen in about half of patients; it is usually a mono- or oligoarthritis in the lower extremities and does not usually cause erosions or deformity.

Eye involvement is seen in half of all patients and may be seen in up to ~70% of males. It is most commonly a bilateral panuveitis. A hypopyon, seen in ~10% of patients with eye disease, is an intense inflammation in the anterior chamber and is quite specific for Behçet syndrome. Ocular involvement develops usually in the first 2 years after fulfillment of diagnostic criteria and is most severe during the first few years and then tends to abate. Male gender, posterior involvement, frequent attacks (>3 per year), strong vitreous opacity, and macular edema are poor prognostic factors.

Vascular disease is seen in up to 40% of patients. It is associated with intensive thrombosis and runs a relapsing course. Several well-defined venous vascular associations are seen; superficial and deep-vein thrombosis, Budd-Chiari syndrome, inferior vena cava syndrome, pulmonary artery involvement, intracardiac thrombosis, and cerebral venous sinus thrombosis frequently cluster in various combinations. Pulmonary artery aneurysms carry a 5-year mortality rate of 20–25%.

Prevalence of neurologic involvement is ~5%, with about three-quarters of patients presenting with parenchymal involvement, while the remaining cases present with cerebral venous sinus thrombosis. These two forms rarely occur together. Parenchymal involvement usually affects the telencephalic-diencephalic junction, brainstem, and spinal cord. Patients may present with a subacute onset of severe headache, cranial nerve palsy, dysarthria, ataxia, and hemiparesis.

Prevalence of gastrointestinal involvement changes significantly across different populations (up to 50% in the Far East but rare in the Middle East). Clinical and endoscopic appearance of intestinal involvement can be similar to, and thus cannot easily be differentiated from, Crohn's disease. Ulcers tend to be single or less than five, are usually confined to the ileocecal area, are more likely to be deep and round, and are prone to perforate; perianal and rectal area involvement are rare. In practice, it is difficult to distinguish Behçet syndrome from Crohn's disease unless extraintestinal manifestations are present.

TREATMENT

Behçet Syndrome

Treatment is guided by type and severity of involvement, with the goal of preventing long-term damage. Most new manifestations tend to present within the first 5 years, and for most patients, the natural course is one of diminishing symptoms culminating in potential remission, frequently not requiring ongoing treatment with medications. Patient characteristics, such as being young and male, need to be kept in mind when making treatment decisions, as these patients tend to have a worse prognosis. In most patients, tapering and/or stopping their medications in 2–3 years after the symptoms have improved should be attempted.

Oral ulcers can be managed with topical glucocorticoids and on an as-needed basis if mild. Lesions resistant to local measures may require systemic treatment with colchicine, oral glucocorticoids, immunosuppressants such as apremilast, azathioprine, or a tumor necrosis factor (TNF)-α inhibitor such as infliximab. A similar treatment approach can be used for genital ulcers and other mucocutaneous manifestations. Patients may need a combination of medications, at least initially, to control disease activity.

Eye involvement, given its frequency and potential morbidity, requires early and aggressive treatment with brief courses of glucocorticoids and longer-term treatment with an immunosuppressant. Azathioprine is usually the preferred agent in clinical practice. TNF inhibitors infliximab or adalimumab can also be used, either as first-line monotherapy or more commonly in combination with systemic glucocorticoids and azathioprine, for control of disease activity. Cyclosporine can also be considered in combination regimens; monotherapy with interferon is another option. Glucocorticoids can be tapered in many patients after active disease has been controlled, whereas immunosuppressants are generally continued for at least 2 years with plans to potentially taper them also based on treatment response and ongoing disease activity.

Gastrointestinal involvement is treated with glucocorticoids plus an immunosuppressant such as azathioprine alone or in combination with infliximab.

Venous thrombotic events are treated by controlling systemic inflammation with immunosuppressive medications (usually azathioprine or, for more severe cases, cyclophosphamide), rather than using anticoagulants. However, if venous thrombotic events occur, standard anticoagulation treatment can be given, provided there is a low risk of bleeding and there are no coexistent pulmonary artery aneurysms. For central nervous system involvement, the combination of azathioprine and a TNF inhibitor is usually the first choice.

377 Inflammatory Myopathies

Steven A. Greenberg, Anthony A. Amato

This chapter focuses on the major types of inflammatory myopathies (IMs), including dermatomyositis (DM), polymyositis (PM), immune-mediated necrotizing myopathy (IMNM), antisynthetase syndrome (ASyS), and inclusion body myositis (IBM) **(Table 377-1)**. Other IMs include those caused by infection, eosinophilic myositis, granulomatous myositis, and myositis triggered by checkpoint inhibitors. Of note, inflammatory cell infiltrates can also be occasionally seen in muscle biopsies of hereditary myopathies (e.g., muscular dystrophies, metabolic myopathies), sporadic late-onset nemaline myopathy (SLONM), and toxic myopathies.

Epidemiologic studies suggest that the incidence of IM grouped together is up to 16 cases per 100,000 with prevalence in the range of 14–32 per 100,000. Defining the actual incidence and prevalence of the individual myositides is limited, however, by different diagnostic criteria employed in various epidemiologic studies, an increasing recognition of ASyS and IMNM, as well as the frequent misdiagnosis of IBM. Idiopathic PM without signs of an overlap syndrome is quite rare compared to DM, ASyS, IBM, and IMNM that occur in roughly similar frequencies. DM can occur in children (juvenile DM), while IBM always occurs in adults and is the most common cause of myopathy in those aged >50. DM, PM, and ASyS are more common in women, while IBM is more common in men.

DIAGNOSTIC APPROACH AND DIFFERENTIAL DIAGNOSIS

The approach to patients with suspected myopathy is detailed in **Chap. 460**. In any patient presenting with weakness, the first step is to localize the site of the lesion by history and clinical findings **(Chap. 26)**. Weakness could be caused by a process in the cerebral hemispheres, spinal cord **(Chap. 453)**, anterior horn cell **(Chap. 448)**, peripheral nerve

TABLE 377-1 Inflammatory Myopathies: Clinical and Laboratory Features

DISORDER	SEX	AGE OF ONSET	RASH	PATTERN OF WEAKNESS	LABORATORY FEATURES	MUSCLE BIOPSY	CELLULAR INFILTRATE	RESPONSE TO IS THERAPY	COMMON ASSOCIATED CONDITIONS
DM	F > M	Childhood and adult	Yes	Proximal > distal	Normal or increased CK (up to 50× normal or higher); various MSAs (anti-MDA5, anti-TIF1, anti-Mi-2, anti-NXP2)	Perimysial and perivascular inflammation; IFN-1 regulated proteins (MHC-1, MxA), MAC deposition on capillaries	CD4+ dendritic cells; B cells; macrophages	Yes	Myocarditis, ILD, malignancy, vasculitis, other CTDs
PM	F > M	Adult	No	Proximal > distal	Increased CK (up to 50× normal or higher)	Endomysial and perivascular inflammation; ubiquitous expression of MHC-1	CD8+ T cells; macrophages; plasma cells	Yes	Myocarditis, ILD, other CTDs
IMNM	M = F	Children and adults	No	Proximal > distal	Elevated CK (>10× normal or higher); anti-HMGCR or anti-SRP antibodies	Necrotic muscle fibers; minimal inflammatory infiltrate; MHC-I and MAC deposition on sarcolemma of scattered nonnecrotic muscle fibers	Macrophages in necrotic fibers undergoing phagocytosis	Yes	Malignancy, CTD, HMGCR antibody cases can be triggered by statin use
ASyS	F > M	Children and adults	Sometimes	Proximal > distal	Elevated CK (>10× normal or higher); antisynthetase antibodies	Perimysial and perivascular inflammation; perimysial fragmentation with alkaline phosphatase staining; perimysial muscle damage with necrosis; MHC-I, HLA-DR, and MAC deposition on sarcolemma of perifascicular muscle fibers	CD4+ dendritic cells; B cells; macrophages	Yes	Nonerosive arthritis, ILD, Raynaud's phenomenon, mechanic hands, and fever
IBM	M > F	Older adults (>50 years)	No	Proximal and distal; predilection for: finger/ wrist flexors, knee extensors	Normal or mildly increased CK (usually <10× normal); anti-cN-1A antibodies; large granular lymphocytes on flow cytometry and reduced CD4/CD8 ratio with increased CD8 count	Endomysial and perivascular inflammation; ubiquitous expression of MHC-1 and HLA-DR; rimmed vacuoles; p62, LC3, TDP-43 aggregates; EM: 15–18 nm tubulofilaments; ragged red and COX-negative fibers	CD8+ T cells; macrophages; plasma cells; myeloid dendritic cells; large granular lymphocytes	None or minimal	Granular lymphocytic leukemia/ lymphocytosis, sarcoidosis, sicca or Sjögren's syndrome

Abbreviations: CK, creatine kinase; cN-1A, cytosolic 5′-nucleotidase 1A; CTDs, connective tissue diseases; COX, cytochrome oxidase; DM, dermatomyositis; F, female; g, immunoglobulin; IBM, inclusion body myositis; IFN-1, type 1 interferon; ILD, interstitial lung disease; IS, immunosuppressive; M, male; MAC, membrane attack complex; MDA5, melanoma differentiation antigen; MHC-1, major histocompatibility antigen 1; MSA, myositis-specific autoantibodies; NCP2, nuclear matrix protein 2 (NXP2); NM, necrotizing myopathy; PM, polymyositis; TIF1, transcriptional intermediary factor 1.

(Chaps. 457–458), neuromuscular junction **(Chap. 459)**, or muscle **(Chap. 460)**. Past medical history, medication use, and family history, combined with a detailed clinical examination and an appreciation for the pattern of muscle involvement (e.g., what muscles are weak and atrophic or hypertrophic as well as the presence of scapular winging, early contractures, sensory abnormalities, fasciculations, or rash), help differentiate myopathies from other neuromuscular disorders and the different types of myopathies from each other **(see Chap. 460)**. For example, atrophy with fasciculations suggests a neurogenic process such as amyotrophic lateral sclerosis, fatigable weakness on examination points to a neuromuscular junction defect such as myasthenia gravis, and concomitant sensory symptoms suggest a central process such as a spinal cord disorder or a polyneuropathy. Scapular winging, calf hypertrophy or atrophy, and early contractures before significant weakness develops would strongly suggest a muscular dystrophy, particularly if there is a positive family history. A heliotrope rash combined with Gottron papules (below) and dilated nailfold capillaries is diagnostic for DM. The presence of atrophy and weakness of the flexor forearm muscles and quadriceps in a person aged >50 years is most likely IBM.

When the site of the lesion cannot be localized based on history and clinical examination alone, laboratory testing is required. Serum creatine kinase (CK) is the most sensitive laboratory marker of muscle destruction. Not all myopathies are associated with elevated CK levels, but a markedly elevated CK (e.g., >2000 U/L) is almost always due to a myopathy. A slightly elevated CK can also be seen in neurogenic disorders, however. Myositis-associated and myositis-specific antibodies (MSAs) help to distinguish subtypes of IM, as discussed below. Electromyography (EMG) and nerve conductions studies (NCS) are useful in localizing the site of the lesion but are less specific in helping to determine the actual cause of a myopathy. EMG can be useful at times in guiding what muscle to biopsy, especially if muscles typically biopsied are normal on clinical examination. Imaging skeletal muscle can be helpful in assessing muscle involvement and revealing fatty replacement, atrophy, or edema within muscle or surrounding fascia.

A muscle biopsy is often required to definitively distinguish one myopathy from another, if there is no characteristic dermatomyositis rash or myositis specific autoantibody. However, a muscle biopsy should be performed in every case of suspected PM to exclude IBM (if not clinically apparent) and other causes of myopathy. Diagnosis of IMNM is by definition based upon histologic findings but again is not needed if a patient has clinical features and anti-3-hydroxy-3-methylglutaryl-coenzyme reductase (HMGCR) or anti–signal recognition particle (SRP) antibodies. It is important to biopsy a muscle that is clinically affected but not too weak (e.g., Medical Research Council grade 4 out of 5 in strength); otherwise, one may just see end-stage muscle. A biopsy should always be coordinated with an experienced muscle histopathology laboratory.

Patients with severe muscle pain, subjective weakness, and fatigue with normal strength and function on examination are not likely to have an IM. Polymyalgia rheumatica should be considered in older

individuals with an elevated erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP) but normal CK and EMG. Fibromyalgia is likely in patients with a normal laboratory workup. In general, a muscle biopsy is not indicated unless there is objective weakness, an abnormal EMG, or elevated CK.

SPECIFIC DISORDERS

DERMATOMYOSITIS

Clinical Features DM manifests with symmetric, proximal greater than distal weakness along with a characteristic rash that includes the heliotrope rash (erythematous discoloration of eyelids with periorbital edema), Gottron sign (erythematous rash over the extensor surfaces of joints such as the knuckles, elbows, knees, and ankles), Gottron papules (raised erythematous rash over knuckles) (Fig. 377-1), V-sign (rash on the sun-exposed anterior neck and chest), shawl sign over the back of the neck and shoulders, nail bed telangiectasias, and subcutaneous calcium deposits. The weakness and rash usually accompany one another but can be separated by several months. Furthermore, beyond "classic DM" with prominent muscle and skin manifestations, there is a spectrum of involvement such that some patients have skin-predominant disease (only with a rash called amyopathic DM, or minimal muscle disease called hypomyopathic DM), while others may present mainly with weakness and little or no visible skin changes. Patients may also have myalgias, arthralgias, dysphagia, and dysarthria. Cutaneous disease activity is highly relevant in DM; in comparison to other debilitating skin diseases including cutaneous lupus erythematosus, psoriasis, and atopic dermatitis, skin symptoms in DM patients are associated with an overall reduction in life quality. Pruritus can be especially debilitating. Dyspnea can occur from ventilatory muscle weakness or intrinsic lung involvement including interstitial lung disease (ILD), bronchopneumonia, and alveolitis. Pulmonary manifestations are often associated with anti-MDA-5 antibodies or with antisynthetase antibodies; myositis associated with the ASyS is now considered a distinct disorder (discussed below). DM can present in children (juvenile DM) or in adults. There is a higher risk for malignancy in adult-onset cases, ~15% within the first 2–3 years.

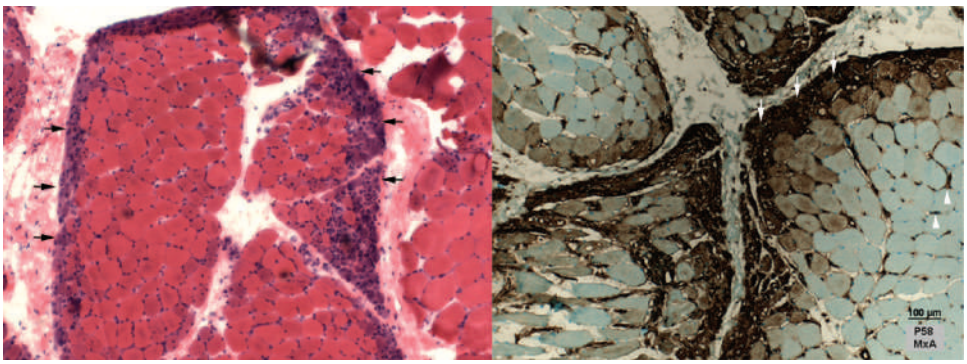

FIGURE 377-1 Cutaneous manifestations of dermatomyositis. ***A.*** Macular erythema plaques (Gottron sign) and erythematous papules (Gottron papules) on extensor surface of fingers and ***B.*** elbow. ***C.*** Macular erythema plaques over anterior neck and chest (V-sign) and ***D.*** the posterior neck, shoulder, and upper back (Shawl sign). ***E.*** Nail bed changes with dilated capillaries.

Laboratory Features Serum CK levels are elevated in 70–80% of patients; in 10% of those with normal CK, serum aldolase may be increased. Antinuclear antibodies can be positive but are a nonspecific finding. The myositis-specific antibodies (MSAs) that are specific for DM include anti–complex nucleosome remodeling histone deacetylase (anti-Mi-2), anti–transcription intermediary factor 1-γ (anti-TIF1-γ), anti–melanoma differentiation-associated gene 5 (anti-MDA5), anti–nuclear matrix protein 2 (anti-NXP-2), and anti–small ubiquitin-like modifier activating enzyme (anti-SAE). These antibodies are usually associated with characteristic clinical features, and recent studies suggest that they are also directly involved in the pathogenesis of DM. Mi-2 antibodies are found in 15–20% of patients with DM and are typically associated with an acute onset, a florid rash, and prominent weakness but a good response to therapy and a favorable prognosis. Anti-MDA5 antibodies are found in 10–20% of DM patients and up to 65% of patients with clinically amyopathic DM. This antibody is associated with palmar rash, severe skin ulcerations from ischemia, and rapidly progressive ILD. Anti-TIF1-γ, also known as p155, antibodies are found in adult cancer-associated DM with an 89% specificity and 70% sensitivity. Thus, enhanced vigilance for underlying cancer is especially important in these patients. Anti-NXP-2 antibodies are found in as many as 17% of patients with DM and are also associated with calcinosis, subcutaneous edema, distal weakness, and dysphagia, as well as with cancer. Anti-SAE antibodies are present in 1.5–8% of DM and are associated with an underlying cancer in 14–57% of patients. Most manifest with a skin rash alone, and CK is often normal, but approximately one-third of patients have elevated aldolase levels. ILD can also be seen in anti-SAE DM, but unlike anti-MDA-5 amyopathic DM, the ILD is usually mild.

EMG of weak muscles shows increased insertional and spontaneous activity in the form of positive sharp waves and fibrillation potentials, or complex repetitive discharges along with early recruitment of small-amplitude, short-duration, polyphasic motor units. These findings are nonspecific and can also be seen in other myopathies. Skeletal muscle magnetic resonance imaging (MRI muscle) reveals edema in affected muscles and sometimes more specific findings of abnormalities of fascia suggesting fasciitis.

Histopathology and Pathogenesis The characteristic histopathologic abnormality on muscle biopsy is perifascicular atrophy (Fig. 377-2*A*); however, this finding is present in perhaps only 50% of patients. Immunohistochemical staining for myxovirus resistance protein A (MxA) is diagnostically more sensitive and highly specific (Fig. 377-2*B*). The inflammatory cell infiltrate is predominantly perivascular and located in the perimysium and is composed primarily of macrophages, B cells, and plasmacytoid dendritic cells. Recent studies have highlighted some variability in histologic abnormalities associated with different MSAs. Skin biopsies reveal cell-poor interface dermatitis, which is analogous to the perifascicular atrophy in that the basal

A B

FIGURE 377-2 Perifascicular atrophy and myxovirus resistance protein A (MxA) expression in dermatomyositis. ***A.*** Perifascicular myofibers (*black arrows*) bordering on disrupted perimysial connective tissue are atrophic and basophilic on hematoxylin and eosin (H&E) stains. ***B.*** Perifascicular myofibers (*white arrows*) show intense staining for MxA protein along a gradient from superficial to deep; all capillaries show intense MxA expression (*white arrowheads*).

layer of keratinocytes is most damaged; the inflammatory infiltrate is typically absent or minimal and, when present, is located mainly at the border zone of the dermis and epidermis.

The pathogenesis of DM was traditionally attributed to an antibody-mediated attack on endothelial cells, followed by complement-mediated destruction of capillaries and watershed ischemia of muscle fibers. However, subsequent studies suggest that this is not likely the case. Immunoglobulin deposition is largely absent on endothelial cells, and complement deposition may be a secondary phenomenon. There is increasing evidence that the microvasculopathy and skin and muscle damage associated with DM are primarily due to toxicity from type I interferon (IFN)–mediated pathways, most likely IFN-β. As mentioned, there is increasing evidence that the MSAs are directly pathogenic. For example, anti-Mi-2 antibodies appear to be capable of entering myonuclei and inhibiting the CHD4/NuRD complex in the nucleosome.

Prognosis In the absence of malignancy, prognosis is generally favorable in patients with DM, with 5-year survival rates ranging from 70 to 93%. Poor prognostic features are increased age, associated ILD, cardiac disease, and late or previous inadequate treatment.

POLYMYOSITIS

Clinical Features PM is a heterogenous group of disorders that usually presents with symmetric and proximal weakness that worsens over several weeks to months. As with DM, there can be associated heart, lung, and joint involvement as well as an increased risk of cancer. Some epidemiologic studies suggest that the risk of cancer in PM is less than that in DM, but these older series likely included patients with IBM and dystrophies with inflammation who were misdiagnosed as having PM.

Laboratory Features CK levels are always elevated in uncontrolled PM. A normal CK should alert clinicians to the possibility of IBM. EMG and skeletal muscle imaging can be abnormal, but the findings are not specific **(Fig. 377-3)**.

Histopathology and Pathogenesis Because PM is a heterogeneous category, muscle pathology varies substantially. Most often, patients with nonspecific inflammatory cells present in perimysial more often than endomysial locations have been categorized as PM. A small minority of patients have a mononuclear inflammatory infiltrate that surrounds fibers with sarcolemmal expression of major histocompatibility complex (MHC-I) molecules **(Fig. 377-4)**. There is debate as to whether a true invasion of myofibers occurs in PM or rather always indicates IBM. The inflammatory infiltrate predominantly consists of CD8+ T cells and macrophages located in the endomysial, perimysial, and perivascular regions. PM is heterogeneous, and its varied forms of pathogenesis are poorly understood.

Prognosis Most patients with PM improve with immunotherapies but usually require lifelong treatment. Some retrospective studies suggest that PM does not respond as well as DM to these therapies. However, many of these older series of "PM" likely included patients who actually had IMNM, IBM, or other myopathies (including muscular dystrophies) that do not respond to immunotherapies. As in DM, poor prognostic features are cancer, increased age, lung or cardiac involvement, and late or previously inadequate treatment.

OVERLAP SYNDROMES

The term *overlap syndrome* is applied when an inflammatory myopathy is associated with other well-defined connective tissue diseases (CTDs) such as scleroderma, mixed connective tissue disease (MCTD), Sjögren's syndrome, systemic lupus erythematosus (SLE), or rheumatoid arthritis. Overlap syndromes are usually responsive to immunotherapies. The exception is Sjogren's syndrome with coexisting IBM.

IMMUNE-MEDIATED NECROTIZING MYOPATHY

Clinical Features IMNM, or autoimmune necrotizing myopathy, is characterized by the acute or insidious onset of symmetric, proximal more than distal weakness. Dysphagia, dysarthria, or myalgia may occur. Patients may have an underlying CTD (usually scleroderma or MCTD) or cancer (paraneoplastic necrotizing myopathy), or the condition may be idiopathic. There are at least two distinct forms of IMNM associated with specific autoantibodies (anti-HMGCR and anti-SRP). Anti-HMGCR myopathy can be seen in patients receiving statins, inhibitors of HMGCR, particularly in those aged >50 years. However, anti-HMGCR myopathy can develop in children and young adults without a history of statin use and can mimic a limb girdle muscular dystrophy. Unlike the more common "toxic" myopathy associated with statin use, anti-HMGCR myopathy does not improve when statins are discontinued. Anti-SRP myopathies are notable for the presence of anti-SRP antibodies and a typically subacute, aggressive, and relatively refractory course.

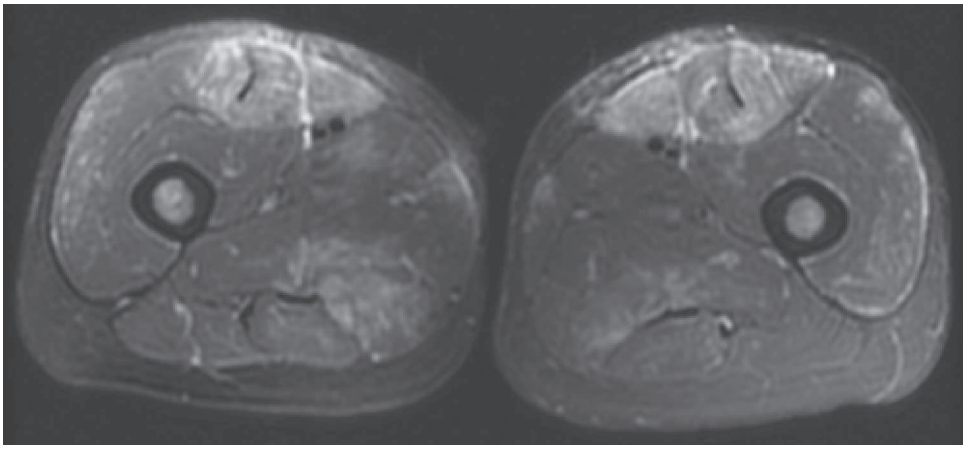

FIGURE 377-3 Skeletal muscle magnetic resonance imaging (MRI) with short T1 inversion recovery (STIR) imaging in polymyositis. MRI of the thigh demonstrates bright signal indicative of edema/inflammation, particularly in the rectus femoris muscle. This contrasts with MRI in inclusion body myositis in which there is more selective involvement of the vastus lateralis and medialis with relative sparing of the rectus femoris (see Fig. 377-7*F* and *G*).

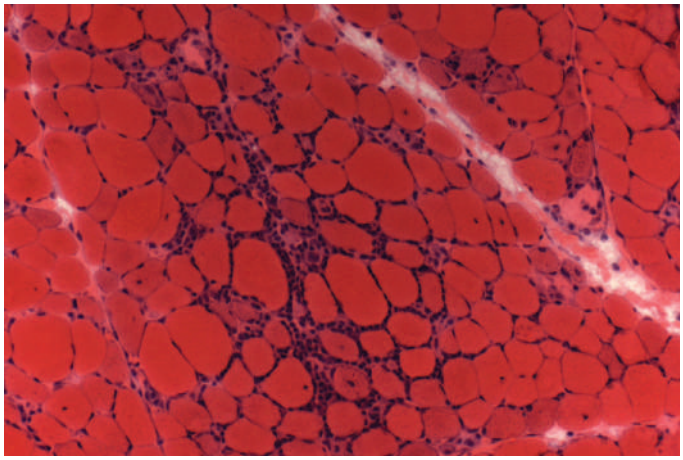

FIGURE 377-4 Pathology of polymyositis. Muscle biopsy demonstrates endomysial infiltrates surrounding nonnecrotic muscle fibers.

Laboratory Features CK levels are markedly elevated (usually >10 × normal) in IMNM and are associated with titers of anti-HMGCR or anti-SRP antibodies. EMG often shows increased insertional and spontaneous activity, including myotonic discharges. Skeletal muscle imaging findings are nonspecifically abnormal.

Histopathology and Pathogenesis Muscle biopsies reveal multifocal necrotic and regenerating muscle fibers with a paucity of inflammatory cells **(Fig. 377-5)**. However, some patients with anti-HMGCR myopathy have endomysial, macrophage-predominant infiltrates similar to what is seen in PM. Overexpression of MHC-I and membrane attack complex (MAC) molecules may be evident on sarcolemma of nonnecrotic fibers, and MAC deposition present on capillaries. The pathogenesis of IMNM is not completely understood and likely varies depending on subtype. A trial of a complement inhibitor in both anti-HMGCR and anti-SRP myopathies failed to demonstrate any efficacy, so IMNM in these subtypes does not appear to be primarily complement driven. Interestingly, pathogenic biallelic variants in the *HMGCR* gene result in proximal weakness, myalgias, high CK, and dystrophic changes on skeletal muscle MRI and biopsies. Recent studies suggest that HMGCR antibodies may bind to the receptor on the sarcolemma and lead to accumulation of acetyl-CoA and subsequently an increase in lipids within muscle fibers. Recent studies also suggest that anti-SRP antibodies are directly causal to the associated IMNM.

Prognosis Anti-HMGCR myopathy is often responsive to intravenous immunoglobulin (IVIG) monotherapy. However, anti-SRP myopathy and seronegative IMNM are generally much more difficult to treat, and aggressive immunotherapy is usually required. The progressive course despite immunotherapy and the marked weakness with atrophy can lead to a misdiagnosis of a limb girdle muscular dystrophy. There may be an increased incidence of cancer in patients with anti-HMGCR myopathy; thus, patients should undergo a malignancy workup.

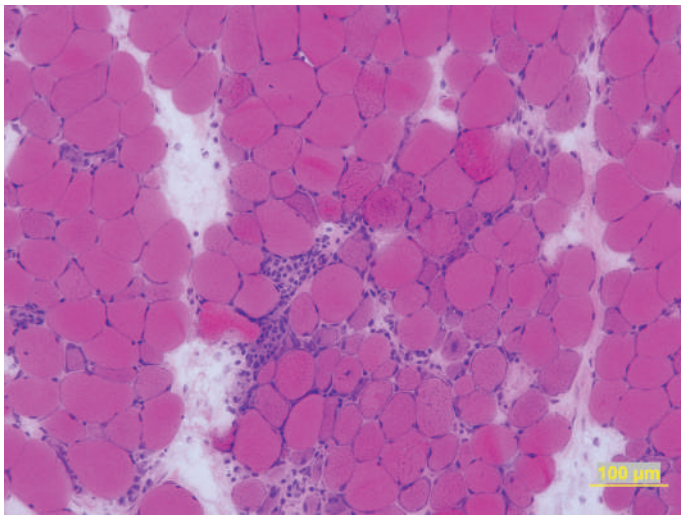

FIGURE 377-5 Pathology of immune-mediated necrotizing myopathy. Muscle biopsy demonstrates scattered necrotic fibers with inflammatory infiltrate confined to those fibers undergoing myophagocytosis along with a few regenerating fibers.

ANTISYNTHETASE SYNDROME

Clinical Features The presence of myositis, nonerosive arthritis, ILD, Raynaud's phenomenon, mechanic hands, and fever associated with antibodies against aminoacyl-tRNA synthetase constitute the ASyS. Some patients have an erythematous rash, and muscle biopsies share histopathologic features of DM, which likely accounts for many of these patients being classified as having DM.

Laboratory Features Antibodies against aminoacyl-tRNA synthetases are the most common MSA, present in 25–35% of patients with myositis. These include anti-Jo-1 (histidyl), anti-PL-7 (threonyl), anti-PL-12 (alanyl), anti-EJ (glycyl), anti-OJ (isoleucyl), anti-KS (asparaginyl), anti-Ha (tyrosyl), anti-Zo (phenylalanyl), and other less common antibodies. The most common aminoacyl-tRNA synthetase antibody is anti-Jo-1. CK is usually elevated in patients with ASyS and myositis. Those with ILD demonstrate reduced forced vital capacity and diffusion capacity on pulmonary function tests. Spiral chest computed tomography (CT) scans are best at demonstrating the honeycomb pattern of ILD. Skeletal muscle MRI and EMG show abnormalities similar to DM, PM, and IMNM.

Histopathology and Pathogenesis Muscle biopsies demonstrate a predilection for perimysial damage including perimysial fragmentation and staining with alkaline phosphatase **(Fig. 377-6)**, plasmacytoid dendritic cells and macrophages in the perimysium and around blood vessels, and MAC deposition on capillaries. Also similar to DM, there is perifascicular muscle fiber damage, but with ASyS, there is more perifascicular muscle fiber necrosis compared to DM, in which perifascicular atrophy is more prominent. MHC-I, MHC-II (HLA-DR), and MAC deposits on muscle fibers may be seen on sarcolemma of perifascicular muscle fibers. The HLA-DR expression on muscle fibers suggests that ASyS is more driven by gamma-IFN than type 1 IFN. Recent studies suggest that the various antibodies may be directly pathogenic by binding to specific aminoacyl-tRNA synthetases thereby impairing protein synthesis. More work needs to be done to confirm these observations.

Prognosis Most patients respond to treatment, although ASyS can be difficult to treat, in particular for patients with interstitial lung disease. Aggressive treatment, often with early rituximab, is warranted in such cases. There does not appear to be an increased risk of malignancy.

INCLUSION BODY MYOSITIS

Clinical Features IBM usually manifests in patients over the age of 50 years and is slightly more common in men than women. It is associated with slowly progressive weakness and muscle atrophy that has a predilection for early involvement of the wrist and finger flexors in the arms and quadriceps in the legs **(Fig. 377-7)**. Weakness is often asymmetric. Dysphagia is common and rarely can be the presenting feature. These clinical features can help distinguish IBM from PM and other forms of myopathy. The mean duration from onset of symptoms to use of wheelchair or scooter is ~15 years. There is no known increase in risk of malignancy.

Laboratory Features CK levels can be normal or only slightly elevated (usually <10 times normal). Antibodies targeting cytosolic 5′-nucleotidase 1A (cN-1A) are detected in the blood in a third to more than two-thirds of IBM patients and are a highly specific diagnostic biomarker for IBM among patients with myopathy. Other blood biomarkers for IBM include the presence of an abnormal population of large granular lymphocytes on flow cytometry and a reduced CD4/CD8

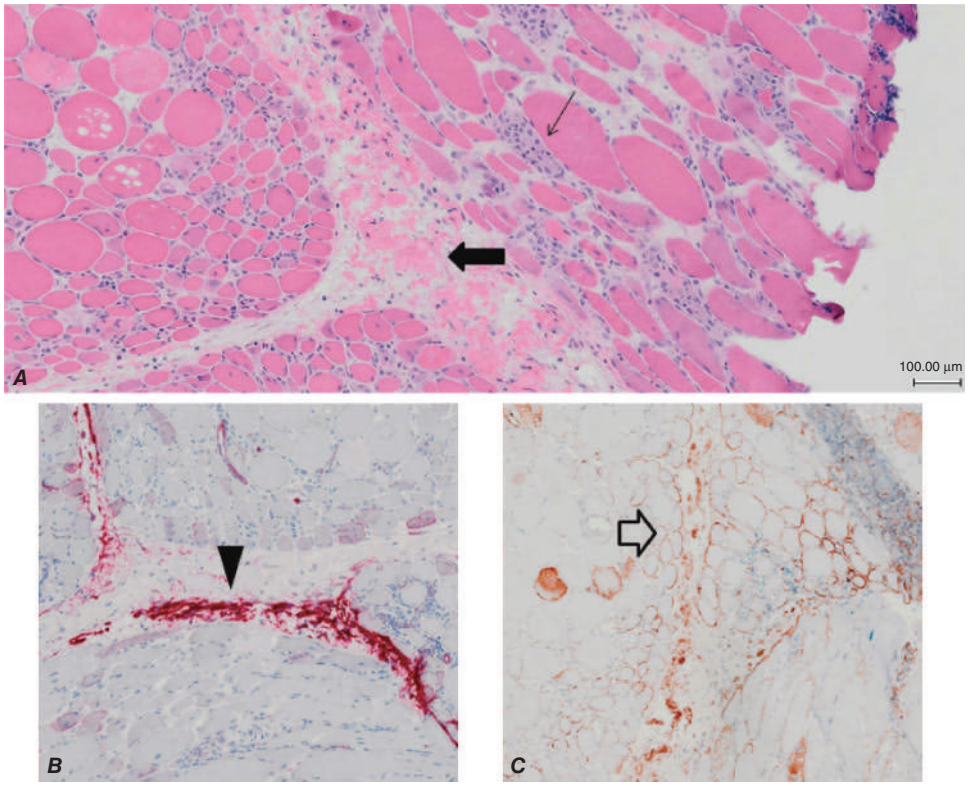

FIGURE 377-6 Pathology of myositis with anti-Jo-1 antibodies (antisynthetase syndrome). ***A.*** Perifascicular/perimysial muscle fiber atrophy and necrosis (*thin arrow*) associated with perimysial connective tissue is edematous and fragmented in appearance (*thick arrow*), hematoxylin and eosin stain. ***B.*** The perimysial connective tissue intensely stains red with alkaline phosphatase stain (*arrowhead*). ***C.*** Immunostaining demonstrates deposition of membrane attack complex (MAC) deposits on the sarcolemma of nonnecrotic perifascicular muscle fibers (*open arrow*).

ratio with an increased CD8 count. Needle EMG may demonstrate large-amplitude, long-duration motor unit potentials that can be misinterpreted as neurogenic but reflect the chronicity of the myopathy. Muscle MRI may show a predilection for involvement of the flexor digitorum profundus in the arms and the vastus medialis and lateralis muscles with sparing of the rectus femoris muscle.

Histopathology and Pathogenesis Muscle biopsies demonstrate endomysial inflammatory infiltrates predominantly composed of highly differentiated CD8+ CD57+ T cells that express killer cell lectin-like receptor G1 (KLRG1) molecules, plus macrophages, that surround and invade nonnecrotic muscle fibers expressing MHC-I and MHC-II on the sarcolemma, along with fibers with rimmed vacuoles, cytochrome oxidase (COX)–negative fibers, and inclusions on light or electron microscopy **(Fig. 377-8)**. The inclusions contain beta-sheet misfolded proteins (amyloid) but are difficult to appreciate with routine Congo red stain (they are seen on frozen but not paraffin sections). Immunostaining for p62 appears to be the most sensitive stain for detection of these inclusions. Importantly, rimmed vacuoles may not be seen in as many as 20–30% of muscle biopsies. In such cases, the presence of mitochondrial abnormalities (ragged red and COX-negative fibers) and immunostaining demonstrating p62 inclusions are

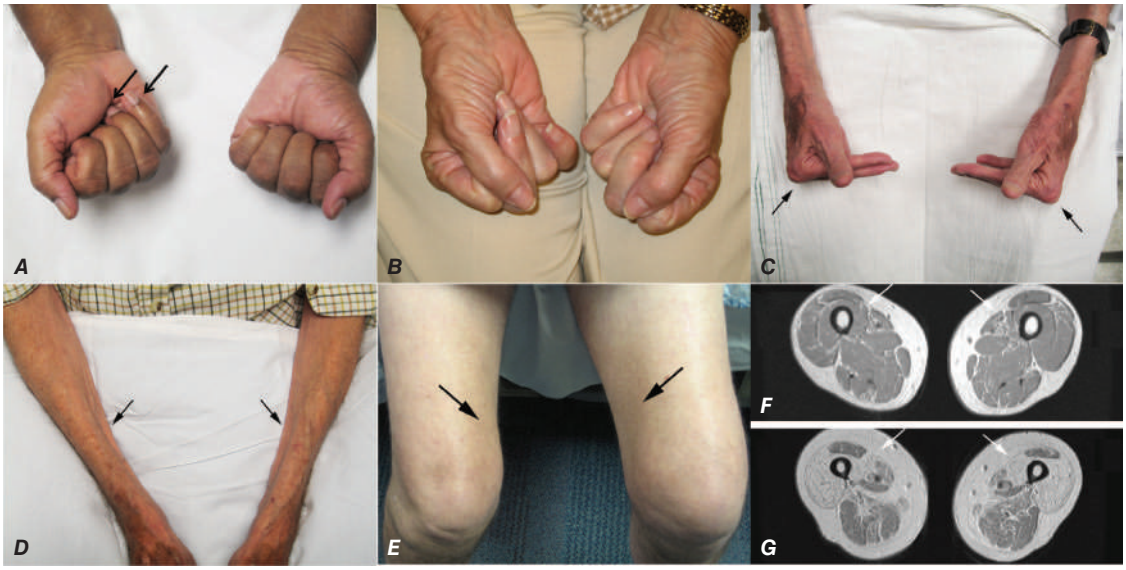

FIGURE 377-7 Muscle manifestations of inclusion body myositis (IBM; *A–C*). Finger flexor weakness can be (***A***) subtle and multifocal (*black arrows*), (***B***) moderate, or (***C***) severe. Note that even with complete paralysis of deep and superficial finger flexors, metacarpophalangeal joint flexion (*arrows*) is often maintained due to preservation of lumbricals. ***D.*** Ventral forearm atrophy (*arrows*). ***E.*** Atrophy of medial thighs due to loss of vastus medialis (*arrows*). ***F.*** Early IBM, with relatively preserved vastus medialis (*arrows*), in contrast to (***G***) advanced IBM with marked fibrous replacement of vastus medialis (*arrows*).

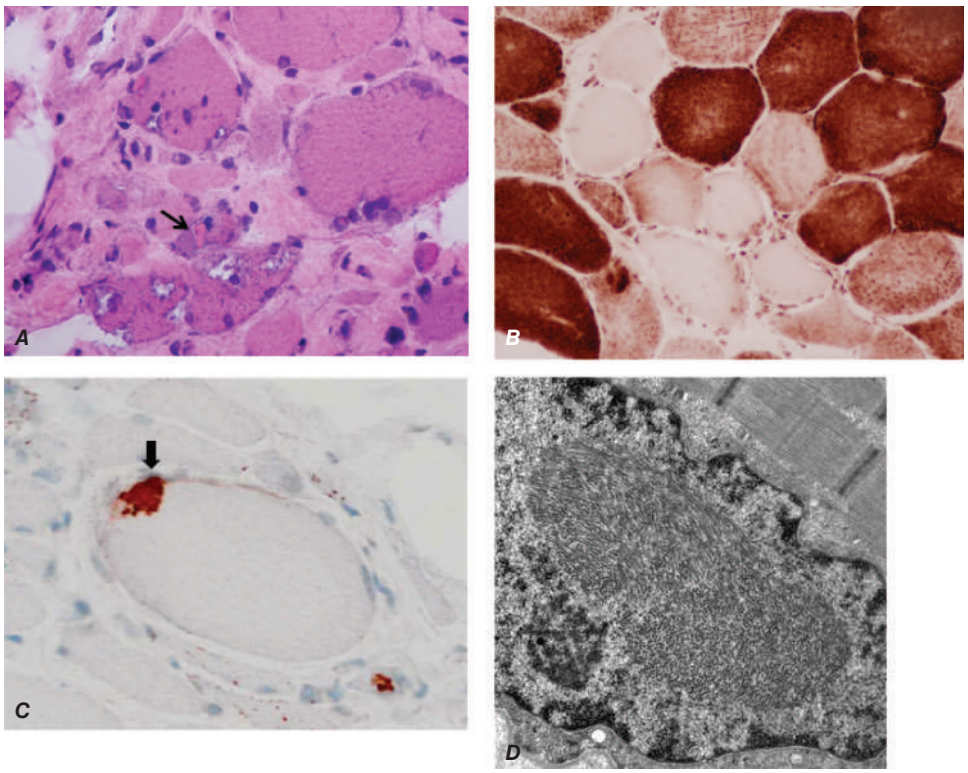

FIGURE 377-8 Pathology of inclusion body myositis. ***A.*** Scattered muscle fibers with rimmed vacuoles and rare fibers with eosinophilic inclusions (*arrow*), hematoxylin and eosin stain. ***B.*** Cytochrome oxidase stain demonstrates an increased number of pale-staining or COX-negative muscle fibers. ***C.*** Cytoplasmic inclusions stain positive with p62 within a muscle fiber (*thick arrow*). ***D.*** Electromicroscopy reveals 15- to 21-nm tubulofilamentous inclusions within a myonucleus.

helpful in distinguishing IBM from PM (aside from the clinical pattern of muscle weakness). Immunostaining also demonstrates that TAR DNA-binding protein 43 (TDP-43), an intranuclear RNA/DNA-binding protein involved in the regulation of RNA processing, is extruded from the myonuclei in IBM. This is similar to what is found in neurons of patients with neurodegenerative disorders such as frontotemporal dementia **(Chap. 443)** and amyotrophic lateral sclerosis **(Chap. 448)**.

The pathogenesis of IBM is poorly understood. The prominent adaptive immune system abnormalities related to T-cell inflammation and the presence of a relatively specific autoantibody against a muscle protein indicate an autoimmune attack on muscle. The chronic and highly inflammatory environment within muscles in IBM may alter protein synthesis and degradation pathways in part via aberrant immunoproteasome expression. Additional histologic features, typically referred to as "degenerative," include aggregation of various proteins including markers of endoplasmic reticulum (ER) stress and autophagy (e.g., p62 and LC3). Involvement of ER stress and autophagy has also been observed in other autoimmune diseases, such as primary biliary cholangitis (PBC), inflammatory bowel disease, and ankylosing spondylitis, some of which can be highly refractory to immunotherapy. As noted above, TDP-43, which is important for normal splicing of messenger RNA, is extruded from myonuclei in IBM; loss of TDP-43–mediated splicing repression likely leads to abnormal inclusion of cryptic exons in skeletal muscle and aberrant translation of muscle proteins. Whether this tissue damage results directly from a pathogenic immune response or a secondary neurodegenerative process is unclear at this time.

Prognosis The myopathy is slowly progressive and is not typically responsive to immunotherapies. Most patients require a scooter or wheelchair within 10–15 years of onset of symptoms.

TREATMENT OF INFLAMMATORY MYOPATHIES (TABLE 377-2)

DM, PM, ASyS, and IMNM are typically responsive to immunotherapy. High-dose glucocorticoids are considered the first-line treatment. There is uncertainty regarding when to start second-line agents (e.g., methotrexate, azathioprine, mycophenolate, immunoglobulin, or rituximab). The clinician must weigh with the patient the increased risks of immunosuppression versus possible benefits (e.g., faster improvement, steroid-sparing effects, and/or avoidance of morbidities associated with long-term glucocorticoid use). It is our general practice to start a second-line agent (typically methotrexate) with glucocorticoids in patients with severe weakness or other organ system involvement (e.g., myocarditis, ILD), those with increased risk of steroid complications (e.g., diabetics, osteoporosis, or postmenopausal women), and patients with IMNM who are known to have difficult-to-treat myositis. When treatment is initiated with prednisone alone, a second-line agent is added in patients who fail to significantly improve after 2–4 months of treatment or in those who cannot be tapered to a low dose of prednisone. Many patients with IMNM do not respond to prednisone alone or even prednisone plus a second-line agent in combination. Many require triple therapy with prednisone, methotrexate, and IVIG and, if this fails, rituximab. In our experience and that of others, anti-HMGCR myopathy often responds to monotherapy with IVIG.

Unfortunately, IBM does not typically respond to any known immunotherapy. The mainstay of treatment is physical and occupational therapy to improve function, and swallowing therapy (and sometimes esophageal dilation or cricopharyngeal myotomy) in those with dysphagia.

GENERAL GUIDELINES FOR USE OF SPECIFIC IMMUNOTHERAPIES

Glucocorticoids Treatment is initiated with prednisone (0.75–1.5 mg/kg up to 100 mg) administered as a daily morning single dose (the most common dose used in adults is 60 mg daily). In patients with severe weakness or comorbidities (e.g., ILD, myocarditis), treatment with a short course of intravenous methylprednisolone (1 g daily for 3 days) is recommended prior to starting oral glucocorticoids. Patients are generally maintained on high-dose prednisone until strength normalizes or until improvement in strength has reached a plateau (usually 3–6 months). Subsequently, prednisone can be tapered by 5 mg every 2–4 weeks. Once the dose is reduced to 20 mg every day or every other day,

TABLE 377-2 Immunotherapies for Inflammatory Myopathies

THERAPY	ROUTE	DOSE	SIDE EFFECTS	MONITOR
Prednisone	Oral	0.75–1.5 mg/kg per day to start	Hypertension, fluid and weight gain, hyperglycemia, hypokalemia, cataracts, gastric irritation, osteoporosis, infection, aseptic femoral necrosis	Weight, blood pressure, serum glucose/potassium, cataract formation
Methylprednisolone	Intravenous	1 g in 100 mL/normal saline over 1–2 h, daily or every other day for 3–6 doses	Arrhythmia, flushing, dysgeusia, anxiety, insomnia, fluid and weight gain, hyperglycemia, hypokalemia, infection	Heart rate, blood pressure, serum glucose/potassium
Azathioprine	Oral	2–3 mg/kg per day; single a.m. dose	Flu-like illness, hepatotoxicity, pancreatitis, leukopenia, macrocytosis, neoplasia, infection, teratogenicity	Blood count, liver enzymes
Methotrexate	Oral Subcutaneously	7.5–20 mg weekly, single or divided doses; 1 day a week dosing 20–50 mg weekly; 1 day a week dosing	Hepatotoxicity, pulmonary fibrosis, infection, neoplasia, infertility, leukopenia, alopecia, gastric irritation, stomatitis, teratogenicity Same as oral	Liver enzymes, blood count Same as oral
Cyclophosphamide	Oral Intravenous	1.5–2 mg/kg per day; single a.m. dose 0.5–1.0 g/m^2 per month × 6–12 months	Bone marrow suppression, infertility, hemorrhagic cystitis, alopecia, infections, neoplasia, teratogenicity	Blood count, urinalysis
Cyclosporine	Oral	4–6 mg/kg per day, split into two daily doses	Nephrotoxicity, hypertension, infection, hepatotoxicity, hirsutism, tremor, gum hyperplasia, teratogenicity	Blood pressure, creatinine/BUN, liver enzymes, cyclosporine levels
Tacrolimus	Oral	0.1–0.2 mg/kg per day in two divided doses	Nephrotoxicity, hypertension, infection, hepatotoxicity, hirsutism, tremor, gum hyperplasia, teratogenicity	Blood pressure, creatinine/BUN, liver enzymes, tacrolimus levels
Mycophenolate mofetil	Oral	Adults (1–1.5 g BID) Children (600 mg/m^2 per dose BID) (no >1 g/d in patients with renal failure)	Bone marrow suppression, hypertension, tremor, diarrhea, nausea, vomiting, headache, sinusitis, confusion, amblyopia, cough, teratogenicity, infection, neoplasia	Blood count
Intravenous immunoglobulin	Intravenous	2 g/kg over 2–5 days; then 1 g/kg every 4–8 weeks as needed	Hypotension, arrhythmia, diaphoresis, flushing, nephrotoxicity, headache, aseptic meningitis, anaphylaxis, stroke	Heart rate, blood pressure, creatinine/BUN
Rituximab	Intravenous	A course is typically 750 mg/m^2 (up to 1 g) and repeated in 2 weeks Courses are then repeated usually every 6–18 months	Infusion reactions (as per IVIG), infection, progressive multifocal leukoencephalopathy	Some check B-cell count prior to subsequent courses (but this may not be warranted)

Abbreviations: BUN, blood urea nitrogen; IVIG, intravenous immunoglobulin.

the taper is slowed to 2.5 mg every 2–4 weeks. The goal is to taper prednisone to ≤10 mg daily. Although most patients improve, the response may not be complete and many will require at least a small dose of prednisone or a second-line agent to have a sustained remission. Serum CK levels are monitored; however, dose adjustments of prednisone and other immunotherapies are primarily based on the objective clinical examination and not the CK levels or the patients' subjective response. When no response is noted after an adequate trial of high-dose prednisone, alternative diagnoses (e.g., IBM or an inflammatory muscular dystrophy) and a repeat muscle biopsy should be considered.

Relapse of the myositis needs to be distinguished from steroid myopathy. Features suggesting a steroid myopathy include weakness developing while on high dosage, a normal serum CK, clinical features of steroid excess such as ecchymoses and "moon facies," and absence of muscle membrane irritability on EMG. By contrast, patients experiencing relapses of myositis may become weaker during the prednisone taper, have increasing serum CK levels, and display abnormal spontaneous activity on EMG.

Intravenous Immunoglobulin IVIG is most often used in patients refractory to prednisone and at least one second-line immunosuppressive agent. However, the ProDERM Trial Group found IVIG to be effective in a randomized, controlled trial in patients with DM, leading to U.S. Food and Drug Administration (FDA) approval. Thus, IVIG can be administered as first-line therapy in DM. In addition, IVIG is effective as a monotherapy in anti-HMGCR myopathy and may be the treatment of choice. A dose of 2 g/kg is divided over 2–5 days, and repeat infusions are given at monthly intervals for at least 3 months. Subsequently, intervals can be lengthened or dosage decreased: 2 g/kg every 2 months or 1 g/kg per month.

SECOND-LINE THERAPIES

Methotrexate Methotrexate is usually the second-line treatment of choice because most authorities believe it works faster than other agents. An oral dose of 5 or 7.5 mg/week is initiated and then gradually increased as needed up to 25 mg/week. If there is no improvement after 1 month of 25 mg/week of oral methotrexate, a switch to weekly parenteral (usually subcutaneous) methotrexate is the next step, with dose escalation by 5 mg weekly; only rarely is a dose >35 mg/week used. The major side effects of methotrexate are alopecia, stomatitis, ILD, teratogenicity, oncogenicity, risk of infection, and pulmonary fibrosis, along with bone marrow, renal, and liver toxicity. Patients are concomitantly treated with folate or folinic acid.

Azathioprine A recommended initial dose is 50 mg/d in adults, which can be increased by 50 mg every 2 weeks up to 2–3 mg/kg per day. Approximately 12% of patients develop a systemic reaction characterized by fever, abdominal pain, nausea, vomiting, and anorexia that requires discontinuation of the drug. The major practical limitation of azathioprine is that 6–18 months of treatment are usually required before benefit can be seen. Patients can be prescreened for thiopurine methyltransferase (TPMT) deficiency that is associated with severe bone marrow toxicity from this drug.

Mycophenolate Mofetil This drug inhibits the proliferation of T and B lymphocytes by blocking purine synthesis. It appears to be effective in different forms of myositis and is the second-line treatment of choice for myositis patients with ILD. The starting dose is 1.0 g twice daily and can be increased to 3 g daily in divided doses, if necessary. Mycophenolate is excreted through the kidneys; therefore, the dose should be decreased in patients with renal insufficiency. An advantage

of mycophenolate compared to other immunosuppressive agents is the lack of renal or hepatic toxicity.

Rituximab Rituximab is a monoclonal antibody directed against CD20+ B cells. A large randomized controlled trial found no benefit, but there were flaws in the study design. Most authorities feel that rituximab can be beneficial in some patients who are refractory to prednisone and at least one of the other second-line agents. The typical dosage is 750 mg/m^2 (up to 1 g) IV with a second infusion 2 weeks later and with repeat courses (375 mg/m^2 as a single infusion or with a second infusion 2 weeks apart) every 6–18 months as needed.

Drugs in Clinical Trials Trials of a monoclonal antibody to block IFN-β and drugs to target downstream pathways (e.g., JAK-1) are ongoing in DM and other forms of myositis. Studies targeting the neonatal Fc receptor (FcRn) to decrease myositis-specific antibodies are underway in DM, ASyS, and IMNM, as are trials with chimeric antigen receptor (CAR) T-cell therapy. Ongoing trials in IBM include rapamycin as well as a trial of a monoclonal antibody binding to KLRG1 to deplete highly differentiated muscle-invading T cells.

MYOSITIS ASSOCIATED WITH CHECKPOINT INHIBITORS

Autoimmune neurologic complications, including inflammatory neuropathy **(Chap. 458)**, myasthenia gravis **(Chap. 459)**, and myositis, can occur with use of immune checkpoint inhibitors (anti-CTLA-4, anti-PD-1, and anti-PD-L1) to treat various cancers. Patients with myositis often develop muscle pain and weakness (axial musculature and proximal limbs) after one or two cycles. Myocarditis can also develop. Additionally, diplopia with extraocular weakness along with dysphagia and dysarthria suggesting the co-occurrence of myasthenia gravis (MG) may be present. In such cases, an elevated CK level helps support the diagnosis of myositis, while acetylcholine receptor antibodies or decremental response on slow repetitive nerve stimulation can establish the diagnosis of MG. Endomysial inflammatory cell infiltrates composed of macrophages expressing PD-L1 and CD8+ lymphocytes expressing PD-1, overexpression of MHC-I on sarcolemma of muscle fibers, and scattered necrotic and regenerating fibers can be found on muscle biopsies.

The immune checkpoint inhibitor should be discontinued, but most patients require concurrent treatment with glucocorticoids or IVIG. Patients generally improve over several months, during which time immunotherapy can be tapered. There are rare reports of patients with mild myositis who were able to be successfully re-treated with an immune checkpoint inhibitor.

MYOSITIS ASSOCIATED WITH COVID-19 INFECTION

Early series of patients hospitalized with COVID-19 report that as many as 44% of patients experience muscle pain or fatigue and 33% have elevated CK levels. Rare cases are complicated by myoglobinuria. Histopathology can demonstrate inflammatory cell infiltration and necrotic muscle fibers. In autopsy series, SARS-CoV-2 has not been demonstrated in muscle fibers, and the myositis is felt in most, if not all, to be due to cytokine storm. Whether COVID-19 infection can induce a chronic autoimmune myositis is controversial; there have been a number of reports of various types of IM, some with MSA, in patients following COVID-19 infection, but temporal associations do not equal causation.

GLOBAL ISSUES

There is a lack of epidemiologic data with regard to the incidence and prevalence of various subtypes of IM throughout the world. Complicating the issue is disease awareness and the inability to obtain and process muscle biopsies and MSAs, particularly in less developed countries. Nevertheless, each of these disorders occurs throughout the world. The specific environmental triggers and genetic risk factors are likely variable. Interestingly, a report from Japan found that 28% of IBM patients had evidence of exposure to hepatitis C, which was much higher than seen in the Western Hemisphere and also more common than seen in PM and healthy population controls in Japan. HIV-associated PM and IBM are more commonly encountered in areas endemic for HIV, and recent studies suggest most of these "PM" patients turn out to have IBM and can develop symptoms at an earlier age (e.g., in the 30s). Interestingly, while most cases of anti-HMGCR myopathy in North America and Europe are associated with prior statin use, the majority of such cases in Asia are not. Pyomyositis and parasitic myositis are clearly more common in the tropics. The prevalence of different types of cancers varies in different parts of the world, an important consideration with respect to paraneoplastic myositis. For example, nasopharyngeal cancer is particularly common in Asia; thus, assessment for this type of cancer should be considered in the workup of patients from high-risk regions.

378 Relapsing Polychondritis

Marcela A. Ferrada, Peter C. Grayson

Relapsing polychondritis (RP) is a rare systemic disease characterized by recurrent inflammation in cartilaginous structures. Involvement of the ears, nose, respiratory tract, and joints are hallmark features of the disease; however, other organs can be affected including the eyes, inner ear, nervous system, skin, and cardiovascular system. Some patients with RP may be concomitantly diagnosed with other rheumatologic diseases, such as Sjögren's syndrome or systemic lupus erythematosus. Recurrent chondritis of the ears and nose in older male patients with severe systemic inflammation and progressive bone marrow failure is associated with acquired hematologic mutations in *UBA1*, a condition now known as the VEXAS (vacuoles, E1 enzyme, X-linked, autoinflammatory, somatic) syndrome. Prompt recognition and accurate diagnosis of RP or VEXAS syndrome are essential to prevent life-threatening complications of these diseases.

The epidemiology of RP is poorly characterized. The disease is commonly reported to primarily affect middle-aged adults without a strong sex predilection; some cohort studies report female predilection,

but large, population-based studies typically show equal sex distribution. Children can be affected; however, these data are limited to case reports. Rare instances of familial aggregation have also been reported. The estimated incidence rate of disease is 0.7–3.5 cases per million per year, and prevalence estimates range from 4.5–25 cases per million. Epidemiologic data in RP are limited to older studies, typically evaluating population distributions more than three decades ago in cohorts from Europe and North America. Given the diagnostic challenges encountered in this condition, these data may underestimate the true prevalence of disease. Although RP has been reported in many regions of the world, whether racial or ethnic differences are associated with variable clinical features or outcomes is not known.

PATHOLOGY AND PATHOPHYSIOLOGY

Histologic findings from biopsy of affected cartilage are dependent on the timing of tissue sampling. In acute disease, a mixed inflammatory infiltrate of myeloid and lymphoid populations is observed at the cartilage interface. Over time, cartilage destruction is marked by lacunar breakdown and loss of chondrocytes, replaced by fibrosis. Biopsy of affected cartilage may cause morbidity, and there are no features on histology that are specifically diagnostic for RP. Therefore, biopsy is often reserved when there is a high suspicion of conditions that mimic RP, particularly infectious diseases and malignancies.

Although genetic, environmental, and immunologic aspects of the disease have been studied in humans and in animal models, the exact mechanisms that drive the disease are unclear. Limited studies in animal models support the concept that autoimmunity to cartilage components may play a role in RP. Immunization of specific animals to type II collagen, type IX collagen, or matrillin-1 can recapitulate various aspects of the clinical phenotypes observed in patients with RP; however, the performance characteristics of these antibodies in clinical practice are poor to differentiate RP from other diseases. Autoantibodies to type II collagen have been reported in small cohorts of patients with RP but are neither sensitive nor specific to be considered as an acceptable diagnostic marker of disease. Observational cohort data suggest that B-cell–depleting therapies are not particularly effective to treat the condition, arguing against a strong primary role of antibody-mediated disease.

Acute phase reactants (e.g., erythrocyte sedimentation rate or C-reactive protein) are not reliably elevated in patients with RP. Proinflammatory cytokines and chemokines related to both innate and adaptive immunity have been identified in association with RP; however, these findings are not consistent and, therefore, are not routinely measured to guide management in clinical practice.

CLINICAL MANIFESTATIONS AND ORGAN INVOLVEMENT

RP is associated with a wide range of clinical manifestations. In the absence of a diagnostic blood test, a detailed medical history and physical examination are the most essential tools for diagnosis and, most importantly, further management. Because disease activity is intermittent and patients may not exhibit clear signs of inflammation during direct evaluation, it is crucial to consider the patient's symptoms over time and to review any provided photographic documentation of disease features.

Ears, Nose, and Throat Ear involvement is one of the most common clinical manifestations of relapsing polychondritis, affecting 80–90% of the patients. However, there are no clear definitions of ear chondritis, and patient descriptions of pain and associated symptoms are variable. The typical description includes involvement of only the cartilaginous aspect of the ear (pinnae) **(Fig. 378-1*A* and *B*)**. However, a subset of patients may report pain in the ears with minimal associated findings visualized on physical examination, such as mild swelling or erythema **(Fig. 378-1*C*)**. Although damage to the cartilaginous portion of the external ear (i.e., "cauliflower ear") is observed in RP **(Fig. 378-1*D*)**, it is present only in a small number of patients, usually in the setting of recurrent episodes of ear inflammation. Questions that can be helpful to elicit the nature of ear pain include asking about onset, duration, and triggers. Common triggers include minimal trauma to the ear (such as from lying on the effected side or wearing glasses) or temperature changes.

Patients usually describe a sensation of pressure at the bridge of the nose that may not be accompanied by other associated symptoms. Some patients may have overt redness and swelling of the bridge or tip of nose, but this is less common **(Fig. 378-2*A*)**. While a "saddle nose" has been described as a typical clinical finding in RP, many patients will not develop an obvious nasal deformity **(Fig. 378-2*B*)**. The nasal septum and nasal passages should always be evaluated in patients with suspected RP, as many patients can have septal ulcers and mucosal inflammation. In contrast to granulomatosis with polyangiitis (GPA) where a saddle nose deformity is usually associated with a septal perforation **(Chap. 375)**, patients with RP who have a saddle nose deformity usually do not have

A ***B***

FIGURE 378-1 Representation of ear involvement in relapsing polychondritis. ***A and B.*** Examples of typical ear chondritis, with significant inflammation of the pinnae. ***C.*** Mild ear cartilage inflammation. ***D.*** Cartilage damage.

C D

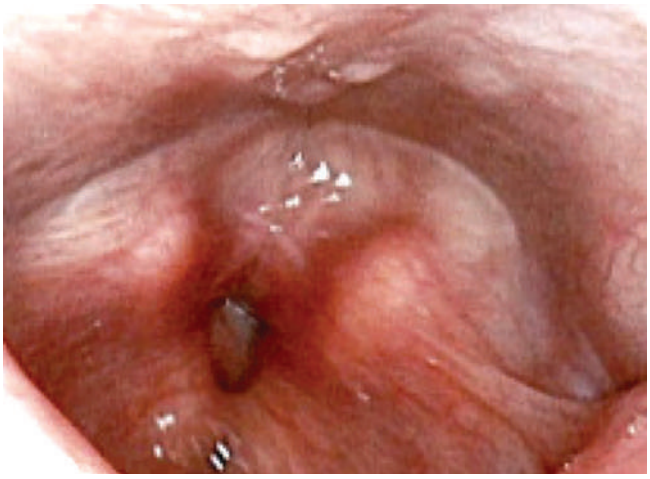
FIGURE 378-1 (Continued)

a septal perforation, as most of the nasal perforations in patients with RP are located anteriorly.

Patients can have complaints of throat pain or a sensation of globus, usually described as a "choking sensation." Patients can also report pain on the anterior aspect of the neck, in some cases associated with erythema, usually located at the level of the thyroid cartilage.

Upper and Lower Airway Conditions like subglottic stenosis may manifest acutely or subacutely, leading to cough, voice changes, or breathlessness. Severe narrowing can result in stridor, requiring urgent medical attention to avoid mortality **(Fig. 378-3*A*)**. Often misdiagnosed as adult-onset asthma, timely recognition of airway involvement is important to prevent chronic damage to the large airways, which can result in tracheomalacia, bronchomalacia, or tracheal calcification **(Fig. 378-3*B* and *C*)**. Patients with intermittent episodes of wheezing and with a review of symptoms positive for possible RP should be followed closely and further evaluated for lower airway involvement.

Musculoskeletal • **JOINTS** RP is associated with a nonerosive inflammatory arthritis that can affect small and large peripheral joints and as well as the axial skeleton. Erosions have been described in the sacroiliac joints but not in other joints. The most common large joint affected is the knees, often presenting with effusions. The pattern of small joint involvement emulates rheumatoid arthritis, without erosions or deformities.



TENOSYNOVITIS Different tendons can be affected including Achilles and peroneal tendons.

COSTOCHONDRAL JOINTS Located at the rib-sternum junction, these joints are frequently inflamed in RP, producing constant pain that

A B

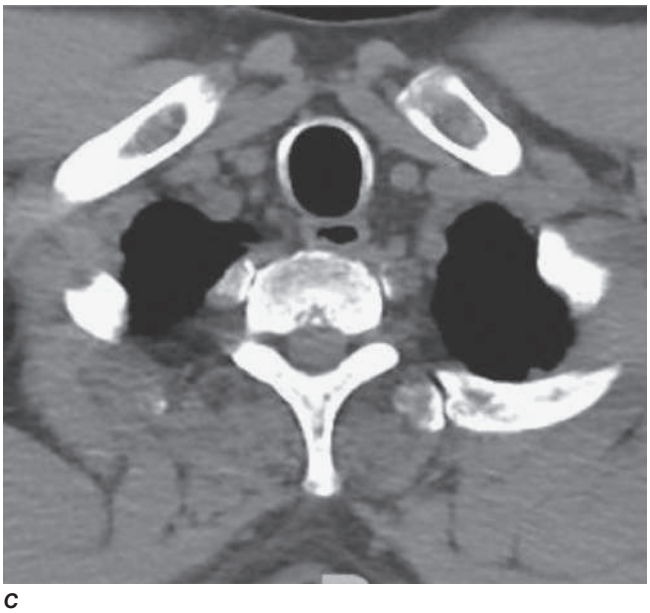


FIGURE 378-2 Nose involvement in relapsing polychondritis. ***A.*** Redness and swelling of the base and tip of the nose. ***B.*** Saddle nose deformity.

A

B

C

stands out due to its unique severe quality. Pain due to costochondritis can be so severe that patients will seek evaluation in the emergency room due to concerns for an acute coronary event. The pain is bilateral, reproducible with palpation, and not associated with movement of the affected rib.

Inner Ear All patients with RP should undergo hearing tests to evaluate for conductive and sensorineural hearing loss. During the physical exam, the ear canal should be evaluated as some patients can have severe inflammation or eustachian tube dysfunction leading to conductive hearing loss. The presence of dizziness necessitates further evaluation through maneuvers like finger-to-nose, Romberg, and nystagmus to rule out vestibular involvement.

Ocular Involvement Episcleritis is the most frequent type of ocular inflammation in RP. It might coincide with other flare symptoms or occur independently. Although rare, features suggesting scleritis mandate urgent ophthalmologic evaluation due to its potential catastrophic outcomes, including vision loss, scleromalacia, or global rupture necessitating enucleation **(Fig. 378-5*A*)**.

Cardiovascular Patients with mouth and genital ulcers with inflamed cartilage (MAGIC) syndrome may exhibit symptoms seen in Behçet's syndrome **(Chap. 376)**, including pathergy and gastrointestinal involvement. These patients can also have large-vessel vasculitis involving the aorta.

Neurologic The diagnosis of neurologic involvement due to RP is one of exclusion. All possible etiologies including infection and malignancy should be ruled out before attributing the clinical findings to RP; however, encephalitis and meningitis can be seen in RP.

DIAGNOSIS

There are no circulating or tissue-based biomarkers with adequate performance characteristics to function as a diagnostic test for RP. As such, diagnosis is based primarily on clinical pattern recognition informed by a comprehensive review of systems and physical examination. Several diagnostic criteria have been proposed; however, these criteria were developed in small cohorts, are largely based on expert opinion, and have not been formally validated. *McAdam's criteria* require presence of three of six symptoms, including bilateral auricular chondritis, nonerosive seronegative inflammatory polyarthritis, nasal chondritis, ocular inflammation, respiratory tract chondritis, or vestibular/cochlear dysfunction. *Damiani and Levine* modified McAdam's criteria to include either three clinical features or one clinical feature with histologic evidence of chondritis or two clinical features with clinical response to glucocorticoids, dapsone, or both. *Michet's criteria* propose three major criteria (inflammation of ear, nose, or respiratory tract) and four minor criteria (ocular inflammation, hearing loss, vestibular dysfunction, and seronegative inflammatory arthritis) and require fulfillment of two major criteria or one major plus two minor criteria to establish the diagnosis. Another important limitation of these criteria is the lack of precise definitions of organ involvement.

The differential diagnosis for RP includes conditions that mimic chondritis in specific cartilaginous organs and systemic diseases for which chondritis may be a manifestation. *Ear chondritis* can be mimicked by infectious and cutaneous diseases of the external ear, traumatic otohematoma, or red ear syndrome. Various infectious diseases and angiocentric centrofacial lymphoma can mimic *nasal chondritis*. Asthma, traumatic airway stenosis, infectious diseases, and congenital disorders involving the airway can mimic *airway chondritis*. Systemic diseases that mimic RP include GPA **(Chap. 375)** and autoinflammatory diseases **(Chap. 381)**. GPA can be differentiated from RP in part by the presence of antineutrophil cytoplasmic autoantibodies (ANCA) and glomerulonephritis, which are not features of RP. Presence of cytopenia, most notably macrocytosis and lymphopenia, in older male patients should trigger consideration of *genetic testing* and *bone marrow assessment* for VEXAS.

Audiometry to assess hearing loss and *dynamic expiratory phase computed tomography of the chest* to assess tracheobronchomalacia are critical studies that should be performed in all patients with suspected

RP to define the extent of disease involvement. *Direct laryngoscopy* can be useful to visualize cartilage damage and inflammation in the upper airway; however, *bronchoscopy* to visualize the lower airway can exacerbate disease and should be performed with caution. *Echocardiography* can assess valvular heart disease. *Fluorodeoxyglucose–positron emission tomography* may have utility to detect inflammation in the large arteries and the larger airways. *Biopsy of affected cartilage* often yields nonspecific findings and should be reserved to exclude mimicking conditions.

TREATMENT

Relapsing Polychondritis

Patients with RP can present to diverse specialists prior to diagnosis that can include multiple emergency room visits. Internal medicine doctors are typically among the first to encounter patients who present with the initial manifestations of RP and are instrumental in starting the initial treatment regimen.

Because RP is a systemic and heterogeneous disease, clinical management should typically involve multidisciplinary teams, including otolaryngologists (ear, nose, and throat specialists) and pulmonologists. Given the disease's propensity to progressively involve various organs, it is crucial to perform initial testing to define organ damage. If possible, patients should be referred to a rheumatologist for comprehensive evaluation, diagnosis confirmation, and the establishment of a tailored treatment plan.

Glucocorticoids are the cornerstone of initial treatment for inflammation in RP, with dosages tailored to the severity of the disease and the specific organs involved. In cases where life-threatening organ involvement, such as the airway, is present, high doses of glucocorticoids (e.g., 1 mg/kg of prednisone or an equivalent glucocorticoid) should be rapidly initiated. For patients with milder disease, lower doses of glucocorticoids can be trialed. Different disease-modifying agents can be used to treat the disease including methotrexate, leflunomide, mycophenolate, anti-interleukin-6, or tumor necrosis factor inhibitors. Due to the heterogeneity of the disease, treatment strategies are often determined by the predominant clinical phenotype.

379 Sarcoidosis

Alicia K. Gerke

Sarcoidosis is a systemic inflammatory disease of unknown cause characterized by the formation of nonnecrotizing granulomatous inflammation. Sarcoidosis affects the lung in >90% of cases but can afflict almost any other organ system as well. The disease was first described >150 years ago by Dr. Jonathan Hutchinson of London, England, as a skin malady of symmetrical purple plaques (later termed lupus pernio) and raised red lesions (Mortimer's malady). In 1899, the skin lesions were noted to be "sarkoid" by Caeser Boeck, a Norwegian dermatologist, as they resembled sarcoma, albeit the lesions were largely benign and granulomatous in their histology. The advent of imaging and other clinical technology later unveiled the multiorgan involvement associated with sarcoidosis. However, despite even modern advances in immunology, genetics, and genomics, there is still considerable mystery regarding the exact etiology of the inflammation and the factors that contribute to variability of disease presentation and clinical course. Because of this considerable heterogeneity and lack of large, randomized treatment trials, decisions regarding diagnosis and management continue to be challenging.

EPIDEMIOLOGY

Sarcoidosis occurs throughout the world, affecting all genders, races, and ages. Epidemiologic studies regarding the incidence, prevalence, and mortality rates of sarcoidosis are difficult to conduct and compare; this is due to the potential for nonstandardized case definition, differing methods of case acquisition, and lack of known etiology. Regional variabilities due to race and gender, as well as phenotypic variability, further confound epidemiologic measurements. Taken as a whole, epidemiologic studies highlight the variation in disease globally.

INCIDENCE AND PREVALENCE

The incidence and prevalence of sarcoidosis vary by race, gender, geographic region, ethnicity, and season. An increased familial risk has been noted. The highest incidence in the world occurs in African Americans (35.5 per 100,000) and Northern European populations (24 per 100,000) as described by studies from the United States and Sweden. A higher incidence occurring in women is consistent across most studies, although the ratio does not usually exceed 2:1. The U.S. Black Women's Health Study cohort found a particularly high annual incidence of 71 per 100,000 and a prevalence of 2%. Some studies suggest an increase in incidence over time in the populations of some countries such as the United States and Japan. Peak incidence of the disease occurs between 35 and 45 years of age, but a significant proportion of cases do happen after age 55, with men manifesting disease earlier than women. The overall perceived incidence rate may be underestimated, as identification of subclinical sarcoidosis may only be possible in screening population studies or at autopsy. Certain occupations and exposures and an elevated body mass index have been identified as risk factors for development of sarcoidosis, whereas smoking is associated with reduced odds of incident sarcoidosis. Seasonal variation is also reported, with a predominance of diagnoses occurring in the springtime.

Differences in presentation and severity are also seen among populations. Cardiac and ocular involvement are more commonly observed in Japanese populations, whereas Europeans tend to develop erythema nodosum, which is uncommon among Japanese and black populations. Several studies suggest that overall severity is higher in black populations, with black patients presenting with more frequent involvement of extrapulmonary disease and three times the likelihood of familial disease. Women are at increased risk for developing erythema nodosum and ocular, musculoskeletal, and neurologic disease, while men are at higher risk for hypercalcemia. While most sarcoidosis patients have lung involvement, black and female patients tend to have more severe lung disease. Finally, lower income has also been associated with severity of disease and potentially greater disability and impairment (particularly increased dyspnea and onset of new organ involvement), suggesting that socioeconomic status may impact disease course.

MORTALITY

Mortality rates vary considerably based on the study setting, with population screenings noting lower rates of mortality than those reported from referral centers. These occurrences may reflect differences in disease severity. Analysis of death certificates from the United States shows an average age- and gender-adjusted mortality rate of 4.32 per 1,000,000. Mortality rates are higher in women and in African Americans. Pulmonary fibrosis is the leading cause of death in this population. Lower mortality rates are seen in Japan, with estimates at 0.1 per million people. In Japan, mortality from sarcoidosis itself is usually attributed to cardiac involvement, whereas in Europeans and Americans, respiratory mortality predominates.

ETIOLOGY

The cause of sarcoidosis is unknown; however, current evidence strongly indicates a heightened host immune response to an undetermined environmental exposure in a genetically susceptible individual. It is unknown if there are multiple different antigens that induce the same disease process. The immunologic response in sarcoidosis appears to be physiologic, although it is either exaggerated or is deficient in its regulatory mechanisms. The transmissibility of the immune response also supports the presence of an antigen. For example, the Kveim-Siltzbach reagent (historically used to diagnose sarcoidosis) is a homogenate of human splenic tissue from patients with sarcoidosis that, when injected into the skin, induces a systemic granulomatous response in patients with early sarcoidosis. In a similar fashion, transplant recipients can develop a sarcoid-like inflammatory response after receiving organ tissue from another person with sarcoidosis.

Histologic inflammatory responses like sarcoidosis occur in the lungs of patients with known inorganic and organic exposures such as beryllium, mycobacteria, or fungi, resulting in these antigens being studied as potential causes. Mycobacterial proteins (e.g., mKatG, ESAT-6, mycobacterial superoxide dismutase A, antigen 85A, heat shock proteins) have been found disproportionately in sarcoidosis granulomas. Heightened macrophage immune responses against these peptides within blood and bronchoalveolar lavage (BAL) have also been noted in patients with sarcoidosis. In a similar manner in other cohorts, *Cutibacterium acnes* (formerly *Propionibacterium acnes*) has been implicated. A genetic predisposition is also suspected, as antigen recognition and presentation molecule polymorphisms have been associated with sarcoidosis development and phenotype. Similarly, gene–environment interactions have been identified, suggesting a complex interaction of a susceptible host in a predisposing environment.

Epidemiologically, the role of antigens in pulmonary sarcoidosis is further supported by case-cluster events and occupational association. Whereas numerous familial case clusters support a genetic predisposition to sarcoidosis in at least a proportion of cases, spatial clustering of nonrelated sarcoidosis cases suggests exposure to an inciting environmental antigen. For example, a baseline higher incidence is noted in U.S. firefighters, with an annual incidence of sarcoidosis occurring in 13–15 per 100,000 individuals. Following the World Trade Center event and building collapses, the rates of "sarcoid-like" disease were 86 per 100,000 in the first year and 22 per 100,000 over the next 4 years, with the highest risk associated with working in the debris piles. Interestingly, the cases included not only those with lung disease but also those with multisystem involvement, which would not be expected from a localized inhalational exposure. Additionally, employment in agriculture, teaching, metalworking, radiation, cotton ginning, and automobiles has also been associated with sarcoidosis.

Increased rates of sarcoidosis have been found in association with environmental exposures. Musty or humid environments, mold and mildew, insecticides, air conditioning, raising birds, and exposure to wood stoves/burning and fireplaces have been associated with increased risk of sarcoidosis. On the other hand, smoking is consistently a negative predictor of disease; the mechanism of this is unknown, although it is perhaps related to immunomodulatory effects of nicotine and smoke. These epidemiologic studies would indicate that the inciting exposure may be a bioaerosol or an inorganic agent, which may explain some of the epidemiologic variability of clinical presentation by race, age, gender, and ethnicity. Additionally, the inciting antigen may not be a single agent; rather, differing antigens may exist for each individual or population.

PATHOGENESIS

Like other granulomatous processes, granulomas of sarcoidosis are presumably forming around a poorly degradable or insoluble material that is identified and presented to lymphocytes by dendritic cells or macrophages via the major histocompatibility complex (Fig. 379-1). The initial innate immune response triggers the production of cytokines and chemokines that begin the cascade of granulomatous inflammation, attracting cells of the adaptive immune response. Activated lymphocytes and mononuclear cells migrate to the site of granulomatous inflammation in a process driven by amplification of oligoclonal T cells of undefined antigenic specificity. Type 1 (T_H1) immune polarization is the immunopathogenic hallmark of sarcoidosis, characterized by highly polarized CD4+ T_H1 lymphocytes and less so by CD8+ lymphocytes,

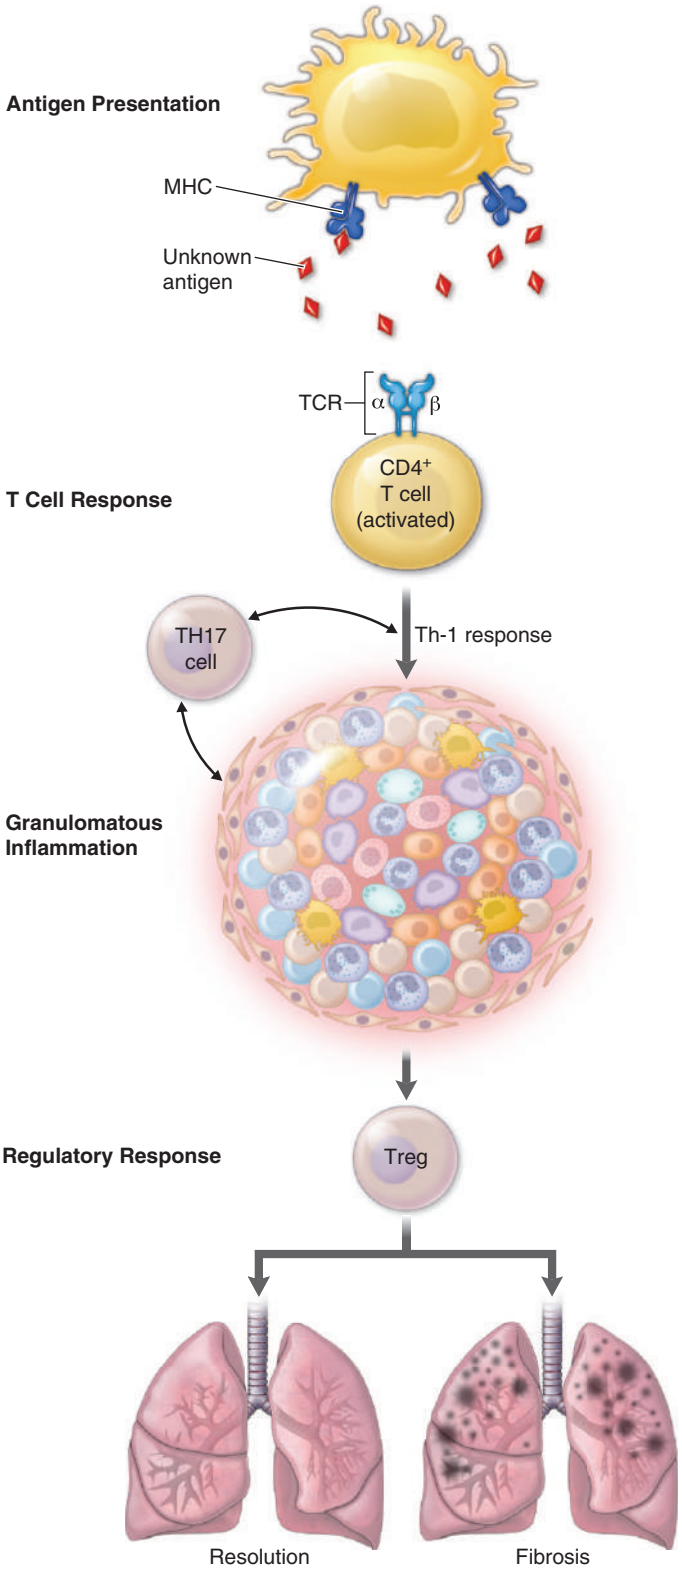

FIGURE 379-1 Immunopathogenesis of sarcoidosis. Granulomatous inflammation of sarcoidosis is presumed to be due to a heightened immune response to an undetermined antigen in a genetically predisposed individual. The antigen presentation via the major histocompatibility complex (MHC) activates CD4+ T cells, leading to a polarized T_H1 response. Activated lymphocytes, macrophages, and monocytes migrate to sites of inflammation, leading to a cascade of tightly formed noncaseating granulomas. Altered T-regulatory (Treg) and T_H17 responses are thought to be involved in lack of resolution of granulomatous inflammation or progression to fibrosis in some cases.

producing interferon-gamma (IFN-γ). T_H1-promoting immunoregulatory cytokines and chemokines (interleukin [IL]-1, IL-2, IL-15, IL-18, CXCR3) are consistently upregulated at sites of inflammation, propagating the immune response, activating macrophages, and forming granulomas. The accumulation of inflammatory cells at granuloma formation sites appears to be the result of both in situ proliferation and redistribution of the peripheral blood to the lung. Alterations in regulatory T cells and T_H17 cells may also play a role in the body's inability to control the inflammation. Although most patients with sarcoidosis eventually recover, the critical step as to why some patients with sarcoidosis transition to fibrosis is not understood.

CLINICAL PRESENTATION

The clinical presentation of patients varies considerably from asymptomatic to progressive organ dysfunction. Acute-onset presentation is seen in Löfgren syndrome in up to 10% of sarcoidosis cases (fever, erythema nodosum, ankle arthralgias, bilateral hilar lymphadenopathy) and, less commonly, Heerfordt syndrome (facial nerve palsy, fever, anterior uveitis, and bilateral enlargement of the parotid glands). These acute presentations typically have an excellent prognosis with full spontaneous resolution. In subacute or chronic cases, symptoms such as chronic cough, dyspnea, atypical chest pain, or intermittent joint or muscle pain tend to have a more insidious onset. In rare cases, presentation of sarcoidosis can be fatal, usually related to heart failure, sudden cardiac death, or neurologic involvement.

Symptoms vary depending on organ involvement and intensity of inflammatory response; therefore, patients can present to different clinical specialists. Nonspecific symptoms of fevers, malaise, night sweats, and weight loss are often present. More fulminant and organ-threatening symptoms can include acute hypercalcemia, blindness, arrhythmias, heart block, or neurologic demise, necessitating hospitalization. Cardiopulmonary symptoms such as cough, chest pain, or shortness of breath can mimic more common diseases, contributing to delays in diagnosis. In many cases, findings of sarcoidosis are found incidentally on imaging, prompting further workup.

ESTABLISHING A DIAGNOSIS

The diagnosis of sarcoidosis is made using three main criteria: (1) a compatible clinical presentation, (2) the presence of nonnecrotizing granulomatous inflammation in one or more tissues, and (3) exclusion of alternative causes of granulomatous inflammation. The diagnostic workup for sarcoidosis should also include assessment of extent and severity of organ involvement, a review of prognostic factors, and a determination of whether therapy will benefit the patient.

If a compatible clinical picture or radiographic finding suggests sarcoidosis, then biopsy should be considered as the next step. There are no well-established, clinically useful diagnostic serum biomarkers that can secure a diagnosis. Noninvasive sites for biopsy can include skin, conjunctiva, or superficial lymph nodes, but in cases where lung involvement and mediastinal/hilar lymphadenopathy are the prominent feature, bronchoscopy is the preferred method for diagnosis. Endobronchial ultrasound-guided lymph node sampling has high diagnostic yield and low procedural risk. BAL studies of lymphocyte subpopulations can be performed and characteristically reveal an elevated percentage of lymphocytes. A CD4:CD8 lymphocyte ratio >3.5 supports a diagnosis of sarcoidosis, particularly when combined with consistent clinical and radiographic findings (albeit a normal ratio does not exclude sarcoidosis). BAL is also important to exclude infection. Granulomas can line all segments of airway walls, providing the "cobblestone" appearance seen during bronchoscopy. If needed, transbronchial lung tissue biopsies can also be done to confirm sarcoidosis with lung infiltrates. Endoscopic ultrasound through the esophagus can be considered as an alternative biopsy approach based on clinical presentation and location of inflammation. Rarely, surgical lung biopsy or mediastinoscopy may be indicated when less invasive procedures have proven nondiagnostic and no other accessible sites for biopsy have been identified. ^{18}F-fluorodeoxyglucose (FDG) positron emission tomography (PET)–computed tomography (CT) can also be helpful to identify active tissue inflammation and a site to biopsy in difficult cases.

In some cases, the clinical presentation can be so compelling that lymph node sampling may not be necessary. For example, this can occur in patients with classic Löfgren syndrome, Heerfordt syndrome, or lupus pernio. Similarly, deferring biopsy in asymptomatic patients with symmetrical bilateral hilar lymphadenopathy may be considered based on patient-oriented discussions. In all cases, however, close clinical follow-up is still recommended, as the diagnosis of sarcoidosis is never fully secure.

PATHOLOGY

The sarcoidosis granuloma is an organized collection of macrophages, epithelioid cells, and multinucleated giant cells (which form as the epithelioid cells fuse). These cells are surrounded by a well-circumscribed rim of lymphocytes and fibroblasts. CD4+ T lymphocytes are also found interspersed within the granuloma center, while CD8+ T lymphocytes and B lymphocytes reside at the periphery. Sarcoidosis granulomas are nonnecrotizing; however, punctuate necrosis may be present on rare occasions. More abundant necrosis strongly indicates alternative causes of granulomatous inflammation such as infection, and loosely formed nonnecrotizing granulomas would suggest an alternative diagnosis such as hypersensitivity pneumonitis **(Fig. 379-2)**. Additionally, inclusions occasionally appear in sarcoidosis granulomas; these can include asteroid bodies, birefringent calcium carbonate or oxalate crystals, Schaumann bodies, and Hamazaki-Wesenberg bodies (especially in lymph nodes). Although most inflammatory granulomas tend to resolve, hyalinization and fibrosis of the granulomas can occur.

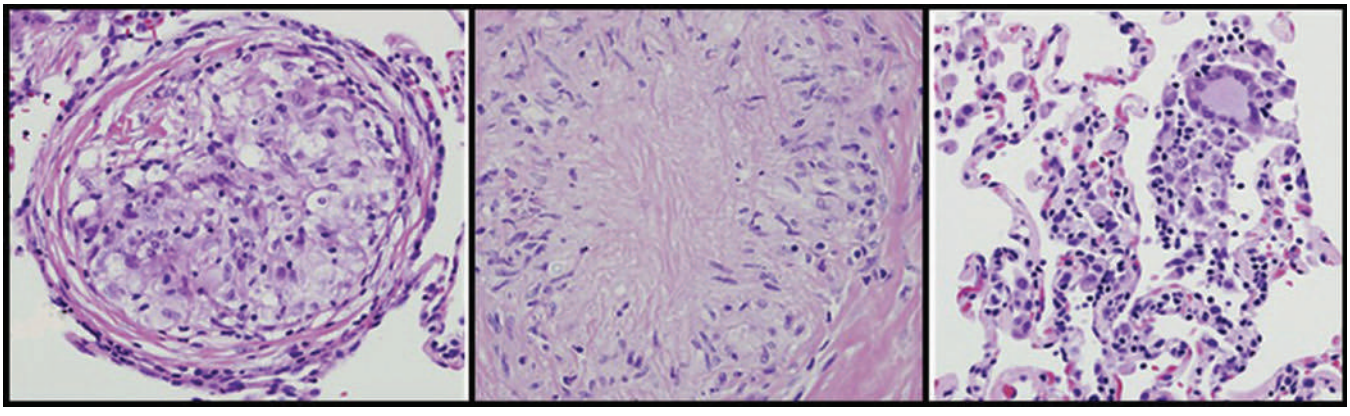

FIGURE 379-2 Comparison of granulomas. (***A***) The sarcoidosis granuloma is tightly formed and nonnecrotizing. (***B***) The infectious granuloma as seen in tuberculosis or fungal infections is tightly formed but with a necrotizing center. (***C***) The granuloma in hypersensitivity pneumonitis is loosely formed and without necrosis.

TABLE 379-1 Common Exclusionary Causes of Granulomatous Disease in the Diagnosis of Sarcoidosis

INFECTIONS	OTHER INFLAMMATORY DISEASES	MALIGNANCY RELATED
Mycobacterial infection • Tuberculosis • Atypical mycobacteria Fungal infection • Histoplasmosis • Coccidiomycosis • Blastomycosis • Aspergillosis • Cryptococcus Parasitic infection • Toxoplasmosis • Schistosomiasis Other bacterial and viral infection (less common) • Herpes zoster • Tularemia (*Francisella tularensis*) • Q fever (*Coxiella burnetii*) • *Bartonella henselae*	Environmental exposure • Hypersensitivity pneumonitis • Aspiration pneumonitis • Chronic beryllium disease • Silicosis • Talc inhalation or injection • Local or systemic reaction to tattoo ink Medication sarcoid-like reaction • Immune checkpoint inhibitors • Antiretroviral therapy • Interferon • TNF-α antagonist Autoimmune/Inflammatory • ANCA-associated vasculitis • Granulomatous-lymphocytic interstitial lung disease (associated with common variable immunodeficiency) • IgG4-related disease • Rheumatoid nodules • Inflammatory bowel disease • Bronchocentric granulomatosis	Malignancy • Local granulomatous reaction surrounding tumor • Systemic sarcoid-like reaction to malignancy Chemotherapy or immunotherapy • Sarcoid-like reaction

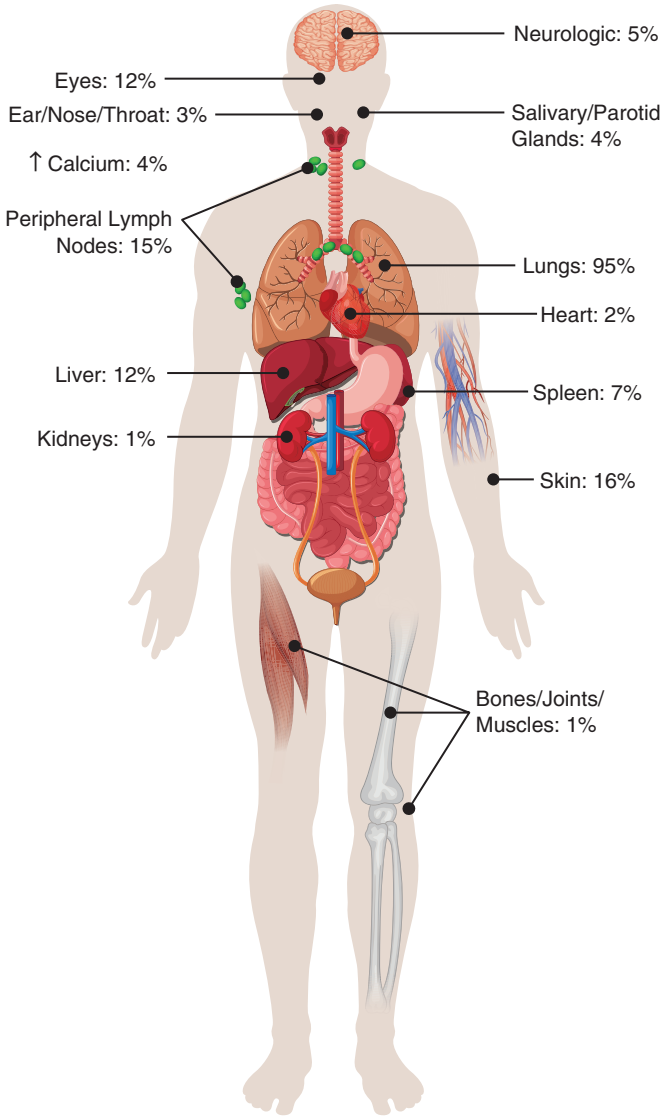

FIGURE 379-3 Frequency of organ involvement in sarcoidosis. Organ involvement upon presentation. *(RP Baughman et al: Am J Respir Crit Care Med 164:1885, 2001.)*

A histopathologic examination of the involved organ tissue reveals granulomas in sarcoidosis; however, diagnosis heavily relies on exclusion of other causes of granulomas. The differential diagnosis can be broad and must be considered in the clinical context (Table 379-1). A careful history assessment for environmental exposures or other inflammatory diseases is imperative to secure confidence in the diagnosis of sarcoidosis. Infections can be difficult to differentiate from sarcoidosis and require special histologic stains and cultures. Necrotizing sarcoidosis granulomatosis, characterized by necrosis, is a rare and less well-established entity that often involves vasculitis. Given the numerous causes of granulomatous inflammation and disease mimics, the diagnosis of sarcoidosis is never made with absolute certainty, and new symptoms or signs that occur during the disease process should be fully evaluated.

DIAGNOSTIC EVALUATION

The initial evaluation of sarcoidosis patients includes a complete history and physical exam, as well as assessment of organ involvement and severity of disease. Once diagnosis is suspected, a full review of symptoms is warranted to elucidate any potential pulmonary and extrapulmonary involvement, as about half of patients will have extrapulmonary involvement. Almost every organ system in the body can be affected by sarcoidosis (Fig. 379-3). A baseline set of testing (at minimum) should be done in all patients on initial evaluation, including pulmonary function tests, chest imaging, a baseline ophthalmologic investigation to evaluate for clinically silent uveitis, and an electrocardiogram (ECG) (Table 379-2). Serum tests for abnormal calcium metabolism and any significant hepatic, renal, or hematologic involvement should also be performed. Hematologic abnormalities are frequent and can be attributed to redistribution of T cells to sites of disease, splenic sequestration, granulomatous bone marrow involvement, or immune mediation. Routine asymptomatic follow-up testing is more controversial regarding its utility, but repeat testing should be done to evaluate the onset of any new signs or symptoms as the disease evolves. Abnormal initial testing may require further workup.

ORGAN INVOLVEMENT

LUNGS

The lungs are involved in >90% of patients with sarcoidosis. Pulmonary function tests are important to measure initial lung impairment and to assess improvement or deterioration over time. Many patients have normal lung function testing or a normal lung exam despite the presence of granulomatous inflammation and abnormal imaging findings. A restrictive pattern is often seen in those with more

Note: Further testing is dependent upon signs or symptoms indicating potential organ involvement.

advanced disease, and airflow obstruction can occur in up to one-third of patients. Sarcoidosis tends to be upper-lobe predominant on lung imaging. Chest x-rays are classically used to "stage," or describe the pattern of presentation in the lungs, known as Scadding stages (Fig. 379-4). Although chest CT is not indicated in every patient, it is commonly performed to determine extent of lung disease and to guide biopsies. Sarcoidosis granulomas have a lymphangitic distribution in the lung along the pleural and subpleural areas and interlobular septa and around the bronchovascular bundles. Classic findings of sarcoidosis on chest CT scans are widespread small nodules with a bronchovascular and subpleural distribution (Fig. 379-5*A*, *B*), thickened interlobular septa, mediastinal and hilar lymphadenopathy, and conglomerate masses with architectural distortion (Fig. 379-5*C*). In advanced cases of pulmonary involvement, CT findings include honeycombing, cyst or cavity formation, and bronchiectasis. Nodular sarcoidosis or necrotizing sarcoid granulomatosis can present with nodular masses. Pleural effusions tend to be indirectly related (e.g., infections, heart failure), but rarely, sarcoidosis can cause lymphocytic, exudative pleural effusions. Upper respiratory tract involvement can also occur rarely within the larynx, pharynx, and sinuses and is associated with more chronic severe disease.

Progressive pulmonary fibrosis with irreversible scarring is a significant cause of complications and death in patients with sarcoidosis. Fibrosis can be complicated by cavitary lung disease, chronic pulmonary aspergillosis or aspergillomas, and pulmonary hypertension. Airflow obstruction is common in these patients due to central airway scarring and distortion of the lung structure. Fibrosis can occur even in the setting of anti-inflammatory therapy.

HEART

Granulomas can infiltrate any part of the heart, causing rhythm abnormalities, heart failure, pericardial effusion, and even sudden death. In the broader general population, cardiac sarcoidosis is the cause of a significant proportion of cases of new-onset atrioventricular block, cardiomyopathy, and ventricular dysrhythmias, particularly in younger age groups. Clinical evidence of cardiac involvement in patients with

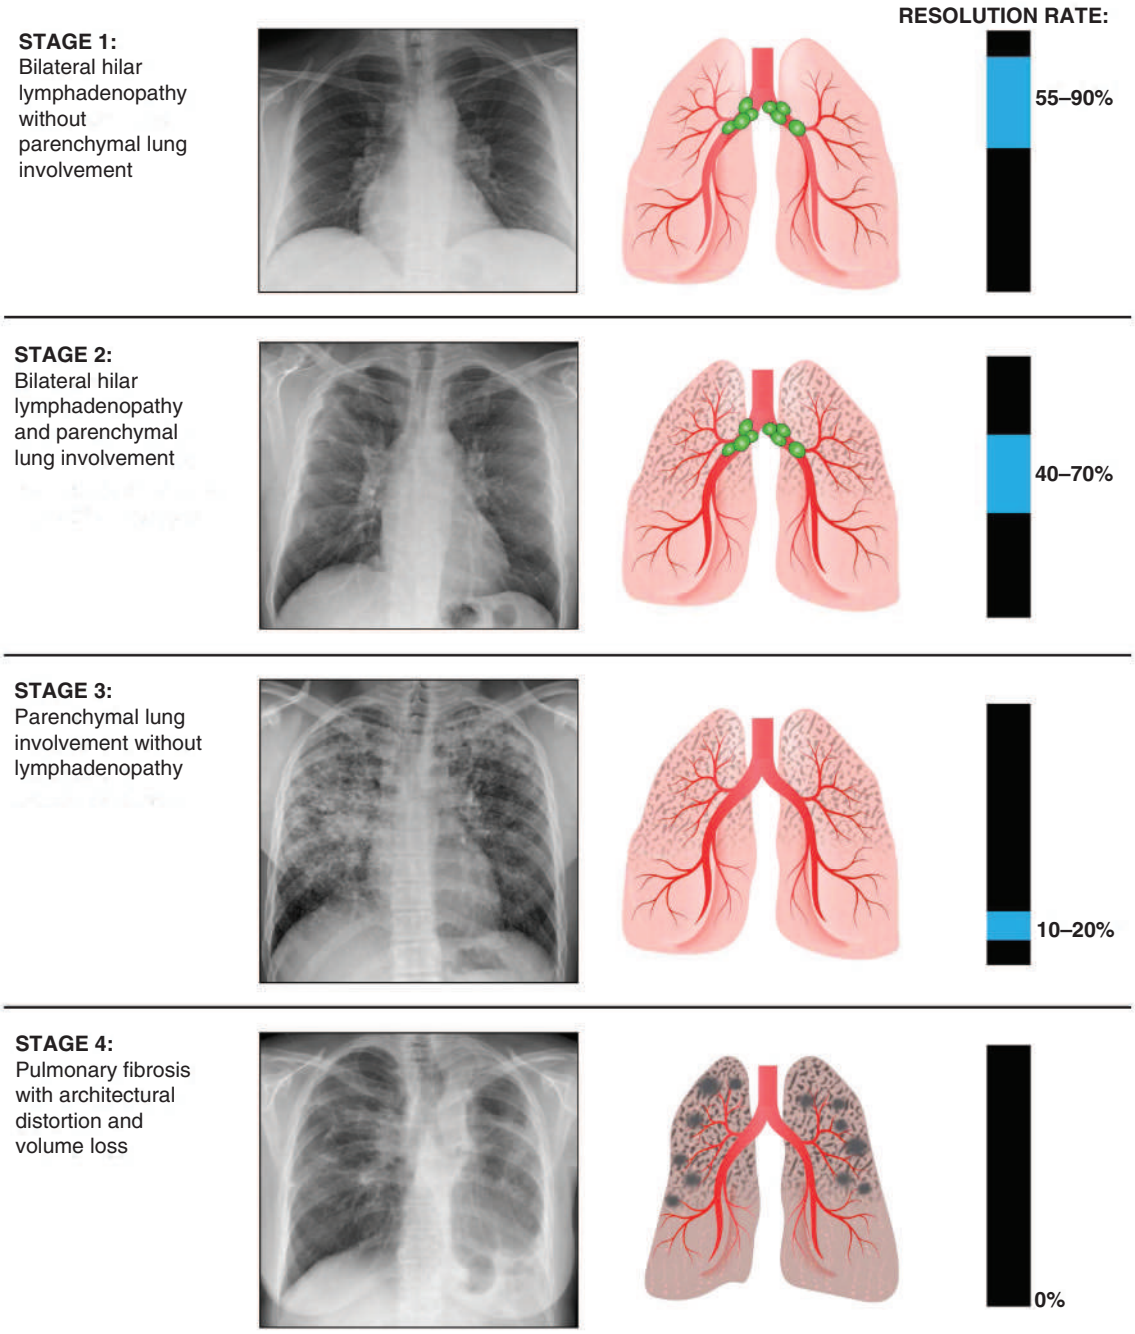

FIGURE 379-4 Scadding stages in sarcoidosis.

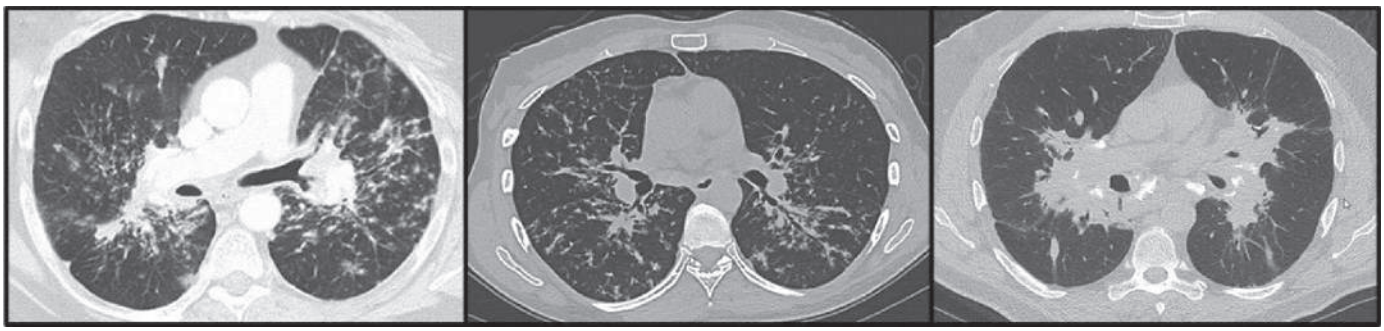

FIGURE 379-5 Imaging findings in sarcoidosis. (***A and B***) Chest computed tomography images of sarcoidosis show widespread small nodules in a perilymphatic and subpleural distribution and prominent bronchovascular bundle thickening. (***C***) Large peribronchovascular mass-like consolidations extending along the hila along with partially calcified mediastinal and hilar lymphadenopathy in a patient with sarcoidosis.

known sarcoidosis is found in <5% of U.S. sarcoidosis patients and 23% of Japanese patients, although autopsy studies suggest a higher rate of subclinical involvement. Severity of pulmonary involvement does not appear to predict the presence of cardiac sarcoidosis, and therefore every patient should be queried for potential cardiac symptoms, as cardiac sarcoidosis can have life-threatening complications. Isolated cardiac sarcoidosis can also rarely occur.

Sudden death is the most common cause of death among cardiac sarcoidosis patients, and it can occur as the initial presentation of the disease. Ventricular tachycardia is the most frequent tachyarrhythmia, but atrial tachycardias are also found in relation to ventricular dysfunction, dilated atria, or severe pulmonary disease. Heart failure is most often due to involvement of the myocardium but can also be caused by infiltration of valves or papillary muscles. Predictors of sudden death include severity of heart failure, left ventricular end-diastolic diameter, and sustained ventricular tachycardia.

Diagnosis of cardiac sarcoidosis can be difficult, since gold-standard biopsies lack sensitivity due to the patchy presence of granulomas in cardiac tissue, predominant location at base of the heart, and the lack of right ventricular involvement. ECG should be obtained on initial evaluation of every patient with sarcoidosis to reveal the presence of any conduction block, ST-T wave abnormalities, Q waves, frequent premature ventricular complexes, or resting tachycardia. Symptoms or unexpected abnormalities on ECG should prompt further cardiac evaluation, which can include a Holter monitor, signal-averaged ECG, or further cardiac imaging.

Several imaging tests are used for evaluating and diagnosing cardiac sarcoidosis. Historically, thallium-201 scintigraphy or technetium-sestamibi single-photon emission CT nuclear scans have been used to identify segmental defects that correspond either to a granulomatous disease or a fibrous scar. In contrast to coronary artery disease, patients with cardiac sarcoidosis have perfusion defects that reverse with exercise or dipyridamole, termed *reverse redistribution*. More current imaging studies now support the use of enhanced cardiac magnetic resonance imaging (MRI) as a preferred diagnostic tool due to its superior resolution and ability to detect early myocardial involvement with high sensitivity and specificity. Cardiac PET/CT can also be used in some cases to detect the presence of active inflammation in cases where cardiac MRI is unavailable, unable to be done (noncompatible devices or claustrophobia), or inconclusive. The use of these imaging techniques has largely obviated the need for myocardial biopsy in the diagnosis of cardiac involvement.

In patients with rhythm disturbances, prompt referral to an electrophysiologist is warranted for consideration of potential mapping or implantation of cardiac devices. Echocardiography can help identify ventricular dysfunction, valve dysfunction, abnormal septal wall thickness, or wall motion abnormalities that may also be contributing to the clinical picture.

Traditional treatments for cardiac arrhythmias and heart failure are indicated depending on the presentation, as well as immunosuppressive medications. The optimal amount of time dedicated to the course of immunosuppressive therapy is unclear, although the presence of cardiac sarcoidosis generally portends a more chronic and protracted course. Serial imaging and response to therapy can help guide potential therapy duration. Heart transplantation can be considered for refractory severe cardiac sarcoidosis, resulting in better short- and intermediate-term survival rates as compared to other transplant recipients.

PULMONARY ARTERY HYPERTENSION

Pulmonary hypertension (PH) in sarcoidosis, classified as a World Health Organization group 5 cause of PH, can complicate the clinical course and contribute significantly to morbidity and mortality. Pulmonary hypertension in sarcoidosis may be due to granulomatous vasculitis, pulmonary arterial occlusion by lymphadenopathy, thrombosis, pulmonary venous occlusion, destruction of the vascular bed, left heart dysfunction due to myocardial involvement, portopulmonary hypertension from associated liver cirrhosis, or hypoxic vasoconstriction related to parenchymal abnormalities. In some cases, precapillary PH can occur in the absence of other cardiopulmonary disease, resembling idiopathic PH. Evaluation for PH should be sought in patients who have symptoms that are disproportionate to the amount of parenchymal disease, have extensive parenchymal abnormalities, desaturate on 6-min walk test, or have a low diffusing capacity.

Echocardiography is a useful noninvasive technique screening test to evaluate pulmonary pressures, systolic or diastolic function, and valvular disease; however, right heart catheterization is the gold standard for diagnosis. Treating granulomatous disease with corticosteroids may result in the improvement of pulmonary pressures in some, but not all, cases, and pulmonary vasodilator therapy can be considered on a case-by-case basis.

NERVOUS SYSTEM INVOLVEMENT

Sarcoidosis affecting the nervous system is highly associated with systemic disease but also can occur in the absence of significant pulmonary or systemic disease. Cranial nerve involvement, particularly with the facial and optic nerves, is the most common manifestation and can be a result of granulomatous basal meningitis or direct involvement of the nerve. Facial nerve palsy is associated with good prognosis compared to other neurologic findings. Neurosarcoidosis has a predilection for the base of the brain. Inflammation of the hypothalamus and pituitary gland can cause neuroendocrine abnormalities that can persist even after immunosuppressive treatment. Other findings can include space-occupying masses, acute or chronic meningitis, peripheral neuropathy, and neuromuscular or spinal cord involvement. Rare presentations include seizures or neuropsychiatric symptoms.

Gadolinium-enhanced MRI is the preferred test for evaluating brain parenchyma, meninges, dura, and the spinal cord. MRI findings of leptomeningeal or parenchymal enhancement or multiple white matter lesions in a periventricular distribution are the more common abnormalities and are sensitive diagnostic findings. However, the appearance of sarcoidosis lesions is often nonspecific, mimicking malignancies or infections. Chest imaging can be helpful in diagnosis since many patients will have a pulmonary abnormality that can be biopsied. Cerebrospinal fluid (CSF) analysis most often reveals mononuclear cell pleocytosis and/or elevated proteins. Elevated CSF angiotensin-converting enzyme, high soluble IL-2 receptor, increased lysozyme,

decreased glucose, and oligoclonal bands can also be seen but are not diagnostic. CSF analysis is important to help exclude infection. Histologic confirmation of disease in the brain or spinal cord is occasionally necessary when significant diagnostic uncertainty exists or a patient is not responding to therapy. Otherwise, a diagnosis can be established with an acceptable degree of certainty by biopsy of a nonneurologic site, such as the lung, together with consistent clinical features and imaging and exclusion of other causes.

Peripheral nerves can also be affected in sarcoidosis. Pain is a common symptom among sarcoidosis patients and may be related to neuropathic or fibromyalgia syndromes. Small-fiber neuropathy has increasingly been noted to be a cause of pain and autonomic dysfunction. Large-fiber neuropathies can be evaluated by performing nerve biopsy or nerve conduction studies. Unfortunately, pain syndromes, regardless of their underlying cause, often do not respond well to immunosuppressive medications.

CUTANEOUS

Sarcoidosis causes many forms of skin lesions, with maculopapular, nodular eruptions and plaques being the most common types involving granulomatous inflammation of the tissue itself. Other skin lesions include infiltration of old scars or tattoos, hypo- and hyperpigmented areas, scales, annular lesions, ulcerations, and subcutaneous nodules or masses. Most of the time, lesions are not painful or pruritic. Nonspecific, nongranulomatous lesions of erythema nodosum are a well-established manifestation of sarcoidosis, commonly found in Europeans and women. Lesions are raised, tender, erythematous bumps or nodules found on the anterior legs and often a prominent feature of Löfgren syndrome. Lupus pernio is a distinctive chronic lesion and consists of indurated plaques and violaceous discoloration of the nose, cheeks, lips, and ears, and frequently involves the nasal mucosa **(Fig. 379-6)**. This lesion appears most commonly among members of the African-American female population. Lupus pernio is often associated with more severe disease including bone cysts, pulmonary fibrosis, and a prolonged clinical course. Overall, skin lesions can be treated with topical or injected corticosteroids, although disfiguring or symptomatic lesions may need systemic therapy.

EYE INVOLVEMENT

Ocular sarcoidosis can affect any part of the eye or orbit, with clinical manifestations ranging from asymptomatic to permanent vision loss. Given the potential for permanent vision loss, ophthalmologic examination is recommended on initial exam in sarcoidosis patients and with any change in visual symptoms. Uveitis (anterior, posterior, or panuveitis) is the most common manifestation and is often bilateral. Chronic uveitis may lead to synechiae formation, glaucoma, cataracts, cystoid macular edema, and blindness. Optic neuropathy can lead to sudden permanent vision loss and should be treated as an emergency with immediate initiation of immunosuppressive therapy. Other eye lesions include conjunctival or eyelid granulomas, lacrimal gland enlargement, keratoconjunctivitis sicca, dacryocystitis, retinal vasculitis, and periorbital swelling. If conjunctival nodules are present, biopsy can be a relatively noninvasive way to obtain diagnostic tissue.

LIVER

Hepatic granulomas are found very frequently in patients with pulmonary sarcoidosis (up to 80% in some autopsy studies) but are much less often clinically significant (up to 15%). Conversely, hepatic sarcoidosis can occur without involving the lungs. Liver function tests are abnormal in up to one-third of sarcoidosis cases, with an elevated alkaline phosphatase as the most common lab abnormality. Elevated transaminases are also frequent, while elevated bilirubin levels are more indicative of significant progressive sarcoidosis liver disease. Hepatomegaly is commonly seen. Patients who do present with symptoms experience abdominal pain, pruritus, fevers, weight loss, and jaundice. Hepatic sarcoidosis can infrequently progress to chronic cholestasis, hepatocellular disease, portal hypertension, Budd-Chiari syndrome, or cirrhosis. The pattern of presentation depends on the extent and location of granulomatous inflammation and fibrosis in the liver. Imaging of the liver often shows hepatomegaly and/or small, innumerable nodules of low attenuation. Extensive evaluation of alternative causes should be performed when cases of isolated hepatic granulomas are involved, because liver granulomas are associated with a large differential diagnosis. Immunosuppressives may be effective when a patient experiences symptomatic liver dysfunction, but not in every case. Liver transplantation remains a viable option when hepatic failure occurs.

MUSCULOSKELETAL

Acute arthritis (such as that seen in Löfgren syndrome) is common in sarcoidosis, especially early in the course of disease. Pain is a potential indication to treat. Chronic arthritis or synovitis is rarer than the acute presentations. The most common joints affected by sarcoidosis are the ankles, knees, elbows, wrists, and small joints of the hands and feet. Bone lesions, characteristically identified as lacy, reticular osteolytic lesions on radiographs, can be frequently asymptomatic but occasionally cause pain. Bone marrow involvement can cause hematologic abnormalities such as anemia and lymphopenia.

Cases of symptomatic muscle involvement present with pain, tenderness, or weakness and have physical findings that are consistent with myositis, chronic myopathy, or muscle nodules. Myopathy is more commonly found in women and can be the sole presentation of disease. MRI or nuclear bone scans are useful to identify active inflammation in patients with musculoskeletal symptoms or to differentiate nonsarcoidosis causes. Electromyogram studies and biopsy may also be helpful in the diagnostic workup.

HYPERCALCEMIA

Hypercalcemia occurs in only about 10–20% of patients with sarcoidosis, but hypercalciuria is much more frequent and is seen in up to 50%

FIGURE 379-6 Cutaneous sarcoidosis. Extensive involvement of the nose and philtrum extending onto the cheeks is seen. The lesions include confluent papules and plaques, some of which are vaguely annular on the philtrum. *(Courtesy of Dr. Misha Rosenbach, MD.)*

of patients. High calcium levels are due to dysregulated production of the active form of vitamin D (1,25-hydroxyvitamin D_3 or calcitriol) by activated macrophages and granulomas in the setting of abundant cytokines such as IFN-γ. Normally, conversion of vitamin D to its active form is a highly regulated process that occurs in the kidney via the action of 1-alpha-hydroxylase (CYP27B1) controlled by parathyroid gland. The conversion of vitamin D to calcitriol by macrophages occurs unregulated, causing increased intestinal absorption and bone resorption and thereby raising serum calcium despite low parathyroid hormone levels. Hypercalcemia, left untreated, leads to nephrocalcinosis and subsequent renal dysfunction. Patients with evidence of hypercalcemia should monitor vitamin D intake, avoid excessive sunlight, and maintain hydration. In severe acute symptomatic cases, hypercalcemia is a cause of hospital admission requiring more urgent corticosteroid therapy.

KIDNEY

Renal dysfunction is mostly related to hypercalcemia and nephrocalcinosis associated with sarcoidosis, rather than direct granulomatous infiltration. However, sarcoidosis can cause interstitial nephritis (with and without granulomas), which is generally responsive to treatment. Urinalysis usually reveals sterile pyuria, bland sediment, or mild proteinuria.

LYMPHOID SYSTEM

Peripheral lymphadenopathy can be the presenting sign of sarcoidosis in a minority of cases. The extrathoracic glands most frequently involved are the cervical, axillary, epitrochlear, and inguinal glands. Enlarged glands are discrete, movable, and nontender without ulceration or drainage. Splenomegaly in sarcoidosis is common but is usually clinically silent. Hypodense nodules can be seen on imaging. Infrequently, splenic involvement may cause pressure, pain, constitutional symptoms, or hematologic abnormalities that require splenectomy.

PAROTID GLANDS

Parotid or salivary involvement occurs in 4% of sarcoidosis patients, often associated with Heerfordt syndrome (parotitis, uveitis, fever, facial palsy). Patients with parotid gland involvement can be asymptomatic or present with painful, swollen glands or xerostomia. Parotid enlargement is self-limiting in many cases and can present like Sjögren's syndrome.

GASTROINTESTINAL TRACT

Gastrointestinal tract involvement is a rare manifestation of sarcoidosis and most commonly involves the stomach than any other parts. Patients may present with dysphagia, bleeding, nausea or vomiting, pain, weight loss, or obstructive symptoms.

REPRODUCTIVE ORGANS

Granulomas may occur in the reproductive system, most commonly appearing within the female uterus or the male epididymis. Given the rarity of involvement, any new nodules or masses in these organs require careful attention to exclude malignancy.

CLINICAL COURSE AND PROGNOSIS

In just over half of patients, the disease resolves spontaneously; however, a significant proportion (30–40%) of patients will have chronic disease that threatens vital organs or causes debilitating symptoms, necessitating treatment. Chronic symptoms can be progressive or waxing and waning. Predicting clinical course on presentation in any one individual is difficult, given lack of known prognostic biomarkers. Research studies are often confounded by the variable clinical course and the lack of correlation of serum and radiographic measures to the intensity of granulomatous response. Most cases of sarcoidosis will show improvement in chest radiography or spirometry after 2 years of follow-up, including treated and untreated. Serious extrapulmonary involvement (e.g., cardiac, central nervous system, hepatic) occurs in 4–7% of sarcoidosis patients at presentation and can develop as the disease evolves. Relapses are common and are associated with shorter treatment duration. Acute exacerbations of pulmonary sarcoidosis are thought to occur in over one-third of patients, although they are not well-defined.

Death related to sarcoidosis itself does occur in 1–5% patients because of progressive respiratory insufficiency, complications of pulmonary scarring (e.g., hemoptysis, infection, aspergilloma), central nervous system involvement, liver failure, or myocardial involvement (heart failure, cardiac block, sudden cardiac death, or arrhythmias). Differing mortality rates reflect variances in disease severity, referral bias, and diverse genetic and epidemiologic factors of the populations studied. For instance, most deaths occurring in the United States and Northern Europe are due to pulmonary complications, whereas a vast majority of deaths due to sarcoidosis in Japanese patients are from cardiac involvement. Complications of immunosuppressive therapies can also contribute indirectly to mortality. Transplantation of the lungs, heart, liver, or kidneys can be lifesaving in severe progressive cases.

CLINICAL FACTORS OF PROGNOSTIC SIGNIFICANCE

Overall, patients with a more robust initial immune response have a better prognosis than those with more subacute or chronic presentation. Patients that present with Löfgren or Heerfordt syndromes tend to have an excellent prognosis with spontaneous remission in up to 80%. Löfgren syndrome occurs in 20–30% of Caucasians with sarcoidosis, particularly Northern Europeans, and <5% of Asians and African Americans. Erythema nodosum and fever usually remit spontaneously within 6 weeks, while resolution of lymphadenopathy may be delayed for over a year. Immunosuppressive therapy is rarely necessary. On the other hand, adverse clinical prognostic factors include lupus pernio, chronic uveitis, older age, chronic hypercalcemia, nephrocalcinosis, African origins, pulmonary hypertension, fibrotic pulmonary sarcoidosis, sinus involvement, cystic bone lesions, neurosarcoidosis, and cardiac involvement. Parenchymal infiltrates associated with Scadding radiographic stages do not predict activity, progression of lung disease, or extrapulmonary involvement but do reveal overall resolution rates (Fig. 379-4).

PREDICTIVE VALUE OF SERUM, BRONCHOALVEOLAR LAVAGE, AND GENETICS

There are no current clinically used biomarkers that can predict clinical course in any one case. Serum angiotensin-converting enzyme (ACE) levels, derived from macrophages, are not largely useful as a diagnostic or prognostic tool due to low sensitivity. However, ACE levels have been employed to monitor systemic disease activity, as they correlate roughly with the granulomatous burden. Similarly, the T-cell–derived soluble IL-2 receptor lacks sensitivity for diagnosis but correlates with disease activity and may predict relapse rate. In BAL fluid, the high CD4:CD8 ratio, although supporting a diagnosis, does not correlate with disease progression or need for treatment, but higher values seem to implicate a better overall prognosis. Increased percentages of BAL neutrophils (or eosinophils) appear to be present in a higher proportion of individuals with progression. In genetics, certain human leukocyte antigen (HLA) haplotypes have been associated with acute and chronic phenotypes. Similarly, variants of butyrophilin-like 2 (*BTNL2*), tumor necrosis factor alpha (*TNF*-α), and annexin A11 (*ANXA11*) genes have been associated with worse prognosis. Unfortunately, these and multiple other serum and BAL markers lack generalizability and utility in the clinical realm for any one individual.

FOLLOW-UP AND MONITORING

To assess prognosis and determine the need for therapy, longitudinal surveillance of sarcoidosis should be most intensive during the 2-year period following presentation with decreasing frequency as time goes on. When therapy has started, follow-up of response and side effects should be done in 1–3 months and, once stable on therapy, every 3–6 months. Once in full remission, patients should be followed for a few years to assess for relapses; however, lengthier observation may be necessary based on severity of disease or residual organ dysfunction. Follow-up testing should include symptoms, a complete physical exam, imaging of affected organs, periodic pulmonary function testing, and

markers of specific organ dysfunction. Choice of imaging depends on clinical scenario and can include chest x-rays, CT scans, and in some rarer cases, PET/CT or MRI. Any development of new symptoms over time should prompt full evaluation of that organ system.

TREATMENT

Sarcoidosis

Treatment decisions in sarcoidosis are complex, and medication options tend to be guided by expert opinion, uncontrolled trials, and only a few larger randomized controlled trials. There is no cure for sarcoidosis; the goal of treatment is to suppress granulomatous inflammation, prevent irreversible organ fibrosis, and alleviate debilitating symptoms as the disease evolves. With the high side effect profile of corticosteroids and other immunosuppressive therapy, it is first important to identify those cases in which therapy is indicated. For example, treatment is not indicated for asymptomatic stage I disease, which has an inherent high rate of spontaneous resolution. Mild symptoms may be closely monitored, and topical immunosuppressive therapies are preferred for skin disease if possible. Oral immunosuppressive therapy should be reserved for those who have significant symptoms, disfigurement, or dangerous impending organ damage. In pulmonary disease, this may include worsening cough and shortness of breath, moderate to severe parenchymal lung involvement, or a progressive decline in pulmonary function. In each case of sarcoidosis, the risks and toxicity of immunosuppression must be considered in comparison to the potential benefit of treatment.

Corticosteroids remain the mainstay of first-line treatment, although controversy exists regarding whether they alter the natural history. Oral steroids have been shown to improve chest x-ray imaging scores, symptoms, and spirometry in the short term. There are limited data beyond 2 years to indicate whether oral steroids have any modifying effect on long-term disease progression or mortality. In cases of intolerance or toxicity to corticosteroids, inability to taper corticosteroids, or refractory disease, alternative steroid-sparing immunosuppressives can be considered **(Table 379-3)**. In choosing a therapy, clinicians should take into consideration the presence of comorbid conditions such as osteoporosis, diabetes, cataracts, or glaucoma that may be aggravated by corticosteroids. Organ transplantation is occasionally necessary in cases of progressive organ damage including lungs, liver, heart, and kidney. Sarcoidosis can recur in transplanted organs but is rarely a cause of organ failure after transplant.

CORTICOSTEROIDS

When it is determined that treatment is indicated, corticosteroids are generally used as first-line therapy given efficacy and ease of use. Generally, prednisone or an equivalent corticosteroid is started at 0.5 mg/kg per day or ~20–40 mg/d for 4 weeks, and then reduced to a maintenance dose that will control symptoms and disease progression, ideally below 10 mg/d. Higher starting doses are not largely effective in most cases of sarcoidosis and are associated with increased morbidity. Lower induction doses can be considered based on severity of presentation, side effect tolerance, and rate of disease progression. More aggressive therapeutic approaches with higher doses or in association with other immunosuppression can be considered in life- or organ-threatening situations such as seen in central nervous system involvement, ocular involvement leading to vision loss, or extensive myocardial inflammation. In a subgroup of cases with very mild pulmonary symptoms such as cough, inhaled corticosteroids may be considered for symptom control but have not been shown to be of benefit in the larger sarcoidosis population.

STEROID-SPARING THERAPIES

As the landscape of drug development broadens, treatment options have expanded beyond corticosteroids to include several anti-inflammatories drawn from treatment of other rheumatologic conditions (Table 379-3). The choice of steroid-sparing agent often depends on several clinical factors (e.g., alcohol use, desire for pregnancy, known pharmacogenetic profiles, comorbidities such as liver or renal dysfunction), but methotrexate is the most recommended second-line therapy due to its efficacy and favorable side effect profile. Azathioprine appears to be equally effective, although

TABLE 379-3 Treatments for Sarcoidosis

	DRUG NAME	DOSE RANGE	CONSIDERATIONS
Initial therapy	Corticosteroids (prednisone, prednisolone)	20–40 mg/d initial, tapered to 7.5–15 mg/d	Consider taper early based on clinical improvement Monitor bone health Consider implications of weight gain Assess risk of diabetes Monitor eye exams (glaucoma and cataracts)
Common second-line therapies	Methotrexate	7.5–20 mg/wk orally or subcutaneously	Concurrent administration with folic acid Monitor liver and renal function and blood counts Contraindicated with significant alcohol use
	Leflunomide	10–20 mg/d	Monitor liver and renal function and blood counts In cases of toxicity, consider cholestyramine to accelerate clearance
	Azathioprine	50–200 mg/d or 1–2 mg/kg/d	Monitor liver and renal function and blood counts Consider thiopurine methyltransferase activity level
	Mycophenolate	1000–3000 mg/d	Monitor blood counts Enteric-coated option available (note: different dose range)
	Hydroxychloroquine	200–400 mg/d	Periodic eye exams for retinopathy Assess QT (monitor drug interactions) Effective for skin or hypercalcemia, but not for pulmonary
Refractory disease or inability to taper corticosteroids	Infliximab	3–5 mg/kg intravenously at weeks 0 and 2, and then every 4–8 weeks	Tuberculosis screening prior to use Avoid use in heart failure Allergic reactions possible with infusion Longer term association with demyelination syndrome and malignancy Can induce sarcoid-like reactions
	Adalimumab	40 mg subcutaneous every 1–2 weeks (exact dose unknown)	Similar precautions and adverse events as infliximab

potentially has higher rates of infectious complications. Other medications that can be considered second-line treatment include leflunomide or mycophenolate mofetil. Hydroxychloroquine can also be an effective immunomodulator, particularly for skin disease or hypercalcemia, but is not recommended for lung disease.

If all second-line therapies have been exhausted due to intolerance, inefficacy, or inability to taper corticosteroids, tumor necrosis factor (TNF) inhibitors can be considered. TNF-α is produced by the activated macrophages of the granuloma and contributes to propagation of inflammation in sarcoidosis. Infliximab and adalimumab are monoclonal antibodies that target TNF-α. Infliximab has garnered the most supporting data, with randomized controlled trials and larger case series showing positive effects on pulmonary function, imaging, and inflammatory cytokine levels, particularly in those with more severe disease. Adalimumab has shown efficacy in smaller series, particularly in ocular sarcoidosis. Etanercept, on the other hand, a TNF receptor antagonist, has been shown to be ineffective for sarcoidosis and should not be used for treatment. Other therapies targeting different aspects of the immune response are also considered at times in refractory cases including anti-B-cell therapy and antifibrotic medications.

IMMUNOSUPPRESSIVE MONITORING

While on immunosuppressive therapy, close attention to prevention of toxicity is important in the care plan, and monitoring should follow published rheumatologic guideline recommendations. Bisphosphonates should be considered to minimize steroid-induced osteoporosis, and regular eye exams should be obtained with corticosteroid use and hydroxychloroquine. When assessing a medication choice, it is also important to consider pregnancy risk, as many second-line agents have adverse reproductive effects.

DURATION OF TREATMENT

The exact duration of treatment may differ between individuals based on severity of disease but is ~1 year for most patients. Shorter courses of therapy have been associated with higher relapse rates, although they can be considered for particularly responsive cases. For pulmonary involvement, the greatest amount of improvement is seen within the first weeks to months of therapy; therefore, tapering of corticosteroids to a lower maintenance dose should be considered with early follow-up to minimize long-term toxicity. Longer courses of treatment may be necessary for life-threatening or refractory disease. Relapses are treated with the last known effective dosing regimen.

APPROACH TO THE PATIENT

Sarcoidosis

Comprehensive treatment of the patient with sarcoidosis includes not only suppression of granulomatous inflammation but also consideration of medication side effects and evaluation of fatigue, psychological health, and pain. Up to 80% of patients with sarcoidosis experience multifactorial fatigue, which can persist even after treatment and remission. Fatigue can be due to medications, sleep disorders, pain, and the granulomatous inflammation itself. It is associated with extrapulmonary involvement. Neuropathic pain or autonomic dysfunction may require symptomatic care. Formalized physical training has been shown to improve exercise capacity, strength, and fatigue in patients with sarcoidosis. Depression is also highly prevalent in chronic sarcoidosis, associated with female sex, dyspnea, and poor access to care. Cognitive impairment contributing to decreased quality of life is well-noted but poorly understood. Patient-centered care of the entire constellation of effects of sarcoidosis can include neuropsychiatric evaluation, sleep therapy, exercise therapy, pain relief, and lifestyle modifications. An individualized plan is necessary for every patient to address the benefits of anti-inflammatory treatments, associated comorbidities, and maintenance of quality of life while living with sarcoidosis.

380 IgG4-Related Disease

John H. Stone

IgG4-related disease (IgG4-RD) is a fibroinflammatory condition characterized by a tendency to form tumefactive lesions. The clinical manifestations of this disease, however, are protean, as IgG4-RD can affect virtually any organ system. The disease has a particular predilection for targeting blood vessels of any size on either the venous or arterial side of the circulation and is therefore regarded as a variable-vessel vasculitis. Commonly affected organs are the pancreas, biliary tree, major salivary glands (submandibular, parotid), periorbital tissues, kidneys, lungs, lymph nodes, and retroperitoneum. In addition, IgG4-RD involvement of the meninges, aorta, prostate, thyroid, pericardium, skin, and other organs is well described. The disease affects the brain parenchyma, the joints, the bone marrow, and the bowel mucosa only rarely.

The pathologic findings are consistent across all affected organs. These findings include a lymphoplasmacytic infiltrate with a high percentage of IgG4-positive plasma cells; a characteristic pattern of fibrosis termed "storiform" (from the Latin *storea*, for "woven mat"); a tendency to target blood vessels, particularly veins, through an obliterative process ("obliterative phlebitis"); and a mild to moderate tissue eosinophilia. Although the pathology is consistent from organ to organ, it is essentially never diagnostic in and of itself. Classification criteria emphasize the importance of careful correlation among clinical, serologic, radiologic, and pathologic findings in deciding whether a patient should be classified as having IgG4-RD. Biopsy is not required in order to establish the diagnosis in classic cases, but most patients undergo a biopsy at some point in the evaluation in order to exclude malignancy.

IgG4-RD encompasses a number of conditions previously regarded as separate, organ-specific entities. A condition once known as "lymphoplasmacytic sclerosing pancreatitis" became the paradigm of IgG4-RD in 2000, when Japanese investigators recognized that these patients had elevated serum concentrations of IgG4. This form of sclerosing pancreatitis is now termed type 1 (IgG4-related) autoimmune pancreatitis (AIP). By 2003, extrapancreatic disease manifestations had been identified in patients with type 1 AIP, and descriptions of IgG4-RD in other organs followed. *Mikulicz's disease*, once considered to be a subset of Sjögren's syndrome that affected the lacrimal, parotid, and submandibular glands, is one of the most common presentations of IgG4-RD.

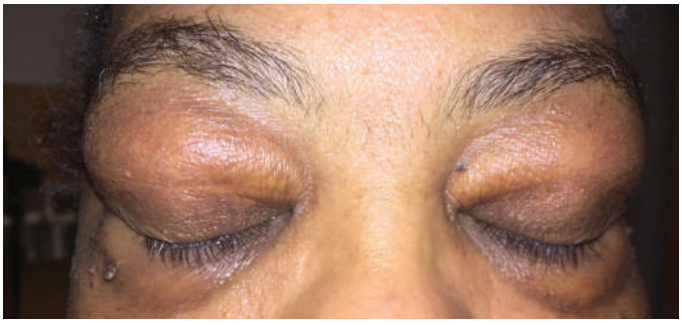
CLINICAL FEATURES

The major organ lesions are summarized in **Table 380-1**. IgG4-RD usually presents subacutely, and even in the setting of multiorgan disease, most patients do not have fevers or high elevations of C-reactive protein levels. Some patients, however, experience substantial weight loss over periods of months. This is generally because of exocrine

TABLE 380-1 Organ Manifestations of IgG4-Related Disease

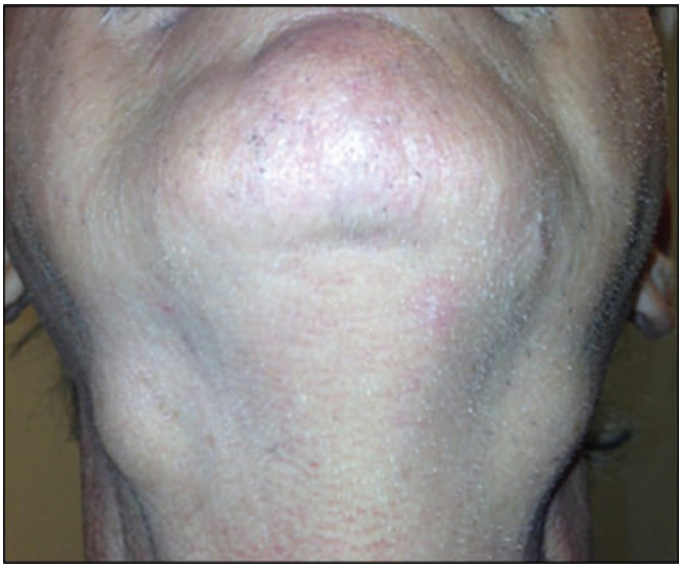
ORGAN	MAJOR CLINICAL FEATURES
Orbits and periorbital tissues	Painless eyelid or periocular tissue swelling; orbital pseudotumor; dacryoadenitis; dacryocystitis; orbital myositis; and mass lesions extending into the pterygopalatine fossa and infiltrating along the trigeminal nerve
Ears, nose, and sinuses	Allergic phenomena (nasal polyps, asthma, allergic rhinitis, peripheral eosinophilia); nasal obstruction, rhinorrhea, anosmia, chronic sinusitis; occasional bone-destructive lesions
Salivary glands	Submandibular and/or parotid gland enlargement (isolated bilateral submandibular gland involvement more common); minor salivary glands sometimes involved
Meninges	Headache, radiculopathy, cranial nerve palsies, or other symptoms resulting from spinal cord compression; tendency to form mass lesions; magnetic resonance imaging (MRI) shows marked thickening and enhancement of dura
Hypothalamus and pituitary	Clinical syndromes resulting from involvement of the hypothalamus and pituitary, e.g., anterior pituitary hormone deficiency, central diabetes insipidus, or both; imaging reveals thickened pituitary stalk or mass formation on the stalk, swelling of the pituitary gland, or mass formation within the pituitary
Lymph nodes	Generalized lymphadenopathy or localized disease adjacent to a specific affected organ; the lymph nodes involved are generally 1–2 cm in diameter and nontender
Thyroid gland	Riedel's thyroiditis; fibrosing variant of Hashimoto's thyroiditis
Lungs	Asymptomatic finding on lung imaging; cough, hemoptysis, dyspnea, pleural effusion, or chest discomfort; associated with parenchymal lung involvement, pleural disease, or both; four main clinical lung syndromes: inflammatory pseudotumor, paravertebral mass often extending over several vertebrae, central airway disease, localized or diffuse interstitial pneumonia; pleural lesions have severe, nodular thickening of the visceral or parietal pleura with diffuse sclerosing inflammation, sometimes associated with pleural effusion
Aorta	Asymptomatic finding on radiologic studies; surprise finding at elective aortic surgery; aortic dissection; clinicopathologic syndromes described include lymphoplasmacytic aortitis of thoracic or abdominal aorta, aortic dissection, periaortitis and periarteritis, and inflammatory abdominal aneurysm
Retroperitoneum	Backache, lower abdominal pain, lower extremity edema, hydronephrosis from ureteral involvement, asymptomatic finding on radiologic studies. Classic radiologic appearance is periaortic inflammation extending caudally to involve the iliac vessels.
Kidneys	Tubulointerstitial nephritis; membranous glomerulonephritis in a small minority; asymptomatic tumoral lesions, typically multiple and bilateral, are sometimes detected on radiologic studies; renal involvement strongly associated with hypocomplementemia
Pancreas	Type 1 autoimmune pancreatitis, presenting as mild abdominal pain; weight loss; acute, obstructive jaundice, mimicking adenocarcinoma of the pancreas (including a pancreatic mass); between 20 and 50% of patients present with acute glucose intolerance; imaging shows diffuse (termed "sausage-shaped pancreas") or segmental pancreatic enlargement, with loss of normal lobularity; a mass often raises the suspicion of malignancy
Biliary tree and liver	Obstructive jaundice associated with autoimmunity in most cases; weight loss; steatorrhea; abdominal pain; and new-onset diabetes mellitus; mimicker of primary sclerosing cholangitis and cholangiocarcinoma
Other organs involved	Gallbladder, liver (mass), breast (pseudotumor), prostate (prostatism), pericardium (constrictive pericarditis), mesentery (sclerosing mesenteritis), mediastinum (fibrosing mediastinitis), skin (erythematous or flesh-colored papules), peripheral nerve (perineural inflammation)

pancreatic failure and the resulting inability of the pancreas to produce sufficient quantities of digestive enzymes. Failure of the endocrine pancreas, resulting in diabetes mellitus, is also common. Clinically apparent disease can evolve over months, years, or even decades before the manifestations within a given organ become sufficiently severe to bring the patient to medical attention. Some patients have disease that is marked by the appearance and then resolution or temporary improvement in symptoms within a particular organ. Other patients accumulate new organ involvement as their disease persists in previously affected organs. Initial misdiagnosis, particularly of cancer, is extremely common because of the disease's tendency to cause mass lesions in the organs it affects. IgG4-RD is also often identified incidentally through radiologic findings.



Multiorgan disease may be evident at diagnosis but can also evolve over months to years. Some patients, however, have disease that appears to be confined to a single organ at the time of diagnosis. Others have subclinical involvement of other organs when the major clinical feature presents. For example, patients with type 1 AIP may have their major disease focus in the pancreas, but thorough investigation through the history and physical examination, blood tests, and cross-sectional imaging may demonstrate disease in multiple other organs.

Two common characteristics of IgG4-RD are allergic disease and the tendency to form tumefactive lesions that mimic malignancies (Fig. 380-1). Many IgG4-RD patients have allergic features such as atopy, eczema, asthma, nasal polyps, sinusitis, and modest peripheral eosinophilia. IgG4-RD also appears to account for a significant proportion of tumorous swellings—pseudotumors—in many organ systems (Fig. 380-2). Some patients undergo major surgeries (e.g., modified Whipple procedures or thyroidectomy) for the purpose of resecting malignancies before the correct diagnosis is identified.



IgG4-RD often causes major morbidity and can lead to organ failure; however, its general pattern is to cause damage in a subacute manner. Destructive bone lesions in the sinuses, head, and middle ear spaces that mimic granulomatosis with polyangiitis occur occasionally in IgG4-RD, but less aggressive lesions are the rule in most organs. In regions such as the retroperitoneum, substantial fibrosis often occurs before the diagnosis is established, leading to ureteral entrapment, hydronephrosis, postobstructive uropathy, and renal atrophy. Undiagnosed or undertreated IgG4-related sclerosing cholangitis can lead to hepatic failure within months. Similarly, IgG4-related aortitis can cause aneurysms and dissections. Substantial renal dysfunction and even renal failure can ensue from IgG4-related tubulointerstitial nephritis, and renal atrophy is a frequent sequel to this disease complication even following apparently effective immunosuppressive therapy. IgG4-related membranous glomerulonephropathy, a less common renal manifestation than tubulointerstitial nephritis, must be distinguished from idiopathic membranous glomerulonephropathy. As a variable-vessel vasculitis, IgG4-RD can target small-, medium-, and large-sized arteries and veins. Patients with longstanding IgG4-RD marked by substantial elevations of serum IgG4 concentrations and other biomarkers are at risk for developing coronary arteritis, marked by wall thickening, periarterial soft tissue encasement, stenosis, calcification, and aneurysms or ectasia.

SEROLOGIC FINDINGS

The majority of patients with IgG4-RD have elevated serum IgG4 concentrations; however, the range of elevation varies widely. Serum concentrations of IgG4 as high as 30 or 40 times the upper limit of normal sometimes occur, usually in patients with disease that affects multiple organ systems simultaneously. Approximately 30% of patients have normal serum IgG4 concentrations despite classic histopathologic and immunohistochemical findings. Such patients tend to have disease that affects fewer organs. Patients with IgG4-related retroperitoneal fibrosis often have normal serum IgG4 concentrations, perhaps because the

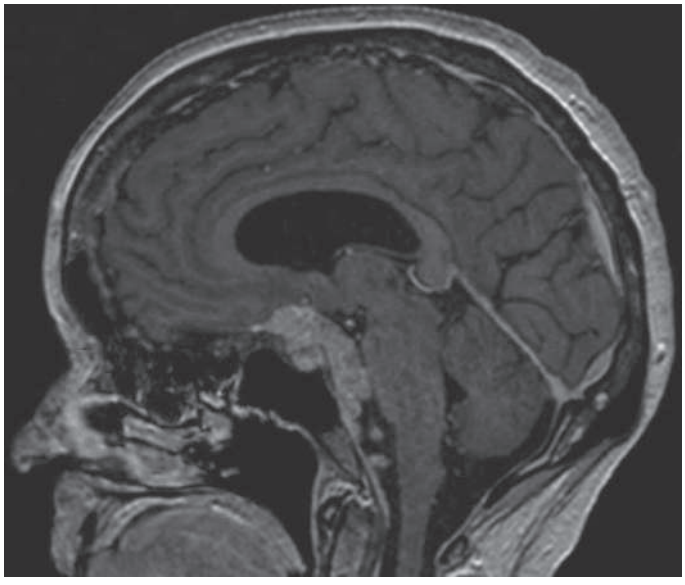
A

B

FIGURE 380-1 A major clinical feature of IgG4-related disease is its tendency to form tumefactive lesions. Shown here are mass lesions of the lacrimal glands, causing supraorbital swelling (***A***) and the submandibular glands (***B***).

process has advanced to a fibrotic stage by the time the diagnosis is considered.

Correlations between serum IgG4 concentrations, disease activity, and the need for treatment are imperfect. Serum IgG4 concentrations typically decline swiftly with the institution of therapy but often do not normalize completely. Patients can achieve clinical remissions yet have persistently elevated serum IgG4 concentrations. Following treatment and a disease response, however, steadily rising serum IgG4 concentrations are useful in identifying patients at risk for clinical flares who should be considered for re-treatment. Clinical relapses occur in some patients despite persistently normal IgG4 concentrations.



IgG4 concentrations in serum are usually measured by nephelometry assays. In the setting of extremely high serum IgG4 concentrations, these assays can generate spuriously low IgG4 values because of the prozone effect. Failure to identify dramatic serum IgG4 elevations can have a substantial impact on patients, because that subset of patients is at greatest risk for multiorgan disease and substantial end-organ injury. The prozone effect should be considered when the results of serologic testing for IgG4 concentrations are normal despite the presence of clinical features that strongly suggest IgG4-RD. This effect can be corrected by dilution of the serum sample in the laboratory.

EPIDEMIOLOGY

The typical patient with IgG4-RD is a middle-aged to elderly man. This epidemiology stands in stark contrast to that of many classic autoimmune conditions, which tend to affect young women. Male patients are approximately 5 years older at the time of diagnosis compared to female patients and have higher degrees of serologic activity, e.g., IgG4 hypergammaglobulinemia or hypocomplementemia. The male-to-female ratio appears to be on the order of 2:1, with even more striking male predominance reported in certain types of internal organ

A

B

FIGURE 380-2 Thickening of extraocular muscles and meninges. (***A***) Magnetic resonance imaging study of the orbits, showing enhancement and enlargement of extraocular muscles in a patient with IgG4-related orbital disease (orbit axial T1 postcontrast fat-saturated image). (***B***) Magnetic resonance imaging study of the brain, showing thickening of the pachymeninges. There is nodular pachymeningeal enhancement at the base of the brain (blue dot), anterior to the pons. There is also abnormal enhancement and thickening of the tentorium cerebelli, interposed between the superior cerebellum and the occipital lobes (sagittal MPRAGE volumetric T1 postcontrast image).

involvement (e.g., the pancreas, kidneys, or retroperitoneum). Among IgG4-RD manifestations that involve organs of the head and neck—the orbits, lacrimal glands, and major salivary glands—the sex ratio may be closer to 1:1.

PATHOLOGY

The key histopathology characteristics of IgG4-RD are a dense lymphoplasmacytic infiltrate **(Fig. 380-3)** that is organized in a storiform pattern, obliterative phlebitis, and a mild to moderate eosinophilic infiltrate. Lymphoid follicles and germinal centers are frequently observed. The infiltrate tends to aggregate around ductal structures when it affects glands. The inflammatory lesion often aggregates into tumefactive masses that destroy the involved tissue.

Obliterative arteritis is observed in some organs, particularly the lung; however, venous involvement is more common (and is indeed a hallmark of IgG4-RD). Several histopathology features are uncommon in IgG4-RD and, when detected, mitigate against the diagnosis of IgG4-RD. These include intense neutrophilic infiltration, leukocytoclasis, granulomatous inflammation, multinucleated giant cells, and fibrinoid necrosis.

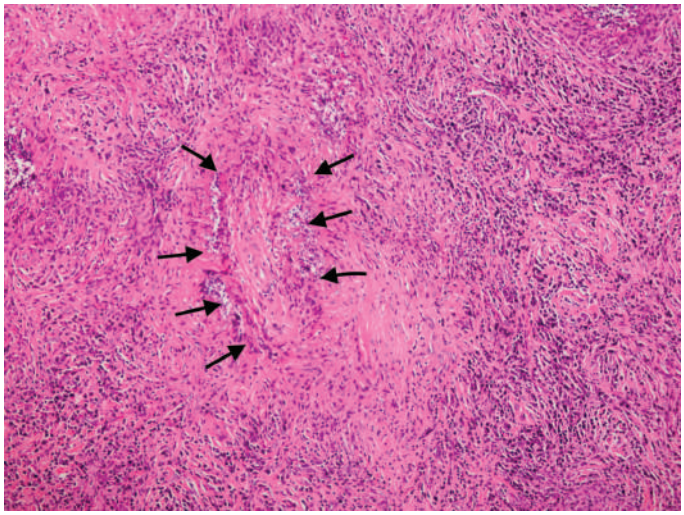


FIGURE 380-3 Hallmark histopathology characteristics of IgG4-related disease (IgG4-RD) are a dense lymphoplasmacytic infiltrate and a mild to moderate eosinophilic infiltrate. The cellular inflammation is often encased in a distinctive type of fibrosis termed "storiform," which often has a basket weave pattern. Abundant fibroblasts and strands of fibrosis accompany the lymphoplasmacytic infiltrate in this figure. Outlined by the *arrowheads* is a vein demonstrating obliterative phlebitis, underscoring the vascular tropism of this disease, which is classified as a variable-vessel vasculitis. This biopsy is from a patient with IgG4-related hypertrophic pachymeningitis. However, the findings are identical to the pathology found in the pancreas, kidneys, lungs, salivary glands, and other organs affected by IgG4-RD.

The inflammatory infiltrate is composed of an admixture of B and T lymphocytes. B cells are typically organized in germinal centers. Plasma cells staining for CD19, CD138, and IgG4 appear to radiate from the germinal centers. In contrast, the T cells, usually CD4+, are distributed more diffusely throughout the lesion and generally represent the most abundant cell type. Fibroblasts, histiocytes, and eosinophils can all be observed in moderate numbers. Some biopsy samples are particularly enriched with eosinophils. In other samples, particularly from long-standing cases, fibrosis predominates.

The histologic appearance of IgG4-RD, although characteristic, should be supplemented by immunohistochemical stains for IgG4 and IgG. IgG4-positive plasma cells predominate within the lesion, but plasma cells containing immunoglobulins from each subclass can be found. The number of IgG4-positive plasma cells can be quantified by either counting the number of cells per high-power field (HPF) or by calculating the ratio of IgG4- to IgG-bearing plasma cells. Tissue fibrosis predominates in the latter phases of organ involvement, and in this relatively acellular phase of inflammation, both the IgG4:total IgG ratio and the pattern of tissue fibrosis are more important than the number of IgG4-positive cells per HPF in establishing the diagnosis. No matter how strongly the histopathology and immunohistochemistry studies favor a diagnosis of IgG4-RD, however, the pathology findings must always be interpreted in the context of clinical, serologic, and radiologic findings. Pathology findings alone are never sufficient for the diagnosis.

PATHOPHYSIOLOGY

Despite the emphasis of IgG4 in the name of this disease, the IgG4 molecule is not believed to play a direct role in the pathophysiology of disease within most organs. The IgG4 molecule can undergo Fab exchange, a phenomenon in which the two halves of the molecule dissociate from each other and reassociate with hemi-molecules of different antigen specificity that have originated from other dissociated IgG4 molecules. Partly as a result of this Fab exchange, IgG4 antibodies do not bind antigen tightly. Moreover, the molecules have low affinities for Fc receptors and C1q and are regarded generally as noninflammatory immunoglobulins. The low affinities for Fc receptors and C1q impair the ability of IgG4 antibodies to induce phagocyte activation, antibody-dependent cellular cytotoxicity, and complement-mediated damage. It is possible, therefore, that the role of IgG4 in this disease is actually as a counterregulatory mechanism rather than part of the primary inflammatory process.

Next-generation sequencing studies of CD4+ effector T cells have demonstrated a unique CD4+ cytotoxic T cell. This cell, also found in abundance at tissue sites of disease, makes interferon gamma, T-cell growth factor-beta, and interleukin-1, all of which may contribute to the storiform fibrosis found in this condition. The cells also elaborate perforin, granzyme A and B, and granulysin, products capable of inducing cytotoxicity. The pronounced oligoclonal expansion of this CD4+ cytotoxic T cell at tissue sites suggests that this cell is a major disease driver.

Oligoclonal expansions of plasmablasts are also present within the blood of patients with IgG4-RD. Continuous antigen presentation by B cells and plasmablasts may support CD4+ cytotoxic T cells, which in turn produce profibrotic cytokines and other molecules, thereby directly mediating tissue injury.

TREATMENT

Vital organ involvement must be treated aggressively, because IgG4-RD can lead to serious organ dysfunction and failure. Aggressive disease can lead quickly to end-stage liver disease, permanent impairment of pancreatic function, renal atrophy, aortic dissection or aneurysms, and destructive lesions in the sinuses and nasopharynx. Not every disease manifestation of IgG4-RD requires immediate treatment, however, because the disease may take an indolent form in some patients. IgG4-related lymphadenopathy, for example, can be asymptomatic for years, without evolution to other disease manifestations. Watchful waiting is prudent in some cases, but monitoring is essential because serious organ involvement may evolve over time, particularly in the setting of persistently rising serum IgG4 concentrations.

Glucocorticoids are the first line of therapy. Treatment regimens, extrapolated from experience with the management of type 1 AIP, generally begin with 40 mg/d of prednisone, with tapering to discontinuation or maintenance doses of 5 mg/d within 2 or 3 months. Although the clinical response to glucocorticoids is usually swift and striking, prolonged steroid-free remissions are uncommon and the risk of steroid-induced morbidity in this middle-aged to elderly patient population is high, particularly in those with baseline comorbidities and pancreatic involvement by IgG4-RD. Few data exist to support the utility of conventional glucocorticoid-sparing agents in this disease.

For patients with relapsing or glucocorticoid-resistant disease, B-cell depletion with rituximab is an excellent second-line therapy. Rituximab treatment (two doses of 1 g IV, separated by ~15 days) leads to a swift decline in serum IgG4 concentrations, suggesting that rituximab achieves its effects in part by preventing the repletion of short-lived plasma cells that produce IgG4. More important than its effects on IgG4 concentrations, however, may be the effect of B-cell depletion on T-cell function. Specific effects of rituximab on the CD4+ cytotoxic T cell described above have been documented in IgG4-RD. The rapidly evolving understanding of the pathophysiology of IgG4-RD suggests several novel targeted approaches to treating the disease, some of which are in clinical trials. Phase 3 clinical trials of treatments targeting CD19+ B lymphocytes are now at advanced stages of recruitment. B-cell–targeted treatment strategies may be appropriate first-line therapy options for some patients following confirmation of their efficacy in clinical trials, particularly for patients at high risk for glucocorticoid toxicity and for those with immediately organ-threatening disease.

381 Familial Mediterranean Fever and Other Hereditary Autoinflammatory Diseases

Daniel L. Kastner

Familial Mediterranean fever (FMF) is the prototype of a group of inherited diseases **(Table 381-1)** that are characterized by recurrent episodes of fever with serosal, synovial, or cutaneous inflammation and, in some individuals, the eventual development of systemic AA amyloidosis **(Chap. 117)**. Because of the relative infrequency of high-titer autoantibodies or antigen-specific T cells, the term *autoinflammatory* has been proposed to describe these disorders, rather than autoimmune. The innate immune system, with its myeloid effector cells and germline receptors for pathogen-associated molecular patterns and endogenous danger signals, plays a predominant role in the pathogenesis of the autoinflammatory diseases. Although the hereditary recurrent fevers comprise an important category of the autoinflammatory diseases, other inherited disorders of inflammation in which recurrent fever plays a less prominent role are now also considered to be autoinflammatory.

BACKGROUND AND PATHOPHYSIOLOGY

FMF was first recognized among Armenians, Arabs, Turks, and non-Ashkenazi (primarily North African and Iraqi) Jews. With the advent of genetic testing, FMF has been documented with increasing frequency among Ashkenazi Jews, Italians, and other Mediterranean and Middle Eastern populations, and occasional cases have been confirmed even in the absence of known Mediterranean ancestry. FMF is generally regarded as recessively inherited, but there is an increasing awareness of clear-cut clinical cases with only a single demonstrable genetic mutation, and for certain relatively rare FMF mutations, there is strong evidence for dominant inheritance. Particularly in countries where families are small, a positive family history can only be elicited in ~50% of cases. DNA testing demonstrates carrier frequencies as high as 1:10 among affected populations, most likely due to some selective advantage.

The FMF gene encodes a 781-amino-acid, ~95-kDa protein denoted *pyrin* that is expressed in granulocytes, eosinophils, monocytes, dendritic cells, and synovial and peritoneal fibroblasts. The N-terminal 92 amino acids of pyrin define a motif, the PYRIN domain, that mediates homotypic protein-protein interactions and has been found in several other proteins, including cryopyrin (NLRP3), which is mutated in three other recurrent fever syndromes. Through the interaction of its PYRIN domain with an intermediary adaptor protein, pyrin nucleates the formation of a macromolecular *pyrin inflammasome* to activate caspase-1 (interleukin [IL] 1β–converting enzyme) and thereby IL-1β and IL-18 secretion and gasdermin D-mediated cell death (pyroptosis). Certain bacterial toxins that block leukocyte cytoskeletal assembly by inactivating RhoA GTPase trigger pyrin inflammasome activation as a part of the normal host defense. At a molecular level, FMF-associated mutations are considered gain-of-function, and in FMF patients, the threshold for pyrin inflammasome activation is thus reduced. Population genetic and immune functional studies support a role for bubonic plague pandemics in selecting for FMF founder mutations that had arisen in Biblical times in the Middle East.

ACUTE ATTACKS

Febrile episodes in FMF may begin even in early infancy; 90% of patients have had their first attack by age 20. Typical FMF episodes generally last 24–72 h, with arthritic attacks tending to last somewhat longer. In some patients, the episodes occur with great regularity, but more often, the frequency of attacks varies over time, ranging from as often as once every few days to remissions lasting several years. Attacks are often unpredictable, although some patients relate them to physical exertion, emotional stress, or menses; pregnancy may be associated with remission.

If measured, fever is nearly always present throughout FMF attacks. Severe hyperpyrexia and even febrile seizures may be seen in infants, and fever is sometimes the only manifestation of FMF in young children.

Over 90% of FMF patients experience abdominal attacks at some time. Episodes range in severity from dull, aching pain and distention with mild tenderness on direct palpation to severe generalized pain with absent bowel sounds, rigidity, rebound tenderness, and air-fluid levels on upright radiographs. Computed tomography (CT) scanning may demonstrate a small amount of fluid in the abdominal cavity. If such patients undergo exploratory laparotomy, a sterile, neutrophil-rich peritoneal exudate is present, sometimes with adhesions from previous episodes. Ascites is rare.

Pleural attacks are usually manifested by unilateral, sharp, stabbing chest pain. Radiographs may show atelectasis and sometimes an effusion. If performed, thoracentesis demonstrates an exudative fluid rich in neutrophils. After repeated attacks, pleural thickening may develop.

FMF arthritis is most frequent among individuals homozygous for the M694V mutation, which is especially common in the non-Ashkenazi Jewish population. Acute arthritis in FMF is usually monoarticular, affecting the knee, ankle, or hip, although other patterns can be seen. Large sterile effusions rich in neutrophils are frequent, without commensurate erythema or warmth. Even after repeated arthritic attacks, radiographic changes are rare. Before the advent of colchicine prophylaxis, chronic arthritis of the knee or hip was seen in ~5% of FMF patients with arthritis. Chronic sacroiliitis can occur in FMF irrespective of the HLA-B27 antigen, even in the face of colchicine therapy. In the United States, FMF patients are much more likely to have arthralgia than arthritis.

The most characteristic cutaneous manifestation of FMF is erysipelas-like erythema, a raised erythematous rash that most commonly occurs on the dorsum of the foot, ankle, or lower leg alone or in combination with abdominal pain, pleurisy, or arthritis. Biopsy demonstrates perivascular infiltrates of granulocytes and monocytes. This rash is seen most often in M694V homozygotes.

Exercise-induced (nonfebrile) myalgia is common in FMF, and a small percentage of patients develop a protracted febrile myalgia that can last several weeks. Symptomatic pericardial disease is rare, although small pericardial effusions may be noted on echocardiography. Unilateral acute scrotal inflammation may occur in prepubertal boys. Aseptic meningitis has been reported in FMF, but the causal connection is controversial. Vasculitis, including IgA vasculitis (Henoch-Schönlein purpura) and polyarteritis nodosa **(Chap. 375)**, may be seen at increased frequency in FMF. The M694V FMF mutation has been shown to be a risk factor for Behçet's syndrome **(Chap. 376)** and ankylosing spondylitis **(Chap. 374)**.

Laboratory features of FMF attacks are consistent with acute inflammation and include an elevated erythrocyte sedimentation rate,

TABLE 381-1 The Hereditary Recurrent Fever Syndromes

	FMF	TRAPS	HIDS/MKD	MWS	FCAS	NOMID
Ethnicity	Jewish, Arab, Turkish, Armenian, Italian	Any ethnic group	Predominantly Dutch, northern European	Any ethnic group	Any ethnic group	Any ethnic group
Inheritance	Recessive or dominant[a]	Dominant	Recessive	Dominant	Dominant	Most commonly de novo mutations; somatic mosaicism in a significant minority
Gene/chromosome	*MEFV*/16p13.3	*TNFRSF1A*/12p13	*MVK*/12q24	*NLRP3*/1q44	*NLRP3*/1q44	*NLRP3*/1q44
Protein	Pyrin	p55 TNF receptor	Mevalonate kinase	NLRP3 (cryopyrin)	NLRP3 (cryopyrin)	NLRP3 (cryopyrin)
Attack length	1–3 days	Often >7 days	3–7 days	1–2 days	Minutes–3 days	Continuous, with flares
Serosa	Pleurisy, peritonitis; asymptomatic pericardial effusions	Pleurisy, peritonitis, pericarditis	Abdominal pain, but seldom peritonitis; pleurisy, pericarditis uncommon	Abdominal pain; pleurisy, pericarditis rare	Rare	Rare
Skin	Erysipeloid erythema	Centrifugally migrating erythema	Diffuse maculopapular rash; oral ulcers	Diffuse urticaria-like rash	Cold-induced urticaria-like rash	Diffuse urticaria-like rash
Joints	Acute monoarthritis; chronic hip arthritis (rare)	Acute monoarthritis, arthralgia	Arthralgia, oligoarthritis	Arthralgia, large joint oligoarthritis	Polyarthralgia	Epiphyseal, patellar overgrowth, clubbing
Muscle	Exercise-induced myalgia common; protracted febrile myalgia rare	Migratory myalgia	Uncommon	Myalgia common	Sometimes myalgia	Sometimes myalgia
Eyes, ears	Uncommon	Periorbital edema, conjunctivitis	Uncommon	Conjunctivitis, episcleritis, optic disc edema; sensorineural hearing loss	Conjunctivitis	Conjunctivitis, uveitis, optic disc edema, blindness, sensorineural hearing loss
CNS	Aseptic meningitis rare	Headache	Headache	Headache	Headache	Aseptic meningitis, seizures
Amyloidosis	Most common in M694V homozygotes	~15% of cases, most often cysteine mutations, T50M	Sometimes associated with V377I/I268T *MVK* genotype	~25% of cases	Uncommon	Late complication
Treatment	Oral colchicine prophylaxis, IL-1 inhibitors for refractory cases	Glucocorticoids, IL-1 inhibitors, etanercept	NSAIDs for fever; IL-1 inhibitors	Canakinumab, rilonacept, anakinra	Canakinumab, rilonacept, anakinra	Anakinra

[a]A substantial percentage of patients with clinical FMF have only a single demonstrable *MEFV* mutation on DNA sequencing.

Abbreviations: CNS, central nervous system; FCAS, familial cold autoinflammatory syndrome; FMF, familial Mediterranean fever; HIDS/MKD, hyperimmunoglobulinemia D with periodic fever syndrome, also known as mevalonate kinase deficiency; IL, interleukin; MWS, Muckle-Wells syndrome; NOMID, neonatal-onset multisystem inflammatory disease; NSAIDs, nonsteroidal anti-inflammatory drugs; TNF, tumor necrosis factor; TRAPS, TNF receptor-associated periodic syndrome.

leukocytosis, thrombocytosis (in children), and elevations in C-reactive protein, fibrinogen, haptoglobin, and serum immunoglobulins. Transient albuminuria and hematuria may also be seen.

AMYLOIDOSIS

Before the advent of colchicine prophylaxis, systemic amyloidosis was a common complication of FMF. It is caused by deposition of a fragment of serum amyloid A, an acute-phase reactant, in the kidneys, adrenals, intestine, spleen, lung, and testes **(Chap. 117)**. Amyloidosis should be suspected in patients who have proteinuria between attacks; renal or rectal biopsy is used most often to establish the diagnosis. Risk factors include the M694V homozygous genotype, positive family history (independent of FMF mutational status), the *SAA1* genotype, male gender, noncompliance with colchicine or IL-1 inhibitory therapy, and national origin (with amyloid risk paralleling infant mortality rate).

DIAGNOSIS

For typical cases, physicians experienced with FMF can often make the diagnosis on clinical grounds alone. Clinical criteria sets for FMF have been shown to have high sensitivity and specificity in parts of the world where the pretest probability of FMF is high. Genetic testing can provide a useful adjunct in ambiguous cases or for physicians not experienced in FMF. Most of the more severe disease-associated FMF mutations are in exon 10 of the gene. An updated, expert-curated list of mutations (as well as benign nonpathogenic polymorphisms) for FMF and other hereditary autoinflammatory diseases can be found online at *http://fmf.igh.cnrs.fr/infevers/*.

Genetic testing has permitted a broadening of the clinical spectrum and geographic distribution of FMF and may be of prognostic value. Most studies indicate that M694V homozygotes have an earlier age of onset and a higher frequency of arthritis, rash, and amyloidosis. In contrast, the E148Q variant in exon 2 is quite common in certain Asian populations and is more likely to affect overall levels of inflammation than to cause clinical FMF. E148Q is sometimes found in *cis* with exon 10 mutations, which may increase the penetrance of the exon 10 mutation. Only ~70% of patients with clinically typical FMF have two identifiable mutations in *trans*, consistent with the concept that FMF mutations are gain-of-function with regard to inflammasome activation, with a dosage effect. In those cases in which only a single mutation is identified, clinical judgment is very important, and sometimes a therapeutic trial of colchicine or an IL-1 inhibitor may help to confirm the diagnosis.

If a patient is seen during their first attack, the differential diagnosis may be broad, although delimited by the specific organ involvement. After several attacks, the differential diagnosis may include the other hereditary recurrent fever syndromes (Table 381-1); the syndrome of periodic fever with aphthous ulcers, pharyngitis, and cervical adenopathy (PFAPA); systemic-onset juvenile rheumatoid arthritis or adult Still's disease; porphyria; hereditary angioedema; inflammatory bowel disease; and, in women, gynecologic disorders.

TREATMENT

Familial Mediterranean Fever

The initial treatment of choice for FMF is daily oral colchicine, which decreases the frequency and intensity of attacks and prevents the development of amyloidosis in compliant patients. Intermittent dosing at the onset of attacks is not as effective as daily prophylaxis and is of unproven value in preventing amyloidosis. The usual adult dose of colchicine is 1.2–1.8 mg/d, which causes substantial reduction in symptoms in two-thirds of patients and some improvement in >90%. Children may require lower doses, although not proportionately to body weight.

Common side effects of colchicine include bloating, abdominal cramps, lactose intolerance, and diarrhea. They can be minimized by starting at a low dose and gradually advancing as tolerated, splitting the dose, use of simethicone for flatulence, and avoidance of dairy products. If taken by either parent at the time of conception, colchicine may cause a small increase in the risk of trisomy 21 (Down's syndrome). Colchicine is usually continued during pregnancy, because the risk of miscarriage due to FMF attacks is thought to outweigh any effect of colchicine on fetal development. In elderly patients with renal insufficiency, colchicine can cause a myoneuropathy characterized by proximal muscle weakness and elevation of the creatine kinase. Cyclosporine inhibits hepatic excretion of colchicine by its effects on the multidrug resistance 1 (MDR1) transport system, sometimes leading to colchicine toxicity in patients who have undergone renal transplantation for amyloidosis. Intravenous colchicine should not be administered to patients already taking oral colchicine, because severe, sometimes fatal, toxicity has been observed in this setting.

For FMF patients who do not respond to colchicine or cannot tolerate therapeutic doses, injectable IL-1 inhibitors may be used. Based on a randomized placebo-controlled phase 3 trial, monthly subcutaneous administration of the monoclonal anti-IL-1β antibody canakinumab received U.S. Food and Drug Administration (FDA) approval for this indication. In a small randomized placebo-controlled trial, weekly subcutaneous rilonacept, a recombinant IL-1 receptor fusion protein, significantly reduced the frequency of attacks. There is also substantial anecdotal experience with daily subcutaneous anakinra, a recombinant IL-1 receptor antagonist, in preventing the acute attacks of FMF and, in some cases, reducing established amyloid deposits. Bone marrow transplantation has been suggested for refractory FMF, but the risk-benefit ratio is usually regarded as unacceptable.

OTHER HEREDITARY RECURRENT FEVERS

TNF RECEPTOR–ASSOCIATED PERIODIC SYNDROME

Tumor necrosis factor (TNF) receptor–associated periodic syndrome (TRAPS) is caused by dominantly inherited mutations in the extracellular domains of the 55-kDa TNF receptor (TNFR1, p55). Although originally described in a large Irish family (and hence the name *familial Hibernian fever*), TRAPS has a broad ethnic distribution. TRAPS episodes often begin in childhood. The duration of attacks ranges from 1 to 2 days to as long as several weeks, and in severe cases, symptoms may be nearly continuous. In addition to peritoneal, pleural, and synovial attacks similar to FMF, TRAPS patients frequently have ocular inflammation (most often conjunctivitis and/or periorbital edema), and a distinctive migratory myalgia with overlying painful erythema may be present. TRAPS patients generally respond better to glucocorticoids than to prophylactic colchicine. Untreated, ~15% develop amyloidosis. The diagnosis of TRAPS is based on the demonstration of a *TNFRSF1A* mutation in the presence of characteristic symptoms. Two particular variants, R92Q and P46L, are common in certain populations and may act more as functional polymorphisms than as disease-causing mutations. In contrast, pathogenic *TNFRSF1A* mutations, including a number of substitutions at highly conserved cysteine residues, are associated with intracellular TNFR1 misfolding, aggregation, and retention, with consequent ligand-independent kinase activation, mitochondrial reactive oxygen species production, and proinflammatory cytokine release. Etanercept, a TNF inhibitor, ameliorates TRAPS attacks, but the long-term experience with this agent has been less favorable. IL-1 inhibition has been beneficial in a large percentage of the patients in whom it has been used, and monthly, subcutaneous canakinumab has received FDA approval for the treatment of TRAPS. Monoclonal anti-TNF antibodies should be avoided, because they may exacerbate TRAPS attacks.

HYPERIMMUNOGLOBULINEMIA D WITH PERIODIC FEVER SYNDROME (ALSO KNOWN AS MEVALONATE KINASE DEFICIENCY)

Hyperimmunoglobulinemia D with periodic fever syndrome (HIDS) is a recessively inherited recurrent fever syndrome found primarily in individuals of northern European ancestry. It is caused by mutations in mevalonate kinase (*MVK*), encoding an enzyme involved in the synthesis of cholesterol and nonsterol isoprenoids, including geranylgeranyl pyrophosphate. The latter compound is essential for proper localization of RhoA GTPase to the cell membrane, and the mislocalization of RhoA leads to its inactivation and the consequent activation of the pyrin inflammasome. HIDS attacks usually begin in infancy and last 3–5 days. Clinically distinctive features include painful cervical adenopathy, a diffuse maculopapular rash sometimes affecting the palms and soles, and aphthous ulcers; pleurisy is rare. Amyloidosis has been observed associated with the V377I/I268T *MVK* genotype. Although originally defined by the persistent elevation of serum IgD, disease activity is not related to IgD levels, and some patients with FMF or TRAPS may have modestly increased serum IgD. Moreover, occasional patients with *MVK* mutations and recurrent fever have normal IgD levels, while all patients with mutations have markedly elevated urinary mevalonate levels during their attacks. For these reasons, some have proposed renaming this disorder *mevalonate kinase deficiency* (MKD). Monthly, subcutaneous canakinumab has been approved by the FDA for the treatment of HIDS/MKD.

NLRP3-ASSOCIATED AUTOINFLAMMATORY DISEASE (ALSO KNOWN AS THE CRYOPYRINOPATHIES OR CRYOPYRIN-ASSOCIATED PERIODIC SYNDROMES)

Three hereditary febrile syndromes, familial cold autoinflammatory syndrome (FCAS), Muckle-Wells syndrome (MWS), and neonatal-onset multisystem inflammatory disease (NOMID), are all caused by mutations in *NLRP3* (formerly known as *CIAS1*), the gene encoding cryopyrin (or NLRP3), and represent a clinical spectrum of disease. FCAS patients develop chills, fever, headache, arthralgia, conjunctivitis, and an urticaria-like rash in response to generalized cold exposure. In MWS, an urticarial rash is noted, but it is not usually induced by cold; MWS patients also develop fevers, abdominal pain, limb pain, arthritis, conjunctivitis, and, over time, sensorineural hearing loss. NOMID is the most severe of the three disorders, with chronic aseptic meningitis, a characteristic arthropathy, and rash. Like the FMF protein pyrin, cryopyrin has an N-terminal PYRIN domain, allowing the formation of an *NLRP3 inflammasome* that mediates caspase-1 activation, IL-1β and IL-18 release, and pyroptosis. Peripheral blood leukocytes from patients with FCAS, MWS, and NOMID release increased amounts of IL-1β upon in vitro stimulation, relative to healthy controls. Macrophages from cryopyrin-deficient mice exhibit decreased IL-1β production in response to certain gram-positive bacteria, bacterial RNA, and monosodium urate crystals. Patients with all three cryopyrinopathies or cryopyrin-associated periodic syndromes (CAPS) show a dramatic response to injections of IL-1 inhibitors. Bimonthly canakinumab and weekly rilonacept are approved by the FDA for the treatment of FCAS and MWS, whereas daily anakinra is approved for the treatment of NOMID.

Approximately one-third of patients with clinical manifestations of NOMID do not have germline mutations in *NLRP3*, but they have been found to be mosaic for somatic *NLRP3* mutations. Such patients also

respond dramatically to IL-1 inhibition. Somatic mosaicism in *NLRP3* has been reported rarely in Schnitzler's syndrome, which presents in middle age with recurrent fever, urticarial rash, elevated acute-phase reactants, monoclonal IgM gammopathy, and abnormal bone remodeling. IL-1 inhibition is the treatment of choice for Schnitzler's syndrome.

PERIODIC FEVER WITH APHTHOUS STOMATITIS, PHARYNGITIS, AND CERVICAL ADENITIS

Periodic fever with aphthous stomatitis, pharyngitis, and cervical adenitis (PFAPA) is the most common periodic fever syndrome in children, notable for the almost clock-like regularity of episodes and the tendency for resolution of attacks by early adulthood. PFAPA tends to run in families, but not in a Mendelian fashion. Common shared variants in the *IL12A*, *IL10*, *STAT4,* and *CCR1-CCR3* loci confer susceptibility for a spectrum of phenotypes ranging from common aphthous ulcers to PFAPA to Behçet's syndrome. Therapeutic options for PFAPA include intermittent glucocorticoids; daily oral colchicine, cimetidine, or apremilast; or tonsillectomy/adenoidectomy.

OTHER INHERITED AUTOINFLAMMATORY DISEASES

In the quarter century since the concept of autoinflammation was first proposed, over 60 monogenic autoinflammatory diseases have been described. These discoveries have enabled the understanding of the innate immune system through the lens of human disease and highlight the fact that many cellular homeostatic pathways have evolved to double as direct or indirect innate sensing mechanisms for microbial infection.

The inflammasomopathies are caused by germline or somatic mutations in genes encoding structural components of one of the inflammasomes or of proteins that regulate inflammasome activity, and include FMF, HIDS, and CAPS. Dominantly inherited mutations in the *PSTPIP1* gene lead to noncanonical activation of the pyrin inflammasome and the syndrome of pyogenic arthritis with pyoderma gangrenosum and acne (PAPA). Patients present with episodes of sterile pyogenic arthritis often induced by trauma, severe pyoderma gangrenosum, and severe cystic acne usually beginning in puberty. Arthritic manifestations often respond to IL-1 inhibition. Dominantly inherited mutations in *NLRC4* activate the NLRC4 inflammasome, causing increased IL-1 and IL-18 production. Patients may present with infantile enterocolitis or life-threatening recurrent macrophage activation syndrome later in life. Milder mutations are associated with a cold urticaria syndrome. Inflammasomopathies caused by mutations in *NLRP1* and in the IL-1 receptor antagonist gene (*IL1RN*) have also been described.

Another subset of autoinflammatory diseases is characterized by excessive production of type I interferons. These interferonopathies may be caused by mutations in sensors of intracellular nucleic acids that, under physiologic conditions, would trigger a response to viral infection. For example, de novo germline gain-of-function mutations in *TMEM173* cause constitutive activation of STING, a sensor for intracellular double-stranded DNA, causing severe vasculopathy and pulmonary fibrosis. Retrograde transport of STING from the Golgi apparatus to the endoplasmic reticulum is important for STING inactivation. Loss-of-function mutations in *COPA,* which encodes a chaperone protein involved in retrograde STING transport, cause an autoinflammatory disease characterized by diffuse alveolar hemorrhage or interstitial lung disease, arthritis, and glomerulopathy (COPA syndrome). Mutations in several other genes involved in nucleic acid sensing and/or metabolism cause type I interferonopathies collectively denoted Aicardi-Gutières syndrome. Yet another class of type I interferonopathy is caused by Mendelian or digenic mutations in various components of the proteasome and is sometimes denoted chronic atypical neutrophilic dermatosis with lipodystrophy and elevated temperature (CANDLE) syndrome.

A third subset of autoinflammatory diseases, the relopathies, involves mutations in genes encoding proteins that mediate or regulate NF-κB activation or TNF-induced cell death. These include the genes encoding several ubiquitin ligases and deubiquitinases that, when mutated, may cause clinical syndromes of panniculitis (*OTULIN*), Behçet's-like mucosal ulcerations (*TNFAIP3, RELA*), arthritis (*SHARPIN*), or lymphadenopathy/organomegaly (*RIPK1*). *Blau's syndrome* is caused by mutations in *NOD2* (also known as *CARD15*), which senses certain bacterial products and induces NF-κB activation. Blau's syndrome is caused by gain-of-function mutations in *NOD2/CARD15* and is characterized by granulomatous dermatitis, uveitis, and arthritis; distinct *NOD2/CARD15* variants predispose to Crohn's disease in a non-Mendelian fashion. Autoinflammatory disease associated with certain common variants of *NOD2/CARD15* has been denoted Yao's syndrome, but the causal relationship, if any, between these variants and autoinflammatory phenotypes remains uncertain. ROSAH (retinal dystrophy, optic nerve edema, splenomegaly, anhidrosis, and headaches) syndrome is a relatively newly recognized dominantly inherited autoinflammatory disease caused by gain-of-function mutations in *ALPK1,* encoding a novel kinase that serves as a sensor for bacterial seven-carbon sugars and activates NF-κB. Many patients lose their vision by adulthood; fevers, arthritis, and elevated acute-phase reactants are also frequently observed.

Although the exact disease mechanism remains to be established, recessive loss-of-function germline mutations in the gene encoding adenosine deaminase 2 (ADA2) cause a vasculopathy that can manifest as livedoid rash, early-onset lacunar strokes, and/or polyarteritis nodosa **(Chap. 375)**. TNF inhibitors are highly effective in preventing strokes in these patients. Deficiency of ADA2 (DADA2) may also present with immunodeficiency or bone marrow failure.

Myeloid-restricted somatic mutations in an essential ubiquitylation enzyme have recently been implicated in a severe adult-onset autoinflammatory disease called VEXAS (vacuoles, E1 enzyme, X-linked, autoinflammatory, somatic) syndrome, which can present as relapsing polychondritis **(Chap. 378)**, Sweet's syndrome, vasculitis, or myelodysplastic syndrome. VEXAS syndrome is estimated to affect ~1 in 4000 men over the age of 50.

Finally, it should be noted that several common, genetically complex disorders are now sometimes considered autoinflammatory, because of evidence that elements of the innate immune system, such as the inflammasome, play a role in the pathogenesis and may thus lead to novel therapeutic strategies. Two prominent examples are gout and atherosclerosis. Recent data have implicated endothelial inflammasome activation in the disruption of the blood-brain barrier induced by sepsis.

GLOBAL CONSIDERATIONS

All the disorders discussed in this chapter have been observed in multiple populations. However, as noted herein, FMF is most frequently observed in Mediterranean and Middle Eastern populations and HIDS in northern European populations, particularly the Dutch. A recessive founder mutation in *ADA2* is particularly common in the Middle East and is associated with polyarteritis nodosa.

382 Approach to Articular and Musculoskeletal Disorders

John J. Cush

Musculoskeletal disorders affect one in three (approximately 127 million) in the U.S., and account for 15–25% of all outpatient visits in the United States. The Centers for Disease Control and Prevention estimates that 54.4 million U.S. adults (22.7%) have physician-diagnosed arthritis. While many patients will have self-limited conditions requiring minimal evaluation and symptomatic therapy, specific musculoskeletal presentations may herald a more serious condition that requires further evaluation or laboratory testing to establish a diagnosis. The goal of the musculoskeletal evaluation is to formulate a differential diagnosis that leads to an accurate diagnosis and timely therapy, while avoiding excessive diagnostic testing and unnecessary treatment (Table 382-1). There are several urgent conditions that must be diagnosed promptly to avoid damage and morbidity. These "red flag" diagnoses include septic arthritis, acute crystal-induced arthritis (e.g., gout), and fracture. Each is suspected by an acute onset of monoarticular or focal musculoskeletal pain.

Most individuals with musculoskeletal complaints can be diagnosed with a thorough history and a comprehensive physical and musculoskeletal examination. The initial encounter should determine whether the musculoskeletal complaint signals a red flag condition (septic arthritis, gout, or fracture) or not. The evaluation should ascertain if the complaint is (1) *articular* or *nonarticular*, (2) *inflammatory* or *noninflammatory*, (3) *acute* or *chronic*, and (4) *localized (monoarticular)* or *widespread (polyarticular)*. The term arthralgia (joint pain) is not synonymous with arthritis, with the latter implying pathology of articular structures. Arthralgia is common and may be a symptom of arthritis.

By answering these four questions, the musculoskeletal presentation can be characterized (e.g., acute inflammatory monoarthritis or a chronic noninflammatory, nonarticular widespread pain) to narrow the diagnostic possibilities. Many musculoskeletal disorders resemble each other at the outset, and some may take weeks or months (but not years) to evolve into a recognizable diagnostic entity. This consideration should temper the desire to establish a definitive diagnosis at the first encounter.

TABLE 382-1 Evaluation of Patients with Musculoskeletal Complaints

Goals
Accurate diagnosis
Timely provision of therapy
Avoidance of unnecessary diagnostic testing
Identification of "red flag" conditions
Approach
Determine the chronology (acute vs chronic)
Determine the nature of the pathologic process (inflammatory vs noninflammatory)
Anatomic localization of complaint (articular vs nonarticular)
Determine the extent of involvement (monoarticular, polyarticular, focal, widespread)
Consider the most common disorders first
Consider the need for diagnostic testing
Formulate a differential diagnosis

ARTICULAR OR NONARTICULAR

The musculoskeletal evaluation must discriminate the anatomic origin(s) of the patient's complaint. For example, ankle pain may result from pathologic conditions involving disparate anatomic structures, including gouty arthritis, calcaneal fracture, Achilles tendinitis, plantar fasciitis, or entrapment neuropathy. Distinguishing between articular and nonarticular conditions requires a thorough examination. Articular structures include the synovium, synovial fluid, articular cartilage, intraarticular ligaments, joint capsule, and juxtaarticular bone. Nonarticular (or periarticular) structures, such as supportive extraarticular ligaments, tendons, bursae, muscle, fascia, bone, nerve, and overlying skin, may be involved in the pathologic process. Musculoskeletal complaints ascribed to the joints are more frequently of nonarticular origin and may be misconstrued as arthritis. Distinguishing between articular and nonarticular/periarticular pain may be challenging to the inexperienced examiner. Articular disorders are distinguished by deep or diffuse pain, limited range of motion on active and passive movement, and swelling (from synovial proliferation, effusion, or bony enlargement), crepitation, instability, "locking," or deformity. By contrast, nonarticular disorders tend to be painful on active, but not passive (or assisted), range of motion. Periarticular conditions often demonstrate point or focal tenderness in regions adjacent to articular structures, may radiate or be elicited with a specific movement or position, and have physical findings remote from the joint capsule. Nonarticular disorders seldom demonstrate swelling, crepitus, instability, or deformity.

INFLAMMATORY OR NONINFLAMMATORY

Early on, the examiner should determine whether the underlying pathologic process is inflammatory or noninflammatory. Inflammatory disorders may be infectious (*Neisseria gonorrhoeae* or *Mycobacterium tuberculosis*), crystal-induced (gout, pseudogout), immune-related (rheumatoid arthritis [RA], systemic lupus erythematosus [SLE]), reactive (rheumatic fever, reactive arthritis), or idiopathic. Inflammatory disorders may be suggested by any of the four cardinal signs of inflammation (erythema, warmth, pain, or swelling), systemic symptoms (fever, rash, weight loss), or laboratory evidence of inflammation (elevated erythrocyte sedimentation rate [ESR] or C-reactive protein [CRP], thrombocytosis, anemia of chronic disease, or hypoalbuminemia). Articular stiffness often accompanies chronic musculoskeletal disorders. The duration of stiffness may be prolonged (hours) with inflammatory disorders (such as RA or polymyalgia rheumatica [PMR]) and improves with activity. By contrast, short-lived or intermittent stiffness (also known as gel phenomenon) is typical of noninflammatory conditions (such as osteoarthritis [OA]), is brief in duration (≤45 min), and is exacerbated by activity. Fatigue may be profound with inflammation (as seen in RA and PMR) but may also be seen with fibromyalgia (a noninflammatory disorder), chronic pain, poor sleep, depression, anemia, cardiac failure, endocrinopathy, malnutrition, deconditioning, or chronic illness.

Noninflammatory disorders may be related to trauma (rotator cuff tear), repetitive use (bursitis, tendinitis), degeneration or ineffective repair (OA), neoplasm (pigmented villonodular synovitis), or pain amplification (fibromyalgia). Noninflammatory disorders are often characterized by pain without synovial swelling or warmth, absence of inflammatory or systemic features, intermittent gel phenomena and normal (for age) or negative laboratory investigations.

The musculoskeletal complaint can be refined and categorized by noting the chronology, pathology, locale, and distribution of the complaint (e.g., acute inflammatory monoarthritis, chronic noninflammatory, nonarticular widespread pain). Narrowing the diagnostic considerations can clarify the need for immediate diagnostic or therapeutic intervention or for continued observation. Figure 382-1 presents an algorithmic approach to the evaluation of patients with musculoskeletal complaints. This approach relies on clinical and historic features, rather than laboratory testing, to diagnose the most common rheumatic disorders.

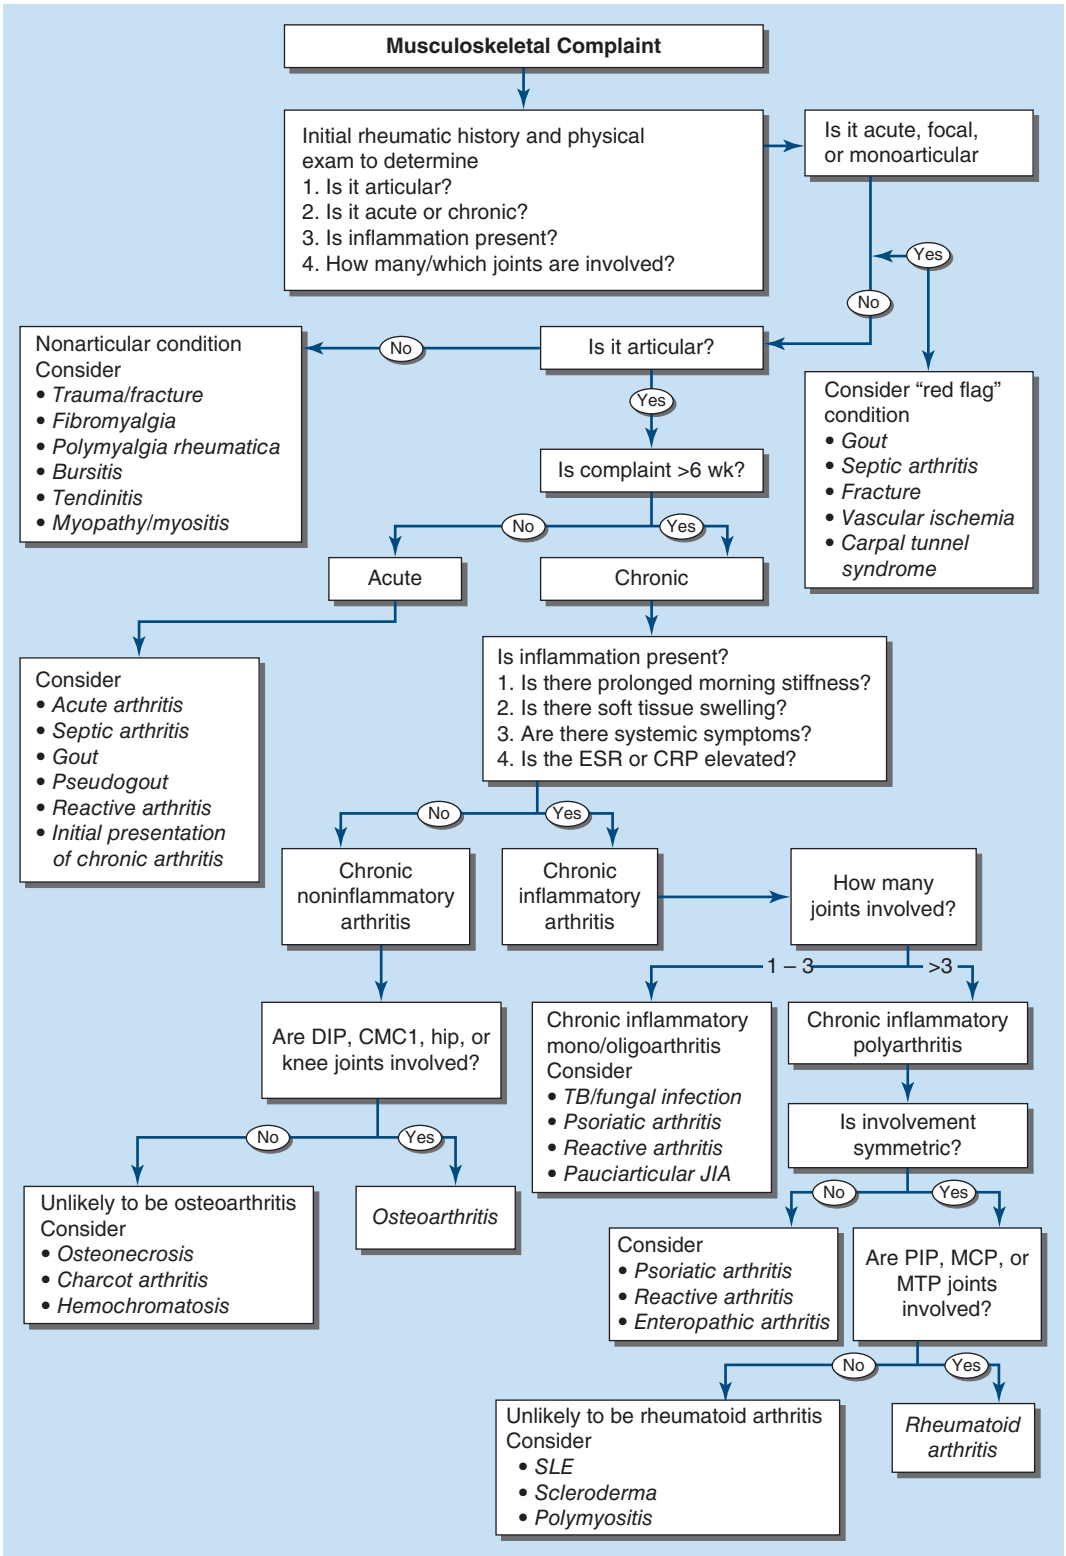

FIGURE 382-1 Algorithm for the diagnosis of musculoskeletal complaints. An approach to formulating a differential diagnosis (shown in italics). CMC, carpometacarpal; CRP, C-reactive protein; DIP, distal interphalangeal; ESR, erythrocyte sedimentation rate; JIA, juvenile idiopathic arthritis; MCP, metacarpophalangeal; MTP, metatarsophalangeal; PIP, proximal interphalangeal; PMR, polymyalgia rheumatica; SLE, systemic lupus erythematosus; TB, tuberculosis.

A simpler, alternative approach would consider the most commonly encountered conditions first, based on the age of the subject. The most prevalent causes of musculoskeletal complaints are shown in **Fig. 382-2**. Because trauma, fracture, low back pain, overuse syndromes, and fibromyalgia are among the most common causes of musculoskeletal pain, these should be considered with each new encounter. If excluded, other frequently occurring disorders should be considered according to the patient's age. Hence, those under age 60 years are commonly affected by repetitive use/strain disorders, gout (men only), RA, spondyloarthritis, and uncommonly, infectious arthritis. Patients over 60 years old are frequently affected by OA, crystal (gout and pseudogout) arthritis, PMR, osteoporotic fracture, and uncommonly, septic arthritis. Notably, these conditions are between 10 and 100 times more prevalent than other serious autoimmune conditions, such as SLE, systemic sclerosis (scleroderma), polymyositis, and vasculitis.

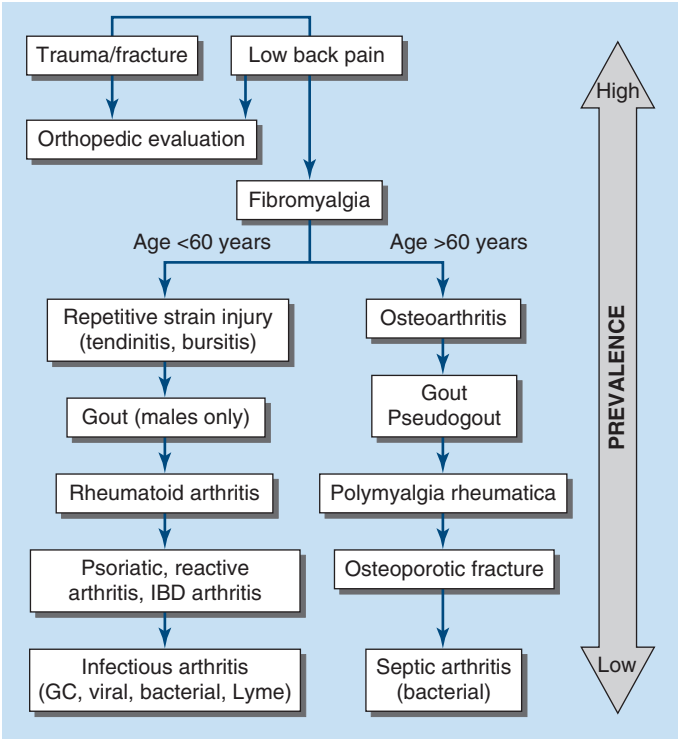

FIGURE 382-2 Algorithm for consideration of the most common musculoskeletal conditions. GC, gonococcal; IBD, inflammatory bowel disease.

CLINICAL HISTORY

Historic features may reveal important insights into the diagnosis. Aspects of the patient profile, complaint chronology, extent of joint involvement, and precipitating factors can provide important information. Certain diagnoses are more frequent in different *age* groups. SLE and gonococcal arthritis occur more frequently in young adults, whereas fibromyalgia and RA are frequent in middle age, and OA and PMR are more prevalent in the elderly. *Sex* and *race* should also be considered. Gout, spondyloarthritis, and ankylosing spondylitis are more common in men, whereas RA, lupus, fibromyalgia, osteoarthritis, and osteoporosis are more frequent in women. *Racial predilections* are common. Thus, PMR, giant cell arteritis, and granulomatosis with polyangiitis (GPA) commonly affect whites, whereas sarcoidosis and SLE more commonly affect African Americans. *Familial aggregation* is unlikely for most arthropathies but may be seen with ankylosing spondylitis, gout, and Heberden's nodes of OA.

The *onset, duration, and evolution* of the complaint are equally important. An abrupt onset is typical of septic arthritis or gout, whereas OA, RA, and fibromyalgia may have more indolent presentations. Musculoskeletal disorders are typically classified by symptom duration as either acute (≤6 weeks) or chronic (>6 weeks). Acute arthropathies tend to be infectious, crystal-induced, or reactive. Chronic conditions may include noninflammatory or immune-mediated (e.g., OA, RA, polymyositis) and nonarticular disorders (e.g., fibromyalgia).

The patients' complaints may evolve differently and be classified as chronic (OA), additive (RA, psoriatic arthritis), intermittent (crystal or Lyme arthritis), or migratory (rheumatic fever, gonococcal or viral arthritis).

The *distribution* of articular involvement is often informative. The number of joints involved defines the complaint as *monoarticular* (one joint), *oligoarticular* or *pauciarticular* (two or three joints), or *polyarticular* (four or more joints). Monoarticular and oligoarticular conditions share similar etiologies. While crystal and infectious arthritis are often mono- or oligoarticular, OA and RA are usually polyarticular. Nonarticular disorders may be classified as either focal or widespread. Tendinitis and carpal tunnel syndrome are typically focal, whereas weakness and myalgia (from polymyositis or fibromyalgia) have more widespread presentations. Joint involvement in RA tends to be symmetric and polyarticular. By contrast, spondyloarthritis, reactive arthritis, and gout are often asymmetric and oligoarticular. OA and psoriatic arthritis may be either symmetric or asymmetric and oligo- or polyarticular. The upper extremities are frequently involved in RA and OA, whereas lower extremity arthritis is characteristic of reactive arthritis and gout at their onset. Involvement of the spine is common in OA and axial spondyloarthritis but is infrequent in RA, with the notable exception of the cervical spine.

The clinical history may also identify *precipitating events*, such as trauma (osteonecrosis, meniscal tear), drug administration (Table 382-2),

TABLE 382-2 Drug-Induced Musculoskeletal Conditions

Arthralgias

Quinidine, cimetidine, beta blockers, quinolones, chronic acyclovir, interferons, IL-2, nicardipine, vaccines, rifabutin, aromatase inhibitors, HIV protease inhibitors, DPP-4 inhibitors (sitagliptin, linagliptin, alogliptin), paclitaxel, checkpoint inhibitors (ipilimumab, pembrolizumab, nivolumab, atezolizumab, durvalumab, cemiplimab), denosumab, teriparatide, abaloparatide, voriconazole

Myalgias/myopathy

Glucocorticoids, penicillamine, hydroxychloroquine, AZT, lovastatin, simvastatin, atorvastatin, pravastatin, clofibrate, amiodarone, interferon, IL-2, alcohol, cocaine, paclitaxel, docetaxel, imatinib mesylate, colchicine, quinolones, cyclosporine, tacrolimus, protease inhibitors, checkpoint inhibitors

Drug-induced dermatomyositis

Hydroxyurea, statins, lipid-lowering agents, penicillamine, immune checkpoint inhibitors, trastuzumab, and tumor necrosis factor inhibitors

Tendon rupture/tendinitis

Quinolones, glucocorticoids, isotretinoin, statins, aromatase inhibitors, collagenase injections

Drug-induced enthesitis

Dupilumab, voriconazole, immune checkpoint inhibitors, fluoroquinolones, retinoids and fluorinated agents

Gout

Diuretics, aspirin, cytotoxics, cyclosporine, tacrolimus, alcohol, moonshine, pyrazinamide, ethambutol, fructose-containing soft drinks, nicotinic acid.

Drug-induced lupus

Hydralazine, procainamide, quinidine, phenytoin, carbamazepine, methyldopa, isoniazid, chlorpromazine, lithium, penicillamine, tetracyclines, TNF inhibitors, ACE inhibitors, ticlopidine, terbinafine, aromatase inhibitors, ethosuximide, vedolizumab, immune checkpoint inhibitors, trastuzumab

Drug-induced subacute lupus

Proton pump inhibitors, calcium channel blockers (diltiazem), ACE inhibitors, TNF inhibitors, terbinafine, interferons (α and β-1a), paclitaxel, docetaxel, gemcitabine, capecitabine, aromatase inhibitors, HCTZ

Osteonecrosis/atypical fractures

Glucocorticoids, alcohol, radiation, bisphosphonates

Osteopenia

Glucocorticoids, chronic heparin, phenytoin, aromatase inhibitors, antiandrogen therapy, thiazolidinediones

Psoriasis

TNF inhibitors, beta blockers, lithium, hydroxychloroquine, chloroquine, minocycline, ACE inhibitors, terbinafine, checkpoint inhibitors

Systemic sclerosis (scleroderma)

Vinyl chloride, bleomycin, baricitinib, pentazocine, organic solvents, carbidopa, tryptophan, rapeseed oil

Raynaud's phenomenon

Cisplatin, bleomycin, beta blockers, clonidine, bromocriptine, ergot alkaloids, cocaine, methylphenidate, dextroamphetamine, phentermine, interferon therapy, tyrosine kinase inhibitors

Vasculitis

Allopurinol, amphetamines, cocaine (often levamisole adulterated), cannabis, thiazides, penicillamine, propylthiouracil, montelukast, TNF inhibitors, hepatitis B vaccine, trimethoprim/sulfamethoxazole, minocycline, hydralazine, apixaban

Abbreviations: ACE, angiotensin-converting enzyme; AZT, zidovudine; HCTZ, hydrochlorothiazide; IL-2, interleukin 2; TNF, tumor necrosis factor.

recent infection (reactive arthritis, hepatitis, chikungunya), or illnesses that may underlie the patient's complaint. Certain comorbidities may have musculoskeletal consequences. This is especially so for diabetes mellitus (carpal tunnel syndrome), renal insufficiency (gout), depression or insomnia (fibromyalgia), myeloma (spinal pain), cancer (myositis), and osteoporosis (fracture). Similarly, there may be musculoskeletal effects with drug use, such as glucocorticoids (osteonecrosis, septic arthritis), diuretics, or chemotherapy (gout) (Table 382-2).

Lastly, an adapted and thorough *rheumatic review of systems* may identify musculoskeletal diagnoses by their associated systemic features, such as fever (Still's disease, infection), rash (SLE, psoriatic arthritis), nail abnormalities (psoriatic or reactive arthritis), myalgias (fibromyalgia, statin- or drug-induced myopathy), or weakness (polymyositis, neuropathy). Musculoskeletal and autoimmune conditions can be suggested by involvement of other organ systems including the eyes (Behçet's disease, sarcoidosis, spondyloarthritis), gastrointestinal tract (systemic sclerosis, inflammatory bowel disease), genitourinary tract (reactive arthritis, gonococci), or nervous system (Lyme disease, vasculitis).

FIBROMYALGIA

Fibromyalgia is a common masquerader of musculoskeletal complaints and is often misdiagnosed or not considered. Fibromyalgia **(see Chap. 385)** is a pain amplification disorder heralded by sleep disturbance, exaggerated pain and sensitivity (owing to lowered pain thresholds), and a multiplicity of symptoms, yet a paucity of abnormalities on clinical examination or laboratory testing. Tender "trigger points" may be elicited over the epicondyles, trochanteric bursae, anserine bursae, and specific muscles (gluteal, trapezius, supraspinatus). Fibromyalgia is characterized by widespread aches and pains, even though presenting symptoms may be fewer or focal. Fibromyalgia often coexists with numerous comorbidities including irritable bowel syndrome, dysmenorrhea, migraine, depression, anxiety, memory loss, nonanatomic paresthesia or dysesthesia, fatigue, myalgias, temporomandibular joint pain, hypermobility, and multiple chemical sensitivities. Fibromyalgia affects over 5 million Americans. Early consideration of this very common disorder can avert needless investigation, therapy, and concern for those afflicted (Fig. 382-2).

THE ELDERLY PATIENT

The incidence of rheumatic diseases rises with age, such that 58% of those >65 years will have joint complaints. Musculoskeletal complaints in the elderly are usually ascribed to aging and arthritis, but may also be related to sarcopenia, deconditioning, poor sleep, and malnutrition. Musculoskeletal disorders may also be overlooked because the signs and symptoms may be insidious or overshadowed by comorbidities or care access issues. These difficulties are compounded by the diminished reliability of laboratory testing in the elderly, who often manifest nonpathologic abnormal results. For example, the ESR (that rises with age) may be misleadingly elevated, and low-titer positive tests for rheumatoid factor (RF) and antinuclear antibodies (ANAs) may be seen in up to 15% of elderly patients. Although nearly all rheumatic disorders afflict the elderly, geriatric patients are particularly prone to OA, osteoporosis, osteoporotic fractures, gout, pseudogout, rotator-cuff disorders, PMR, vasculitis, septic arthritis, depression, and drug-induced disorders (Table 382-2). The elderly should be approached in the same manner as other patients with musculoskeletal complaints, but with an emphasis on identifying the potential rheumatic consequences of comorbidities and therapies used in the elderly. The physical examination should identify the nature of the musculoskeletal complaint as well as coexisting diseases that may influence diagnosis and choice of treatment.

THE HOSPITALIZED PATIENT

The hospitalized patient with rheumatic complaints may pose a diagnostic challenge owing to symptom severity, acute plus chronic disease, and greater interplay of comorbidities. Patients with rheumatic disorders tend to be admitted for one of several reasons: (1) acute onset of inflammatory arthritis (possibly gout or septic arthritis); (2) undiagnosed systemic or febrile illness; (3) musculoskeletal trauma; (4) exacerbation or deterioration of an existing musculoskeletal disorder (e.g., SLE); or (5) new medical diagnoses (e.g., thrombotic event, lymphoma, infection) arising in patients with an established rheumatic disorder. Notably, patients with chronic inflammatory disorders (e.g., RA, SLE, psoriatic arthritis) are at increased risk of infection, cardiovascular events, pulmonary disorders, and neoplasia. Rheumatic patients need not be admitted to hospital for widespread pain, serologic abnormalities, or the initiation of new therapies.

Acute monoarticular inflammatory arthritis is a "red flag" presentation (e.g., septic arthritis, gout, pseudogout) that may require arthrocentesis and hospitalization if infection is suspected. New-onset inflammatory polyarthritis has a wide differential diagnosis (e.g., RA, hepatitis-related arthritis, chikungunya arthritis, serum sickness, drug-induced lupus, SLE, polyarticular septic arthritis) and may require targeted laboratory investigations more so than synovial fluid analyses. Patients with febrile, multisystem disorders require exclusion of crystal (gout, pseudogout), infectious, or neoplastic etiologies and an evaluation driven by the dominant symptom/finding with the greatest specificity. Febrile conditions worthy of consideration may include vasculitis (PMR, giant cell arteritis, GPA), adult-onset Still's disease, SLE, antiphospholipid syndrome, IgG4-related disease, and sarcoidosis. A preexisting rheumatic diagnosis (e.g., SLE, RA, ankylosing spondylitis) should be confirmed by careful history and examination and review of medical records, as this will influence the ensuing in-patient evaluation. Notably, when patients with established rheumatic disease are admitted to the hospital, it is usually not for their autoimmune disorder, but rather a comorbid or new medical problem or complication of drug therapy.

Acute gout, pseudogout, or infection, may arise during hospitalization and immobilization. Unfortunately, overly aggressive and unfocused laboratory testing may yield abnormal findings that are better explained by the patient's preexisting condition (chronic lung, renal, or liver disease) rather than a new inflammatory or autoimmune disorder (lupus, vasculitis).

MUSCULOSKELETAL EXAMINATION

The goal of the physical examination is to ascertain the structures involved, the nature of the underlying pathology, the functional consequences of the process, and the presence of systemic or extraarticular manifestations. A knowledge of topographic and functional anatomy is necessary to identify the primary site(s) of involvement and differentiate articular from nonarticular disorders. The musculoskeletal examination depends on careful inspection, palpation, contralateral comparison, and a variety of specific physical maneuvers to elicit diagnostic signs **(Table 382-3)**. Although most articulations of the appendicular skeleton can be examined in this manner, inspection and palpation are not possible for many axial (e.g., zygapophyseal) and inaccessible (e.g., sacroiliac or hip) joints. For such joints, there is a greater reliance on specific maneuvers and imaging for assessment.

Examination of involved and uninvolved joints will determine whether *pain, warmth, erythema*, or *swelling* is present. The locale and level of pain elicited by palpation or movement should be quantified. Examination of 28 easily palpated joints (proximal interphalangeals [PIPs], metacarpophalangeals [MCPs], wrists, elbows, shoulders, and knees) can quantify the number of tender or swollen joints (0–28) involved. Careful examination should distinguish between true articular swelling (caused by bony hypertrophy, synovial effusion or proliferation) and nonarticular (or periarticular) involvement, which usually extends beyond the normal joint margins. Cautious palpation can distinguish synovial effusion (fluctuant swelling) from synovial hypertrophy (grape-like compressibility) and bony hypertrophy (firm as a nut). Small to moderate knee effusions may be identified by the "bulge sign" or "ballottement of the patellae." Bursal effusions (e.g., effusions of the olecranon or prepatellar bursa) are often focal and periarticular, overlie

TABLE 382-3 Glossary of Musculoskeletal Terms

Crepitus
A palpable (less commonly audible) vibratory or crackling sensation elicited with joint motion; fine joint crepitus is common and often insignificant in large joints; coarse joint crepitus indicates advanced cartilaginous and degenerative changes (as in osteoarthritis)

Subluxation
Alteration of joint alignment such that articulating surfaces incompletely approximate each other

Dislocation
Abnormal displacement of articulating surfaces such that the surfaces are not in contact

Range of motion
For diarthrodial joints, the arc of measurable movement through which the joint moves in a single plane

Contracture
Loss of full movement resulting from a fixed resistance caused either by tonic spasm of muscle (reversible) or by fibrosis of periarticular structures (permanent)

Deformity
Abnormal shape, size, or alignment resulting from bony hypertrophy, malalignment of articulating structures, or damage to periarticular supportive structures

Enthesitis
Inflammation of the entheses (tendinous or ligamentous insertions on bone)

Epicondylitis
Infection or inflammation involving an epicondyle

bony prominences, and are fluctuant with defined borders. Joint *stability* (indicative of periarticular support and integrity) can be assessed by stabilizing the proximal joint and applying manual stress to the distal appendage in different planes. *Subluxation* or *dislocation*, which may be secondary to traumatic, mechanical, or inflammatory causes, can be assessed by inspection and palpation. Joint *swelling* or *volume* can be assessed by palpation. Distention of the articular capsule usually causes pain and evident enlargement or fluctuance. The patient will attempt to minimize the pain by maintaining the joint in the position of least intraarticular pressure and greatest volume (usually partial flexion). With chronicity, this may lead to flexion contracture. Active and passive *range of motion* should be assessed in all planes, with contralateral comparison. A goniometer may be used to accurately quantify the arc of movement. Each joint should be passively moved through its full range of motion (including, as appropriate, flexion, extension, rotation, abduction, adduction, lateral bending, inversion, eversion, supination, pronation, medial/lateral deviation, and plantar- or dorsiflexion). Extremes in range of motion and connective tissue laxity may be seen with hypermobility syndrome, Ehlers-Danlos syndrome, or Marfan's syndrome. Limitation of motion or contractures are frequently caused by inflammation, effusion, pain, deformity, or neuromyopathic causes. If passive motion exceeds active motion, a periarticular process (e.g., tendinitis, tendon rupture, or myopathy) should be considered. *Contractures* may reflect antecedent synovial inflammation, trauma, or chronic immobilization. Minor joint *crepitus* is common during joint palpation and maneuvers, but if it becomes coarser or louder, it may indicate significant cartilage degeneration and degenerative changes (e.g., OA). Joint *deformity* usually indicates a long-standing or aggressive pathologic process. Deformities may result from ligamentous destruction, soft tissue contracture, bony enlargement, ankylosis, erosive disease, subluxation, trauma, or loss of proprioception. Examination of the musculature will document strength, atrophy, pain, or spasm. Appendicular muscle weakness should be characterized as proximal or distal. Muscle strength should be assessed by observing the patient's performance (e.g., walking, rising from a chair, grasping, writing). Motor strength may also be graded on a 5-point scale: 0 for no movement; 1 for trace movement or twitch; 2 for movement with gravity eliminated; 3 for movement against gravity only; 4 for movement against gravity and resistance; and 5 for normal strength. The examiner should assess for (often overlooked) nonarticular or periarticular involvement, especially when articular complaints are not supported by objective findings referable to the joint capsule. The identification of soft tissue or nonarticular pain will prevent unwarranted and often expensive laboratory or imaging evaluations. Specific maneuvers may reveal common nonarticular abnormalities, such as a carpal tunnel syndrome (best identified by Durkan's test or Tinel's sign). Other examples of soft tissue abnormalities include olecranon bursitis, epicondylitis (e.g., tennis elbow), enthesitis (e.g., Achilles tendinitis), and tender trigger points associated with fibromyalgia.

REGIONAL RHEUMATIC COMPLAINTS

Focal musculoskeletal complaints may exhibit a predictable pattern of onset, evolution, and localization and are best diagnosed by their localization, along with select maneuvers or tests. Four commonly involved anatomic regions—the hand, shoulder, hip, and knee—are reviewed here.

HAND PAIN

Focal or unilateral hand pain may result from trauma, overuse, infection, or reactive or crystal-induced arthritis. By contrast, bilateral hand complaints commonly suggest a degenerative (e.g., OA), systemic, or inflammatory/immune (e.g., RA) etiology. The distribution or pattern of joint involvement is suggestive of certain disorders **(Fig. 382-3)**. Thus, OA (or degenerative arthritis) may manifest as distal interphalangeal (DIP) and PIP joint pain with bony hypertrophy leading to Heberden's and Bouchard's nodes, respectively. Pain, with or without bony swelling, involving the base of the thumb (first carpometacarpal joint) is also highly suggestive of OA. By contrast, RA manifests as an additive, symmetric, polyarticular arthritis involving the PIP, MCP, intercarpal, and carpometacarpal joints (wrist) with pain and palpable synovial tissue hypertrophy. Psoriatic arthritis may mimic the pattern of joint involvement seen in OA (DIP and PIP joints) but can be

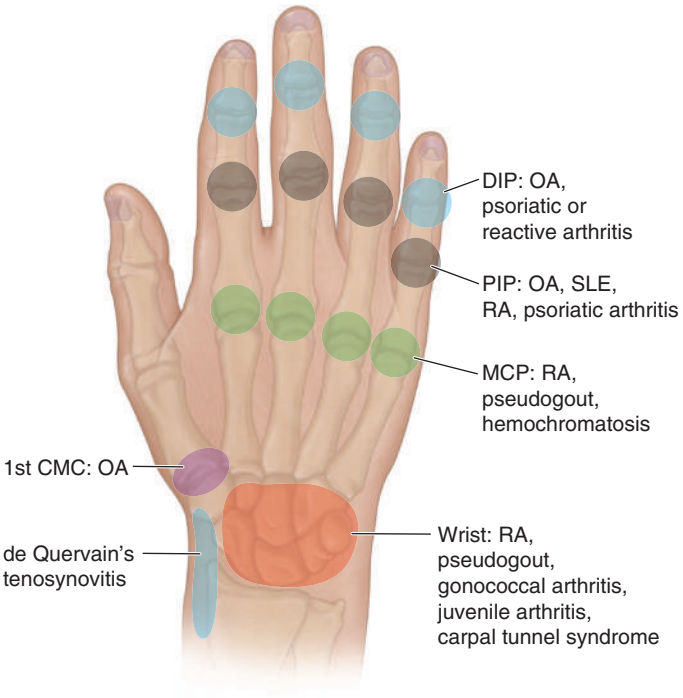

FIGURE 382-3 Sites of hand or wrist involvement and their potential disease associations. CMC, carpometacarpal; DIP, distal interphalangeal; MCP, metacarpophalangeal; OA, osteoarthritis; PIP, proximal interphalangeal; RA, rheumatoid arthritis; SLE, systemic lupus erythematosus. *(Reproduced with permission from JJ Cush et al [eds], Evaluation of musculoskeletal complaints, in Rheumatology: Diagnosis and Therapeutics, 2nd ed. Philadelphia, Lippincott Williams & Wilkins, 2005.)*

distinguished by the presence of inflammation (erythema, warmth, synovial swelling), with or without carpal involvement, nail pitting, or onycholysis. Whereas lateral or medial subluxations at the PIP or DIP joints are most likely due to inflammatory OA or psoriatic arthritis, dorsal or ventral deformities (swan neck or boutonnière deformities) are typical of RA. Hemochromatosis should be considered when degenerative changes (bony hypertrophy) are seen at the second and third MCP joints with associated radiographic chondrocalcinosis or episodic, inflammatory wrist arthritis.

Dactylitis manifests as soft tissue swelling of the whole digit and may have a sausage-like appearance. Common causes of dactylitis include psoriatic arthritis, spondyloarthritis, juvenile spondylitis, enthesitis-related arthropathy, mixed connective tissue disease, systemic sclerosis, sarcoidosis, and sickle cell disease. Soft tissue swelling over the dorsum of the hand and wrist may suggest an inflammatory extensor tendon tenosynovitis possibly caused by gonococcal infection, gout, tuberculosis, RA, or giant cell tumor. Tenosynovitis is suggested by swelling or pitting edema (with or without warmth) and may be confirmed when the soft tissue swelling tracks with tendon movement during flexion and extension of fingers, or when pain is induced while stretching the extensor tendon sheaths (flexing the digits distal to the MCP joints and maintaining the wrist in a fixed, neutral position). Volar (palmar) tendon swellings may be from tenosynovitis, Dupuytren's contractures, tendon nodules, or synovial cysts.

Focal wrist pain localized to the radial aspect may be caused by de Quervain's tenosynovitis resulting from inflammation of the tendon sheath(s) involving the abductor pollicis longus or extensor pollicis brevis (Fig. 382-3). This commonly results from occupational or repetitive overuse or follows pregnancy and can be diagnosed with Finkelstein's test. A positive test is present when radial wrist pain is induced after the thumb is flexed and placed inside a clenched fist and the patient actively deviates the hand downward with ulnar deviation at the wrist. Carpal tunnel syndrome is another common disorder of the upper extremity and results from compression of the median nerve within the carpal tunnel. Manifestations include pain in the wrist that may radiate with paresthesia to the thumb, second and third fingers, and radial half of the fourth finger and, at times, atrophy of thenar musculature. Carpal tunnel syndrome is commonly associated with pregnancy, edema, trauma, OA, inflammatory arthritis, and infiltrative disorders (e.g., amyloidosis). The diagnosis may be suggested by a positive Durkan's test or Tinel's sign. With each test, paresthesia in a median nerve distribution is induced or increased by 30 s of compression over the carpal tunnel (Durkan's test) or "thumping" the volar aspect of the wrist and median nerve (Tinel's sign). The low sensitivity and moderate specificity of these tests may require nerve conduction velocity testing to confirm a suspected diagnosis.

SHOULDER PAIN

Shoulder involvement is common in those with a history of trauma, fibromyalgia, infection, inflammatory arthritis, occupational risks, or previous cervical surgery or disease. The patient should be questioned as to the activities or movement(s) that elicit shoulder pain. While arthritis is suggested by pain on movement in all planes, pain with specific or active (not passive) motion suggests a periarticular (nonarticular) process. Shoulder pain may originate in the glenohumeral or acromioclavicular joints, subacromial (subdeltoid) bursa, or periarticular soft tissues (e.g., fibromyalgia, rotator cuff tear/tendinitis) **(Fig. 382-4)**. Shoulder pain may be referred from the cervical spine but may also be referred from intrathoracic lesions (e.g., a Pancoast tumor), gallbladder, liver, or diaphragmatic disease. These same visceral causes may also manifest as focal scapular pain. Fibromyalgia should be suspected when glenohumeral pain is accompanied by diffuse periarticular (i.e., subacromial, bicipital) pain, tender points (i.e., trapezius or supraspinatus), and a sleep disturbance. The shoulder should be put through its full range of motion, both active and passive (with examiner assistance) movements: forward flexion, extension, abduction, adduction, and internal and external rotation. Glenohumeral pain and pathology are best detected by placing the thumb anteriorly over the glenohumeral joint, just medial and inferior to the coracoid process, and applying pressure anteriorly while internally and externally rotating the humeral head. Synovial effusion or tissue is seldom palpable in the shoulder, but, if present, may suggest infection, RA, amyloidosis, or an acute tear of the rotator cuff. The examiner should apply direct manual pressure over the subacromial bursa that lies lateral to and immediately beneath the acromion (Fig. 382-4). Subacromial bursitis is a frequent cause of shoulder pain. Anterior to the subacromial bursa, the bicipital tendon traverses the bicipital groove. This tendon is best identified by palpating it in its groove as the patient rotates the humerus internally and externally. Direct pressure over the tendon may reveal pain indicative of bicipital tendinitis. Palpation of the acromioclavicular joint may disclose local pain, bony hypertrophy, or, uncommonly, synovial swelling. Whereas OA and RA commonly involve the acromioclavicular joint, OA only involves the glenohumeral joint with trauma, occupational causes, or osteonecrosis.

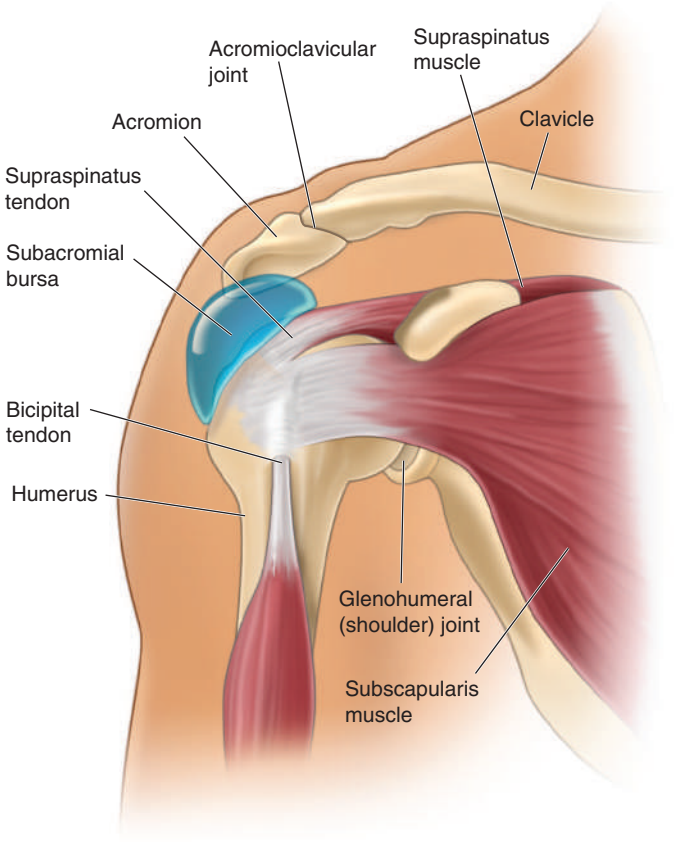

FIGURE 382-4 Origins of shoulder pain. The schematic diagram of the shoulder indicates, with *arrows*, the anatomic origins of shoulder pain.

Rotator cuff tendinitis or tears are a very common cause of shoulder pain, especially in those who are active, manual laborers or have inflammatory arthritis. Nearly 30% of the elderly with shoulder pain will have rotator cuff tendinitis or tear as a primary cause. The rotator cuff is formed by four tendons that attach the scapula to the proximal humerus (supraspinatus, infraspinatus, teres minor, and subscapularis tendons). Of these, the supraspinatus muscle is the most commonly damaged. Rotator cuff tendinitis is suggested by pain on active abduction (but not passive abduction), pain over the lateral deltoid muscle, night pain, and evidence of the impingement signs (pain with overhead arm activities). The Neer test for impingement is performed by the examiner raising the patient's arm into forced flexion while stabilizing and preventing rotation of the scapula. A positive sign is present if pain develops before 180° of forward flexion. Tear of the rotator cuff is common in the elderly and often results from trauma; it may manifest in the same manner as tendinitis. The drop arm test is abnormal with supraspinatus pathology and is demonstrated by passive abduction of the arm to 90° by the examiner. If the patient is

unable to hold the arm up actively or unable to lower the arm slowly without dropping, the test is positive. Tendinitis or tear of the rotator cuff is best confirmed by magnetic resonance imaging (MRI) or ultrasound.

KNEE PAIN

Knee pain may result from intraarticular (OA, RA) or periarticular (anserine bursitis, collateral ligament strain) processes or be referred from hip pathology (fracture). A careful history should delineate the chronology of the knee complaint and whether there are predisposing conditions, trauma, medications, or activities that may underlie the complaint. For example, patellofemoral disease (e.g., OA) may cause anterior knee pain that worsens with climbing stairs. Observing the patient's gait may identify a knee, hip, or foot disorder. The knee should be carefully inspected in the upright (weight-bearing) and supine positions for swelling, erythema, malalignment, visible trauma, muscle wasting, and leg length discrepancy (measuring from the anterior superior iliac crest to medial malleolus, with contralateral comparison). The most common malalignment in the knee is *genu varum* (bowlegs) or *genu valgum* (knock-knees) resulting from asymmetric cartilage loss medially or laterally, respectively. Bony swelling of the knee joint commonly results from hypertrophic osseous changes seen with disorders such as OA and neuropathic arthropathy. Swelling caused by hypertrophy of the synovium or synovial effusion may manifest as a fluctuant, ballotable, or soft tissue enlargement in the suprapatellar pouch (suprapatellar reflection of the synovial cavity) or regions lateral and medial to the patella. Synovial effusions may also be detected by balloting the patella downward toward the femoral groove or by eliciting a "bulge sign." With the knee extended, the examiner should manually compress, or "milk," synovial fluid down from the suprapatellar pouch and lateral to the patellae. The application of manual pressure lateral to the patella may cause an observable shift in synovial fluid (bulge) to the medial aspect. The examiner should note that this maneuver is only effective in detecting small to moderate effusions (<100 mL). Inflammatory disorders such as RA, gout, pseudogout, and psoriatic arthritis may involve the knee joint and produce significant pain, swelling, or warmth. A popliteal or *Baker's cyst* may be palpated with the knee partially flexed and is best viewed posteriorly with the patient standing and knees fully extended to visualize isolated or unilateral popliteal swelling or fullness.

Anserine bursitis is an often-missed periarticular cause of knee pain in adults. The pes anserine bursa underlies the insertion of the conjoined tendons (sartorius, gracilis, semitendinosus) on the anteromedial proximal tibia and may be painful following trauma, overuse, or inflammation (bursitis). It is often tender (rarely inflamed) in patients with fibromyalgia, obesity, and knee OA. Other forms of bursitis may also present as knee pain. The prepatellar bursa is superficial and is located over the inferior portion of the patella. The infrapatellar bursa is deeper and lies beneath the patellar ligament before its insertion into the tibial tubercle.

Internal derangement of the knee, from trauma or degenerative processes, implies mechanical disruption of articulating surfaces by damage to cartilage or ligaments or fracture. Damage to the meniscal cartilage (medial or lateral) frequently presents as chronic or intermittent knee pain. Such injury should be suspected when there is a history of trauma, athletic activity, or chronic knee arthritis, and when the patient relates symptoms of "locking," "buckling," or "giving way" of the knee. With the knee flexed 90° and the patient's foot on the table, pain elicited during palpation over the joint line or when the knee is stressed laterally or medially may suggest a meniscal tear. A positive McMurray test may also indicate a meniscal tear. To perform this test, the knee is first flexed at 90°, and the leg is then extended while the lower extremity is simultaneously torqued medially or laterally. A painful click during inward rotation may indicate a lateral meniscus tear, and pain during outward rotation may indicate a tear in the medial meniscus. Lastly, damage to the cruciate ligaments should be suspected with acute onset of pain, possibly with swelling, a history of trauma, or a synovial fluid aspirate that is grossly bloody. Examination of the cruciate ligaments is best accomplished by eliciting a drawer sign. With the patient recumbent, the knee should be partially flexed and the foot stabilized on the examining surface. The examiner should manually attempt to displace the tibia anteriorly or posteriorly with respect to the femur. If anterior movement is detected, then anterior cruciate ligament damage is likely. Conversely, significant posterior movement may indicate posterior cruciate damage. Contralateral comparison will assist the examiner in detecting significant anterior or posterior movement. Collateral ligament damage is suggested by pain on palpation or manual stretch of the ligament (medial or lateral).

HIP PAIN

The hip is best evaluated by observing the patient's gait and assessing range of motion. The vast majority of patients reporting "hip pain" localize their pain unilaterally to the posterior gluteal musculature **(Fig. 382-5)** with radiation down the posterolateral aspect of the thigh,

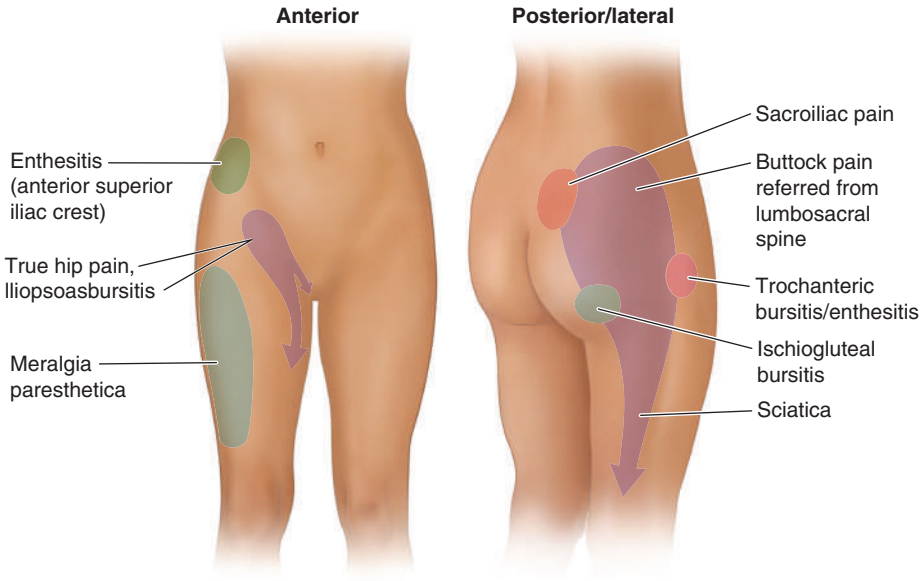

FIGURE 382-5 Origins of hip pain and dysesthesias. *(Reproduced with permission from JJ Cush et al [eds], Evaluation of musculoskeletal complaints, in Rheumatology: Diagnosis and Therapeutics, 2nd ed. Philadelphia, Lippincott Williams & Wilkins, 2005.)*

with or without associated low back pain. This presentation frequently results from degenerative arthritis of the lumbosacral spine or disks and commonly follows a dermatomal distribution with involvement of nerve roots between L4 and S1. Sciatica is caused by impingement of the L4, L5, or S1 nerve (i.e., from a herniated disk) and manifests as unilateral neuropathic pain extending from the gluteal region down the posterolateral leg to the foot. Some individuals instead localize their "hip pain" laterally to the area overlying the trochanteric bursa. Because of the depth of this bursa, swelling and warmth are usually absent. Diagnosis of trochanteric bursitis or enthesitis can be confirmed by inducing point tenderness over the trochanteric bursa. Gluteal and trochanteric pain are common findings in fibromyalgia. Range of movement may be limited by pain. Pain from the "true" hip joint is less common and tends to be located anteriorly, over the inguinal ligament; may radiate medially to the groin; and is worsened by adduction or rotation of the hip. Uncommonly, iliopsoas bursitis may mimic true hip joint pain. Pain associated with iliopsoas bursitis is localized to the groin or anterior thigh and tends to worsen with hyperextension of the hip; many patients prefer to flex and externally rotate the hip to reduce the pain from a distended iliopsoas bursa.

TELEHEALTH EVALUATION

Telemedicine has grown significantly in recent years as a means of remote patient assessment and clinical care. Engagement of patients via electronic telecommunication allows for virtual patient evaluations with a time, cost, and convenience advantage, but can be a disadvantage for the elderly or technologically disadvantaged populations. Telemedicine requires quality audio and video connections and is appropriate for patient education, monitoring, and routine disease assessments. Patients evaluated by telemedicine should undergo the same medical history and inquiry as a routine clinic evaluation but will differ in the scope of examination and maneuvers. The virtual (televideo) musculoskeletal examination may be appropriate and effective in many, with a reliance on functional observation, range of motion, patient self-examination, and contralateral comparison. Specifically, the televideo exam should assess the following: (1) patient gait (to assess lower extremity abnormalities); (2) rising from a seated position (to assess for weakness); (3) cervical range of motion (flexion, extension, lateral bending); (4) upper extremity assessment by contralateral comparison (e.g., "praying hands," "make a fist," "flex wrists," and "hands on ears, elbows out" to assess shoulder range of motion); and (5) side-by-side inspection of knees, ankles, and feet. Telehealth evaluations are contingent on clinical experience, knowledge of and familiarity with the patient, and training the patient on the use of technology and goals and limits of a televideo visit. Telephone-only assessments do not qualify as telehealth visits.

LABORATORY INVESTIGATIONS

Most musculoskeletal disorders can be logically diagnosed by a complete history and physical examination. An additional objective of the initial encounter is to determine whether additional investigations or immediate therapy is required. Laboratory evaluation is indicated with (1) monoarticular presentations; (2) traumatic or inflammatory conditions; (3) the presence of neurologic findings; (4) systemic manifestations; or (5) chronic symptoms (>6 weeks) and a lack of response to symptomatic measures. The extent and nature of the additional investigation should be dictated by the clinical features and suspected pathologic process. Laboratory tests should be used to confirm a specific clinical diagnosis and not be used to screen or evaluate patients with vague rheumatic complaints. Indiscriminate use of broad batteries of diagnostic tests and radiographic procedures is rarely a useful or cost-effective means to establish a diagnosis.

Besides a complete blood count, including a white blood cell (WBC) and differential count, the routine evaluation should include a determination of an acute-phase reactant such as the ESR or CRP, which can be useful in discriminating inflammatory from noninflammatory disorders. Both are inexpensive, easily obtained, and may be elevated with infection, inflammation, autoimmune disorders, neoplasia, pregnancy, renal insufficiency, advanced age, or hyperlipidemia. Extreme elevation of the acute-phase reactants (CRP, ESR) is seldom seen without evidence of serious illness (e.g., sepsis, pleuropericarditis, PMR, giant cell arteritis, Still's disease). Conversely, not all active, inflammatory or autoimmune conditions will have an elevated ESR or CRP; in active SLE and RA patients, nearly 50% will have normal ESR and CRP results.

Serum uric acid determinations are useful in the diagnosis of gout and in monitoring the response to urate-lowering therapy. Uric acid, the product of purine metabolism, is primarily excreted in the urine. Serum values range from 238 to 516 μmol/L (4.0–8.6 mg/dL) in men; lower values (178–351 μmol/L [3.0–5.9 mg/dL]) seen in women are caused by the uricosuric effects of estrogen. Urinary uric acid levels are normally <750 mg per 24 h. Although hyperuricemia is associated with an increased incidence of gout and nephrolithiasis, levels may not correlate with the severity of disease. Uric acid levels (and the risk of gout) may be increased by inborn errors of metabolism (Lesch-Nyhan syndrome), disease states (renal insufficiency, myeloproliferative disease, psoriasis), or drugs (alcohol, cytotoxic therapy, thiazides). Although nearly all patients with gout will demonstrate hyperuricemia at some time during their illness, up to 50% of patients will have normal serum uric acid levels during an acute gouty attack. Monitoring serum uric acid is useful in assessing the response to urate-lowering therapy or chemotherapy, with the target goal being a serum urate <6 mg/dL (<5 mg/dL if tophi are present).

Serologic tests for RF, cyclic anti-citrullinated peptide (CCP or ACPA) antibodies, ANAs, complement levels, Lyme and antineutrophil cytoplasmic antibodies (ANCAs), or antistreptolysin O (ASO) titer should be carried out only when there is sufficient clinical evidence to suggest a specific diagnosis. These have poor predictive value when used for screening, particularly when the pretest probability is low. There is little value to repeated or serial serologic testing. Although 4–5% of a healthy population will have positive tests for RF and ANAs, only 1% and <0.4% of the population will have RA or SLE, respectively. IgM RF (autoantibodies against the Fc portion of IgG) is found in 80% of patients with RA and is moderately specific as it may also be seen in low titers in patients with chronic infections (tuberculosis, leprosy, hepatitis); other autoimmune diseases (SLE, Sjögren's syndrome); and chronic pulmonary, hepatic, or renal disease. When considering RA, both serum RF and anti-CCP antibodies should be obtained, as these are complementary. Both are comparably sensitive, but CCP antibodies are more specific than RF. In RA, the presence of high titers of anti-CCP or RF antibodies, or double positivity, may indicate a greater risk for more severe, erosive polyarthritis. ANAs are found in nearly all patients with SLE and may also be seen in patients with other autoimmune diseases (polymyositis, systemic sclerosis, antiphospholipid syndrome, Sjögren's syndrome), drug-induced lupus (Table 382-2), chronic thyroid, liver, or renal disorders, and advanced age. Positive ANAs are found in 5% of adults, up to 15% of elderly or chronically ill individuals, and up to 80% of patients with thyroid disease. The ANA test is very sensitive but poorly specific for lupus, as only 1–2% of all positive results will be caused by lupus alone. The interpretation of a positive ANA test may depend on the magnitude of the titer and the pattern observed by immunofluorescence microscopy **(Table 382-4)**. Diffuse and speckled patterns are least specific, whereas a peripheral, or rim, pattern (related to autoantibodies against double-strand [native] DNA) is highly specific and suggestive of lupus. Centromeric patterns are seen in patients with limited cutaneous systemic sclerosis (*c*alcinosis, *R*aynaud's phenomenon, *e*sophageal involvement, *s*clerodactyly, *t*elangiectasia [CREST] syndrome), primary biliary sclerosis, Sjögren's syndrome, or thyroiditis, and nucleolar patterns may be seen in patients with diffuse cutaneous systemic sclerosis or inflammatory myositis. More detailed serologic autoantibody profiling may be appropriate when specific autoimmune disorders (Sjögren's, dermatomyositis, systemic sclerosis) are diagnosed, but should not be employed as screening tests.

Aspiration and analysis of synovial fluid are always indicated in acute monoarthritis or when an infectious or crystal-induced arthropathy is suspected. Synovial fluid may distinguish between noninflammatory

TABLE 382-4 Antinuclear Antibody (ANA) Patterns and Clinical Associations

ANA PATTERN	ANTIGEN IDENTIFIED	CLINICAL CORRELATE
Diffuse	Deoxyribonucleoprotein	Nonspecific
	Histones	Drug-induced lupus, lupus
Peripheral (rim)	ds-DNA	50% of SLE (specific)
Speckled	U1-RNP	>90% of MCTD
	Sm	30% of SLE (specific)
	Ro (SS-A)	Sjögren's 60%, SCLE, neonatal lupus, ANA (–) lupus
	La (SS-B)	50% of Sjögren's, 15% lupus
	Scl-70 (topoisomerase I)	40% of diffuse cutaneous systemic sclerosis
	Jo-1 (histidyl t-RNA synthetase)	PM with pneumonitis + arthritis
Nucleolar	RNA polymerase I, others	40% of PSS
Centromere	Kinetochore	75% CREST (limited cutaneous systemic sclerosis), PBC, Sjögren's, thyroiditis

Abbreviations: CREST, *c*alcinosis, *R*aynaud's phenomenon, *e*sophageal involvement, *s*clerodactyly, and *t*elangiectasia; MCTD, mixed connective tissue disease; PBC, primary biliary cirrhosis; PSS, progressive systemic sclerosis; SCLE, subacute cutaneous lupus erythematosus; SLE, systemic lupus erythematosus.

and inflammatory processes by analysis of the appearance, viscosity, and cell count. Tests for synovial fluid glucose, protein, lactate dehydrogenase, lactic acid, or autoantibodies are not recommended as they have no diagnostic value. Normal synovial fluid is clear or a pale straw color and is viscous, primarily because of the high levels of hyaluronate. Noninflammatory synovial fluid is clear, viscous, and amber-colored, with a WBC count of <2000/μL and a predominance of mononuclear cells. The viscosity of synovial fluid is assessed by expressing fluid from the syringe one drop at a time. Normally, there is a stringing effect, with a long tail behind each synovial drop. Effusions caused by OA or trauma will have normal viscosity or "string sign." Inflammatory fluid is turbid and yellow, with an increased WBC count (2000–50,000/μL) and a polymorphonuclear leukocyte predominance. Inflammatory fluid has reduced viscosity (no stringing), diminished hyaluronate, and little or no tail following each drop of synovial fluid. Such effusions are found in RA, gout, and other inflammatory arthritides. Septic fluid is opaque and purulent, with a WBC count usually >50,000/μL, a predominance of polymorphonuclear leukocytes (>75%), and low viscosity. Such effusions are typical of septic arthritis but may also occur with RA or gout. Lastly, hemorrhagic synovial fluid (hemarthrosis) may be seen with trauma (ligament or cartilage tears), osteochondral fracture, neuropathic arthritis, or coagulopathy. An algorithm for synovial fluid aspiration and analysis is shown in Fig. 382-6. Synovial fluid should be analyzed immediately for appearance, viscosity, and cell count. Monosodium urate crystals (observed in gout) are seen by polarized microscopy and are long, needle-shaped, negatively birefringent, and usually intracellular. In chondrocalcinosis and pseudogout, calcium pyrophosphate dihydrate crystals are usually short, rhomboid-shaped, and positively birefringent. Whenever infection is suspected, synovial fluid should be Gram stained and cultured and tested by metagenomic sequencing, when appropriate. If gonococcal arthritis is suspected, nucleic acid amplification tests should be used to detect either *Chlamydia trachomatis* or *N. gonorrhoeae* infection. Synovial fluid from patients with chronic monoarthritis should also be cultured for *M. tuberculosis* and fungi. Last, it should be noted that crystal-induced arthritis and septic arthritis occasionally occur together in the same joint.

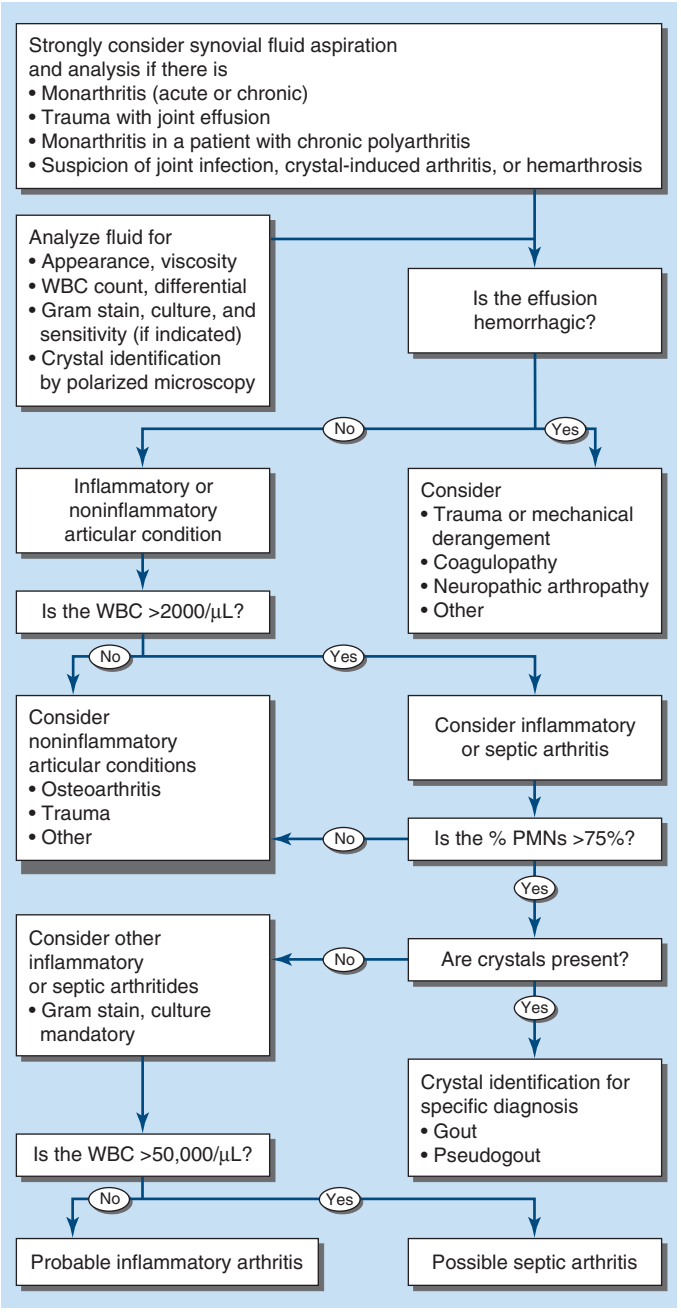

FIGURE 382-6 Algorithmic approach to the use and interpretation of synovial fluid aspiration and analysis. PMNs, polymorphonuclear (leukocytes); WBC, white blood cell count.

DIAGNOSTIC IMAGING

Conventional radiography has been a valuable tool in the diagnosis and staging of articular disorders. Plain x-rays are most appropriate and cost effective when there is a history of trauma, suspected chronic infection, progressive disability, or monoarticular involvement; when therapeutic alterations are considered; or when a baseline assessment is desired for what appears to be a chronic process. However, in acute or early arthritis, early radiography is rarely helpful in establishing a diagnosis and may only reveal soft tissue swelling or juxtaarticular demineralization. As the disease progresses, conventional radiographs may disclose calcification (of soft tissues, cartilage, or periarticular bone), joint space narrowing, erosions, bony ankylosis, new bone formation (sclerosis, osteophytes, or periostitis), or subchondral cysts may develop and suggest specific clinical entities. Advanced imaging with computed tomography (CT) or magnetic resonance imaging (MRI) is more expensive but may reveal the extent of articular or periarticular involvement. Consultation with a radiologist will help define the optimal imaging modality, technique, or positioning to optimize interpretation and prevent the need for further studies.

Additional imaging techniques may be indicated in selected circumstances or when conventional radiography is inadequate or

nondiagnostic (Table 382-5). *Ultrasonography* is useful in the detection of soft tissue abnormalities (tendinitis, tenosynovitis, enthesitis, bursitis), crystal deposition, and entrapment neuropathies. Lower cost, better technology, and enhanced site-specific transducers now allow for wider use and diagnostic specificity, especially when considering synovial (Baker's) cysts, rotator cuff tears, tendinitis (PMR) and tendon injury, and crystal deposition on cartilage. Use of power Doppler allows for early detection of synovitis and bony erosions. *Radionuclide scintigraphy* is a very sensitive, but poorly specific, means of detecting inflammatory or metabolic alterations in bone or periarticular soft tissue structures (Table 382-5). Scintigraphy is best suited for total-body assessment (extent and distribution) of skeletal involvement (neoplasia, Paget's disease) or the assessment of patients with undiagnosed polyarthralgias, looking for occult arthritis or inflammation. The use of scintigraphy has declined with greater use, specificity, and declining cost of ultrasound and MRI. MRI has largely replaced scintigraphy in diagnosing osseous infection, neoplasia, inflammation, increased blood flow, bone remodeling, heterotopic bone formation, or avascular necrosis. Gallium scanning uses ^{67}Ga, which binds serum and cellular transferrin and lactoferrin and is preferentially taken up by neutrophils, macrophages, bacteria, and tumor tissue (e.g., lymphoma). As such, it is primarily used in the identification of occult infection or malignancy. Scanning with ^{111}In-labeled WBCs has been used to detect osteomyelitis and infectious or inflammatory arthritis. Despite their utility, ^{111}In-labeled WBC and ^{67}Ga scanning have also been largely replaced by MRI, except when there is a suspicion of septic joint or prosthetic joint infections.

CT provides detailed visualization of the axial skeleton. Articulations previously considered difficult to visualize by radiography (e.g., zygapophyseal, sacroiliac, sternoclavicular, hip joints) can be evaluated using CT. CT has been demonstrated to be useful in the diagnosis of low back pain (e.g., spinal stenosis vs herniated disk), sacroiliitis, osteoid osteoma, and stress fractures. Helical or spiral CT (with or without contrast angiography) is a novel technique that is rapid, cost effective, and sensitive in diagnosing pulmonary embolism or obscure fractures, often in the setting of initially equivocal findings. High-resolution CT can be advocated in the evaluation of suspected or established infiltrative lung disease (e.g., systemic sclerosis or rheumatoid lung). The recent use of hybrid (positron emission tomography [PET] or single-photon emission CT [SPECT]) CT scans in metastatic evaluations has incorporated CT to provide better anatomic localization of scintigraphic abnormalities.

^{18}F-Fluorodeoxyglucose (FDG) is the most used radiopharmaceutical in PET scanning. FDG-PET/CT scans are rarely indicated in septic or inflammatory arthritis but have been useful in the evaluation of patients with undiagnosed fever, systemic illness, or suspected large vessel vasculitis. FDG-PET may be better at assessing inflammation, whereas MRI and CT can better define the extent of tissue damage. Dual-energy CT (DECT) scanning, developed in urology to identify urinary calculi, has been a highly sensitive and specific method used to identify and quantify uric acid deposition in tissues (Fig. 382-7).

MRI has significantly revolutionized the imaging of musculoskeletal structures, especially in patients with traumatic, systemic, infectious, or neoplastic disorders. MRI has the advantages of providing multiplanar images with fine anatomic detail and contrast resolution (Fig. 382-8) to visualize fascia, vessels, nerve, muscle, cartilage, ligaments, tendons, pannus, synovial effusions, and bone marrow.

Because of its sensitivity to changes in marrow fat, MRI is a sensitive but nonspecific means of detecting osteonecrosis, osteomyelitis, and marrow inflammation indicating overlying synovitis or osteitis (Fig. 382-8). Because of its enhanced soft tissue resolution, MRI is more sensitive than arthrography or CT in the diagnosis of soft tissue injuries (e.g., meniscal and rotator cuff tears); intraarticular derangements; marrow abnormalities (osteonecrosis, myeloma); and spinal cord or nerve root damage, synovitis, or cartilage damage or loss. Although more costly with a longer procedural time than CT, MRI has become the preferred technique when evaluating trauma and complex musculoskeletal disorders.

TABLE 382-5 Diagnostic Imaging Techniques for Musculoskeletal Disorders

METHOD	COST[a]	CURRENT INDICATIONS	CAVEATS
Ultrasound	++	Synovial (Baker's) cysts Rotator cuff tears Bursitis, tendinitis, tendon injury Enthesitis Carpal tunnel syndrome Urate or calcium pyrophosphate deposition on cartilage Early detection of synovial inflammation or erosions Ultrasound-guided injection/ arthrocentesis	Operator dependent
Radionuclide scintigraphy	++	Metastatic bone survey Evaluation of Paget's disease Identifying occult arthritis in patients with undiagnosed polyarthralgia Acute infection Prosthetic infection Acute osteomyelitis Acute and chronic infection Acute osteomyelitis	Low sensitivity Resolution issues
^{99m}Tc	++	Arthritis Inflammation Degeneration Metastases Infection	Ionizing radiation exposure
^{111}In-WBC	+++	Septic arthritis	
^{67}Ga	++++	Prosthetic joint infection	
Computed tomography (CT)	++++	Herniated intervertebral disk Sacroiliitis Spinal stenosis Spinal trauma Osteoid osteoma Stress fracture	Ionizing radiation exposure Contrast use Availability of CT angiography
Dual-energy CT	+++	Uric acid deposition Tophus localization	Not widely available
Magnetic resonance imaging	++++	Avascular necrosis Osteomyelitis Septic arthritis, infected prosthetic joints Sacroiliitis Intraarticular derangement and soft tissue injury Derangements of axial skeleton and spinal cord Herniated intervertebral disk Pigmented villonodular synovitis Inflammatory and metabolic muscle pathology	Cost Contrast use No ionizing radiation Soft tissue detail
FDG-PET CT	+++++++		Very expensive Whole-body scanning Limited availability Ionizing radiation exposure

[a]Imaging cost, relative to conventional radiography.

383 Osteoarthritis

David T. Felson, Tuhina Neogi

Osteoarthritis (OA) is the most common type of arthritis. Its high prevalence, especially in the elderly, and its negative impact on physical function make it a leading cause of disability in the elderly. Because of the aging of Western populations and because obesity, a major risk factor, is increasing in prevalence, the occurrence of OA is on the rise.

OA affects certain joints yet spares others (Fig. 383-1). Commonly affected joints include the hip, knee, and first metatarsal phalangeal joint (MTP) and cervical and lumbosacral spine. In the hands, the distal and proximal interphalangeal joints and the base of the thumb are often affected. Usually spared are the wrist, elbow, and ankle. Our joints were designed, in an evolutionary sense, for brachiating apes, animals that still walked on four limbs. We thus develop OA in joints that were ill designed for human tasks such as pincer grip (OA in the thumb base) and walking upright (OA in knees and hips). Some joints, like the ankles, may be spared because their articular cartilage may be uniquely resistant to loading stresses.

OA can be diagnosed based on structural abnormalities or on the symptoms these abnormalities evoke. According to cadaveric studies, by elderly years, structural changes of OA are nearly universal. These include cartilage loss (seen as joint space loss on x-rays) and osteophytes. Many persons with x-ray evidence of OA have no joint symptoms, and although the prevalence of structural abnormalities is of interest in understanding disease pathogenesis, what matters more from a clinical perspective is the prevalence of symptomatic OA. Symptoms, usually joint pain, determine disability, visits to clinicians, and disease costs.

Symptomatic OA of the knee (pain on most days of a recent month plus x-ray evidence of OA in that knee) occurs in ~12% of persons age ≥60 in the United States and 6% of all adults age ≥30. Symptomatic hip OA is roughly one-third as common as disease in the knee. Although radiographic hand OA and the appearance of bony enlargement in affected hand joints (Fig. 383-2) are extremely common in older persons, most affected persons have no pain. Even so, painful hand OA occurs in ~10% of elderly individuals and often produces measurable limitation in function.

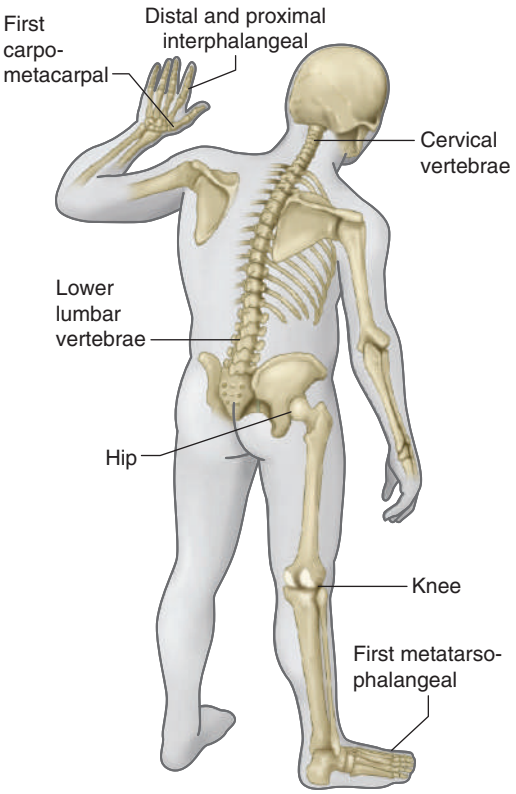

FIGURE 383-1 Joints commonly affected by osteoarthritis.

FIGURE 383-2 Severe osteoarthritis of the hands affecting the distal interphalangeal joints (Heberden's nodes) and the proximal interphalangeal joints (Bouchard's nodes). There is no clear bony enlargement of the other common site in the hands, the thumb base.

The prevalence of OA rises strikingly with age, being uncommon in adults aged <40 and highly prevalent in those aged >60. It is also a disease that, at least in middle-aged and elderly persons, is much more common in women than in men.

X-ray evidence of OA is common in the lower back and neck, but back pain and neck pain have not been tied to findings of OA on x-ray. Thus, back pain and neck pain are treated separately (Chaps. 18 and 19).

GLOBAL CONSIDERATIONS

With the aging of the populations, both the prevalence of OA and the amount of disability worldwide related to OA have been increasing, especially in developed countries where many are living into old age. Hip OA is rare in China and in immigrants from China to the United States. Anatomic differences between Chinese and white hips may account for much of the difference in hip OA prevalence, with white hips having a higher prevalence of anatomic predispositions to the development of OA. However, OA in the knees is at least as common, if not more so, in Chinese as in whites from the United States, and knee OA represents a major cause of disability in China, especially in rural areas.

DEFINITION

OA is joint failure, a disease in which all structures of the joint have undergone pathologic change, often in concert. The pathologic sine qua non of disease is hyaline articular cartilage loss, present in a focal and, initially, nonuniform manner. This is accompanied by increasing thickness and sclerosis of the subchondral bony plate, by outgrowth of osteophytes at the joint margin, by stretching of the articular capsule, by variable degrees of synovitis, and by weakness of muscles bridging the joint. In knees, meniscal degeneration is part of the disease. There are numerous pathways that lead to joint failure, but the initial step is often joint injury in the setting of a failure of protective mechanisms.

JOINT PROTECTIVE MECHANISMS AND THEIR FAILURE

Joint protectors include joint capsule and ligaments, muscle, sensory afferents, and underlying bone. Joint capsule and ligaments serve as joint protectors by providing a limit to excursion, thereby fixing the range of joint motion.

Synovial fluid reduces friction between articulating cartilage surfaces, thereby serving as a protector against friction-induced cartilage wear. This lubrication function depends on *hyaluronic acid* and on *lubricin*, a mucinous glycoprotein secreted by synovial fibroblasts whose concentration diminishes after joint injury and in the face of synovial inflammation.

The ligaments, along with overlying skin and tendons, contain mechanoreceptor sensory nerves. These mechanoreceptors fire at different frequencies throughout a joint's range of motion, providing feedback by way of the spinal cord to muscles and tendons. As a consequence, these muscles and tendons assume the right tension at appropriate points in joint excursion to act as optimal joint protectors, anticipating joint loading.

Muscles and tendons that bridge the joint are key joint protectors. Focal stress across the joint is minimized by muscle contraction that decelerates the joint before impact and assures that when joint impact arrives, it is distributed broadly across the joint surface.

Failure of these joint protectors increases the risk of joint injury and OA. For example, in animals, OA develops rapidly when a sensory nerve to the joint is sectioned and joint injury induced. Similarly, in humans, Charcot's arthropathy, a severe and rapidly progressive OA, develops when minor joint injury occurs in the presence of posterior column peripheral neuropathy. Another example of joint protector failure is rupture of ligaments, a well-known cause of the early development of OA.

CARTILAGE AND ITS ROLE IN JOINT FAILURE

A thin rim of tissue at the ends of two opposing bones, cartilage is lubricated by synovial fluid to provide an almost frictionless surface across which these two bones move. The compressible stiffness of cartilage compared to bone provides the joint with impact-absorbing capacity.

The earliest changes of OA may occur in cartilage, and abnormalities there can accelerate disease development. The two major macromolecules in cartilage are type 2 collagen, which provides cartilage its tensile strength, and aggrecan, a proteoglycan macromolecule linked with hyaluronic acid, which consists of highly negatively charged glycosaminoglycans. In normal cartilage, type 2 collagen is woven tightly, constraining the aggrecan molecules in the interstices between collagen strands, forcing these highly negatively charged molecules into close proximity. The aggrecan molecule, through electrostatic repulsion of its negative charges, gives cartilage its compressive stiffness. Chondrocytes, the cells within this avascular tissue, synthesize all elements of the matrix and produce enzymes that break it down **(Fig. 383-3)**. Cartilage matrix synthesis and catabolism are in a dynamic equilibrium influenced by the cytokine and growth factor environment. Mechanical and osmotic stress on chondrocytes induces these cells to alter gene expression and increase production of inflammatory cytokines and matrix-degrading enzymes. While chondrocytes synthesize numerous enzymes, matrix metalloproteinases (MMPs; especially collagenases and ADAMTS-5) are critical enzymes in the breakdown of cartilage matrix.

Local inflammation accelerates the development and progression of osteoarthritis and increases the likelihood that an osteoarthritic joint will be painful. Some of this inflammation may be induced by mechanical stimuli, so called mechanoinflammation. The synovium, cartilage, and bone all influence disease development through cytokines, chemokines, and even complement activation (Fig. 383-3). Matrix fragments released from cartilage stimulate synovium, which releases inflammatory cytokines, and they, in turn, induce chondrocytes to synthesize other proinflammatory molecules. Ultimately, the combination of effects on chondrocytes triggers matrix degradation. Growth factors are also part of this complex network, with bone morphogenetic protein 2 (BMP-2) and transforming growth factor β (TGF-β) playing prominent roles in stimulating the development of osteophytes. Triggered by local vascular endothelial growth factor (VEGF) synthesis, blood vessels invade cartilage and, with them, come nerves that may bring nociceptive innervation.

With aging, articular chondrocytes develop a senescence-associated secretory phenotype, exhibiting a decline in synthetic capacity and producing proinflammatory mediators and matrix-degrading enzymes. These chondrocytes are unable to maintain tissue homeostasis (such as after insults of a mechanical or inflammatory nature). Thus, with age, cartilage is easily damaged by minor sometimes unnoticed injuries, including those that are part of daily activities.

OA cartilage is characterized by gradual depletion of aggrecan, an unfurling of the tightly woven collagen matrix, and loss of type 2 collagen. With these changes comes increasing vulnerability of cartilage, which loses its compressive stiffness.

RISK FACTORS

Risk factors for OA can be understood in terms of their effect either on joint vulnerability or joint loading. On the one hand, a vulnerable joint whose protectors are dysfunctional can develop OA with minimal levels of loading, perhaps even levels encountered during everyday activities. On the other hand, in a young joint with competent protectors, a

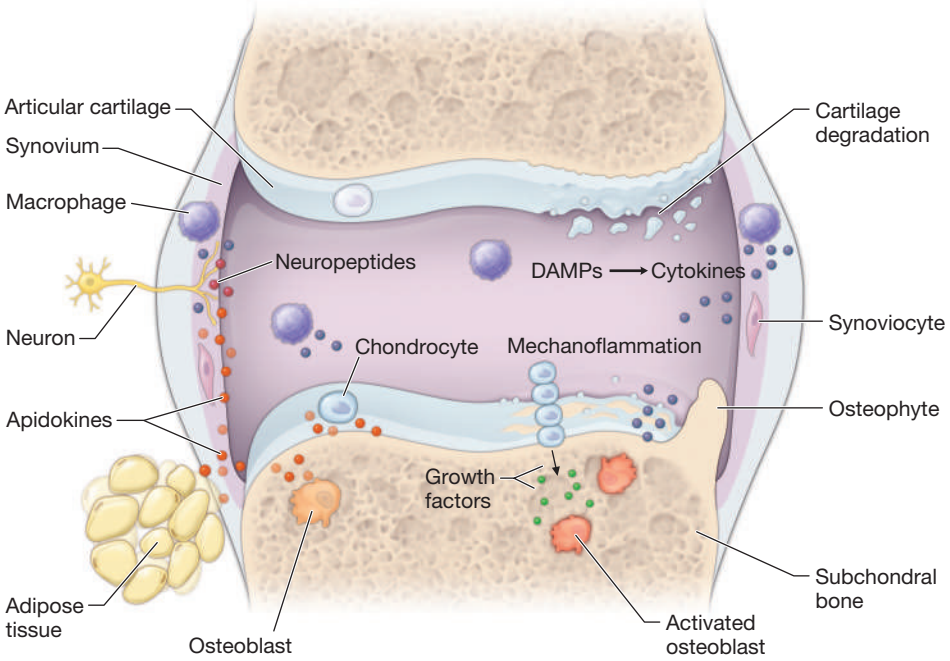

FIGURE 383-3 Selected factors involved in the osteoarthritic process including chondrocytes, bone, and synovium. Synovitis causes release of cytokines, alarmins, damage-associated molecular pattern (DAMP) molecules, and complement, which activate chondrocytes through cell-surface receptors. Chondrocytes produce matrix molecules (collagen type 2, aggrecan) and the enzymes responsible for the degradation of the matrix (e.g., ADAMTS-5 and matrix metalloproteinases [MMPs]). Bone invasion occurs through the calcified cartilage, triggered by vascular endothelial growth factor (VEGF) and other growth factors. *(Reproduced with permission from De Roover A et al: Fundamentals of osteoarthritis: Inflammatory mediators in osteoarthritis. Osteoarthritis Cart 31:1303, 2023.)*

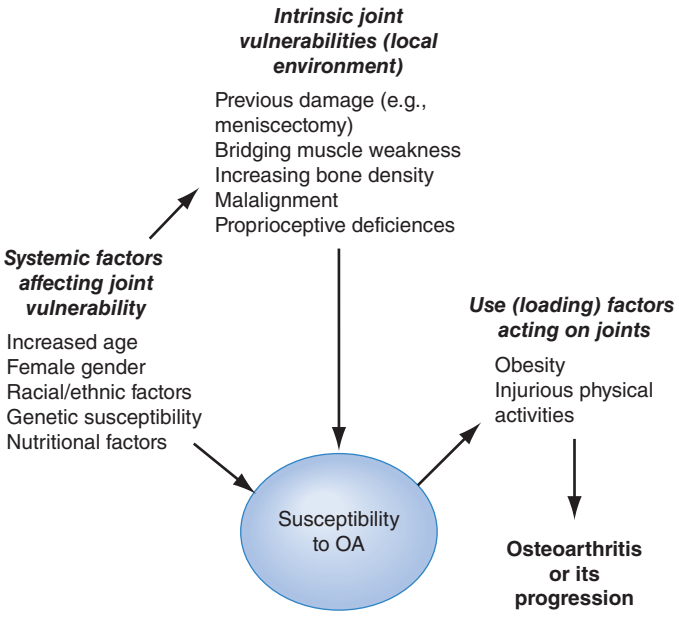

FIGURE 383-4 Risk factors for osteoarthritis (OA) either contribute to the susceptibility of the joint (systemic factors or factors in the local joint environment) or increase risk by the load they put on the joint. Usually, a combination of loading and susceptibility factors is required to cause disease or its progression.

major acute injury or long-term overloading is necessary to precipitate disease (Fig. 383-4).

SYSTEMIC RISK FACTORS THAT AFFECT JOINT VULNERABILITY

Age is the most potent risk factor for OA. Radiographic evidence of OA is rare in individuals aged <40; however, in some joints, such as the hands, OA occurs in >50% of persons aged >70. Aging increases joint vulnerability through several mechanisms. Whereas dynamic loading of joints stimulates matrix synthesis by chondrocytes in young cartilage, aged cartilage is less responsive to these stimuli. As a consequence of this failure to synthesize matrix with loading, cartilage thins with age, and thinner cartilage experiences higher shear stress and is at greater risk of damage. Also, joint protectors fail more often with age. Muscles that bridge the joint become weaker with age and respond less quickly to oncoming impulses. Sensory nerve input slows with age, retarding the feedback loop of mechanoreceptors to muscles and tendons related to their tension and position. Ligaments stretch with age, making them less able to absorb impulses. These factors work in concert to increase the vulnerability of older joints to OA.

Older women are at high risk of OA in all joints, a risk that increases as women reach their sixth decade. Although hormone loss with menopause may contribute to this risk, there is little understanding of the unique vulnerability of older women versus men.

HERITABILITY AND GENETICS AND THEIR RELATION TO JOINT VULNERABILITY

OA is a heritable disease, but its heritability is mostly joint specific. Nearly 60–65% of OA in hips or hands may be attributed to shared genetics within a family. However, heritability of knee OA is, at most, 30%, with some studies suggesting no heritability at all. Knees are susceptible to nongenetic factors like activities that affect joint loading and risk of injury. On the other hand, many people with OA develop "generalized OA" or multisite OA, but the involvement of multiple joints with OA is usually a consequence of aging rather than genetics.

The best replicated genetic variant known to increase OA risk lies in the locus for growth differentiation factor 5 (GDF5). It affects epigenetic regulation of GDF5 activity, resulting in reduction in GDF5 expression. GDF5 probably affects joint shape, a mechanism by which genes increase disease risk. Minor abnormalities in joint shape can make a joint vulnerable to damage if focal stresses across the joint increase.

RISK FACTORS IN THE JOINT ENVIRONMENT

Some risk factors increase vulnerability of the joint through local effects on the joint environment. With changes in joint anatomy, for example, load across the joint is no longer distributed evenly across the joint surface, but rather shows an increase in focal stress. In the hip, three uncommon developmental abnormalities occurring in utero or in childhood—congenital dysplasia, Legg-Perthes disease, and slipped capital femoral epiphysis—leave a child with distortions of hip joint anatomy that often lead to OA later in life. Girls are predominantly affected by acetabular dysplasia, a mild form of congenital dysplasia, whereas the other abnormalities more often affect boys. Depending on the severity of the anatomic abnormalities, hip OA occurs either in young adulthood (severe abnormalities) or middle age (mild abnormalities). Femoroacetabular impingement can develop during adolescence. It is a clinical syndrome in which an outgrowth of bone at the femur's head/neck junction thought to develop during closure of the growth plate results in abnormal contact between the femur and acetabulum, especially during hip flexion and rotation. This leads to cartilage and labral damage, to hip pain, and ultimately in later life, to an increased risk of hip OA.

Major injuries to a joint also can produce anatomic abnormalities that leave the joint susceptible to OA. For example, a fracture through the joint surface often causes OA in joints in which the disease is otherwise rare such as the ankle and the wrist. Avascular necrosis can lead to collapse of dead bone at the articular surface, producing anatomic irregularities and subsequent OA.

Tears of ligamentous and fibrocartilaginous structures that protect the joints, such as the anterior cruciate ligament or meniscus in the knee and the labrum in the hip, can lead to premature OA. Meniscal tears increase with age and, when chronic, are often asymptomatic but lead to adjacent cartilage damage and accelerated OA. Even recalled injuries in which the affected person never received a diagnosis may increase risk of OA. For example, in the Framingham Study subjects, men with a history of major knee injury, but no surgery, had a 3.5-fold increased risk for subsequent knee OA.

Another source of anatomic abnormality is malalignment across the joint (Fig. 383-5), a factor best studied in the knee. Varus (bow-legged) knees with OA are at exceedingly high risk of cartilage loss in the medial or inner compartment of the knee, whereas valgus (knock-kneed) malalignment predisposes to rapid cartilage loss in the lateral compartment. Malalignment causes this effect by increasing stress on a focal area of cartilage, which then breaks down; it also causes damage to bone underlying the cartilage, producing bone marrow lesions seen on magnetic resonance imaging (MRI). Malalignment in the knee often produces such a substantial increase in focal stress within the knee (as evidenced by its destructive effects on subchondral bone) that severely malaligned knees may be destined to progress regardless of the status of other risk factors.

Weakness in the quadriceps muscles bridging the knee increases the risk of the development of painful OA in the knee, especially in women.

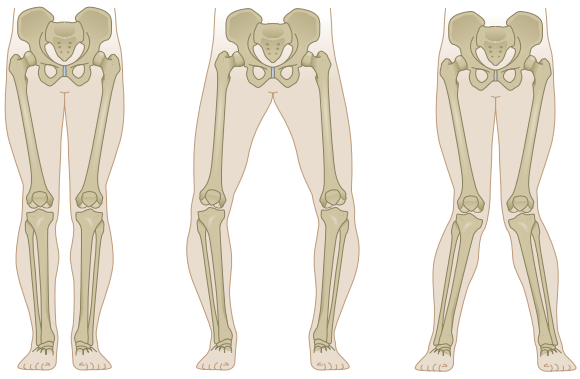

FIGURE 383-5 The two types of limb malalignment in the frontal plane: varus, in which the stress is placed across the medial compartment of the knee joint, and valgus, which places excess stress across the lateral compartment of the knee.

High bone density also increases OA risk, especially risk of a subtype of OA characterized by large osteophytes.

LOADING FACTORS

Obesity Three to six times body weight is transmitted across the knee during single-leg stance. Any increase in weight may be multiplied by this factor to reveal the excess force across the knee in overweight persons during walking. Obesity is a potent risk factor for the development of knee OA and, less so, for hip OA. It is a stronger risk factor for disease in women than in men, and for women, the relationship of weight to the risk of disease is linear, so that with each pound increase in weight, there is a commensurate increase in risk. Not only is obesity a risk factor for OA in weight-bearing joints, but obese persons have more pain from the disease. Weight loss greater than 10% of body weight reduces cartilage loss and, in most affected persons, alleviates pain.

Obesity's effect on the development and progression of disease, especially in knees, is mediated mostly through the increased loading in weight-bearing joints that occurs in overweight persons. However, high levels of leptin, an adipokine, are associated with increasing pain severity in OA regardless of the joint affected.

Repeated Use of Joint and Exercise There are two categories of repetitive joint use: occupational use and leisure time physical activities. Workers who, over many years, perform repetitive tasks as part of their occupations are at high risk of developing OA in joints they use repeatedly. Workers whose jobs require regular knee bending or lifting or carrying heavy loads have a high rate of knee OA. One reason why workers may get disease is that during long days at work, their muscles may gradually become exhausted, no longer serving as effective joint protectors.

It is widely recommended for people to adopt an exercise-filled lifestyle, and long-term studies of exercise suggest no consistent association of exercise with OA risk in most persons. However, persons who already have injured joints may put themselves at greater risk by engaging in certain types of exercise. For example, persons who have already sustained major knee injuries are at increased risk of progressive knee OA as a consequence of running. In addition, compared to nonrunners, elite runners (professional runners and those on Olympic teams) have high risks of both knee and hip OA. Lastly, although recreational runners are not at increased risk of knee OA, studies suggest that they have a modest increased risk of disease in the hip.

PATHOLOGY

The pathology of OA provides evidence of the involvement of many joint structures in disease. Cartilage initially shows surface fibrillation and irregularity. As disease progresses, focal erosions develop there, and these eventually extend to the subjacent bone. With further progression, cartilage erosion down to bone expands to involve a larger proportion of the joint surface, even though OA remains a focal disease with nonuniform loss of cartilage.

After an injury to cartilage, chondrocytes undergo mitosis and clustering. Although the metabolic activity of these chondrocyte clusters is high, the net effect of this activity is to promote proteoglycan depletion in the matrix surrounding the chondrocytes. This is because the catabolic activity is greater than the synthetic activity. As disease develops, collagen matrix becomes damaged, the negative charges of proteoglycans get exposed, and cartilage swells from ionic attraction to water molecules. Because in damaged cartilage proteoglycans are no longer forced into close proximity, cartilage does not bounce back after loading as it did when healthy, and cartilage becomes vulnerable to further injury.

With loss of cartilage comes alteration in subchondral bone. Stimulated by growth factors and cytokines, osteoclasts and osteoblasts in the bony plate just underneath cartilage become activated. Bone formation produces a thickening of the subchondral plate that occurs even before cartilage ulcerates. Trauma to bone during joint loading may be the primary factor driving this bone response, with healing from injury (including microcracks) inducing remodeling. Small areas of osteonecrosis usually exist in joints with advanced disease. Bone death may also be caused by bone trauma with shearing of microvasculature, leading to a cutoff of vascular supply to some bone areas.

At the margin of the joint, near areas of cartilage loss, osteophytes form. These start as outgrowths of new cartilage, and with neurovascular invasion from the bone, this cartilage ossifies. Osteophytes are an important radiographic hallmark of OA.

The synovium produces lubricating fluids that minimize shear stress during motion. In healthy joints, the synovium consists of a single discontinuous layer filled with fat and containing two types of cells, macrophages and fibroblasts, but in OA, it can sometimes become edematous and inflamed. There is a migration of macrophages from the periphery into the tissue, and cells lining the synovium proliferate. Inflammatory cytokines and alarmins secreted by the synovium activate chondrocytes to produce enzymes that accelerate destruction of matrix.

Additional pathologic changes occur in the capsule, which stretches, becomes edematous, and can become fibrotic.

The pathology of OA is not identical across joints. In hand joints with severe OA, for example, there are often cartilage erosions in the center of the joint probably produced by bony pressure from the opposite side of the joint.

Basic calcium phosphate and calcium pyrophosphate dihydrate crystals are present microscopically in most joints with end-stage OA. Their role in osteoarthritic cartilage is unclear, but their release from cartilage into the joint space and joint fluid likely triggers synovial inflammation, which can, in turn, produce release of cytokines and trigger nociceptive stimulation.

SOURCES OF PAIN

Because healthy cartilage is aneural, cartilage loss alone is not accompanied by much pain. Thus, pain in OA likely arises from structures outside the cartilage. Innervated structures in the joint include the synovium, ligaments, joint capsule, muscles, and subchondral bone. Most of these are not visualized by x-ray, and the severity of x-ray changes in OA correlates poorly with pain severity. However, in later stages of OA, loss of cartilage integrity accompanied by neurovascular invasion may contribute more to pain.

Based on MRI studies in osteoarthritic knees comparing those with and without pain and on studies mapping tenderness in unanesthetized joints, likely sources of pain include synovial inflammation, joint effusions, and bone marrow edema. Modest synovitis develops in many but not all osteoarthritic joints. The presence of synovitis on MRI is correlated with the presence and severity of knee pain, and potentially with pain sensitization. Capsular stretching from fluid in the joint stimulates nociceptive fibers there, inducing pain. Increased focal loading as part of the disease not only damages cartilage but probably also injures the underlying bone. As a consequence, bone marrow edema appears on the MRI; histologically, this edema signals the presence of microcracks and scar, which are the consequences of trauma. These lesions may stimulate bone nociceptive fibers. Pain may arise from outside the joint also, including bursae near the joints. Common sources of pain near the knee are anserine bursitis and iliotibial band syndrome.

Much of the pain experienced in OA occurs when nociceptors in the joint are stimulated during weight-bearing activities. However, the pain may eventually become more constant and present at rest, and this suggests other mechanisms contribute to the pain experience. The pathologic changes of OA may lead to alterations in nervous system signaling (Chap. 18). Specifically, peripheral nociceptors can become more responsive to sensory input, known as peripheral sensitization, and there can also be an increase in facilitated central ascending nociceptive signaling, known as central sensitization. Individuals with OA may also have insufficient descending inhibitory modulation. Some individuals may be genetically predisposed to becoming sensitized; however, regardless of the etiology, these nervous system alterations are associated with more severe pain, contribute to the presence of allodynia and hyperalgesia in patients with OA, and may predispose to development of chronic pain.

CLINICAL FEATURES

Joint pain from OA is primarily activity-related in the early stages of the disease. Pain comes on either during or just after joint use and then gradually resolves. Examples include knee or hip pain with going up or

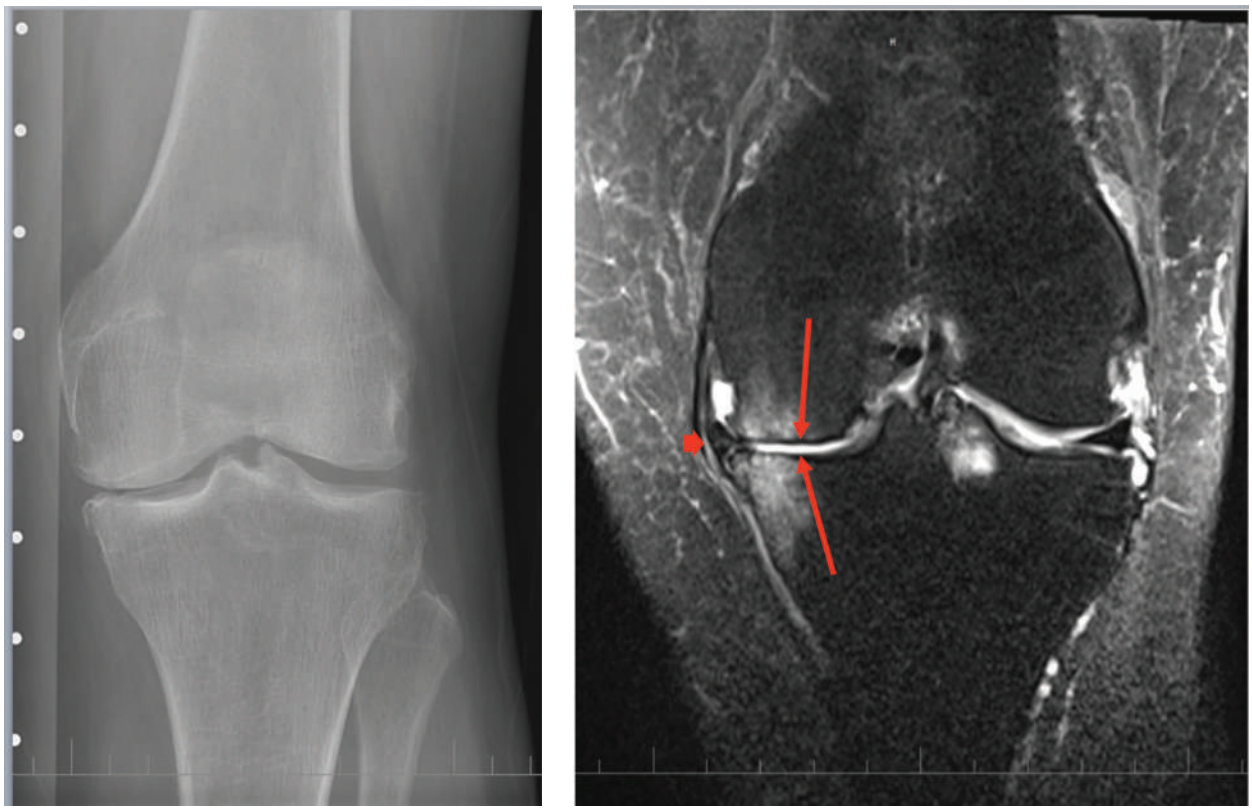

FIGURE 383-6 X-ray and magnetic resonance imaging (MRI) of knee with medial osteoarthritis. X-ray shows osteophytes at the medial and lateral tibia and femur and joint space narrowing of the medial tibiofemoral joint. Coronal intermediate-weighted fat-suppressed MRI confirms the presence of medial and lateral osteophytes and the medial tibiofemoral joint space narrowing. There is diffuse denuded area with no cartilage remaining at the weight-bearing medial tibiofemoral joint (*arrows*). There is also a severe medial meniscus extrusion (*arrowhead*). Bone marrow lesions, which provide evidence of bone injury, are present at medial tibia, medial femur, and intraspinous tibial region. Cartilage focal defects are also seen at the lateral weight-bearing femur and tibia.

down stairs, pain in weight-bearing joints when walking, and, for hand OA, pain when cooking. Early in disease, pain is episodic, triggered often by overactive use of a diseased joint, such as a person with knee OA taking a long run and noticing a few days of pain thereafter. As disease progresses, the pain becomes continuous and even begins to be bothersome at night. Stiffness of the affected joint may be prominent, but morning stiffness is usually brief (<30 min).

In knees, buckling may occur, in part, from weakness of muscles crossing the joint. Mechanical symptoms, such as buckling, catching, or locking, could also signify internal derangement, like an anterior cruciate ligament or meniscal tear; however, these symptoms, which are common in persons with knee OA, need to be further evaluated only if they develop after an acute knee injury. In the knee, pain with activities requiring knee flexion, such as stair climbing and arising from a chair, often emanates from the patellofemoral compartment of the knee, which does not actively articulate until the knee is bent ~35°.

OA is the most common cause of chronic knee pain in persons aged >45, but the differential diagnosis is long. Inflammatory arthritis is likely if there is prolonged morning stiffness, and many other joints are affected. Bursitis occurs commonly around knees and hips. A physical examination should focus on whether tenderness is over the joint line (at the junction of the two bones around which the joint is articulating) or outside of it. Anserine bursitis, medial and distal to the knee, is an extremely common cause of chronic knee pain that may respond to a glucocorticoid injection. Prominent nocturnal pain in the absence of end-stage OA merits a distinct workup. For hip pain, OA can be detected by loss of internal rotation on passive movement, and pain isolated to an area lateral to the hip joint usually reflects the presence of trochanteric bursitis.

No blood tests are routinely indicated for workup of patients with OA unless symptoms and signs suggest inflammatory arthritis. Examination of the synovial fluid is often more helpful diagnostically than an x-ray. If the synovial fluid white count is >1000/μL, inflammatory arthritis or gout or pseudogout is likely, the latter two being also identified by the presence of crystals.

Radiographs are not indicated in the workup of OA. They should be ordered only when joint pain and physical findings are not typical of OA or if pain persists after inauguration of treatment effective for OA. In OA, imaging findings **(Fig. 383-6)** correlate poorly with the presence and severity of pain. Further, in both knees and hips, radiographs may be normal in early disease as they are insensitive to cartilage loss and other early findings.

Although MRI may reveal the extent of pathology in an osteoarthritic joint, it is not indicated as part of the diagnostic workup. Findings such as meniscal tears and cartilage and bone lesions occur not only in most patients with OA in the knee but also in most older persons without joint pain. MRI findings rarely warrant a change in therapy.

TREATMENT

Osteoarthritis

The goals of the treatment of OA are to alleviate pain and minimize loss of physical function. To the extent that pain and loss of function are consequences of inflammation, of weakness across the joint, and of laxity and instability, the treatment of OA involves addressing each of these impairments. Comprehensive therapy consists of a multimodality approach including physical modalities and pharmacologic elements.

Foundational to OA management is patient education and self-management strategies. Patients with mild and intermittent symptoms may need only symptomatic management and/or treatments aimed at weight loss, physical activity, exercise, and

self-management strategies. Patients with ongoing, disabling pain are likely to need both physical modalities and pharmacotherapy.

Treatments for knee OA have been more completely evaluated than those for hip and hand OA or for disease in other joints. Thus, although the principles of treatment are identical for OA in all joints, we shall focus below on the treatment of knee OA, noting specific recommendations for disease in other joints, especially when they differ from those for the knee.

PHYSICAL MANAGEMENT MODALITIES

Because OA is a mechanically driven disease, the mainstay of treatment involves altering loading across the painful joint and improving the function of joint protectors, so they can better distribute load across the joint. Ways of lessening focal load across the joint include:

1. Avoiding painful activities as these are usually activities that overload the joint
2. Improving the strength and conditioning of muscles that bridge the joint to optimize their function
3. Unloading the joint, either by redistributing load within the joint with a brace or a splint or by unloading the joint during weight bearing with a cane or a crutch

The simplest treatment for many patients is to avoid activities that precipitate pain. For example, for the middle-aged patient whose long-distance running brings on symptoms of knee OA, a less demanding form of weight-bearing activity may alleviate all symptoms. For an older person whose daily walks up and down hills bring on knee pain, routing these away from hills might eliminate symptoms.

Weight loss is a central strategy for those who are overweight or obese, particularly for knee OA. Each pound of weight loss has a multiplier effect, unloading both knees and hips and probably relieving pain in those joints. Depending on how much weight loss occurs, bariatric surgery and drugs that cause weight loss such as glucagon-like peptide 1 receptor agonists (GLP1R agonists) often reduce pain and may slow structural disease progression.

In hand joints affected by OA, splinting, by limiting motion, often minimizes pain for patients with involvement especially in the base of the thumb. Weight-bearing joints such as knees and hips can be unloaded by using a cane in the hand opposite the affected joint for partial weight bearing. A physical therapist can help teach the patient how to use the cane optimally, including ensuring that its height is optimal for unloading. Crutches or walkers can serve a similar beneficial function.

Exercise Osteoarthritic pain in knees or hips during weight bearing results in lack of activity and poor mobility, and because OA is so common, the inactivity that results increases the risk of cardiovascular disease and obesity. Aerobic capacity is poor in most elders with symptomatic knee OA, worse than others of the same age.

Weakness in muscles that bridge osteoarthritic joints is multifactorial in etiology. First, there is a decline in strength with age. Second, with limited mobility comes disuse muscle atrophy. Third, patients with painful knee or hip OA alter their gait to lessen loading across the affected joint, and this further diminishes muscle use. Fourth, "arthrogenous inhibition" may occur, whereby contraction of muscles bridging the joint is inhibited by a nerve afferent feedback loop emanating in a swollen and stretched joint capsule; this prevents attainment of voluntary maximal strength. Because adequate muscle strength and conditioning are critical to joint protection, weakness in a muscle that bridges a diseased joint makes the joint more susceptible to further damage and pain. The degree of weakness correlates strongly with the severity of joint pain and the degree of physical limitation. One of the cardinal elements of the treatment of OA is to improve the functioning of muscles surrounding the joint.

Trials in knee and hip OA have shown that exercise lessens pain and improves physical function. Most effective exercise regimens consist of aerobic and/or resistance training, the latter of which focuses on strengthening muscles across the joint. Treatment guidelines strongly recommend exercise for knee and hip OA with no hierarchy regarding type of exercise due to lack of sufficient head-to-head data. Exercises are likely to be effective especially if they train muscles for the activities a person performs daily. Activities that increase pain in the joint should be avoided. Range-of-motion exercises, which do not strengthen muscles, and isometric exercises that strengthen muscles, but not through range of motion, are unlikely to be effective by themselves. Low-impact exercises, including water aerobics and water resistance training, are often better tolerated by patients than exercises involving impact loading, such as running or treadmill exercises. Evidence suggests that high-intensity strengthening is no more effective in reducing knee pain than less aggressive strengthening regimens. The exercise regimen needs to be individualized to optimize effectiveness, and patients should be referred to an exercise class or a therapist who can create an individualized regimen. In addition to conventional exercise regimens, tai chi may be effective for knee OA. However, there is no strong evidence that patients with hand OA benefit from therapeutic exercise.

Adherence over the long term is the major challenge to an exercise prescription. In trials involving patients with knee OA who were engaged in exercise treatment, from a third to over half of patients stopped exercising by 6 months. Less than 50% continued regular exercise at 1 year. The strongest predictor of a patient's continued exercise is a previous personal history of successful exercise. Physicians should reinforce the exercise prescription at each clinic visit, help the patient recognize barriers to ongoing exercise, and identify convenient times for exercise to be done routinely. Mobile health and wearable technologies are increasingly being used to encourage adherence to exercise. The combination of exercise with calorie restriction and weight loss is especially effective in lessening pain.

Correction of Malalignment Malalignment in the frontal plane (varus-valgus) markedly increases the stress across the joint, which can lead to progression of disease and to pain and disability (Fig. 383-5). Correcting varus-valgus malalignment, either surgically or with bracing, may relieve pain in persons whose knees are malaligned. However, correcting malalignment is often challenging. Fitted braces that straighten varus knees by putting valgus stress across the knee can be effective. Unfortunately, many patients are unwilling to wear a realigning knee brace; in addition, in patients with obese legs, braces may slip with usage and lose their realigning effect. Braces are indicated for willing patients who can learn to put them on correctly and on whom they do not slip. Shoes modified with rubber hemispheres on the sole that alter alignment of the proximal knee have shown efficacy in trials especially if worn for brief periods daily over several months.

Pain from the patellofemoral compartment of the knee can be caused by tilting of the patella or patellar malalignment with the patella riding laterally in the femoral trochlear groove. Using a patellar brace to realign the patella, or tape to pull the patella back into the trochlear sulcus or reduce its tilt, can lessen patellofemoral pain. However, patients may find it difficult to apply tape, with skin irritation common, and, like realigning braces, patellar braces may slip.

Although their effect on malalignment is questionable, neoprene sleeves pulled up to cover the knee lessen pain and are easy to use and popular among patients. The explanation for their therapeutic effect on pain is unclear.

In patients with knee OA, acupuncture produces modest pain relief compared to placebo needles and may be an adjunctive treatment, though placebo effect is likely high. In patients with refractory joint pain from OA, radiofrequency ablation of the nerves innervating the joint has been shown to provide prolonged pain relief, although long-term safety is unknown.

PHARMACOTHERAPY

Although approaches involving physical modalities constitute its mainstay, pharmacotherapy serves an important adjunctive role

in OA treatment for symptom management. Available drugs are administered using oral, topical, and intraarticular routes. To date, there are no available drugs that alter the disease process itself.

Acetaminophen, Nonsteroidal Anti-Inflammatory Drugs (NSAIDs), and Cyclooxygenase-2 (COX-2) Inhibitors The treatment effect of acetaminophen (paracetamol) in OA is small and not considered clinically meaningful **(Table 383-1)**. However, for a minority of patients, it is adequate to control symptoms, in which case more toxic drugs such as oral NSAIDs can be avoided.

NSAIDs are the most popular drugs to treat osteoarthritic pain. They can be administered either topically or orally. In clinical trials, oral NSAIDs produce ~30% greater improvement in pain than high-dose acetaminophen. Response to NSAIDs varies greatly across patients. Occasional patients treated with NSAIDs experience dramatic pain relief, whereas others experience little improvement. Initially, NSAIDs should be administered topically or taken orally on an "as-needed" basis because side effects are less frequent with low intermittent doses. For those with mild symptoms, topical NSAIDs may be sufficient to reduce pain. If topicals or occasional oral medication use is insufficiently effective, then daily treatment may be indicated, with an anti-inflammatory dose selected (Table 383-1).

Topical NSAIDs absorbed through the skin have plasma concentrations an order of magnitude lower than the same amount of drug administered orally. However, when these drugs are administered topically over a superficial joint (knees, hands, but not hips), the drug can be found in joint tissues such as the synovium and cartilage. Generally, topical NSAIDs are slightly less efficacious than oral agents, but have far fewer gastrointestinal (GI) and systemic side effects. Topical NSAIDs often cause local skin irritation where the medication is applied, inducing redness, burning, or itching (see Table 383-1).

Oral NSAIDs are often effective in reducing moderate or severe joint pain, but they have substantial and frequent side effects, the most common of which is upper GI toxicity, including dyspepsia, nausea, bloating, GI bleeding, and ulcer disease. Certain oral agents including celecoxib and nabumetone are safer to the stomach than others. Major NSAID-related GI side effects can occur in patients who do not complain of upper GI symptoms. Patients should be reminded to take low-dose aspirin and ibuprofen or naproxen at different times during the day to avoid a drug interaction.

Because of the increased rates of cardiovascular events associated with conventional NSAIDs such as diclofenac, many of these drugs are not appropriate long-term treatment choices for older persons with OA, especially those at high risk of heart disease or stroke. The American Heart Association has identified COX-2 inhibitors as putting patients at high risk, although low doses of celecoxib (≤200 mg/d) are not associated with an elevation of risk. Naproxen is a safe NSAID from a cardiovascular perspective, but it does have GI toxicity.

There are other common side effects of NSAIDs, including the tendency to develop edema because of prostaglandin inhibition of afferent blood supply to glomeruli in the kidneys and, for similar reasons, a predilection toward reversible renal insufficiency. Blood pressure may increase modestly in some NSAID-treated patients. Oral NSAIDs should not be used in patients with stage 3, 4, or 5 renal disease.

Intraarticular Injections: Glucocorticoids, Hyaluronic Acid, and Other Products Because synovial inflammation is likely to be a major cause of pain in patients with OA, local anti-inflammatory treatments administered intraarticularly may be effective in ameliorating pain for up to 3 months. Glucocorticoid injections provide such efficacy, but response is variable, with some patients having little relief of pain, whereas most experience pain relief lasting up to several months. Synovitis, a major cause of joint pain in OA, may abate after an injection, and this correlates with the reduction in knee pain severity. Glucocorticoid injections are useful to get patients over acute flares of pain. Repeated injections may cause minor amounts of cartilage loss, but these do not appear to increase risk of disease progression, worsening pain, functional limitations, or the need for surgery.

Hyaluronic acid injections can be given for treatment of symptoms in knee and hip OA, but most evidence suggests they have little efficacy versus placebo (Table 383-1).

Few rigorous studies of intraarticular stem cell therapy and platelet-rich plasma (PRP) have been conducted to date. Further, the composition of the injected biologic materials reflecting stem cells or PRP has not been standardized, making it challenging to compare across studies due to variability in formulation.

Other Classes of Drugs and Nutraceuticals Opioids have only modest short-term efficacy in treating pain in hip or knee OA without evidence of long-term benefit and, given concerns about opioid dependency, should be avoided. If NSAIDs are ineffective, one option is the use of duloxetine, which is U.S. Food and Drug Administration approved for OA. Duloxetine may be particularly efficacious when knee pain is part of a syndrome of widespread pain.

Biologic agents and disease-modifying agents used for rheumatoid arthritis have been tested for OA, but trials have mostly been negative. Notable exceptions are two randomized trials for hand OA, one of 6 weeks of prednisolone and the other of 6 months of methotrexate. Both trials demonstrated reductions in hand pain compared with placebo. In a large randomized trial, GLP1R agonists reduced knee pain in obese patients.

TABLE 383-1 Pharmacologic Treatment for Osteoarthritis

TREATMENT	MAXIMAL DOSAGE	COMMENTS
Oral NSAIDs and COX-2 inhibitors		Take with food. Increased risk of myocardial infarction and stroke for some NSAIDs. High rates of gastrointestinal side effects, including ulcers and bleeding. Patients at high risk for gastrointestinal side effects should also take either a proton pump inhibitor or misoprostol.[a] There is an increase in gastrointestinal side effects or bleeding when taken with acetylsalicylic acid. Can also cause edema and renal insufficiency.
Naproxen	375–500 mg bid	
Salsalate	1500 mg bid	
Ibuprofen	600–800 mg qid/tid	
Celecoxib	100–200 mg qd	
Acetaminophen	Up to 2 g/d	Of limited efficacy; conditionally recommended.
Opiates		Common side effects include dizziness, sedation, nausea, vomiting, dry mouth, constipation, urinary retention, and pruritus. Addiction risk. Less efficacious than oral NSAIDs.
Topical NSAIDs		Rub onto hands/knees. Few systemic side effects.
Diclofenac Na 1% gel	4 g qid	Skin irritation common.
Capsaicin	0.025–0.075% cream tid/qid	Can irritate mucous membranes.
Intraarticular injections		
Steroids	Various	
Hyaluronans	Varies from 3 to 5 weekly injections	Mild to moderate pain at injection site. Controversy exists regarding efficacy.

[a]Patients at high risk include those with previous gastrointestinal events, persons ≥60 years, and persons taking glucocorticoids. Trials have shown the efficacy of proton pump inhibitors and misoprostol in the prevention of ulcers and bleeding. Misoprostol is associated with a high rate of diarrhea and cramping; therefore, proton pump inhibitors are more widely used to reduce NSAID-related gastrointestinal symptoms.

Abbreviations: COX-2, cyclooxygenase-2; NSAIDs, nonsteroidal anti-inflammatory drugs.

Recent guidelines recommend against the use of glucosamine or chondroitin for OA. Large publicly supported trials have failed to show that, compared with placebo, these compounds relieve pain in persons with disease. Curcumin has anti-inflammatory effects and may alleviate pain in OA.

Optimal pharmacologic therapy for OA is often achieved by trial and error, with each patient having idiosyncratic responses to specific treatments. Placebo (or contextual) effects may account for 50% of more of treatment effects in OA, and certain modes of treatment delivery including intraarticular injections have greater contextual effects than others such as pills. When medical therapies have failed and the patient has an unacceptable reduction in their quality of life and ongoing pain and disability, then at least for knee and hip OA, total joint arthroplasty is indicated.

SURGERY

Based on data from randomized trials, the efficacy of arthroscopic debridement and lavage in persons with OA is no greater than that of sham surgery for relief of pain or disability. Further, if a meniscal tear is present, as is often the case in persons with knee OA, trials have shown that arthroscopic meniscectomies do not relieve knee pain or improve function long-term, nor do they reduce catching or locking symptoms.

On the other hand, for patients with knee OA isolated to the medial compartment, operations to realign the knee to lessen medial loading can relieve pain. These include a high tibial osteotomy, in which the tibia is broken just below the tibial plateau and realigned to load the lateral, nondiseased compartment, or a unicompartmental replacement with realignment. Each surgery may provide the patient with years of pain relief before a total knee replacement is required.

Ultimately, when the patient with knee or hip OA has failed nonsurgical treatments with limitations of pain or function that compromise their quality of life, patients with reasonable expectations and readiness for surgery should be referred for total knee or hip arthroplasty. These are highly efficacious operations that relieve pain and improve function in the vast majority of patients, although pain elimination occurs in almost all patients getting a hip replacement but only ~80% of those undergoing knee replacement. Currently, failure rates from loosening or infection for both are ~1% per year, with higher rates in obese patients. The chance of surgical success is greater in centers where at least 25 such operations are performed yearly or with surgeons who perform multiple operations annually. The timing of knee or hip replacement is critical. If the patient suffers for many years until their functional status has declined substantially, with considerable muscle weakness, postoperative functional status may not improve to a level achieved by others who underwent operation earlier in their disease course.

Cartilage Regeneration Chondrocyte transplantation has not been found to be efficacious in OA, perhaps because OA includes pathology of joint mechanics, which is not corrected by chondrocyte transplants. Similarly, abrasion arthroplasty (chondroplasty) has not been well studied for efficacy in OA, but it produces fibrocartilage in place of damaged hyaline cartilage. Both surgical attempts to regenerate and reconstitute articular cartilage are more likely to be efficacious early in disease when joint malalignment and many of the other noncartilage abnormalities that characterize OA have not yet developed.

384 Gout and Other Crystal-Associated Arthropathies

Hyon K. Choi

The use of polarizing light microscopy during synovial fluid analysis in 1961 by McCarty and Hollander and the subsequent application of other crystallographic techniques, such as electron microscopy, energy-dispersive elemental analysis, and x-ray diffraction, have allowed investigators to identify the pathogenic roles of different microcrystals, including monosodium urate (MSU), calcium pyrophosphate (CPP), calcium apatite (apatite), and calcium oxalate (CaOx), in inducing acute or chronic arthritis or periarthritis **(Table 384-1)**. The clinical manifestations that result from these crystals have substantial similarities but also have notable differences. Given their therapeutic implications, the need to perform synovial fluid analysis to distinguish the type of crystal involved should be emphasized. Polarized light microscopy alone can identify most typical crystals, except for apatite. Aspiration and analysis of effusions are also important to assess the possibility of infection. Crystal shedding from inert deposits triggered by certain factors is considered a key process behind episodic manifestation of acute inflammation (gout or pseudogout) involving activation of inflammasome and potent proinflammatory cytokines such as interleukin (IL) 1β. Furthermore, physical, inflammatory, and catalytic effects (involving metalloproteinase, collagenase, or prostaglandin E_2) of crystal deposits on the cartilage and other joint structures can lead to chronic erosive or destructive changes in the articular structures.

GOUT

PATHOGENESIS

Gout is a hyperuricemic metabolic condition, typically manifested by episodic inflammatory arthritis with disabling pain, typically among middle-aged to elderly men and postmenopausal women. It stems from an increased body pool of urate due to chronic hyperuricemia, leading to supersaturation and crystal formation of MSU within the joints and connective tissue and inflammatory reactions to the crystals **(Fig. 384-1)**. Although chronic hyperuricemia is a prerequisite for the development of gout, other factors influence subsequent MSU crystallization and inflammatory reactions (Fig. 384-1); a minority of hyperuricemic individuals develop gout during their lifetime. Considered often as a part of the insulin resistance syndrome, hyperuricemia and gout are associated with multiple cardiometabolic-kidney comorbidities, including obesity, hypertension, type 2 diabetes, myocardial infarction, stroke, chronic kidney disease (CKD), and urate nephrolithiasis; modifiable

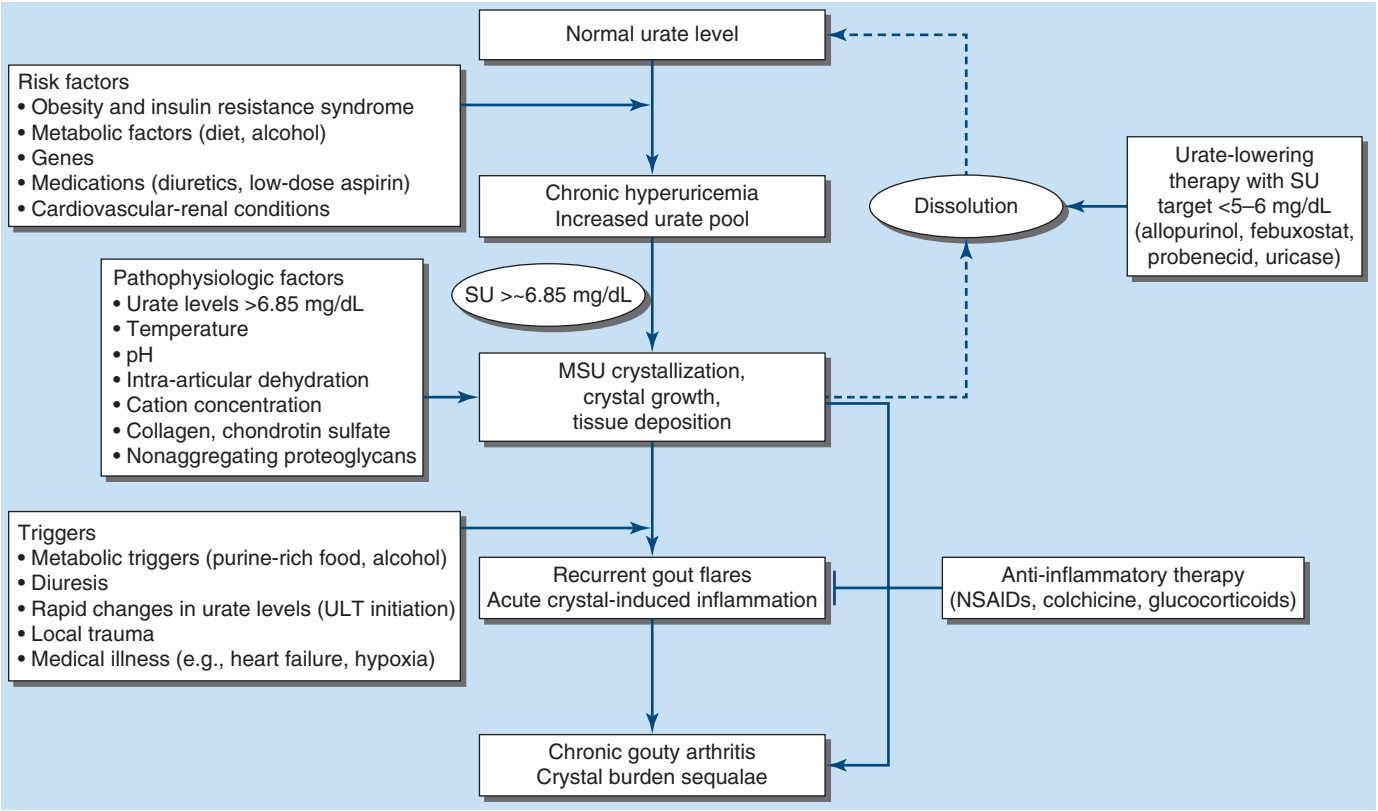

FIGURE 384-1 Pathogenesis of gout and therapeutic targets. Metabolic and some genetic factors contribute to the development of chronic hyperuricemia. Gout stems from an increased body pool of urate due to chronic hyperuricemia, leading to supersaturation and crystal formation and deposition of monosodium urate (MSU; tophi) within the joints and connective tissue. Synovial tophi are usually walled off, but certain triggers may loosen them from the organic matrix, leading to crystal shedding and interaction with synovial cell lining and residential inflammatory cells, initiating an acute gout flare. In some individuals, growing MSU crystal deposition leads to chronic gouty arthritis with subcutaneous tophi. Anti-inflammatory therapy targets the downstream process of crystal-induced inflammation, whereas ultimate control of gout requires correction of the underlying central cause, chronic hyperuricemia with increased urate pool. NSAIDs, nonsteroidal anti-inflammatory drugs; SU, sodium urate; ULT, urate-lowering therapy.

risk factors include obesity, Western diet, alcohol, sedentary lifestyle, and diuretics (Fig. 384-1).

Humans are the only mammals known to develop gout spontaneously as they often develop hyperuricemia with their evolutionary species-wide loss of uricase, which converts urate into the highly water-soluble compound allantoin. At physiologic pH, uric acid exists largely as urate, the ionized form, given its weak acidic property (pKa, 5.8).

The systemic urate concentration reflects a balance between dietary intake, endogenous synthesis, and excretion. Hyperuricemia arises predominantly from impaired urate excretion (90%) or, less commonly, from overproduction (10%), with many cases involving both mechanisms. The pathways leading to urate overproduction, implicated in hyperuricemia and gout, are delineated in **Fig. 384-2**. Most instances of endogenous urate overproduction are linked to salvaged purines from increased cell turnover in proliferative and inflammatory disorders, such as hematologic malignancies and psoriasis, pharmacologic agents that elevate urate synthesis, like chemotherapy, or tissue hypoxia. A minority of hyperuricemia cases (10%) are due to inherited metabolic disorders, including heightened activity of 5′-phosphoribosyl 1-pyrophosphate (PRPP) synthetase or deficits in hypoxanthine-guanine phosphoribosyl transferase (HPRT) (Fig. 384-2). Genetic mutations causing PRPP synthetase overactivity result in an accelerated production of PRPP, purine nucleotides, and urate, culminating in conditions like gout and urate nephrolithiasis.

Approximately two-thirds of daily uric acid elimination occurs through renal excretion, with the remaining one-third via the gastrointestinal tract. Within the renal proximal tubule, distinct transporter systems are responsible for urate reabsorption and secretion. The reabsorption of urate at the apical membrane of the proximal tubule is sodium-dependent. This process involves the sodium-driven uptake of certain anions, which in turn promotes apical urate-anion exchange primarily through URAT1 and OAT10 transporters. Subsequently, urate is excreted across the basolateral membrane via the GLUT9 transporter. This mechanism underlies the notable anti-uricosuric actions of agents like pyrazinoate (PZA) and nicotinate. Meanwhile, urate entry into the intestinal tract is facilitated in part by ABCG2, a high-capacity urate efflux transporter encoded by the *ABCG2* gene and also present in the renal proximal tubular epithelium. In the intestine, urate undergoes degradation by gut bacteria (intestinal uricolysis).

In gout, urate crystals trigger a robust inflammatory response by stimulating the synthesis and release of inflammatory mediators. Central to this process is the phagocytosis of MSU crystals by neutrophils, which amplifies inflammation. Preceding neutrophil recruitment are events in the synovium and joint vasculature, involving activation of resident synovial phagocytes, including monocytes/macrophages and mast cells, and the NOD-like receptor protein 3 (NLRP3) inflammasome. This leads to the generation of pro-interleukin (IL)-1 and IL-1β, as well as other proinflammatory molecules like IL-6, IL-8, and tumor necrosis factor (TNF)-α.

Neutrophils respond to MSU crystals with a respiratory burst, releasing inflammatory agents such as lysosomal enzymes, superoxide anion, leukotriene B4, IL-1, and other cytokines and chemokines. The cellular mechanisms for neutrophil chemotaxis and activation involve kinases, phospholipases, chemoattractants, adhesion molecules, and other factors, highlighting the intense nature of the inflammatory response in gout.

If left untreated, gout can progress to chronic gouty arthritis, frequently with low-grade persistent synovitis and erosive deformities due to growing deposition of MSU crystals surrounded by granulomatous inflammation (tophi). Tophi, often found in proteoglycan-rich tissues like joints and tendons, encapsulate this chronic inflammatory process. These tophi engage both innate and adaptive immunity, representing a dynamic response to MSU crystals. Although occasionally exhibiting acute inflammatory signs, tophi predominantly signify a chronic inflammatory state in gout.

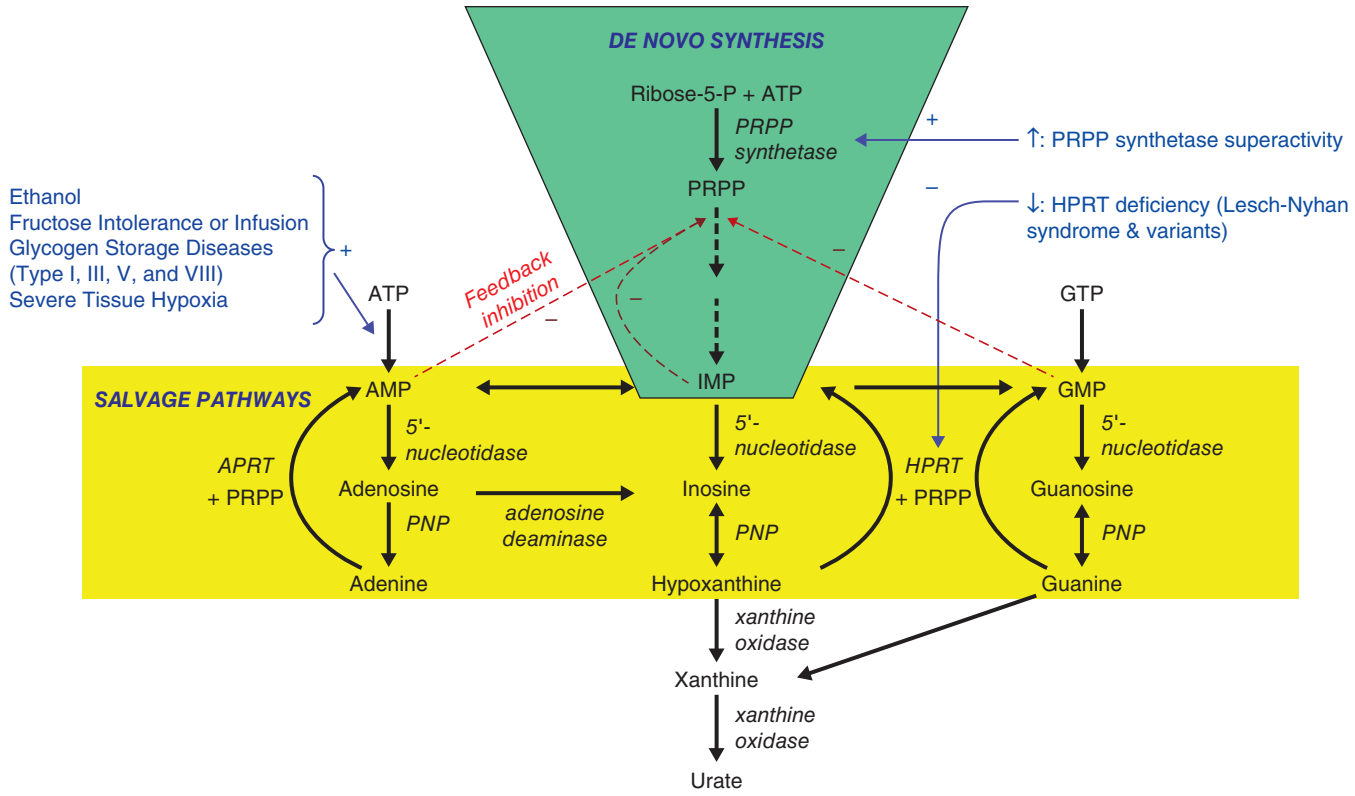

FIGURE 384-2 Urate production pathways implicated in the pathogenesis of gout. The de novo synthesis starts with 5′-phosphoribosyl 1-pyrophosphate (PRPP). PRPP is produced by addition of a further phosphate group from adenosine triphosphate (ATP) to the modified sugar ribose-5-phosphate. This step is performed by the family of PRPP synthetase (PRS) enzymes. Mutations in the PRS genes can result in overactivity of the pathway. Superactivity of PRS is an X chromosome-linked inborn error of metabolism, which leads to increased rate of PRPP, purine nucleotide, and urate production, in association with gout and urate urolithiasis. In addition, purine bases derived from tissue nucleic acids are reutilized through the salvage pathway. The enzyme hypoxanthine-guanine phosphoribosyl transferase (HPRT) salvages hypoxanthine to inosine monophosphate (IMP) and guanine to guanosine monophosphate (GMP). Mutations in the gene encoding HPRT are associated with a spectrum of disease that ranges from hyperuricemia alone to hyperuricemia with profound neurological and behavioral dysfunction (Lesch-Nyhan syndrome). Hypoxanthine cannot be reutilized without HPRT, and can only be degraded to urate. Both the underutilization of PRPP and decrease in IMP and GMP levels in the salvage pathway further contributes to hyperuricemia by feedback inhibition on de novo purine synthesis. The HPRT is located on the X chromosome and 250 different mutations of the gene have been described. Further, conditions associated with net ATP degradation lead to the accumulation of adenosine diphosphate (ADP) and adenosine monophosphate (AMP), which can be rapidly degraded to uric acid. These conditions are displayed in left upper corner. PNP, Purine nucleotide phosphorylase; APRT, adenine phosphoribosyl transferase.

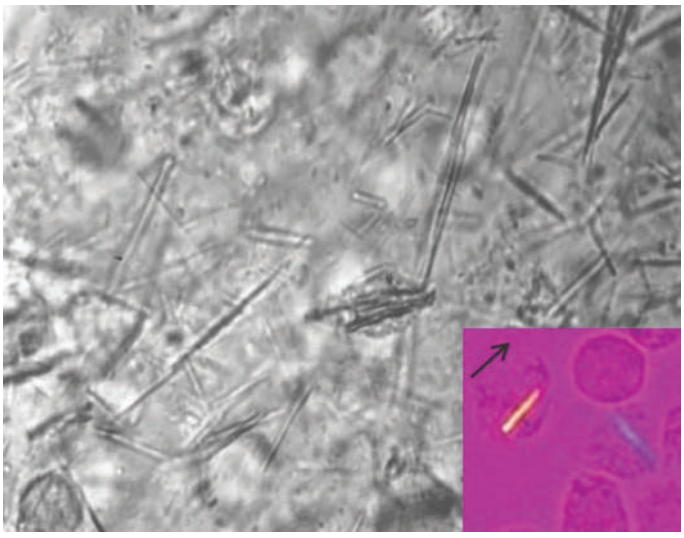
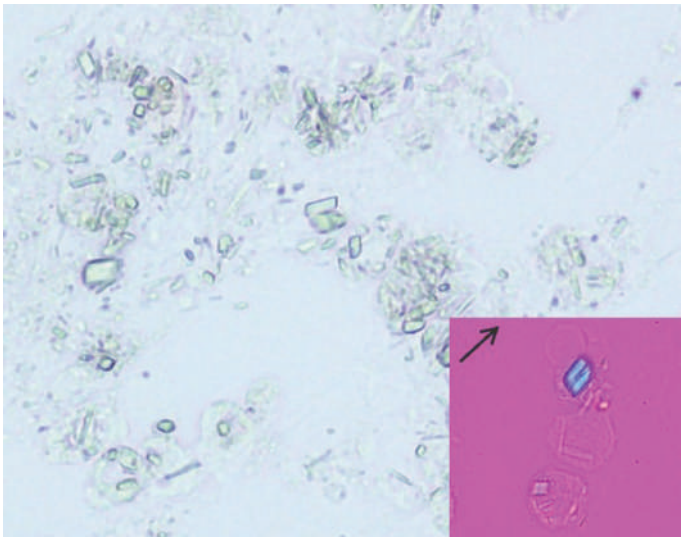
CLINICAL MANIFESTATIONS



Early clinical manifestation of gout is characterized by acute recurrent gout flares. Usually, only one joint is affected initially, although oligo- and polyarticular gout flares can develop over time. The metatarsophalangeal joint of the first toe is involved in 70–90% of cases (podagra), followed by tarsal joints, ankles, and knees. Finger, wrist, and elbow joints can also be involved, although more often in elderly patients or in advanced disease. The gout flares often begin at night to early morning, constituting one of the most painful conditions experienced by humans. The affected joints and periarticular areas rapidly become warm, red, tender, and substantially swollen with a clinical appearance that often mimics that of cellulitis (pseudocellulitis). Typical flares tend to subside spontaneously within 1–2 weeks, and most patients have intervals of varying length with no residual symptoms until the next episode (intercritical gout). Triggers of gout flares include purine-rich food, alcohol, diuretic use, initial introduction of urate-lowering therapy, local trauma, and medical illnesses such as congestive heart failure and respiratory hypoxic conditions (Fig. 384-1).

Usually after years of gout flares without treatment, chronic gouty arthritis can develop, associated with ongoing synovitis, subcutaneous tophi, deformity, and bony destruction. Less commonly, chronic gouty arthritis will be the only manifestation, and more rarely, gout can manifest only as tophi. Women represent only 5–20% of all patients with gout. Most women with gout are postmenopausal and elderly; tend to have osteoarthritis, hypertension, or mild renal insufficiency; and usually are receiving diuretics. Premenopausal gout is rare, although kindreds of precocious gout in young women caused by decreased renal urate clearance and renal insufficiency have been described.



Genetic mutations in the *HPRT* gene are linked to a diverse range of clinical manifestations, extending from isolated hyperuricemia to severe neurologic and behavioral abnormalities (Lesch-Nyhan syndrome). In the absence of functional HPRT, hypoxanthine cannot be recycled and is exclusively converted to urate. This enzymatic deficiency leads to underuse of PRPP and a reduction in inosine monophosphate (IMP) and guanosine monophosphate (GMP) levels in the purine salvage pathway. These alterations contribute to hyperuricemia through feedback inhibition of de novo purine synthesis (Fig. 384-2). Owing to the X-linked inheritance of these enzyme defects, males who are homozygous for the mutation exhibit the disease phenotype. Carrier females, particularly postmenopausal, may develop gout and urinary tract stones. Notably, the presence of hyperuricemia in prepubertal boys should prompt consideration of these specific enzymatic deficits.

DIAGNOSIS

Laboratory Diagnosis Even if characteristic clinical features strongly suggest gout, the presumptive diagnosis ideally should be confirmed by needle aspiration of involved joints or tophaceous deposits. Acute septic arthritis, other crystal-associated arthropathies, palindromic rheumatism, and psoriatic arthritis can mimic clinical presentations of gout. During acute gout flares, needle-shaped MSU crystals typically are present both intracellularly and extracellularly (Fig. 384-3). Under compensated polarized light, these crystals show bright, negative birefringence. Synovial fluid appears cloudy due to the increased numbers of leukocytes (e.g., from 5000–75,000/μL). Large amounts of crystals occasionally produce a thick, pasty, chalky joint fluid or drainage from distended tophus. Because bacterial infection can coexist with MSU crystals in synovial fluid, joint fluid is often stained and cultured for potential septic arthritis. MSU crystals also can often be demonstrated in the first metatarsophalangeal joint and

in knees not acutely involved with gout, making arthrocentesis of these joints useful for the diagnosis of gout between flares.

While chronic hyperuricemia is a prerequisite in the pathogenesis of gout, serum urate levels can be normal or low at the time of an acute flare, as inflammatory cytokines' uricosuric property (e.g., IL-6) can lower the level by ~2 mg/dL. This tends to limit the value of serum urate testing in the setting of an acute flare. Nevertheless, serum urate levels are almost always elevated at some time in a gout patient's lifetime, and thus, it is important to seek historical or postflare serum urate values as a diagnostic clue or therapeutic target to urate-lowering therapy. Serum creatinine, liver function tests, hemoglobin, white blood cell (WBC) count, hemoglobin A_{1c}, and serum lipids are usually obtained at baseline to assess possible risk factor and comorbidities requiring treatment or monitored for potential adverse effects of gout treatments.

Radiographic Features Musculoskeletal ultrasound can timely aid early diagnosis by revealing a double-contour sign overlying the articular cartilage (signifying MSU deposition). Similarly, dual-energy computed tomography (CT) that utilizes two different energy beams and identifies MSU based on its chemical composition can indicate specific presence of MSU crystals. In plain radiography, cystic changes, well-defined erosions with sclerotic margins (often with overhanging bony edges), and soft tissue masses are characteristic features of advanced gout with tophaceous deposits, although these findings are typically absent in earlier stages of gout.

TREATMENT

Acute Gout Care

Although nonpharmacologic measures, such as ice pack application and rest of the involved joints, can be helpful, the mainstay of acute gout care is the administration of anti-inflammatory drugs such as colchicine, nonsteroidal anti-inflammatory drugs (NSAIDs), and glucocorticoids (Fig. 384-1). The choice of these options largely depends on the patients' comorbidities, concurrent medications, and previous response if recurrent flares. Early initiation of anti-inflammatories helps abort or reduce the severity of flares. Thus, for recurrent flares in established gout patients, patients can be provided a supply of their medications ready to start at the first sign of a flare. Oral colchicine is effective, particularly if used early in a gout flare. A low-dose regimen (1.2 mg with the first sign of a flare, followed by 0.6 mg in 1 h and subsequent-day dosing depending on response) is as effective as, and better tolerated than, the formerly used higher-dose regimens. Colchicine is eliminated from the body through P-glycoprotein (also known as MDR1) in the liver, small intestine, and kidneys as well as via enteric and hepatic cytochrome P450 3E4 (CYP3A4). As such, the dose, particularly for prolonged use, is reduced among patients with renal disease or when used with P-glycoprotein or CYP3A4 inhibitors such as clarithromycin or tacrolimus; additional caution is warranted among patients with hepatorenal impairment. NSAIDs are used most often in individuals without complicating comorbidities; NSAIDs given in full anti-inflammatory doses are effective in the vast majority of patients (e.g., indomethacin, 25–50 mg tid; naproxen, 500 mg bid; ibuprofen, 800 mg tid; and celecoxib, 800 mg followed by 400 mg 12 h later, then 400 mg bid).

Glucocorticoids given orally (e.g., prednisone, 30–50 mg/d as the initial dose and gradually tapered with the resolution of the attack) or as an intramuscular injection can be effective even in polyarticular gout. For a single joint or a few involved joints, intraarticular glucocorticoid injection is effective and well tolerated. With the central role of the inflammasome and IL-1β in gout flares, anakinra or canakinumab is a useful option when other treatments are contraindicated or have failed.

URATE-LOWERING THERAPY

Ultimate control of gout requires correction of the underlying chronic hyperuricemia with increased urate pool, the central cause for gout. Attempts to normalize serum urate to a subsaturation point (typically, <300–360 μmol/L [5.0–6.0 mg/dL]) to prevent recurrent gout flares and eliminate tophi are critical and entail a commitment to urate-lowering regimens that are required usually for life (Fig. 384-1). Urate-lowering drug therapy should be considered when, as in most patients, the hyperuricemia cannot be corrected by risk factor interventions (control of body weight, healthy diet, limitation of alcohol use, decreased consumption of fructose-rich foods and beverages, and avoidance of thiazide and loop diuretics). The decision to initiate urate-lowering drug therapy usually is made considering the number of gout flares (e.g., two or more attacks yearly), severity and duration of flares, or the patient's willingness to commit to long-term therapy. Urate-lowering therapy should be initiated in any patient who already has subcutaneous tophi or chronic gouty arthritis or known uric acid nephrolithiasis.

Allopurinol, a xanthine oxidase inhibitor, is the first-line urate-lowering drug among gout patients. Allopurinol can be given in a single morning dose, starting at 100 mg daily or less and titrating up (to 800 mg daily) to achieve a target serum urate level <5–6 mg/dL (i.e., a subsaturation point of MSU crystals) (Fig. 384-1). In patients

with CKD, the starting allopurinol dose should be lowered depending on the CKD levels; for example, with an estimated glomerular filtration rate of <30 mL/min, one would start at 50 mg daily and titrate up slowly. Starting at a low dose and titrating up reduces the risk of severe cutaneous adverse reactions (SCARs), including Stevens-Johnson syndrome and toxic epidermal necrolysis, as well as the risk of gout flares associated with rapid serum urate reduction due to introduction of urate-lowering therapy (Fig. 384-1). Allopurinol is generally well tolerated, but mild cutaneous reactions can develop in ~2% of users. SCARs to allopurinol are rare but can be life-threatening, and thus, appropriate precaution is advised. Presence of CKD, higher allopurinol initial dosing (e.g., >100 mg daily in CKD patients), and *HLA-B*5801* carriage are important risk factors. As the *HLA-B*5801* carriage rate is high among Southeast Asian (except for Japanese descendants), Pacific Islander/Native Hawaiian, and black patients (leading to racial disparity in the risk of SCARs), screening for *HLA-B*5801* should be performed before starting allopurinol in these populations. If patients carry the *HLA-B*5801* allele, an alternative urate-lowering agent should be administered. Febuxostat is another xanthine oxidase inhibitor that is predominantly metabolized by glucuronide formation and oxidation in the liver and considered to not require dose adjustment in moderate to severe chronic kidney disease. It has also been used in patients who carry the *HLA-B*5801* allele.

Uricosuric agents such as probenecid are considered second-line urate-lowering therapies for gout and can be used in patients with good renal function either alone or in combination with xanthine oxidase inhibitors such as allopurinol. Probenecid can be started at a dose of 250 mg twice daily and increased gradually as needed up to 3 g/d to achieve and maintain a target serum urate level. Probenecid is generally not effective in patients with serum creatinine levels >177 μmol/L (2 mg/dL); benzbromarone (not available in the United States) is another uricosuric drug that is more effective in patients with CKD. Pegloticase is a pegylated uricase that is available for patients who do not tolerate or fail full doses of other treatments. It is often used in combination with methotrexate to reduce immunogenicity, which can lead to a loss of efficacy and infusion reactions. Therapies used to treat common cardiometabolic comorbidities of gout can also help lower serum urate levels, including losartan, amlodipine, fenofibrate, and sodium-glucose cotransporter-2 inhibitors (SGLT2i). Given their approved multiple cardiometabolic-kidney indications, SGLT2i can be beneficial for gout patients, offering both urate reduction and comprehensive comorbidity care.

Urate-lowering drugs are generally not initiated during active ongoing gout flares, given the potential worsening of the flare by acutely lowering serum urate levels. However, urate-lowering therapy can be started during the resolution phase of or after a gout flare, together with anti-inflammatory prophylaxis (e.g., colchicine 0.6 mg one to two times daily or naproxen 250 mg twice daily) to reduce the risk of the flares that often occur with the initiation of urate-lowering therapy. These paradoxical flares are presumed to be inflammatory reactions to MSU crystals shed from dissolution of organized MSU deposits (synovial tophi) induced by rapid serum urate reduction (Fig. 384-1). As such, faster urate reduction has been associated with higher risk of flares in clinical trials of urate-lowering drugs. Continuing concomitant anti-inflammatory prophylaxis is usually recommended until the patient is normouricemic and without gouty attacks for 3–6 months or tophi disappear.

CALCIUM PYROPHOSPHATE DEPOSITION DISEASE

CPP deposition (CPPD) predominately affects the elderly, with a doubling prevalence of CPPD in articular tissues with each decade >60 years of age (e.g., prevalence of nearly 50% for those >85 years old). In most cases, this process is asymptomatic with uncertain underlying etiology, although it is likely that biochemical changes in aging or diseased cartilage favor CPP crystal nucleation. Increased levels of inorganic pyrophosphate in cartilage matrix are thought to be a central pathogenic process in patients with CPPD arthritis, analogous to hyperuricemia in gout. This pyrophosphate can combine with calcium to form CPP crystals in cartilage matrix vesicles or on collagen fibers. Most inorganic pyrophosphate in cartilage matrix originates from breakdown of extracellular ATP. The ATP efflux (and thus the levels of inorganic pyrophosphate) is tightly regulated by a multipass membrane protein, ANKH. As such, mutations in the *ANKH* gene, as described in both familial and sporadic cases, have been found to increase elaboration and extracellular transport of pyrophosphate. The increase in pyrophosphate production is also related to enhanced activity of ATP pyrophosphohydrolase and 5′-nucleotidase, which catalyze the reaction of ATP to adenosine and pyrophosphate. Decreased levels of cartilage glycosaminoglycans and increased activities of transglutaminase enzymes may contribute to the deposition of CPP crystals.

TABLE 384-2 Factors and Conditions Associated with Calcium Pyrophosphate Crystal Deposition Disease

Aging
Osteoarthritis
Postmeniscectomy or joint trauma
Familial-genetic
Endocrine-metabolic conditions
Primary hyperparathyroidism
Hemochromatosis
Hypophosphatasia
Hypomagnesemia
Certain drugs: thiazide and loop diuretics, potentially proton pump inhibitors
Malabsorption
Gitelman's syndrome
Gout
X-linked hypophosphatemic rickets
Familial hypocalciuric hypercalcemia

Similar to MSU crystals, release of CPP crystals into the joint space is followed by the phagocytosis of those crystals by monocyte-macrophages and neutrophils, which respond by releasing chemotactic and inflammatory substances and activating the inflammasome.

A minority of patients with CPPD arthropathy have metabolic abnormalities or hereditary CPPD **(Table 384-2)**. As such, the presence of CPPD arthritis in individuals aged <50 years should lead to consideration of these metabolic disorders and inherited forms of disease, including those identified in a variety of ethnic groups. Included among endocrine-metabolic conditions are hyperparathyroidism, hemochromatosis, hypophosphatasia, and hypomagnesemia. These associations suggest that a variety of different metabolic products may enhance CPP crystal deposition either by directly altering cartilage or by inhibiting inorganic pyrophosphatases. Investigation of younger patients with CPPD should include inquiry for evidence of familial aggregation and evaluation of serum calcium, phosphorus, alkaline phosphatase, magnesium, iron, and transferrin.

CLINICAL MANIFESTATIONS

Acute CPP crystal arthritis, originally termed *pseudogout* by McCarty and co-workers, often mimics acute gout flares with similar articular findings of substantial inflammation. There are several clinical clues that suggest CPP crystal arthritis. The knee is the joint most commonly affected, followed by the wrist, while the first metatarsophalangeal joint (podagra) is rarely affected. Other affected joints include the shoulder, ankle, elbow, and hands. Also, initial episodes of acute attacks tend to last longer than typical gout flares, even up to weeks to months. Acute attacks present sometimes with systemic signs such as fever, chills, and elevated acute-phase reactants. Acute CPP crystal arthritis may be precipitated by trauma, severe medical illness, or surgery, especially parathyroidectomy, as it leads to rapid diminution of serum calcium and magnesium levels, causing dissolution and shedding of crystal.

Chronic CPP crystal arthritis has several patterns; the most common form is a polyarticular arthritis resembling osteoarthritis (pseudoosteoarthritis). The clinical picture mimics that of progressive

osteoarthritis, characterized by unusually severe joint damage in atypical joints for osteoarthritis, such as metacarpophalangeal, wrist, elbow, shoulder, or ankle joints. Other less common forms include chronic symmetric synovitis that is clinically similar to rheumatoid arthritis, severe destructive disease that may radiographically mimic neuropathic arthritis, intervertebral disk and ligament calcification with restriction of spine mobility, the crowned dens syndrome, spinal stenosis (most commonly seen in the elderly), and rarely, tumoral deposits of CPP crystals in soft tissues.

If radiographs or ultrasound reveal punctate and/or linear radiodense deposits within fibrocartilaginous joint menisci or articular hyaline cartilage (*chondrocalcinosis*), the diagnostic likelihood of CPPD disease is further increased. *Definitive diagnosis* requires demonstration of typical rhomboid or rodlike crystals (generally weakly positively birefringent or nonbirefringent with polarized light) in synovial fluid or articular tissue (Fig. 384-3). In the absence of joint effusion or indications to obtain a synovial biopsy, chondrocalcinosis is presumptive of CPPD. One exception is chondrocalcinosis due to CaOx in some patients with chronic renal failure.

In as many as 50% of cases, episodes of CPP crystal-induced inflammation are associated with low-grade fever and, on occasion, temperatures as high as 40°C (104°F). In such cases, synovial fluid analysis with microbial cultures is essential to rule out the possibility of infection. In fact, infection in a joint with any microcrystalline deposition process can lead to crystal shedding and subsequent synovitis from both crystals and microorganisms. The leukocyte count in synovial fluid in acute CPPD can range from several thousand cells to 100,000 cells/μL, with the mean being ~24,000 cells/μL and the predominant cell being the neutrophil. CPP crystals may be seen inside tissue fragments and fibrin clots and in neutrophils (Fig. 384-3). CPP crystals may coexist with MSU and apatite in some cases.

TREATMENT

CPPD Disease

Anti-inflammatory treatment for acute CPP crystal arthritis is largely adapted from that for gout flares, including ice pack applications with rest, joint fluid aspiration and glucocorticoid injection, oral colchicine, NSAIDs, and systemic glucocorticoids. Severe polyarticular attacks can also be treated with the IL-1β antagonist anakinra. For patients with frequent recurrent attacks, prophylactic treatment with daily colchicine can be helpful. For chronic CPP crystal arthritis, there is no effective way to remove CPP crystal deposits from cartilage and synovium (unlike urate-lowering agents in gout). Limited studies suggest that NSAIDs (with a gastric protective agent if required), colchicine, low-dose glucocorticoids, hydroxychloroquine, or methotrexate may be helpful for chronic synovitis. Patients with progressive destructive large-joint arthropathy may require joint replacement.

CALCIUM APATITE DEPOSITION DISEASE

PATHOGENESIS

Apatite is the primary mineral of normal bone and teeth. Abnormal accumulation of basic calcium phosphates, largely carbonate substituted apatite, can occur in areas of tissue damage (dystrophic calcification), hypercalcemic or hyperparathyroid states (metastatic calcification), connective tissue diseases (calcinosis), and other conditions **(Table 384-3)**. In chronic renal failure, hyperphosphatemia can contribute to extensive apatite deposition both in and around joints (tumoral calcinosis, calciphylaxis). Familial aggregation is rarely seen. Synovial lining cell or fibroblast cultures exposed to apatite (or CPP) crystals can undergo mitosis and markedly increase the release of prostaglandin E_2, various cytokines, and collagenases and neutral proteases, underscoring the destructive potential of abnormally stimulated synovial lining cells.

Although the true incidence of apatite arthritis is not known, 30–50% of patients with osteoarthritis have apatite microcrystals in their synovial fluid. Such crystals frequently can be identified in clinically stable osteoarthritic joints, but they are more likely to come to attention in persons experiencing acute or subacute worsening of joint pain and swelling.

TABLE 384-3 Clinical Manifestations of Apatite Crystal Deposition

Periarticular
Calcific periarthritis (e.g., supraspinatus tendon apatite deposit rupture)
Bursitis and tendinitis
Hydroxyapatite pseudopodagra
Polyarticular involvement
Asymptomatic deposition
Articular
Hemorrhagic shoulder effusions in the elderly (Milwaukee shoulder)
Chronic destructive arthropathy
Chronic erosive monoarthritis (resembling erosive osteoarthritis)
Acute synovitis
Association with osteoarthritis
Secondary apatite crystal deposition
Tumoral calcinosis
Hyperparathyroidism
Calciphylaxis (renal failure/long-term dialysis)
Connective tissue diseases (e.g., systemic sclerosis, dermatomyositis)
Heterotopic calcification after neurologic catastrophes (e.g., stroke, spinal cord injury)
Fibrodysplasia ossificans progressiva

CLINICAL MANIFESTATIONS

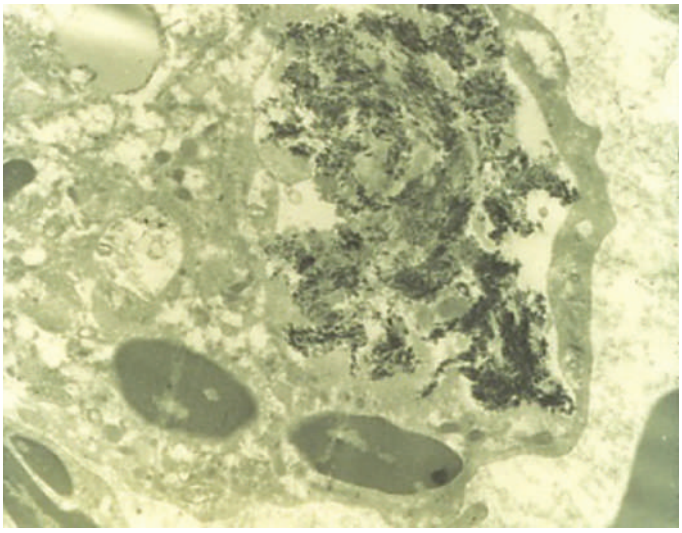
Periarticular or articular deposits can present with acute reversible inflammation and/or chronic damage to the joint capsule, tendons, bursa, or articular surfaces (Table 384-3). The most common sites of apatite deposition include bursae and tendons in and/or around the knees, shoulders, hips, and fingers. These deposits can also be asymptomatic radiographic abnormalities.

Apatite aggregates are often present in synovial fluid in an extremely destructive chronic arthropathy of the elderly that occurs most often in the shoulders (Milwaukee shoulder) and in a similar process in hips, knees, and erosive osteoarthritis of fingers (Table 384-3). Joint destruction is associated with damage to cartilage and supporting structures, leading to instability and deformity. Progression tends to be indolent. Symptoms range from minimal to severe pain and disability that may lead to joint replacement surgery.

DIAGNOSIS

Intra- and/or periarticular calcifications with or without erosive, destructive, or hypertrophic changes may be seen on radiographs **(Fig. 384-4)**. They should be distinguished from the linear calcifications typical of CPPD.

The synovial fluid leukocyte count in apatite arthritis is usually low (<2000/μL) despite dramatic symptoms, with predominance of mononuclear cells. Definitive diagnosis of apatite arthropathy, also called basic calcium phosphate disease, depends on identification of crystals from synovial fluid or tissue (Fig. 384-4). Individual crystals are very small and can be seen only by electron microscopy. Clumps of crystals may appear as 1- to 20-μm shiny intra- or extracellular nonbirefringent globules or aggregates that stain purplish with Wright's stain and bright red with alizarin red S. Absolute identification depends on electron microscopy with energy-dispersive elemental analysis, x-ray diffraction, infrared spectroscopy, or Raman microspectroscopy, but these techniques usually are not required in clinical diagnosis.



TREATMENT

Calcium Apatite Deposition Disease

Treatment of apatite arthritis or periarthritis is nonspecific. Acute attacks of bursitis or synovitis may be self-limiting, resolving in

A

B

FIGURE 384-4 ***A.*** Radiograph showing calcification due to apatite crystals surrounding an eroded joint. ***B.*** An electron micrograph demonstrates dark needle-shaped apatite crystals within a vacuole of a synovial fluid mononuclear cell (30,000×).

days to several weeks. Aspiration of effusions and the use of either NSAIDs or oral colchicine for 2 weeks or intra- or periarticular injection of a depot glucocorticoid appear to shorten the duration and intensity of symptoms. Periarticular apatite deposits may be resorbed with resolution of attacks. Agents to lower serum phosphate levels may lead to resorption of deposits in renal failure patients receiving hemodialysis. In patients with underlying severe destructive articular changes, response to medical therapy is usually less rewarding.

CaOx DEPOSITION DISEASE

PATHOGENESIS

In chronic renal disease, CaOx deposits have long been recognized in visceral organs, blood vessels, bones, and cartilage and are now known to be one of the causes of arthritis in chronic renal failure. Thus far, reported patients have been dependent on long-term hemodialysis or peritoneal dialysis **(Chap. 323)**, and many had received ascorbic acid supplements. Ascorbic acid is metabolized to oxalate, which is inadequately cleared in uremia and by dialysis. Such supplements and foods high in oxalate content usually are avoided in dialysis programs because of the risk of enhancing hyperoxalosis and its sequelae.

CaOx aggregates can be found in bone, articular cartilage, synovium, and periarticular tissues. From these sites, crystals may be shed, causing acute synovitis. Persistent aggregates of CaOx can, like apatite and CPP crystals, stimulate synovial cell proliferation and enzyme release, resulting in progressive articular destruction. *Primary oxalosis* is a rare hereditary metabolic disorder **(Chap. 431)** that can lead to acute or chronic CaOx arthritis, periarthritis, and bone disease during later years of illness.

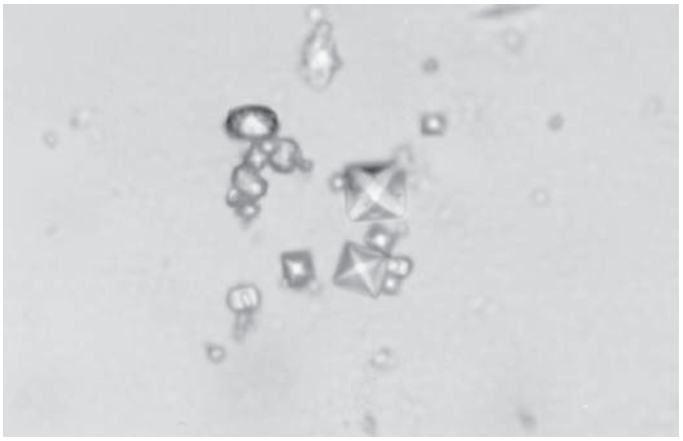


FIGURE 384-5 Bipyramidal and small polymorphic calcium oxalate crystals from synovial fluid are a classic finding in calcium oxalate arthropathy (ordinary light microscopy; 400×).

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Clinical features of acute CaOx arthritis may not be distinguishable from those due to MSU, CPP, or apatite. Deposits have been documented in fingers, wrists, elbows, knees, ankles, and feet. Radiographs may reveal chondrocalcinosis or soft tissue calcifications. CaOx-induced synovial effusions are usually noninflammatory, with <2000 leukocytes/μL, or mildly inflammatory. Neutrophils or mononuclear cells can predominate. CaOx crystals have a variable shape and variable birefringence to polarized light. The most easily recognized forms are bipyramidal, have strong birefringence **(Fig. 384-5)**, and stain with alizarin red S.

TREATMENT

Calcium Oxalate Deposition Disease

Treatment of CaOx arthropathy with NSAIDs, colchicine, intraarticular glucocorticoids, and/or an increased frequency of dialysis has produced only slight improvement. In primary oxalosis, liver transplantation has induced a significant reduction in crystal deposits **(Chaps. 356 and 431)**.

385 Fibromyalgia

Leslie J. Crofford

DEFINITION

Fibromyalgia (FM) is characterized by chronic widespread musculoskeletal pain and tenderness. Although FM is defined primarily as a pain syndrome, patients also commonly report associated neuropsychological symptoms of fatigue, unrefreshing sleep, cognitive dysfunction, anxiety, and depression. Patients with FM have an increased prevalence of other syndromes associated with pain and fatigue, including myalgic encephalitis/chronic fatigue syndrome (Chap. 461), temporomandibular disorder, chronic headaches, irritable bowel syndrome, interstitial cystitis/painful bladder syndrome, and other pelvic pain syndromes. These are collectively referred to as chronic primary or chronic overlapping pain conditions. Available evidence implicates the central nervous system as key to maintaining pain and other core symptoms of FM and related conditions. The presence of FM is associated with substantial negative consequences for physical and social functioning.

EPIDEMIOLOGY

Worldwide prevalence is ~2%, with a prevalence of ~4% in women and <1% in men. There is some variability depending on the method of ascertainment; however, the prevalence data are similar across world regions and socioeconomic classes. Cultural factors may play a role in determining whether patients with FM symptoms seek medical attention; however, even in cultures in which secondary gain is not expected to play a significant role, the prevalence of FM remains in this range. In clinical settings, a diagnosis of FM is far more common in women than in men, with a ratio of ~8:1. In population studies, the ratio of women to men is closer to 3:1. The prevalence of FM is much higher in patients with rheumatic diseases such as rheumatoid arthritis or systemic lupus erythematosus, where up to 30% have comorbid FM. Additional risk factors include sleep disturbances, physical inactivity, and overweight or obesity.

CLINICAL MANIFESTATIONS

Pain and Tenderness At presentation, patients with FM most commonly report "pain all over." Widespread pain is operationalized as being present both above and below the waist on both sides of the body and involving the axial skeleton (neck, back, or chest). The pain attributable to FM is poorly localized, difficult to ignore, severe in its intensity, and associated with a reduced functional capacity. For a diagnosis of FM, pain should have been present most of the day on most days for at least 3 months.

The pain of FM is associated with tenderness and increased evoked pain sensitivity. In clinical practice, this elevated sensitivity may be identified by pain induced by the pressure of a blood pressure cuff or skin roll tenderness. More formally, an examiner may complete a tender-point examination in which the examiner uses the thumbnail to exert pressure of ~4 kg/m^2 (or the amount of pressure leading to blanching of the tip of the thumbnail) on well-defined musculotendinous sites. Previously, the classification criteria of the American College of Rheumatology required that 11 of 18 sites be perceived as painful on exam for a diagnosis of FM. In practice, tenderness is a continuous variable, and strict application of a categorical threshold for diagnosis is not necessary. Newer criteria eliminate the need for identification of tender points and focus instead on patient-reported clinical symptoms of widespread or multisite pain and neuropsychological symptoms (Fig. 385-1). The newer criteria perform well in clinical settings in comparison to the older, tender-point criteria. When subjective criteria are applied to populations, the result is an increase in prevalence of FM and a change in the sex ratio (see "Epidemiology," earlier).

Patients with FM often have peripheral pain generators that are thought to serve as triggers for the more widespread pain attributed to central nervous system factors. Potential pain generators such as arthritis, bursitis, tendinitis, neuropathies, and other inflammatory or degenerative conditions should be identified by history and physical examination. More subtle pain generators may include joint hypermobility and scoliosis. In addition, patients may have chronic myalgias triggered by infectious, metabolic, or psychiatric conditions that can serve as triggers for the development of FM. These conditions are often identified in the differential diagnosis of patients with FM, and a major challenge is to distinguish the ongoing pain of a triggering condition from FM pain that is occurring as a consequence of a comorbid condition and that should itself be treated.

Neuropsychological Symptoms In addition to widespread pain, FM patients typically report fatigue, stiffness, sleep disturbance, cognitive dysfunction, anxiety, and depression. These symptoms are present to varying degrees in most FM patients but are not present in every patient or at all times in a given patient. Relative to pain, such symptoms may, however, have an equal or even greater impact on function and quality of life. Fatigue is highly prevalent in patients in primary care who ultimately are diagnosed with FM. Pain, stiffness, and fatigue often are worsened by exercise or unaccustomed activity. The sleep complaints include difficulty falling asleep, difficulty staying asleep, and early-morning awakening. Regardless of the specific complaint, patients awake feeling unrefreshed. Patients with FM may meet criteria for restless legs syndrome and sleep-disordered breathing; frank sleep apnea can also be documented. Cognitive issues are characterized as difficulties with attention or concentration, problems with word retrieval, and short-term memory loss. Studies have demonstrated altered cognitive function in these domains in patients with FM, although speed of processing is age appropriate. Symptoms of anxiety and depression are common, and the lifetime prevalence of mood disorders in patients with FM approaches 80%. Although depression is neither necessary nor sufficient for the diagnosis of FM, it is important to screen for major depressive disorders by querying for depressed mood and anhedonia. Analysis of genetic factors that are likely to predispose to FM reveals shared neurobiologic pathways with mood disorders, providing the basis for comorbidity (see later in this chapter).

Overlapping Syndromes FM is considered as part of a group of conditions called chronic overlapping pain syndromes because of the propensity to coexist with other syndromes that may share underlying mechanisms. Review of systems often reveals headaches, facial/jaw pain, regional myofascial pain particularly involving the neck or back, and arthritis. Visceral pain involving the gastrointestinal tract, bladder, and pelvic or perineal region is often present as well. It is important for patients to understand that shared pathways may mediate symptoms and treatment strategies effective for one condition may help with global symptom management.

Comorbid Conditions FM is often comorbid with chronic musculoskeletal, infectious, metabolic, or psychiatric conditions. Whereas FM affects only ~2% of the general population, it occurs in ~10–30% of patients with degenerative or inflammatory rheumatic disorders, likely because these conditions serve as peripheral pain generators to alter central pain-processing pathways. The proposition that there may be an inflammatory or autoimmune etiology for FM in some patients has not been rigorously tested to date. It is particularly important for clinicians to be sensitive to pain management of these comorbid conditions so that when FM emerges—characterized by pain outside the boundaries of what could reasonably be explained by the triggering condition, development of neuropsychological symptoms, or tenderness on physical examination—treatment of central pain processes will be undertaken as opposed to a continued focus on treatment of peripheral or inflammatory causes of pain.

Psychosocial Considerations Symptoms of FM often have their onset and are exacerbated during periods of perceived stress. This pattern may reflect an interaction among central stress physiology, vigilance or anxiety, and central pain-processing pathways. An understanding of current psychosocial stressors will aid in patient

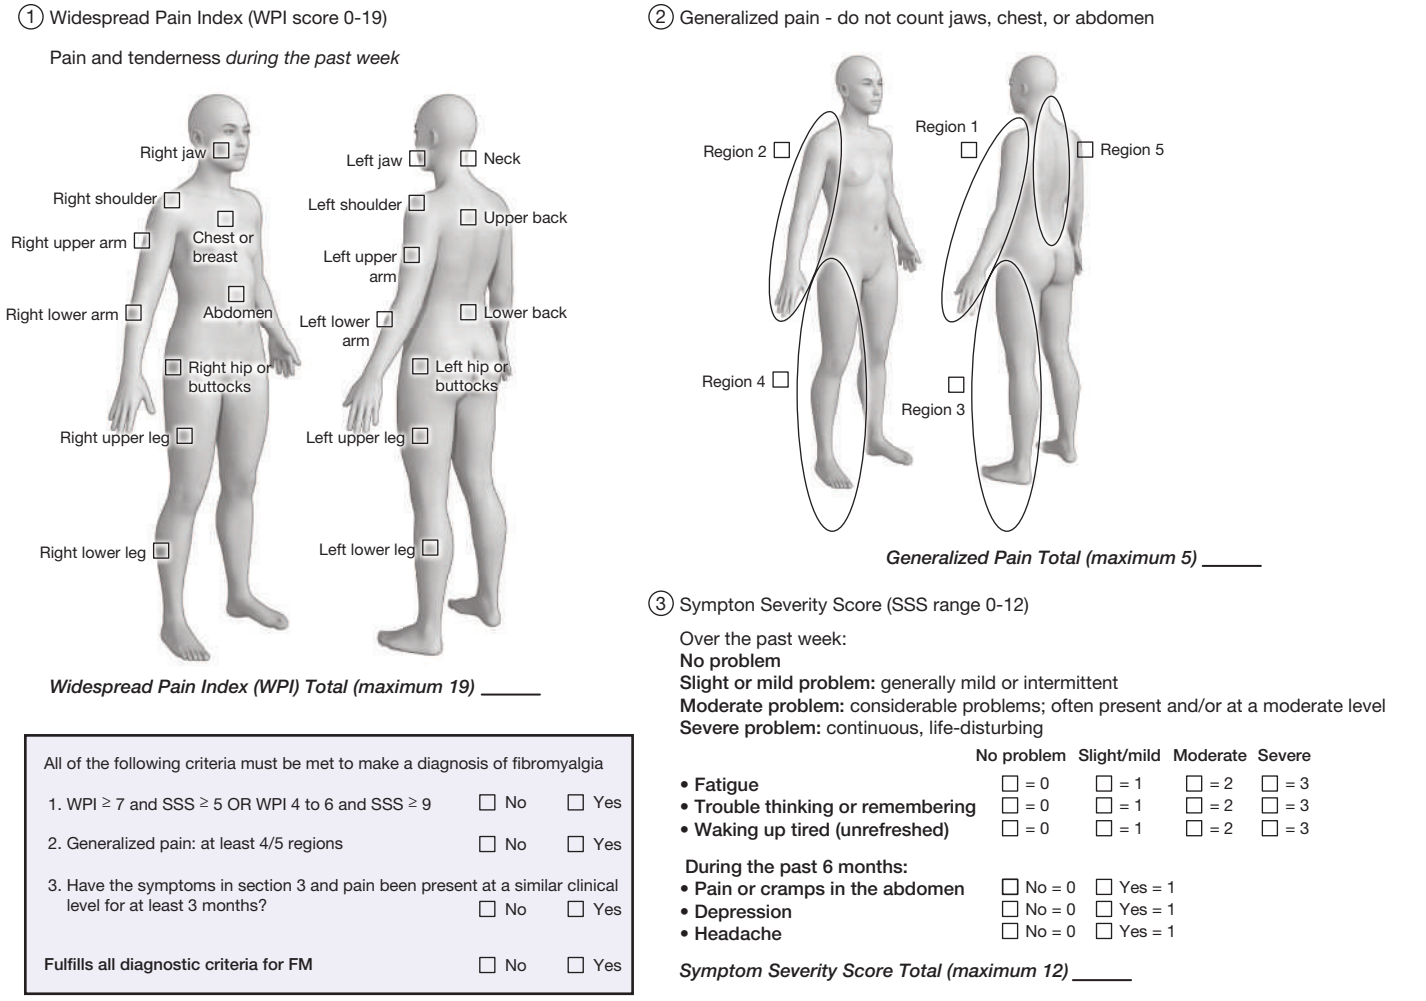

FIGURE 385-1 Fibromyalgia (FM) 2016 diagnostic criteria. *(Figure created using data from F Wolfe et al: Semin Arthritis Rheum 46:319, 2016.)*

management, as many factors that exacerbate symptoms cannot be addressed by pharmacologic approaches. Furthermore, there is a high prevalence of exposure to previous interpersonal and other forms of violence in patients with FM and related conditions. If posttraumatic stress disorder is an issue, the clinician should be aware of it and consider treatment options.

Functional Impairment It is crucial to evaluate the impact of FM symptoms on function and role fulfillment. In defining the success of a management strategy, improved function is a key measure. Functional assessment should include physical, mental, and social domains. Recognition of the ways in which role functioning falls short will be helpful in establishing treatment goals.

DIFFERENTIAL DIAGNOSIS

Because musculoskeletal pain is such a common complaint, the differential diagnosis of FM is broad. Table 385-1 lists some of the more common conditions that should be considered. Patients with inflammatory causes for widespread pain should be identifiable on the basis of specific history, physical findings, and laboratory or radiographic tests.

LABORATORY OR RADIOGRAPHIC TESTING

Routine laboratory and radiographic tests yield normal results in FM without comorbidities. Thus, diagnostic testing is focused on identification of other diagnoses and evaluation for pain generators or comorbid conditions (Table 385-2). Most patients with new chronic widespread pain should be assessed for the most common entities in the differential diagnosis. Radiographic testing should be used very sparingly and only for diagnosis of inflammatory arthritis. After the patient has been evaluated thoroughly, repeat testing is discouraged unless the symptom complex changes. Particularly to be discouraged is magnetic resonance imaging (MRI) of the spine unless there are features suggesting inflammatory spine disease or neurologic symptoms.

GENETICS AND PHYSIOLOGY

As in most complex diseases, it is likely that a number of genes contribute to vulnerability to the development of FM. To date, these genes appear to be in pathways controlling pain and stress responses. Some of the genetic underpinnings of FM are shared across other chronic pain conditions. Genes associated with metabolism, transport, and receptors of serotonin and other monoamines have been implicated in FM and overlapping conditions. Genes associated with other pathways involved in pain transmission have also been described as vulnerability factors for FM. Taken together, the pathways in which polymorphisms have been identified in FM patients further implicate central factors in mediation of the physiology that leads to the clinical manifestations of FM.

Psychophysical testing of patients with FM has demonstrated altered sensory afferent pain processing and impaired descending noxious inhibitory control leading to hyperalgesia and allodynia. Functional MRI and other research imaging procedures clearly demonstrate activation of the brain regions involved in the experience of pain in response to stimuli that are innocuous in study participants without FM. Pain perception in FM patients is influenced by the emotional and cognitive dimensions, such as catastrophizing and perceptions of control, providing a solid basis for recommendations for cognitive and behavioral treatment strategies.

Studies have indicated that some patients meeting criteria for FM may have a small fiber neuropathy. There have also been early reports of a possible autoimmune etiology for changes in the

peripheral nervous system in patients with FM. Other studies have identified alterations in expressed gene or metabolic signatures in peripheral blood. These studies raise the possibility that confirmatory diagnostic testing could be developed in the future to assist in the diagnosis of FM.

APPROACH TO THE PATIENT

Fibromyalgia

FM is common and has an extraordinary impact on the patient's function and health-related quality of life. Optimal management requires prompt diagnosis and assessment of pain, function, and psychosocial context. Physicians and other health professionals can be helpful in managing some of the symptoms and impact of FM. Developing a partnership with patients is essential for improving the outcome of FM, with a goal of understanding the factors involved, implementing a treatment strategy, and choosing appropriate nonpharmacologic and pharmacologic treatments.

TREATMENT

Fibromyalgia

NONPHARMACOLOGIC TREATMENT

Patients with chronic pain, fatigue, and other neuropsychological symptoms require a framework for understanding the symptoms that have such an important impact on their function and quality of life. Explaining the genetics, triggers, and physiology of FM can be an important adjunct in relieving associated anxiety and in reducing the overall cost of health care resources. In addition, patients must be educated regarding expectations for treatment. The physician should focus on improved function and quality of life rather than elimination of pain. Illness behaviors, such as frequent physician visits, should be discouraged and behaviors that focus on improved function strongly encouraged.

Treatment strategies should include physical conditioning, with encouragement to begin at low levels of aerobic exercise and to proceed with slow but consistent advancement. Physical activity and exercise are consistently found to be the most helpful strategies. Exercise programs are helpful in reducing tenderness and enhancing self-efficacy. Patients who have been physically inactive may do best in supervised or water-based programs at the start. Strength training may be recommended after patients reach their aerobic goals. The U.S. Food and Drug Administration has approved devices including a laser therapy device and a transcutaneous electric nerve stimulation (TENS) device. A large randomized, placebo-controlled trial showed that TENS reduces movement-evoked pain and fatigue. Meditative movement therapies, such as qigong, yoga, or Tai Chi, may be helpful to manage symptoms. Other defined physical therapies such as acupuncture or hydrotherapy may also be considered. Cognitive-behavioral strategies to improve sleep hygiene and reduce illness behaviors can also be helpful in management.

PHARMACOLOGIC APPROACHES

It is essential for the clinician to treat any comorbid triggering condition and to clearly delineate for the patient the treatment goals for each medication. For example, glucocorticoids or nonsteroidal anti-inflammatory drugs may be useful for management of inflammatory triggers but are not effective against FM-related symptoms. At present, the treatment approaches that have proved most successful in FM patients target afferent or descending pain pathways. **Table 385-3** lists the drugs with demonstrated effectiveness. It should be emphasized that strong opioid analgesics are to be avoided in patients with FM. These agents have no demonstrated efficacy in FM and are associated with adverse effects that can worsen both symptoms and function. Tramadol, an opioid with mild serotonin-noradrenaline reuptake inhibitor activity, has been studied in this population with indication of efficacy, however its use is generally discouraged due to opioid-related adverse effects. Use of single agents to treat multiple symptom domains is strongly encouraged. For example, if a patient's symptom complex is dominated by pain and sleep disturbance, use of an agent that exerts both analgesic and sleep-promoting effects is desirable. These agents include cyclobenzaprine, sedating antidepressants such as amitriptyline, and alpha-2-delta ligands such as gabapentin and pregabalin. For patients whose pain is associated with fatigue, anxiety, or depression, drugs that have both analgesic and antidepressant/anxiolytic effects, such as duloxetine or milnacipran, may be the best first choice.

TABLE 385-3 Pharmacologic Agents Effective for Treatment of Fibromyalgia

DRUG	DOSE
Muscle relaxant	
Cyclobenzaprine	10–40 mg daily, at bedtime or in divided doses up to 4×/d
Antidepressants: balanced serotonin-norepinephrine reuptake inhibitors	
Amitryptiline[a]	10–50 mg/d; recommended to take at bedtime
Duloxetine[b,c]	60 mg/d; begin at 30 mg/d for 1 week
Milnacipran[b,c]	50 mg bid; titrate over 7 days[d]
Anticonvulsants: ligand of the alpha-2-delta subunit of voltage-gated calcium channels	
Pregabalin[b]	150–450 mg/d; begin at 75 mg bid for at least 1 week
Analgesic	
Tramadol	37.5 mg tramadol + 325 mg acetaminophen up to 4×/d

386 Arthritis Associated with Systemic Disease, and Other Arthritides

Carol A. Langford, Brian F. Mandell

ARTHRITIS ASSOCIATED WITH SYSTEMIC DISEASE

ARTHROPATHY OF ACROMEGALY

Acromegaly is the result of excessive production of growth hormone by a pituitary gland adenoma **(Chap. 392)**. The excessive secretion of growth hormone along with insulin-like growth factor I stimulates cartilage, periarticular connective tissue, and bone, resulting osteoarthritis, back pain, muscle weakness, and carpal tunnel syndrome. Diagnosis is usually between 40 and 50 years, but 5% are younger than 20.

Osteoarthritis is a common feature, affecting one or multiple knees, shoulders, hips, wrists, and fingers. Importantly, wrist involvement is not prominent in primary osteoarthritis. Initial radiographic widening of the joint space results from cartilage hypertrophy. The newly synthesized cartilage is abnormally susceptible to fissuring and damage. Ligamental laxity of joints further contributes to joint discomfort. As cartilage degrades, the joint space narrows and radiographic osteoarthritis develops. Joint fluid, if obtained, is usually noninflammatory. Chondrocalcinosis may occur, and calcium pyrophosphate dihydrate crystals present in the cartilage, when shed into the joint, can elicit attacks of pseudogout (calcium pyrophosphate arthropathy). Back pain is extremely common, perhaps as a result of spine hypermobility. Spine radiographs show normal or widened intervertebral disk spaces, anterior osteophytes, and ligamental calcification. The latter changes may mimic diffuse idiopathic skeletal hyperostosis. Dorsal kyphosis in conjunction with rib enlargement contributes to the development of the barrel chest in acromegalic patients. The hands and feet become enlarged as a result of soft tissue proliferation. The fingers are thickened and have "spadelike" distal tufts. Joint pains may persist after treatment of the acromegaly. One-third of patients have a thickened heel pad. Approximately one-third of patients exhibit Raynaud's phenomenon. Carpal tunnel syndrome occurs in about half of patients due to median nerve compression by excess connective tissue. Patients with acromegaly may develop proximal muscle weakness, which is thought to be caused by a noninflammatory effect of growth hormone on muscle. Serum muscle enzymes and electromyograms are normal.

ARTHROPATHY OF HEMOCHROMATOSIS

Hemochromatosis is a disorder of iron storage. Excessive intestinal absorption of iron leads to iron deposition in parenchymal cells, which results in impairment of organ function **(Chap. 426)**. Symptoms of hemochromatosis usually begin between the ages of 40 and 60 but can appear earlier. Arthropathy (20–40% of patients) usually begins after the age of 50 and may be the first clinical feature of hemochromatosis. The arthropathy is an osteoarthritis-like disorder affecting the small joints of the hands and later the larger joints, such as knees, ankles, shoulders, and hips. The second and third metacarpophalangeal joints of both hands are often the first and most prominent joints affected, providing a clue to the possibility of hemochromatosis because these joints are not predominantly affected by "routine" osteoarthritis. Patients experience some morning stiffness and pain with use of involved joints. The affected joints are enlarged and mildly tender. Hand pain in patients with hemochromatosis starts at an earlier age than in patients with primary osteoarthritis and may cause less disability due to the general sparing of the proximal thumb joint. The joint space narrows with subchondral sclerosis, subchondral cysts, and juxtaarticular proliferation of bone. Hooklike osteophytes of the metacarpophalangeal (MCP) joints are seen in up to 20% of patients; although they are regarded as a characteristic feature of hemochromatosis, they can also occur in primary osteoarthritis. However, dominant radiographic and clinical findings in the second and third MCP joints warrant evaluation of ferritin and iron/total iron-binding capacity levels. The typical radiographic changes of primary osteoarthritis in the proximal interphalangeal, distal interphalangeal, and first carpometacarpal joints are often not striking. The synovial fluid is noninflammatory. The synovium shows mild to moderate proliferation of iron-containing lining cells, fibrosis, and minimal inflammation. In approximately half of patients, there is calcium pyrophosphate deposition, and some patients may develop calcium pyrophosphate arthritis **(Chap. 384)**. An early diagnosis is suggested by high serum transferrin saturation, which is more sensitive than ferritin elevation.

Iron may damage the articular cartilage in several ways. Iron catalyzes superoxide-dependent lipid peroxidation, which may play a role in joint damage. In animal models, ferric iron has been shown to interfere with collagen formation and increase the release of lysosomal enzymes from cells in the synovial membrane. Iron inhibits synovial tissue pyrophosphatase (in vitro) and thus may result in chondrocalcinosis.

TREATMENT

Arthropathy of Hemochromatosis

The treatment of hemochromatosis is repeated phlebotomy. Phlebotomy often has little effect on established arthritis, which, along with chondrocalcinosis, may progress. Symptom-based treatment of the arthritis consists of administration of acetaminophen and nonsteroidal anti-inflammatory drugs (NSAIDs), as tolerated. Acute calcium pyrophosphate arthropathy flares are treated with

high doses of an NSAID or a short course of glucocorticoids. Colchicine may have efficacy in treating and limiting the number of flares. Advanced osteoarthritis can be treated with arthroplasty.

HEMOPHILIC ARTHROPATHY

Hemophilia is a sex-linked recessive genetic disorder characterized by the absence or deficiency of factor VIII (hemophilia A, or classic hemophilia) or factor IX (hemophilia B, or Christmas disease) (Chap. 121). Hemophilia A constitutes 85% of cases. Spontaneous hemarthrosis is a common problem with both types of untreated hemophilia and can lead to a deforming arthritis. The severity of hemarthrosis is related to the degree of clotting factor deficiency. Hemarthrosis is not common in other disorders of coagulation such as von Willebrand disease, factor V deficiency, oral anticoagulation, or thrombocytopenia.

Hemarthrosis occurs after 1 year of age, when a child begins to walk and run. The joints most commonly affected are the knees, ankles, elbows, shoulders, and hips. Small joints of the hands and feet are occasionally involved.

In the initial stage of arthropathy, hemarthrosis produces a warm, tensely swollen, and painful joint. Blood in the joint remains liquid because of the absence of intrinsic clotting factors and the absence of tissue thromboplastin in the synovium. The synovial blood is resorbed over a period of ≥1 week, with the precise interval depending on the size of the hemarthrosis. Joint function usually returns to normal or baseline in ~2 weeks. Low-grade temperature elevation may accompany hemarthrosis, but a fever >38.3°C (101°F) warrants concern about infection, and joint aspiration should be considered.

Recurrent hemarthrosis may result in chronic noninflammatory, fibrotic arthropathy. The joints remain swollen, and flexion deformities may develop. Joint motion may be restricted and function severely limited.

Bleeding into muscle and soft tissue also causes musculoskeletal dysfunction. When bleeding into the iliopsoas muscle occurs, the hip is held in flexion because of the pain, resulting in a hip flexion contracture. Rotation of the hip is generally preserved, distinguishing this from hemarthrosis or hip synovitis. Expansion of the hematoma may place pressure on the femoral nerve, resulting in femoral neuropathy. Hemorrhage into a closed compartment space, such as the calf or the volar compartment in the forearm, can result in muscle necrosis, neuropathy, and flexion deformities of the ankles, wrists, and fingers. When bleeding involves periosteum or bone, a painful pseudotumor forms. These pseudotumors occur distal to the elbows or knees in children and improve with treatment of hemophilia. Surgical removal is indicated if the pseudotumor continues to enlarge. In adults, pseudotumors develop in the femur and pelvis and are usually refractory to treatment. When bleeding occurs in muscle, cysts may develop within the muscle. Needle aspiration of a cyst is relatively contraindicated because it can induce further bleeding; however, if the cyst becomes secondarily infected, drainage may be necessary (after factor repletion).

Septic arthritis is rare in hemophilia but is difficult to distinguish from acute hemarthrosis on physical examination. If there is serious suspicion of an infected joint, the joint should be aspirated immediately, the fluid cultured, and empiric treatment with broad-spectrum antibiotics administered, with coverage including *Staphylococcus*, until culture results become available. Clotting factor deficiency should be corrected before arthrocentesis to minimize the risk of traumatic bleeding. Notably, low-grade fevers can occur in the setting of acute hemarthrosis.

Radiographs of joints reflect the stage of disease. Initially there is only capsule distention; later, juxtaarticular osteopenia, marginal erosions, and subchondral cysts may develop. Late in the disease, the joint space is narrowed and there is bony overgrowth similar to that in osteoarthritis. Blood collections may calcify.

TREATMENT

Musculoskeletal Bleeding

The treatment of musculoskeletal bleeding is initiated with the immediate infusion of factor VIII or IX at the first sign of joint or muscle hemorrhage. Patients who have developed factor inhibitors are at elevated risk for joint damage and may benefit from receiving recombinant activated factor VII or activated prothrombin complex concentrate. The joint should be splinted in gentle forced extension, as tolerated, to avoid contracture. Analgesia should be provided; nonselective NSAIDs, which can diminish platelet function, should be avoided if possible. Selective cyclooxygenase-2 inhibitors do not interfere with platelet function, although cardiovascular, renal, and gastrointestinal concerns should be considered. Synovectomy—open or arthroscopic—may be attempted to limit future bleeding and fibrosis in patients with chronic symptomatic synovial proliferation and recurrent hemarthrosis, although hypertrophied synovium is highly vascular and subject to bleeding. Open surgical synovectomy has been associated with decreased range of motion. Both require aggressive prophylaxis against bleeding. Radiosynovectomy with either yttrium-90 silicate or phosphorus-31 colloid has been effective and may be attempted if available when surgery is not advised. Total joint replacement is indicated for severe joint destruction and incapacitating pain.

ARTHROPATHIES ASSOCIATED WITH HEMOGLOBINOPATHIES

Sickle Cell Disease Sickle cell disease (Chap. 103) is associated with several musculoskeletal abnormalities (Table 386-1). Children aged <5 years may develop diffuse swelling, tenderness, and warmth of the hands and feet lasting 1–3 weeks. This condition, referred to as *sickle cell dactylitis* or *hand-foot syndrome*, has also been observed in sickle cell thalassemia. Dactylitis is believed to result from infarction of the bone marrow and cortical bone leading to periostitis and soft tissue swelling. Radiographs show periosteal elevation, subperiosteal new-bone formation, and areas of radiolucency and increased density involving the metacarpals, metatarsals, and proximal phalanges. These bone changes disappear after several months. The syndrome leaves little or no residual damage. This syndrome is rarely seen after age 5.

Sickle cell crisis is associated with periarticular and long bone pain, occasionally with joint effusions. The joint and periarticular areas are warm and tender. Knees and elbows are most often affected, but other joints can be involved. Joint effusions are usually noninflammatory, but acute synovial infarction can cause a sterile joint effusion with a high neutrophil count. Scintigraphic studies have shown decreased marrow uptake adjacent to the involved joint. The treatment for sickle cell crisis is detailed in Chap. 103.

Patients with sickle cell disease seem predisposed to osteomyelitis, perhaps related to splenic dysfunction, which commonly involves the long tubular bones (Chap. 136); *Salmonella* is a particularly associated cause (Chap. 171). Radiographs of the involved site initially show periosteal elevation, with subsequent disruption of the cortex. Treatment of the infection results in healing of the bone lesion. Sterile bone infarction resulting from vasoocclusion secondary to the sickling of red cells can occur and contribute to the painful crises. Bone infarction also occurs in patients with sickle cell trait and sickle cell thalassemia (Chap. 103). In children, infarction of the epiphyseal growth plate may interfere with normal growth of the affected extremity. Radiographically, infarction of the bone cortex results in periosteal elevation and irregular cortical thickening. Infarction in the bone marrow leads to lysis, fibrosis, and new bone formation. Clinical distinction between osteomyelitis and bone infarctions can be difficult; nuclear imaging may be helpful.

TABLE 386-1 Musculoskeletal Abnormalities in Sickle Cell Disease

Sickle cell dactylitis	Avascular necrosis
Joint effusions in sickle cell crises	Bone changes secondary to marrow hyperplasia
Osteomyelitis	Septic arthritis
Infarction of bone	Gouty arthritis
Infarction of bone marrow	Synovial infarction

Avascular necrosis of the femoral head occurs in ~5% of patients. It also occurs in the humeral head and less commonly in the distal femur, tibial condyles, distal radius, vertebral bodies, and other juxtaarticular sites. Periarticular damage may contribute to the development of osteoarthritis. Radiography of the affected joint may show patchy radiolucency and density followed by collapse or change in bone shape, but magnetic resonance imaging (MRI) is a far more sensitive technique for detecting early avascular necrosis. Joint replacements may markedly reduce pain and improve function.

Septic arthritis is occasionally encountered in sickle cell disease (Chap. 135). Multiple joints may be infected. Joint infection may result from bacteremia due to splenic dysfunction or from contiguous osteomyelitis. The more common microorganisms include *Staphylococcus aureus* and *Streptococcus*. *Salmonella* does not cause septic arthritis as frequently as it causes osteomyelitis. Acute gouty arthritis may occur in young patients with sickle cell disease, as up to 40% of patients are hyperuricemic due to increased urate generation and interstitial renal disease. Attacks may be polyarticular, and diagnostic arthrocentesis should be performed to distinguish infection from gout or synovial infarction.

The bone marrow hyperplasia in sickle cell disease results in widening of the medullary cavities, thinning of the cortices, and coarse trabeculations and central cupping of the vertebral bodies. These changes are also seen to a lesser degree in patients with sickle cell thalassemia. In normal individuals, red marrow is located mostly in the axial skeleton, but in sickle cell disease, red marrow is found in the bones of the extremities and even in the tarsal and carpal bones. Vertebral compression may lead to dorsal kyphosis, and softening of the bone in the acetabulum may result in protrusio acetabuli.

Thalassemia A congenital disorder of hemoglobin synthesis, β thalassemia is characterized by impaired production of β chains (Chap. 103). Bone and joint abnormalities occur in β thalassemia, being most common in the major and intermedia types. In one study, ~50% of patients with β thalassemia had evidence of symmetric ankle arthropathy characterized by a dull aching pain that was aggravated by weight bearing. The onset came most often in the second or third decade of life. The degree of ankle pain in these patients varied. Symptoms eventually abated in a few patients. Synovial fluid from two patients was noninflammatory. Radiographs of the ankle showed osteopenia, widened medullary spaces, thin cortices, and coarse trabeculations—findings that are consistent with bone marrow expansion. The joint space was preserved. Iron staining was found in the bone trabeculae, in osteoid, in the cement line, and in the synovium. This arthropathy was considered to be secondary to the underlying bone pathology and was treated with analgesics and splints as well as transfusions in some patients to decrease hematopoiesis and bone marrow expansion.

In patients with β-thalassemia major and β-thalassemia intermedia, other joints are also involved, including the knees, hips, and shoulders. Gouty arthritis and septic arthritis have been reported. Avascular necrosis is not a feature of thalassemia because there is vasoocclusion leading to thrombosis and infarction.

β-Thalassemia minor (also known as *β-thalassemia trait*) is likewise associated with joint manifestations. Chronic seronegative oligoarthritis affecting predominantly ankles, wrists, and elbows has been described; the affected patients had mild persistent synovitis without large effusions or joint erosions. Recurrent episodes of acute asymmetric arthritis have also been reported; episodes last <1 week and may affect the knees, ankles, shoulders, elbows, wrists, and metacarpal phalangeal joints. The mechanism underlying this arthropathy is unknown. Treatment with NSAIDs is not particularly effective. Patients receiving frequent transfusions may be more likely to have circulating antinuclear antibodies, but not systemic lupus erythematosus.

MUSCULOSKELETAL DISORDERS ASSOCIATED WITH HYPERLIPIDEMIA

(See also Chap. 419) Musculoskeletal or cutaneous manifestations may be the first clinical indication of a hereditary disorder of lipoprotein metabolism. Patients with rare familial hypercholesterolemia (previously referred to as *type II hyperlipoproteinemia*) may have recurrent migratory polyarthritis involving the knees and other large peripheral joints and, to a lesser degree, peripheral small joints. Pain ranges from moderate to incapacitating. The involved joints can be warm, erythematous, swollen, and tender. Arthritis usually has a sudden onset, lasts from a few days to 2 weeks, and does not cause joint damage and suggest an acute gout flare. These may be recurrent. Synovial fluid from involved joints is not inflammatory and contains no crystals. Flares may be inflammatory periarthritis or peritendinitis and not true arthritis. Attacks of tendinitis, including the large Achilles and patellar tendons, may come on gradually and last only a few days or may be acute as described above. Patients may be asymptomatic between attacks. Achilles tendinitis and other joint manifestations often precede the appearance of xanthomas and may be the first clinical indication of hyperlipoproteinemia. Attacks of tendinitis have been reported following initiation of a lipid-lowering drug. Over time, patients may develop tendinous xanthomas in the Achilles, patellar, and extensor tendons of the hands and feet. Xanthomas have also been reported in the peroneal tendon, the plantar aponeurosis, and the periosteum overlying the distal tibia. These xanthomas are located within tendon fibers. Tuberous xanthomas are soft subcutaneous masses located over the extensor surfaces of the elbows, knees, and hands as well as on the buttocks. They appear during childhood in homozygous patients and after the age of 30 in heterozygous patients. Patients with elevated plasma levels of very-low-density lipoprotein (VLDL) and triglycerides (previously referred to as *type IV hyperlipoproteinemia*) may also have a mild inflammatory arthritis affecting large and small peripheral joints, usually in an asymmetric pattern, with only a few joints involved at a time. The onset of arthritis usually comes in middle age. Radiographs may show juxtaarticular osteopenia and cystic lesions. Large bone cysts have been noted in a few patients. Xanthoma and bone cysts are also observed in other lipoprotein disorders. The pathogenesis of arthritis in patients with familial hypercholesterolemia or with elevated levels of VLDL and triglycerides is not well understood. NSAIDs or analgesics usually provide adequate relief of symptoms when used on an as-needed basis.

Patients may improve clinically as they are treated with lipid-lowering agents; however, patients treated with an HMG-CoA reductase inhibitor may experience myalgias, and rare patients develop myopathy or myositis. Testing for anti-HMGCR autoantibodies in patients with elevated muscle enzymes on treatment may identify the patients with statin-induced necrotizing autoimmune myopathy who require aggressive immunosuppressive therapy. Myositis (and gout) has been reported with the use of niacin (Chap. 377) but is less common than myalgias.

Musculoskeletal syndromes have not clearly been associated with the more common mixed hyperlipidemias seen in general practice. The incidence of gout is increased in patients taking bempedoic acid.

OTHER ARTHRITIDES

NEUROPATHIC JOINT DISEASE

Neuropathic joint disease (Charcot joint) is a progressive destructive arthritis associated with loss of pain sensation, proprioception, or both. Normal muscular reflexes that modulate joint movement are impaired. Without these protective mechanisms, joints are subjected to repeated trauma, resulting in progressive cartilage and bone damage. Diabetes mellitus is the most frequent cause of neuropathic joint disease (Fig. 386-1). A variety of other disorders are associated with neuropathic arthritis, including tabes dorsalis, leprosy, yaws, syringomyelia, meningomyelocele, congenital indifference to pain, peroneal muscular atrophy (Charcot-Marie-Tooth disease), and amyloidosis. An arthritis resembling neuropathic joint disease has been reported in patients who have received frequent intraarticular glucocorticoid injections, but this was not observed in a series of patients with knee osteoarthritis who received intraarticular glucocorticoid injections every 3 months for 2 years. The distribution of joint involvement depends on the underlying neurologic disorder (Table 386-2). In tabes dorsalis, the knees,

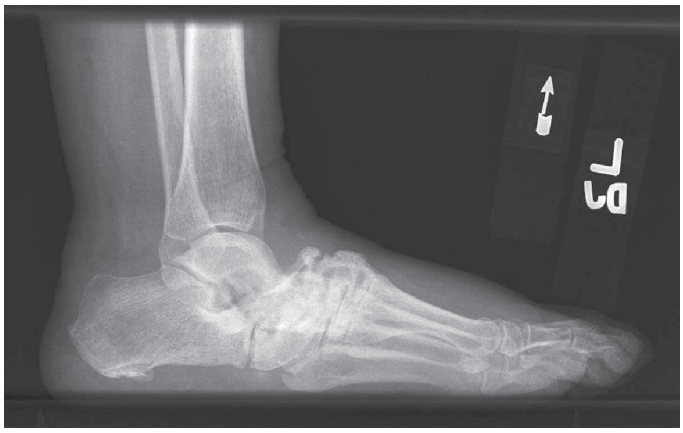

FIGURE 386-1 Charcot arthropathy associated with diabetes mellitus. Lateral foot radiograph demonstrating complete loss of the arch due to bony fragmentation and dislocation in the midfoot. *(Courtesy of Andrew Neckers, MD, and Jean Schils, MD; with permission.)*

hips, and ankles are most commonly affected; in syringomyelia, the glenohumeral joint, elbow, and wrist; and in diabetes mellitus, the tarsal and tarsometatarsal joints.

PATHOLOGY AND PATHOPHYSIOLOGY

The pathologic changes in the neuropathic joint are similar to those found in the severe osteoarthritic joint. There is fragmentation and eventual loss of articular cartilage with eburnation of the underlying bone. Osteophytes are found at the joint margins. With more advanced disease, erosions are present on the joint surface. Fractures, devitalized bone, intraarticular loose bodies, and microscopic fragments of cartilage and bone may be present.

At least two underlying mechanisms are believed to be involved in the pathogenesis of neuropathic arthritis. An abnormal autonomic nervous system is thought to be responsible for the dysregulated blood flow to the joint with subsequent resorption of bone. Loss of bone, particularly in the diabetic foot, may be the initial finding. With the loss of deep pain, proprioception, and protective neuromuscular reflexes, the joint is subjected to repeated microtrauma, resulting in ligamental tears and bone fractures. The injury that may follow frequent intraarticular glucocorticoid injections is thought to be due to the analgesic effect of glucocorticoids, leading to overuse of an already damaged joint with accelerated cartilage damage, although steroid-induced cartilage damage is more common in animal species than in humans. There have been reports of accelerated joint damage occurring in some animals and occasional patients with the therapeutic use of nerve growth factor antagonists. It is not understood why only a few patients with neuropathy develop clinically evident neuropathic arthritis.

CLINICAL MANIFESTATIONS

Neuropathic joint disease usually begins in a single joint and then becomes apparent in other joints, depending on the underlying neurologic disorder. The involved joint becomes progressively enlarged as a result of bony overgrowth and synovial effusion. Free-floating cartilage and bone fragments may cause mechanical joint symptoms. Neuropathic joints may develop rapidly, and a totally disorganized joint with multiple bony fragments may evolve within weeks or months. Less pain is reported by patients than would be anticipated from the degree of joint damage, but they may experience sudden pain from intraarticular fractures of osteophytes.

TABLE 386-2 Disorders Associated with Neuropathic Joint Disease

Diabetes mellitus	Amyloidosis
Tabes dorsalis	Leprosy
Meningomyelocele	Congenital indifference to pain
Syringomyelia	Peroneal muscular atrophy

Neuropathic arthritis is estimated to occur in patients with diabetes mellitus with an incidence of ~0.5%, usually at ≥50 years in a patient who has had diabetes for several years, but exceptions occur. The tarsal and tarsometatarsal joints are most often affected, with the metatarsophalangeal and talotibial joints next most commonly involved. Patients often attribute the onset of foot pain to antecedent trauma such as twisting of the foot. Neuropathic changes may develop rapidly after a foot fracture or dislocation. The foot and ankle are often swollen. Downward collapse of the tarsal bones leads to convexity of the sole, referred to as a "rocker foot." Large osteophytes may protrude from the top of the foot. Calluses frequently form over the metatarsal heads and may lead to infected ulcers and osteomyelitis. The value of protective inserts and orthotics, as well as regular foot examination, cannot be overstated. Radiographs may show resorption and tapering of the distal metatarsal bones. The term *Lisfranc fracture-dislocation* is sometimes used to describe the destructive changes at the tarsometatarsal joints.

DIAGNOSIS

The diagnosis of neuropathic arthritis is based on the clinical features and characteristic radiographic findings in a patient with underlying sensory neuropathy. The differential diagnosis of neuropathic arthritis depends on the severity of the process and includes osteomyelitis, avascular necrosis, advanced osteoarthritis, stress fractures, and calcium pyrophosphate deposition disease. Patients may have more than one of these conditions. Imaging in neuropathic arthritis initially shows changes of osteoarthritis with joint space narrowing, subchondral bone sclerosis, osteophytes, and joint effusions; marked destructive and hypertrophic changes occur later. The radiographic findings of neuropathic arthritis may be difficult to differentiate from those of osteomyelitis, especially in the diabetic foot. The joint margins in a neuropathic joint tend to be distinct, while in osteomyelitis, they are blurred. Imaging studies may be helpful, but cultures of tissue from the joint are often required to exclude osteomyelitis. MRI and nuclear scans using indium-111–labeled white blood cells, which may show increased uptake in osteomyelitis but not in a neuropathic joint, may occasionally be useful. A technetium bone scan will not distinguish osteomyelitis from neuropathic arthritis, as increased uptake is observed in both. The joint fluid in neuropathic arthritis is noninflammatory; it may be xanthochromic or even bloody and contain fragments of synovium, cartilage, and bone. The finding of calcium pyrophosphate dihydrate crystals supports the diagnosis of crystal-associated arthropathy. In the absence of such crystals, an increased number of synovial neutrophils suggests possible osteomyelitis.

TREATMENT

Neuropathic Joint Disease

The primary focus of treatment is to stabilize the joint. Treatment of the underlying disorder, even if successful, does not usually affect established joint disease. Braces and splints are helpful. Their use requires close surveillance, because patients may be unable to appreciate pressure from a poorly adjusted brace. In the diabetic patient, early recognition of Charcot foot and its treatment—prohibition of weight bearing by the foot for at least 8 weeks—may prevent severe disease from developing. Fusion of an unstable joint may improve function and reduce pain, but nonunion is frequent, especially when immobilization of the joint is inadequate.

HYPERTROPHIC OSTEOARTHROPATHY AND CLUBBING

Hypertrophic osteoarthropathy (HOA) is characterized by clubbing of digits and, in more advanced stages, by periosteal new-bone formation. Primary or familial HOA may begin in childhood. Secondary HOA is associated with intrathoracic malignancies, suppurative and some hypoxemic lung diseases, congenital heart disease, hepatopulmonary disease, and a variety of other disorders. Clubbing is almost always a feature of HOA but can also occur as an isolated finding **(Fig. 386-2)**.

FIGURE 386-2 Clubbing of the fingers. *(Photo contributor Alan B. Storrow, MD.)*

The presence of clubbing in isolation may be congenital or represent either an early stage or one element in the spectrum of HOA. Isolated acquired clubbing has the same clinical significance as clubbing associated with periostitis.

Pathology and Pathophysiology of Acquired HOA In HOA, bone changes in the distal extremities begin as periostitis followed by new bone formation. At this stage, a radiolucent area may be observed between the new periosteal bone and the subjacent cortex. As the process progresses, multiple layers of new bone are deposited and become contiguous with the cortex, with consequent cortical thickening. The outer portion of the bone is laminated in appearance, with an irregular surface. Initially, the process of periosteal new-bone formation involves the proximal and distal diaphyses of the tibia, fibula, radius, and ulna and, less frequently, the femur, humerus, metacarpals, metatarsals, and phalanges. Occasionally, scapulae, clavicles, ribs, and pelvic bones are also affected. Radionuclide studies show pericortical linear uptake along the cortical margins of long bones that may precede any radiographic changes. The distribution of bone manifestations is usually bilateral and symmetric. The soft tissue overlying the distal third of the arms and legs may be thickened. Proliferation of connective tissue occurs in the nail bed and volar pad of digits, giving the distal phalanges a clubbed appearance. Small blood vessels in the clubbed digits are dilated and have thickened walls. In addition, the number of arteriovenous anastomoses is increased.

Many theories have been suggested for the pathogenesis of HOA, but several have been disproved or have not explained the condition's development in all clinical disorders with which it is associated. Current hypotheses have in common the concept that circulating cells or growth factors bypass clearance by the lungs and circulate to the periphery where they stimulate connective tissue proliferation. A role for platelets in the development of HOA has been proposed. Megakaryocytes and large platelet particles present in the venous circulation are fragmented in their passage through normal lung; in patients with cyanotic congenital heart disease or other disorders associated with right-to-left shunts, these large platelet particles bypass the lung and reach the distal extremities, where they interact with endothelial cells. Increased levels of platelet-derived growth factor (PDGF), vascular endothelial growth factor (VEGF), and other factors stimulate the proliferation of connective tissue and periosteum. Elevated plasma levels of von Willebrand factor antigen have been found in patients with both primary and secondary forms of HOA, supporting the concept of endothelial activation or damage.

Clinical Manifestations A form of primary familial HOA, referred to as *pachydermoperiostitis* or *Touraine-Solente-Golé syndrome*, usually begins insidiously at puberty. The disorder is inherited as an autosomal dominant trait with variable expression and is nine times more common among boys than among girls. Approximately one-third of patients have a family history of primary HOA.

Primary HOA is characterized by clubbing, periostitis, and unusual skin features. A small number of patients with this syndrome do not express clubbing. The skin changes and periostitis are prominent features of this syndrome. The skin becomes thickened and coarse. Deep nasolabial folds develop, and the forehead may become furrowed. The skin is often greasy, and there may be excessive sweating of the hands and feet. Patients may also experience acne vulgaris, seborrhea, and folliculitis. In a few patients, the skin over the scalp becomes very thick and corrugated, a feature that has been descriptively termed *cutis verticis gyrata*. The distal extremities, particularly the legs, become markedly thickened as a consequence of the proliferation of new bone and soft tissue. The periostitis usually is not painful, distinguishing it from secondary HOA. Clubbing of the fingers may be extensive, producing large, bulbous deformities and clumsiness. Clubbing also affects the toes. Patients may experience articular and periarticular pain, especially in the ankles and knees, and joint motion may be mildly restricted by periarticular bone overgrowth. Noninflammatory effusions without synovial proliferation occur in the wrists, knees, and ankles. Associated abnormalities observed in patients with primary HOA include hypertrophic gastropathy, bone marrow failure, gynecomastia, and cranial suture defects. In patients with primary HOA, the many symptoms disappear when adulthood is reached.

HOA secondary to an underlying disease occurs more frequently than primary HOA. It accompanies a variety of disorders and may precede clinical features of the associated disorder by months. Clubbing is more frequent than the full syndrome of HOA in patients with associated illnesses. Because clubbing evolves over months and is usually asymptomatic, it is often recognized first by the physician and not the patient. Patients may experience a burning sensation in their fingertips. Clubbing is characterized by widening of the fingertips, enlargement of the distal volar pad, convexity of the nail contour, and the loss of the normal 15° angle between the proximal nail and cuticle. The thickness of the digit at the base of the nail is greater than the thickness at the distal interphalangeal joint. An objective measurement of finger clubbing can be made by determining the diameter at the base of the nail and at the distal interphalangeal joint of all 10 digits. Clubbing is present when the sum of the individual digit ratios is >10. At the bedside, clubbing can be appreciated by having the patient place the dorsal surface of the distal phalanges of the fourth fingers together with the nails opposing each other. Normally, an open area is visible between the bases of the opposing fingernails; when clubbing is present, this open space is no longer visible. The base of the nail feels spongy when compressed, and the nail can be easily rocked on its bed. When clubbing is advanced, the finger may have a drumstick appearance, and the distal interphalangeal joint can be hyperextended. Periosteal involvement in the distal extremities may produce a burning or deep-seated aching pain. The pain, which can be quite incapacitating, is aggravated by dependency and relieved by elevation of the affected limbs. Pressure applied over the distal forearms and legs or gentle percussion of distal long bones like the tibia may be quite painful.

Patients may experience joint pain, most often in the ankles, wrists, and knees. The small joints of the hands are rarely affected. Severe joint or long bone pain may be the presenting symptom of an underlying lung malignancy and may precede the appearance of clubbing. In addition, the progression of HOA tends to be more rapid when associated with malignancies, most notably bronchogenic carcinoma. Noninflammatory but variably painful knee effusions may occur prior to the appearance of clubbing and symptoms of distal periostitis. Unlike primary HOA, secondary HOA does not commonly include excessive sweating and oiliness of the skin or thickening of the facial skin.

HOA occurs in 5–10% of patients with intrathoracic malignancies, the most common being bronchogenic carcinoma and pleural tumors **(Table 386-3)**. Lung metastases infrequently cause HOA. HOA is also seen in patients with intrathoracic infections, including lung abscesses, empyema, and bronchiectasis, but is uncommon in pulmonary tuberculosis. HOA may accompany chronic interstitial pneumonitis, sarcoidosis, and cystic fibrosis. In cystic fibrosis, clubbing is more common than the full syndrome of HOA. Other causes of clubbing include congenital heart disease with right-to-left shunts, bacterial endocarditis, Crohn's disease, ulcerative colitis, sprue, and neoplasms of the esophagus, liver, and small and large bowel. In patients who

[a]Unilateral involvement. [b]Bilateral lower-extremity involvement.

have congenital heart disease with right-to-left shunts, clubbing alone occurs more often than the full syndrome of HOA.

Unilateral clubbing has been found in association with aneurysms of major extremity arteries, with infected arterial grafts, and with arteriovenous fistulas of brachial vessels. Clubbing of the toes but not the fingers has been associated with an infected abdominal aortic aneurysm and patent ductus arteriosus. Clubbing of a single digit may follow trauma and has been reported in tophaceous gout and sarcoidosis. While clubbing occurs more commonly than the full syndrome in most diseases, periostitis in the absence of clubbing has been observed in the affected limb of patients with infected arterial grafts.

Hyperthyroidism (Graves' disease), treated or untreated, is occasionally associated with clubbing and periostitis of the bones of the hands and feet. This condition is referred to as *thyroid acropachy* and may result from similar factors that stimulate the growth of retrobulbar connective tissue. Periostitis may be asymptomatic and occurs in the midshaft and diaphyseal portion of the metacarpal and phalangeal bones. Significant hand-joint pain may occur; this pain may respond to successful therapy for thyroid dysfunction. The long bones of the extremities are seldom affected. Elevated levels of long-acting thyroid stimulator are found in the sera of these patients.

TREATMENT

Hypertrophic Osteoarthropathy

The treatment of HOA aims to identify the associated disorder and treat it appropriately. The symptoms and signs of HOA may disappear completely with removal of or effective chemotherapy for a tumor or with antibiotic therapy for a chronic pulmonary infection and drainage of the infected site. Vagotomy or percutaneous block of the vagus nerve leads to symptomatic relief in some patients. NSAIDs or analgesics may help control symptoms of HOA.

COMPLEX REGIONAL PAIN SYNDROME

The reflex sympathetic dystrophy syndrome is now referred to as *complex regional pain syndrome, type 1*. This syndrome is characterized by pain, sometimes with swelling, usually of a distal extremity, accompanied by variable vasomotor instability, trophic skin changes, and the rapid development of bony demineralization. Complex regional pain syndrome, including its treatment, is covered in greater detail in Chap. 451.

TIETZE SYNDROME AND COSTOCHONDRITIS

Tietze syndrome is manifested by painful swelling of one or more costochondral articulations. The age of onset is usually before 40, and both sexes are affected equally. In most patients, only one joint is involved, usually the second or third costochondral joint. The onset of anterior chest pain may be sudden or gradual. The pain may radiate to the arms or shoulders and is aggravated by sneezing, coughing, deep inspirations, or twisting motions of the chest. The term *costochondritis* is often used interchangeably with *Tietze syndrome*, but some authors restrict the latter term to pain of the costochondral articulations with swelling. Costochondritis is observed in patients aged >40 years; it tends to affect the third, fourth, and fifth costochondral joints, and occurs more often in women. Both syndromes may superficially mimic cardiac or pulmonary-vascular causes of pain. Rheumatoid and psoriatic arthritis, ankylosing spondylitis, and reactive arthritis may involve costochondral joints but are readily distinguished by the presence of other clinical features. Other anterior chest wall pain syndromes are xiphoidalgia and the slipping rib syndrome, which usually involves the tenth or lower ribs and causes pain below the rib cage that can be reproduced or exacerbated by gently hooking the examiner's fingers around the rib and exerting mild caudal traction. Malignancies can invade the ribs, thoracic spine, or chest wall and produce symptoms suggesting Tietze syndrome, as can thoracic herpes zoster. Patients with osteomalacia may have significant rib pain, with or without documented microfractures; this can be suggested by documenting very low vitamin D levels and nuclear bone imaging. Analgesics, anti-inflammatory drugs, and local glucocorticoid injections usually relieve symptoms of costochondritis/Tietze syndrome. Care should be taken to avoid overdiagnosing these syndromes in patients with acute chest pain syndromes; many patients are tender to overly vigorous palpation of the costochondral joints.

MYOFASCIAL PAIN SYNDROME

Myofascial pain syndrome is characterized by multiple areas of localized musculoskeletal pain and tenderness often in association with tender points that can fluctuate in intensity. The pain is deep and aching and may be accompanied by a burning sensation. Myofascial pain may be regional following trauma, overuse, or prolonged static contraction of a muscle or muscle group, which may occur when an individual is reading or writing at a desk or working at a computer. This type of pain may be associated with underlying osteoarthritis of the neck or low back. Pain may be referred from tender points to defined areas distant from the area of original tenderness. Palpation of the tender point reproduces or accentuates the pain. The tender points are usually located in the center of a muscle belly, but they can occur at other sites such as costosternal junctions, the xiphoid process, ligamentous and tendinous insertions, fascia, and fatty areas. Notably tender point sites in muscles are also present in pain-free patients. Myofascial pain most often involves the posterior neck, low back, shoulders, and chest. Chronic pain in the muscles of the posterior neck may involve referral of pain from a tender point in the erector neck muscle or upper trapezius to the head, leading to persistent headaches that may last for days. Tender points in the paraspinal muscles of the low back may refer pain to the buttock. Pain may be referred down the leg from a tender point in the gluteus medius and can mimic sciatica. Lateral hip trochanteric area tenderness may radiate down the lateral leg. A tender point in the infraspinatus muscle may produce local and referred pain over the lateral deltoid and down the outside of the arm into the hand, and a tender point medial to the scapula can radiate to the anterior chest or arm in a distribution that can mimic coronary pain. Injection of a local anesthetic such as 1% lidocaine into the tender point site often results in at least transient pain relief. Another useful technique is first to spray an agent such as ethyl chloride from the tender point toward the area of referred pain and then to stretch the muscle. This maneuver may need to be repeated several times. Massage and application of ultrasound to the affected area also may be beneficial. Attention to posture and resting positions can be helpful in preventing abnormal muscle tension. The prognosis in most patients is good. In some patients, regionally localized myofascial pain syndrome may seem to evolve into or be part

of previously unrecognized generalized fibromyalgia **(Chap. 385)**. Abnormal or nonrestorative sleep is a common accompaniment in these patients and should be specifically addressed, as fatigue and "brain fog" are often present.

NEOPLASIAS AND ARTHRITIS

Primary tumors and tumor-like disorders of synovium are uncommon but should be considered in the differential diagnosis of chronic monoarticular joint disease. In addition, metastases to bone and primary bone tumors adjacent to a joint may produce joint symptoms, occasionally with joint effusions.

Pigmented villonodular synovitis (*PVNS*), likely the same process causing tenosynovial giant cell tumors, is characterized by slowly progressive, benign proliferation of tenosynovial tissue. This usually involves a single large joint or tendon. The most common age of onset is in the third decade, and women are affected slightly more often than men. The proliferating tissue usually displays clonal chromosomal translocations, often involving the colony stimulating factor-1 (CSF-1) pathway, which influences the proliferation and maturation of mononuclear cells and macrophages. This provides a target for potential therapy.

The synovium has a brownish color and numerous large, fingerlike villi and nodules. There is marked hyperplasia of synovial cells in the stroma of the villi. Hemosiderin and lipids are found in the cytoplasm of macrophages and in the interstitial tissue. Multinucleated giant cells may be present. The proliferative synovium may behave as a simple mass or as a more diffuse invasive tissue growing into the adjacent cartilage and bone.

The clinical picture of PVNS is characterized by the insidious onset of progressive swelling and pain in affected joints or tendons, most commonly the knee or flexor tendons of the hand. Other commonly affected joints include the hips, ankles, calcaneocuboid joints, elbows, and small joints of the fingers or toes. A multifocal form of PVNS occurs less commonly. Tendon sheaths in the wrist, ankle, or foot may be involved. Symptoms of pain, a catching sensation, and stiffness are often mild and intermittent for years before the patient seeks medical attention. Radiographs may show joint space narrowing, erosions, and subchondral cysts. The diagnosis of PVNS is strongly suggested by gradient echo MRI, which reveals a synovial mass lesion of low signal intensity typical of tissue containing hemosiderin **(Fig. 386-3)**. The joint fluid may contain blood and is often dark red or almost black in color. Lipid-containing macrophages may be present in the fluid.

The treatment for PVNS, if needed, is open or arthroscopic synovectomy. Irradiation of the involved joint has been successful in some patients but may cause a delayed malignant transformation. Treatment directed at inhibiting the CSF-1 pathway activated kinase has demonstrated efficacy.

Synovial chondromatosis is a disorder characterized by multiple focal metaplastic growths of normal-appearing cartilage in the synovium or tendon sheath. Segments of cartilage break loose and continue to grow as loose bodies. When calcification and ossification of loose bodies occur, the disorder is referred to as *synovial osteochondromatosis*. The disorder is usually monoarticular and affects young to middle-aged individuals. The knee is most often involved, followed by hip, elbow, and shoulder. Symptoms are pain, swelling, and decreased motion of the joint. Radiographs may show several rounded calcifications within the joint cavity. Treatment is synovectomy; as in PVNS, the growths may recur.

Synovial sarcoma is a malignant neoplasm often found near a large joint of upper or lower extremities, commonly in the legs. It seldom arises within the joint itself. Synovial sarcomas constitute 10% of soft tissue sarcomas. The tumor is believed to arise from primitive mesenchymal tissue that differentiates into epithelial and/or spindle cells. Small foci of calcification may be present in the tumor mass. Synovial sarcoma occurs most often in young male adults. The tumor presents as a slowly growing deep-seated mass near a joint, without much pain. The area of the knee is the most common site, followed by the foot, ankle, elbow, and shoulder. Other primary sites include the buttocks, abdominal wall, retroperitoneum, and mediastinum. The tumor spreads along tissue planes. The most common site of visceral metastasis is the lung. The diagnosis is made by biopsy and must be distinguished from PVNS. Treatment consists of wide resection of the tumor, including adjacent muscle and regional lymph nodes, followed by chemotherapy and radiation therapy. Amputation of the involved distal extremity may be required. Chemotherapy may be beneficial in some patients with metastatic disease. Isolated pulmonary metastases can be surgically removed. The 5-year survival rate with treatment depends on the staging of the tumor, ranging from ~25% to ≥60%. Synovial sarcomas tend to recur locally and metastasize to regional lymph nodes, lungs, and skeleton.

In addition to the rare direct metastases of solid cell tumors to the highly vascular synovium, neoplasia arising from nonarticular organ sites can affect joints in other ways. Acute leukemias in children can mimic juvenile systemic inflammatory arthritis with severe joint pain and fever. In adults, chronic and acute myeloid leukemia rarely infiltrates the synovium. Hairy cell leukemia has a peculiar tendency to cause episodic inflammatory oligoarthritis and tenosynovitis; these episodes are dramatic and mimic acute gout flares. They respond to potent anti-inflammatory therapy with glucocorticoids; with remission of the leukemia, they may abate. Lymphomas, usually of T-cell origin, may also involve the synovium.

Carcinomas can be associated with several paraneoplastic articular syndromes, including HOA (discussed above). Acute palmar fasciitis with polyarthritis is a well-described but rare condition associated with certain cancers, mainly adenocarcinomas. Clinically, this syndrome is abrupt in onset, with pain in the metacarpophalangeal and proximal interphalangeal joints of the hands and rapidly evolving contractures of the fingers due to thickening of the palmar (flexor) tendons. A similar syndrome, although less dramatic in onset, can occur in diabetics. Paraneoplastic arthritis has been described and may occur in several patterns: asymmetric disease predominantly affecting the lower extremity joints and symmetric polyarthritis with hand joint involvement. Tumors are often found after the onset of the arthritis, and many patients have a preceding period of malaise or weight loss. The onset is often acute, and patients tend to be older men. These features should raise the specter of an underlying malignancy (or a viral infection such as hepatitis C) as the cause of the arthritis. In one series, the symptoms resolved with successful therapy for the malignancy and did not recur with relapse of the malignancy. Dermatomyositis and necrotizing myopathy have well-described associations with neoplasms and may include joint pain and arthritis as part of the clinical presentation. Malignancy-associated arthritis may be initially responsive to NSAIDs and to treatment of the primary neoplasm.

Immune checkpoint inhibitors, increasingly used to treat various malignancies, are now well recognized to elicit severe, autoimmune, inflammatory, organ-targeted reactions including myositis, polymyalgia rheumatica, and polyarthritis.

387 Periarticular Disorders of the Extremities

Carol A. Langford

Periarticular disorders are common musculoskeletal abnormalities that can affect people of all ages. This chapter reviews some of the more frequently encountered periarticular disorders.

BURSITIS

Bursitis is inflammation of a bursa, which is a thin-walled sac lined with synovial tissue. Adults typically have over 150 bursae that function to facilitate movement of tendons and muscles over bony prominences. Excessive frictional forces from overuse, trauma, systemic disease (e.g., rheumatoid arthritis, gout), or infection may cause bursitis. Although any bursa has the ability to become inflamed, certain bursal structures are more prone to developing bursitis because of their location and the mechanical stresses they are subject to. *Subacromial bursitis* (subdeltoid bursitis) is the most common form of bursitis and often accompanies rotator cuff tendinitis. The subacromial bursa, which is contiguous with the subdeltoid bursa, is located between the undersurface of the acromion and the humeral head and is covered by the deltoid muscle. Patients most often experience pain in the anterolateral aspect of the shoulder. As it can develop in the setting of other shoulder disorders, directed examination and imaging are particularly important to rule these out. *Trochanteric bursitis* (also called *greater trochanteric pain syndrome*) is a tendinopathy of the gluteus medius and/or minimus muscles that occurs with or without inflammation of the bursa located around the insertion of the gluteus medius onto the greater trochanter of the femur. Patients experience pain over the lateral aspect of the hip and upper thigh and have tenderness over the posterior aspect of the greater trochanter, often most noticeable when lying on their side. External rotation and resisted abduction of the hip elicit pain, as will direct pressure applied to the bursa. *Olecranon bursitis* involves the posterior elbow, often presenting with visible swelling over the olecranon. In settings where this area becomes acutely inflamed with redness and/or warmth, infection or gout should be excluded by aspirating the bursa and performing a Gram stain and culture on the fluid as well as examining the fluid for urate crystals. *Achilles bursitis* (also called subcutaneous calcaneal bursitis) impacts the bursa located between the skin and the Achilles tendon and is most often caused by overuse and ill-fitting shoes. *Retrocalcaneal bursitis* impacts a deeper bursa that is located between the calcaneus and posterior surface of the Achilles tendon. This bursa facilitates sliding of the Achilles tendon over the calcaneus and can become inflamed as a result of repetitive movement, trauma, or in association with spondyloarthritis, rheumatoid arthritis, or gout. Patients experience pain at the back of the heel and swelling along the medial and/or lateral side of the tendon. *Ischial bursitis* affects the bursa separating the gluteus medius from the ischial tuberosity and typically occurs from prolonged sitting on hard surfaces. *Iliopsoas bursitis* affects the iliopsoas bursa, the largest bursa in the body, which lies between the anterior aspect of the hip joint and the iliopsoas muscle. Bursitis in this location is associated with overuse or an underlying systemic disease process. Patients experience pain over the area, made worse by hip extension and flexion, which must be differentiated from pain originating within the hip joint. *Anserine bursitis* is an inflammation of the bursa located over the medial side of the tibia just below the knee joint under the conjoint tendon of the sartorius, gracilis, and semitendinosus muscles. Pain can be elicited on climbing stairs and by direct pressure over the bursa about 5 cm below the medial knee joint line. *Prepatellar bursitis* occurs in the bursa situated between the patella and overlying skin and is caused by kneeling on hard surfaces. Gout or infection may also occur at this site. Bursitis is typically diagnosed by history and physical examination, but ultrasound may play a useful role in selected instances for diagnosis and directed guidance of glucocorticoid injection. Treatment of bursitis consists of prevention of aggravating factors, rest of the involved part, administration of a topical or systemic nonsteroidal anti-inflammatory drug (NSAID) where appropriate for an individual patient, or local glucocorticoid injection.

ROTATOR CUFF TENDINITIS AND IMPINGEMENT SYNDROME

Tendinitis of the rotator cuff (also called *impingement syndrome*) is the major cause of a painful shoulder. The rotator cuff consists of the tendons of the supraspinatus, infraspinatus, subscapularis, and teres minor muscles, and inserts on the humeral tuberosities. Of the tendons forming the rotator cuff, the supraspinatus tendon is the most often affected, because of its potential for impingement between the humeral head and the undersurface of the anterior third of the acromion and coracoacromial ligament above **(Fig. 387-1)**. The tendon of the infraspinatus and that of the long head of the biceps are less commonly involved. Subacromial bursitis often accompanies this syndrome. Symptoms can appear without a triggering cause or after injury or

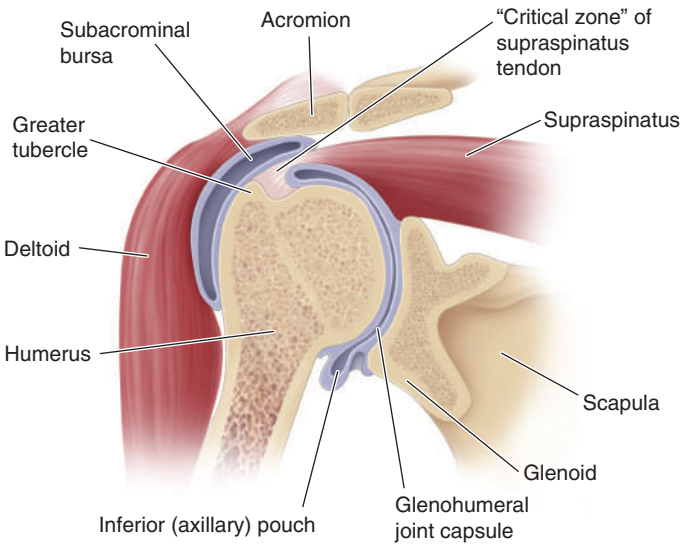

FIGURE 387-1 Coronal section of the shoulder illustrating the relationships of the glenohumeral joint, the joint capsule, the subacromial bursa, and the rotator cuff (supraspinatus tendon). *(Reproduced with permission from F Kozin, in WJ Koopman [ed]: Arthritis and Allied Conditions, 13th ed, Baltimore, Williams & Wilkins, 1997.)*

overuse, especially with occupations or sports that involve elevation of the arm with forward flexion such as baseball, tennis, or swimming. Work and home ergonomic issues have also increasingly been raised as contributing factors. Patients typically experience a dull aching in the shoulder, which may interfere with sleep. Severe pain occurs when the arm is actively abducted into an overhead position, with the arc between 60° and 120° being especially painful. Tenderness is present over the lateral aspect of the humeral head just below the acromion. NSAIDs, local glucocorticoid injection, and physical therapy may relieve symptoms. Surgical decompression of the subacromial space may be necessary in patients refractory to conservative treatment.

ROTATOR CUFF TEARS

Rotator cuff tears may be acute, subacute, or chronic. Acute tears can occur related to sports, falling on an outstretched arm, or lifting a heavy object. Subacute and chronic tears are more common and develop in middle-aged and older patients, where the cause of the tear is likely multifactorial. Osteoarthritis is a risk factor for rotator cuff tears. Symptoms are pain along with weakness of abduction and external rotation of the shoulder. There is no single examination finding that can diagnose a torn rotator cuff, although this can be suggested by a range of maneuvers that include a painful abduction arc above 90°, failure to control shoulder adduction (drop arm test), or weakness in external rotation. The diagnosis is established by ultrasound or magnetic resonance imaging (MRI). Multiple factors influence management including symptom duration, degree of the tear (partial or full thickness), level of pain and disability, functional status, severity of osteoarthritis if present, and individual patient characteristics. Surgical referral should be pursued in patients with acute or acute-on-chronic tears that are moderate to severe with functional loss. Surgery may also be indicated in patients who fail to respond to conservative measures.

CALCIFIC TENDINITIS

Calcific tendinitis is characterized by deposition of calcium salts, primarily hydroxyapatite, within a tendon. The shoulder is the main site of involvement with calcific deposits in or around the rotator cuff tendons, with the supraspinatus tendon being involved in 63% of patients. The condition usually develops after age 40. Although the mechanism through which calcification is initiated is unknown, the process is felt to go through different phases. It is not felt to be due to overuse or systemic disease, although links have been seen with diabetes and thyroid disorders and a genetic predisposition has been questioned. Calcification within the tendon may evoke acute inflammation, producing sudden and severe shoulder pain, but may also be asymptomatic. Diagnosis of calcific tendinitis can be made by radiograph or ultrasound. Most cases are self-limited and respond to conservative therapy with physical therapy and/or NSAIDs. For patients with refractory pain, ultrasound-guided percutaneous needle aspiration and lavage, extracorporeal shock wave therapy, or surgery has been used.

BICIPITAL TENDINITIS AND RUPTURE

Bicipital tendinitis is produced by friction on the tendon of the long head of the biceps as it passes through the bicipital groove. When the inflammation is acute, patients experience anterior shoulder pain that radiates down the biceps into the forearm. Abduction and external rotation of the arm are painful and limited with tenderness over the bicipital groove. Pain may be elicited along the course of the tendon by resisting supination of the forearm with the elbow at 90° (Yergason's test). Acute rupture of the tendon may occur with vigorous exercise of the arm and is often painful. In a healthy and active patient, it should be repaired surgically as soon as possible after the rupture occurs. Rupture of the tendon in an older person may be associated with little or no pain and is recognized by the presence of persistent swelling of the biceps produced by the retraction of the long head of the biceps. Surgery is usually not necessary in this setting.

DE QUERVAIN'S TENOSYNOVITIS

De Quervain's tenosynovitis is the result of inflammation involving the abductor pollicis longus and the extensor pollicis brevis as these tendons pass through a fibrous sheath at the radial styloid process. The usual cause is repetitive twisting of the wrist. It may also occur in pregnancy and in parents who hold their babies with the thumb outstretched. Patients experience pain on grasping or pinching with their thumb. Swelling and tenderness are often present over the radial styloid process. A positive Finkelstein test can be elicited by having the patient place the thumb in the palm, closing the fingers over it, and then ulnar deviating the wrist, which results in pain over the involved tendon sheath in the area of the radial styloid. Initial treatment consists of wrist splinting and NSAIDs. When severe or refractory, local glucocorticoid injections can be effective.

PATELLAR TENDINITIS

Patellar tendinitis involves the patellar tendon at its attachment to the lower pole of the patella. Patients may experience pain when jumping during sports, going up stairs, or doing deep knee squats. Tenderness is noted on examination over the lower pole of the patella. Treatment consists of rest, icing, and NSAIDs, followed by physical therapy.

DRUG-INDUCED TENDINOPATHIES

With the broadening range of pharmacologic agents, the potential for drug-induced tendinopathies has become increasingly recognized. The drug classes most associated with tendinopathies include quinolones, glucocorticoids, aromatase inhibitors, and statins. Although any tendon can be affected, the tendons of the lower extremities are most often impacted, particularly the Achilles tendon. The pathophysiologic mechanisms responsible for drug-induced tendinopathies remain unknown. Presenting features include pain and potentially swelling over the tendon, although some patients may first present with tendon rupture. Ultrasound and MRI can provide information on tendon structure and integrity in support of the diagnosis. When suspected, the potential agent should be withdrawn and not reintroduced where possible. Tendon ruptures may require surgery.

ILIOTIBIAL BAND SYNDROME

The iliotibial band is a thick connective tissue that runs from the ilium to the tibia. Iliotibial band syndrome most commonly presents with aching or burning pain where the band courses over the lateral femoral condyle of the knee; pain may also radiate up the thigh, toward the hip. Predisposing factors for iliotibial band syndrome include a varus alignment of the knee, distance running, poorly fitted shoes, or running on uneven terrain. Treatment consists of rest, NSAIDs, physical therapy, and addressing modifiable risk factors. Glucocorticoid injection into the area of tenderness can provide relief, but running must be avoided for at least 2 weeks after the injection. Surgical release of the iliotibial band has been helpful in rare patients for whom conservative treatment has failed.

ADHESIVE CAPSULITIS

Adhesive capsulitis ("frozen shoulder") is characterized by pain and restricted movement of the shoulder, usually in the absence of intrinsic shoulder disease. It most often develops in the setting of reduced arm mobility following bursitis or tendinitis of the shoulder, fractures, or recovery from surgery but can occur without an antecedent event. Adhesive capsulitis has been associated with systemic disorders such as diabetes mellitus, chronic pulmonary disease, myocardial infarction, and thyroid disease. Pathologically, the capsule of the shoulder is thickened, and a mild chronic inflammatory infiltrate and fibrosis may be present.

Adhesive capsulitis occurs more commonly in women over age 50. Pain and stiffness usually develop gradually but can rapidly progress. Night pain is often present in the affected shoulder and interferes with sleep. The shoulder is tender to palpation, and both active and passive movements are restricted. The diagnosis is based on physical examination showing a reduced range of motion in the shoulder that is not due to other causes. There are no diagnostic findings by plain radiograph, ultrasound, or MRI, but these can be used to rule out other conditions.

In most patients, the condition improves spontaneously 1–3 years after onset. While pain usually improves, many patients are left with

some limitation of shoulder motion. Early mobilization of the arm following a shoulder injury may prevent the development of this disorder. Physical therapy provides the foundation of treatment for adhesive capsulitis. Local glucocorticoid injection and NSAIDs may also provide relief of symptoms. Slow but forceful injection of contrast material into the joint may lyse adhesions and stretch the capsule, resulting in improvement of shoulder motion. Manipulation under anesthesia may be helpful in some patients.

LATERAL EPICONDYLITIS

Lateral epicondylitis, also known as tennis elbow, is a painful condition involving the soft tissue over the lateral aspect of the elbow. The pain originates at or near the site of attachment of the common extensors to the lateral epicondyle and may radiate into the forearm and dorsum of the wrist. The pain is usually linked to work or recreational activities that involve repeated motions of wrist extension and supination against resistance. Most patients with this disorder injure themselves in activities other than tennis, such as pulling weeds, carrying suitcases or briefcases, or using a screwdriver. The injury in tennis usually occurs when hitting a backhand with the elbow flexed. The pain can be reproduced by shaking hands or opening doors.

The treatment is usually rest with avoidance of activities that would aggravate the elbow along with an NSAID. Ultrasound, icing, and friction massage may also help relieve pain. When pain is severe, the elbow is placed in a sling or splinted at 90° of flexion. A one-time local glucocorticoid injection can be considered for severe, acute pain, but repeat injections should be avoided. After 4–6 weeks of rest, the patient should begin physical therapy to strengthen and increase flexibility of the extensor muscles. A forearm band placed 2.5–5.0 cm below the elbow may help to reduce tension on the extensor muscles at their attachment to the lateral epicondyle. The patient should be advised to restrict activities requiring forcible extension and supination of the wrist. The patient may continue to experience mild pain but, with care, can usually avoid the return of debilitating pain. In recalcitrant cases, ultrasound-guided needle tenotomy and injection of platelet-rich plasma have been used. Occasionally, surgical release of the extensor aponeurosis may be necessary.

MEDIAL EPICONDYLITIS

Medial epicondylitis is an overuse syndrome resulting in pain over the medial side of the elbow with radiation into the forearm. The cause of this syndrome is considered to be repetitive resisted motions of wrist flexion and pronation, which lead to microtears at the origin of the pronator teres and forearm flexors, particularly the flexor carpi radialis. This overuse syndrome is usually seen in patients aged >35 years and is much less common than lateral epicondylitis. It occurs most often in work-related repetitive activities and with recreational activities such as swinging a golf club or throwing a baseball. On physical examination, there is tenderness just distal to the medial epicondyle over the origin of the forearm flexors. Pain can be reproduced by resisting wrist flexion and pronation with the elbow extended. Radiographs are usually normal.

The initial treatment of medial epicondylitis is conservative, involving rest, NSAIDs, friction massage, ultrasound, and icing. Some patients may require splinting. For severe pain, a one-time local glucocorticoid injection can be considered. Patients should be instructed to rest for at least 4–6 weeks followed by physical therapy once the pain has subsided. In patients with chronic debilitating medial epicondylitis that remains unresponsive after at least a year of treatment, surgical release of the flexor muscle at its origin may be necessary and is often successful.

PLANTAR FASCIITIS

Plantar fasciitis is a common cause of foot pain in adults. The pain originates at or near the site of the plantar fascia attachment to the medial tuberosity of the calcaneus. Factors that increase the risk of developing plantar fasciitis include obesity, pes planus (flat foot or absence of the foot arch when standing), pes cavus (high-arched foot), limited dorsiflexion of the ankle, prolonged standing, walking on hard surfaces, and faulty shoes. In runners, excessive running and a change to a harder running surface may precipitate plantar fasciitis.

The diagnosis of plantar fasciitis can usually be made on the basis of history and physical examination alone. Patients experience severe pain with the first steps on arising in the morning or following inactivity during the day. The pain usually lessens with weight-bearing activity but then increases with continued activity. Pain is made worse on walking barefoot or going up stairs. On examination, tenderness is elicited on palpation over the inferior heel at the attachment site of the plantar fascia to the calcaneus. Imaging may be indicated when the diagnosis is not clear. Plain radiographs may show heel spurs, which are of little diagnostic significance. Ultrasonography in plantar fasciitis can demonstrate thickening of the fascia and diffuse hypoechogenicity, indicating edema at the attachment of the plantar fascia to the calcaneus. MRI is a sensitive method for detecting plantar fasciitis, but it is usually not required to establish the diagnosis.

Resolution of symptoms occurs within 12 months in >80% of patients with plantar fasciitis. Initial treatment consists of ice, heat, massage, stretching, and eliminating inciting activities. Orthotics provide medial arch support and can be effective. Some patients may benefit from foot strapping or taping or by wearing a night splint designed to keep the ankle in a neutral position. A short course of NSAIDs can be given to patients who do not have contraindications. Local glucocorticoid injections have also been shown to be efficacious but may carry an increased risk for plantar fascia rupture. Plantar fasciotomy is reserved for patients who have failed to improve after at least 6–12 months of conservative treatment.

Section 1 Endocrinology

388 Approach to the Patient with Endocrine Disorders

J. Larry Jameson

The management of endocrine disorders has applied principles of precision medicine before the term was commonly used (Chap. 5). A general goal is to maintain or restore homeostasis using precise homone measurements to titrate treatment regimens. Effective patient management requires a broad understanding of intermediary metabolism, reproductive physiology, bone metabolism, and growth. Accordingly, the practice of endocrinology is intimately linked to a conceptual framework for understanding hormone secretion, hormone action, and principles of feedback control (Chap. 389). The endocrine system is evaluated primarily by measuring hormone concentrations, arming the clinician with valuable diagnostic information. Most disorders of the endocrine system are amenable to effective treatment once the correct diagnosis is established. Endocrine deficiency disorders are treated with physiologic hormone replacement; hormone excess conditions, which usually are caused by benign glandular adenomas, are managed by removing tumors surgically or reducing hormone levels medically.

SCOPE OF ENDOCRINOLOGY

Classically, the specialty of endocrinology encompasses the study of glands and the hormones they produce. Over time, the field has expanded because of the discovery of hormones and growth factors produced by the brain, gastrointestinal (GI) tract, musculoskeletal system, and other nonglandular organs. The term *endocrine* was coined by Starling to contrast the actions of hormones secreted internally (*endocrine*) with those secreted externally (*exocrine*) or into a lumen, such as the GI tract. The term *hormone*, derived from a Greek phrase meaning "to set in motion," aptly describes the dynamic actions of hormones as they elicit cellular responses and regulate physiologic processes through feedback mechanisms.

Unlike many other specialties in medicine, it is not possible to define endocrinology strictly along anatomic lines. The classic endocrine glands—pituitary, thyroid, parathyroid, pancreatic islets, adrenals, and gonads—communicate broadly with other organs through the nervous system, hormones, cytokines, and growth factors. In addition to its traditional synaptic functions, the brain produces a vast array of peptide hormones, and this has led to the discipline of neuroendocrinology. Through the production of hypothalamic releasing factors, the central nervous system (CNS) exerts a major regulatory influence over pituitary hormone secretion (Chap. 390). The peripheral nervous system stimulates the adrenal medulla. The immune and endocrine systems are also intimately intertwined. The adrenal hormone cortisol is a powerful immunosuppressant. Cytokines and interleukins (ILs) have profound effects on the functions of the pituitary, adrenal, thyroid, and gonads. Common endocrine diseases such as autoimmune thyroid disease and type 1 diabetes mellitus are caused by dysregulation of immune surveillance and tolerance. Less common diseases such as polyglandular failure, Addison's disease, and lymphocytic hypophysitis also have an immunologic basis. Immune therapies for cancer and various autoimmune diseases can initiate autoimmune endocrine disease as a side effect of treatment.

The interdigitation of endocrinology with physiologic processes in other specialties sometimes blurs the role of hormones. For example, hormones play an important role in maintenance of blood pressure, intravascular volume, and peripheral resistance in the cardiovascular system. Vasoactive substances such as catecholamines, angiotensin II, endothelin, and nitric oxide are involved in dynamic changes of vascular tone in addition to their multiple roles in other tissues. The heart is the principal source of atrial natriuretic peptide, which acts in classic endocrine fashion to induce natriuresis at a distant target organ (the kidney). Erythropoietin, a traditional circulating hormone, is made in the kidney and stimulates erythropoiesis in bone marrow (Chap. 66). The kidney is also integrally involved in the renin-angiotensin axis (Chap. 398) and is a primary target of several hormones, including parathyroid hormone (PTH), mineralocorticoids, fibroblast growth factor 23 (FGF23), and vasopressin. The GI tract produces a vast array of peptide hormones, such as glucagon-like peptide 1 (GLP1), cholecystokinin, ghrelin, gastrin, secretin, and vasoactive intestinal peptide, among many others. Carcinoid and islet tumors can secrete excessive amounts of these hormones, leading to specific clinical syndromes (Chap. 89). Many of these GI hormones are also produced in the CNS, where their functions are poorly understood. Adipose tissue produces leptin, which acts centrally to control appetite, along with adiponectin, resistin, and other hormones that regulate metabolism. As hormones such as inhibin, ghrelin, and leptin are discovered, they become integrated into the science and practice of medicine on the basis of their functional roles rather than their tissues of origin.

Characterization of hormone receptors frequently reveals unexpected relationships to factors in nonendocrine disciplines. The growth hormone (GH) and leptin receptors, for example, are members of the cytokine receptor family. The G protein–coupled receptors (GPCRs), which mediate the actions of many peptide hormones, are used in numerous physiologic processes, including vision, smell, and neurotransmission.

PATHOLOGIC MECHANISMS OF ENDOCRINE DISEASE

Endocrine diseases can be divided into three major types of conditions: (1) hormone excess, (2) hormone deficiency, and (3) hormone resistance (Table 388-1).

CAUSES OF HORMONE EXCESS

Syndromes of hormone excess can be caused by neoplastic growth of endocrine cells, autoimmune disorders, and excess hormone administration. Benign endocrine tumors, including parathyroid, pituitary, and adrenal adenomas, often retain the capacity to produce hormones, reflecting the fact that these tumors are relatively well differentiated. Many endocrine tumors exhibit subtle defects in their "set points" for feedback regulation. For example, in Cushing's disease, impaired feedback inhibition of adrenocorticotropic hormone (ACTH) secretion is associated with autonomous function. However, the tumor cells are less sensitive to feedback inhibition, as evidenced by ACTH suppression at higher doses of dexamethasone (e.g., high-dose dexamethasone test) (Chap. 398). Similar set point defects are also typical of parathyroid adenomas and autonomously functioning thyroid nodules.

The molecular basis of some endocrine tumors, such as the multiple endocrine neoplasia (MEN) syndromes (MEN1, 2A, 2B), has provided important insights into tumorigenesis (Chap. 402). MEN1 is characterized primarily by the triad of parathyroid, pancreatic islet, and pituitary tumors. MEN2 predisposes to medullary thyroid carcinoma, pheochromocytoma, and hyperparathyroidism. The *MEN1* gene, located on chromosome 11q13, encodes a tumor-suppressor gene, menin. Analogous to the paradigm first described for retinoblastoma, the affected individual inherits a mutant copy of the *MEN1* gene, and tumorigenesis ensues after a somatic "second hit" leads to loss of function of the normal *MEN1* gene (through deletion or point mutations).

In contrast to inactivation of a tumor-suppressor gene, as occurs in MEN1 and most other inherited cancer syndromes, MEN2 is caused by activating mutations in a single allele. In this case, activating mutations of the *RET* protooncogene, which encodes a receptor tyrosine kinase,

TABLE 388-1 Causes of Endocrine Dysfunction

TYPE OF ENDOCRINE DISORDER	EXAMPLES
Hyperfunction	
Neoplastic	
Benign	Pituitary adenomas, hyperparathyroidism, autonomous thyroid or adrenal nodules
Malignant	Adrenal cancer, medullary thyroid cancer, carcinoid
Ectopic	Ectopic ACTH, SIADH secretion
Genetic predisposition	MEN1, MEN2
Autoimmune	Graves' disease
Iatrogenic	Cushing's syndrome, hypoglycemia
Infectious/inflammatory	Subacute thyroiditis
Activating receptor mutations	LH, TSH, Ca^{2+}, PTH receptors, $G_s\alpha$
Hypofunction	
Autoimmune	Hashimoto's thyroiditis, type 1 diabetes mellitus, Addison's disease, polyglandular failure
Iatrogenic	Radiation-induced hypopituitarism, hypothyroidism, surgical
Infectious/inflammatory	Adrenal insufficiency, hypothalamic sarcoidosis
Hormone mutations	GH, LHβ, FSHβ, vasopressin
Enzyme defects	21-Hydroxylase deficiency
Developmental defects	Kallmann's syndrome, Turner's syndrome, transcription factors
Nutritional/vitamin deficiency	Vitamin D deficiency, iodine deficiency
Hemorrhage/infarction	Sheehan's syndrome, adrenal insufficiency
Hormone Resistance	
Receptor mutations	
Membrane	GH, vasopressin, LH, FSH, ACTH, GnRH, GHRH, PTH, leptin, Ca^{2+}
Nuclear	AR, TR, VDR, ER, GR, PPARγ
Signaling pathway mutations	Albright's hereditary osteodystrophy
Postreceptor	Type 2 diabetes mellitus, leptin resistance

Abbreviations: ACTH, adrenocorticotropic hormone; AR, androgen receptor; ER, estrogen receptor; FSH, follicle-stimulating hormone; GH, growth hormone; GHRH, growth hormone–releasing hormone; GnRH, gonadotropin-releasing hormone; GR, glucocorticoid receptor; LH, luteinizing hormone; MEN, multiple endocrine neoplasia; PPAR, peroxisome proliferator activated receptor; PTH, parathyroid hormone; SIADH, syndrome of inappropriate antidiuretic hormone; TR, thyroid hormone receptor; TSH, thyroid-stimulating hormone; VDR, vitamin D receptor.

lead to thyroid C-cell hyperplasia in childhood before the development of medullary thyroid carcinoma. Elucidation of this pathogenic mechanism has allowed early genetic screening for *RET* mutations in individuals at risk for MEN2, permitting identification of those who may benefit from prophylactic thyroidectomy and biochemical screening for pheochromocytoma and hyperparathyroidism.

Mutations that activate hormone receptor signaling have been identified in several GPCRs. For example, activating mutations of the luteinizing hormone (LH) receptor cause a dominantly transmitted form of male-limited precocious puberty, reflecting premature stimulation of testosterone synthesis in Leydig cells **(Chap. 403)**. Activating mutations in these GPCRs are located predominantly in the transmembrane domains and induce receptor coupling to $G_s\alpha$ even in the absence of hormone. Consequently, adenylate cyclase is activated, and cyclic adenosine monophosphate (AMP) levels increase in a manner that mimics hormone action. A similar phenomenon results from activating mutations in $G_s\alpha$. When these mutations occur early in development, they cause McCune-Albright syndrome. When they occur only in somatotropes, the activating $G_s\alpha$ mutations cause GH-secreting tumors and acromegaly **(Chap. 392)**.

In autoimmune Graves' disease, antibody interactions with the thyroid-stimulating hormone (TSH) receptor mimic TSH action, leading to hormone overproduction **(Chap. 394)**. Analogous to the effects of activating mutations of the TSH receptor, these stimulating autoantibodies induce conformational changes in the TSH receptor that release it from a constrained state, thereby triggering receptor coupling to G proteins, and signaling induces excess thyroid hormone synthesis and secretion.

CAUSES OF HORMONE DEFICIENCY

Most examples of hormone deficiency states can be attributed to glandular destruction caused by autoimmunity, surgery, infection, inflammation, infarction, hemorrhage, or tumor infiltration (Table 388-1). Autoimmune damage to the thyroid gland (Hashimoto's thyroiditis) and pancreatic islet β cells (type 1 diabetes mellitus) are examples of relatively common endocrine diseases. Mutations in a number of hormones, hormone receptors, transcription factors, enzymes, and channels can also lead to hormone deficiencies.

HORMONE RESISTANCE

Most severe hormone resistance syndromes are due to inherited defects in membrane receptors, nuclear receptors, or the pathways that transduce receptor signals. These disorders are characterized by defective hormone action despite the presence of increased hormone levels. In complete androgen resistance, for example, mutations in the androgen receptor result in a female phenotypic appearance in genetic (XY) males, even though LH and testosterone levels are increased **(Chap. 402)**. In addition to these relatively rare genetic disorders, more common acquired forms of functional hormone resistance include insulin resistance in type 2 diabetes mellitus, leptin resistance in obesity, and GH resistance in catabolic states. The pathogenesis of functional resistance involves receptor downregulation and postreceptor desensitization of signaling pathways; functional forms of resistance are generally reversible.

CLINICAL EVALUATION OF ENDOCRINE DISORDERS

Because most glands are relatively inaccessible, the physical examination usually focuses on the manifestations of hormone excess or deficiency as well as direct examination of palpable glands, such as the thyroid and gonads. For these reasons, it is important to evaluate patients in the context of their presenting symptoms, review of systems, family and social history, and exposure to medications that may affect the endocrine system. Astute clinical skills are required to detect subtle symptoms and signs suggestive of underlying endocrine disease. For example, a patient with Cushing's syndrome may manifest specific findings, such as central fat redistribution, skin striae, and proximal muscle weakness, in addition to features seen commonly in the general

population, such as obesity, plethora, hypertension, and glucose intolerance. Similarly, the insidious onset of hypothyroidism—with fatigue, mental slowing, dry skin, and other features—can be difficult to distinguish from similar, nonspecific findings in the general population. Clinical judgment that is based on knowledge of disease prevalence and pathophysiology is required to decide when to embark on more extensive evaluation of these disorders. Laboratory testing plays an essential role in endocrinology by allowing quantitative assessment of hormone levels and dynamics. Radiologic imaging tests such as computed tomography (CT) scan, magnetic resonance imaging (MRI),

TABLE 388-2 Examples of Prevalent Endocrine and Metabolic Disorders in the Adult

DISORDER	APPROXIMATE PREVALENCE IN ADULTS[a]	SCREENING/TESTING RECOMMENDATIONS[b]	CHAPTER(S)
Obesity	40% Obese, BMI ≥30 70% Overweight, BMI ≥25	Calculate BMI Measure waist circumference Exclude secondary causes Consider comorbid complications	414
Type 2 diabetes mellitus	>10%	Beginning at age 45, screen every 3 years, or earlier in high-risk groups: FPG >126 mg/dL Random plasma glucose >200 mg/dL An elevated HbA_{1c} Consider comorbid complications	415
Hyperlipidemia	20–25%	Cholesterol screening at least every 5 years; more often in high-risk groups Lipoprotein analysis (LDL, HDL) for increased cholesterol, CAD, diabetes Consider secondary causes	419
Metabolic syndrome	35%	Measure waist circumference, FPG, BP, lipids	420
Hypothyroidism	5–10%, women 0.5–2%, men	TSH; confirm with free T_4	396
Graves' disease	1–3%, women 0.1%, men	TSH, free T_4	395
Thyroid nodules and neoplasia	2–5% palpable >25% by ultrasound	Physical examination or ultrasound of thyroid Fine-needle aspiration biopsy	397
Osteoporosis	5–10%, women 2–5%, men	Bone mineral density measurements in women >65 years or in postmenopausal women or men at risk Exclude secondary causes	423
Hyperparathyroidism	0.1–0.5%, women > men	Serum calcium PTH, if calcium is elevated Assess comorbid conditions	422
Infertility	10%, couples	Investigate both members of couple Semen analysis in male Assess ovulatory cycles in female Specific tests as indicated	403,404
Polycystic ovarian syndrome	5–10%, women	Free testosterone, DHEAS Consider comorbid conditions	404
Hirsutism	5–10%	Free testosterone, DHEAS Exclude secondary causes Additional tests as indicated	406
Menopause	Median age, 51	FSH	407
Hyperprolactinemia	15% in women with amenorrhea or galactorrhea	PRL level MRI, if not medication-related	392
Erectile dysfunction	10–25%	Careful history, PRL, testosterone Consider secondary causes (e.g., diabetes)	409
Hypogonadism, male	1–2%	Testosterone, LH	403
Gynecomastia	15%	Often, no tests are indicated Consider Klinefelter's syndrome Consider medications, hypogonadism, liver disease	403
Klinefelter's syndrome	0.2%, men	Karyotype Testosterone	402
Vitamin D deficiency	10%	Measure serum 25-OH vitamin D Consider secondary causes	421
Turner's syndrome	0.03%, women	Karyotype Consider comorbid conditions	402

[a]The prevalence of most disorders varies among ethnic groups and with aging. Data based primarily on U.S. population. [b]See individual chapters for additional information on evaluation and treatment. Early testing is indicated in patients with signs and symptoms of disease and in those at increased risk.

Abbreviations: BMI, body mass index; BP, blood pressure; CAD, coronary artery disease; DHEAS, dehydroepiandrosterone; FPG, fasting plasma glucose; FSH, follicle-stimulating hormone; HbA_{1c}, hemoglobin A_{1c}; HDL, high-density lipoprotein; LDL, low-density lipoprotein; LH, luteinizing hormone; MRI, magnetic resonance imaging; PRL, prolactin; PTH, parathyroid hormone; TSH, thyroid-stimulating hormone.

ultrasound, and thyroid scan are also used for the diagnosis of endocrine disorders. However, these tests generally are employed only after a hormonal abnormality has been established by biochemical testing.

HORMONE MEASUREMENTS AND ENDOCRINE TESTING

Immunoassays are the most important diagnostic tool in endocrinology, as they allow sensitive, specific, and quantitative determination of steady-state and dynamic changes in hormone concentrations. Immunoassays use antibodies to detect specific hormones. For many peptide hormones, these measurements are now configured to use two different antibodies to increase binding affinity and specificity. There are many variations of these assays; a common format involves using one antibody to capture the antigen (hormone) onto an immobilized surface and a second antibody, coupled to a chemiluminescent (immunochemiluminescent assay [ICMA]) or radioactive (immunoradiometric assay [IRMA]) signal, to detect the antigen. These assays are sensitive enough to detect plasma hormone concentrations in the picomolar to nanomolar range, and they can readily distinguish structurally related proteins, such as PTH from PTH-related peptide (PTHrP). A variety of other techniques are used to measure specific hormones, including mass spectroscopy, various forms of chromatography, and enzymatic methods; bioassays are now used rarely. Mass spectroscopy is increasingly being used given its ability to quantitatively measure large numbers of peptides or steroids simultaneously.

Most hormone measurements are based on plasma or serum samples. However, urinary hormone determinations remain useful for the evaluation of some conditions. Urinary collections over 24 h provide an integrated assessment of the production of a hormone or metabolite, many of which vary during the day. It is important to ensure complete collections of 24-h urine samples; simultaneous measurement of creatinine provides an internal control for the adequacy of collection and can be used to normalize some hormone measurements. A 24-h urine-free cortisol measurement largely reflects the amount of unbound cortisol, thus providing a reasonable index of biologically available hormone. Other commonly used urine determinations include 17-hydroxycorticosteroids, 17-ketosteroids, vanillylmandelic acid, metanephrine, catecholamines, 5-hydroxyindoleacetic acid, and calcium.

The value of quantitative hormone measurements lies in their correct interpretation in a clinical context. The normal range for most hormones is relatively broad, often varying by a factor of two- to tenfold. The wide normal range reflects the effects of binding proteins as well as circadian rhythms and other physiologic variables. The normal ranges for many hormones are sex- and age-specific. Thus, using the correct normative database is an essential part of interpreting hormone tests. The pulsatile nature of hormones and factors that can affect their secretion, such as sleep, meals, and medications, must also be considered. Cortisol values increase fivefold between midnight and dawn; reproductive hormone levels vary dramatically during the female menstrual cycle.

For many endocrine systems, much information can be gained from basal hormone testing, particularly when different components of an endocrine axis are assessed simultaneously. For example, low testosterone and elevated LH levels suggest a primary gonadal disease, whereas a hypothalamic-pituitary disorder is likely if both LH and testosterone are low. Because TSH is a sensitive indicator of thyroid function, it is generally recommended as a first-line test for thyroid disorders. An elevated TSH level is almost always the result of primary hypothyroidism, whereas a low TSH is most often caused by thyrotoxicosis. These predictions can be confirmed by determining the free thyroxine level. In the less common circumstance when free thyroxine and TSH are both low, it is important to consider secondary hypopituitarism caused by hypothalamic-pituitary disease. Elevated calcium and PTH levels suggest hyperparathyroidism, whereas PTH is suppressed in hypercalcemia caused by malignancy or granulomatous diseases. A suppressed ACTH in the setting of hypercortisolemia, or increased urine free cortisol, is seen with hyperfunctioning adrenal adenomas.

It is not uncommon, however, for baseline hormone levels associated with pathologic endocrine conditions to overlap with the normal range. In this circumstance, dynamic testing is useful to separate the two groups further. There are a multitude of dynamic endocrine tests, but all are based on principles of feedback regulation, and most responses can be rationalized based on principles that govern the regulation of endocrine axes. *Suppression tests* are used in the setting of suspected endocrine hyperfunction. An example is the dexamethasone suppression test used to evaluate Cushing's syndrome **(Chaps. 392 and 398)**. *Stimulation tests* generally are used to assess endocrine hypofunction. The ACTH stimulation test, for example, is used to assess the adrenal gland response in patients with suspected adrenal insufficiency. Other stimulation tests use hypothalamic-releasing factors such as corticotropin-releasing hormone (CRH) and growth hormone–releasing hormone (GHRH) to evaluate pituitary hormone reserve **(Chap. 392)**. Insulin-induced hypoglycemia evokes pituitary ACTH and GH responses. Stimulation tests based on reduction or inhibition of endogenous hormones are now used infrequently. Examples include metyrapone inhibition of cortisol synthesis and clomiphene inhibition of estrogen feedback.

SCREENING AND ASSESSMENT OF COMMON ENDOCRINE DISORDERS

Many endocrine disorders are prevalent in the adult population **(Table 388-2)** and can be diagnosed and managed by general internists, family practitioners, or other primary health care providers. The high prevalence and clinical impact of certain endocrine diseases justify vigilance for features of these disorders during routine physical examinations; laboratory screening is indicated in selected high-risk populations.

389 Mechanisms of Hormone Action

J. Larry Jameson

The endocrine system, composed of various glands and the hormones they produce, regulates growth, metabolism, homeostasis, and reproduction. Because hormones circulate and act via receptors in target tissues, they serve to coordinate physiologic responses to external or internal cues. For example, the light-dark cycle, sensed through the visual system, modulates hypothalamic corticotropin-releasing hormone (CRH), which increases pituitary adrenocorticotropin hormone (ACTH) production, leading to increased adrenal cortisol production before the time of waking in the morning. Increased cortisol, in turn, circulates throughout the body, acting via the nuclear glucocorticoid receptor, to activate numerous genetic programs that influence metabolism, the cardiovascular system, behavior, and the immune system. This chapter provides an overview of the different types of hormones and how they function at the cellular level to control myriad physiologic processes.

CLASSES OF HORMONES

Hormones can be divided into five major types: (1) *amino acid derivatives* such as dopamine, catecholamine, and thyroid hormone; (2) *small neuropeptides* such as gonadotropin-releasing hormone (GnRH),

thyrotropin-releasing hormone (TRH), somatostatin, and vasopressin; (3) *large proteins* such as insulin, luteinizing hormone (LH), and parathyroid hormone (PTH); (4) *steroid hormones* such as cortisol and estrogen that are synthesized from cholesterol-based precursors; and (5) *vitamin derivatives* such as retinoids (vitamin A) and vitamin D. A variety of *peptide growth factors*, such as insulin-like growth factor 1 (IGF1), share actions with hormones but often act more locally. As a rule, amino acid derivatives and peptide hormones interact with cell-surface membrane receptors. Steroids, thyroid hormones, vitamin D, and retinoids are lipid-soluble and bind to intracellular nuclear receptors, although many also interact with membrane receptors or intracellular signaling proteins as well.

HORMONE AND RECEPTOR FAMILIES

Hormones and receptors can be grouped into families, reflecting structural similarities and evolutionary origins **(Table 389-1)**. The evolution of these families generates diverse but highly selective pathways of hormone action. Understanding these relationships is useful to extrapolate structural and mechanistic insights gleaned from one hormone or receptor to other family members.

The glycoprotein hormone family, consisting of thyroid-stimulating hormone (TSH), follicle-stimulating hormone (FSH), LH, and human chorionic gonadotropin (hCG), illustrates many features of evolutionarily related hormones. The glycoprotein hormones are heterodimers that share the α subunit in common; the β subunits are distinct and confer specific biologic actions. The overall three-dimensional architecture of the β subunits is similar, reflecting the locations of conserved disulfide bonds that constrain protein conformation. Evolutionary analysis suggests that the β-subunit genes arose from a common ancestral gene through gene duplication and divergence to evolve new biologic functions.

As hormone families expand and diverge, their receptors have co-evolved to create new biologic functions. Related G protein–coupled receptors (GPCRs), for example, have evolved for each of the glycoprotein hormones. These receptors are also structurally similar, and each is coupled predominantly to the $G_s\alpha$ signaling pathway. Because of co-evolution with respective hormones to achieve specificity, there is minimal overlap of hormone binding. For example, TSH binds with high specificity to the TSH receptor but interacts minimally with the LH or FSH receptors. Nonetheless, there can be subtle physiologic consequences of hormone cross-reactivity with other receptors. Very high levels of hCG during pregnancy weakly stimulate the TSH receptor and increase thyroid hormone levels, resulting in feedback inhibition and a compensatory decrease in TSH.

IGF1 and IGF2 have structural similarities that are most apparent when precursor forms of the proteins are compared. In contrast to the high degree of specificity seen with the glycoprotein hormones, there is moderate cross-talk among the members of the insulin/IGF family. High concentrations of an IGF2 precursor produced by certain tumors (e.g., sarcomas) can cause hypoglycemia, partly because of binding to insulin and IGF1 receptors. High concentrations of insulin also bind to the IGF1 receptor, accounting for some of the clinical manifestations seen in conditions with chronic hyperinsulinemia.

Another important example of receptor cross-talk is seen with PTH and parathyroid hormone–related peptide (PTHrP) **(Chap. 422)**. PTH is produced by the parathyroid glands, whereas PTHrP is expressed at high levels during development and by a variety of tumors **(Chap. 98)**. These hormones have amino acid sequence similarity, particularly in their amino-terminal regions. Both hormones bind to the PTH1R receptor that is expressed in bone and kidney. Excessive production of either hormone results in hypercalcemia and hyperphosphatemia, making it difficult to distinguish hyperparathyroidism from hypercalcemia of malignancy solely on the basis of serum chemistries. However, sensitive and specific assays for PTH and PTHrP now allow these disorders to be distinguished.

Based on their specificities for DNA-binding sites, the nuclear receptor family can be subdivided into type 1 receptors (glucocorticoid receptor, mineralocorticoid receptor, androgen receptor, estrogen receptor, progesterone receptor) that bind steroids and type 2 receptors (thyroid hormone receptor, vitamin D receptor, retinoic acid receptor, peroxisome proliferator activated receptor) that bind thyroid hormone, vitamin D, retinoic acid, or lipid derivatives, respectively. Certain functional domains in nuclear receptors, such as the zinc finger DNA-binding domains, are highly conserved. However, selective amino acid differences within this domain confer DNA sequence specificity. The hormone-binding domains are more variable, providing great diversity in the array of small molecules that bind to different nuclear receptors. With few exceptions, hormone binding is highly specific for a single type of nuclear receptor. One exception involves the glucocorticoid and mineralocorticoid receptors. Because the mineralocorticoid receptor also binds glucocorticoids with high affinity, an enzyme (11β-hydroxysteroid dehydrogenase) in renal tubular cells inactivates glucocorticoids, allowing selective renal responses to mineralocorticoids such as aldosterone. However, when very high glucocorticoid concentrations occur, as in Cushing's syndrome, the glucocorticoid degradation pathway becomes saturated, allowing excessive cortisol levels to bind mineralocorticoid receptors leading to sodium retention and potassium wasting. This phenomenon is particularly pronounced in ectopic ACTH syndromes **(Chap. 398)**. Another example of relaxed nuclear receptor specificity involves the estrogen receptor, which can bind an array of compounds, some of which have little apparent structural similarity to the high-affinity ligand estradiol. This feature of the estrogen receptor makes it susceptible to activation by "environmental estrogens" such as resveratrol, octylphenol, and many other aromatic hydrocarbons. However, this lack of specificity provides an opportunity to synthesize clinically useful antagonists (e.g., tamoxifen) and selective estrogen response modulators (SERMs) such as raloxifene. These compounds generate distinct estrogen receptor conformations that alter receptor interactions with components of the transcription machinery (see below), thereby conferring their unique actions.

TABLE 389-1 Examples of Membrane Receptor Families and Signaling Pathways

RECEPTORS	EFFECTORS	SIGNALING PATHWAYS
G Protein–Coupled Seven-Transmembrane Receptor (GPCR)		
LH, FSH, TSH, β-adrenergic	$G_s\alpha$, adenylate cyclase	Stimulation of cyclic AMP production, protein kinase A
Glucagon, PTH, PTHrP, ACTH, MSH, GHRH, CRH	Ca^{2+} channels	Calmodulin, Ca^{2+}-dependent kinases
Somatostatin, α-adrenergic	$G_i\alpha$	Inhibition of cyclic AMP production Activation of K^+, Ca^{2+} channels
TRH, GnRH	G_q, G_{11}	Phospholipase C, diacylglycerol, IP_3, protein kinase C, voltage-dependent Ca^{2+} channels
Receptor Tyrosine Kinase		
Insulin, IGF-I	Tyrosine kinases, IRS	MAP kinases, PI 3-kinase; AKT
Cytokine Receptor–Linked Kinase		
GH, PRL	JAK, tyrosine kinases	STAT, MAP kinase, PI 3-kinase, IRS-1
Serine Kinase		
Activin, TGF-β, MIS	Serine kinase	Smads

Abbreviations: IP_3, inositol triphosphate; IRS, insulin receptor substrates; MAP, mitogen-activated protein; MSH, melanocyte-stimulating hormone; PI, phosphatidylinositol; RSK, ribosomal S6 kinase; TGF-β, transforming growth factor β. For all other abbreviations, see text. Note that most receptors interact with multiple effectors and activate networks of signaling pathways.

HORMONE SYNTHESIS AND PROCESSING

The synthesis of peptide hormones and their receptors occurs through a classic pathway of gene expression: transcription → mRNA → protein → posttranslational protein processing → intracellular sorting, followed by membrane integration or secretion.

Many hormones are embedded within larger precursor polypeptides that are proteolytically processed to yield the biologically active hormone. Examples include proopiomelanocortin (POMC) → ACTH; proglucagon → glucagon; proinsulin → insulin; and pro-PTH → PTH, among others. In many cases, such as POMC and proglucagon, these precursors generate multiple biologically active peptides. For example, proglucagon generates glucagon, as well as glucagon-like peptide 1 (GLP1), among other peptides. It is provocative that hormone precursors are typically inactive, presumably adding an additional level of control through peptide processing. Prohormone conversion occurs not only for peptide hormones but also for certain steroids (testosterone → dihydrotestosterone) and thyroid hormone ($T_4 \rightarrow T_3$).

Peptide precursor processing is intimately linked to intracellular sorting pathways that transport proteins to appropriate vesicles and enzymes, resulting in specific cleavage steps, followed by protein folding and translocation to secretory vesicles. Hormones destined for secretion are translocated across the endoplasmic reticulum guided by an amino-terminal signal sequence that subsequently is cleaved. Cell-surface receptors are inserted into the membrane via short segments of hydrophobic amino acids that remain embedded within the lipid bilayer. During translocation through the Golgi and endoplasmic reticulum, hormones and receptors are subject to a variety of post-translational modifications, such as glycosylation and phosphorylation, which can alter protein conformation, modifying circulating half-life and biological activity.

Synthesis of most steroid hormones is based on modifications of the precursor, cholesterol. Multiple regulated enzymatic steps are required for the synthesis of testosterone **(Chap. 403)**, estradiol **(Chap. 404)**, cortisol **(Chap. 398)**, and vitamin D **(Chap. 421)**. This large number of synthetic steps predisposes to multiple genetic and acquired disorders of steroidogenesis.

Endocrine genes contain regulatory DNA elements similar to those found in many other genes, but their exquisite control by hormones reflects the presence of specific hormone response elements. For example, the TSH genes are repressed directly by thyroid hormones acting through the thyroid hormone receptor (TR), a member of the nuclear receptor family. Steroidogenic enzyme gene expression requires specific transcription factors, such as steroidogenic factor 1 (SF1), acting in conjunction with signals transmitted by trophic hormones (e.g., ACTH or LH). Once activated, SF1 functions as a master regulator, inducing a large array of genes required for steroidogenic and metabolic pathways required for steroid synthesis. For some hormones, substantial regulation occurs at the level of translational efficiency. Insulin biosynthesis, although it requires ongoing gene transcription, is regulated primarily at the translational and secretory levels in response to the levels of glucose or amino acids.

HORMONE SECRETION, TRANSPORT, AND DEGRADATION

The circulating level of a hormone is determined by its rate of secretion and its half-life. After protein processing, peptide hormones (e.g., GnRH, insulin, growth hormone [GH]) are stored in secretory granules. As these granules mature, they are poised beneath the plasma membrane for imminent release into the circulation. In most instances, the stimulus for hormone secretion is a releasing factor or neural signal that induces rapid changes in voltage-gated channel activity or intracellular calcium concentrations, leading to secretory granule fusion with the plasma membrane and release of its contents into the extracellular environment and bloodstream. Steroid hormones, in contrast, diffuse into the circulation as they are synthesized. Thus, their secretory rates are closely aligned with rates of synthesis. For example, ACTH and LH induce steroidogenesis by stimulating the activity of the *st*eroidogenic *a*cute *r*egulatory (StAR) protein, which transports cholesterol into the mitochondrion. These hormones also induce other rate-limiting enzymatic steps (e.g., cholesterol side-chain cleavage enzyme, CYP11A1) in specific steroidogenic pathways.

Hormone transport and degradation dictate the rapidity with which a hormonal signal decays. Some hormone signals are evanescent (e.g., somatostatin), whereas others are longer-lived (e.g., TSH). Because somatostatin exerts effects in virtually every tissue, a short half-life allows its concentrations and actions to be controlled locally. Structural modifications that impair somatostatin degradation have been useful for generating long-acting therapeutic analogues such as octreotide **(Chap. 392)**. In contrast, the actions of TSH are highly specific for the thyroid gland. Its prolonged half-life generates relatively constant serum levels even though TSH is secreted in discrete pulses.

An understanding of circulating hormone half-life is important for achieving physiologic hormone replacement, as the frequency of dosing and the time required to reach steady state are intimately linked to rates of hormone decay. T_4, for example, has a circulating half-life of 7 days. Consequently, >1 month is required to reach a new steady state, and single daily doses are sufficient to achieve constant hormone levels. T_3, in contrast, has a half-life of 1 day. Its administration is associated with more dynamic serum levels, and it must be administered two to three times per day. Similarly, synthetic glucocorticoids vary widely in their half-lives; those with longer half-lives (e.g., dexamethasone) are associated with greater suppression of the hypothalamic-pituitary-adrenal (HPA) axis. Most protein hormones (e.g., ACTH, GH, prolactin [PRL], PTH, LH) have relatively short half-lives (<20 min), leading to sharp peaks of secretion and decay. The only accurate way to profile the pulse frequency and amplitude of these hormones is to measure levels in frequently sampled blood (every 10 min or less) over long durations (8–24 h). Because this is not practical in a clinical setting, an alternative strategy is to pool three to four blood samples drawn at about 30-min intervals or interpret the results in the context of a relatively wide normal range. Rapid hormone decay is useful in certain clinical settings. For example, the short half-life of PTH allows the use of intraoperative PTH levels to confirm successful removal of a parathyroid adenoma. This is particularly valuable diagnostically when there is a possibility of multicentric disease or parathyroid hyperplasia, as occurs with multiple endocrine neoplasia (MEN) or renal insufficiency.

Many hormones circulate in association with serum-binding proteins. Examples include (1) T_4 and T_3 binding to thyroxine-binding globulin (TBG), albumin, and thyroxine-binding prealbumin (TBPA); (2) cortisol binding to cortisol-binding globulin (CBG); (3) androgen and estrogen binding to sex hormone–binding globulin (SHBG); (4) IGF1 and IGF2 binding to multiple IGF-binding proteins (IGFBPs); (5) GH interactions with GH-binding protein (GHBP), a circulating fragment of the GH receptor extracellular domain; and (6) activin binding to follistatin. These interactions provide a hormone reservoir, prevent otherwise rapid degradation of unbound hormones, restrict hormone access to certain sites (e.g., IGFBPs), and modulate the levels of unbound, or "free," hormone concentrations. Although a variety of binding protein abnormalities have been identified, most have little clinical consequence aside from creating diagnostic problems. For example, TBG deficiency can reduce total thyroid hormone levels greatly, but the free concentrations of T_4 and T_3 remain normal. Liver disease and certain medications can also influence binding protein levels (e.g., estrogen increases TBG) or cause displacement of hormones from binding proteins (e.g., salsalate displaces T_4 from TBG). In general, only unbound hormone is available to interact with receptors and thus elicit a biologic response. Short-term perturbations in binding proteins change the free hormone concentration, which in turn induces compensatory adaptations through feedback loops. SHBG changes in women are an exception to this self-correcting mechanism. When SHBG decreases because of insulin resistance or androgen excess, the unbound testosterone concentration is increased, potentially contributing to hirsutism in women with polycystic ovary syndrome (PCOS) **(Chap. 406)**. The increased unbound testosterone level does not result in an adequate compensatory feedback correction because estrogen, not testosterone, is the primary regulator of the reproductive axis.

An additional exception to the unbound hormone hypothesis involves megalin, a member of the low-density lipoprotein (LDL) receptor family that serves as an endocytotic receptor for thyroglobulin, carrier-bound vitamins A and D, and SHBG-bound androgens and estrogens. After internalization, the carrier proteins are degraded in lysosomes and release their bound ligands within the cells. Other membrane transporters have also been identified for thyroid hormones.

Hormone degradation can be an important mechanism for regulating concentrations locally. As noted above, 11β-hydroxysteroid dehydrogenase inactivates glucocorticoids in renal tubular cells, preventing actions through the mineralocorticoid receptor. Thyroid hormone deiodinases convert T_4 to T_3 and can inactivate T_3. During development, degradation of retinoic acid by Cyp26b1 prevents primordial germ cells in the male from entering meiosis, as occurs in the female ovary.

HORMONE ACTION THROUGH RECEPTORS

Receptors for hormones are divided into two major classes: membrane and nuclear. *Membrane receptors* primarily bind peptide hormones and catecholamines. *Nuclear receptors* bind small molecules that can diffuse across the cell membrane, such as steroids and vitamin D. Certain general principles apply to hormone-receptor interactions regardless of the class of receptor. Hormones bind to receptors with specificity and an affinity that generally coincides with the dynamic range of circulating hormone concentrations. Low concentrations of free hormone (usually 10^{-12} to 10^{-9} *M*) rapidly associate and dissociate from receptors in a bimolecular reaction such that the occupancy of the receptor at any given moment is a function of hormone concentration and the receptor's affinity for the hormone. Receptor numbers vary greatly in different target tissues, providing one of the major determinants of tissue-specific responses to circulating hormones. For example, ACTH receptors are located almost exclusively in the adrenal cortex, and LH receptors are found predominantly in the gonads. In contrast, insulin and TRs are widely distributed, reflecting the need for metabolic responses in all tissues.

MEMBRANE RECEPTORS

Membrane receptors for hormones can be divided into several major groups: (1) seven-transmembrane GPCRs, (2) tyrosine kinase receptors, (3) cytokine receptors, and (4) serine kinase receptors (Fig. 389-1). The *seven-transmembrane GPCR family* binds a huge array of hormones, including large proteins (e.g., LH, PTH), small peptides (e.g., TRH, somatostatin), catecholamines (epinephrine, dopamine), and even minerals (e.g., calcium). The extracellular domains of GPCRs vary widely in size and are the major binding site for large hormones. The transmembrane-spanning regions are composed of hydrophobic α-helical domains that traverse the lipid bilayer. Like some channels, these domains are thought to circularize and form a hydrophobic pocket into which certain small ligands fit. Hormone binding induces conformational changes in these domains, transducing structural changes to the intracellular domain, which is a docking site for G proteins.

The large family of *G proteins*, so named because they bind guanine nucleotides (guanosine triphosphate [GTP], guanosine diphosphate [GDP]), provides great diversity for coupling receptors to different signaling pathways. G proteins form a heterotrimeric complex that is composed of various α and βγ subunits (Fig. 389-2). The α subunit contains the guanine nucleotide–binding site and an intrinsic GTPase that hydrolyzes GTP → GDP. The βγ subunits are tightly associated and modulate the activity of the α subunit as well as mediating their own effector signaling pathways. G protein activity is regulated by a cycle that involves GTP hydrolysis and dynamic interactions between the α and βγ subunits. Hormone binding to the receptor induces GDP dissociation, allowing Gα to bind GTP and dissociate from the βγ complex. Under these conditions, the Gα subunit is activated and mediates signal transduction through various enzymes, such as adenylate cyclase and phospholipase C. GTP hydrolysis to GDP allows reassociation with the βγ subunits and restores the inactive state. G proteins interact with other cellular proteins, including kinases, channels, G protein–coupled receptor kinases (GRKs), and arrestins, that mediate signaling as well as receptor desensitization and recycling.

A variety of endocrinopathies result from mutations in GPCRs that alter their interactions with G proteins (Table 389-2). Loss-of-function mutations are generally recessive and inactivate the relevant hormone signaling pathway. Because many of these receptors are important for development as well as signaling, patient presentations resemble glandular failure syndromes (e.g., mutations in LH-R, FSH-R, TSH-R). Gain-of-function (GOF) mutations are more complex. Selected GOF mutations induce conformational changes in the GPCR that mimic the activated state normally induced by hormone binding. These GOF mutations result in a constitutively active state in which G protein coupling stimulates cell signaling pathways, most commonly via cyclic adenosine 5′-monophosphate (cAMP) and protein kinase A. When mutations occur in the germline, the conditions are heritable and present in early life (e.g., LH-R, TSH-R). Sporadic, somatic mutations can also occur and result in clonal expansion of hyperfunctioning cells.

Mutations in the TSH-R illustrate the range of possible clinical consequences of GPCR mutations. Recessive inactivating mutations in the TSH-R cause congenital hypothyroidism with thyroid gland hypoplasia and resistance to TSH. Clinically, the hormone profile resembles primary hypothyroidism with low T_4 and high TSH. On the other hand, germline activating mutations cause congenital hyperthyroidism. The disorder is autosomal dominant because an activating mutation of one TSH-R allele is sufficient to induce cellular hyperfunction and disease. Because the TSH-R is activated in every cell of the thyroid, there is hyperplastic growth and hyperfunction that resembles the pathology seen in Graves' disease. This unusual disorder presents in infancy and must be distinguished from the more common clinical circumstance in which maternal antibodies in women with active or previously treated Graves' disease cross the placenta and stimulate the thyroid gland of the fetus. If an activating TSH-R mutation occurs later in life, in the somatic tissue, there is clonal expansion of the thyrocyte harboring the mutation, ultimately leading to an autonomous hyperfunctioning thyroid nodule. Of note, a similar condition can be caused by somatic mutations in $G_s\alpha$. In this case, the $G_s\alpha$ GTPase is inactivated and GTP cannot be converted to GDP. Consequently, the $G_s\alpha$ signaling pathway in this particular cell is constitutively active, mimicking chronic TSH stimulation and again leading to clonal expansion and an autonomous hyperfunctioning thyroid nodule. About one-third of hyperfunctioning "hot" thyroid nodules harbor sporadic mutations in either the TSH-R or $G_s\alpha$ (TSH-R mutations are more common).

$G_s\alpha$ mutations in tissues other than the thyroid can also cause endocrine disease. For example, $G_s\alpha$ mutations in pituitary somatotropes

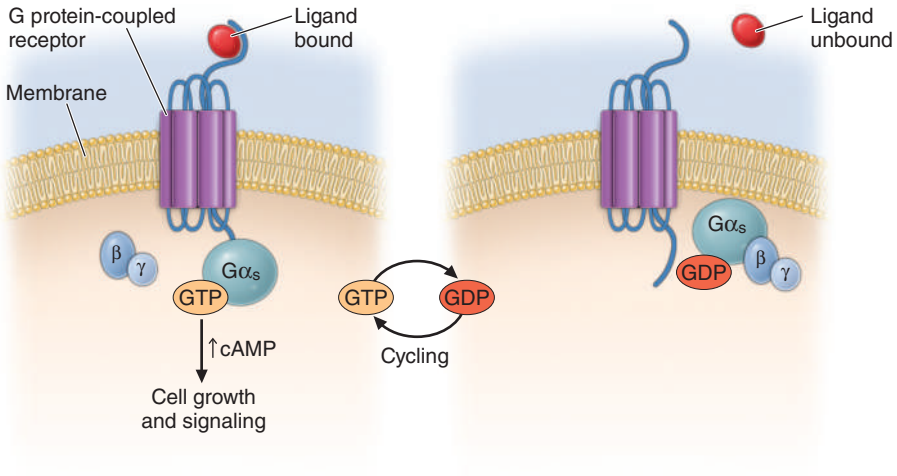

FIGURE 389-2 G protein signaling. G protein–coupled receptors (GPCRs) signal via the family of G proteins, so named because they bind guanylyl nucleotides. In the example shown, a GPCR bound to a ligand induces GDP dissociation, allowing $G_s\alpha$ to bind GTP and dissociate from the βγ complex. GTP-bound $G_s\alpha$ increases cAMP production by adenylyl cyclase and activates the protein kinase A pathway. Not shown are separate signaling pathways activated by the βγ complex. When GTP is converted to GDP by an intrinsic GTPase, the βγ subunits reassociate with GDP-bound $G_s\alpha$ and the complex returns to an inactive state. As noted in the text, mutations in $G_s\alpha$ that eliminate GTPase activity result in constitutive activation of receptor signaling pathways because GTP-bound $G_s\alpha$ cannot be converted to its GDP-bound inactive state. cAMP, cyclic adenosine 5′-monophosphate; GDP, guanosine diphosphate; $G_s\alpha$, G protein α; GTP, guanosine triphosphate.

mimic activation of the growth hormone–releasing hormone (GHRH) pathway and lead to GH-producing adenomas and acromegaly. Rarely, mutations in other components of the protein kinase A pathway in somatotropes can also cause GH-producing adenomas. $G_s\alpha$ mutations that occur early in development (typically mosaic) cause McCune-Albright syndrome **(Chap. 424)**, and the clinical features are manifest because the activated G protein pathway mimics the actions of various hormones (PTH, melanocyte-stimulating hormone [MSH], TSH, GHRH) in different tissues. Germline inactivating $G_s\alpha$ mutations cause a range of disorders that are transmitted and expressed in a complex manner because the locus is imprinted **(Chap. 422)**. These conditions include Albright's hereditary osteodystrophy (AHO), pseudopseudohypoparathyroidism (PPHP), and pseudohypoparathyroidism types 1b, 1c, and 2.

The *tyrosine kinase receptors* transduce signals for insulin and a variety of growth factors, such as IGF1, epidermal growth factor (EGF), nerve growth factor, platelet-derived growth factor, and fibroblast growth factors. The cysteine-rich extracellular domains contain binding sites for the growth factors. After ligand binding, this class of receptors undergoes autophosphorylation, inducing interactions with intracellular adaptor proteins such as Shc and insulin receptor substrates (IRS). In the case of the insulin receptor, multiple kinases are activated, including the Raf-Ras-MAPK and the Akt/protein kinase B pathways. The tyrosine kinase receptors play a prominent role in cell growth and differentiation as well as in intermediary metabolism.

The GH and PRL receptors belong to the *cytokine receptor* family. Analogous to the tyrosine kinase receptors, ligand binding induces receptor interaction with intracellular kinases—the Janus kinases (JAKs), which phosphorylate members of the signal transduction and activators of transcription (STAT) family—as well as with other signaling pathways (Ras, PI3-K, MAPK). The activated STAT proteins translocate to the nucleus and stimulate expression of target genes.

The *serine kinase receptors* mediate the actions of activins, transforming growth factor β, müllerian-inhibiting substance (MIS; also known as anti-müllerian hormone [AMH]), and bone morphogenic proteins (BMPs). This family of receptors (consisting of type I and II subunits) signals through proteins termed *smads* (fusion of terms for *Caenorhabditis elegans* sma + mammalian mad). Like the STAT proteins, the smads serve a dual role of transducing the receptor signal and acting as transcription factors. The pleomorphic actions of these growth factors dictate that they act primarily in a local (paracrine or autocrine) manner. Binding proteins such as follistatin (which binds activin and other members of this family) function to inactivate the growth factors and restrict their distribution.

Disease-causing mutations also occur in each of these classes of receptors. For example, insulin receptor mutations cause an extreme form of insulin resistance. GH receptor mutations cause Laron-type dwarfism, characterized by low IGF1 and high GH. AMH receptor mutations cause persistent müllerian duct syndrome. These hormone resistance syndromes are autosomal recessive and relatively uncommon. Unlike the GPCRs, activating mutations are unusual, although they do occur for the RET tyrosine kinase receptor, which causes the autosomal dominant disorder MEN type 2 (MEN2) **(Chap. 400)**.

NUCLEAR RECEPTORS

The family of nuclear receptors has nearly 100 members, many of which are still classified as orphan receptors because their ligands, if they exist, have not been identified **(Fig. 389-3)**. Otherwise, most nuclear receptors are classified on the basis of their ligands. Although all nuclear receptors ultimately act to increase or decrease gene transcription, some (e.g., glucocorticoid receptor) reside primarily in the cytoplasm, whereas others (e.g., TR) are located in the nucleus. After ligand binding, the cytoplasmically localized receptors translocate to the nucleus. There is growing evidence that certain ligands and their nuclear receptors (e.g., glucocorticoid, estrogen) can also act at the membrane or in the cytoplasm to modulate signal transduction pathways, providing a mechanism for cross-talk between membrane and nuclear receptors.

The structures of nuclear receptors have been studied extensively, including by x-ray crystallography. The DNA-binding domain, consisting of two zinc fingers, contacts specific DNA recognition sequences in target genes. Most nuclear receptors bind to DNA as dimers. Consequently, each monomer recognizes an individual DNA motif, referred to as a "half-site." The steroid receptors, including the glucocorticoid, estrogen, progesterone, and androgen receptors, bind to DNA as homodimers. Consistent with this twofold symmetry, their DNA recognition half-sites are palindromic. The thyroid, retinoid, peroxisome proliferator activated, and vitamin D receptors bind to DNA preferentially as heterodimers in combination with retinoid X receptors (RXRs). Their DNA half-sites are typically arranged as direct repeats.

The carboxy-terminal hormone-binding domains mediate transcriptional control. For type II receptors such as TR and retinoic acid receptor (RAR), co-repressor proteins bind to the receptor in the absence of ligand and silence gene transcription. Hormone binding induces conformational changes in the receptor, triggering the release of co-repressors and the recruitment of coactivators that stimulate transcription. Thus, these receptors are capable of mediating dynamic changes in the level of gene activity. Disease states can be associated with defective regulation of these events. For example, in promyelocytic leukemia, fusion of RARα to other nuclear proteins causes aberrant gene silencing that prevents normal cellular differentiation. Treatment with retinoic acid reverses this repression and allows cellular differentiation and apoptosis to occur. Most type 1 steroid receptors interact weakly with co-repressors, but ligand binding still induces interactions with an array of coactivators. X-ray crystallography shows that various SERMs induce distinct estrogen receptor conformations. The tissue-specific responses caused by these agents in breast, bone, and uterus appear to reflect distinct interactions with various coactivators. The receptor-coactivator complex stimulates gene transcription by several pathways, including (1) recruitment of enzymes

TABLE 389-2 Genetic Causes of G protein Receptor Disorders

RECEPTOR	DISORDER	GENETICS
LH	Leydig cell hypoplasia (male)	AR, inactivating
	Primary amenorrhea, resistance to LH (female)	AR, inactivating
	Familial male precocious puberty (male)	AD, activating
	Leydig cell adenoma, precocious puberty (male)	Sporadic, activating
FSH	Hypergonadotropic ovarian failure (female)	AR, inactivating
	Hypospermia (male)	AR, inactivating
	Ovarian hyperstimulation (female)	Sporadic, activating
TSH	Congenital hypothyroidism, TSH resistance	AR, AD, inactivating
	Nonautoimmune familial hyperthyroidism	AD, activating
	Hyperfunctioning thyroid adenoma	Sporadic, activating
GnRH	Hypogonadotropic hypogonadism	AR, inactivating
Kisspeptin	Hypogonadotropic hypogonadism	AR, inactivating
	Precocious puberty	AD, activating
Prokineticin	Precocious puberty	Sporadic, activating
TRH	Central hypothyroidism	AR, inactivating
GHRH	GH deficiency	AR, inactivating
PTH	Blomstrand chondrodysplasia	AR, inactivating
	Jansen metaphyseal chondrodysplasia	AD, activating
Calcium sensing receptor	Familial hypocalciuric hypercalcemia	AD, inactivating
	Neonatal severe hyperparathyroidism	AR, inactivating
	Familial hypocalcemic hypercalciura	AD, activating
Arginine vasopressin receptor 2	Nephrogenic diabetes insipidus	XL, inactivating
	Nephrogenic SIADH	XL, activating
ACTH	Familial ACTH resistance	AR, inactivating
	ACTH-independent Cushing syndrome	Sporadic, activating
Melanocortin 4	Severe obesity	Codominant, inactivating

Abbreviations: ACTH, adrenocorticotropin hormone; AD, autosomal dominant; AR, autosomal recessive; FSH, follicle-stimulating hormone; GH, growth hormone; GHRH, growth hormone–releasing hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone; PTH, parathyroid hormone; SIADH, syndrome of inappropriate antidiuretic hormone secretion; TRH, thyrotropin-releasing hormone; TSH, thyroid-stimulating hormone; XL, X-linked.

(histone acetyl transferases) that modify chromatin structure, (2) interactions with additional transcription factors on the target gene, and (3) direct interactions with components of the general transcription apparatus to enhance the rate of RNA polymerase II–mediated transcription. Studies of nuclear receptor–mediated transcription reveal relatively rapid (e.g., 30–60 min) cycling of transcription complexes on any specific target gene.

Nuclear receptor mutations are an important cause of endocrine disease. Androgen receptor mutations cause androgen insensitivity syndrome (AIS) **(Chap. 402)**. Because the androgen receptor is located on the X chromosome, phenotypic expression is more commonly manifest than with other nuclear receptor disorders. Affected individuals with AIS are XY phenotypic females with retained testes and male-range testosterone levels. Tissue insensitivity to androgens varies based on the severity of the mutation. Müllerian structures are absent because Sertoli cells of the testis produce AMH during development. Female carriers of androgen receptor mutations are phenotypically normal. Recessive mutations of the estrogen, glucocorticoid, and vitamin D receptors occur but are rare.

Thyroid hormone receptor β (TRβ) mutations have an unusual pathophysiology. They are autosomal dominant and function via a "dominant negative" mechanism to cause resistance to thyroid hormone (RTH) **(Chap. 394)**. The mutations occur in selected regions of the TRβ hormone-binding domain and preserve the ability of the mutant receptor to heterodimerize with RXR, interact with corepressors, and bind to DNA regulatory sites. The mutant receptors function as antagonists of receptors from the normal copy of the TRβ gene. Affected patients have high T_4 and T_3 and inappropriately elevated (unsuppressed) TSH, reflecting impaired feedback regulation of the hypothalamic-pituitary-thyroid axis. Organ systems are variably resistant to thyroid hormones based on the relative expression of TRβ and TRα. Mutations in the genes encoding TRα and PPARγ can also cause disease by functioning in an analogous dominant negative manner.

FUNCTIONS OF HORMONES

The functions of individual hormones are described in detail in subsequent chapters. Nevertheless, it is useful to illustrate how most biologic responses require the integration of several different hormone pathways. The physiologic functions of hormones can be divided into three general types: (1) growth and differentiation, (2) maintenance of homeostasis, and (3) reproduction.

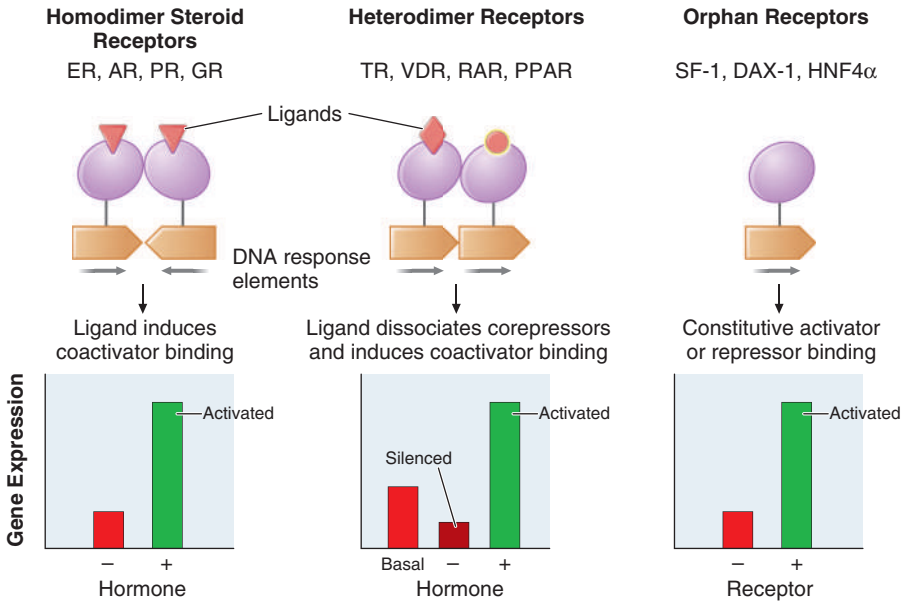

FIGURE 389-3 Nuclear receptor signaling. AR, androgen receptor; DAX, *d*osage-sensitive sex-reversal, *a*drenal hypoplasia congenita, *X* chromosome; ER, estrogen receptor; GR, glucocorticoid receptor; HNF4α, hepatic nuclear factor 4α; PPAR, peroxisome proliferator activated receptor; PR, progesterone receptor; RAR, retinoic acid receptor; SF-1, steroidogenic factor-1; TR, thyroid hormone receptor; VDR, vitamin D receptor.

GROWTH

Multiple hormones and nutritional factors mediate the complex phenomenon of growth (Chap. 390). Short stature may be caused by GH deficiency, hypothyroidism, Cushing's syndrome, precocious puberty, malnutrition, chronic illness, or genetic abnormalities that affect the epiphyseal growth plates (e.g., *FGFR3* and *SHOX* mutations). Many factors (GH, IGF1, thyroid hormones) stimulate growth, whereas others (sex steroids) lead to epiphyseal closure. Understanding these hormonal interactions is important in the diagnosis and management of growth disorders. For example, delaying exposure to high levels of sex steroids may enhance the efficacy of GH treatment.

MAINTENANCE OF HOMEOSTASIS

Although virtually all hormones affect homeostasis, the most important among them are the following:

1. Thyroid hormone—controls ~25% of basal metabolism in most tissues.
2. Cortisol—exerts a permissive action for many hormones in addition to its own direct effects.
3. PTH—regulates calcium and phosphorus levels.
4. Vasopressin—regulates serum osmolality by controlling renal free-water clearance.
5. Mineralocorticoids—control vascular volume and serum electrolyte (Na^+, K^+) concentrations.
6. Insulin—maintains euglycemia in the fed and fasted states.

The defense against hypoglycemia is an impressive example of integrated hormone action (Chap. 418). In response to the fasting state and falling blood glucose, insulin secretion is suppressed, resulting in decreased glucose uptake and enhanced glycogenolysis, lipolysis, proteolysis, and gluconeogenesis to mobilize fuel sources. If hypoglycemia develops (usually from insulin administration or sulfonylureas), an orchestrated counterregulatory response occurs—glucagon and epinephrine rapidly stimulate glycogenolysis and gluconeogenesis, whereas GH and cortisol act over several hours to raise glucose levels and antagonize insulin action.

Although free-water clearance is controlled primarily by vasopressin, cortisol and thyroid hormone are also important for facilitating renal tubular responses to vasopressin (Chap. 393). PTH and vitamin D function in an interdependent manner to control calcium metabolism (Chap. 421). PTH stimulates renal synthesis of 1,25-dihydroxyvitamin D, which increases calcium absorption in the gastrointestinal tract and enhances PTH action in bone. Increased calcium, along with vitamin D, feeds back to suppress PTH, thus maintaining calcium balance.

Depending on the severity of a specific stress and whether it is acute or chronic, multiple endocrine and cytokine pathways are activated to mount an appropriate physiologic response. In severe acute stress such as trauma or shock, the sympathetic nervous system is activated, and catecholamines are released, leading to increased cardiac output and a primed musculoskeletal system. Catecholamines also increase mean blood pressure and stimulate glucose production. Multiple stress-induced pathways converge on the hypothalamus, stimulating several hormones, including vasopressin and CRH. These hormones, in addition to cytokines (tumor necrosis factor α, interleukin [IL] 2, IL-6), increase ACTH and GH production. ACTH stimulates the adrenal gland, increasing cortisol, which in turn helps sustain blood pressure and dampen the inflammatory response. Increased vasopressin acts to conserve free water.

REPRODUCTION

The stages of reproduction include (1) sex determination during fetal development (Chap. 402); (2) sexual maturation during puberty (Chaps. 403 and 404); (3) conception, pregnancy, lactation, and child rearing (Chap. 404); and (4) cessation of reproductive capability at menopause (Chap. 407). Each of these stages involves an orchestrated interplay of multiple hormones, a phenomenon well illustrated by the dynamic hormonal changes that occur during each 28-day menstrual cycle. In the early follicular phase, pulsatile secretion of LH and FSH stimulates the progressive maturation of the ovarian follicle. This results in gradually increasing estrogen and progesterone levels, leading to enhanced pituitary sensitivity to GnRH, which, when combined with accelerated GnRH secretion, triggers the LH surge and rupture of the mature follicle. Inhibin, a protein produced by the granulosa cells, enhances follicular growth and feeds back to the pituitary to selectively suppress FSH without affecting LH. Growth factors such as EGF and IGF1 modulate follicular responsiveness to gonadotropins. Vascular endothelial growth factor and prostaglandins play a role in follicle vascularization and rupture.

During pregnancy, the increased production of PRL, in combination with placentally derived steroids (e.g., estrogen and progesterone), prepares the breast for lactation. Estrogens induce the production of progesterone receptors, allowing for increased responsiveness to progesterone. In addition to these and other hormones involved in lactation, the nervous system and oxytocin mediate the suckling response and milk release.

HORMONAL FEEDBACK REGULATORY SYSTEMS

Feedback control, both negative and positive, is a fundamental feature of endocrine systems. Each of the major hypothalamic-pituitary-hormone axes is governed by negative feedback, a process that maintains hormone levels within a relatively narrow range (Chap. 390). Examples of hypothalamic-pituitary negative feedback include (1) thyroid hormones on the TRH-TSH axis, (2) cortisol on the CRH-ACTH axis, (3) gonadal steroids on the GnRH-LH/FSH axis, and (4) IGF1 on the GHRH-GH axis (Fig. 389-4). These regulatory loops include both positive (e.g., TRH, TSH) and negative (e.g., T_4, T_3) components, allowing for exquisite control of hormone levels. As an example, a small reduction of thyroid hormone triggers a rapid increase of TRH and TSH secretion, resulting in thyroid gland stimulation and increased thyroid hormone production. When thyroid hormone reaches a normal level, it feeds back to suppress TRH and TSH, and a new steady state is attained. Feedback regulation also occurs for endocrine systems that do not involve the pituitary gland, such as calcium feedback on PTH, glucose inhibition of insulin secretion, and leptin feedback on the hypothalamus. An understanding of feedback regulation provides important insights into endocrine testing paradigms (see below).

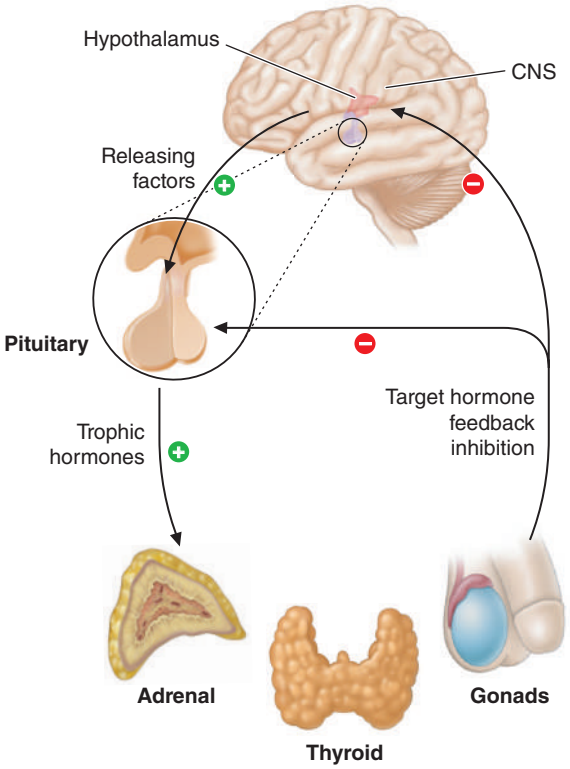

FIGURE 389-4 Feedback regulation of endocrine axes. CNS, central nervous system.

Positive feedback control also occurs but is not well understood. The primary example is estrogen-mediated stimulation of the midcycle LH surge. Although chronic low levels of estrogen are inhibitory, gradually rising estrogen levels stimulate LH secretion. This effect, which is illustrative of an endocrine rhythm (see below), involves activation of the hypothalamic GnRH pulse generator. In addition, estrogen-primed gonadotropes are extraordinarily sensitive to GnRH, leading to amplification of LH release.

PARACRINE AND AUTOCRINE CONTROL

The previously mentioned examples of feedback control involve classic endocrine pathways in which hormones are released by one gland and act on a distant target gland. However, local regulatory systems, often involving growth factors, are increasingly recognized. *Paracrine regulation* refers to factors released by one cell that act on an adjacent cell in the same tissue. For example, somatostatin secretion by pancreatic islet δ cells inhibits insulin secretion from nearby β cells. *Autocrine regulation* describes the action of a factor on the same cell from which it is produced. IGF1 acts on many cells that produce it, including chondrocytes, breast epithelium, and gonadal cells. Unlike endocrine actions, paracrine and autocrine control are difficult to document because local growth factor concentrations cannot be measured readily.

Anatomic relationships of glandular systems also greatly influence hormonal exposure: the physical organization of islet cells enhances their intercellular communication; the portal vasculature of the hypothalamic-pituitary system exposes the pituitary to high concentrations of hypothalamic releasing factors; testicular seminiferous tubules gain exposure to high testosterone levels produced by the interdigitated Leydig cells; the pancreas receives nutrient information and local exposure to peptide hormones (incretins) from the gastrointestinal tract; and the liver is the proximal target of insulin action because of portal drainage from the pancreas.

HORMONAL RHYTHMS

The feedback regulatory systems described above are superimposed on hormonal rhythms that are used for adaptation to the environment. Seasonal changes, the daily occurrence of the light-dark cycle, sleep, meals, and stress are examples of the many environmental events that affect hormonal rhythms. The *menstrual cycle* is repeated on average every 28 days, reflecting the time required to follicular maturation, ovulation, and potential implantation **(Chap. 390)**. Essentially all pituitary hormone rhythms are entrained to sleep and to the *circadian cycle*, generating reproducible patterns that are repeated approximately every 24 h. The HPA axis, for example, exhibits characteristic peaks of ACTH and cortisol production in the early morning, with a nadir during the night. Recognition of these rhythms is important for endocrine testing and treatment. Patients with Cushing's syndrome characteristically exhibit increased midnight cortisol levels compared with normal individuals **(Chap. 398)**. In contrast, morning cortisol levels are similar in these groups, as cortisol is normally high at this time of day in normal individuals. The HPA axis is more susceptible to suppression by glucocorticoids administered at night as they blunt the early-morning rise of ACTH. Understanding these rhythms allows glucocorticoid replacement that mimics diurnal production by administering larger doses in the morning than in the afternoon. Disrupted sleep rhythms can alter hormonal regulation. For example, sleep deprivation causes mild insulin resistance, food craving, and hypertension, which are reversible, at least in the short term. Emerging evidence indicates that circadian clock pathways not only regulate sleep-wake cycles but also play important roles in virtually every cell type. For example, tissue-specific deletion of clock genes alters rhythms and levels of gene expression, as well as metabolic responses in liver, adipose, and other tissues.

Other endocrine rhythms occur on a more rapid time scale. Many peptide hormones are secreted in discrete bursts every few hours. LH and FSH secretion are exquisitely sensitive to GnRH pulse frequency. Intermittent pulses of GnRH are required to maintain pituitary sensitivity, whereas continuous exposure to GnRH causes pituitary gonadotrope desensitization. This feature of the hypothalamic-pituitary-gonadotrope axis forms the basis for using long-acting GnRH agonists to treat central precocious puberty or to decrease testosterone levels in the management of prostate cancer. It is important to be aware of the pulsatile nature of hormone secretion and the rhythmic patterns of hormone production in relating serum hormone measurements to normal values. For some hormones, integrated markers have been developed to circumvent hormonal fluctuations. Examples include 24-h urine collections for cortisol, the measurement of IGF1 as a biologic marker of GH action, and HbA_{1c} as an index of long-term (weeks to months) blood glucose control.

Often, one must interpret endocrine data only in the context of other hormones. For example, PTH levels typically are assessed in combination with serum calcium concentrations. A high serum calcium level in association with elevated PTH is suggestive of hyperparathyroidism, whereas a suppressed PTH in the setting of hypercalcemia is more likely to be caused by hypercalcemia of malignancy, or other causes of hypercalcemia. Similarly, when T_4 and T_3 concentrations are low, TSH should be elevated, reflecting reduced feedback inhibition. When this is not the case, it is important to consider secondary hypothyroidism, which is caused by a defect at the level of the pituitary.

390 Physiology of Anterior Pituitary Hormones

Shlomo Melmed, J. Larry Jameson

The anterior pituitary often is referred to as the "master gland" because, together with the hypothalamus, it orchestrates the complex regulatory functions of many other endocrine glands. The anterior pituitary gland produces six major hormones: (1) prolactin (PRL), (2) growth hormone (GH), (3) adrenocorticotropic hormone (ACTH), (4) luteinizing hormone (LH), (5) follicle-stimulating hormone (FSH), and (6) thyroid-stimulating hormone (TSH) **(Table 390-1)**. Pituitary hormones are secreted in a pulsatile manner, reflecting regulation by an array of specific hypothalamic releasing factors. Each of these pituitary hormones elicits specific trophic responses in peripheral target tissues including the adrenal, thyroid, and gonads, as well as tissues involved in metabolism (e.g., liver, breast, bone). Elicited hormonal products of peripheral glands, in turn, exert feedback control at the level of the hypothalamus and pituitary to modulate pituitary function **(Fig. 390-1)**. Pituitary tumors cause characteristic hormone excess syndromes. Hormone deficiency may be inherited or acquired. Fortunately, there are efficacious treatments for many pituitary hormone excess and deficiency syndromes. Nonetheless, these diagnoses are often elusive; this emphasizes the importance of recognizing subtle clinical manifestations and performing the correct laboratory diagnostic tests. **For discussion of disorders of the posterior pituitary or neurohypophysis, see Chap. 393.**

TABLE 390-1 Anterior Pituitary Hormone Expression and Regulation

CELL	CORTICOTROPE	SOMATOTROPE	LACTOTROPE	THYROTROPE	GONADOTROPE
Tissue-specific transcription factor	T-Pit	Prop-1, Pit-1	Prop-1, Pit-1	Prop-1, Pit-1, TEF	SF-1, DAX-1

ANATOMY AND DEVELOPMENT

ANATOMY

The pituitary gland weighs ~600 mg and is located within the sella turcica ventral to the diaphragma sella; it consists of anatomically and functionally distinct anterior and posterior lobes. The bony sella is contiguous to vascular and neurologic structures, including the cavernous sinuses, cranial nerves, and optic chiasm. Thus, expanding intrasellar pathologic processes may have significant central mass effects in addition to their endocrinologic impact.

Hypothalamic neural cells synthesize specific releasing and inhibiting hormones that are secreted directly into the portal vessels of the pituitary stalk. Blood supply of the pituitary gland comes from the superior and inferior hypophyseal arteries **(Fig. 390-2)**. The hypothalamic-pituitary portal plexus provides the major blood source for the anterior pituitary, allowing reliable transmission of hypothalamic peptide pulses without significant systemic dilution; consequently, anterior pituitary cells are exposed to specific releasing or inhibiting factors and in turn release their respective hormones as discrete pulses into the systemic circulation **(Fig. 390-3)**.

The posterior pituitary is supplied by the inferior hypophyseal arteries. In contrast to the anterior pituitary, the posterior lobe is directly innervated by hypothalamic neurons (supraopticohypophyseal and tuberohypophyseal nerve tracts) via the pituitary stalk **(Chap. 393)**. Thus, posterior pituitary production of arginine vasopressin (AVP) and oxytocin is particularly sensitive to neuronal damage by lesions that affect the pituitary stalk or hypothalamus.

PITUITARY DEVELOPMENT

The embryonic differentiation and maturation of anterior pituitary cells have been elucidated in considerable detail. Pituitary development from Rathke's pouch involves a complex interplay of lineage-specific transcription factors expressed in pluripotent Sox2-expressing precursor cells and gradients of locally produced growth factors (Table 390-1). The transcription factor Prop-1 induces pituitary development of Pit-1-specific lineages as well as gonadotropes. The transcription factor Pit-1 determines cell-specific expression of GH, PRL, and TSH in somatotropes, lactotropes, and thyrotropes. Expression of high levels of estrogen receptors in cells that contain Pit-1 favors PRL expression, whereas thyrotrope embryonic factor (TEF) induces TSH expression. Pit-1 binds to GH, PRL, and TSH gene regulatory elements, providing a mechanism for determining specific pituitary hormone phenotypic stability. Gonadotrope cell development is further defined by the cell-specific expression of the nuclear receptors steroidogenic factor (SF-1) and *d*osage-sensitive sex reversal, *a*drenal hypoplasia critical region, on chromosome *X*, gene *1* (DAX-1). Development of corticotrope cells, which express the proopiomelanocortin (*POMC*) gene, requires the T-Pit transcription factor. Abnormalities of pituitary development can be caused by inherited mutations of developmental transcription factors including Pit-1, Prop-1, SF-1, DAX-1, and T-Pit, resulting in selective or combined pituitary hormone deficit syndromes.

ANTERIOR PITUITARY HORMONES

Each anterior pituitary hormone is under unique control, and each exhibits highly specific normal and dysregulated secretory characteristics.

PROLACTIN

Synthesis PRL consists of 198 amino acids and has a molecular mass of 21,500 kDa; it is weakly homologous to GH and human placental lactogen (hPL), reflecting the duplication and divergence of a common GH-PRL-hPL precursor gene. PRL is synthesized in lactotropes, which constitute ~20% of anterior pituitary cells. Lactotropes and somatotropes are derived from a common precursor cell that may give rise to a tumor that secretes both PRL and GH. Lactotrope cell hyperplasia develops during pregnancy and the first few months of lactation. These transient functional changes in the lactotrope population are induced by estrogen to increase PRL production.

Secretion Normal adult serum PRL levels are about 10–25 μg/L in women and 10–20 μg/L in men. PRL secretion is pulsatile, with the highest secretory peaks occurring during non–rapid eye movement (non-REM) sleep. Peak serum PRL levels (up to 30 μg/L) occur between 4:00 and 6:00 A.M. The circulating half-life of PRL is ~50 min.

PRL is unique among the pituitary hormones in that the predominant hypothalamic control mechanism is inhibitory, reflecting tonic dopamine-mediated suppression of PRL release. This regulatory pathway accounts for the spontaneous PRL hypersecretion that occurs with pituitary stalk section, often a consequence of head trauma or compressive mass lesions at the skull base. Pituitary dopamine type 2 (D_2) receptors mediate inhibition of PRL synthesis and secretion. Targeted disruption (gene knockout) of the murine D_2 receptor in mice results in hyperprolactinemia and lactotrope proliferation. As discussed below, dopamine agonists play a central role in the management of hyperprolactinemic disorders.

Thyrotropin-releasing hormone (TRH) (pyro Glu-His-Pro-NH_2) is a hypothalamic tripeptide that elicits PRL release within 15–30 min after intravenous injection. TRH primarily regulates TSH, and the physiologic relevance of TRH for PRL regulation is unclear **(Chap. 394)**.

Serum PRL levels rise transiently after exercise, meals, sexual intercourse, minor surgical procedures, general anesthesia, chest wall injury, acute myocardial infarction, and other forms of acute stress. PRL levels increase markedly (about tenfold) during pregnancy and

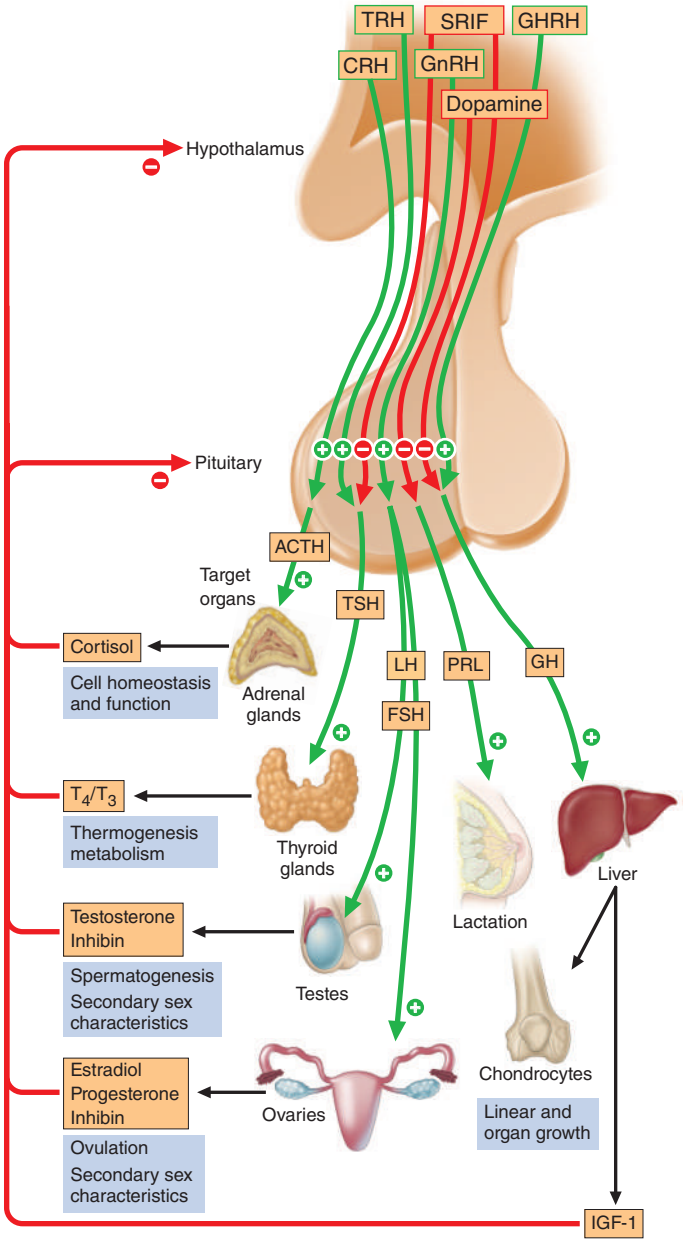

FIGURE 390-1 Diagram of pituitary axes. Hypothalamic hormones regulate anterior pituitary trophic hormones that in turn determine target gland secretion. Peripheral hormones feed back to negatively regulate hypothalamic and pituitary hormones. For abbreviations, see text.

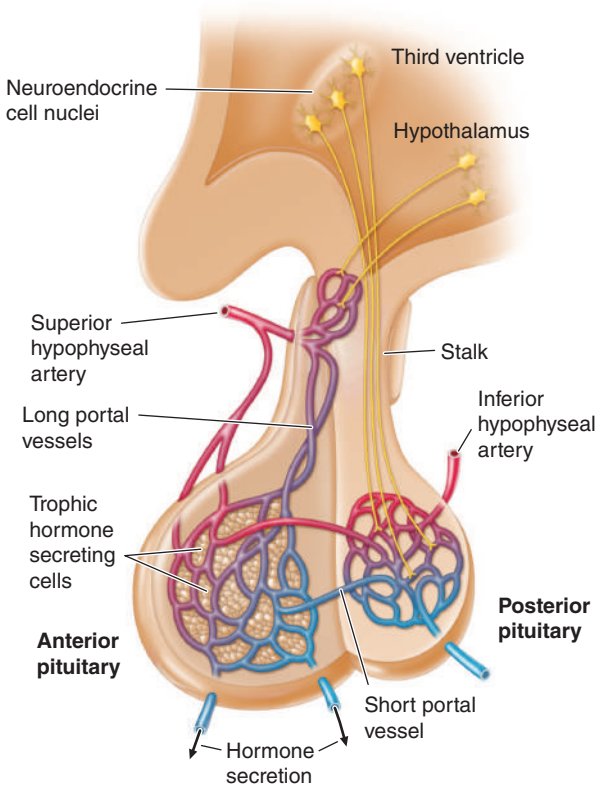

FIGURE 390-2 Diagram of hypothalamic-pituitary vasculature. The hypothalamic nuclei produce hormones that traverse the portal system and impinge on anterior pituitary cells to regulate pituitary hormone production. Posterior pituitary hormones are derived from direct neural extensions.

decline rapidly within 2 weeks of parturition. If breast-feeding is initiated, basal PRL levels remain elevated; suckling stimulates transient reflex increases in PRL levels that last for ~30–45 min. Breast suckling activates afferent neural pathways in the hypothalamus that induce PRL release. With time, suckling-induced responses diminish and interfeeding PRL levels return to normal.

Action The PRL receptor is a member of the type I cytokine receptor family that also includes GH and interleukin (IL) 6 receptors. Ligand binding induces receptor dimerization and intracellular signaling by Janus kinase (JAK), which stimulates translocation of the signal transduction and activators of transcription (STAT) family to activate target genes. Mutations of the PRL receptor result in PRL insensitivity, hyperprolactinemia, and oligomenorrhea. When homozygous, PRL receptor mutations cause agalactia, demonstrating that PRL action is necessary for lactation. In the breast, the lobuloalveolar epithelium proliferates in response to PRL, placental lactogens, estrogen, progesterone, and local paracrine growth factors, including insulin-like growth factor 1 (IGF-1).

PRL acts to induce and maintain lactation and to suppress both reproductive function and sexual drive. These functions are geared toward ensuring that maternal lactation is sustained and not interrupted by pregnancy. PRL inhibits reproductive function by suppressing hypothalamic gonadotropin-releasing hormone (GnRH) and pituitary gonadotropin secretion and by impairing gonadal steroidogenesis in both women and men. In the ovary, PRL blocks folliculogenesis and inhibits granulosa cell aromatase activity, leading to hypoestrogenism and anovulation. PRL also has a luteolytic effect, generating a shortened, or inadequate, luteal phase of the menstrual cycle. In men, attenuated LH secretion leads to low testosterone levels and decreased spermatogenesis. These hormonal changes decrease libido and reduce fertility in patients with hyperprolactinemia.

GROWTH HORMONE

Synthesis GH is the most abundant anterior pituitary hormone, and GH-secreting somatotrope cells constitute up to 50% of the total anterior pituitary cell population. Mammosomatotrope cells, which coexpress PRL with GH, can be identified by using double immunostaining techniques. Somatotrope development and GH transcription

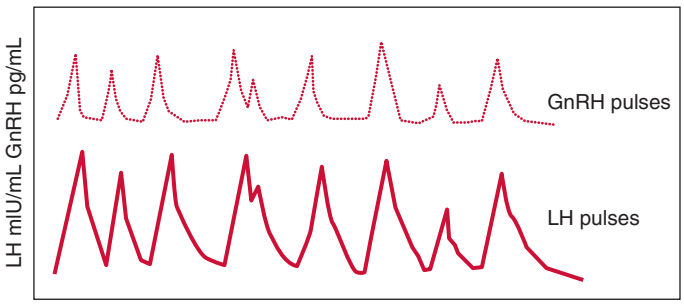

FIGURE 390-3 Hypothalamic gonadotropin-releasing hormone (GnRH) pulses induce secretory pulses of luteinizing hormone (LH).

are determined by expression of the cell-specific Pit-1 nuclear transcription factor. Five distinct genes encode GH and related proteins. The pituitary GH gene (*hGH-N*) produces two alternatively spliced products that give rise to 22-kDa GH (191 amino acids) and a less abundant 20-kDa GH molecule with similar biologic activity. Placental syncytiotrophoblast cells express a GH variant (*hGH-V*) gene; the related hormone human chorionic somatotropin (HCS) is expressed by distinct members of the gene cluster.

Secretion GH secretion is controlled by complex hypothalamic and peripheral factors. *GH-releasing hormone* (GHRH) is a 44-amino-acid hypothalamic peptide that stimulates GH synthesis and release. Ghrelin, an octanoylated gastric-derived peptide, and synthetic agonists of the *GHS-R* induce GHRH and also directly stimulate GH release. *Somatostatin* (somatotropin-release inhibiting factor [SRIF]) is synthesized in the medial preoptic area of the hypothalamus and inhibits GH secretion. GHRH is secreted in discrete spikes that elicit GH pulses, whereas SRIF sets basal GH secretory tone. SRIF also is expressed in many extrahypothalamic tissues, including the central nervous system (CNS), gastrointestinal tract, and pancreas, where it also acts to inhibit islet hormone secretion. *IGF-1*, the peripheral target hormone for GH, feeds back to inhibit GH; estrogen induces GH, whereas chronic glucocorticoid excess suppresses GH release, leading to growth delay in children.

Surface receptors on the somatotrope regulate GH synthesis and secretion. The GHRH receptor is a G protein–coupled receptor (GPCR) that signals through the intracellular cyclic AMP pathway to stimulate somatotrope cell proliferation as well as GH production. Inactivating mutations of the GHRH receptor cause profound growth deficiency (dwarfism). A distinct surface receptor for ghrelin, the gastric-derived GH secretagogue, is expressed in both the hypothalamus and pituitary. Somatostatin binds to five distinct receptor subtypes (SST1 to SST5); SST2 and SST5 subtypes preferentially suppress GH (and TSH) secretion, while SST5 predominantly suppresses ACTH secretion.

GH secretion is pulsatile, with highest peak levels occurring at night, generally correlating with sleep onset. GH secretory rates decline markedly with age so that hormone levels in middle age are ~15% of pubertal levels. These changes are paralleled by an age-related decline in lean muscle mass. GH secretion is also reduced in obese individuals, although IGF-1 levels may not be suppressed, suggesting a change in the setpoint for feedback control. Elevated GH levels occur within an hour of deep sleep onset as well as after exercise, physical stress, and trauma and during sepsis. Integrated 24-h GH secretion is higher in women and is also enhanced by estrogen replacement, likely reflective of increased peripheral GH resistance. Using standard assays, random GH measurements are undetectable in ~50% of daytime samples obtained from healthy subjects and are also undetectable (<1 μg/L) in most obese and elderly subjects. Thus, single random GH measurements do not distinguish patients with adult GH deficiency from those with GH levels in the normal range.

GH secretion is profoundly influenced by nutritional factors. Using ultrasensitive GH assays with a sensitivity of 0.002 μg/L, a glucose load suppresses GH to <0.7 μg/L in women and to <0.07 μg/L in men. Increased GH pulse frequency and peak amplitudes occur with chronic malnutrition or prolonged fasting. GH is stimulated by oral ghrelin receptor agonists, intravenous L-arginine, dopamine, and apomorphine (a dopamine receptor agonist), as well as by α-adrenergic pathways. β-Adrenergic blockade induces basal GH and enhances GHRH- and insulin-evoked GH release.

Action The pattern of GH secretion may affect tissue responses. The higher GH pulsatility observed in men compared with the relatively continuous basal GH secretion in women may be an important biologic determinant of linear growth patterns and liver enzyme induction.

The 70-kDa peripheral GH receptor protein has structural homology with the cytokine/hematopoietic superfamily. A fragment of the receptor extracellular domain generates a soluble GH binding protein (GHBP) that binds to circulating GH. The liver and cartilage express the greatest number of GH receptors. GH binding to preformed receptor dimers is followed by internal rotation and subsequent signaling through the JAK/STAT pathway. Activated STAT proteins translocate to the nucleus, where they modulate expression of GH-regulated target genes. GH analogues that bind to the receptor but are incapable of mediating receptor signaling are potent antagonists of GH action. A GH receptor antagonist (pegvisomant) is approved for treatment of acromegaly.

GH induces protein synthesis and nitrogen retention and also impairs glucose tolerance by antagonizing insulin action. GH also stimulates lipolysis, leading to increased circulating fatty acid levels, reduced omental fat mass, and enhanced lean body mass. GH promotes sodium, potassium, and water retention and elevates serum levels of inorganic phosphate. Linear bone growth occurs as a result of complex hormonal and growth factor actions, including those of IGF-1. GH stimulates epiphyseal prechondrocyte differentiation. These precursor cells produce IGF-1 locally, and their proliferation is also responsive to the growth factor.

Insulin-Like Growth Factors Although GH exerts direct effects in target tissues, many of its physiologic effects are mediated indirectly through IGF-1, a potent growth and differentiation factor. The liver is the major source of circulating IGF-1. In peripheral tissues, IGF-1 also exerts local paracrine actions that appear to be both dependent on and independent of GH. Thus, GH administration induces circulating IGF-1 as well as stimulating local IGF-1 production in multiple tissues.

Both IGF-1 and IGF-2 are bound to high-affinity circulating IGF-binding proteins (IGFBPs) that regulate IGF availability and bioactivity. Levels of IGFBP3 are GH dependent, and it serves as the major carrier protein for circulating IGF-1. GH deficiency and malnutrition usually are associated with low IGFBP3 levels. IGFBP1 and IGFBP2 regulate local tissue IGF action but do not bind appreciable amounts of circulating IGF-1.

Serum IGF-1 concentrations are profoundly affected by physiologic factors. Levels increase during puberty, peak at 16 years, and subsequently decline by >80% during the aging process. IGF-1 concentrations are higher in women than in men. Because GH is the major determinant of hepatic IGF-1 synthesis, abnormalities of GH synthesis or action (including pituitary failure, GHRH receptor defect, GH receptor defect, or pharmacologic GH receptor blockade) lead to reduced IGF-1 levels. Hypocaloric states are associated with GH resistance; IGF-1 levels are therefore low with cachexia, malnutrition, and sepsis. In acromegaly, IGF-1 levels are high and reflect a log-linear relationship with circulating GH concentrations.

IGF-1 PHYSIOLOGY Injected IGF-1 (100 μg/kg) induces hypoglycemia, and lower doses improve insulin sensitivity in patients with severe insulin resistance and diabetes. In cachectic subjects, IGF-1 infusion (12 μg/kg per h) enhances nitrogen retention and lowers cholesterol levels. Longer-term subcutaneous IGF-1 injections enhance protein synthesis and are anabolic. Although bone formation markers are induced, bone turnover also may be stimulated by IGF-1. IGF-1 is approved for use in patients with GH-resistance syndromes.

IGF-1 side effects are dose dependent, and overdose may result in hypoglycemia, hypotension, fluid retention, temporomandibular jaw pain, and increased intracranial pressure, all of which are reversible. Retinal damage and avascular femoral head necrosis have been reported. Chronic excess IGF-1 administration presumably would result in features of acromegaly.

ADRENOCORTICOTROPIC HORMONE

(See also Chap. 398).

Synthesis ACTH-secreting corticotrope cells constitute ~20% of the pituitary cell population. ACTH (39 amino acids) is derived from the POMC precursor protein (266 amino acids) that also generates several other peptides, including β-lipotropin, β-endorphin, met-enkephalin, α-melanocyte-stimulating hormone (α-MSH), and corticotropin-like intermediate lobe protein (CLIP). The *POMC* gene is potently suppressed by glucocorticoids and induced by corticotropin-releasing

hormone (CRH), AVP, and proinflammatory cytokines, including IL-6, as well as leukemia inhibitory factor.

CRH, a 41-amino-acid hypothalamic peptide synthesized in the paraventricular nucleus as well as in higher brain centers, is the predominant stimulator of ACTH synthesis and release. The CRH receptor is a GPCR that is expressed on the corticotrope and signals to induce *POMC* transcription.

Secretion ACTH secretion is pulsatile and exhibits a characteristic circadian rhythm, peaking at about 6:00 A.M. and reaching a nadir about midnight. Adrenal glucocorticoid secretion, which is driven by ACTH, follows a parallel diurnal pattern. ACTH circadian rhythmicity is determined by variations in secretory pulse amplitude rather than changes in pulse frequency. Superimposed on this endogenous rhythm, ACTH levels are increased by physical and psychological stress, exercise, acute illness, and insulin-induced hypoglycemia.

Glucocorticoid-mediated negative regulation of the hypothalamic-pituitary-adrenal (HPA) axis occurs as a consequence of both hypothalamic CRH suppression and direct attenuation of pituitary *POMC* gene expression and ACTH release. In contrast, loss of cortisol feedback inhibition, as occurs in primary adrenal failure, results in extremely high ACTH levels.

Acute inflammatory or septic insults activate the HPA axis through the integrated actions of proinflammatory cytokines, bacterial toxins, and neural signals. The overlapping cascade of ACTH-inducing cytokines (tumor necrosis factor [TNF]; IL-1, -2, and -6; and leukemia inhibitory factor) activates hypothalamic CRH and AVP secretion, pituitary *POMC* gene expression, and local pituitary paracrine cytokine networks. The resulting cortisol elevation restrains the inflammatory response and enables host protection. Concomitantly, cytokine-mediated central glucocorticoid receptor resistance impairs glucocorticoid suppression of the HPA. Thus, the neuroendocrine stress response reflects the net result of highly integrated hypothalamic, intrapituitary, and peripheral hormone and cytokine signals acting to regulate cortisol secretion.

Action The major function of the HPA axis is to maintain metabolic homeostasis and mediate the neuroendocrine stress response, largely by inducing adrenal cortisol production. ACTH induces adrenocortical steroidogenesis by sustaining adrenal cell proliferation and function. The receptor for ACTH, designated *melanocortin-2 receptor*, is a GPCR that induces steroidogenesis by stimulating a cascade of steroidogenic enzymes **(Chap. 398)**.

GONADOTROPINS: FSH AND LH

Synthesis and Secretion Gonadotrope cells constitute ~10% of anterior pituitary cells and produce two gonadotropin hormones—LH and FSH. Like TSH and human chorionic gonadotropin, LH and FSH are glycoprotein hormones that contain α and β subunits. The α subunit is common to these glycoprotein hormones; specificity of hormone function is conferred by the β subunits, which are expressed by separate genes.

Gonadotropin synthesis and release are dynamically regulated. This is particularly true in women, in whom rapidly fluctuating gonadal steroid levels vary throughout the menstrual cycle. Hypothalamic GnRH, a 10-amino-acid peptide, regulates the synthesis and secretion of both LH and FSH. Brain kisspeptin, a product of the *KISS1* gene, regulates hypothalamic GnRH release. GnRH is secreted in discrete pulses every 60–120 min, and the pulses in turn elicit LH and FSH pulses (Fig. 390-3). The pulsatile mode of GnRH input is essential to its action; pulses prime gonadotrope responsiveness, whereas continuous GnRH exposure induces desensitization. Based on this phenomenon, long-acting GnRH agonists are used to suppress gonadotropin levels in children with precocious puberty and in men with prostate cancer **(Chap. 92)** and are used in some ovulation-induction protocols to reduce levels of endogenous gonadotropins **(Chap. 404)**. Estrogens act at both the hypothalamus and the pituitary to modulate gonadotropin secretion. Chronic estrogen exposure is inhibitory, whereas rising estrogen levels, as occur during the preovulatory surge, exert positive feedback to enhance pituitary responsiveness and to increase gonadotropin pulse frequency and amplitude. Progesterone slows GnRH pulse frequency but enhances gonadotropin responses to GnRH. Testosterone feedback in men also occurs at the hypothalamic and pituitary levels and is mediated in part by its conversion to estrogens.

Although GnRH is the main regulator of LH and FSH secretion, FSH synthesis is also under distinct control by the gonadal peptides inhibin and activin, members of the transforming growth factor β (TGF-β) family. Inhibin selectively suppresses FSH, whereas activin stimulates FSH synthesis **(Chap. 404)**.

Action The gonadotropin hormones interact with their respective GPCRs expressed in the ovary and testis, evoking germ cell development and maturation and steroid hormone biosynthesis. In women, FSH regulates ovarian follicle development and stimulates ovarian estrogen production. LH mediates ovulation and maintenance of the corpus luteum. In men, LH induces Leydig cell testosterone synthesis and secretion, and FSH stimulates seminiferous tubule development and regulates spermatogenesis.

THYROID-STIMULATING HORMONE

Synthesis and Secretion TSH-secreting thyrotrope cells constitute 5% of the anterior pituitary cell population. TSH shares a common α subunit with LH and FSH but contains a specific TSH β subunit. TRH is a hypothalamic tripeptide (pyroglutamyl histidylprolinamide) that acts through a pituitary GPCR to stimulate TSH synthesis and secretion; it also stimulates the lactotrope cell to secrete PRL. TSH secretion is stimulated by TRH, whereas thyroid hormones, dopamine, somatostatin, and glucocorticoids suppress TSH by overriding TRH induction. Thyroid hormones are the predominant negative regulator of TSH production.

Thyrotrope cell proliferation and TSH secretion are both induced when negative feedback inhibition by thyroid hormones is removed. Thus, thyroid damage (including surgical thyroidectomy), radiation-induced hypothyroidism, chronic thyroiditis, and prolonged goitrogen exposure are associated with increased TSH levels. Long-standing untreated hypothyroidism can lead to elevated TSH levels, which may be associated with thyrotrope hyperplasia and pituitary enlargement and may sometimes be evident on magnetic resonance imaging.

Action TSH is secreted in pulses, although the excursions are modest in comparison to other pituitary hormones because of the low amplitude of the pulses and the relatively long half-life of TSH. Consequently, single determinations of TSH suffice to precisely assess its circulating levels. TSH binds to a GPCR on thyroid follicular cells to stimulate thyroid hormone synthesis and release **(Chap. 394)**.

391 Hypopituitarism

Shlomo Melmed, J. Larry Jameson

Deficient production of anterior pituitary hormones leads to features of hypopituitarism. Impaired production of one or more of the anterior pituitary trophic hormones can result from inherited disorders; more commonly, adult hypopituitarism is acquired and reflects the compressive mass effects of tumors or the consequences of local pituitary or hypothalamic traumatic, autoimmune, inflammatory, or vascular damage. These processes also may impair synthesis or secretion of hypothalamic hormones, with resultant pituitary failure (Table 391-1).

DEVELOPMENTAL CAUSES OF HYPOPITUITARISM

Pituitary dysplasia may result in aplastic, hypoplastic, or ectopic pituitary gland development. Because pituitary development follows midline cell migration from the nasopharyngeal Rathke's pouch, midline craniofacial disorders may be associated with pituitary dysplasia. Acquired pituitary failure in the newborn also can be caused by birth trauma, including cranial hemorrhage, asphyxia, and breech delivery.

A large number (>50) of transcription factors and growth factors are critical for the development of the hypothalamus and pituitary gland and the function of differentiated anterior pituitary cell lineages. Mutations have been described in the *HESX1, SOX2, SOX3, LHX3, LHX4, OTX, GLI2, PAX6, BMP4, ARNT2, FGF8, FGFR1, SHH, PROKR2, GPR161, IGSF1, PITX2,* and *CHD7* genes, among others. Heterozygous loss-of-function or autosomal recessive mutations disrupt hypothalamic and pituitary development at different developmental stages, causing a wide array of phenotypes ranging from severe syndromic midline and other defects to combined pituitary hormone defects or isolated hormone deficiencies. Depending on the gene involved, the pituitary may be hypoplastic, hyperplastic, or ectopic. Midline defects include variable combinations of abnormal development of the eyes, corpus collosum, vertebrae, and genital systems. Pituitary dysfunction ranges from isolated hormone deficiency to combined pituitary hormone deficiency (CPHD) and arginine vasopressin deficiency (AVP-D).

In addition to these syndromic developmental disorders, some mutations affect specific pituitary cell lineages. For example, Pit-1 mutations cause combined growth hormone (GH), prolactin (PRL), and thyroid-stimulating hormone (TSH) deficiencies. These patients usually present with growth failure and varying degrees of hypothyroidism. The pituitary may appear hypoplastic on magnetic resonance imaging (MRI). Prop-1 is expressed early in pituitary development and appears to be required for Pit-1 function. Familial and sporadic *PROP1* mutations result in combined GH, PRL, TSH, and gonadotropin deficiency. Over 80% of these patients have growth retardation; by adulthood, all are deficient in TSH and gonadotropins, and a small minority later develop adrenocorticotropic hormone (ACTH) deficiency. Because of gonadotropin deficiency, these individuals do not enter puberty spontaneously. In some cases, the pituitary gland appears enlarged on MRI. *TPIT* mutations result in ACTH deficiency associated with hypocortisolism. Mutations in *NR5A1* (also known as steroidogenic factor 1 [*SF1*]) impair development of gonadotropes, as well as adrenal/gonadal development.

HYPOTHALAMIC ENDOCRINE DYSFUNCTION

Hypothalamic disorders can affect temperature regulation, appetite, sleep-wake cycles, autonomic systems, behavior, and memory, as well as multiple endocrine systems. Selected examples of hypothalamic disorders that affect the endocrine system are described below.

Kallmann Syndrome Kallmann syndrome results from defective hypothalamic gonadotropin-releasing hormone (GnRH) synthesis and is associated with anosmia or hyposmia due to olfactory bulb agenesis or hypoplasia (Chap. 403). Classically, the syndrome may also be associated with color blindness, optic atrophy, nerve deafness, cleft palate, renal abnormalities, cryptorchidism, and neurologic abnormalities such as mirror movements. The initial genetic cause was the X-linked *KAL* gene, mutations of which impair embryonic migration of GnRH neurons from the hypothalamic olfactory placode to the hypothalamus. Since then, more than a dozen additional genetic abnormalities, in addition to *KAL* mutations, have been found to cause isolated GnRH deficiency. Autosomal recessive (i.e., *GPR54, KISS1*) and dominant (i.e., *FGFR1*) modes of transmission have been described, and there is a growing list of genes associated with GnRH deficiency (including *GNRH1, PROK2, PROKR2, CHD7, PCSK1, FGF8, NELF, WDR11, TAC3, TACR3*, and *SEMA3E*). Some patients have oligogenic

[a]Trophic hormone failure associated with pituitary compression or destruction usually occurs sequentially: growth hormone > follicle-stimulating hormone > luteinizing hormone > thyroid-stimulating hormone > adrenocorticotropic hormone. During childhood, growth retardation is often the presenting feature, and in adults, hypogonadism is the earliest symptom.

Abbreviations: CTLA-4, cytotoxic T lymphocyte antigen 4; PD-1, programmed cell death protein 1; PD-L1, programmed cell death protein ligand 1.

mutations in which mutations in a combination of different genes lead to the phenotype. Associated clinical features, in addition to GnRH deficiency, vary depending on the genetic cause. GnRH deficiency prevents progression through puberty. Males present with delayed puberty and pronounced hypogonadal features, including micropenis, probably the result of low testosterone levels during infancy. Females present with primary amenorrhea and failure of secondary sexual development.

Kallmann syndrome and other causes of congenital GnRH deficiency are characterized by low luteinizing hormone (LH) and follicle-stimulating hormone (FSH) levels and low concentrations of sex steroids (testosterone or estradiol). In sporadic cases of isolated gonadotropin deficiency, the diagnosis is often one of exclusion after other known causes of hypothalamic-pituitary dysfunction have been eliminated. Repetitive GnRH administration restores normal pituitary gonadotropin responses, pointing to a hypothalamic defect in these patients.

Long-term treatment of males with human chorionic gonadotropin (hCG) or testosterone restores pubertal development and secondary sex characteristics; women can be treated with cyclic estrogen and progestin. Fertility may be restored by the administration of gonadotropins or by using a portable infusion pump to deliver subcutaneous, pulsatile GnRH.

Bardet-Biedl Syndrome This very rare genetically heterogeneous disorder is characterized by intellectual disability, renal abnormalities, obesity, and hexadactyly, brachydactyly, or syndactyly. Central AVP-D may or may not be associated. GnRH deficiency occurs in 75% of males and half of affected females. Retinal degeneration begins in early childhood, and most patients are blind by age 30. Numerous subtypes of Bardet-Biedl syndrome have been identified, with genetic linkage to at least nine different loci. Several of the loci encode genes involved in basal body cilia function, and this may account for the diverse clinical manifestations.

Leptin and Leptin Receptor Mutations Deficiencies of leptin or its receptor cause a broad spectrum of hypothalamic abnormalities, including hyperphagia, obesity, and central hypogonadism (Chap. 413). Decreased GnRH production in these patients results in attenuated pituitary FSH and LH synthesis and release.

Prader-Willi Syndrome This is a contiguous gene syndrome that results from deletion of the paternal copies of the imprinted *SNRPN* gene, the *NECDIN* gene, and possibly other genes on chromosome 15q. Prader-Willi syndrome is associated with hypogonadotropic hypogonadism, hyperphagia-obesity, chronic muscle hypotonia, intellectual disability, and adult-onset diabetes mellitus. Multiple somatic defects also involve the skull, eyes, ears, hands, and feet. Diminished hypothalamic oxytocin- and AVP-producing nuclei have been reported. Deficient GnRH synthesis is suggested by the observation that chronic GnRH treatment restores pituitary LH and FSH release.

■ ACQUIRED HYPOPITUITARISM

Hypopituitarism may be caused by accidental or neurosurgical trauma; vascular events such as apoplexy; pituitary or hypothalamic neoplasms, craniopharyngioma, lymphoma, or metastatic tumors; inflammatory disease such as lymphocytic hypophysitis; autoimmune hypophysitis associated with checkpoint inhibitor cancer immunotherapy; infiltrative disorders such as sarcoidosis, hemochromatosis (Chap. 426), and tuberculosis; or irradiation.

Patients with brain injury, including from contact sports trauma, motor vehicle accidents, explosive causes, subarachnoid hemorrhage, and irradiation, can experience transient or long-term hypopituitarism. These traumatic and vascular conditions likely account for about 5% of hypopituitarism, reflecting the growing prevalence and recognition of these disorders. Long-term periodic endocrine follow-up is indicated because hypothalamic or pituitary dysfunction will develop in 25–40% of these patients.

Hypothalamic Infiltration Disorders Sarcoidosis, histiocytosis X, amyloidosis, and hemochromatosis frequently involve both hypothalamic and pituitary neuronal and neurochemical tracts. Consequently, AVP-D is a common presentation, reported in half of patients with these disorders. Growth retardation is seen if attenuated GH secretion occurs before puberty. Hypogonadotropic hypogonadism and hyperprolactinemia are also common.

Inflammatory Lesions Pituitary damage and subsequent secretory dysfunction can be seen with chronic site infections such as tuberculosis, with opportunistic fungal infections associated with AIDS, and in tertiary syphilis. Other inflammatory processes, such as granulomas and sarcoidosis, should be considered in the differential diagnosis of imaging studies suggestive of a pituitary adenoma. These lesions may cause extensive hypothalamic and pituitary damage, leading to hormone deficiencies.

Cranial Irradiation Cranial irradiation may result in long-term hypothalamic and pituitary dysfunction, especially in children and adolescents, as they are more susceptible to damage after whole-brain or head and neck therapeutic irradiation. The development of subsequent hormonal abnormalities correlates strongly with irradiation dosage and the time interval after completion of radiotherapy. Up to two-thirds of patients ultimately develop hormone insufficiency after a median dose of 50 Gy (5000 rad) directed at the skull base. The development of hypopituitarism occurs over 5–15 years and usually reflects hypothalamic damage rather than primary destruction of pituitary cells. Although the pattern of hormone loss is variable, GH deficiency is most common, followed by gonadotropin, TSH, and ACTH deficiency. When deficiency of one or more hormones is documented, the possibility of diminished reserve of other hormones is likely. Accordingly, anterior pituitary function should be continually evaluated over the long term in previously irradiated patients, and replacement therapy instituted when appropriate (see below).

Lymphocytic Hypophysitis This occurs most often in postpartum women; it usually presents with hyperprolactinemia and MRI evidence of a prominent pituitary mass that often resembles an adenoma, with mildly elevated PRL levels. Pituitary failure caused by diffuse lymphocytic infiltration may be transient or permanent but requires immediate evaluation and treatment. Rarely, isolated pituitary hormone deficiencies have been described, suggesting a selective autoimmune process targeted to specific cell types. Most patients manifest symptoms of progressive mass effects with headache and visual disturbance. The erythrocyte sedimentation rate often is elevated. Because it may be indistinguishable from a pituitary adenoma on MRI, hypophysitis should be considered in a postpartum woman with a newly diagnosed pituitary mass before an unnecessary surgical intervention is undertaken. The inflammatory process often resolves after several months of glucocorticoid treatment, and pituitary function may be restored, depending on the extent of damage.

Immunotherapy and Hypophysitis Pituitary cells express cytotoxic T lymphocyte antigen-4 (CTLA-4), and up to 20% of patients receiving cancer immunotherapy with CTLA-4 inhibitors (e.g., ipilimumab) may develop hypophysitis with heterogeneously associated thyroid, adrenal, islet, and gonadal failure. Hypophysitis is also reported with PD-1/PD-L1 inhibitors (e.g., pembrolizumab and nivolumab) and may show delayed presentation. HLA type DQ0602 is associated with checkpoint inhibitor–associated hypophysitis in 39% of such patients. Pituitary hormone replacement, with or without high-dose glucocorticoids, may be safely tolerated with continued immunotherapy.

Pituitary Apoplexy Acute intrapituitary hemorrhagic vascular events can cause substantial damage to the pituitary and surrounding sellar structures. Pituitary apoplexy may occur spontaneously in a preexisting pituitary adenoma; postpartum (Sheehan's syndrome); or in association with diabetes, hypertension, sickle cell anemia, or acute shock. The hyperplastic enlargement of the pituitary, which occurs normally during pregnancy, increases the risk for hemorrhage and infarction. Apoplexy is an endocrine emergency that may result in severe hypoglycemia, hypotension and shock, central nervous system

(CNS) hemorrhage, and death. Acute symptoms may include severe headache with signs of meningeal irritation, bilateral visual changes, ophthalmoplegia, and, in severe cases, cardiovascular collapse and loss of consciousness. Pituitary computed tomography (CT) or MRI may reveal signs of intratumoral or sellar hemorrhage, with pituitary stalk deviation and compression of pituitary tissue.

Patients with no evident visual loss or impaired consciousness can be observed and managed conservatively with high-dose glucocorticoids. Those with significant or progressive visual loss, cranial nerve palsy, or loss of consciousness require urgent surgical decompression. Visual recovery after sellar surgery is inversely correlated with the length of time after the acute event. Therefore, severe ophthalmoplegia or visual deficits are indications for early surgery. Hypopituitarism is common after apoplexy.

Empty Sella A partial or apparently totally empty sella is often an incidental MRI finding and may sometimes be associated with intracranial hypertension. These patients usually have normal pituitary function, implying that the surrounding rim of pituitary tissue is fully functional. Hypopituitarism, however, may develop insidiously. Pituitary adenomas also may undergo clinically silent infarction and involution with development of a partial or totally empty sella by cerebrospinal fluid (CSF) filling the dural herniation. Rarely, small but functional pituitary adenomas may arise within the rim of normal pituitary tissue, and they are not always visible on MRI.

PRESENTATION AND DIAGNOSIS

The clinical manifestations of hypopituitarism depend on which hormones are lost and the extent of the hormone deficiency (see below). GH deficiency causes growth disorders in children and leads to abnormal body composition in adults. Gonadotropin deficiency causes menstrual disorders and infertility in women and decreased sexual function, infertility, and loss of secondary sexual characteristics in men. TSH and ACTH deficiencies usually develop later in the course of pituitary failure. TSH deficiency causes growth retardation in children and features of hypothyroidism in children and adults. Secondary adrenal insufficiency caused by ACTH deficiency leads to hypocortisolism with relative preservation of mineralocorticoid production. PRL deficiency causes failure of lactation. When lesions involve the posterior pituitary, polyuria and polydipsia reflect loss of AVP secretion. In patients with long-standing pituitary damage, epidemiologic studies document an increased mortality rate, primarily from increased cardiovascular and cerebrovascular disease. Previous head or neck irradiation is also a determinant of increased mortality rates in patients with hypopituitarism, especially from cerebrovascular disease.

LABORATORY INVESTIGATION

Biochemical diagnosis of pituitary insufficiency is made by demonstrating low levels of respective pituitary trophic hormones in the setting of low levels of target organ hormones. For example, low free thyroxine in the setting of a low or inappropriately normal TSH level suggests secondary hypothyroidism. Similarly, a low testosterone level without elevation of gonadotropins suggests hypogonadotropic hypogonadism. Provocative tests may be required to assess pituitary reserve **(Table 391-2)**. GH responses to insulin-induced hypoglycemia, arginine, glucagon, L-dopa, growth hormone–releasing hormone (GHRH), or growth hormone–releasing orally active ghrelin receptor agonist macimorelin can be used to assess GH reserve. Corticotropin-releasing hormone (CRH) administration induces ACTH release, and administration of synthetic ACTH (cosyntropin) evokes adrenal cortisol release as an indirect indicator of pituitary ACTH reserve **(Chap. 398)**. ACTH reserve is most reliably assessed by measuring ACTH and cortisol levels during insulin-induced hypoglycemia. However, this test should be performed cautiously in patients with suspected adrenal insufficiency because of enhanced susceptibility to hypoglycemia and hypotension. Administering insulin to induce hypoglycemia is contraindicated in patients with active coronary artery disease or known seizure disorders.

TREATMENT

Hypopituitarism

Hormone replacement therapy, including glucocorticoids, thyroid hormone, sex steroids, GH, and AVP, is usually safe and free of complications. Treatment regimens that mimic physiologic hormone production allow for maintenance of satisfactory clinical homeostasis. Effective dosage schedules are outlined in **Table 391-3**. Patients in need of glucocorticoid replacement require especially careful dose adjustments during stressful events such as acute illness, dental procedures, trauma, and hospitalization.

DISORDERS OF GROWTH AND DEVELOPMENT

Skeletal Maturation and Somatic Growth The growth plate is dependent on a variety of hormonal stimuli, including GH, insulin-like growth factor (IGF)-1, sex steroids, thyroid hormones, paracrine and circulating growth factors (e.g., fibroblast growth factor family), and cytokines. The growth-promoting process also requires caloric energy, amino acids, vitamins, and trace metals and consumes ~10% of normal energy production. Malnutrition impairs chondrocyte activity, increases GH resistance, and leads to reduced circulating IGF-1 and IGF binding protein (IGFBP)-3 levels.

Linear bone growth rates are very high in infancy and are pituitary dependent. Mean growth velocity is ~6 cm/year in later childhood and usually is maintained within a given range on a standardized percentile chart. Peak growth rates occur during midpuberty when bone age is 12 (girls) or 13 (boys). Secondary sexual development is associated with elevated sex steroids that cause progressive epiphyseal growth plate closure. *Bone age* is delayed in patients with all forms of true GH deficiency or GH receptor defects that result in attenuated GH action.

Short stature may occur as a result of constitutive intrinsic growth defects or because of acquired extrinsic factors that impair growth. In general, delayed bone age in a child with short stature is suggestive of a hormonal or systemic disorder, whereas normal bone age in a short child is more likely to be caused by a genetic cartilage dysplasia or growth plate disorder **(Chap. 425)**.

GH Deficiency in Children Isolated GH deficiency is characterized by short stature, micropenis, increased fat, high-pitched voice, and a propensity to hypoglycemia due to relatively unopposed insulin action. Familial modes of inheritance are seen in at least one-third of these individuals and may be autosomal dominant, recessive, or X-linked. About 10% of children with GH deficiency have mutations in the *GH-N* gene, including gene deletions and a wide range of point mutations. Mutations in transcription factors Pit-1 and Prop-1, which control somatotrope development (see above), result in GH deficiency in combination with other pituitary hormone deficiencies, which may become manifest only in adulthood. The diagnosis of *idiopathic GH deficiency* should be made only after known molecular defects have been rigorously excluded.

GHRH RECEPTOR MUTATIONS Recessive mutations of the GHRH receptor gene in subjects with severe proportionate dwarfism are associated with low basal GH levels that cannot be stimulated by exogenous GHRH, GH-releasing peptide, or insulin-induced hypoglycemia, as well as anterior pituitary hypoplasia. The syndrome exemplifies the importance of the GHRH receptor for determining somatotrope proliferation and hormonal responsiveness.

GH INSENSITIVITY This is caused by defects of GH receptor structure or signaling. Homozygous or heterozygous mutations of the GH receptor are associated with partial or complete GH insensitivity and growth failure (*Laron syndrome*). The diagnosis is based on normal or high GH levels, with decreased circulating GH-binding protein (GHBP), and low IGF-1 levels. Very rarely, defective IGF-1, IGF-1 receptor, or IGF-1 signaling defects are also encountered. *STAT5B* mutations result in both immunodeficiency as well as abrogated GH signaling, leading to short stature with normal or elevated GH levels and low IGF-1 levels. Circulating GH receptor antibodies may rarely cause peripheral GH insensitivity.

TABLE 391-2 Tests of Pituitary Sufficiency

HORMONE	TEST	BLOOD SAMPLES	INTERPRETATION
GH	Insulin tolerance test: Regular insulin (0.05–0.15 U/kg IV)	–30, 0, 30, 60, 120 min for glucose and GH	Glucose <40 mg/dL; GH should be >3 μg/L
	GHRH/L-arginine test: GHRH 1 μg/kg IV and arginine 30 g IV over 30 min	0, 15, 30, 45, 60, 120 min for GH	Normal GH response is BMI dependent: 11 μg/L if BMI <25 kg/m^2, 8 μg/L if BMI 25-20, and 4 μg/L if BMI ≥30 Not available in the United States
	Ghrelin receptor agonist test: 0.5 mg/kg PO	0, 30, 45, 60, 90 min for GH	Normal response is GH >2.8 μg/L
	Glucagon test: 1 mg IM (1.5 mg if body weight >90 kg)	0, 30, 60, 90, 120, 150, 180, 210, 240 for GH	Normal response is GH >3.0 μg/L if BMI <25 kg/m^2 or if BMI 25-30 and low pretest probability, and GH >1.0 μg/L if BMI 25-30 and high pretest probability or if BMI >30
	L-Dopa test: 500 mg PO	0, 30, 60, 120 min for GH	Normal response is GH >3 μg/L
PRL	TRH test: 200–500 μg IV	0, 20, and 60 min for TSH and PRL	Normal PRL is >2 μg/L and increase >200% of baseline
ACTH	Insulin tolerance test: Regular insulin (0.05–0.15 U/kg IV)	–30, 0, 30, 60, 90 min for glucose and cortisol	Glucose <40 mg/dL Cortisol should increase by >7 μg/dL or to >20 μg/dL
	CRH test: 1 μg/kg CRH IV at 8 A.M.	0, 15, 30, 60, 90, 120 min for ACTH and cortisol	Basal ACTH increases 2- to 4-fold and peaks at 20–100 pg/mL Cortisol levels >20–25 μg/dL
	Metyrapone test: Metyrapone (30 mg/kg) at midnight	Plasma 11-deoxycortisol and cortisol at 8 A.M.; ACTH can also be measured	Plasma cortisol should be <4 g/dL to assure an adequate response Normal response is 11-deoxycortisol >7.5 μg/dL or ACTH >75 pg/mL
	Standard ACTH stimulation test: ACTH 1-24 (cosyntropin), 0.25 mg IM or IV	0, 30, 60 min for cortisol and aldosterone	Normal response is cortisol >21 μg/dL and aldosterone response >4 ng/dL above baseline
	Low-dose ACTH test: ACTH 1-24 (cosyntropin), 1 μg IV	0, 30, 60 min for cortisol	Cortisol should be >21 μg/dL
	3-day ACTH stimulation test consists of 0.25 mg ACTH 1-24 given IV over 8 h each day		Cortisol >21 μg/dL
TSH	Basal thyroid function tests: T_4, T_3, TSH	Basal measurements	Low free thyroid hormone levels in the setting of TSH levels that are not appropriately increased indicate pituitary insufficiency
	TRH test: 200–500 μg IV	0, 20, 60 min for TSH and PRL[a]	TSH should increase by >5 mU/L unless thyroid hormone levels are increased
LH, FSH	LH, FSH, testosterone, estrogen	Basal measurements	Basal LH and FSH should be increased in postmenopausal women Low testosterone levels in the setting of low LH and FSH indicate pituitary insufficiency
	GnRH test: GnRH (100 μg) IV	0, 30, 60 min for LH and FSH	In most adults, LH should increase by 10 IU/L and FSH by 2 IU/L Normal responses are variable
Multiple hormones	Combined anterior pituitary test: GHRH (1 μg/kg), CRH (1 μg/kg), GnRH (100 μg), TRH (200 μg) are given IV	–30, 0, 15, 30, 60, 90, 120 min for GH, ACTH, cortisol, LH, FSH, and TSH	Combined or individual releasing hormone responses must be elevated in the context of basal target gland hormone values and may not be uniformly diagnostic (see text)

[a]Evoked PRL response indicates lactotrope integrity.

Abbreviations: T_3, triiodothyronine; T_4, thyroxine; TRH, thyrotropin-releasing hormone. For other abbreviations, see text.

NUTRITIONAL SHORT STATURE Caloric deprivation and malnutrition, uncontrolled diabetes, and chronic renal failure represent secondary causes of abrogated GH receptor function. These conditions also stimulate production of proinflammatory cytokines, which act to exacerbate the block of GH-mediated signal transduction. Children with these conditions typically exhibit features of acquired short stature with normal or elevated GH and low IGF-1 levels.

PSYCHOSOCIAL SHORT STATURE Emotional and social deprivation lead to growth retardation accompanied by delayed speech, discordant hyperphagia, and an attenuated response to administered GH. A nurturing environment restores growth rates.

PRESENTATION AND DIAGNOSIS

Short stature is commonly encountered in clinical practice, and the decision to evaluate these children requires clinical judgment in association with auxologic data and family history. Short stature should be evaluated comprehensively if a patient's height is >3 standard deviations below the mean for age or if the growth rate has decelerated. Skeletal maturation is best evaluated by measuring a radiologic bone age, which is based mainly on the degree of wrist bone growth plate fusion. Final height can be predicted using standardized scales (Bayley-Pinneau or Tanner-Whitehouse) or estimated by adding 6.5 cm (boys) or subtracting 6.5 cm (girls) from the midparental height.

LABORATORY INVESTIGATION

Because GH secretion is pulsatile, GH deficiency is best assessed by examining the response to provocative stimuli, including exercise, insulin-induced hypoglycemia, and other pharmacologic tests that normally increase GH to >7 μg/L in children. Random GH measurements do not distinguish children with normal GH levels from those with true GH deficiency. Adequate adrenal and thyroid hormone replacement should be assured before testing. Age-matched IGF-1 levels are not sufficiently sensitive or specific to make the diagnosis but can be useful to confirm GH deficiency. Pituitary MRI may reveal pituitary mass lesions or structural defects. Molecular analyses for known mutations should be undertaken when the cause of short stature remains cryptic or when additional clinical features suggest a genetic cause.

TABLE 391-3 Hormone Replacement Therapy for Adult Hypopituitarism[a]

HORMONE DEFICIT	HORMONE REPLACEMENT
ACTH	Hydrocortisone (10–20 mg/d in divided doses)
	Cortisone acetate (15–25 mg/d in divided doses)
	Prednisone (5 mg A.M.)
TSH	L-Thyroxine (0.075–0.15 mg daily)
FSH/LH	Males
	Testosterone gel (5–10 g/d)
	Testosterone skin patch (5 mg/d)
	Testosterone enanthate (200 mg IM every 2 weeks)
	Females
	Conjugated estrogen (0.65–1.25 mg qd for 25 days)
	Progesterone (5–10 mg qd) on days 16–25
	Estradiol skin patch (0.025–0.1 mg every week), adding progesterone on days 16–25 if uterus intact
	For fertility: menopausal gonadotropins, human chorionic gonadotropins
GH	Adults: Somatotropin (0.1–1.25 mg SC qd)
	Children: Somatotropin (0.02–0.05 mg/kg per day)
AVP	Intranasal desmopressin (5–20 g twice daily)
	Oral 300–600 μg qd

[a]All doses shown should be individualized for specific patients and should be reassessed during stress, surgery, or pregnancy. Male and female fertility requirements should be managed as discussed in **Chaps. 403** and **404**.

Note: For abbreviations, see text.

TABLE 391-4 Features of Adult Growth Hormone Deficiency

Clinical
Impaired quality of life
Decreased energy and drive
Poor concentration
Low self-esteem
Social isolation
Body composition changes
Increased body fat mass
Central fat deposition
Increased waist-to-hip ratio
Decreased lean body mass
Reduced exercise capacity
Reduced maximum O_2 uptake
Impaired cardiac function
Reduced muscle mass
Cardiovascular risk factors
Impaired cardiac structure and function
Abnormal lipid profile
Decreased fibrinolytic activity
Atherosclerosis
Omental obesity
Imaging
Pituitary: mass or structural damage
Bone: reduced bone mineral density
Abdomen: excess omental adiposity
Laboratory
Evoked GH <3 ng/mL
IGF-1 and IGFBP-3 low or normal
Increased LDL cholesterol
Concomitant gonadotropin, TSH, and/or ACTH reserve deficits may be present

Abbreviation: LDL, low-density lipoprotein. For other abbreviations, see text.

TREATMENT

Disorders of Growth and Development

Replacement therapy with recombinant GH (0.02–0.05 mg/kg per day SC) restores growth velocity in GH-deficient children to ~10 cm/year. If pituitary insufficiency is documented, other associated hormone deficits should be corrected, especially adrenal steroids. In selected situations, GH treatment may be combined with strategies to delay puberty (e.g., GnRH agonist) or reduce sex steroids (e.g., aromatase inhibitors) as a means to mitigate sex steroid effect on epiphyseal closure. GH treatment is also moderately effective for accelerating growth rates in children with Turner syndrome and chronic renal failure. Treating psychosocial or constitutional (idiopathic) short stature with GH is not uniformly recommended as these children may only experience modest additive growth, which should be weighed against GH cost and side effect profiles.

In patients with GH insensitivity and growth retardation due to mutations of the GH receptor, treatment with IGF-1 bypasses the dysfunctional GH receptor.

ADULT GH DEFICIENCY

Adult GH deficiency (AGHD) usually is caused by acquired hypothalamic or pituitary somatotrope damage. Acquired pituitary hormone deficiency follows a typical pattern in which loss of adequate GH reserve foreshadows subsequent hormone deficits. The sequential order of hormone loss is usually GH → FSH/LH → TSH → ACTH. Patients previously diagnosed with childhood-onset GH deficiency should be retested as adults to affirm the diagnosis.

PRESENTATION AND DIAGNOSIS

The clinical features of AGHD include changes in body composition, lipid metabolism, and quality of life as well as cardiovascular dysfunction **(Table 391-4)**. Body composition changes are common and include reduced lean body mass, increased fat mass with selective deposition of intraabdominal visceral fat, and increased waist-to-hip ratio. Hyperlipidemia, left ventricular dysfunction, hypertension, and increased plasma fibrinogen levels also may be present. Bone mineral content is reduced, with resultant increased fracture rates. Patients may experience social isolation, depression, and difficulty maintaining gainful employment. Adult hypopituitarism is associated with a threefold increase in cardiovascular mortality rates in comparison to age- and sex-matched controls, and this may be due to GH deficiency, as patients in these studies were replaced with other deficient pituitary hormones.

LABORATORY INVESTIGATION

AGHD is rare, and in light of the nonspecific nature of associated clinical symptoms, patients appropriate for testing should be selected carefully on the basis of well-defined criteria. With few exceptions, testing should be restricted to patients with the following predisposing factors: (1) pituitary surgery, (2) pituitary or hypothalamic tumor or granulomas, (3) history of cranial irradiation, (4) radiologic evidence of a pituitary lesion, and (5) childhood requirement for GH replacement therapy. The transition of a GH-deficient adolescent to adulthood requires retesting to document subsequent AGHD. Up to 20% of patients previously treated for childhood-onset GH deficiency are found to be GH sufficient on repeat testing as adults.

A significant proportion (~25%) of truly GH-deficient adults have low-normal IGF-1 levels. Thus, as in the evaluation of GH deficiency in children, valid age-matched IGF-1 measurements provide a useful index of therapeutic responses but are not sufficiently precise for diagnostic purposes. The most validated test to distinguish pituitary-sufficient patients from those with AGHD is insulin-induced (0.05–0.1 U/kg) hypoglycemia. After glucose reduction to ~40 mg/dL, most individuals experience neuroglycopenic symptoms **(Chap. 418)**, and peak GH release occurs at 60 min and remains elevated for up to 2 h. About 90% of healthy adults exhibit GH responses >5 μg/L; AGHD is defined by a peak GH response to hypoglycemia of <3 μg/L. Although insulin-induced hypoglycemia is safe when performed under appropriate

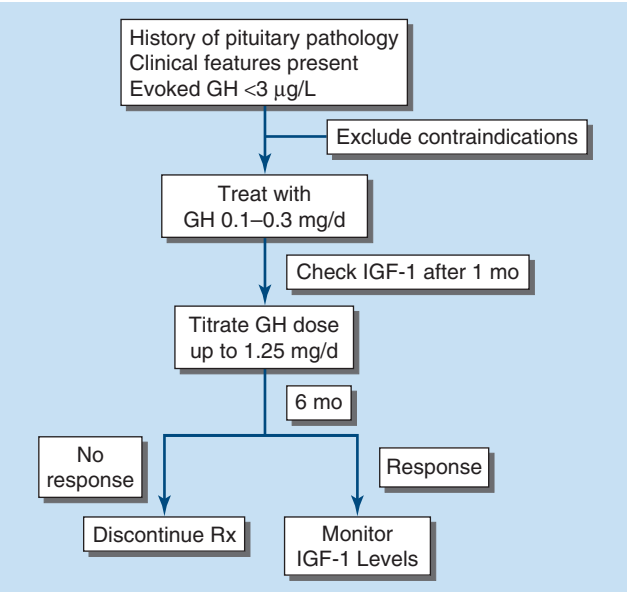

FIGURE 391-1 Management of adult growth hormone (GH) deficiency. IGF, insulin-like growth factor; Rx, treatment.

supervision, it is contraindicated in patients with diabetes, ischemic heart disease, cerebrovascular disease, or epilepsy and in elderly patients. Alternative stimulatory tests include intravenous arginine (30 g), GHRH (1 μg/kg), oral ghrelin receptor agonist (0.5 mg/kg), and glucagon (1 mg). Combinations of these tests may evoke GH secretion in subjects who are not responsive to a single test.

TREATMENT

Adult GH Deficiency

Once the diagnosis of AGHD is unequivocally established, replacement of GH may be indicated. Contraindications to therapy include the presence of an active neoplasm, intracranial hypertension, and uncontrolled diabetes and retinopathy. The starting adult dose of 0.1–0.2 mg/d should be titrated (up to a maximum of 1.25 mg/d) to maintain IGF-1 levels in the mid-normal range for age- and sex-matched controls **(Fig. 391-1)**. Women require higher doses than men, and elderly patients require less GH. Long-term GH maintenance sustains normal IGF-1 levels and is associated with persistent body composition changes (e.g., enhanced lean body mass and lower body fat). High-density lipoprotein cholesterol increases, but total cholesterol and insulin levels may not change significantly. Lumbar spine bone mineral density increases, but this response is gradual (>1 year). Many patients note significant improvement in quality of life when evaluated by standardized questionnaires. The effect of GH replacement on mortality rates in GH-deficient patients is currently the subject of long-term prospective investigation. Recently approved long-acting GH preparations for patients with AGHD require weekly injections. Ideally, dosing should be titrated to achieve normal but not supra-normal IGF-1 levels. Early reports indicate that side effects appear similar to subcutaneous formulations.

About 30% of patients exhibit reversible dose-related fluid retention, joint pain, and carpal tunnel syndrome, and up to 40% exhibit myalgias and paresthesia. Patients receiving insulin require careful monitoring for dosing adjustments, as GH is a potent counterregulatory hormone for insulin action. Patients with type 2 diabetes mellitus may initially develop further insulin resistance. However, glycemic control usually improves with the sustained loss of abdominal fat associated with long-term GH replacement. Headache, increased intracranial pressure, hypertension, and tinnitus occur rarely. Pituitary tumor regrowth and progression of skin lesions or other tumors have not been encountered in long-term surveillance programs with appropriate replacement doses.

ACTH DEFICIENCY

PRESENTATION AND DIAGNOSIS

Secondary adrenal insufficiency occurs as a result of pituitary ACTH deficiency. It is characterized by fatigue, weakness, anorexia, nausea, vomiting, and, occasionally, hypoglycemia. In contrast to primary adrenal failure, hypocortisolism associated with pituitary failure usually is not accompanied by hyperpigmentation or mineralocorticoid deficiency.

ACTH deficiency is commonly due to glucocorticoid withdrawal after treatment-associated suppression of the hypothalamic-pituitary-adrenal (HPA) axis. Isolated ACTH deficiency may occur after surgical resection of an ACTH-secreting pituitary adenoma that has suppressed the HPA axis; this phenomenon is in fact suggestive of a surgical cure. The mass effects of other pituitary adenomas or sellar lesions may lead to ACTH deficiency, usually in combination with other pituitary hormone deficiencies. Partial ACTH deficiency may be unmasked in the presence of an acute medical or surgical illness, when clinically significant hypocortisolism reflects diminished ACTH reserve. Rarely, *TPIT* or *POMC* mutations result in primary ACTH deficiency.

LABORATORY DIAGNOSIS

Inappropriately low ACTH levels in the setting of low cortisol levels are characteristic of diminished ACTH reserve. Low basal serum cortisol levels are associated with blunted cortisol responses to ACTH stimulation and impaired cortisol response to insulin-induced hypoglycemia or testing with metyrapone or CRH. **For a description of provocative ACTH tests, see Chap. 398.**

TREATMENT

ACTH Deficiency

Glucocorticoid replacement therapy improves most features of ACTH deficiency. The total daily dose of hydrocortisone replacement preferably should not exceed 20 mg daily, divided into two or three doses. Prednisone (5 mg each morning) is longer acting and has fewer mineralocorticoid effects than hydrocortisone. Some authorities advocate lower maintenance doses in an effort to avoid cushingoid side effects. Doses should be increased severalfold during periods of acute illness or stress. Patients should wear medical alert bracelets and/or carry identification cards with information about their glucocorticoid requirements.

GONADOTROPIN DEFICIENCY

Hypogonadism is the most common presenting feature of adult hypopituitarism even when other pituitary hormones are also deficient. It is often a harbinger of hypothalamic or pituitary lesions that impair GnRH production or delivery through the pituitary stalk. As noted below, hypogonadotropic hypogonadism is a common presenting feature of hyperprolactinemia.

A variety of inherited and acquired disorders are associated with *isolated hypogonadotropic hypogonadism* **(Chap. 403)**. Hypothalamic defects associated with GnRH deficiency include Kallmann syndrome and mutations in more than a dozen genes that regulate GnRH neuron migration, development, and function (see above). Mutations in *GPR54, DAX1, NR5A1*, kisspeptin, the GnRH receptor, and the LHβ or FSHβ subunit genes also cause pituitary gonadotropin deficiency. Acquired forms of GnRH deficiency leading to hypogonadotropism are seen in association with anorexia nervosa, stress, starvation, and extreme exercise but also may be idiopathic. Hypogonadotropic hypogonadism in these disorders is reversed by removal of the stressful stimulus or by caloric replenishment.

PRESENTATION AND DIAGNOSIS

In premenopausal women, hypogonadotropic hypogonadism presents as diminished ovarian function leading to oligomenorrhea or amenorrhea, infertility, decreased vaginal secretions, decreased libido, and breast atrophy. In hypogonadal adult men, secondary testicular failure

is associated with decreased libido and potency, infertility, decreased muscle mass with weakness, reduced beard and body hair growth, soft testes, and characteristic fine facial wrinkles. Osteoporosis occurs in both untreated hypogonadal women and men.

LABORATORY INVESTIGATION

Central hypogonadism is associated with low or inappropriately normal serum gonadotropin levels in the setting of low sex hormone concentrations (testosterone in men, estradiol in women). Because gonadotropin secretion is pulsatile, valid assessments may require repeated measurements or the use of pooled serum samples. Men have reduced sperm counts.

Intravenous GnRH (100 μg) stimulates gonadotropes to secrete LH (which peaks within 30 min) and FSH (which plateaus during the ensuing 60 min). Normal responses vary according to menstrual cycle stage, age, and sex of the patient. Generally, LH levels increase about threefold, whereas FSH responses are less pronounced. In the setting of gonadotropin deficiency, a normal gonadotropin response to GnRH indicates intact pituitary gonadotrope function and suggests a hypothalamic abnormality. An absent response, however, does not reliably distinguish pituitary from hypothalamic causes of hypogonadism. For this reason, GnRH testing usually adds little to the information gained from baseline evaluation of the hypothalamic-pituitary-gonadotrope axis except in cases of isolated GnRH deficiency (e.g., Kallmann syndrome).

MRI examination of the sellar region and assessment of other pituitary functions usually are indicated in patients with documented central hypogonadism.

TREATMENT

Gonadotropin Deficiency

In males, testosterone replacement is necessary to achieve and maintain normal growth and development of the external genitalia, secondary sex characteristics, male sexual behavior, and androgenic anabolic effects, including maintenance of muscle function and bone mass. Testosterone may be administered by intramuscular injections every 1–4 weeks or by using skin patches or testosterone gels **(Chap. 403)**. Gonadotropin injections (hCG or human menopausal gonadotropin [hMG]) over 12–18 months are used to restore fertility. Pulsatile GnRH therapy (25–150 ng/kg every 2 h), administered by a subcutaneous infusion pump, is also effective for treatment of hypothalamic hypogonadism when fertility is desired.

In premenopausal women, cyclical replacement of estrogen and progesterone maintains secondary sexual characteristics and integrity of genitourinary tract mucosa and prevents premature osteoporosis **(Chap. 404)**. Gonadotropin therapy is used for ovulation induction. Follicular growth and maturation are initiated using hMG or recombinant FSH; hCG or human luteinizing hormone is subsequently injected to induce ovulation. As in men, pulsatile GnRH therapy can be used to treat hypothalamic causes of gonadotropin deficiency.

ARGININE VASOPRESSIN DEFICIENCY

See Chap. 393 for diagnosis and treatment of AVP-D.

Shlomo Melmed, J. Larry Jameson

HYPOTHALAMIC, PITUITARY, AND OTHER SELLAR MASSES

EVALUATION OF SELLAR MASSES

Local Mass Effects Clinical manifestations of sellar lesions vary, depending on the anatomic location of the mass and the direction of its extension **(Table 392-1)**. The dorsal sellar diaphragm presents the least resistance to soft tissue expansion from the sella; consequently, pituitary adenomas frequently extend in a suprasellar direction. Bony invasion may occur as well, especially through the sellar floor to the sphenoid sinus **(Fig. 392-1)**.

Headaches are common features of small intrasellar tumors, even with no demonstrable suprasellar extension. Because of the confined nature of the pituitary, small changes in intrasellar pressure stretch the dural plate; however, headache severity correlates poorly with adenoma size or extension.

Suprasellar extension can lead to visual loss by several mechanisms, the most common being compression of the optic chiasm. Rarely, direct invasion of the optic nerves or obstruction of cerebrospinal fluid (CSF) flow leading to secondary visual disturbances can occur. Pituitary stalk compression by a hormonally active or inactive intrasellar mass may compress the portal vessels, disrupting pituitary access to hypothalamic hormones and dopamine; this results in early hyperprolactinemia and later concurrent loss of other pituitary hormones. This "stalk section" phenomenon may also be caused by trauma, whiplash injury with posterior clinoid stalk compression, or skull base fractures. Lateral mass invasion may impinge on the cavernous sinus and compress its neural contents, leading to cranial nerve III, IV, and VI palsies as well as effects on the ophthalmic and maxillary branches of the fifth cranial nerve **(Chap. 452)**. Patients may present with diplopia, ptosis, ophthalmoplegia, and decreased facial sensation, depending on the extent of neural damage. Extension into the sphenoid sinus indicates that the pituitary mass has eroded through the sellar floor (Fig. 392-1). Aggressive tumors rarely invade the palate roof and cause nasopharyngeal obstruction, infection, and CSF leakage. Temporal and frontal lobe involvement may rarely lead to uncinate seizures, personality disorders, and anosmia. Direct hypothalamic encroachment by an invasive pituitary mass may cause important metabolic sequelae, including precocious puberty or hypogonadism, arginie vasopressin deficiency (AVP-D), sleep disturbances, dysthermia, and appetite disorders.

Magnetic Resonance Imaging Sagittal and coronal T1-weighted magnetic resonance imaging (MRI) before and after administration of gadolinium allows precise visualization of the pituitary gland with

TABLE 392-1 Features of Sellar Mass Lesions[a]

IMPACTED STRUCTURE	CLINICAL IMPACT
Pituitary	Hypogonadism Hypothyroidism Growth failure, adult growth hormone deficiency Hypoadrenalism Hyperprolactinema (stalk compression)
Optic chiasm	Loss of red perception Bitemporal hemianopia Superior or bitemporal field defect Scotoma Blindness
Hypothalamus	Temperature dysregulation Appetite and thirst disorders Obesity Arginine vasopression deficiency Sleep disorders Behavioral dysfunction Autonomic dysfunction
Cavernous sinus	Ophthalmoplegia with or without ptosis or diplopia Facial numbness
Frontal lobe	Personality disorder Anosmia
Brain	Headache Hydrocephalus Psychosis Dementia Laughing seizures

[a]As the intrasellar mass expands, it first compresses intrasellar pituitary tissue, then usually invades dorsally through the dura to lift the optic chiasm or laterally to the cavernous sinuses. Bony erosion is rare, as is direct brain compression. Microadenomas may present with headache.

clear delineation of the hypothalamus, pituitary stalk, pituitary tissue and surrounding suprasellar cisterns, cavernous sinuses, sphenoid sinus, and optic chiasm. Pituitary gland height ranges from 6 mm in children to 8 mm in adults; during pregnancy and puberty, the height may reach 10–12 mm. The upper aspect of the adult pituitary is flat or slightly concave, but in adolescent and pregnant individuals, this surface may be convex, reflecting physiologic pituitary enlargement. The stalk should be midline and vertical.

Anterior pituitary gland soft tissue consistency is slightly heterogeneous on MRI, and signal intensity resembles that of brain matter on T1-weighted imaging **(Fig. 392-2)**. Adenoma density is usually lower than that of surrounding normal tissue on T1-weighted imaging, and the signal intensity increases with T2-weighted images. Computed tomography (CT) scan is reserved to define the extent of bony erosion or the presence of calcification.

Sellar masses are encountered commonly as incidental findings on MRI, and most are pituitary adenomas (incidentalomas). In the absence of hormone hypersecretion, these small intrasellar lesions can be monitored safely with MRI, which is performed annually and then less often if there is no evidence of further growth. Resection should be considered for incidentally discovered larger macroadenomas, because about one-third become invasive or cause local pressure effects. If hormone hypersecretion is identified, specific therapies are indicated as described below. When larger masses (>1 cm) are encountered, they should also be distinguished from nonadenomatous lesions. Meningiomas often are associated with bony hyperostosis; craniopharyngiomas may have calcifications and are usually hypodense, whereas gliomas are hyperdense on T2-weighted images.

Ophthalmologic Evaluation Because optic tracts may be contiguous to an expanding pituitary mass, reproducible visual field assessment using perimetry techniques should be performed on all patients with sellar mass lesions that impinge the optic chiasm **(Chap. 34)**. Bitemporal hemianopia, often more pronounced superiorly, is observed classically. It occurs because nasal ganglion cell fibers, which cross in the optic chiasm, are especially vulnerable to compression of the ventral optic chiasm. Occasionally, homonymous hemianopia occurs from postchiasmal compression or monocular temporal field loss from prechiasmal compression. Invasion of the cavernous sinus can produce diplopia from ocular motor nerve palsy. Early diagnosis reduces the risk of optic atrophy, vision loss, or eye misalignment.

Laboratory Investigation The presenting clinical features of functional pituitary adenomas (e.g., acromegaly, prolactinoma, or Cushing's disease) should guide the laboratory studies **(Table 392-2)**. However, for a sellar mass with no obvious clinical features of hormone excess, laboratory studies are geared toward determining the nature of the tumor and assessing the possible presence of hypopituitarism. When a pituitary adenoma is suspected based on MRI, initial hormonal evaluation usually includes (1) basal prolactin (PRL); (2) insulin-like growth factor (IGF)-1; (3) 24-h urinary free cortisol (UFC) and/or overnight oral dexamethasone (1 mg) suppression test; (4) α subunit, follicle-stimulating hormone (FSH), and luteinizing hormone (LH); and (5) thyroid function tests. Additional hormonal evaluation may be indicated based on the results of these tests. Pending more detailed assessment of hypopituitarism, a menstrual history, measurement of testosterone and 8 A.M. cortisol levels, and thyroid function tests usually identify patients with pituitary hormone deficiencies that require hormone replacement before further testing or surgery **(Chap. 391)**.

Histologic Evaluation Immunohistochemical staining of pituitary tumor specimens obtained at transsphenoidal surgery for hormones as well as cell-type specific transcription factors confirms clinical and laboratory studies and provides a histologic diagnosis when hormone studies are equivocal and in cases of clinically nonfunctioning tumors.

TREATMENT

Hypothalamic, Pituitary, and Other Sellar Masses

OVERVIEW

Successful management of sellar masses requires accurate diagnosis as well as selection of optimal therapeutic modalities. Most pituitary tumors are benign and slow growing. Clinical features result from local mass effects and hormonal hyper- or hyposecretion syndromes caused directly by the adenoma or occurring as a consequence of treatment. Thus, lifelong management and follow-up are necessary for these patients.

MRI with gadolinium enhancement for pituitary visualization, new advances in transsphenoidal surgery and in stereotactic radiotherapy, and novel therapeutic agents have improved pituitary tumor management. The goals of pituitary tumor treatment include normalization of excess pituitary secretion, amelioration of symptoms and signs of hormonal hypersecretion syndromes, and shrinkage or ablation of large tumor masses with relief of adjacent structure compression. Residual anterior pituitary function should be preserved during treatment and sometimes can be restored by removing the tumor mass. Ideally, adenoma recurrence should be prevented.

TRANSSPHENOIDAL SURGERY

Transsphenoidal resection is the desired surgical approach for pituitary tumors, except for the rare invasive suprasellar mass surrounding the frontal or middle fossa or the optic nerves or invading posteriorly behind the clivus, which may require transcranial approaches. Intraoperative microscopy facilitates visual distinction between adenomatous and normal pituitary tissue as well as microdissection of small tumors that may not be visible by MRI **(Fig. 392-3)**. Endoscopic techniques with three-dimensional intraoperative localization enable better visualization and access to tumor tissue. Transsphenoidal surgery also avoids cranial invasion and manipulation of brain tissue required by subfrontal surgical

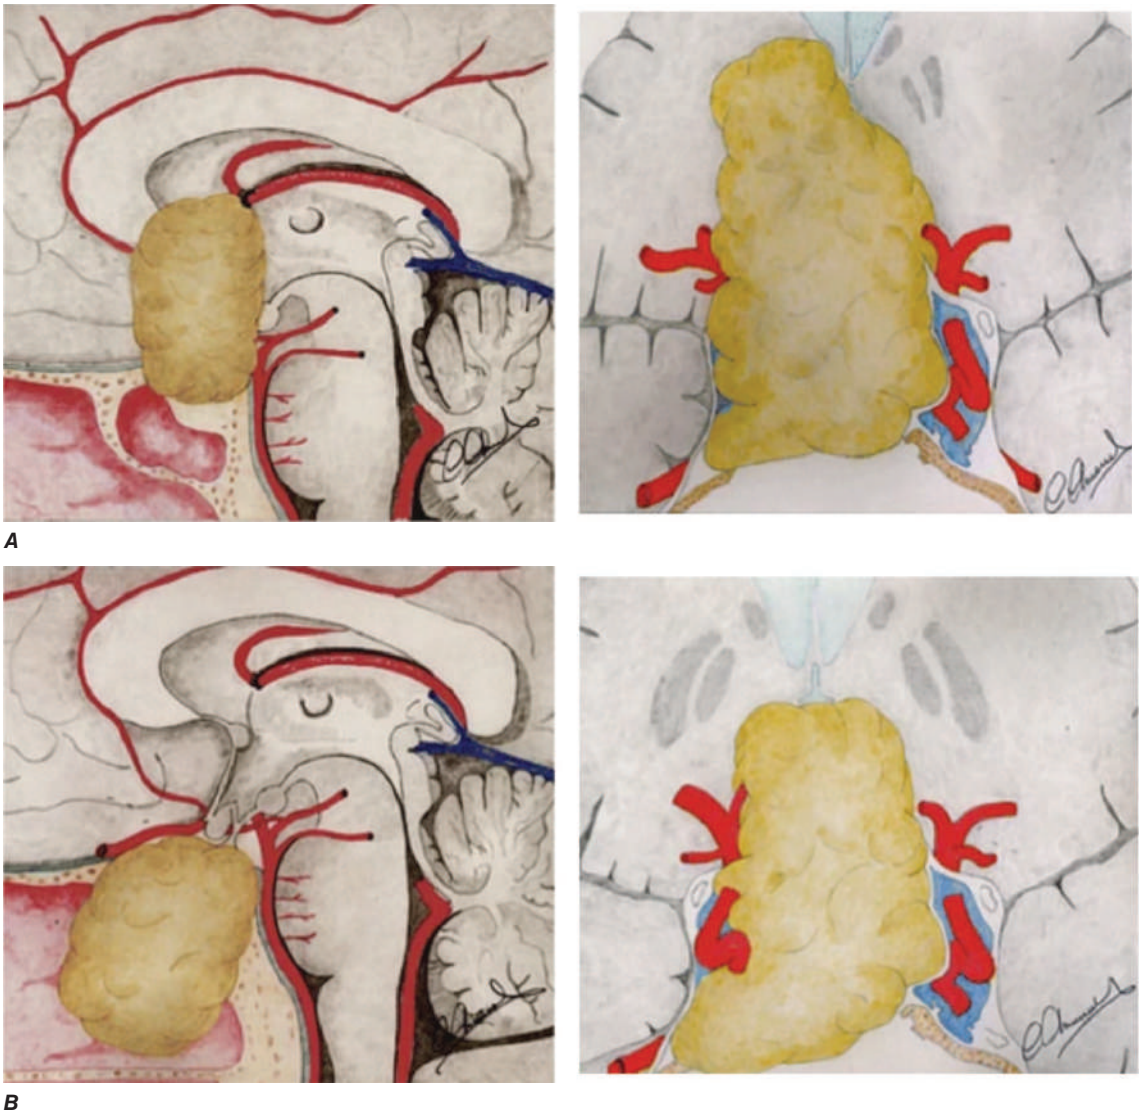

FIGURE 392-1 Expanding pituitary mass. Pituitary mass expansion may ***(A)*** impinge vital soft tissue structures and ***(B)*** invade the sphenoid sinus. *(Reproduced with permission from P Cappabianca et al: Size does not matter. The intrigue of giant adenomas: a true surgical challenge. Acta Neurochir (Wien) 156:2217, 2014.)*

approaches. Individual surgical experience is a major determinant of outcome efficacy with these techniques.

In addition to correction of hormonal hypersecretion, pituitary surgery is indicated for mass lesions that impinge on surrounding structures. Surgical decompression and resection are required for an expanding pituitary mass, which may be asymptomatic or accompanied by persistent headache, progressive visual field defects, cranial nerve palsies, hydrocephalus, and, occasionally, intrapituitary hemorrhage and apoplexy. Transsphenoidal surgery rarely is used for pituitary tissue biopsy to establish a histologic diagnosis. Whenever possible, the pituitary mass lesion should be selectively excised; normal pituitary tissue should be manipulated or resected only when critical for effective mass dissection. Nonselective hemihypophysectomy or total hypophysectomy may be indicated if no hypersecreting mass lesion is clearly discernible, multifocal lesions are present, or the remaining nontumorous pituitary tissue is obviously necrotic. This strategy, however, increases the likelihood of postoperative hypopituitarism and the need for lifelong hormone replacement.

Preoperative mass effects, including visual field defects and compromised pituitary function, may be reversed by surgery, particularly when the deficits are not long-standing. For large and invasive tumors, it is necessary to determine the optimal balance between maximal tumor resection and preservation of anterior pituitary hormonal function, especially for preserving growth and

TABLE 392-2 Screening Tests for Functional Pituitary Adenomas

	TEST	COMMENTS
Acromegaly	Serum IGF-1 Oral glucose tolerance test with GH obtained at 0, 30, and 60 min	Interpret IGF-1 relative to age- and sex-matched controls Normal subjects should suppress growth hormone to <1 μg/L
Prolactinoma	Serum PRL	Exclude medications MRI of the sella should be ordered if PRL is elevated
Cushing's disease	24-h urinary free cortisol Dexamethasone (1 mg) at 11 P.M. and fasting plasma cortisol measured at 8 A.M. Late night salivary cortisol ACTH assay CRH stimulation test with measurements of cortisol and ACTH from peripheral and/or petrosal sinus blood	Ensure urine collection is total and accurate Normal subjects suppress to <5 μg/dL Distinguishes adrenal adenoma (ACTH suppressed) from ectopic ACTH or Cushing's disease (ACTH normal or elevated) The CRH test is used primarily to distinguish pituitary adenomas from ectopic ACTH sources
Gonadotropinoma	Baseline FSH, LH, free α subunit, ovarian hyperstimulation, estrogen (females), testosterone (males) TRH stimulation test with assays for LH, FSH, free α subunit, free LHβ, free FSHβ subunits	Rare; more commonly nonfunctioning adenomas Consider screening for hypopituitarism Some gonadotropinomas exhibit an inappropriate gonadotropin response to TRH
TSH-producing adenoma	Free T_4, free T_3, TSH, free α subunit	Key feature is an inappropriately normal or high TSH in the setting of elevated free T_4 and T_3

Abbreviations: ACTH, adrenocorticotropin hormone; CRH, corticotropin-releasing hormone; FSH, follicle-stimulating hormone; GH, growth hormone; IGF-1, insulin-like growth factor 1; LH, luteinizing hormone; MRI, magnetic resonance imaging; PRL, prolactin; TSH, thyroid-stimulating hormone.

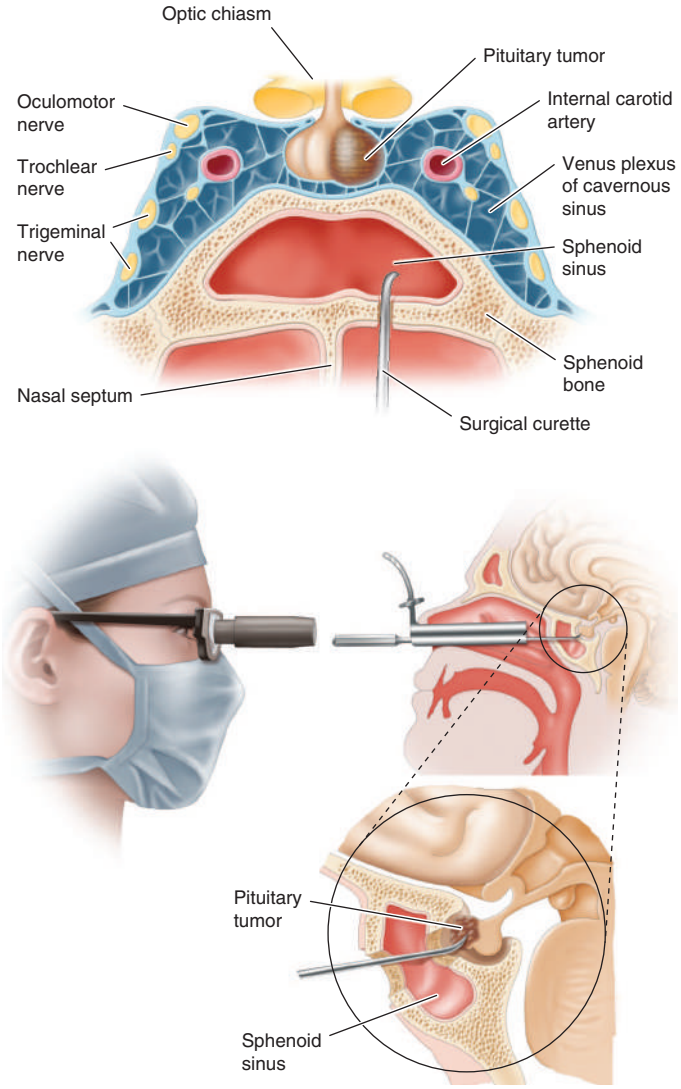

FIGURE 392-3 Transsphenoidal resection of pituitary mass via the endonasal approach.

reproductive function in younger patients. Tumor invasion outside the sella is rarely amenable to surgical cure, and the surgeon must judge the risk-versus-benefit ratio of extensive tumor resection.

Side Effects Tumor size, the degree of invasiveness, and experience of the surgeon largely determine the incidence of surgical complications. Operative mortality rate is ~1%. Transient AVP-D and hypopituitarism occur in up to 20% of patients. Permanent AVP-D, cranial nerve damage, nasal septal perforation, or visual disturbances may be encountered in up to 10% of patients. CSF leaks occur in 4% of patients. Less common complications include carotid artery injury, loss of vision, hypothalamic damage, and meningitis. Permanent side effects are rare after surgery for microadenomas.

RADIATION

Radiation is used either as a primary therapy for pituitary or parasellar masses or, more commonly, as an adjunct to surgery or medical therapy. Focused megavoltage irradiation is achieved by precise MRI localization, using a high-voltage linear accelerator and accurate isocentric rotational arcing. A major determinant of accurate irradiation is reproduction of the patient's head position during multiple visits and maintenance of absolute head immobility. A total of <50 Gy (5000 rad) is given as 180 cGy (180 rad) fractions divided over ~6 weeks. Stereotactic radiosurgery delivers a large single high-energy dose from a cobalt-60 source (Gamma Knife), linear accelerator, or cyclotron. Long-term effects of Gamma Knife surgery appear to be similar to those encountered with conventional radiation. Proton beam therapy is available in some centers and provides concentrated radiation doses within a localized region.

The role of radiation therapy in pituitary tumor management depends on the nature and anatomic location of the tumor, the age of the patient, and the availability of surgical and radiation expertise. Because of its relatively slow onset of action, radiation therapy is usually reserved for postsurgical management. As an adjuvant to surgery, radiation is used to treat residual tumor in an attempt to prevent persistent growth or recurrence. Irradiation offers the only means for potentially ablating significant postoperative residual nonfunctioning tumor tissue. By contrast, PRL-, growth hormone (GH)–, adrenocorticotropin hormone (ACTH)–, and thyrotropin (thyroid-stimulating hormone [TSH])–secreting residual tumor tissues are amenable to medical therapy.

Side Effects In the short term, radiation may cause transient nausea and weakness. Alopecia and loss of taste and smell may be more long-lasting. Failure of pituitary hormone synthesis is common in patients who have undergone head and neck or pituitary-directed irradiation. More than 50% of patients develop loss of GH, ACTH, TSH, and/or gonadotropin secretion within 10 years, usually due to hypothalamic damage. Lifelong follow-up with testing of anterior pituitary hormone reserve is therefore required after radiation treatment. Optic nerve damage with impaired vision due to optic neuritis is reported in ~2% of patients who undergo pituitary irradiation. Cranial nerve damage is uncommon now that radiation doses are <2 Gy (200 rad) at any one treatment session and the maximum dose is <50 Gy (5000 rad). The use of stereotactic radiotherapy reduces the risk of damage to adjacent structures. Conventional

radiotherapy for pituitary tumors has been associated with adverse mortality rates, mainly from cerebrovascular disease. The cumulative risk of developing a secondary tumor after conventional radiation is 1.3% after 10 years and 1.9% after 20 years.

MEDICAL

Medical therapy for pituitary tumors is highly specific and depends on tumor type. For prolactinomas, dopamine agonists are the treatment of choice. For acromegaly, somatostatin receptor ligands (SRLs) and a GH receptor antagonist are indicated. For TSH-secreting tumors, SRLs and occasionally dopamine agonists are indicated. ACTH-secreting tumors may respond to SRLs, and adrenal-directed therapy may also be of benefit. Nonfunctioning tumors are generally not responsive to medications and require surgery and/or irradiation.

SELLAR MASSES

Sellar masses may arise from brain, hypothalamic, or pituitary tissues. Each exhibit features related to the lesion location but also unique to the specific etiology. Unique MRI characteristics inform the differential diagnosis of pituitary masses **(Fig. 392-4)**.

Lesions involving the anterior and preoptic hypothalamic regions cause paradoxical vasoconstriction, tachycardia, and hyperthermia. Acute hyperthermia usually is due to a hemorrhagic insult, but poikilothermia may also occur. Central disorders of thermoregulation result from posterior hypothalamic damage. The *periodic hypothermia syndrome* is characterized by episodic attacks of rectal temperatures <30°C (86°F), sweating, vasodilation, vomiting, and bradycardia **(Chap. 477)**. Damage to the ventromedial hypothalamic nuclei by craniopharyngiomas, hypothalamic trauma, or inflammatory disorders may be associated with *hyperphagia* and *obesity*. This region appears to contain an energy-satiety center where melanocortin receptors are influenced by leptin, insulin, pro-opiomelanocortin (POMC) products, and gastrointestinal peptides **(Chap. 413)**. Polydipsia and hypodipsia are associated with damage to central osmoreceptors located in preoptic nuclei **(Chap. 393)**. Slow-growing hypothalamic lesions can cause increased somnolence and disturbed sleep cycles as well as obesity, hypothermia, and emotional outbursts. Lesions of the central hypothalamus may stimulate sympathetic neurons, leading to elevated serum catecholamine and cortisol levels. These patients are predisposed to cardiac arrhythmias, hypertension, and gastric erosions.

Craniopharyngiomas are benign, suprasellar cystic masses that present with headaches, visual field deficits, and variable degrees of hypopituitarism. They are derived from Rathke's pouch and arise near the pituitary stalk, commonly extending into the suprasellar cistern. Craniopharyngiomas are often large, cystic, and locally invasive. Many are partially calcified, exhibiting a characteristic appearance on skull x-ray and CT images. More than half of all patients present before age 20, usually with signs of increased intracranial pressure, including headache, vomiting, papilledema, and hydrocephalus. Associated symptoms include visual field abnormalities, personality changes and cognitive deterioration, cranial nerve damage, sleep difficulties, and weight gain accompanied by features of the metabolic syndrome. Hypopituitarism is documented in ~90%, and AVP-D occurs in ~10% of patients. About half of affected children present with growth retardation. MRI is generally superior to CT for evaluating cystic structure and tissue components of craniopharyngiomas. CT is useful to define calcifications and evaluate invasion into surrounding bony structures and sinuses.

Treatment usually involves transcranial or transsphenoidal surgical resection followed by postoperative radiation of residual tumor. Surgery alone is curative in less than half of patients because of recurrences due to adherence to vital structures or because of small tumor deposits in the hypothalamus or brain parenchyma. The goal of surgery is to remove as much tumor as possible without risking complications associated with efforts to remove firmly adherent or inaccessible tissue. In the absence of radiotherapy, ~75% of craniopharyngiomas recur, and 10-year survival is <50%. In patients with incomplete resection, radiotherapy improves 10-year survival to 70–90% but is associated with increased risk of secondary malignancies. Most patients require lifelong pituitary hormone replacement. As some craniopharyngiomas (particularly papillary) are associated with activated *BRAF* V600E mutations, use of BRAF inhibitors (dabrafenib or vemurafenib) either alone or in combination with MEK inhibitors (trametinib or cobimetinib) has resulted in long-term growth responses in some patients.

Developmental failure of Rathke's pouch obliteration may lead to *Rathke's cysts*, which are small (<5 mm) cysts entrapped by squamous epithelium and are found in ~20% of individuals at autopsy. Although

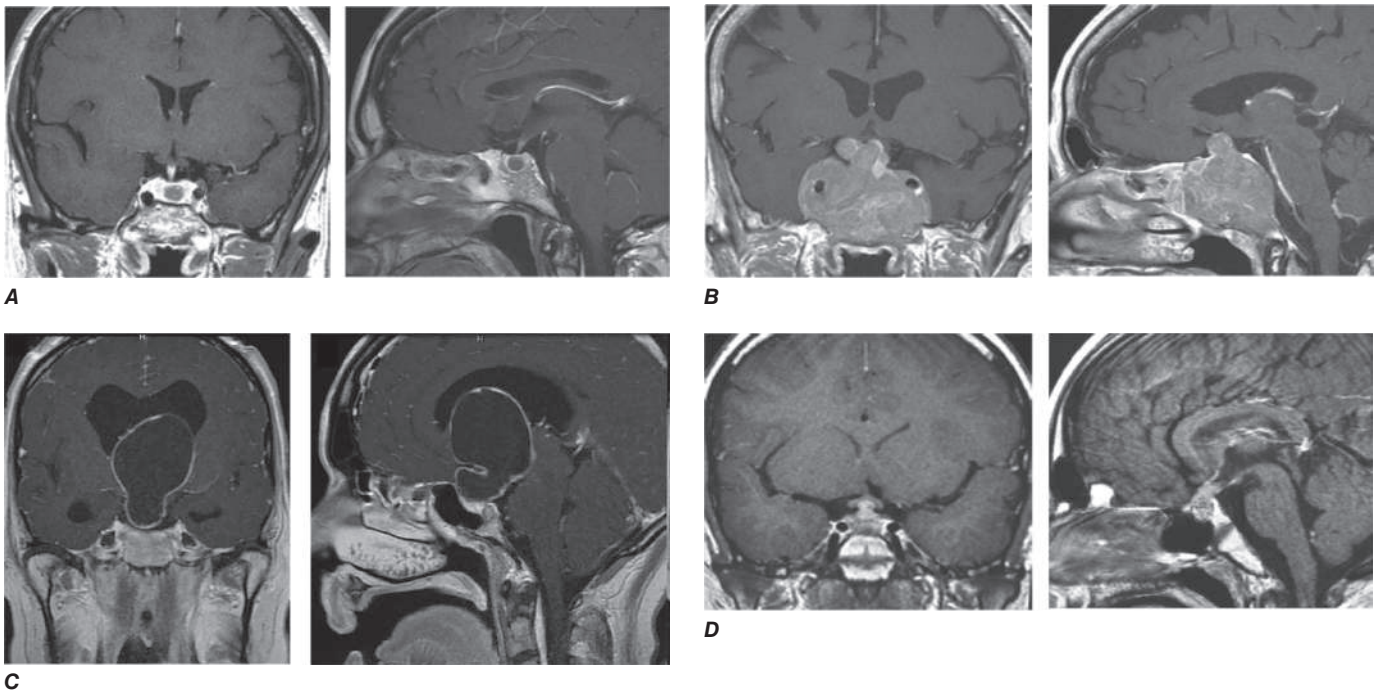

FIGURE 392-4 Imaging differential diagnosis of sellar masses. *A.* Microadenoma. ***B.*** Macroadenoma. ***C.*** Craniopharyngioma. ***D.*** Hypophysitis with stalk thickening. *(A, B, D: Used with permission from Vivien Bonert, MD. C: Reproduced with permission from Muller HL: Childhood craniopharyngioma. Recent advances in diagnosis, treatment and follow-up. Horm Res 69:193, 2008.)*

Rathke's cysts do not usually grow and are often diagnosed incidentally, about a third present in adulthood with compressive symptoms, AVP-D, and hyperprolactinemia due to stalk compression. Rarely, hydrocephalus develops. The diagnosis is suggested preoperatively by visualizing the cyst wall on MRI, which distinguishes these lesions from craniopharyngiomas. Cyst contents range from CSF-like fluid to mucoid material. *Arachnoid cysts* are rare and generate an MRI image that is isointense with CSF.

Sellar chordomas usually present with bony clival erosion, local invasiveness, and, on occasion, calcification. Normal pituitary tissue may be visible on MRI, distinguishing chordomas from aggressive pituitary adenomas. Mucinous material may be obtained by fine-needle aspiration.

Meningiomas arising in the sellar region may be difficult to distinguish from nonfunctioning pituitary adenomas. Meningiomas typically enhance on MRI and may show evidence of calcification or bony erosion. Meningiomas may cause compressive symptoms.

Histiocytosis X includes a variety of syndromes associated with foci of eosinophilic granulomas. AVP-D, exophthalmos, and punched-out lytic bone lesions (*Hand-Schüller-Christian disease*) are associated with granulomatous lesions visible on MRI, as well as a characteristic axillary skin rash. Rarely, the pituitary stalk may be involved.

Pituitary metastases occur in ~3% of cancer patients. Bloodborne metastatic deposits are found almost exclusively in the posterior pituitary. Accordingly, AVP-D can be a presenting feature of lung, gastrointestinal, breast, and other pituitary metastases. About half of pituitary metastases originate from breast cancer; ~25% of patients with metastatic breast cancer have such deposits. Rarely, pituitary stalk involvement results in anterior pituitary insufficiency. The MRI diagnosis of a metastatic lesion may be difficult to distinguish from an aggressive pituitary adenoma; the diagnosis may require histologic examination of excised tumor tissue. Primary or metastatic lymphoma, leukemias, and plasmacytomas also occur within the sella.

Hypothalamic hamartomas and *gangliocytomas* may arise from astrocytes, oligodendrocytes, and neurons with varying degrees of differentiation. These tumors may overexpress hypothalamic neuropeptides, including gonadotropin-releasing hormone (GnRH), growth hormone–releasing hormone (GHRH), and corticotropin-releasing hormone (CRH). With GnRH-producing tumors, children present with precocious puberty, psychomotor delay, and laughing-associated seizures. Medical treatment of GnRH-producing hamartomas with long-acting GnRH analogues effectively suppresses gonadotropin secretion and controls premature pubertal development. Rarely, hamartomas also are associated with craniofacial abnormalities; imperforate anus; cardiac, renal, and lung disorders; and pituitary failure as features of *Pallister-Hall syndrome*, which is caused by mutations in the carboxy terminus of the *GLI3* gene. Hypothalamic hamartomas are often contiguous with the pituitary, and preoperative MRI diagnosis may not be possible. Histologic evidence of hypothalamic neurons in tissue resected at transsphenoidal surgery may be the first indication of a primary hypothalamic lesion.

Hypothalamic gliomas and *optic gliomas* occur mainly in childhood and usually present with visual loss. Adults have more aggressive tumors; about a third are associated with neurofibromatosis.

Brain germ cell tumors may arise within the sellar region. They include *dysgerminomas*, which frequently are associated with AVP-D and visual loss. They rarely metastasize. *Germinomas, embryonal carcinomas*, *teratomas*, and *choriocarcinomas* may arise in the parasellar region and produce human chorionic gonadotropin (hCG). These germ cell tumors present with precocious puberty, AVP-D, visual field defects, and thirst disorders. Many patients are GH deficient with short stature.

PITUITARY ADENOMAS AND HYPERSECRETION SYNDROMES

Pituitary adenomas are the most common cause of pituitary hormone hypersecretion and hyposecretion syndromes in adults. They account for ~15% of all intracranial neoplasms and have been identified with a population prevalence of ~80/100,000. At autopsy, up to one-quarter of all pituitary glands harbor an unsuspected microadenoma (<10 mm diameter). Similarly, pituitary imaging detects small clinically inapparent pituitary lesions in at least 10% of individuals.

Pathogenesis Pituitary adenomas are benign neoplasms that arise from one of the five anterior pituitary cell types. The clinical and biochemical phenotypes of pituitary adenomas depend on the cell type from which they are derived. Thus, tumors arising from lactotrope (PRL), somatotrope (GH), corticotrope (ACTH), thyrotrope (TSH), or gonadotrope (LH, FSH) cells hypersecrete their respective hormones **(Table 392-3)**. Plurihormonal tumors express various combinations of GH, PRL, TSH, ACTH, or the glycoprotein hormone α or β subunits. They may be diagnosed by careful immunocytochemistry of specific hormone and transcription factor expression or may manifest as clinical syndromes that combine features of these hormonal hypersecretory syndromes. Morphologically, these tumors may arise from a single polysecreting cell type or include cells with mixed function within the same tumor.

Hormonally active tumors are characterized by autonomous hormone secretion with diminished feedback responsiveness to physiologic inhibitory pathways. Hormone production does not always correlate with tumor size. Small hormone-secreting adenomas may cause significant clinical perturbations, whereas larger adenomas that produce less hormone may be clinically silent and remain undiagnosed (if no central compressive effects occur). About one-third of all adenomas are clinically nonfunctioning and produce no distinct clinical hypersecretory syndrome. Most of them arise from gonadotrope cells and may secrete small amounts of α- and β-glycoprotein hormone subunits or, very rarely, intact circulating gonadotropins. True pituitary carcinomas with documented extracranial metastases are exceedingly rare.

Almost all pituitary adenomas are monoclonal in origin, implying the acquisition of one or more somatic mutations that confer a selective growth advantage. Consistent with their clonal origin, complete surgical resection of small pituitary adenomas usually cures hormone hypersecretion. Nevertheless, hypothalamic hormones such as GHRH and CRH also enhance mitotic activity of their respective pituitary target cells in addition to their role in pituitary hormone regulation. Thus, patients who harbor rare abdominal or chest tumors that produce ectopic GHRH or CRH may present with somatotrope or corticotrope hyperplasia with GH or ACTH hypersecretion.

TABLE 392-3 Classification of Pituitary Adenomas[a]

ADENOMA CELL ORIGIN	HORMONE PRODUCT	CLINICAL SYNDROME
Lactotrope	PRL	Hypogonadism, galactorrhea
Gonadotrope	FSH, LH, subunits	Silent/nonfunctioning, ovarian hyperstimulation, hypogonadism
Somatotrope	GH	Acromegaly/gigantism
Corticotrope	ACTH/none	Cushing's disease or silent
Mixed lactotrope and somatotrope	GH, PRL	Acromegaly, hypogonadism, galactorrhea
Other plurihormonal cell	Any	Mixed
Acidophil stem cell	PRL, GH	Hypogonadism, galactorrhea, acromegaly
Mammosomatotrope	PRL, GH	Hypogonadism, galactorrhea, acromegaly
Thyrotrope	TSH	Thyrotoxicosis
Null cell	None	Hypopituitarism/none
Oncocytoma	None	Hypopituitarism/none

[a]Hormone-secreting tumors are listed in decreasing order of frequency. All tumors may cause local pressure effects, including visual disturbances, cranial nerve palsy, and headache.

Note: For abbreviations, see text.

Several etiologic genetic events have been implicated in the development of pituitary tumors. The pathogenesis of sporadic forms of acromegaly has been particularly informative as a model of tumorigenesis. GHRH, after binding to its G protein–coupled somatotrope receptor, uses cyclic adenosine monophosphate (AMP) as a second messenger to stimulate GH secretion and somatotrope proliferation. A subset (~35%) of GH-secreting pituitary tumors contains sporadic mutations in $G_s\alpha$. These mutations attenuate intrinsic GTPase activity, resulting in constitutive elevation of cyclic AMP, Pit-1 induction, and activation of cyclic AMP response element binding protein (CREB), thereby promoting somatotrope cell proliferation and GH secretion.

Growth factors may also promote pituitary tumor proliferation. Basic fibroblast growth factor (bFGF) is abundant in the pituitary and stimulates pituitary cell mitogenesis, whereas epidermal growth factor receptor (EGFR) signaling induces both hormone synthesis and cell proliferation. Mutations of *USP8* may result in overexpressed EGFR in a subset of ACTH-secreting tumors. Other factors involved in initiation and promotion of pituitary tumors include loss of negative-feedback inhibition (as seen with primary hypothyroidism or hypogonadism) and estrogen-mediated or paracrine angiogenesis. Growth characteristics and neoplastic behavior also may be influenced by activated oncogenes, including *RAS* and pituitary tumor transforming gene (*PTTG*), or inactivation of growth suppressor genes, including *MEG3*. Pituitary adenomas exhibit lineage-specific features of cell-cycle disruption, including cellular senescence, with chromosomal instability and copy number alterations as well as elevated levels of CDK inhibitors. These features underlie the invariably benign nature of these adenomas.

Genetic Syndromes Associated with Pituitary Tumors Several familial syndromes are associated with pituitary tumors, and the genetic mechanisms for some of them have been unraveled **(Table 392-4)**.

Multiple endocrine neoplasia (MEN) 1 is an autosomal dominant syndrome characterized primarily by a genetic predisposition to parathyroid, pancreatic islet, and pituitary adenomas **(Chap. 400)**. MEN 1 is caused by inactivating germline mutations in *MENIN*, a constitutively expressed tumor-suppressor gene located on chromosome 11q13. Loss of heterozygosity or a somatic mutation of the remaining normal *MENIN* allele leads to tumorigenesis. About half of affected patients develop prolactinomas; acromegaly and Cushing's disease are less commonly encountered.

Carney complex is characterized by spotty skin pigmentation, myxomas, and endocrine tumors, including testicular, adrenal, and pituitary adenomas. Acromegaly occurs in ~20% of these patients. A subset of patients has mutations in the R1α regulatory subunit of protein kinase A (*PRKAR1A*).

TABLE 392-4 Familial Pituitary Tumor Syndromes (See Chap. 400)

	GENE MUTATED	CLINICAL FEATURES
Multiple endocrine neoplasia 1 (MEN 1)	*MEN1* (11q13)	Hyperparathyroidism Pancreatic neuroendocrine tumors Foregut carcinoids Adrenal adenomas Skin lesions Pituitary adenomas (40%)
Multiple endocrine neoplasia 4 (MEN 4)	*CDKNIB* (12p13)	Hyperparathyroidism Pituitary adenomas Other tumors
Carney complex	*PRKAR1A* (17q23-24)	Pituitary hyperplasia and adenomas (10%) Atrial myxomas Schwannomas Adrenal hyperplasia Lentigines
Familial pituitary adenomas	*AIP* (11q13.2)	Acromegaly/gigantism (~15% of afflicted families)

McCune-Albright syndrome consists of polyostotic fibrous dysplasia, pigmented skin patches, and a variety of endocrine disorders, including acromegaly, adrenal adenomas, and autonomous ovarian function **(Chap. 424)**. Hormonal hypersecretion results from constitutive cyclic AMP production caused by inactivation of the GTPase activity of $G_s\alpha$. The $G_s\alpha$ mutations occur postzygotically, leading to a mosaic pattern of mutant expression.

Familial acromegaly is a rare disorder in which family members may manifest either acromegaly or gigantism. A subset of families with a predisposition for familial pituitary tumors, especially acromegaly, has been found to harbor germline mutations in the *AIP* gene, which encodes the aryl hydrocarbon receptor interacting protein.

HYPERPROLACTINEMIA

Etiology Hyperprolactinemia is the most common pituitary hormone hypersecretion syndrome in both men and women. PRL-secreting pituitary adenomas (prolactinomas) are the most common cause of PRL levels >200 μg/L (see below). Less pronounced PRL elevation can also be seen with microprolactinomas but is more commonly caused by drugs, pituitary stalk compression, hypothyroidism, or renal failure **(Table 392-5)**.

Pregnancy and lactation are the important physiologic causes of hyperprolactinemia. Sleep-associated hyperprolactinemia reverts to normal within an hour of awakening. Nipple stimulation and sexual orgasm also may increase PRL. Chest wall stimulation or trauma (including chest surgery and herpes zoster) invokes the reflex suckling arc with resultant hyperprolactinemia. Chronic renal failure elevates PRL by decreasing peripheral clearance. Primary hypothyroidism is associated with mild hyperprolactinemia, probably because of compensatory TRH secretion. Mutation of the PRL receptor is a rare cause of hyperprolactinemia.

Lesions of the hypothalamic-pituitary region that disrupt hypothalamic dopamine synthesis, portal vessel delivery, or lactotrope responses are associated with hyperprolactinemia. Thus, hypothalamic tumors, cysts, infiltrative disorders, and radiation-induced damage cause elevated PRL levels, usually in the range of 30–100 μg/L. Plurihormonal adenomas (including GH and ACTH tumors) may hypersecrete PRL directly. Pituitary masses, including clinically nonfunctioning pituitary tumors, may compress the pituitary stalk to cause hyperprolactinemia.

Drug-induced inhibition or disruption of dopaminergic receptor function is a common cause of hyperprolactinemia (Table 392-5). Thus, antipsychotics and antidepressants are a relatively common cause of mild hyperprolactinemia. Most patients receiving risperidone have elevated PRL levels, sometimes exceeding 200 μg/L. Methyldopa inhibits dopamine synthesis, and verapamil blocks dopamine release, also leading to hyperprolactinemia. Hormonal agents that induce PRL include estrogens and thyrotropin-releasing hormone (TRH).

Presentation and Diagnosis Amenorrhea, galactorrhea, and infertility are the hallmarks of hyperprolactinemia in women. If hyperprolactinemia develops before menarche, primary amenorrhea results. More commonly, hyperprolactinemia develops later in life and leads to oligomenorrhea and ultimately to amenorrhea. If hyperprolactinemia is sustained, vertebral bone mineral density can be reduced compared with age-matched controls, particularly when it is associated with pronounced hypoestrogenemia. Galactorrhea is present in up to 80% of hyperprolactinemic women. Although usually bilateral and spontaneous, it may be unilateral or expressed only manually. Patients also may complain of decreased libido, weight gain, and mild hirsutism.

In men with hyperprolactinemia, diminished libido, infertility, and visual loss (from optic nerve compression) are the usual presenting symptoms. Gonadotropin suppression leads to reduced testosterone, impotence, and oligospermia. True galactorrhea is uncommon in men with hyperprolactinemia. If the disorder is long-standing, secondary effects of hypogonadism are evident, including osteopenia, reduced muscle mass, and decreased beard growth.

The diagnosis of idiopathic hyperprolactinemia is made by exclusion of known causes of hyperprolactinemia in the setting of a normal

Note: Hyperprolactinemia >200 μg/L almost invariably is indicative of a prolactin-secreting pituitary adenoma. Physiologic causes, hypothyroidism, and drug-induced hyperprolactinemia should be excluded before extensive evaluation.

pituitary MRI. Some of these patients may harbor small microadenomas below visible MRI sensitivity (~2 mm).

GALACTORRHEA

Galactorrhea, the inappropriate discharge of milk-containing fluid from the breast, is considered abnormal if it persists longer than 6 months after childbirth or discontinuation of breast-feeding. Postpartum galactorrhea associated with amenorrhea is a self-limiting disorder usually associated with moderately elevated PRL levels. Galactorrhea may occur spontaneously, or it may be elicited by nipple pressure. In both men and women, galactorrhea may vary in color and consistency (transparent, milky, or bloody) and arise either unilaterally or bilaterally. Mammography or ultrasound is indicated for bloody discharges (particularly from a single nipple), which may be caused by breast cancer. Galactorrhea is commonly associated with hyperprolactinemia caused by any of the conditions listed in Table 392-5. Acromegaly is associated with galactorrhea in about one-third of patients. Treatment of galactorrhea usually involves managing the underlying disorder (e.g., replacing T_4 for hypothyroidism, discontinuing a medication, treating prolactinoma).

Laboratory Investigation Basal, fasting morning PRL levels (normally <20 μg/L) should be measured to assess hypersecretion. Both false-positive and false-negative results may be encountered. In patients with markedly elevated PRL levels (>1000 μg/L), reported results may be falsely lowered because of assay artifacts; sample dilution is required to measure these high values accurately. Falsely elevated values may be caused by aggregated forms of circulating PRL, which are usually biologically inactive (macroprolactinemia). Hypothyroidism should be excluded by measuring TSH and T_4 levels.

TREATMENT

Hyperprolactinemia

Treatment of hyperprolactinemia depends on the cause of elevated PRL levels. Regardless of the etiology, however, treatment should be aimed at normalizing PRL levels to alleviate suppressive effects on gonadal function, halt galactorrhea, and preserve bone mineral density. Dopamine agonists are effective for most causes of hyperprolactinemia (see the treatment section for prolactinoma, below) regardless of the underlying cause.

If the patient is taking a medication known to cause hyperprolactinemia, the drug should be withdrawn, if possible. For psychiatric patients who require neuroleptic agents, supervised dose titration or the addition of a dopamine agonist can help restore normoprolactinemia and alleviate reproductive symptoms. However, dopamine agonists may worsen the underlying psychiatric condition, especially at high doses. Hyperprolactinemia usually resolves after adequate thyroid hormone replacement in hypothyroid patients or after renal transplantation in patients undergoing dialysis. Resection of hypothalamic or sellar mass lesions can reverse hyperprolactinemia caused by stalk compression and reduced dopamine tone. Granulomatous infiltrates occasionally respond to glucocorticoid administration. In patients with irreversible hypothalamic damage, no treatment may be warranted. In up to 30% of patients with hyperprolactinemia—usually without a visible pituitary microadenoma—the condition may resolve spontaneously.

PROLACTINOMA

Etiology and Prevalence Tumors arising from lactotropes account for about half of all functioning pituitary tumors, with a population prevalence of ~10/100,000 in men and ~30/100,000 in women. Mixed tumors that secrete combinations of GH and PRL, ACTH and PRL, and rarely TSH and PRL are also seen. These plurihormonal tumors are usually recognized by immunohistochemistry, sometimes without apparent clinical manifestations from the production of additional hormones. Microadenomas are classified as <1 cm in diameter and usually do not invade the parasellar region. Macroadenomas are ≥1 cm in diameter and may be locally invasive and impinge on adjacent structures. The female-to-male ratio for microprolactinomas is 20:1, whereas the sex ratio is near 1:1 for macroadenomas. Tumor size generally correlates directly with PRL concentrations; values >250 μg/L usually are associated with macroadenomas. Men tend to present with larger tumors than women, possibly because the features of male hypogonadism are less readily evident. PRL levels remain stable

in most patients, reflecting the slow growth of these tumors. About 5% of microadenomas progress in the long term to macroadenomas.

Presentation and Diagnosis Women usually present with amenorrhea, infertility, and galactorrhea. If the tumor extends outside the sella, visual field defects or other mass effects may be seen. Men often present with impotence, loss of libido, infertility, or signs of central nervous system (CNS) compression, including headaches and visual defects. Assuming that physiologic and medication-induced causes of hyperprolactinemia are excluded (Table 392-5), the diagnosis of prolactinoma is likely with a PRL level >200 μg/L. PRL levels <100 μg/L may be caused by microadenomas, other sellar lesions that decrease dopamine inhibition, or nonneoplastic causes of hyperprolactinemia. For this reason, an MRI should be performed in all patients with hyperprolactinemia. It is important to remember that hyperprolactinemia caused secondarily by the mass effects of nonlactotrope lesions is also corrected by treatment with dopamine agonists despite failure to shrink the underlying mass. Consequently, PRL suppression by dopamine agonists does not necessarily indicate that the underlying lesion is a prolactinoma.

TREATMENT

Prolactinoma

Because microadenomas rarely progress to become macroadenomas, no treatment may be needed if patients are asymptomatic and fertility is not desired; these patients should be monitored by regular serial PRL measurements and MRI scans. For symptomatic microadenomas, therapeutic goals include control of hyperprolactinemia, reduction of tumor size, restoration of menses and fertility, and resolution of galactorrhea. Dopamine agonist doses should be titrated to achieve maximal PRL suppression and restoration of reproductive function (Fig. 392-5). A normalized PRL level does not ensure reduced tumor size. However, tumor shrinkage usually is not seen in those who do not respond with lowered PRL levels. For macroadenomas, formal visual field testing should be performed before initiating dopamine agonists. MRI and visual fields should be assessed at 6- to 12-month intervals until the mass shrinks and annually thereafter until maximum size reduction has occurred.

Oral dopamine agonists (cabergoline and bromocriptine) are the mainstay of therapy for patients with micro- or macroprolactinomas. Dopamine agonists suppress PRL secretion and synthesis as well as lactotrope proliferation. In patients with microadenomas who have achieved normoprolactinemia and significant reduction of tumor mass, the dopamine agonist may be withdrawn after 2 years. These patients should be monitored carefully for evidence of prolactinoma recurrence. About 20% of patients (especially males) are resistant to dopaminergic treatment; these adenomas may exhibit decreased D_2 dopamine receptor numbers or a postreceptor defect. D_2 receptor gene mutations in the pituitary have not been reported.

Cabergoline An ergoline derivative, cabergoline is a long-acting dopamine agonist with high D_2 receptor affinity. The drug effectively suppresses PRL for >14 days after a single oral dose and induces prolactinoma shrinkage in most patients. Cabergoline (0.5–1.0 mg twice weekly) achieves normoprolactinemia and resumption of normal gonadal function in ~80% of patients with microadenomas; galactorrhea improves or resolves in 90% of patients. Cabergoline normalizes PRL and shrinks ~70% of macroprolactinomas. Mass effect symptoms, including headaches and visual disorders, usually improve dramatically within days after cabergoline initiation; improvement of sexual function requires several weeks of treatment but may occur before complete normalization of PRL levels. MRI should be repeated within 16 weeks after initial therapy of macroadenomas as shrinkage of invasive adenomas may be striking (Fig. 392-6). After initial control of PRL levels has been achieved, cabergoline should be reduced to the lowest effective maintenance dose. In ~5% of treated patients harboring a microadenoma, hyperprolactinemia may resolve and not recur when dopamine agonists are discontinued after long-term treatment. Cabergoline also may be effective in patients resistant to bromocriptine. Adverse effects and drug intolerance are encountered less commonly than with bromocriptine.

Bromocriptine The ergot alkaloid bromocriptine mesylate is a dopamine receptor agonist that suppresses PRL secretion. Because it is short-acting, the drug is preferred when pregnancy is desired. Therapy is initiated by administering a low bromocriptine dose (0.625–1.25 mg) at bedtime with a snack, followed by gradually

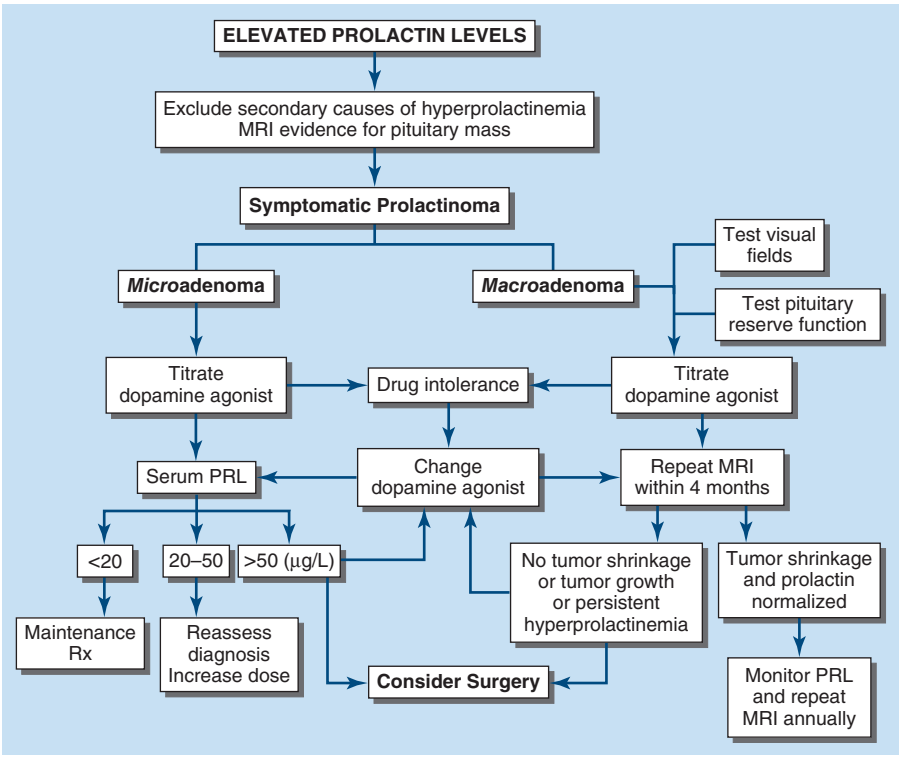

FIGURE 392-5 Management of prolactinoma. MRI, magnetic resonance imaging; PRL, prolactin.

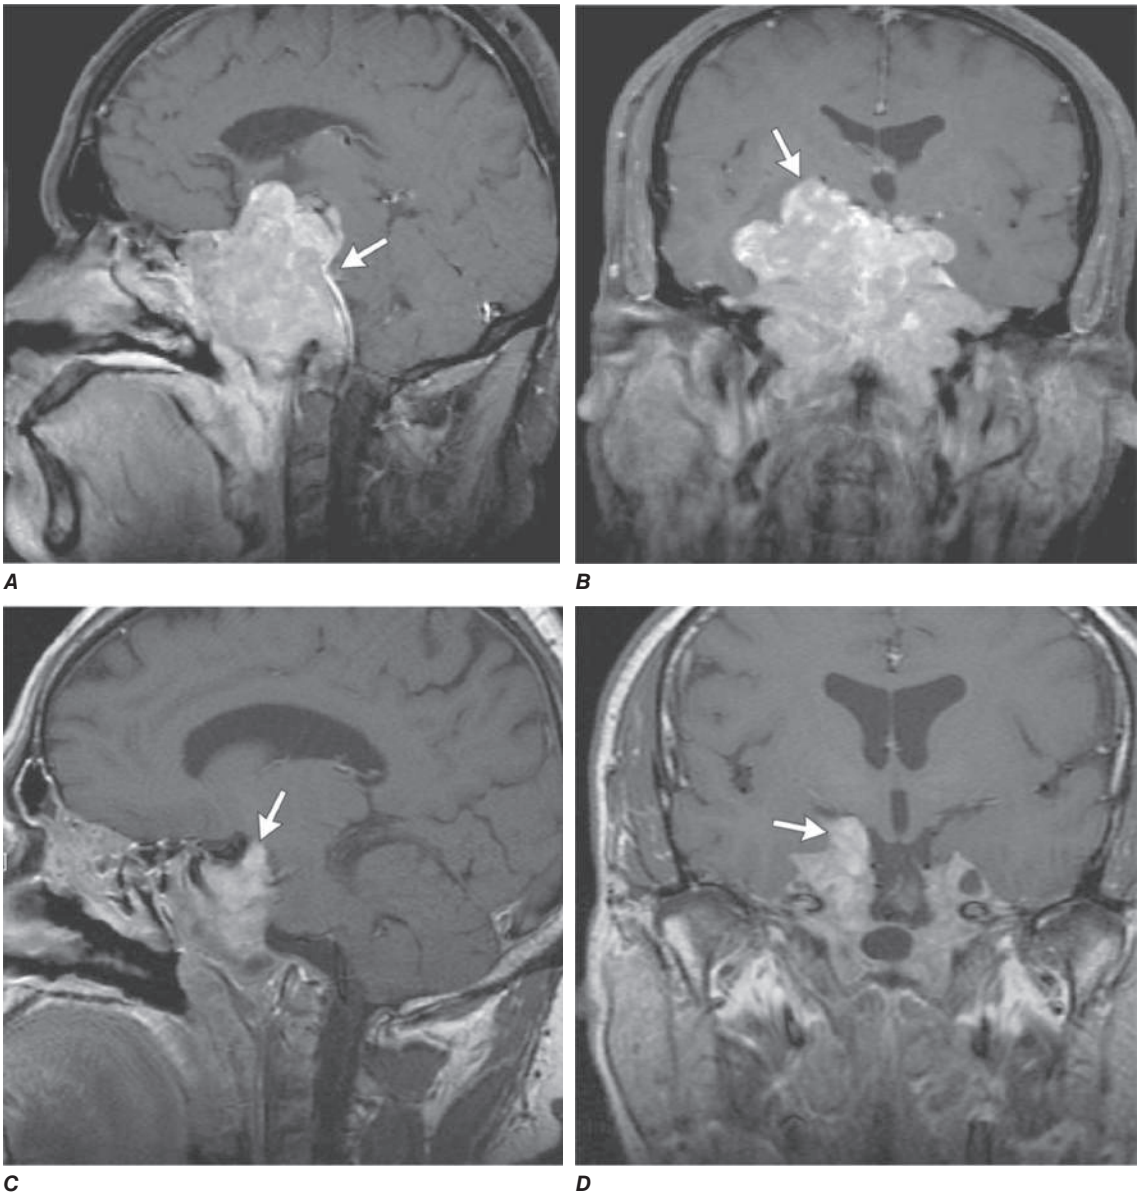

FIGURE 392-6 Large invasive prolactinoma successfully treated with cabergoline. ***A–B.*** Prolactin-secreting macroadenoma in a 32-year-old male measuring 5.6 × 6.9 cm invading the skull base. PRL level was 122,260 μg/L. Four days after cabergoline was started, PRL was 10,823 μg/L and dropped to 772 μg/L after 3 weeks. ***C–D.*** Substantial tumor regression after 40 months of treatment, with PRL levels stable at 25 μg/L. *(Reproduced with permission from M Ahmed, O Al-Nozha: Images in clinical medicine. Large prolactinoma. N Engl J Med 363:177, 2010.)*

increasing the dose. Most patients are controlled with a daily dose of <7.5 mg (2.5 mg tid).

SIDE EFFECTS

Side effects of dopamine agonists include constipation, nasal stuffiness, dry mouth, nightmares, insomnia, and vertigo; decreasing the dose usually alleviates these problems. Nausea, vomiting, and postural hypotension with faintness may occur in ~25% of patients after the initial dose. These symptoms may persist in some patients. In general, fewer side effects are reported with cabergoline. For the ~15% of patients who are intolerant of oral bromocriptine, cabergoline may be better tolerated. Intravaginal administration of bromocriptine is often efficacious in patients with intractable gastrointestinal side effects. Auditory hallucinations, delusions, mood swings, and impulse control disorders have been reported in up to 5% of patients and may be due to the dopamine agonist properties or to the lysergic acid derivative of the compounds. Rare reports of leukopenia, thrombocytopenia, pleural fibrosis, cardiac arrhythmias, and hepatitis have been described. Patients with Parkinson disease who receive at least 3 mg of cabergoline daily have been reported to be at risk for development of cardiac valve regurgitation. Studies analyzing >500 prolactinoma patients receiving recommended doses of cabergoline (up to 2 mg weekly) have shown no evidence for an increased incidence of valvular disorders. Nevertheless, because no controlled prospective studies in pituitary tumor patients are available, it is prudent to perform echocardiograms before initiating standard-dose cabergoline therapy.

Surgery Surgical adenoma debulking may be indicated for dopamine resistance or intolerance as well as the presence of an invasive macroadenoma with compromised vision that fails to improve after drug treatment. Initial PRL normalization is achieved in ~70% of microprolactinomas after surgical resection, but only 40% of macroadenomas can be resected successfully. Follow-up studies have shown that hyperprolactinemia recurs in up to 20% of patients within the first year after surgery; long-term recurrence rates may exceed 50% for macroadenomas. Radiotherapy for prolactinomas is reserved for patients with aggressive tumors that do not respond to maximally tolerated dopamine agonists and/or surgery.

PREGNANCY

The pituitary increases in size during pregnancy, reflecting the stimulatory effects of estrogen and perhaps other growth factors

on pituitary vascularity and lactotrope hyperplasia. About 5% of microadenomas significantly increase in size, but 15–30% of macroadenomas grow during pregnancy. Bromocriptine has been used for >30 years to restore fertility in women with hyperprolactinemia, without evidence of teratogenic effects. Nonetheless, most authorities recommend strategies to minimize fetal exposure to the drug. For women taking bromocriptine who desire pregnancy, mechanical contraception should be used through three regular menstrual cycles to allow for conception timing. When pregnancy is confirmed, bromocriptine should be discontinued and PRL levels followed serially, especially if headaches or visual symptoms occur. For women harboring macroadenomas, regular visual field testing is recommended, and the drug should be reinstituted if tumor growth is apparent. Although pituitary MRI may be safe during pregnancy, this procedure should be reserved for symptomatic patients with severe headache and/or visual field defects. Surgical decompression may be indicated if vision is threatened. Although comprehensive data support the efficacy and relative safety of bromocriptine-facilitated fertility, patients should be advised of potential unknown deleterious effects and the risk of tumor growth during pregnancy. Because cabergoline is long-acting with a high D_2-receptor affinity, it is not recommended for use in women when fertility is desired.

ACROMEGALY

Etiology GH hypersecretion is usually the result of a somatotrope adenoma but may rarely be caused by extrapituitary lesions (Table 392-6). In addition to the more common GH-secreting somatotrope adenomas, mixed mammosomatotrope tumors and acidophilic stem cell adenomas secrete both GH and PRL. In patients with acidophilic stem cell adenomas, features of hyperprolactinemia (hypogonadism and galactorrhea) predominate over the less clinically evident signs of acromegaly. Occasionally, mixed plurihormonal tumors are encountered that also secrete ACTH, the glycoprotein hormone α subunit, or TSH in addition to GH. Patients with partially empty sellae may present with GH hypersecretion due to a small GH-secreting adenoma within the compressed rim of pituitary tissue; some of these may reflect the spontaneous necrosis of tumors that were previously larger. GH-secreting tumors rarely arise from ectopic pituitary tissue remnants in the nasopharynx or midline sinuses.

There are case reports of ectopic GH secretion by tumors of pancreatic, ovarian, lung, or hematopoietic origin. Rarely, excess GHRH production may cause acromegaly because of chronic stimulation of somatotropes. These patients present with classic features of acromegaly, elevated GH levels, pituitary enlargement on MRI, and pathologic characteristics of pituitary hyperplasia. The most common cause of GHRH-mediated acromegaly is a chest or abdominal carcinoid tumor. Although these tumors usually express positive GHRH immunoreactivity, clinical features of acromegaly are evident in only a minority of patients with carcinoid disease. Excessive GHRH also may be elaborated by hypothalamic tumors, usually choristomas or neuromas.

Presentation and Diagnosis Protean manifestations of GH and IGF-1 hypersecretion are indolent and often are not clinically diagnosed for 10 years or more. Acral bony overgrowth results in frontal bossing, increased hand and foot size, mandibular enlargement with prognathism, and widened space between the lower incisor teeth. In children and adolescents, initiation of GH hypersecretion before epiphyseal long bone closure is associated with development of pituitary gigantism (Fig. 392-7). Soft tissue swelling results in increased heel pad thickness, increased shoe or glove size, ring tightening, characteristic coarse facial features, and a large fleshy nose. Other commonly encountered clinical features include hyperhidrosis, a deep and hollow-sounding voice, oily skin, arthropathy, kyphosis, carpal tunnel syndrome, proximal muscle weakness and fatigue, acanthosis nigricans, and skin tags. Generalized visceromegaly occurs, including cardiomegaly, macroglossia, and thyroid gland enlargement.

The most significant clinical impact of GH excess occurs with respect to the cardiovascular system. Cardiomyopathy with arrhythmias, left ventricular hypertrophy, decreased diastolic function, and hypertension ultimately occur in most patients if untreated. Upper airway obstruction with sleep apnea occurs in >60% of patients and is associated with both soft tissue laryngeal airway obstruction and central sleep dysfunction. Diabetes mellitus develops in 25% of patients with acromegaly, and most patients are intolerant of a glucose load (as GH counteracts the action of insulin). Acromegaly is associated with an increased risk of colon polyps and mortality from colonic malignancy; polyps are diagnosed in up to one-third of patients. Overall mortality is increased about threefold and is due primarily to cardiovascular and cerebrovascular disorders and respiratory disease. Unless GH levels are controlled, survival is reduced by an average of 10 years compared with an age-matched control population.

Laboratory Investigation Age-matched serum IGF-1 levels are elevated in acromegaly. Consequently, an IGF-1 level provides a useful laboratory screening measure when clinical features raise the possibility of acromegaly. Owing to the pulsatility of GH secretion, measurement of a single random GH level is not useful for the diagnosis or exclusion of acromegaly and does not correlate with disease severity. The diagnosis of acromegaly is confirmed by demonstrating the failure of GH suppression to <0.4 μg/L within 1–2 h of an oral glucose load (75 g). When ultrasensitive GH assays are used, normal nadir GH levels are even lower (<0.05 μg/L). About 20% of patients exhibit a paradoxical GH rise after glucose. PRL should be measured, as it is elevated in ~25% of patients with acromegaly. Thyroid function, gonadotropins, and sex steroids may be attenuated because of tumor mass effects. Because most patients will undergo surgery with glucocorticoid coverage, tests of ACTH reserve in asymptomatic patients are more efficiently deferred until after surgery.

TREATMENT

Acromegaly

The goal of treatment is to control GH and IGF-1 hypersecretion, ablate or arrest tumor growth, ameliorate comorbidities, restore mortality rates to normal, and preserve pituitary function.

Surgical resection of GH-secreting adenomas is the initial treatment for most patients (Fig. 392-8). SRLs are used as adjuvant

FIGURE 392-7 Features of acromegaly/gigantism. A 22-year-old man with gigantism due to excess growth hormone is shown to the left of his identical twin. The increased height and prognathism (***A***) and enlarged hand (***B***) and foot (***C***) of the affected twin are apparent. Their clinical features began to diverge at the age of ~13 years. *(Reproduced with permission from RF Gagel, IE McCutcheon. Images in clinical medicine. Pituitary gigantism. N Engl J Med 340:524, 1999.)*

treatment for preoperative shrinkage of large invasive macroadenomas, immediate relief of debilitating symptoms, and reduction of GH hypersecretion; in frail patients experiencing morbidity; and in patients who decline surgery or when surgery fails to achieve biochemical control. Irradiation or repeat surgery may be required for patients who cannot tolerate or do not respond to adjunctive medical therapy. The high rate of late hypopituitarism and the slow rate (5–15 years) of biochemical response are the main disadvantages of radiotherapy. Irradiation is also relatively ineffective in normalizing IGF-1 levels. Stereotactic ablation of GH-secreting adenomas by Gamma Knife radiotherapy is promising, but long-term results and side effects appear similar to those observed with conventional radiation. SRLs may be required while awaiting the full benefits of radiotherapy. Systemic comorbid sequelae of acromegaly, including cardiovascular disease, diabetes, and arthritis, should be managed aggressively. Mandibular surgical repair may be indicated.

SURGERY

Transsphenoidal surgical resection by an experienced surgeon is the preferred primary treatment for both microadenomas (remission rate ~70%) and macroadenomas (<50% in remission). Soft tissue swelling improves immediately after tumor resection. GH levels return to normal within an hour, and IGF-1 levels are normalized within 3–4 days. In ~10% of patients, acromegaly may recur several years after apparently successful surgery; hypopituitarism develops in up to 15% of patients after surgery.

SOMATOSTATIN RECEPTOR LIGANDS

SRLs exert their therapeutic effects through SST2 and SST5 receptor subtypes, both expressed by GH-secreting tumors.

The preferred medical treatments for patients with acromegaly include long-acting injectable SRL depot formulations of octreotide and lanreotide as well as oral octreotide capsules. Although responses vary widely in individual patients, meta-analyses indicate that GH and IGF-1 levels are normalized in ~50% of patients. Octreotide acetate is an eight-amino-acid synthetic somatostatin analogue. In contrast to native somatostatin, the analogue is relatively resistant to plasma degradation. It has a 2-h serum half-life and possesses 40-fold greater potency than native somatostatin to suppress GH. *Octreotide LAR* is a sustained-release, long-acting formulation of octreotide incorporated into microspheres that sustain drug levels for several weeks after intramuscular injection. GH suppression occurs for as long as 6 weeks after a 30-mg intramuscular injection; long-term monthly treatment sustains GH and IGF-1 suppression and also reduces pituitary tumor size in ~50% of patients. *Lanreotide*, in a slow-release depot SRL preparation, is a cyclic somatostatin octapeptide analogue that suppresses GH and IGF-1 hypersecretion after a 60-mg subcutaneous injection. Long-term (every 4–6 weeks) administration controls GH hypersecretion in about two-thirds of treated patients and improves patient compliance because of the long interval required between drug injections. *Oral octreotide capsules* (40–80 mg daily) maintain biochemical control in patients previously maintained on injectable formulations. Rapid relief of headache and soft tissue swelling occurs in ~75% of patients within days to weeks of SRL initiation. Most patients report symptomatic improvement, including amelioration of headache, perspiration, obstructive apnea, and cardiac failure. *Pasireotide LAR*, a multireceptor ligand with preferential SST5 binding, has been shown to exhibit efficacy in achieving biochemical control in patients resistant to octreotide or lanreotide preparations.

Side Effects SRLs are well tolerated in most patients. Adverse effects are similar for injectable octreotide and lanreotide as well as for oral octreotide formulation. They are short-lived and mostly relate to drug-induced suppression of gastrointestinal motility and secretion. Transient nausea, abdominal discomfort, fat malabsorption, diarrhea, and flatulence occur in one-third of patients, and these symptoms usually remit within 2 weeks. Gallbladder contractility and emptying are attenuated; up to 30% of patients develop long-term echogenic sludge or asymptomatic cholesterol gallstones. Other side effects include mild glucose intolerance due to transient insulin suppression, asymptomatic bradycardia, hypothyroxinemia, and local injection site discomfort. Pasireotide is associated with similar gastrointestinal side effects but with a higher prevalence of glucose intolerance and new-onset diabetes mellitus.

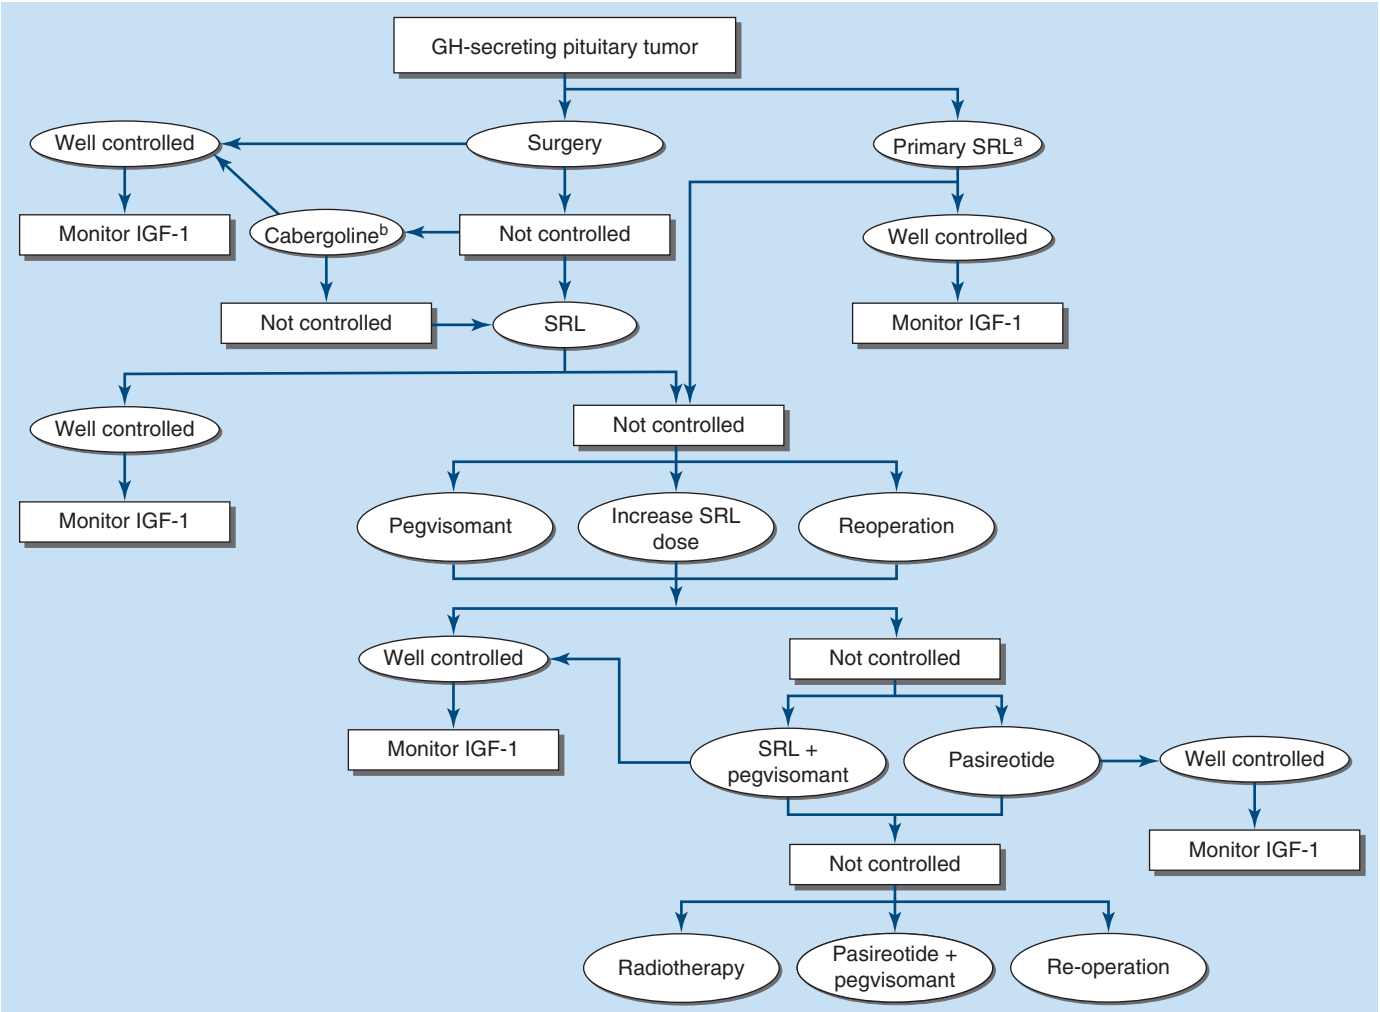

FIGURE 392-8 Management of acromegaly. [a]If curative surgery is not feasible. [b]Consider in cases of mild postoperative GH/IGF-1 elevations. GH, growth hormone; IGF, insulin-like growth factor; SRL, somatostatin receptor ligand (injectable or oral octreotide, or lanreotide).

GH RECEPTOR ANTAGONIST

Pegvisomant antagonizes endogenous GH action by blocking peripheral GH binding to its receptor. Consequently, serum IGF-1 levels are suppressed, reducing the deleterious effects of excess endogenous GH. Pegvisomant is administered by daily subcutaneous injection (10–30 mg) and normalizes IGF-1 in ~70% of patients. GH levels, however, remain elevated as the drug does not target the pituitary adenoma. Side effects include reversible liver enzyme elevation, lipodystrophy, and injection site pain. Tumor size should be monitored by MRI.

Combined treatment with monthly SRLs and weekly or biweekly pegvisomant injections has been used effectively in treatment-resistant patients.

DOPAMINE AGONISTS

Very high doses of cabergoline (0.5 mg/d) may achieve short-lived and modest GH therapeutic efficacy. Combined treatment with octreotide and cabergoline may induce additive biochemical control compared with either drug alone.

RADIATION THERAPY

External radiation therapy or high-energy stereotactic techniques are used as adjuvant therapy for acromegaly. An advantage of radiation is that patient compliance with long-term treatment is not required. Tumor mass is reduced, and GH levels are attenuated over time. However, 50% of patients require at least 8 years for GH levels to be suppressed to <5 μg/L; this level of GH reduction is achieved in ~90% of patients after 18 years but represents suboptimal GH suppression. Patients may require interim medical therapy for several years before attaining maximal radiation benefits. Most patients also experience hypothalamic-pituitary damage, leading to gonadotropin, ACTH, and/or TSH deficiency within 10 years of therapy.

SUMMARY

Surgery is the preferred primary treatment for GH-secreting microadenomas (Fig. 392-8). The high frequency of residual GH hypersecretion after macroadenoma resection usually necessitates adjuvant or primary medical therapy for these larger tumors. Patients unable to receive or respond to unimodal medical treatment may benefit from combined treatments, or they can be offered radiation. Very rarely, repeat surgery may be required.

CUSHING'S DISEASE (ACTH-PRODUCING ADENOMA)

(See also Chap. 398)

Etiology and Prevalence Pituitary corticotrope adenomas (Cushing's disease) account for 70% of patients with endogenous causes of Cushing's syndrome. However, it should be emphasized that iatrogenic hypercortisolism is the most common cause of cushingoid features. Ectopic tumor ACTH production, cortisol-producing adrenal adenomas, adrenal carcinoma, and adrenal hyperplasia account for the other causes; rarely, ectopic tumor CRH production is encountered.

ACTH-producing adenomas account for ~10–15% of all pituitary tumors. Because the clinical features of Cushing's syndrome often lead to early diagnosis, most ACTH-producing pituitary tumors are

relatively small microadenomas. However, macroadenomas also are seen and some ACTH-expressing adenomas are clinically silent. Cushing's disease is 5–10 times more common in women than in men. These pituitary adenomas exhibit unrestrained ACTH secretion, with resultant hypercortisolemia. However, they retain partial suppressibility in the presence of high doses of administered glucocorticoids, providing the basis for dynamic testing to distinguish pituitary from nonpituitary causes of Cushing's syndrome.

Presentation and Diagnosis The diagnosis of Cushing's syndrome presents two great challenges: (1) to distinguish patients with pathologic cortisol excess from those with physiologic or other disturbances of cortisol production and (2) to determine the etiology of pathologic cortisol excess.

Typical features of chronic cortisol excess include thin skin, central obesity, hypertension, plethoric moon facies, purple striae and easy bruisability, glucose intolerance or diabetes mellitus, gonadal dysfunction, osteoporosis, proximal muscle weakness, signs of hyperandrogenism (acne, hirsutism), and psychological disturbances (depression, mania, and psychoses) (Table 392-7). Hematopoietic features of hypercortisolism include leukocytosis, lymphopenia, and eosinopenia. Immune suppression includes delayed hypersensitivity and infection propensity. These protean yet commonly encountered manifestations of hypercortisolism make it challenging to decide which patients mandate formal laboratory evaluation. Certain features make pathologic causes of hypercortisolism more likely; they include characteristic central redistribution of fat, thin skin with striae and bruising, and proximal muscle weakness. In children and young females, early osteoporosis may be particularly prominent. The primary cause of death is cardiovascular disease, but life-threatening infections and risk of suicide are also increased.

Rapid development of features of hypercortisolism associated with skin hyperpigmentation and severe myopathy suggests an ectopic tumor source of ACTH. Hypertension, hypokalemic alkalosis, glucose intolerance, and edema are also more pronounced in these patients. Serum potassium levels <3.3 mmol/L are evident in ~70% of patients with ectopic ACTH secretion but are seen in <10% of patients with pituitary-dependent Cushing's syndrome.

Laboratory Investigation The diagnosis of Cushing's disease is based on laboratory documentation of endogenous hypercortisolism. Measurement of 24-h UFC is a precise and cost-effective screening test. Alternatively, the failure to suppress plasma cortisol after an overnight 1-mg dexamethasone suppression test can be used to identify patients with hypercortisolism. As nadir levels of cortisol occur at night, elevated midnight serum or salivary samples of cortisol are suggestive of Cushing's disease. Basal plasma ACTH levels often distinguish patients with ACTH-independent (adrenal or exogenous glucocorticoid) from those with ACTH-dependent (pituitary, ectopic ACTH) Cushing's syndrome. Mean basal ACTH levels are about eightfold higher in patients with ectopic ACTH secretion than in those with pituitary ACTH-secreting adenomas. However, extensive overlap of ACTH levels in these two disorders precludes using ACTH measurements to make the distinction. Preferably, dynamic testing based on differential sensitivity to glucocorticoid feedback or ACTH stimulation in response to CRH or cortisol reduction is used to distinguish ectopic from pituitary sources of excess ACTH (Table 392-8). Very rarely, circulating CRH levels are elevated, reflecting ectopic tumor-derived secretion of CRH and often ACTH. **For further discussion of dynamic testing for Cushing's syndrome, see Chap. 398.**

Most ACTH-secreting pituitary tumors are <5 mm in diameter, and about half are undetectable by sensitive MRI. The high prevalence of incidental pituitary microadenomas diminishes the ability to distinguish ACTH-secreting pituitary tumors accurately from nonsecreting incidentalomas.

Inferior Petrosal Venous Sampling Because pituitary MRI with gadolinium enhancement is insufficiently sensitive to detect small (<2 mm) pituitary ACTH-secreting adenomas, bilateral inferior petrosal sinus ACTH sampling before and after CRH administration may be required to distinguish these lesions from ectopic ACTH-secreting tumors that may have similar clinical and biochemical characteristics. Simultaneous assessment of ACTH in each inferior petrosal vein and

[a]ACTH-independent causes of Cushing's syndrome are diagnosed by suppressed ACTH levels and an adrenal mass in the setting of hypercortisolism. Iatrogenic Cushing's syndrome is excluded by history.

Abbreviations: ACTH, adrenocorticotropic hormone; CRH, corticotropin-releasing hormone; F, female; M, male; UFC, urinary free cortisol.

in the peripheral circulation provides a strategy for confirming and localizing pituitary ACTH production. Sampling is performed at baseline and 2, 5, and 10 min after intravenous CRH (1 μg/kg) injection. An increased central:peripheral ACTH ratio (>2) before and a peak central:peripheral ACTH ratio >3 after CRH injection confirm the presence of a pituitary ACTH-secreting adenoma. The sensitivity of this test is >95%, with very rare false-positive results. False-negative results may be encountered in patients with aberrant venous drainage. Petrosal sinus catheterizations are technically difficult, and ~0.05% of patients develop neurovascular complications. The procedure should not be performed in patients with hypertension, in patients with known cerebrovascular disease, or in the presence of a well-visualized pituitary adenoma on MRI.

TREATMENT

Cushing's Disease

Selective transsphenoidal resection is the treatment of choice for Cushing's disease **(Fig. 392-9)**. The remission rate for this procedure is ~80% for microadenomas but <50% for macroadenomas. However, surgery is rarely successful when the adenoma is not visible on MRI. After successful tumor resection, most patients experience a postoperative period of symptomatic ACTH deficiency that may last up to 12 months. This usually requires low-dose cortisol replacement, as patients experience steroid withdrawal symptoms and have a suppressed hypothalamic-pituitary-adrenal axis. Biochemical recurrence occurs in ~5% of patients in whom surgery was initially successful. As persistent hypercortisolemia may cause blood clotting defects, prophylactic postoperative thromboembolic management has been advocated for vulnerable patients.

When initial surgery is unsuccessful, repeat surgery is sometimes indicated, particularly when a pituitary source for ACTH is well documented. In older patients, in whom issues of growth and fertility are less important, hemi- or total hypophysectomy may be necessary if a discrete pituitary adenoma is not recognized. Pituitary irradiation may be used after unsuccessful surgery, but it cures only ~15% of patients. Because the effects of radiation are slow and only partially effective in adults, adrenal-targeted steroidogenic inhibitors are used in combination with pituitary irradiation to block adrenal responses to persistently high ACTH levels.

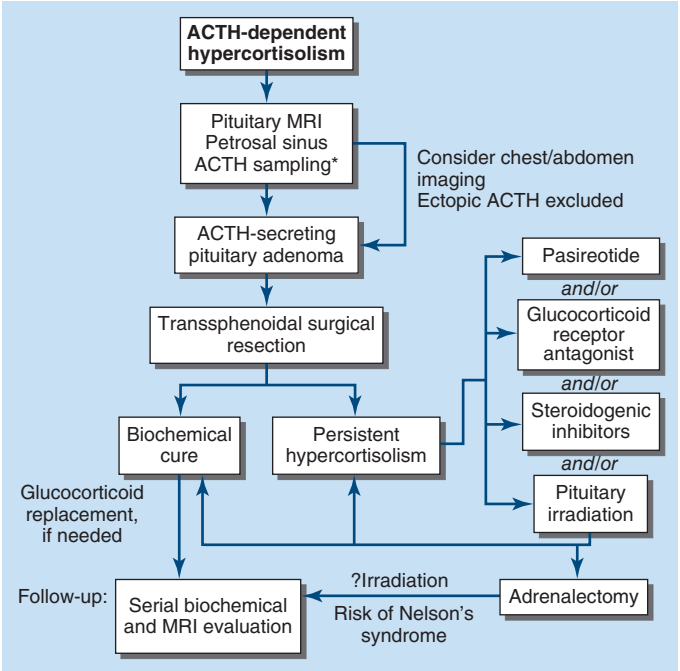

FIGURE 392-9 Management of Cushing's disease. ACTH, adrenocorticotropin hormone; MRI, magnetic resonance imaging; *, Not usually required.

Pasireotide LAR 10–40 mg intramuscularly, an SRL with high affinity for SST5 > SST2 receptor subtypes, may control hypercortisolemia in a subset of patients with ACTH-secreting pituitary tumors when surgery is not an option or has not been successful. The drug lowers plasma ACTH levels and normalizes 24-h UFC levels in ~20% of patients, and up to 40% of patients may experience pituitary tumor shrinkage. Side effects are similar to those encountered for other SRLs and include transient abdominal discomfort, diarrhea, nausea, and gallstones (20% of patients). Notably, hyperglycemia and new-onset diabetes develop in up to 70% of patients, likely due to suppressed pancreatic secretion of insulin and incretins. Because patients with hypercortisolism are insulin-resistant, hyperglycemia should be rigorously managed. The drug requires consistent long-term administration.

Osilodrostat (2 mg twice daily titrated up to 30 mg twice daily), an oral 11β-hydroxylase inhibitor that blocks adrenal gland cortisol biosynthesis, normalized 24-h UFC in 86% of patients. Mild, mostly transient gastrointestinal symptoms are common. Patients should be closely monitored for development of hypocortisolism and adrenal insufficiency. Elevated adrenal hormone precursors may lead to hypokalemia and hypertension. QTc prolongation and possibly increased tumor volume are also reported.

Ketoconazole, an imidazole derivative antimycotic agent, inhibits several P450 enzymes and effectively lowers cortisol in most patients with Cushing's disease when administered twice daily (600–1200 mg/d). Elevated hepatic transaminases, gynecomastia, impotence, gastrointestinal upset, and edema are common side effects.

Levoketoconazole, a 2S,4R enantiomer of ketoconazole, is administered at the same dose/schedule as ketoconazole and has a similar side effect profile.

Mifepristone (300–1200 mg/d), a glucocorticoid receptor antagonist, blocks peripheral cortisol action and is approved to treat hyperglycemia in Cushing's disease. Because the drug does not target the pituitary tumor, both ACTH and cortisol levels remain elevated, thus obviating a reliable circulating biomarker. Side effects are largely due to general antagonism of other steroid hormones and include hypokalemia, endometrial hyperplasia, hypoadrenalism, and hypertension.

Metyrapone (2–4 g/d) inhibits 11β-hydroxylase activity and normalizes plasma cortisol in up to 75% of patients. Side effects include nausea and vomiting, rash, and exacerbation of acne or hirsutism. *Mitotane* (3–6 g/d orally in four divided doses) suppresses cortisol hypersecretion by inhibiting 11β-hydroxylase and cholesterol side-chain cleavage enzymes and by destroying adrenocortical cells. Side effects of mitotane include gastrointestinal symptoms, dizziness, gynecomastia, hyperlipidemia, skin rash, and hepatic enzyme elevation. It also may lead to hypoaldosteronism. Other agents include *aminoglutethimide* (250 mg tid), *trilostane* (200–1000 mg/d), *cyproheptadine* (24 mg/d), and IV *etomidate* (0.3 mg/kg per h). Glucocorticoid insufficiency is a potential side effect of agents used to block steroidogenesis.

The use of steroidogenic inhibitors has decreased the need for bilateral adrenalectomy. Surgical removal of both adrenal glands corrects hypercortisolism but may be associated with significant morbidity rates and necessitates permanent glucocorticoid and mineralocorticoid replacement. Adrenalectomy in the setting of residual corticotrope adenoma tissue predisposes to the development of *Nelson's syndrome*, a disorder characterized by rapid pituitary tumor enlargement and increased pigmentation secondary to high ACTH levels. Prophylactic radiation therapy may be indicated to prevent the development of Nelson's syndrome after adrenalectomy.

NONFUNCTIONING AND GONADOTROPIN-PRODUCING PITUITARY ADENOMAS

Etiology and Prevalence Nonfunctioning pituitary adenomas include those that secrete little or no pituitary hormones into the systemic circulation, as well as tumors that produce too little hormone

to result in recognizable clinical features. They are the most common type of pituitary adenoma and are usually macroadenomas at the time of diagnosis because clinical features are not apparent until tumor mass effects occur. Based on immunohistochemistry, most clinically nonfunctioning adenomas can be shown to originate from gonadotrope cells or from pituitary null cells. These tumors typically produce small amounts of intact gonadotropins (usually FSH) as well as uncombined α, LH β, and FSH β subunits. Tumor secretion may lead to elevated α and FSH β subunits and, very rarely, to increased LH β subunit levels. Some adenomas express α subunits without FSH or LH. A TRH stimulation test often induces an atypical increase of tumor-derived gonadotropins or subunits.

Presentation and Diagnosis Clinically nonfunctioning tumors often present with optic chiasm pressure and other symptoms of local expansion or may be incidentally discovered on an MRI performed for another indication (incidentaloma). Rarely, menstrual disturbances or ovarian hyperstimulation occur in women with large tumors that produce FSH and LH. In these cases, ovaries may have features that resemble polycystic ovarian syndrome and may produce very high levels of estrogen. More commonly, adenoma compression of the pituitary stalk or surrounding pituitary tissue leads to attenuated LH and features of hypogonadism. PRL levels are usually slightly increased, also because of stalk compression. It is important to distinguish this circumstance from true prolactinomas, as nonfunctioning tumors do not shrink in response to treatment with dopamine agonists.

Laboratory Investigation The goal of laboratory testing in clinically nonfunctioning tumors is to classify the type of tumor, identify hormonal markers of tumor activity, and detect possible hypopituitarism. Free α subunit levels may be elevated in 10–15% of patients with nonfunctioning tumors. In female patients, peri- or postmenopausal basal FSH concentrations are difficult to distinguish from tumor-derived FSH elevation. Premenopausal women have cycling FSH levels, also preventing clear-cut diagnostic distinction from tumor-derived FSH. In men, gonadotropin-secreting tumors may be diagnosed because of slightly increased gonadotropins (FSH > LH) in the setting of a pituitary mass. Testosterone levels are usually low despite the normal or increased LH level, perhaps reflecting reduced LH bioactivity or the loss of normal LH pulsatility. Because this pattern of hormone test results is also seen in primary gonadal failure and, to some extent, with aging (Chap. 403), the finding of increased gonadotropins alone is insufficient for the diagnosis of a gonadotropin-secreting tumor. In the majority of patients with gonadotrope adenomas, TRH administration stimulates LH β subunit secretion; this response is not seen in normal individuals. GnRH testing, however, is not helpful for making the diagnosis. For nonfunctioning and gonadotropin-secreting tumors, the diagnosis usually rests on immunohistochemical analyses of surgically resected tumor tissue, as the mass effects of these tumors usually necessitate resection.

Although acromegaly or Cushing's disease usually presents with unique clinical features, clinically inapparent (silent) somatotrope or corticotrope adenomas may only be diagnosed by immunostaining of resected tumor tissue. These silent tumors usually grow more aggressively and account for up to 20% of all nonfunctioning adenomas. If PRL levels are <100 μg/L in a patient harboring a pituitary mass, a nonfunctioning adenoma causing pituitary stalk compression should be considered.

TREATMENT

Nonfunctioning and Gonadotropin-Producing Pituitary Adenomas

As the probability of nonfunctioning microadenoma growth is very low, asymptomatic small nonfunctioning microadenomas with no threat to vision may be followed with an MRI after 3 years, with serial MRI and visual field testing thereafter as needed. However, for macroadenomas, transsphenoidal surgery is indicated to reduce tumor size and relieve compressive mass effects (Fig. 392-10). Although it is not usually possible to remove all adenoma tissue surgically, vision improves in 70% of patients with preoperative visual field defects. Preexisting hypopituitarism that results from tumor mass effects may improve or resolve completely. Beginning ~6 months postoperatively, MRI scans should be performed yearly to detect whether tumor regrowth is occurring. Within 5–6 years after successful surgical resection, ~15% of nonfunctioning tumors recur. When substantial tumor remains after transsphenoidal surgery, adjuvant radiotherapy may be indicated to prevent persistent tumor regrowth. Radiotherapy may be deferred if no postoperative residual mass is evident. Nonfunctioning pituitary tumors respond poorly to dopamine agonist treatment, and SRLs are largely ineffective for shrinking these tumors.

TSH-SECRETING ADENOMAS

TSH-producing macroadenomas are very rare but are often large and locally invasive when they occur. Patients usually present with thyroid goiter and hyperthyroidism, reflecting chronic overproduction of TSH.

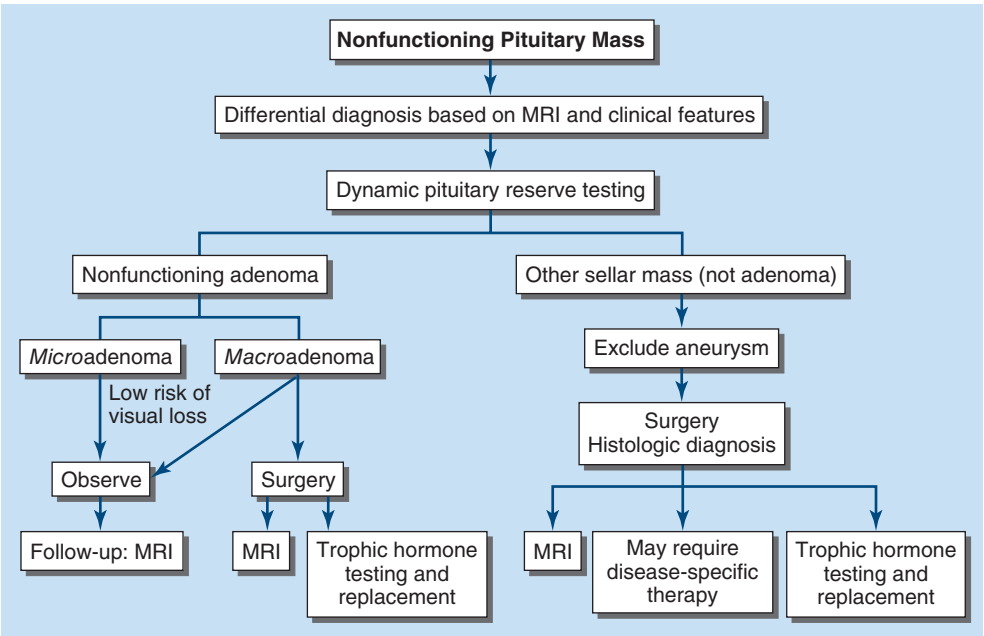

FIGURE 392-10 Management of a nonfunctioning pituitary mass. MRI, magnetic resonance imaging.

Diagnosis is based on demonstrating elevated serum free T_4 levels, inappropriately normal or high TSH secretion, and MRI evidence of a pituitary adenoma. Elevated free glycoprotein hormone α subunits are seen in many patients.

It is important to exclude other causes of inappropriate TSH secretion, such as resistance to thyroid hormone, an autosomal dominant disorder caused by mutations in the thyroid hormone β receptor (Chap. 394). The presence of a pituitary mass and elevated β subunit levels are suggestive of a TSH-secreting tumor. Dysalbuminemic hyperthyroxinemia syndromes, caused by mutations in serum thyroid hormone binding proteins, are also characterized by elevated thyroid hormone levels, but with normal rather than suppressed TSH levels. Moreover, free thyroid hormone levels are normal in these disorders, most of which are familial.

TREATMENT

TSH-Secreting Adenomas

The initial therapeutic approach is to remove or debulk the tumor mass surgically, usually using a transsphenoidal approach. Total resection is not often achieved as most of these adenomas are large and locally invasive. Normal circulating thyroid hormone levels are achieved in about two-thirds of patients after surgery. Thyroid ablation or antithyroid drugs (methimazole and propylthiouracil) can be used to reduce thyroid hormone levels. SRL treatment effectively normalizes TSH and α subunit hypersecretion, shrinks the tumor mass in 50% of patients, and improves visual fields in 75% of patients; euthyroidism is restored in most patients. Because SRLs markedly suppress TSH, biochemical hypothyroidism often requires concomitant thyroid hormone replacement, which may also further control tumor growth.

AGGRESSIVE ADENOMAS

Despite the rarity of malignant transformation and metastatic lesions, a subset of pituitary adenomas undergoes aggressive local growth and central nervous system invasion with high Ki67 levels (>4%). Silent corticotrope and somatotrope tumors, as well as prolactinomas occurring in middle-aged men, are particularly prone to aggressive growth and recurrence. Patients with these tumors usually require an integrated management approach including repeat surgeries and irradiation. Temozolomide has also been used with variable responses.

393 Disorders of the Neurohypophysis

Mirjam Christ-Crain, Mark Sherlock

The posterior pituitary consists of the distal axons of the hypothalamic magnocellular neurons that make up the neurohypophysis. The perikarya (cell bodies) of these axons are located in paired paraventricular and supraoptic nuclei of the hypothalamus. Some of these neurons produce arginine vasopressin (AVP), also known as antidiuretic hormone (ADH); others produce oxytocin. AVP acts on the renal tubules to reduce water loss by concentrating the urine. Oxytocin stimulates postpartum milk letdown in response to suckling, and also elicits socioemotional responses. A deficiency of AVP secretion or action causes a syndrome characterized by the production of large amounts of dilute urine. Excessive or inappropriate AVP production impairs urinary water excretion and predisposes to hyponatremia.

VASOPRESSIN

SYNTHESIS AND SECRETION

AVP is a nonapeptide composed of a six-member disulfide ring and a tripeptide tail (Fig. 393-1). It is synthesized via a polypeptide precursor that includes AVP, neurophysin, and copeptin, all encoded by a single gene on chromosome 20. After preliminary processing and folding, the precursor is packaged in neurosecretory vesicles, where it is transported down the axon. It is further processed to AVP, neurophysin, and copeptin, and stored in neurosecretory vesicles in the posterior pituitary until it is released by exocytosis into peripheral blood.

In healthy individuals, AVP secretion is regulated primarily by the "effective" osmotic pressure, which is determined largely by the plasma concentration of sodium and its anions. This regulation is mediated by specialized cells in the anteromedial hypothalamus, known as *osmoreceptors.* The osmoreceptors receive blood from small perforating branches of the anterior communicating artery. They are extremely sensitive to small changes in the plasma concentration of sodium and its anions but normally are insensitive to other naturally occurring plasma solutes such as urea and glucose. This osmoregulatory system includes inhibitory as well as stimulatory components that function in concert to create an osmotic threshold, or set point, control system. Below this osmotic threshold, plasma AVP is suppressed to levels that permit the development of a maximum water diuresis. Above the threshold, plasma AVP rises steeply in direct proportion to plasma osmolarity, quickly reaching levels sufficient to produce maximum antidiuresis. The absolute levels of plasma osmolarity/sodium at which minimally and maximally effective levels of plasma AVP occur differ from person to person, apparently due to genetic influences on the set and sensitivity of the system. However, the average threshold, or set point, for AVP release corresponds to a plasma osmolarity and sodium of ~275 mosmol/L and 135 meq/L, respectively; levels only 2–4% higher normally result in maximum antidiuresis.

AVP is also secreted in response to a decrease in blood pressure or by volume loss of >10–20%. These hemodynamic (baroregulated) influences are mediated by neuronal afferents that originate in transmural pressure receptors of the heart and large arteries and project via the vagus and glossopharyngeal nerves to the brainstem, which sends postsynaptic projections to the hypothalamus. AVP secretion also can be stimulated by nausea, acute hypoglycemia, glucocorticoid deficiency, smoking, and possibly angiotensin. Emetic stimuli are extremely potent in comparison to osmotic stimuli; they typically elicit immediate, 50- to 100-fold increases in plasma AVP even when the nausea is transient and not associated with vomiting or other symptoms. They act via the emetic center in the medulla and can be blocked completely by treatment with antiemetics such as fluphenazine. There is no evidence that pain or other noxious stresses have any effect on AVP unless they elicit a vasovagal reaction and its associated nausea and hypotension.

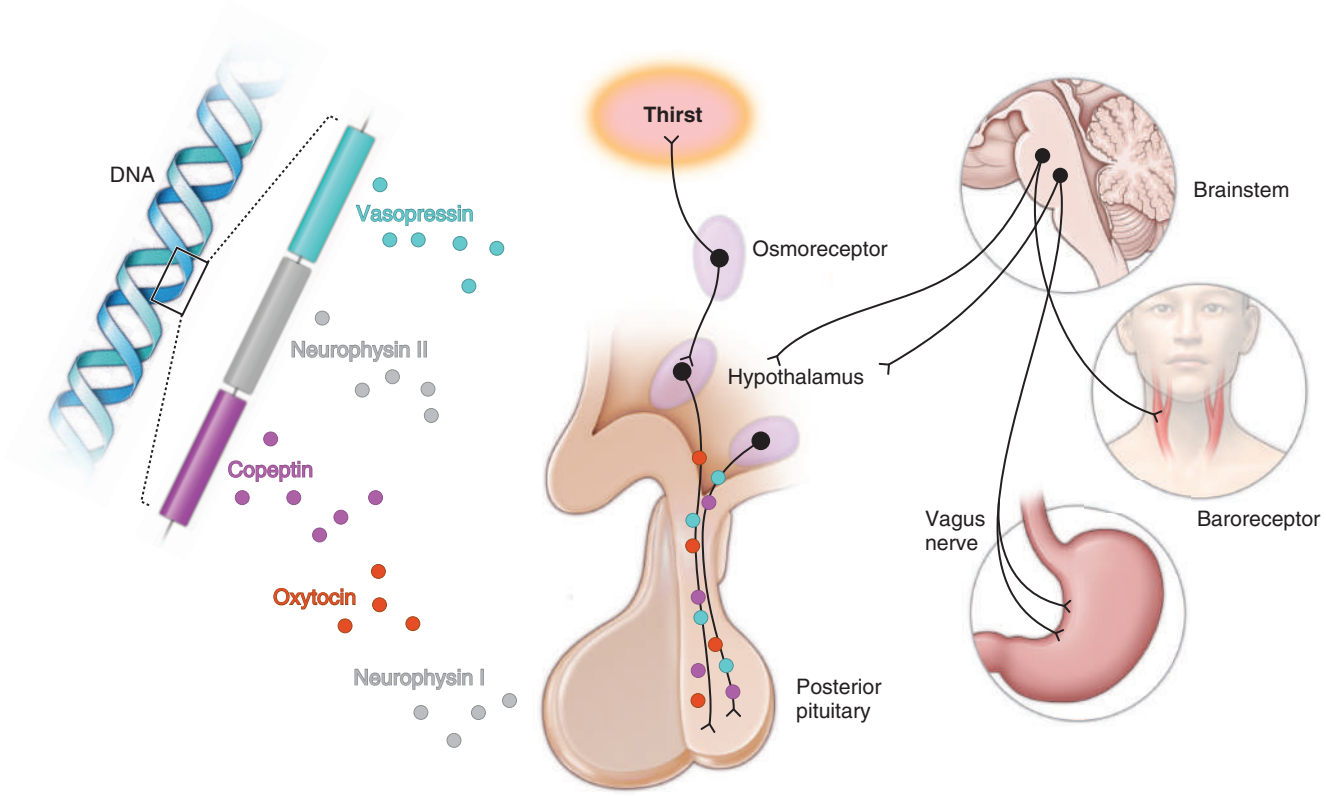

FIGURE 393-1 Primary structure, production, and release of arginine vasopressin (AVP). AVP is a nonapeptide composed of a six-member disulfide ring and a tripeptide tail. It is synthesized via a polypeptide precursor that includes AVP, neurophysin, and copeptin, all encoded by a single gene on chromosome 20. The precursor hormone, pre-pro-vasopressin consists of three peptides: AVP, neurophysin 2, and copeptin.

ACTION

The most important physiologic action of AVP is to reduce water excretion by promoting the concentration of urine. Other physiologic actions of AVP include stimulating ACTH and vasoconstriction. This antidiuretic effect is achieved primarily by increasing the hydro-osmotic permeability of principal cells that line the distal tubule and medullary collecting ducts of the kidney (Fig. 393-2). In the absence of AVP, these cells are impermeable to water and reabsorb little, if any, of the relatively large volume of dilute filtrate that enters from the proximal nephron. In this condition, the rate of urine output can be as high as 0.2 mL/kg per min and the specific gravity and osmolarity as low as ~1.000 and 50 mOsmol/L, respectively. When AVP is secreted, it binds to V_2 receptors on the basal surface of principal cells causing water channels composed of aquaporin-2 (AQ-2) to be inserted into the apical surface of the cell. These channels allow water to flow passively from the lumen through the cell down the osmotic gradient created by the hypertonicity of the renal medulla. The magnitude of this antidiuretic effect varies in direct proportion to plasma AVP, the rate of solute excretion, and the level of hypertonicity in the renal medulla. The maximum antidiuresis achievable in healthy humans occurs at plasma AVP concentrations in the range of 1 to 3 pg/mL and results in a urine osmolarity as high as 1200 mOsmol/L. However, maximum concentrating capacity varies considerably depending on the level of hypertonicity in the renal medulla and that, in turn, is a function of the level and duration of AVP receptor 2 (AVPR2)–stimulated reabsorption of urea in the distal nephron. Hence, if basal AVP stimulation of AVPR2 is low (e.g., a high basal fluid intake in primary polydipsia), the rise in urine osmolarity that occurs immediately after an increase in AVP concentrations may be so blunted as to suggest a defect in antidiuretic function. This reduced concentrating capacity accounts for the shortcomings of the traditional indirect methods for the differential diagnosis of polyuric states (see below).

At high concentrations, AVP also causes contraction of smooth muscle in blood vessels in the skin and gastrointestinal tract, induces glycogenolysis in the liver, and potentiates ACTH release by

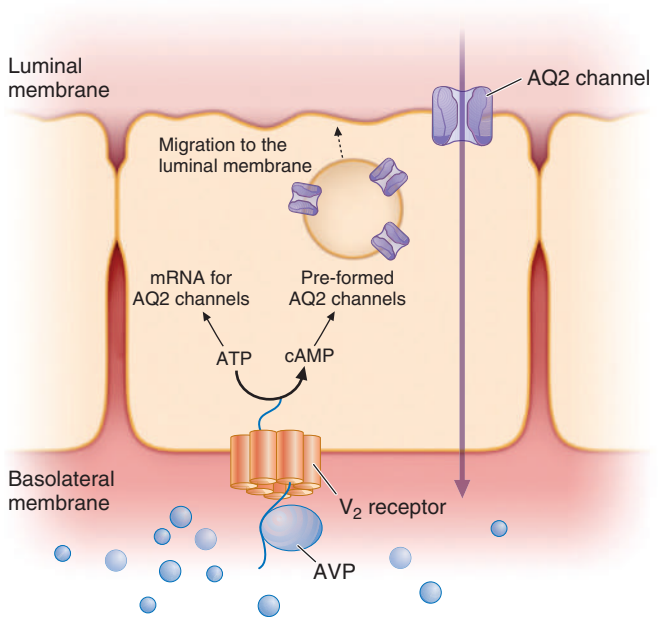

FIGURE 393-2 Antidiuretic effect of arginine vasopressin (AVP) in the regulation of urine volume. In a typical 70-kg adult, the kidney filters ~180 L/d of plasma. Of this, ~144 L (80%) is reabsorbed isosmotically in the proximal tubule and another 8 L (4–5%) is reabsorbed without solute in the descending limb of Henle's loop. In the presence of AVP, solute-free water is reabsorbed osmotically through the principal cells of the collecting ducts, resulting in the excretion of a much smaller volume of concentrated urine. This antidiuretic effect is mediated via a G protein–coupled V_2 receptor that increases intracellular cyclic AMP, thereby inducing translocation of aquaporin 2 (AQP 2) water channels into the apical membrane. The resultant increase in permeability permits an influx of water that diffuses out of the cell through AQP 3 and AQP 4 water channels on the basal-lateral surface. The net rate of flux across the cell is determined by the number of AQP 2 water channels in the apical membrane and the strength of the osmotic gradient between tubular fluid and the renal medulla.

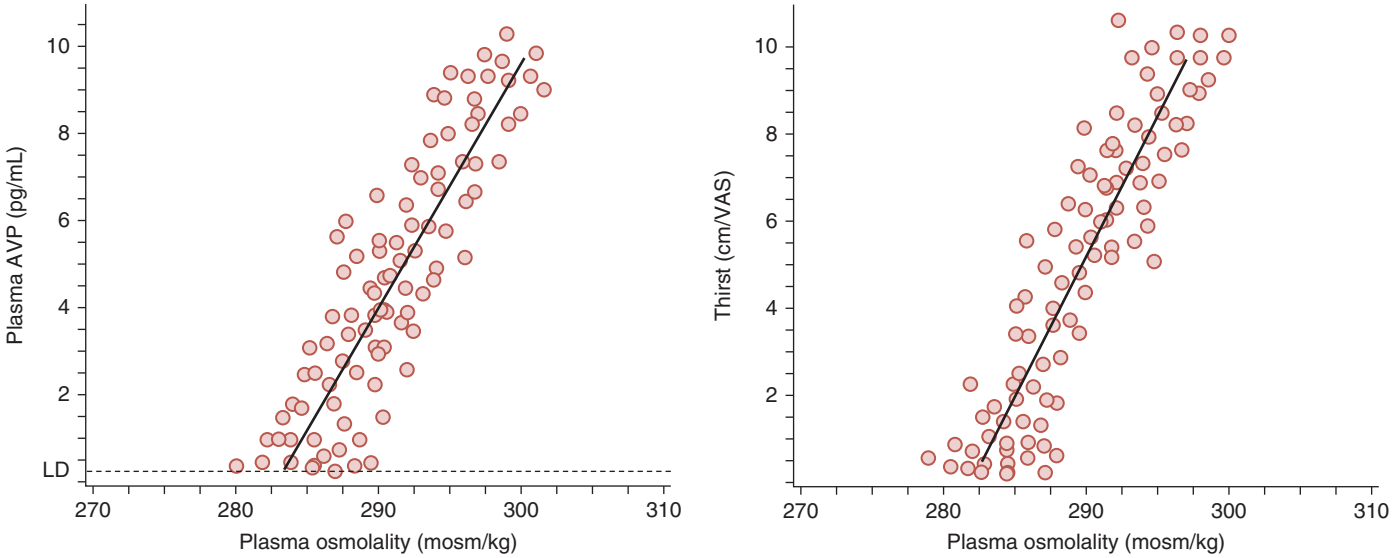

FIGURE 393-3 The relationship of plasma osmolality to arginine vasopressin (AVP) secretion and thirst. VAS, visual analogue scale.

corticotropin-releasing factor. These effects are mediated by V_{1a} or V_{1b} receptors that are coupled to phospholipase C. They may also affect the sensitivity of the baroreceptor and influence sympathetic and parasympathetic outflows to a variety of target organs, including the heart, the peripheral vasculature, and the kidneys.

METABOLISM

AVP distributes rapidly into a space approximately equal to the extracellular fluid volume. It is cleared irreversibly with a half-life ($t_{1/2}$) of 10–30 min. Most AVP clearance is due to degradation in the liver and kidneys. During pregnancy, the metabolic clearance of AVP is increased three- to fourfold due to placental production of an N-terminal peptidase (vasopressinase). Importantly, the synthetic vasopressin analogue desmopressin (DDAVP) is more resistant to N-terminal peptidases, resulting in a longer half-life.

THIRST

Because AVP cannot reduce water loss below a certain minimum level obligated by urinary solute load and evaporation from skin and lungs, a mechanism for ensuring adequate water intake is essential for preventing dehydration. This vital function is performed by the thirst mechanism. Like AVP, thirst and fluid intake are regulated primarily by an osmostat that is localized in the anteromedial hypothalamus and detects very small changes in the plasma concentration of sodium and its anions. The thirst osmostat appears to be "set" about 3% higher than the AVP osmostat **(Fig. 393-3)**. This relationship ensures that thirst, polydipsia, and dilution of body fluids do not occur until plasma osmolarity/sodium exceeds the defensive capacity of the antidiuretic mechanism. Defects in thirst result in hypodipsia/adipsia. The gastrointestinal tract also has a mechanism that detects fluid intake and inhibits thirst and AVP secretion before water is absorbed sufficiently to lower plasma osmolarity/sodium. However, the resultant inhibition of thirst and AVP is transient unless plasma osmolarity/sodium is reduced, and the role of this system in clinical disorders of water balance has not been determined.

OXYTOCIN

Oxytocin (OXT) is also a nonapeptide that differs from AVP at positions 3 and 8 (Fig. 393-1). However, it has relatively little antidiuretic effect and seems to act mainly on mammary ducts to facilitate milk letdown during nursing. It also may help initiate or facilitate labor by stimulating contraction of uterine smooth muscle, but it is not clear if this action is physiologic or necessary for normal delivery. In addition to its release from axonal terminals, OXT is dendritically released into the central extracellular space and directly projected to other brain regions, where it acts as a neurotransmitter. The central oxytocinergic system is key in regulating socioemotional functioning, including attachment and pair bonding, fear extinction, emotion recognition, and empathy.

DEFICIENCIES OF AVP SECRETION AND ACTION

DIABETES INSIPIDUS (AVP DEFICIENCY AND AVP RESISTANCE)

Clinical Characteristics Deficiencies in AVP secretion or action result in the excretion of abnormally large volumes of dilute urine. The 24-h urine volume exceeds 40–50 mL/kg body weight and consequently leads to polydipsia. Signs and symptoms of dehydration (and biochemical hypernatremia) are uncommon unless thirst and/or water intake are also impaired.

Etiology AVP deficiency and AVP resistance should be differentiated from increased AVP metabolism in pregnancy and from primary polydipsia. Primary deficiency of AVP secretion was formerly called *neurogenic*, *pituitary*, *cranial*, or *central diabetes insipidus* but is now referred to as AVP deficiency. It can be caused by a variety of acquired, congenital, or genetic disorders but is often idiopathic **(Table 393-1)**. The most common genetic form is transmitted in an autosomal dominant mode and is caused by diverse mutations in the coding region of one allele of the AVP–neurophysin II (or *AVP-NPII*) gene. Renal insensitivity to the antidiuretic action of AVP leads to AVP resistance, which was formerly known as nephrogenic diabetes insipidus. It can be caused by a drug such as lithium, a disorder such as hypokalemia and hypercalcemia, or by a genetic mutation.

In pregnancy, increased metabolism of AVP may occur due to AVP degradation by an N-terminal aminopeptidase (vasopressinase) produced in the placenta. This is referred to as *gestational AVP deficiency* because the signs and symptoms manifest during pregnancy and usually remit several weeks after delivery.

These forms of AVP deficiency and AVP resistance should be differentiated from excessive intake of fluids, which is commonly referred to as *primary polydipsia*. This disorder is common in patients with neurodevelopmental or psychotic disorders, particularly chronic schizophrenia. Outside the psychiatric setting, it is increasingly seen in the general population owing to the popularity of lifestyle programs and the belief that drinking large amounts of water is healthy and improves cognition (Table 393-1).

TABLE 393-1 Etiology of Polyuria–Polydipsia Syndromes

BASIC DEFECT	ACQUIRED CAUSES	HEREDITARY CAUSES
AVP Deficiency		
Deficiency in AVP synthesis or secretion	• Trauma (surgery, deceleration injury) • Neoplasia (craniopharyngioma, meningioma, germinoma, metastases) • Vascular (cerebral or hypothalamic hemorrhage, infarction or ligation of anterior communicating artery aneurysm) • Granulomatous (histiocytosis, sarcoidosis) • Infectious (meningitis, encephalitis, tuberculosis) • Inflammatory or autoimmune (lymphocytic infundibuloneurohypophysitis, IgG4 neurohypophysitis) • Drug or toxin exposure • Osmoreceptor dysfunction (adipsic DI) • Others (hydrocephalus, ventricular or suprasellar cyst, trauma, and degenerative diseases) • Idiopathic	• Autosomal dominant: *AVP* mutations • Autosomal recessive, type a and b: *AVP* mutations • Autosomal recessive, type c: *WFS1* mutations • Autosomal recessive, type d: *PCSK1* mutations • X-linked recessive: gene unknown
AVP Resistance		
Reduced renal sensitivity to antidiuretic effect of physiologic AVP levels	• Drug exposure (lithium, demeclocycline, cisplatin, etc.) • Hypercalcemia or hypokalemia • Infiltrating lesions (sarcoidosis, amyloidosis, multiple myeloma, etc.) • Vascular disorders (sickle cell anemia) • Mechanical (polycystic kidney disease and urethral obstruction)	• X-linked: *AVPR2* mutations • Autosomal recessive or dominant: *AQP2* mutations
Primary Polydipsia		
Excessive fluid intake at a diminished set point	• Dipsogenic[a] (idiopathic or similar lesions as with central DI) • Psychosis intermittent hyponatremia–polydipsia (PIP) syndrome • Compulsive water drinking • Health enthusiasts	NA
Gestational AVP Deficiency		
Increased enzymatic metabolism of circulating AVP hormone	Pregnancy	NA

[a]Downward resetting of the thirst threshold.

Pathophysiology In AVP deficiency and resistance, the defect in urine concentration increases the rate of water excretion and causes a small (1–2%) decrease in body water and a commensurate increase in plasma osmolarity/sodium, which stimulates thirst and a compensatory increase in water intake. The severity of the defect in antidiuretic function varies significantly from patient to patient. In some patients, AVP deficiency is nearly complete and cannot be overcome by even an intense stimulus such as nausea or severe dehydration. In others, AVP deficiency is incomplete, and a modest stimulus such as a few hours of fluid deprivation, smoking, or a vasovagal reaction is sufficient to concentrate the urine. However, even in patients with a partial defect, the maximum level of urine osmolarity produced by these stimuli is usually less than normal partly because the prior deficiency in basal AVP stimulation temporarily diminishes renal concentrating capacity. Nevertheless, the underlying cause of the AVP deficiency/resistance can be determined by analyzing the relationship of urine osmolarity to plasma AVP/copeptin and of plasma AVP/copeptin to plasma osmolarity/sodium.

The pathophysiology of primary polydipsia is the reverse of that in AVP deficiency or resistance. The increase in fluid intake reduces plasma osmolarity/sodium and leads to a physiologic decrease in AVP secretion. The resultant urinary dilution produces a compensatory increase in urinary free-water excretion that usually offsets the increase in intake and stabilizes plasma osmolarity/sodium at a level below basal. Thus, hyponatremia is uncommon unless the polydipsia is very severe or the compensatory water diuresis is impaired (by another contributory factor that causes AVP release). In diagnostic tests, fluid deprivation or hypertonic saline infusion produces a normal rise in plasma AVP, but the resultant increase in urine concentration is usually subnormal because the capacity of the kidney to concentrate the urine is temporarily diminished by the prior lack of AVP stimulation. Thus, the maximum level of urine osmolarity achieved is often indistinguishable from that produced by fluid deprivation and/or administration of ADH in partial pituitary or partial nephrogenic diabetes insipidus. However, unlike AVP deficiency or resistance, the relationships of the rise in plasma AVP to the rise in plasma and urine osmolarity are both normal in primary polydipsia.

Differential Diagnosis If symptoms of polyuria, nocturia, and/or persistent thirst are present in the absence of glucosuria, the possibility of AVP deficiency or AVP resistance should be evaluated by collecting a 24-h urine on unrestricted fluid intake. If the volume is >40–50 mL/kg per day and/or >3 L/d, further investigations are indicated. If sodium levels are below the normal reference range (<135 mmol/L), this suggests primary polydipsia since these patients can drink themselves into hyponatremia. If sodium levels are above the normal reference range, the diagnosis of AVP deficiency or resistance is likely, and a test with desmopressin (2 μg) followed by a repeat measurement of urine osmolarity will determine if hypotonic polyuria is due to a AVP deficiency or AVP resistance. This is subcutaneous and should be done in hospital to allow reassessment of urinary osmolality. However, in most patients, sodium levels will be in the normal range, making further tests for differential diagnosis necessary **(Fig. 393-4)**.

The indirect water deprivation test was the gold standard for differential diagnosis for many years. This test is based on indirect assessment of AVP activity by measurement of the urine concentration capacity during a prolonged period of dehydration and again after a subsequent injection of an exogenous synthetic AVP analogue, desmopressin. However, the published criteria for interpretation were based on post hoc data from a small number of patients with an overall

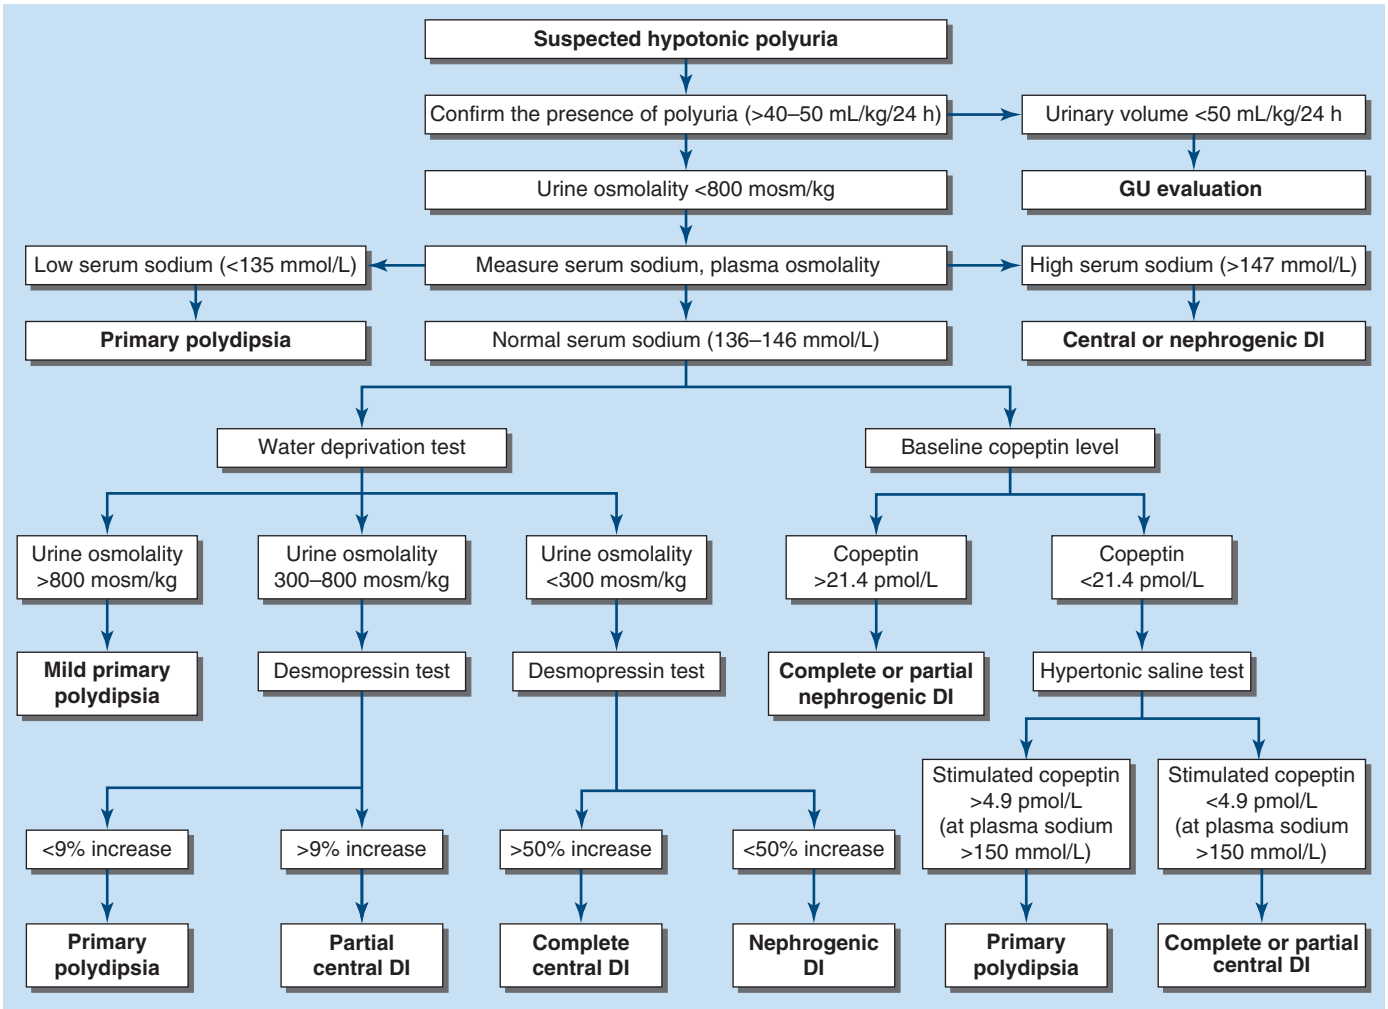

FIGURE 393-4 Algorithm for differential diagnosis of polyuria polydipsia syndrome. If symptoms of polyuria, nocturia, and/or persistent thirst are present in the absence of glucosuria, the possibility of arginine vasopressin (AVP) deficiency or AVP resistance should be evaluated by collecting a 24-h urine on unrestricted fluid intake. If the volume is >50 mL/kg per day with a concomitant urinary osmolality <800 mOsm/kg, serum sodium and plasma osmolality should be measured. If sodium levels are below the normal reference range, it suggests primary polydipsia since these patients can drink themselves into hyponatremia. If sodium levels are above the normal reference range, the diagnosis of AVP deficiency or resistance can be made, and a test with desmopressin (2 μg) followed by a repeat measurement of urine osmolarity will determine if hypotonic polyuria is due to a AVP deficiency or AVP resistance. However, in most patients, sodium levels will be in the normal range, making further tests for differential diagnosis necessary. If copeptin measurement is available, a copeptin-based diagnostic algorithm is used. High baseline copeptin level of >21.4 pmol/L without prior water deprivation identifies AVP resistance. For the more difficult differential diagnosis of AVP deficiency and primary polydipsia, a copeptin level of >4.9 pmol/L at a high sodium level (≥150 mmol/L) after hypertonic saline infusion has an overall diagnostic accuracy of 97% to diagnose AVP deficiency. DI, diabetes insipidus; GU, genitourinary.

diagnostic accuracy of 70% and only 41% for patients with primary polydipsia. To overcome these limitations, direct measurement of AVP was proposed, but despite initial promising results, this method is not in routine clinical use, mainly because of technical limitations of the AVP assay. Copeptin is the C-terminal segment of the AVP prohormone and is an AVP surrogate that is very stable ex vivo (Fig. 393-1). Studies have shown that a high baseline copeptin level of >21.4 pmol/L, without prior water deprivation, unequivocally identifies AVP resistance. For the more difficult differential diagnosis of AVP deficiency and primary polydipsia, a copeptin level of >4.9 pmol/L at a high sodium level (≥150 mmol/L) after hypertonic saline infusion has an overall diagnostic accuracy of 96.5%. Importantly, this test requires close monitoring of sodium levels. Copeptin levels after arginine infusion have also shown promising results in differentiating AVP deficiency from primary polydipsia, but with a lower diagnostic accuracy. Currently, copeptin assays are commercially available in Europe, Australia, India, and Mexico, and tests are pending in several other countries.

Once AVP deficiency has been diagnosed, the underlying pathology must be identified by magnetic resonance imaging (MRI) of the sella and suprasellar regions. Also, assessment of the posterior pituitary and the pituitary stalk can be helpful in the differential diagnosis of AVP deficiency. The pituitary bright spot on MRI (a radiologic marker of neurosecretory vesicles containing AVP) is an area of hyperintensity seen in most healthy individuals, but may be lacking in patients with AVP deficiency. However, the absence of the pituitary bright spot is not sufficient to establish a diagnosis of AVP deficiency since it can be present in early stages of AVP deficiency or can be absent in elderly patients.

Treatment The signs and symptoms of uncomplicated AVP deficiency can be eliminated by treatment with DDAVP, a synthetic analogue of AVP. DDAVP acts selectively at V_2 receptors to increase urine concentration and decrease urine flow in a dose-dependent manner. It is also more resistant to degradation than is AVP and has a three- to fourfold longer duration of action. The dose of DDAVP impacts on the duration of action (i.e., the higher the dose, the greater the duration of action). DDAVP can be given by IV or SC injection, nasal inhalation, or orally by means of a tablet or melt. The doses required to treat AVP deficiency vary depending on the patient and the route of administration. Among adults, doses usually range from 1–2 μg qd or bid by injection, 10–20 μg bid or tid by nasal spray, or 100–400 μg bid or tid orally. The onset of antidiuresis is rapid, ranging from as little as 15 min after injection to 60 min after oral administration. Hyponatremia is the most common complication of desmopressin therapy, with mild depression of plasma sodium concentration (131–134 mmol/L) reported in about a quarter of patients with intact thirst. In 15% of patients,

hyponatremia is more severe, with plasma sodium concentration of <130 mmol/L. Desmopressin escape, which involves intermittently delaying DDAVP for a number of hours to allow a transient aquaresis, reduces the risk of hyponatremia.

Treatment of primary polydipsia focuses on the reduction of excessive fluid intake, optimally in a graded fashion to allow patients to slowly reduce fluids. Treatments to reduce mouth dryness (e.g., ice chips, hard candy to stimulate salivary flow) are also useful to reduce thirst. Pharmacologic therapies have been tried without consistent success. A recent study suggests that glucagon-like peptide 1 (GLP-1) analogues reduce fluid intake, urine output, and thirst perception. AVP resistance is difficult to treat. Patients typically do not respond to desmopressin treatment; however, some patients may respond to high doses if their resistance is only partial. Treatment with conventional doses of a thiazide diuretic and/or amiloride in conjunction with a low-sodium diet and coadministration of nonsteroidal anti-inflammatory drugs (NSAIDs) usually reduces the polyuria and polydipsia, but this combination is nephrotoxic, and careful monitoring of renal function is important. Drug-induced AVP resistance should be treated by discontinuation of the causative agent—most commonly lithium—where possible. Persistent lithium-induced AVP resistance can be treated by hydrochlorothiazide and amiloride. It important to be aware that plasma volume contraction produced by thiazide diuretics can decrease lithium excretion and predispose to lithium toxicity.

HYPODIPSIC/ADIPSIC HYPERNATREMIA

An increase in plasma osmolarity/sodium above the normal range (hypertonic hypernatremia) can be due to a decrease in total body water or an increase in total body sodium. The former results from a failure to drink enough water to replace normal or increased urinary and insensible loss due either to water deprivation or a lack of thirst (hypodipsia/adipsia).

Clinical Characteristics Hypodipsic/adipsic hypernatremia is a rare syndrome characterized by chronic or recurrent hypertonic dehydration that most frequently coexists with AVP deficiency (adipsic diabetes insipidus or adipsic AVP deficiency). The hypernatremia varies widely in severity and is often associated with signs of hypovolemia such as tachycardia, postural hypotension, azotemia, hyperuricemia, and hypokalemia due to secondary hyperaldosteronism. Muscle weakness, pain, rhabdomyolysis, hyperglycemia, hyperlipidemia, thromboembolic disease, acute renal failure, and obtundation can also occur.

Etiology Hypodipsia/adipsia is usually due to abnormalities of osmoreceptors in the anterior hypothalamus that regulate thirst. The defect can result from various congenital malformations of midline brain structures or may be acquired due to diseases such tumors (primary or secondary, and their associated surgery) or aneurysms of the anterior communicating artery, head trauma, granulomatous diseases such as sarcoidosis and histiocytosis, AIDS, and cytomegalovirus encephalitis. Adipsic hypernatremia without demonstrable hypothalamic lesions has also been associated with autoantibodies directed against the subfornical organ.

Pathophysiology A deficiency in osmotically induced thirst results in a failure to drink enough water to replenish obligatory renal and extrarenal losses with resultant significant hypernatremia. Rarely, the regulation of AVP secretion is completely normal, suggesting that the lack of thirst is due to a defect in postosmoreceptor neural pathways to higher cognitive centers.

Differential Diagnosis Hypodipsic/adipsic hypernatremia with or without coexisting AVP deficiency usually can be distinguished from other causes of inadequate fluid intake (e.g., coma, paralysis, restraints, absence of fresh water) by the clinical history and setting as well as measurements of serum and urine osmolality. Previous episodes and/or denial of thirst and failure to drink spontaneously when the patient is conscious, unrestrained, and hypernatremic are virtually diagnostic.

Treatment Hypodipsic hypernatremia can be corrected by administering water orally if the patient is alert and cooperative or by infusing hypotonic fluids (0.45% saline or 5% dextrose) if the patient is not. The amount of free water in liters required to correct the free water deficit should be estimated from body weight in kg and the serum sodium concentration in mmol/L. This amount plus an allowance for continuing insensible and urinary losses should be given over a 24- to 48-h period with close monitoring of serum sodium to ensure that it does not correct too rapidly. Plasma urea/creatinine should be monitored closely for signs of acute renal failure caused by rhabdomyolysis, hypovolemia, and hypotension. Once the patient has been rehydrated, an MRI of the brain and tests of anterior pituitary function should be performed to look for the cause and collateral defects in other hypothalamic functions. A long-term management plan to prevent or minimize recurrence of the fluid and electrolyte imbalance also should be developed. This should include a practical method to regulate fluid intake in accordance with variations in water balance as indicated by changes in body weight or serum sodium determined by home monitoring analyzers, if available. Another potential treatment approach is summarized in Table 393-2.

TABLE 393-2 Approach to the Management of Water Balance for Patients with Adipsic Arginine Vasopressin (AVP) Deficiency

1. Replace AVP with sufficient vasopressin (DDAVP).
2. Monitor fluid input/output initially as an inpatient to achieve eunatremia.
3. Weigh and record patient's eunatremic weight.
4. Recommend 1.5–2 L of fluid intake per day assuming urinary losses are less.
5. Weigh daily.
6. If below eunatremic weight, then replace with equivalent volume of fluid to restore eunatremic weight.
7. Recommend increased fluid intake in times of increased perspiration or ambient temperatures.
8. Regular plasma sodium measurements.

INAPPROPRIATE ANTIDIURESIS (SEE IN MORE DETAIL CHAP. 56)

Clinical Characteristics Syndrome of inappropriate antidiuresis (SIAD) is produced when plasma levels of AVP are elevated at times when the physiologic secretion of AVP from the posterior pituitary would normally be osmotically suppressed. The clinical abnormality is a decrease in the osmotic pressure of body fluids, such that the hallmark of SIAD is hypoosmolality. If hyponatremia is severe or develops acutely, it can cause a variety of neurologic symptoms and signs, such as headache, confusion, anorexia, nausea, vomiting, coma, and convulsions. If the hyponatremia develops gradually or exists for more than a few days, it may be apparently asymptomatic, but even mild hyponatremia is associated with an increased rate of falls and fractures, neurocognitive and neuromuscular symptoms, and increased morbidity and mortality.

Etiology SIAD has many different etiologies, which are summarized in Chap. 56.

Pathophysiology In SIAD, the failure to mount a water diuresis when intake exceeds urinary and insensible loss results in a slight expansion of total body water followed by a modest increase in urinary sodium excretion. As a result, expansion of extracellular volume is minimal, and clinically detectable edema does not develop. However, intracellular volume increases in proportion to the severity and rapidity of the change in plasma sodium. In the brain, this cellular swelling causes an increase in pressure that triggers a variety of symptoms. After several days, the swelling and symptoms may subside due to inactivation of some intracellular solutes and resultant decrease in cellular volume.

Differential Diagnosis Evaluation of urine and serum osmolality and sodium is the most useful investigation in establishing whether the diagnostic criteria for SIAD are met, alongside clinical assessment of volume status. Measurement of serum osmolality is important to exclude non-hypotonic causes of hyponatremia, such

as pseudohyponatremia (due to raised lipids or protein) or translocational hyponatremia (due to raised glucose or exogenous effective osmolytes [e.g., mannitol]). SIAD must then be differentiated from other types of hypotonic hyponatremia. Measurement of urinary osmolality helps to distinguish SIAD from primary polydipsia where urinary osmolality is usually <100–200 mosm/L. Measurement of urinary sodium levels are useful to differentiate hyponatremia with low effective arterial blood volume from hyponatremia with normal effective arterial blood volume. In hypovolemic or hypervolemic hyponatremia with low effective blood volume, the mechanisms to conserve sodium remain intact, resulting in low urine sodium excretion, whereas in SIAD, there is ongoing renal sodium loss. According to guidelines, levels of <30 mmol/L argue for low effective arterial blood volume. Assessment of volume status has been used to classify hyponatremia into hypo-, hyper-, or euvolemic hyponatremia, though the accuracy of the clinical examination is poor. Hypervolemic hyponatremia typically occurs in patients with generalized edema due to severe congestive heart failure or cirrhosis. Hypovolemic hyponatremia occurs in patients with loss of sodium and water due to severe vomiting, diarrhea, diuretic use or primary adrenal insufficiency. In case of euvolemic hyponatremia, secondary adrenal insufficiency should be excluded before SIAD is diagnosed. Measurement of plasma AVP or copeptin has no diagnostic value. It is widely recommended to evaluate thyroid function in the workup of hyponatremia. There is, however, limited evidence for hypothyroidism as a significant cause of hyponatremia.

TREATMENT

Syndrome of Inappropriate Antidiuresis

The management of SIAD differs depending on the underlying etiology as well as the severity and duration of symptoms. In the presence of severe neurologic symptoms, urgent intervention and treatment with hypertonic saline are indicated, aiming for an initial sodium rise of 4–6 mmol with a 100-mL bolus of hypertonic (3%) sodium chloride administered over ~15 min. An initial dose should be followed by clinical reassessment and a repeat dose if there is no clinical response until this target increment has been achieved.

First-line treatment of chronic hyponatremia is fluid restriction, usually in the range of 500 to 1000 mL/d including all liquids, not solely water. However, fluid restriction is often ineffective, especially if urinary osmolality is >500 mosm/L. Second-line treatments when fluid restriction is inadequate are urea or tolvaptan. Urea is a product of hepatic nitrogen metabolism that is renally excreted and exerts an osmotic effect to promote free water excretion. Usually, doses of 30–60 g are sufficient to raise sodium levels. Tolvaptan is an oral vasopressin V_2-receptor antagonist that blocks AVP action in the kidney, inducing a water diuresis and raising sodium levels. Due to the risk of overly rapid correction, low-dose tolvaptan (7.5 mg) has become more widely prescribed in recent years. Other concerns with tolvaptan include cost and risk of liver function derangement seen with sustained higher-dose therapy as used for autosomal dominant polycystic kidney disease.

Demeclocycline is recommended by some as an alternative therapy, but European guidelines do not recommend it due to side effects. Demeclocycline can induce renal AVP resistance, thereby promoting dilute urine excretion. This effect is unpredictable and potential adverse effects include gastrointestinal intolerance, nephrotoxicity, and a photosensitive skin rash. According to a recent study, oral sodium chloride tablets and loop diuretics have a questionable efficacy. SGLT-2 inhibitors act at the sodium-glucose cotransporter in the proximal tubule to reduce resorption of glucose and sodium. SGLT-2 inhibitors induce glycosuria, which is accompanied by increased water excretion due to an osmotic diuresis. This has been shown to increase sodium levels in hospitalized as well as in outpatients with SIAD.

394 Thyroid Gland Physiology and Testing

J. Larry Jameson, Anthony P. Weetman, Susan J. Mandel

The thyroid gland produces two related hormones, thyroxine (T_4) and triiodothyronine (T_3) **(Fig. 394-1)**. Acting through thyroid hormone receptors (TR) α and β, these hormones play a critical role in cell differentiation and organogenesis during development and help maintain thermogenic and metabolic homeostasis in the adult. Autoimmune disorders of the thyroid gland can stimulate overproduction of thyroid hormones (*thyrotoxicosis*) **(Chap. 396)** or cause glandular destruction and hormone deficiency (*hypothyroidism*) **(Chap. 395)**. Benign nodules and various forms of thyroid cancer are relatively common and amenable to detection by physical examination, ultrasound, and other imaging techniques **(Chap. 397)**.

ANATOMY AND DEVELOPMENT

The thyroid (Greek *thyreos*, shield, plus *eidos*, form) consists of two lobes connected by an isthmus. It is located anterior to the trachea between the cricoid cartilage and the suprasternal notch. The normal thyroid is 12–20 g in size, highly vascular, and soft in consistency. Four parathyroid glands, which produce parathyroid hormone **(Chap. 422)**, are located posterior to each pole of the thyroid. The recurrent laryngeal nerves traverse the lateral borders of the thyroid gland and must be identified during thyroid surgery to avoid injury and vocal cord paralysis.

The thyroid gland develops from the floor of the primitive pharynx during the third week of gestation. The developing gland migrates along the thyroglossal duct to reach its final location in the neck. This feature accounts for the rare ectopic location of thyroid tissue at the base of the tongue (lingual thyroid) as well as the occurrence of thyroglossal duct cysts along this developmental tract. Thyroid hormone synthesis begins at about 11 weeks' gestation.

Neural crest derivatives from the ultimobranchial body give rise to thyroid medullary C cells that produce calcitonin, a calcium-lowering hormone. The C cells are interspersed throughout the thyroid gland, although their density is greatest in the juncture of the upper one-third and lower two-thirds of the gland. Calcitonin plays a minimal role in calcium homeostasis in humans, but the C cells are clinically important because they are the cellular origin of medullary thyroid cancer **(Chap. 400)**.

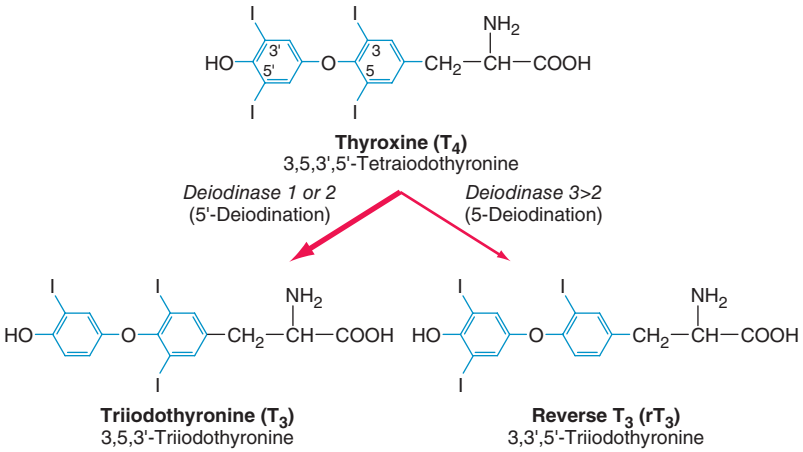

FIGURE 394-1 Structures of thyroid hormones. Thyroxine (T_4) contains four iodine atoms. Deiodination leads to production of the potent hormone triiodothyronine (T_3) or the inactive hormone reverse T_3.

Thyroid gland development is orchestrated by the coordinated expression of several developmental transcription factors. Thyroid transcription factor genes *TTF1*, *TTF2*, *NKX2-1*, *FOXE1*, and paired homeobox-8 (*PAX8*) are expressed selectively, but not exclusively, in the thyroid gland. In combination, they dictate thyroid cell development and the induction of thyroid-specific proteins such as thyroglobulin (Tg), thyroid peroxidase (TPO), the sodium iodide symporter (Na^+/I^-, NIS), and the thyroid-stimulating hormone (TSH) receptor (TSH-R). Mutations in these developmental transcription factors or their downstream target genes are rare causes of thyroid agenesis or dyshormonogenesis, although the causes of most forms of congenital hypothyroidism remain unknown **(see Chap. 395, Table 395-1)**. Because congenital hypothyroidism occurs in ~1 in 4000 newborns, neonatal screening is now performed in most industrialized countries. Transplacental passage of maternal thyroid hormone occurs before the fetal thyroid gland begins to function and provides significant hormone support to a fetus with congenital hypothyroidism. Early thyroid hormone replacement in newborns with congenital hypothyroidism prevents potentially severe developmental abnormalities.

The thyroid gland consists of numerous spherical follicles composed of thyroid follicular cells that surround secreted colloid, a proteinaceous fluid containing large amounts of thyroglobulin, the protein precursor of thyroid hormones **(Fig. 394-2)**. The thyroid follicular cells are polarized—the basolateral surface is apposed to the bloodstream and an apical surface faces the follicular lumen. Increased demand for thyroid hormone is regulated by TSH, which binds to its receptor on the basolateral surface of the follicular cells. This binding leads to Tg reabsorption from the follicular lumen and proteolysis within the cytoplasm, yielding thyroid hormones for secretion into the bloodstream.

REGULATION OF THE THYROID AXIS

TSH, secreted by the thyrotrope cells of the anterior pituitary, plays a pivotal role in control of the thyroid axis and serves as the most useful physiologic marker of thyroid hormone action. TSH is a 31-kDa hormone composed of α and β subunits; the α subunit is common to the other glycoprotein hormones (luteinizing hormone, follicle-stimulating hormone, human chorionic gonadotropin [hCG]), whereas the TSH β subunit is unique to TSH. The extent and nature of carbohydrate modification are modulated by thyrotropin-releasing hormone (TRH) and influence the biologic activity of the hormone.

The thyroid axis is a classic example of an endocrine feedback loop **(Chap. 389)**. Hypothalamic TRH stimulates pituitary production of TSH, which, in turn, stimulates thyroid hormone synthesis and secretion. Thyroid hormones act via negative feedback predominantly through thyroid hormone receptor β2 (TRβ2) to inhibit TRH and TSH production (Fig. 394-2). The "set point" in this axis is established by TSH. TRH is the major positive regulator of TSH synthesis and secretion. Peak TSH secretion occurs ~15 min after administration of exogenous TRH. Dopamine, glucocorticoids, and somatostatin suppress TSH but are not of major physiologic importance except when these agents are administered in pharmacologic doses. Reduced levels of thyroid hormone increase basal TSH production and enhance TRH-mediated stimulation of TSH. High thyroid hormone levels rapidly and directly suppress TSH gene expression and inhibit TRH stimulation of TSH secretion, indicating that thyroid hormones are the dominant regulator of TSH production. Like other pituitary hormones, TSH is released in a pulsatile manner and exhibits a diurnal rhythm; its highest levels occur at night. However, these TSH excursions are modest in comparison to those of other pituitary hormones, in part, because TSH has a relatively long plasma half-life (50 min). Consequently, single measurements of TSH are adequate for assessing its circulating level. TSH is measured using immunoradiometric assays that are highly sensitive and specific. These assays readily distinguish between normal and suppressed TSH values; thus, TSH can be used for the diagnosis of primary hyperthyroidism (low TSH) or primary hypothyroidism (high TSH).

THYROID HORMONE SYNTHESIS, METABOLISM, AND ACTION

THYROID HORMONE SYNTHESIS

Thyroid hormones are derived from Tg, a large iodinated glycoprotein. After secretion into the thyroid follicle, Tg is iodinated on tyrosine

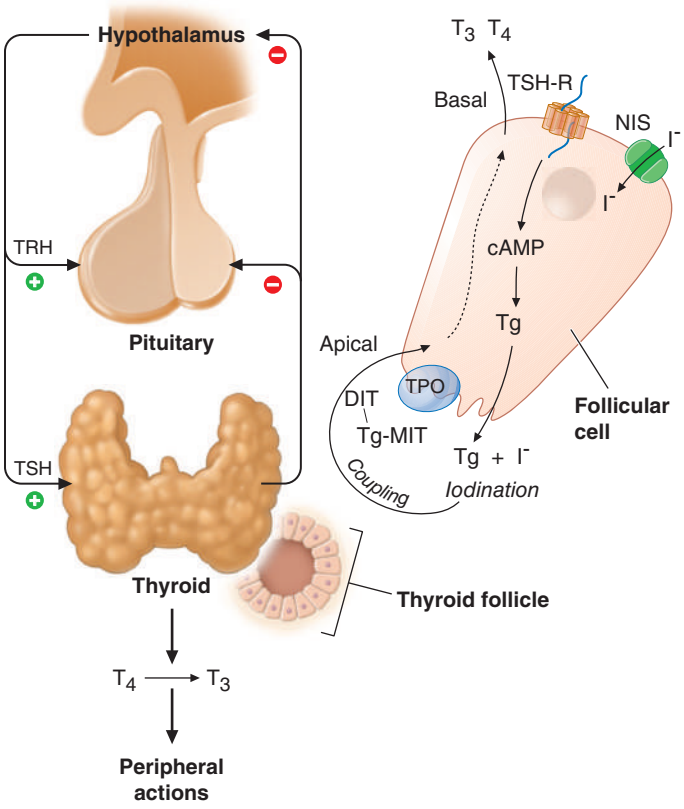

FIGURE 394-2 Regulation of thyroid hormone synthesis. ***Left.*** Thyroid hormones T_4 and T_3 feed back to inhibit hypothalamic production of thyrotropin-releasing hormone (TRH) and pituitary production of thyroid-stimulating hormone (TSH). TSH stimulates thyroid gland production of T_4 and T_3. ***Right.*** Thyroid follicles are formed by thyroid epithelial cells surrounding proteinaceous colloid, which contains thyroglobulin. Follicular cells, which are polarized, synthesize thyroglobulin and carry out thyroid hormone biosynthesis (see text for details). DIT, diiodotyrosine; MIT, monoiodotyrosine; NIS, sodium iodide symporter; Tg, thyroglobulin; TPO, thyroid peroxidase; TSH-R, thyroid-stimulating hormone receptor.

residues that are subsequently coupled via an ether linkage. Reuptake of Tg into the thyroid follicular cell allows proteolysis and the release of newly synthesized T_4 and T_3.

Iodine Metabolism and Transport Iodide uptake is a critical first step in thyroid hormone synthesis. Ingested iodine is bound to serum proteins, particularly albumin. Unbound iodine is excreted in the urine. The thyroid gland extracts iodine from the circulation in a highly efficient manner. For example, 10–25% of radioactive tracer (e.g., ^{123}I) is taken up by the normal thyroid gland over 24 h in an iodine-replete state; this value can rise to 70–90% in Graves' disease. Iodide uptake is mediated by NIS, which is expressed at the basolateral membrane of thyroid follicular cells. NIS is most highly expressed in the thyroid gland, but low levels are present in the salivary glands, lactating breast, and placenta. The iodide transport mechanism is highly regulated, allowing adaptation to variations in dietary supply. Low iodine levels increase the amount of NIS and stimulate uptake, whereas high iodine levels suppress NIS expression and uptake. The selective expression of NIS in the thyroid allows isotopic scanning, treatment of hyperthyroidism, and ablation of thyroid cancer with radioisotopes of iodine, without significant effects on other organs. Mutation of the *NIS* gene is a rare cause of congenital hypothyroidism, underscoring its importance in thyroid hormone synthesis. Another iodine transporter, pendrin, is located on the apical surface of thyroid cells and mediates iodine efflux into the lumen. Mutation of the *pendrin* gene causes *Pendred syndrome*, a disorder characterized by defective organification of iodine, goiter, and sensorineural deafness.

Iodine deficiency is prevalent in many mountainous regions and in central Africa, central South America, and northern Asia **(Fig. 394-3)**. Europe remains mildly iodine-deficient, and health surveys indicate that iodine intake has been falling in the United States and Australia. The World Health Organization (WHO) estimates that about 2 billion people are iodine-deficient, based on urinary excretion data. In areas of relative iodine deficiency, there is an increased prevalence of goiter and, when deficiency is severe, hypothyroidism and cretinism. *Cretinism* is characterized by intellectual disability and growth retardation and occurs when children who live in iodine-deficient regions are not treated with iodine or thyroid hormone to restore normal thyroid hormone levels during early life. These children are often born to mothers with iodine deficiency, and it is likely that maternal thyroid hormone deficiency worsens the condition. The physiologic iodine requirement is higher in lactating women, and iodine turnover is high in infants. Concomitant selenium deficiency may also contribute to the neurologic manifestations of cretinism. Iodine supplementation of salt, bread, and other food substances has markedly reduced the prevalence of cretinism. Unfortunately, however, iodine deficiency remains a common cause of preventable intellectual disability, often because of societal resistance to food additives or the cost of supplementation. In

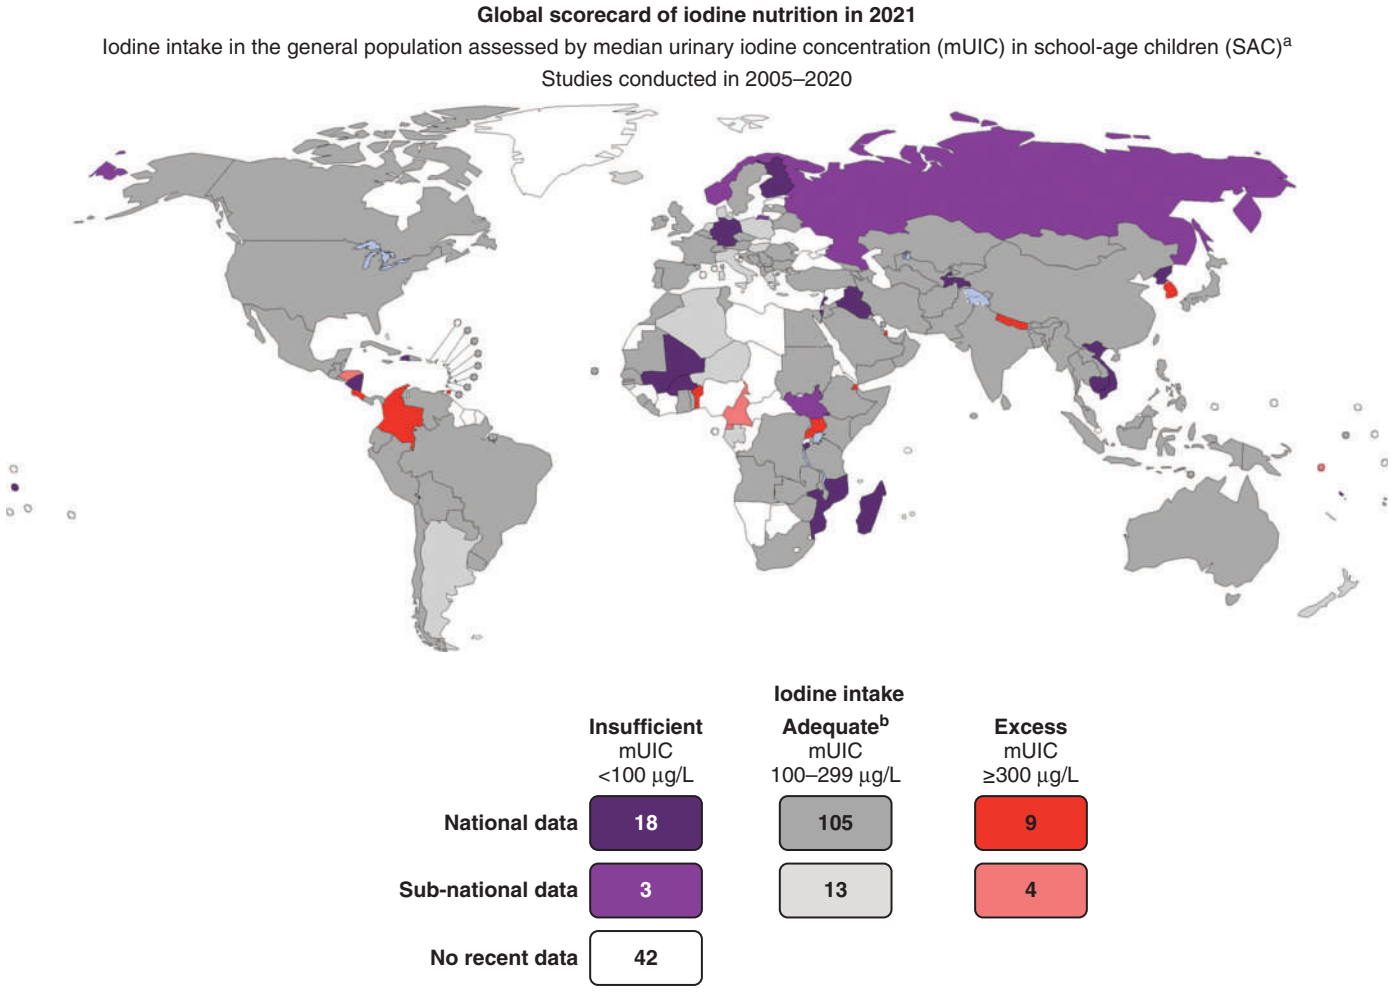

FIGURE 394-3 Worldwide iodine nutrition. [a]In population monitoring of iodine status using urinary iodine concentration (UIC), school-age children (SAC) serve as a proxy for the general population; therefore, preference has been given to studies carried out in SAC. The UIC data have been selected for each country in the following order of priority: data from the most recent known nationally representative survey carried out between 2005 and 2020 in (1) SAC, (2) SAC and adolescents, (3) adolescents, (4) women of reproductive age, (5) other adults (excluding pregnant or lactating women), and (6) other eligible populations. In the absence of recent national surveys, subnational data were used in the same order of priority. Subnational UIC surveys are commonly carried out to provide a rapid assessment of population iodine status, but due to a lack of sampling rigor, they may over- or underestimate the iodine status at the national level and should be interpreted with caution. [b]Adequate iodine intake in SAC corresponds to median UIC values in the range of 100–299 µg/L and includes categories previously referred to as "adequate" (100–199 µg/L) and "more than adequate" (200–299 µg/L). *(Reproduced with permission from The Iodine Global Network. Global scorecard of iodine nutrition in 2021 in the general population based on data in school-age children (SAC). IGN: Ottawa, Canada. 2021.)*

addition to overt cretinism, mild iodine deficiency can lead to subtle reduction of IQ. Oversupply of iodine, through supplements or foods enriched in iodine (e.g., shellfish, kelp), is associated with an increased incidence of autoimmune thyroid disease. The Recommended Dietary Allowance (RDA) is 220 μg iodine per day for pregnant women and 290 μg iodine per day for breastfeeding women. Because the effects of iodine deficiency are most severe in pregnant women and their babies, the American Thyroid Association has recommended that all pregnant and breastfeeding women in the United States and Canada take a prenatal multivitamin containing 150 μg iodine per day. Urinary iodine is >100 μg/L in iodine-sufficient populations.

Organification, Coupling, Storage, and Release After iodide enters the thyroid, it is trapped and transported to the apical membrane of thyroid follicular cells, where it is oxidized in an organification reaction that involves TPO and hydrogen peroxide produced by dual oxidase (DUOX) and DUOX maturation factor (DUOXA). The reactive iodine atom is added to specific tyrosyl residues within Tg, a large (660 kDa) dimeric protein that consists of 2769 amino acids. The iodotyrosines in Tg are then coupled via an ether linkage in a reaction that is also catalyzed by TPO. Either T_4 or T_3 can be produced by this reaction, depending on the number of iodine atoms present in the iodotyrosines. After coupling, Tg is taken back into the thyroid cell, where it is processed in lysosomes to release T_4 and T_3. Uncoupled mono- and diiodotyrosines (MIT, DIT) can be deiodinated by the enzyme iodotyrosine deiodinase, thereby recycling any iodide that is not converted into thyroid hormones.

Disorders of thyroid hormone synthesis are rare causes of congenital hypothyroidism **(Chap. 395)**. The vast majority of these disorders are due to recessive mutations in TPO or Tg, but defects have also been identified in the TSH-R, NIS, pendrin, hydrogen peroxide generation, and iodotyrosine deiodinase, as well as genes involved in thyroid gland development. In the case of biosynthetic defects, the gland is incapable of synthesizing adequate amounts of hormone, leading to increased TSH and a large goiter.

TSH Action TSH regulates thyroid gland function through the TSH-R, a seven-transmembrane G protein–coupled receptor (GPCR). The TSH-R is coupled to the α subunit of stimulatory G protein ($G_s\alpha$), which activates adenylyl cyclase, leading to increased production of cyclic adenosine monophosphate (cAMP). TSH also stimulates phosphatidylinositol turnover by activating phospholipase C. Recessive loss-of-function TSH-R mutations cause thyroid hypoplasia and congenital hypothyroidism. Dominant gain-of-function mutations are rare causes of sporadic or familial hyperthyroidism that is characterized by goiter, thyroid cell hyperplasia, and autonomous function **(Chap. 396)**. Most of these activating mutations occur in the transmembrane domain of the receptor. They mimic the conformational changes induced by TSH binding or the interactions of thyroid-stimulating immunoglobulins (TSIs) in Graves' disease. Activating TSH-R mutations also occur as somatic events, leading to clonal selection and expansion of the affected thyroid follicular cell and autonomously functioning thyroid nodules.

Other Factors That Influence Hormone Synthesis and Release Although TSH is the dominant hormonal regulator of thyroid gland growth and function, a variety of growth factors, most produced locally in the thyroid gland, also influence thyroid hormone synthesis. These include insulin-like growth factor 1 (IGF-1), epidermal growth factor, transforming growth factor β (TGF-β), endothelins, and various cytokines. The quantitative roles of these factors are not well understood, but they are important in selected disease states. In acromegaly, for example, increased levels of growth hormone and IGF-1 are associated with goiter and predisposition to multinodular goiter (MNG). Certain cytokines and interleukins (ILs) produced in association with autoimmune thyroid disease induce thyroid growth, whereas others lead to apoptosis. Iodine deficiency increases thyroid blood flow and upregulates the NIS, stimulating more efficient iodine uptake. Excess iodide transiently inhibits thyroid iodide organification, a phenomenon known as the *Wolff-Chaikoff effect*. In individuals with a normal thyroid, the gland escapes from this inhibitory effect and iodide organification resumes; the suppressive action of high iodide may persist, however, in patients with underlying autoimmune thyroid disease.

THYROID FUNCTION IN PREGNANCY

Five factors alter thyroid function in pregnancy: (1) the transient increase in hCG during the first trimester, which weakly stimulates the TSH-R; (2) the estrogen-induced rise in thyroxine-binding globulin (TBG) during the first trimester, which is sustained during pregnancy; (3) alterations in the immune system, leading to the onset, exacerbation, or amelioration of an underlying autoimmune thyroid disease; (4) increased thyroid hormone metabolism by the placental type III deiodinase; and (5) increased urinary iodide excretion, which can cause impaired thyroid hormone production in areas of marginal iodine sufficiency. Women with a precarious iodine intake (<50 μg/d) are most at risk of developing a goiter during pregnancy or giving birth to an infant with a goiter and hypothyroidism. The WHO recommends a daily iodine intake of 250 μg during pregnancy and lactation, and prenatal vitamins should contain 150 μg per tablet.

The rise in circulating hCG levels during the first trimester is accompanied by a reciprocal fall in TSH that persists into the middle of pregnancy. This reflects the weak binding of hCG, which is present at very high levels, to the TSH-R. Rare individuals have variant TSH-R sequences that enhance hCG binding and TSH-R activation. hCG-induced changes in thyroid function can result in transient gestational hyperthyroidism that may be associated with *hyperemesis gravidarum*, a condition characterized by severe nausea and vomiting and risk of volume depletion. However, antithyroid drugs are not indicated unless concomitant Graves' disease is suspected. Parenteral fluid replacement usually suffices until the condition resolves.

Normative values for most thyroid function tests differ during pregnancy, and if available, trimester-specific reference ranges should be used when diagnosing thyroid dysfunction during pregnancy. TSH levels decrease at the end of the first trimester and then rise as gestation progresses so that the nonpregnant reference ranges can be used from mid-gestation to delivery. Total T_4 and T_3 levels are ~1.5× higher throughout pregnancy, but the free T_4, which is the same or slightly higher at the end of the first trimester, progressively decreases so that by the third trimester, values are often below the nonpregnant lower reference cutoff.

During pregnancy, subclinical hypothyroidism occurs in 2% of women, but overt hypothyroidism is present in only 1 in 500. Prospective randomized controlled trials have not shown a benefit for universal thyroid disease screening in pregnancy. Targeted TSH testing for hypothyroidism is recommended for women planning a pregnancy if they have a strong family history of autoimmune thyroid disease, other autoimmune disorders (e.g., type 1 diabetes), infertility, prior preterm delivery or recurrent miscarriage, or signs or symptoms of thyroid disease, or are older than 30 years. Thyroid hormone requirements are increased by up to 45% during pregnancy in levothyroxine-treated hypothyroid women.

THYROID HORMONE TRANSPORT AND METABOLISM

Serum-Binding Proteins T_4 is secreted from the thyroid gland in about 15-fold excess over T_3 **(Table 394-1)**. Both hormones are bound to plasma proteins, including TBG, transthyretin (TTR, formerly known as thyroxine-binding prealbumin [TBPA]), and albumin. The plasma-binding proteins increase the pool of circulating hormone, delay hormone clearance, and may modulate hormone delivery to selected tissue sites. The concentration of TBG is relatively low (1–2 mg/dL), but because of its high affinity for thyroid hormones ($T_4 > T_3$), it carries ~80% of the bound hormones. Albumin has relatively low affinity for thyroid hormones but has a high plasma concentration (~3.5 g/dL), and it binds up to 10% of T_4 and 30% of T_3. TTR carries ~10% of T_4 but little T_3.

When the effects of the various binding proteins are combined, ~99.98% of T_4 and 99.7% of T_3 are protein-bound. Because T_3 is less

TABLE 394-1 Characteristics of Circulating T_4 and T_3

HORMONE PROPERTY	T_4	T_3
Serum concentrations		
Total hormone	8 μg/dL	0.14 μg/dL
Fraction of total hormone in the unbound form	0.02%	0.3%
Unbound (free) hormone	$21 \times 10^{-12} M$	$6 \times 10^{-12} M$
Serum half-life	7 d	2 d
Fraction directly from the thyroid	100%	20%
Production rate, including peripheral conversion	90 μg/d	32 μg/d
Intracellular hormone fraction	~20%	~70%
Relative metabolic potency	0.3	1
Receptor binding	$10^{-10} M$	$10^{-11} M$

tightly bound than T_4, the fraction of unbound T_3 is greater than unbound T_4, but there is less unbound T_3 in the circulation because it is produced in smaller amounts and cleared more rapidly than T_4. The unbound or "free" concentrations of the hormones are ~2×10^{-11} *M* for T_4 and ~6×10^{-12} *M* for T_3, which roughly correspond to the thyroid hormone receptor–binding constants for these hormones (see below). The unbound hormone is thought to be biologically available to tissues. The homeostatic mechanisms that regulate the thyroid axis are directed toward maintenance of normal concentrations of unbound hormones.

Abnormalities of Thyroid Hormone–Binding Proteins A number of inherited and acquired abnormalities affect thyroid hormone–binding proteins. X-linked TBG deficiency is associated with very low levels of total T_4 and T_3. However, because unbound hormone levels are normal, patients are euthyroid and TSH levels are normal. It is important to recognize this disorder to avoid efforts to normalize total T_4 levels, because this leads to thyrotoxicosis and is futile because of rapid hormone clearance in the absence of TBG. TBG levels are elevated by estrogen, which increases sialylation and delays TBG clearance. Consequently, in women who are pregnant or taking estrogen-containing contraceptives, elevated TBG increases total T_4 and T_3 levels; however, unbound T_4 and T_3 levels are normal. These features are part of the explanation for why women with hypothyroidism require increased amounts of L-thyroxine replacement as TBG levels are increased by pregnancy or estrogen treatment. Mutations in TBG, TTR, and albumin may increase the binding affinity for T_4 and/or T_3 and cause disorders known as *euthyroid hyperthyroxinemia* or *familial dysalbuminemic hyperthyroxinemia* (FDH) (Table 394-2). These disorders result in increased total T_4 and/or T_3, but unbound hormone levels are normal. The familial nature of the disorders, and the fact that TSH levels are normal rather than suppressed, should suggest this diagnosis. Unbound hormone levels (ideally measured by dialysis) are normal in FDH. The diagnosis can be confirmed by using tests that measure the affinities of radiolabeled hormone binding to specific transport proteins or by performing DNA sequence analyses of the abnormal transport protein genes.

Certain medications, such as salicylates and salsalate, can displace thyroid hormones from circulating binding proteins. Although these drugs transiently perturb the thyroid axis by increasing free thyroid hormone levels, TSH is suppressed until a new steady state is reached, thereby restoring euthyroidism. Circulating factors associated with acute illness may also displace thyroid hormone from binding proteins (Chap. 396).

Deiodinases T_4 may be thought of as a precursor for the more potent T_3. T_4 is converted to T_3 by the deiodinase enzymes (Fig. 394-1). Type I deiodinase, which is located primarily in thyroid, liver, and kidneys, has a relatively low affinity for T_4. Type II deiodinase has a higher affinity for T_4 and is found primarily in the pituitary gland, brain, brown fat, and thyroid gland. Expression of type II deiodinase allows it to regulate T_3 concentrations locally, a property that may be important in the context of levothyroxine (T_4) replacement. Type II deiodinase is also regulated by thyroid hormone; hypothyroidism induces the enzyme, resulting in enhanced $T_4 \rightarrow T_3$ conversion in tissues such as brain and pituitary. $T_4 \rightarrow T_3$ conversion is impaired by fasting, systemic illness or acute trauma, oral contrast agents, and a variety of medications (e.g., propylthiouracil, propranolol, amiodarone, glucocorticoids). Type III deiodinase inactivates T_4 and T_3 and is the most important source of reverse T_3 (rT_3), including in the sick euthyroid syndrome. This enzyme is expressed in the human placenta but is not active in healthy individuals. In the sick euthyroid syndrome, especially with hypoperfusion, the type III deiodinase is activated in muscle and liver. Massive hemangiomas and other tumors that express type III deiodinase are a rare cause of consumptive hypothyroidism.

THYROID HORMONE ACTION

Thyroid Hormone Transport Circulating thyroid hormones enter cells by passive diffusion and via specific transporters such as the monocarboxylate 8 transporter (MCT8), MCT10, and organic anion-transporting polypeptide 1C1. Mutations in the *MCT8* gene have been identified in patients with X-linked psychomotor retardation and thyroid function abnormalities (low T_4, high T_3, and high TSH). After entering cells, thyroid hormones act primarily through nuclear receptors, although they also have nongenomic actions through stimulating mitochondrial enzymatic responses and may act directly on blood vessels and the heart through integrin receptors.

Nuclear Thyroid Hormone Receptors Thyroid hormones bind with high affinity to nuclear TRs α and β. Both TRα and TRβ are expressed in most tissues, but their relative expression levels vary among organs; TRα is particularly abundant in brain, kidneys, gonads, muscle, and heart, whereas TRβ expression is relatively high in the pituitary and liver. Both receptors are variably spliced to form unique isoforms. The TRβ2 isoform, which has a unique amino terminus, is selectively expressed in the hypothalamus and pituitary, where it plays a role in feedback control of the thyroid axis (see above). The TRα2

TABLE 394-2 Conditions Associated with Euthyroid Hyperthyroxinemia

DISORDER	CAUSE	TRANSMISSION	CHARACTERISTICS
Familial dysalbuminemic hyperthyroxinemia (FDH)	Albumin mutations, usually R218H	AD	Increased T_4 Normal unbound T_4 Rarely increased T_3
TBG			
Familial excess	Increased TBG production	XL	Increased total T_4, T_3 Normal unbound T_4, T_3
Acquired excess	Medications (estrogen), pregnancy, cirrhosis, hepatitis	Acquired	Increased total T_4, T_3 Normal unbound T_4, T_3
Transthyretin[a]			
Excess	Islet tumors	Acquired	Usually normal T_4, T_3
Mutations	Increased affinity for T_4 or T_3	AD	Increased total T_4, T_3 Normal unbound T_4, T_3
Medications: propranolol, ipodate, iopanoic acid, amiodarone	Decreased $T_4 \rightarrow T_3$ conversion	Acquired	Increased T_4 Decreased T_3 Normal or increased TSH
Resistance to thyroid hormone (RTH)	Thyroid hormone receptor β mutations	AD	Increased unbound T_4, T_3 Normal or increased TSH Some patients clinically thyrotoxic

[a]Also known as thyroxine-binding prealbumin (TBPA).

Abbreviations: AD, autosomal dominant; TBG, thyroxine-binding globulin; TSH, thyroid-stimulating hormone; XL, X-linked.

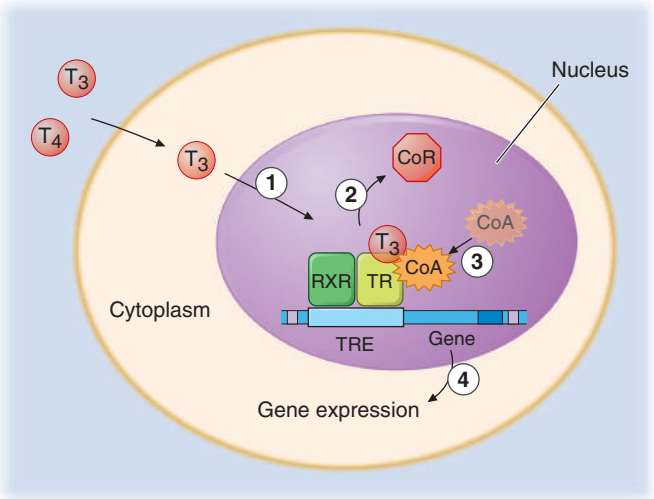

FIGURE 394-4 Mechanism of thyroid hormone receptor action. The thyroid hormone receptor (TR) and retinoid X receptor (RXR) form heterodimers that bind specifically to thyroid hormone response elements (TRE) in the promoter regions of target genes. In the absence of hormone, TR binds co-repressor (CoR) proteins that silence gene expression. The numbers refer to a series of ordered reactions that occur in response to thyroid hormone: (1) T_4 or T_3 enters the nucleus; (2) T_3 binding dissociates CoR from TR; (3) co-activators (CoA) are recruited to the T_3-bound receptor; and (4) gene expression is altered.

isoform contains a unique carboxy terminus that precludes thyroid hormone binding.

The TRs contain a central DNA-binding domain and a C-terminal ligand-binding domain. They bind to specific DNA sequences, termed *thyroid response elements* (TREs), in target genes **(Fig. 394-4)**. The receptors bind as homodimers or, more commonly, as heterodimers with retinoic acid X receptors (RXRs) **(Chap. 389)**. The activated receptor can either stimulate gene transcription (e.g., myosin heavy chain α) or inhibit transcription (e.g., TSH β-subunit gene), depending on the nature of the regulatory elements in the target gene.

Thyroid hormones (T_3 and T_4) bind with similar affinities to TRα and TRβ. However, structural differences in the ligand-binding domains provide the potential for developing receptor-selective agonists or antagonists, and these are under investigation. T_3 is bound with 10–15 times greater affinity than T_4, which explains its increased potency. Although T_4 is produced in excess of T_3, receptors are occupied mainly by T_3, reflecting $T_4 \rightarrow T_3$ conversion by peripheral tissues, T_3 bioavailability in the plasma, and the greater affinity of receptors for T_3. After binding to TRs, thyroid hormone induces conformational changes in the receptors that modify its interactions with accessory transcription factors. Importantly, in the absence of thyroid hormone binding, the aporeceptors bind to co-repressor proteins that inhibit gene transcription. Hormone binding dissociates the co-repressors and allows the recruitment of co-activators that enhance transcription. The discovery of TR interactions with co-repressors explains the fact that TR silences gene expression in the absence of hormone binding. Consequently, hormone deficiency has a profound effect on gene expression because it causes gene repression as well as loss of hormone-induced stimulation. This concept has been corroborated by the finding that targeted deletion of the TR genes in mice has a less pronounced phenotypic effect than hormone deficiency.

Thyroid Hormone Resistance Resistance to thyroid hormone (RTH) is an autosomal dominant disorder characterized by elevated thyroid hormone levels and inappropriately normal or elevated TSH. Individuals with RTH do not, in general, exhibit signs and symptoms that are typical of hypothyroidism because hormone resistance is partial and is compensated by increased levels of thyroid hormone. The clinical features of RTH can include goiter, attention deficit disorder, mild reduction in IQ, delayed skeletal maturation, tachycardia, and impaired metabolic responses to thyroid hormone.

Classical forms of RTH are caused by mutations in the TRβ gene. These mutations, located in restricted regions of the ligand-binding domain, cause loss of receptor function. However, because the mutant receptors retain the capacity to dimerize with RXRs, bind to DNA, and recruit co-repressor proteins, they function as antagonists of the remaining normal TRβ and TRα receptors. This property, referred to as "dominant negative" activity, explains the autosomal dominant mode of transmission. The diagnosis is suspected when unbound thyroid hormone levels are increased without suppression of TSH. Similar hormonal abnormalities are found in other affected family members, although the TRβ mutation arises de novo in ~20% of patients. DNA sequence analysis of the TRβ gene provides a definitive diagnosis. RTH must be distinguished from other causes of euthyroid hyperthyroxinemia (e.g., FDH) and inappropriate secretion of TSH by TSH-secreting pituitary adenomas **(Chap. 392)**. In most patients, no treatment is indicated; the importance of making the diagnosis is to avoid inappropriate treatment of mistaken hyperthyroidism and to provide genetic counseling.

A distinct form of RTH is caused by mutations in the TRα gene. Affected patients have many clinical features of congenital hypothyroidism including growth retardation, skeletal dysplasia, severe constipation, and delayed neurocognitive development. In contrast to RTH caused by mutations in TRβ, thyroid function tests include normal TSH, low or normal T_4, and normal or elevated T_3 levels. These distinct clinical and laboratory features underscore the different tissue distribution and functional roles of TRβ and TRα. Thyroxine treatment appears to alleviate some of the clinical manifestations of patients with RTH caused by TRα mutations.

PHYSICAL EXAMINATION

In addition to the examination of the thyroid itself, the physical examination should include a search for signs of abnormal thyroid function and the extrathyroidal features of ophthalmopathy and dermopathy **(Chap. 396)**. Examination of the neck begins by inspecting the seated patient from the front and side and noting any surgical scars, obvious masses, or distended veins. The thyroid can be palpated with both hands from behind or while facing the patient, using the thumbs to palpate each lobe. It is best to use a combination of these methods, especially when nodules are small. The patient's neck should be slightly flexed to relax the neck muscles. After locating the cricoid cartilage, the isthmus, which is attached to the lower one-third of the thyroid lobes, can be identified and then followed laterally to locate either lobe (normally, the right lobe is slightly larger than the left). By asking the patient to swallow sips of water, thyroid consistency can be better appreciated as the gland moves beneath the examiner's fingers.

Features to be noted include thyroid size, consistency, nodularity, and any tenderness or fixation. An estimate of thyroid size (normally 12–20 g) should be made, and a drawing is often the best way to record findings. Ultrasound imaging provides the most accurate measurement of thyroid volume and nodularity and is useful for assessment of goiter prevalence in iodine-deficient regions. However, ultrasound is not indicated if the thyroid physical examination is normal. The size, location, and consistency of any nodules should also be defined. A bruit or thrill over the gland, located over the insertion of the superior and inferior thyroid arteries (supero- or inferolaterally), indicates increased vascularity, associated with turbulent rather than laminar blood flow, as occurs in hyperthyroidism. If the lower borders of the thyroid lobes are not clearly felt, a goiter may be retrosternal. Large retrosternal goiters can cause venous distention over the neck and difficulty breathing, especially when the arms are raised (Pemberton's sign). With any central mass above the thyroid, the tongue should be extended, as thyroglossal cysts then move upward. The thyroid examination is not complete without assessment for lymphadenopathy in the supraclavicular and cervical regions of the neck.

LABORATORY EVALUATION

Measurement of Thyroid Hormones The enhanced sensitivity and specificity of *TSH assays* have greatly improved laboratory assessment of thyroid function. Because TSH levels change dynamically

in response to alterations of T_4 and T_3, a logical approach to thyroid testing is to first determine whether TSH is suppressed, normal, or elevated. With rare exceptions (see below), a normal TSH level excludes a primary abnormality of thyroid function. This strategy depends on the use of assays for TSH that are sensitive enough to discriminate between the lower limit of the reference interval and the suppressed values that occur with thyrotoxicosis. Extremely sensitive assays can detect TSH levels ≤0.004 mIU/L, but, for practical purposes, assays sensitive to ≤0.01 mIU/L are sufficient. The widespread availability of sensitive TSH assays has rendered the TRH stimulation test obsolete, because the failure of TSH to rise after an intravenous bolus of 200–400 μg TRH has the same implications as a suppressed basal TSH. Because the antibodies used in many TSH assays are biotinylated, biotin supplements containing 1000 μg or more, including biotin in some multivitamins, can interfere with TSH measurements, resulting in falsely low TSH values and falsely high T_4 or T_3 levels. Therefore, patients should be advised to stop taking biotin for at least 2 days prior to thyroid function testing.

The finding of an abnormal TSH level must be followed by measurements of circulating thyroid hormone levels to confirm the diagnosis of hyperthyroidism (suppressed TSH) or hypothyroidism (elevated TSH). Automated immunoassays are widely available for serum *total* T_4 and *total* T_3. T_4 and T_3 are highly protein-bound, and numerous factors (illness, medications, genetic factors) can influence protein binding. It is useful, therefore, to measure the free, or unbound, hormone levels, which correspond to the biologically available hormone pool. Two direct methods are used to measure *unbound thyroid hormones*: (1) unbound thyroid hormone competition with radiolabeled T_4 (or an analogue) for binding to a solid-phase antibody, and (2) physical separation of the unbound hormone fraction by ultracentrifugation or equilibrium dialysis. Although early unbound hormone immunoassays suffered from artifacts, newer assays correlate well with the results of the more technically demanding and expensive physical separation methods. An indirect method that is now less commonly used to estimate unbound thyroid hormone levels is to calculate the free T_3 or free T_4 index from the total T_4 or T_3 concentration and the *thyroid hormone binding ratio* (THBR). The latter is derived from the *T_3-resin uptake test*, which determines the distribution of radiolabeled T_3 between an absorbent resin and the unoccupied thyroid hormone–binding proteins in the sample. The binding of the labeled T_3 to the resin is increased when there is reduced unoccupied protein binding sites (e.g., TBG deficiency) or increased total thyroid hormone in the sample; it is decreased under the opposite circumstances. The product of THBR and total T_3 or T_4 provides the *free T_3 or T_4 index*. In effect, the index corrects for anomalous total hormone values caused by variations in hormone-protein binding.

Total thyroid hormone levels are *elevated* when TBG is increased due to estrogens (pregnancy, oral contraceptives, hormone therapy, tamoxifen, selective estrogen receptor modulators, inflammatory liver disease) and *decreased* when TBG binding is reduced (androgens, nephrotic syndrome). Genetic disorders and acute illness can also cause abnormalities in thyroid hormone–binding proteins, and various drugs (phenytoin, carbamazepine, salicylates, and nonsteroidal anti-inflammatory drugs [NSAIDs]) can interfere with thyroid hormone binding. Because unbound thyroid hormone levels are normal and the patient is euthyroid in all of these circumstances, assays that measure unbound hormone are preferable to those for total thyroid hormones.

For most purposes, the unbound T_4 level is sufficient to confirm thyrotoxicosis, but 2–5% of patients have only an elevated T_3 level (T_3 toxicosis). Thus, unbound T_3 levels should be measured in patients with a suppressed TSH but normal unbound T_4 levels.

There are several clinical conditions in which the use of TSH as a screening test may be misleading, particularly without simultaneous unbound T_4 determinations. Any severe nonthyroidal illness can cause abnormal TSH levels. Although hypothyroidism is the most common cause of an elevated TSH level, rare causes include a TSH-secreting pituitary tumor **(Chap. 392)**, thyroid hormone resistance, and assay artifact. Conversely, a suppressed TSH level, particularly <0.01 mIU/L, usually indicates thyrotoxicosis. However, subnormal TSH levels between 0.01 and 0.1 mIU/L may be seen during the first trimester of pregnancy (due to hCG secretion), after treatment of hyperthyroidism (because TSH can remain suppressed for several months), and in response to certain medications (e.g., high doses of glucocorticoids or dopamine). As above, biotin supplements, generally those containing more than 1000 ug, taken <18 h prior to a blood draw can interfere with biotinylated TSH antibodies and the subsequent streptavidin capture. Importantly, secondary hypothyroidism, caused by hypothalamic-pituitary disease, is associated with a variable (low to high-normal) TSH level, which is inappropriate for the low T_4 level. Thus, *TSH should not be used as an isolated laboratory test to assess thyroid function in patients with suspected or known hypothalamic or pituitary disease*.

Tests for the end-organ effects of thyroid hormone excess or depletion, such as estimation of basal metabolic rate, tendon reflex relaxation rates, or serum cholesterol, are relatively insensitive and are not useful as clinical determinants of thyroid function.

Tests to Determine the Etiology of Thyroid Dysfunction

Autoimmune thyroid disease is detected most easily by measuring circulating antibodies against TPO and Tg. Because antibodies to Tg alone are less common, it is reasonable to measure only TPO antibodies. About 5–15% of euthyroid women and up to 2% of euthyroid men have thyroid antibodies; such individuals are at increased risk of developing thyroid dysfunction. Almost all patients with autoimmune hypothyroidism, and up to 80% of those with Graves' disease, have TPO antibodies, usually at high levels.

TSIs are antibodies that stimulate the TSH-R in Graves' disease. They are most commonly measured by commercially available tracer displacement assays called TRAb (TSH receptor antibody) with the assumption that elevated levels in the setting of clinical hyperthyroidism reflect stimulatory effects on the TSH receptor. A bioassay is less commonly used. Remission rates in patients with Graves' disease after antithyroid drug cessation are higher in patients with disappearance TRAb. Furthermore, the TRAb assay is used to predict both fetal and neonatal thyrotoxicosis caused by transplacental passage of high maternal levels of TRAb or TSI (>3× upper limit of normal) in the last trimester of pregnancy.

Serum Tg levels are increased in all types of thyrotoxicosis except *thyrotoxicosis factitia* caused by self-administration of thyroid hormone. Tg levels are particularly increased in thyroiditis, reflecting thyroid tissue destruction and release of Tg. The main role for Tg measurement, however, is in the follow-up of thyroid cancer patients. After total thyroidectomy and radioablation for patients with thyroid cancer, Tg levels should be <0.2 ng/mL in the absence of anti-Tg antibodies; measurable levels indicate incomplete ablation or recurrent cancer.

Radioiodine Uptake and Thyroid Scanning The thyroid gland selectively transports and organifies radioisotopes of iodine (^{123}I, ^{125}I, ^{131}I) and transports ^{99m}Tc pertechnetate, allowing thyroid imaging for all these isotopes, but quantitation of radioactive tracer fractional uptake for iodine isotopes only.

Nuclear imaging of Graves' disease is characterized by an enlarged gland and increased tracer uptake that is distributed homogeneously. Toxic adenomas appear as focal areas of increased uptake, with suppressed tracer uptake in the remainder of the gland (reflecting suppressed TSH). In toxic MNG, the gland is enlarged—often with distorted architecture—and there are multiple areas of relatively increased (functioning nodules) or decreased tracer uptake (suppressed thyroid parenchyma or nonfunctioning nodules). Subacute, viral, and postpartum thyroiditis are associated with very low uptake because of follicular cell damage and TSH suppression. Thyrotoxicosis factitia is also associated with low uptake because exogenous hormone suppresses TSH. In addition, excessive circulating exogenous iodine (e.g., from dietary sources of iodinated contrast dye) reduces radionuclide uptake even in the presence of increased thyroid hormone production.

Thyroid scintigraphy is not used in the routine evaluation of patients with thyroid nodules but should be performed if the serum TSH level is subnormal to determine if functioning thyroid nodules are present. Functioning or "hot" nodules are almost never malignant, and fine-needle aspiration (FNA) biopsy is not indicated **(see Chap. 397, Fig. 397-3*B*)**. The vast majority of thyroid nodules do not produce thyroid

hormone ("cold" nodules, **see Chap. 397, Fig 397-3A**), and these are more likely to be malignant (~5–10%). Whole-body and thyroid scanning is also used in the treatment and, now less frequently, in the surveillance of thyroid cancer. After thyroidectomy for thyroid cancer, the TSH level is raised by either using a thyroid hormone withdrawal protocol or recombinant human TSH injection **(Chap. 397)**. Administration of either ^{131}I or ^{123}I (in higher activities than used to image the thyroid gland alone) allows whole-body scanning (WBS) to detect the thyroid remnant. WBS imaging is also performed after therapeutic administration of ^{131}I, which confirms remnant ablation and may reveal iodine-avid metastases.

Thyroid Ultrasound Ultrasonography is the most valuable tool for the diagnosis and evaluation of patients with nodular thyroid disease **(Chap. 397)**. Evidence-based guidelines recommend thyroid ultrasonography for all patients suspected of having thyroid nodules by either physical examination or another imaging study. Using 10- to 12-MHz linear transducers, resolution and image quality are excellent, allowing the characterization of nodules and cysts >3 mm. Sonographic patterns that combine suspicious sonographic features are highly suggestive of malignancy (e.g., hypoechoic solid nodules with irregular borders and punctate echogenic foci >90% cancer risk), whereas other patterns correlate with a lower likelihood of cancer (isoechoic solid nodules, 5–10% cancer risk). Some patterns suggest benignity (e.g., spongiform nodules, defined as those with multiple small internal cystic areas, or simple cysts, <3% cancer risk) **(see Chap. 397, Fig. 397-2)**. These patterns have been incorporated into validated risk stratification systems (RSSs) for sonographic imaging of thyroid nodules (American College of Radiology [ACR] Thyroid Imaging Reporting and Data System [TI-RADS], American Thyroid Association, European Thyroid Association [EU-TIRADS] and others) **(see Chap. 397, Fig. 397-1)**. These systems are relatively concordant in the classification of thyroid nodules; they differ in size cutoff recommendations for FNA. Not surprisingly, the RSSs with lower size cutoffs have higher sensitivity and lower specificity for thyroid cancer diagnosis than those with higher cutoffs. Nevertheless, all have been shown to reduce unnecessary FNAs by at least 45%, in part due to the recommendation not to perform FNA of spongiform nodules.

In addition to evaluating thyroid nodules, ultrasound is useful for monitoring nodule size and for the aspiration of nodules or cystic lesions. Ultrasound-guided FNA biopsy of thyroid lesions lowers the rate of inadequate sampling and decreases sample error, thereby reducing both the nondiagnostic and false-negative rates of FNA cytology. Ultrasonography of the central and lateral cervical lymph node compartments is indispensable in the evaluation of thyroid cancer patients, preoperatively and during follow-up. In addition, the all of the RSSs recommend a survey of the cervical lymph nodes as part of every diagnostic thyroid sonographic examination.

395 Hypothyroidism

Anthony P. Weetman, Susan J. Mandel, J. Larry Jameson

HYPOTHYROIDISM

Iodine deficiency remains a common cause of hypothyroidism worldwide. In areas of iodine sufficiency, autoimmune disease (Hashimoto's thyroiditis) and iatrogenic causes (treatment of hyperthyroidism) are most common **(Table 395-1)**.

CONGENITAL HYPOTHYROIDISM

Prevalence Hypothyroidism occurs in about 1 in 2000–4000 newborns, and neonatal screening is performed in most industrialized countries. It may be transient, especially if the mother has thyroid-stimulating hormone (TSH) receptor (TSH-R)–blocking antibodies or has received antithyroid drugs, but permanent hypothyroidism occurs in the majority. The causes of neonatal hypothyroidism include thyroid gland dysgenesis in 65%, inborn errors of thyroid hormone synthesis in 30%, and TSH-R antibody mediated in 5% of affected newborns. The developmental abnormalities are twice as common in girls. Mutations that cause congenital hypothyroidism are being increasingly identified, but most remain idiopathic **(Chap. 394)**. These can be broadly categorized as mutations causing (1) central hypothyroidism because of abnormal hypothalamic-pituitary development or the loss of specific components of the thyrotropin-releasing hormone (TRH)/TSH hormonal pathways; (2) abnormal thyroid gland development or dysgenesis; or (3) abnormal thyroid hormone synthesis and processing, or dyshormonogenesis **(Table 395-2)**. Transplacental passage of maternal thyroid hormone occurs before the fetal thyroid gland begins to function and provides partial hormone support to a fetus with congenital hypothyroidism.

TABLE 395-1 Causes of Hypothyroidism

Primary
Autoimmune hypothyroidism: Hashimoto's thyroiditis, atrophic thyroiditis
Iatrogenic: ^{131}I treatment, subtotal or total thyroidectomy, external irradiation of neck for lymphoma or cancer
Drugs: iodine excess (including iodine-containing contrast media), amiodarone, lithium, antithyroid drugs, *p*-aminosalicylic acid, interferon α and other cytokines, aminoglutethimide, tyrosine kinase inhibitors (e.g., sunitinib), immune checkpoint inhibitors (e.g., ipilimumab, nivolumab, pembrolizumab)
Congenital hypothyroidism: absent or ectopic thyroid gland, dyshormonogenesis, TSH-R mutation
Iodine deficiency
Infiltrative disorders: amyloidosis, sarcoidosis, hemochromatosis, scleroderma, cystinosis, Riedel's thyroiditis
Overexpression of type 3 deiodinase in infantile hemangioma and other tumors
Transient
Silent thyroiditis, including postpartum thyroiditis
Subacute thyroiditis
Withdrawal of supraphysiologic thyroxine treatment in individuals with an intact thyroid
After ^{131}I treatment or subtotal thyroidectomy for Graves' disease
Secondary
Hypopituitarism: tumors, pituitary surgery or irradiation, infiltrative disorders, Sheehan's syndrome, trauma, genetic forms of combined pituitary hormone deficiencies
Isolated TSH deficiency or inactivity
Drugs: bexarotene, mitotane
Hypothalamic disease: tumors, trauma, infiltrative disorders, Prader-Willi syndrome

Abbreviations: TSH, thyroid-stimulating hormone; TSH-R, TSH receptor.

TABLE 395-2 Examples of Genetic Causes of Congenital Hypothyroidism

DEFECTIVE GENE PROTEIN	TYPE OF HYPOTHYROIDISM	INHERITANCE	CONSEQUENCES
PROP-1	Central, hypothyroidism	Homozygous recessive	Combined pituitary hormone deficiencies, including thyroid-stimulating hormone (TSH), with preservation of adrenocorticotropic hormone
PIT-1	Central, hypothyroidism	Homozygous or heterozygous loss of function	Combined deficiencies of growth hormone, prolactin, TSH
IGSF1	Central, hypothyroidism	X-linked loss of function	Loss of TSH receptor (TSH-R) expression, testicular enlargement
TSHβ	Central, hypothyroidism	Heterozygous loss of function	TSH deficiency
TTF-1 (TITF-1)	Primary, thyroid dysgenesis	Heterozygous loss of function	Variable thyroid hypoplasia, choreoathetosis, pulmonary problems
TTF-2 (FOXE-1)	Primary, thyroid dysgenesis	Homozygous recessive	Thyroid agenesis, choanal atresia, spiky hair
PAX-8	Primary, thyroid dysgenesis	Heterozygous loss of function	Thyroid dysgenesis, kidney abnormalities
NKX2-1	Primary, thyroid dysgenesis	Heterozygous loss of function	Thyroid dysgenesis, brain, lung abnormalities
NKX2-5	Primary, thyroid dysgenesis	Heterozygous loss of function	Thyroid dysgenesis, heart abnormalities
GLIS3	Primary, thyroid dysgenesis	Homozygous recessive	Thyroid dysgenesis, neonatal diabetes, facial abnormalities
JAG-1	Primary, thyroid dysgenesis	Heterozygous loss of function	Thyroid dysgenesis, Alagille syndrome type 1, heart abnormalities
TSH receptor	Primary, thyroid dysgenesis and dyshormonogenesis	Homozygous recessive	Resistance to TSH
$G_s\alpha$ (Albright hereditary osteodystrophy)	Primary, thyroid dyshormonogenesis	Heterozygous loss of function, imprinting	Resistance to TSH
Na^+/I^- symporter (SLC5A5)	Primary, thyroid dyshormonogenesis	Homozygous recessive	Inability to transport iodide
DUOX2 (THOX2)	Primary, thyroid dyshormonogenesis	Heterozygous loss of function	Organification defect
DUOXA2	Primary, thyroid dyshormonogenesis	Homozygous recessive	Organification defect
Thyroid peroxidase	Primary, thyroid dyshormonogenesis	Homozygous recessive	Defective organification of iodide
Thyroglobulin	Primary, thyroid dyshormonogenesis	Homozygous recessive	Defective synthesis of thyroid hormone
Pendrin (SLC26A4)	Primary, thyroid dyshormonogenesis	Homozygous recessive	Pendred syndrome: sensorineural deafness and partial organification defect in thyroid
Dehalogenase 1 (IYD)	Primary, thyroid dyshormonogenesis	Homozygous recessive	Loss of iodide reutilization

Clinical Manifestations The majority of infants appear normal at birth, and with the use of biochemical screening, few cases are now diagnosed based on clinical features, which include prolonged jaundice, feeding problems, hypotonia, enlarged tongue, delayed bone maturation, and umbilical hernia. Importantly, permanent neurologic damage results if treatment is delayed. Typical features of adult hypothyroidism may also be present (Table 395-3). Other congenital malformations, especially cardiac, are four times more common in congenital hypothyroidism.

Diagnosis and Treatment Because of the severe neurologic consequences of untreated congenital hypothyroidism, neonatal screening programs have been established. These are generally based on measurement of TSH or T_4 levels in heel-prick blood specimens. When the diagnosis is confirmed, T_4 is instituted at a dose of 10–15 μg/kg per d, and the dose is adjusted by close monitoring of TSH levels. T_4 requirements are relatively great during the first year of life, and a high circulating T_4 level is usually needed to normalize TSH. Early treatment with T_4 results in normal IQ levels, but subtle neurodevelopmental abnormalities may occur in those with the most severe hypothyroidism at diagnosis or when treatment is delayed or suboptimal. If transient hypothyroidism is suspected, or the diagnosis is unclear, treatment can be stopped safely after the age of 3 years followed by further evaluation.

TABLE 395-3 Signs and Symptoms of Hypothyroidism (Descending Order of Frequency)

SYMPTOMS	SIGNS
Tiredness, weakness	Dry coarse skin; cool peripheral extremities
Dry skin	Puffy face, hands, and feet (myxedema)
Feeling cold	Diffuse alopecia
Hair loss	Bradycardia
Difficulty concentrating and poor memory	Peripheral edema
Constipation	Delayed tendon reflex relaxation
Weight gain with poor appetite	Carpal tunnel syndrome
Dyspnea	Serous cavity effusions
Hoarse voice	
Menorrhagia (later oligomenorrhea or amenorrhea)	
Paresthesia	
Impaired hearing	

AUTOIMMUNE HYPOTHYROIDISM

Classification Autoimmune hypothyroidism (Hashimoto's thyroiditis) may be associated with a goiter (*goitrous thyroiditis*) or minimal residual thyroid tissue (*atrophic thyroiditis*). Because the autoimmune process gradually reduces thyroid function, there is a phase of compensation when normal thyroid hormone levels are maintained by a rise in TSH. Although some patients may have minor symptoms, this state is called *subclinical hypothyroidism*. Later, unbound T_4 levels fall and TSH levels rise further; symptoms become more readily apparent at this stage (usually TSH >10 mIU/L), which is referred to as *clinical hypothyroidism* or *overt hypothyroidism*.

Prevalence The mean annual incidence rate of autoimmune hypothyroidism is up to 4 per 1000 women and 1 per 1000 men. It is more common in certain populations, such as the Japanese, probably because of genetic factors and chronic exposure to a high-iodine diet. Hypothyroidism typically occurs between 30 and 50 years of age, and the prevalence of increases with age. The mean age at diagnosis is 60 years, and the prevalence of overt hypothyroidism increases with age. Subclinical hypothyroidism is found in 6–8% of women (10% over the age of 60) and 3% of men. The annual risk of developing clinical hypothyroidism is ~4% when subclinical hypothyroidism is associated with positive thyroid peroxidase (TPO) antibodies.

Pathogenesis In Hashimoto's thyroiditis, there is a marked lymphocytic infiltration of the thyroid with germinal center formation, atrophy of the thyroid follicles accompanied by oxyphil metaplasia, absence of colloid, and mild to moderate fibrosis. In atrophic thyroiditis, the fibrosis is much more extensive, lymphocyte infiltration is less pronounced, and thyroid follicles are almost completely absent. Atrophic thyroiditis usually represents the end stage of Hashimoto's thyroiditis rather than a separate disorder, although a distinct form of marked fibrosis occurs in which the gland is infiltrated with IgG4-positive plasma cells.

As with most autoimmune disorders, susceptibility to autoimmune hypothyroidism is determined by a combination of genetic and environmental factors, and the risk of either autoimmune hypothyroidism or Graves' disease is increased among siblings. HLA-DR polymorphisms are the best documented genetic risk factors for autoimmune hypothyroidism, especially HLA-DR3, DR4, and DR5 in Caucasians. A weak association also exists between polymorphisms in *PTPN22* and *CTLA-4*, which have immunoregulatory functions, and autoimmune hypothyroidism. All these genetic associations are shared by other autoimmune diseases, which may explain the relationship between autoimmune hypothyroidism and other autoimmune diseases, especially type 1 diabetes mellitus, Addison's disease, pernicious anemia, and vitiligo. The role of other contributory loci remains to be clarified. A gene on chromosome 21 may be responsible for the association between autoimmune hypothyroidism and Down's syndrome. The female preponderance of thyroid autoimmunity is most likely due to sex steroid effects on the immune response, but an X chromosome–related genetic factor is also possible and may account for the high frequency of autoimmune hypothyroidism in Turner's syndrome. Environmental susceptibility factors are poorly defined at present. A high iodine or low selenium intake and decreased exposure to microorganisms in childhood increase the risk of autoimmune hypothyroidism. Smoking cessation transiently increases incidence, whereas alcohol intake seems protective. These factors may account for the increase in prevalence over the past two to three decades.

The thyroid lymphocytic infiltrate in autoimmune hypothyroidism is composed of activated T cells as well as B cells. Thyroid cell destruction is primarily mediated by the CD8+ cytotoxic T cells, but local production of cytokines, such as tumor necrosis factor (TNF), interleukin-1 (IL-1), and interferon γ (IFN-γ), derived from the inflammatory infiltrate may render thyroid cells more susceptible to apoptosis mediated by death receptors, such as Fas, and by oxidative stress. These cytokines also impair thyroid cell function directly and induce the expression of other proinflammatory molecules by the thyroid cells themselves, such as cytokines, human leukocyte antigen (HLA) class I and class II molecules, adhesion molecules, CD40, and nitric oxide. Administration of high concentrations of cytokines for therapeutic purposes (especially IFN-α) is associated with increased autoimmune thyroid disease, possibly through mechanisms similar to those in sporadic disease. Novel anticancer and immunomodulatory treatments, such as tyrosine kinase inhibitors, immune checkpoint inhibitors, and alemtuzumab, can also induce thyroiditis via their effects on T-cell regulation.

Antibodies to TPO and thyroglobulin (Tg) are clinically useful markers of thyroid autoimmunity, but any pathogenic effect is restricted to a secondary role in amplifying an ongoing autoimmune response. TPO antibodies fix complement, and complement membrane-attack complexes are present in the thyroid in autoimmune hypothyroidism. However, transplacental passage of Tg or TPO antibodies has no effect on the fetal thyroid, which suggests that T cell–mediated injury is required to initiate autoimmune damage to the thyroid.

Up to 20% of patients with autoimmune hypothyroidism have antibodies against the TSH-R, which, in contrast to thyroid-stimulating immunoglobulin (TSI), do not stimulate the receptor but prevent the binding of TSH. These TSH-R-blocking antibodies, therefore, cause hypothyroidism and, especially in Asian patients, thyroid atrophy. Their transplacental passage may induce transient neonatal hypothyroidism. Rarely, patients have a mixture of TSI and TSH-R-blocking antibodies, and thyroid function can oscillate between hyperthyroidism and hypothyroidism as one or the other antibody becomes dominant. Predicting the course of disease in such individuals is difficult, and they require close monitoring of thyroid function. Bioassays can be used to document that TSH-R-blocking antibodies reduce the cyclic AMP–inducing effect of TSH on cultured TSH-R-expressing cells, but these assays are difficult to perform. Immunoassays for TSH receptor antibodies, which measure whether the patient's serum contains an antibody that can displace either labeled TSH or a monoclonal TSH receptor antibody from the TSH receptor, do not distinguish between these types of functional antibodies, but a positive result in a patient with spontaneous hypothyroidism is strong evidence for the presence of blocking antibodies. The use of these assays does not generally alter clinical management, although it may be useful to confirm the cause of transient neonatal hypothyroidism.

Clinical Manifestations The main clinical features of hypothyroidism are summarized in Table 395-3. The onset is usually insidious, and the patient may become aware of symptoms only when euthyroidism is restored. Patients with Hashimoto's thyroiditis may present because of goiter rather than symptoms of hypothyroidism. The goiter may not be large, but it is usually irregular and firm in consistency. Rarely, uncomplicated Hashimoto's thyroiditis is associated with pain.

Patients with atrophic thyroiditis or the later stage of Hashimoto's thyroiditis present with symptoms and signs of hypothyroidism. The skin is dry, and there is decreased sweating, thinning of the epidermis, and hyperkeratosis of the stratum corneum. Increased dermal glycosaminoglycan content traps water, giving rise to skin thickening without pitting (*myxedema*). Typical features include a puffy face with edematous eyelids and nonpitting pretibial edema **(Fig. 395-1)**. There is pallor, often with a yellow tinge to the skin due to carotene accumulation. Nail growth is retarded, and hair is dry, brittle, difficult to manage, and falls out easily. In addition to diffuse alopecia, there is thinning of the outer third of the eyebrows, although this is not a specific sign of hypothyroidism.

Other common features include constipation and weight gain (despite a poor appetite). In contrast to popular perception, the weight gain is usually modest and due mainly to fluid retention in the myxedematous tissues. Libido is decreased in both sexes, and there may be oligomenorrhea or amenorrhea in long-standing disease, but

FIGURE 395-1 Facial appearance in hypothyroidism. Note puffy eyes and thickened skin.

menorrhagia may occur at an early stage. Fertility is reduced, and the incidence of miscarriage is increased. Prolactin levels are often modestly increased (Chap. 392) and may contribute to alterations in libido and fertility and cause galactorrhea.

Myocardial contractility and pulse rate are reduced, leading to a reduced stroke volume and bradycardia. Increased peripheral resistance may be accompanied by hypertension, particularly diastolic. Blood flow is diverted from the skin, producing cool extremities. Pericardial effusions occur in up to 30% of patients but rarely compromise cardiac function. Although alterations in myosin heavy chain isoform expression have been documented, cardiomyopathy is rare. Fluid may also accumulate in other serous cavities and in the middle ear, giving rise to conductive deafness; sensorineural deafness may also occur. Pulmonary function is generally normal, but dyspnea may be caused by pleural effusion, impaired respiratory muscle function, diminished ventilatory drive, or sleep apnea.

Carpal tunnel and other entrapment syndromes are common, as is impairment of muscle function with stiffness, cramps, and pain. On examination, there may be slow relaxation of tendon reflexes and pseudomyotonia. Memory and concentration are impaired. Experimentally, positron emission tomography (PET) scans examining glucose metabolism in hypothyroid subjects show lower regional activity in the amygdala, hippocampus, and perigenual anterior cingulate cortex, among other regions, and this activity corrects after thyroxine replacement. Rare neurologic problems include reversible cerebellar ataxia, dementia, psychosis, and myxedema coma. *Hashimoto's encephalopathy* has been defined as a steroid-responsive syndrome associated with TPO antibodies, myoclonus, and slow-wave activity on electroencephalography, but the relationship with thyroid autoimmunity or hypothyroidism is not established, and if a patient is euthyroid, levothyroxine (LT4) therapy has not been shown to be efficacious in treatment. The hoarse voice and occasionally clumsy speech of hypothyroidism reflect fluid accumulation in the vocal cords and tongue.

The features described above are the consequence of thyroid hormone deficiency. However, autoimmune hypothyroidism may be associated with signs or symptoms of other autoimmune diseases, particularly vitiligo, pernicious anemia, Addison's disease (Schmidt's syndrome), alopecia areata, and type 1 diabetes mellitus (T1DM). In the polygenic disorder autoimmune polyendocrine syndrome type 2, autoimmune thyroid disease is present in 70–75%, T1DM in 40–60%, and Addison's disease in 40–50%. Less common associations include celiac disease, dermatitis herpetiformis, chronic active hepatitis, rheumatoid arthritis, systemic lupus erythematosus (SLE), myasthenia gravis, autoimmune hypoparathyroidism, primary hypogonadism, and Sjögren's syndrome. Thyroid-associated ophthalmopathy usually occurs in Graves' disease (Chap. 396), but in ~5% of patients, it is associated with autoimmune hypothyroidism.

Autoimmune hypothyroidism is uncommon in children and usually presents with slow growth and delayed facial and dental maturation. The pituitary may be enlarged due to thyrotroph hyperplasia. Myopathy, with muscle swelling, is more common in children than in adults. In most cases, puberty is delayed, but precocious puberty sometimes occurs. There may be intellectual impairment if the onset is before 3 years and the hormone deficiency is severe.

Laboratory Evaluation A summary of the investigations used to determine the existence and cause of hypothyroidism is provided in Fig. 395-2. A normal TSH level excludes primary (but not secondary or central) hypothyroidism. If the TSH is elevated, a free or unbound T_4 level (FT_4) is needed to confirm the presence of clinical hypothyroidism, but T_4 is inferior to TSH when used as a screening test because it will not detect subclinical hypothyroidism. Circulating unbound T_3 levels are normal in ~25% of patients, reflecting adaptive deiodinase responses to hypothyroidism. T_3 measurements are, therefore, not indicated.

Once clinical or subclinical hypothyroidism is confirmed, the etiology is usually easily established by demonstrating the presence of TPO and Tg antibodies, which are present in >95% of patients with autoimmune hypothyroidism. Other abnormal laboratory findings in hypothyroidism may include increased creatine phosphokinase, elevated cholesterol and triglycerides, and anemia (usually normocytic or macrocytic) depending upon the degree and duration of hypothyroidism. Except when accompanied by iron deficiency or B_{12} deficiency from concomitant pernicious anemia, the anemia and other abnormalities gradually resolve with thyroxine replacement.

Differential Diagnosis An asymmetric goiter in Hashimoto's thyroiditis may be confused with a multinodular goiter (MNG) or thyroid carcinoma, in which thyroid antibodies may also be present. Primary thyroid lymphoma (Chap. 397) is rare but strongly associated with preexisting autoimmune thyroiditis. Ultrasound can be used to show the presence of solitary or multiple nodules rather than the thyroid enlargement with heterogeneous echogenicity typical of Hashimoto's thyroiditis. However, ultrasound imaging may also detect pseudonodules, hypoechoic areas likely representing areas of lymphocytic infiltrates, which need to be distinguished from true superimposed nodules as fine-needle aspirate is not warranted for these. Fine-needle aspiration

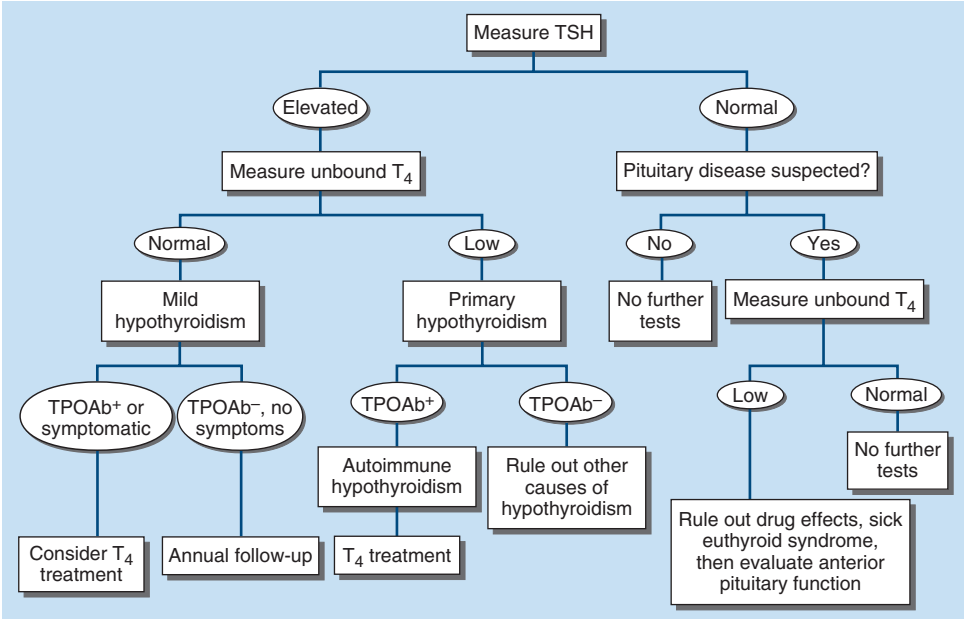

FIGURE 395-2 Evaluation of hypothyroidism. TPOAb$^+$, thyroid peroxidase antibodies present; TPOAb$^-$, thyroid peroxidase antibodies not present; TSH, thyroid-stimulating hormone.

(FNA) biopsy should be performed for all true nodules meeting FNA criteria **(Chap. 397)**. Other causes of hypothyroidism are discussed below and in Table 395-1 but rarely cause diagnostic confusion.

OTHER CAUSES OF HYPOTHYROIDISM

Iatrogenic hypothyroidism is a common cause of hypothyroidism and can often be detected by screening before symptoms develop. In the first 3–4 months after radioiodine treatment for Graves' disease, transient hypothyroidism may occur due to reversible radiation damage. Low-dose thyroxine treatment can be withdrawn if recovery occurs. Because TSH levels are suppressed by hyperthyroidism, unbound T_4 levels are a better measure of thyroid function than TSH in the months following radioiodine treatment. Mild hypothyroidism after subtotal thyroidectomy or lobectomy may also resolve after several months, as the gland remnant is stimulated by increased TSH levels.

Iodine deficiency is responsible for endemic goiter and cretinism but is an uncommon cause of adult hypothyroidism unless the iodine intake is very low or there are complicating factors, such as the consumption of thiocyanates in cassava or selenium deficiency. Although hypothyroidism due to iodine deficiency can be treated with thyroxine, public health measures to improve iodine intake should be advocated to eliminate this problem. Iodized salt or bread or a single bolus of oral or intramuscular iodized oil have all been used successfully.

Paradoxically, chronic iodine excess can also induce goiter and hypothyroidism. The intracellular events that account for this effect are unclear, but individuals with autoimmune thyroiditis are especially susceptible. Iodine excess is responsible for the hypothyroidism that occurs in patients treated with amiodarone **(Chap. 396)**. Other drugs, particularly lithium, may also cause hypothyroidism. Transient hypothyroidism may also be caused by thyroiditis **(Chap. 396)**.

Secondary or central hypothyroidism is usually diagnosed in the context of other anterior pituitary hormone deficiencies; isolated TSH deficiency is very rare **(Chap. 391)**. TSH levels may be low, normal, or even slightly increased in secondary hypothyroidism; the latter is due to secretion of immunoactive but bioinactive forms of TSH. The diagnosis is confirmed by detecting a low unbound T_4 level. The goal of treatment is to maintain free T_4 levels in the upper half of the reference interval because TSH levels cannot be used to monitor therapy.

TREATMENT

Hypothyroidism

CLINICAL HYPOTHYROIDISM

If there is no residual thyroid function, the daily replacement dose of LT4 is usually 1.6 μg/kg body weight (typically 100–150 μg), ideally taken at least 30 min before breakfast. In many patients, however, lower doses suffice until residual thyroid tissue is destroyed. In patients who develop hypothyroidism after the treatment of Graves' disease, there is often underlying autonomous function, necessitating lower replacement doses (typically 75–125 μg/d).

Adult patients under 60 years old without evidence of heart disease may be started on 50–100 μg of LT4 daily. The dose is adjusted on the basis of TSH levels, with the goal of treatment being a normal TSH, ideally in the lower half of the reference range. TSH responses are gradual and should be measured about 6–8 weeks after instituting treatment or after any subsequent change in LT4 dosage. The clinical effects of LT4 replacement are slow to appear. Patients may not experience full relief from symptoms until several months after normal TSH levels are restored. Adjustment of LT4 dosage is made in 12.5- or 25-μg increments if the TSH is high; decrements of the same magnitude should be made if the TSH is suppressed. Patients with a suppressed TSH of any cause, including LT4 overtreatment, have an increased risk of atrial fibrillation and reduced bone density.

About 10–15% of patients may have persistent symptoms despite restoration of euthyroidism with LT4 for reasons that remain unclear. Although desiccated animal thyroid preparations (thyroid extract USP) are available, they are not recommended because the ratio of T_3 to T_4 is nonphysiologic. The use of LT4 combined with liothyronine (triiodothyronine, T_3) has been investigated, but benefit has not been confirmed in prospective studies. There is no place for liothyronine alone as long-term replacement, because the short half-life necessitates three or four daily doses and is associated with fluctuating T_3 levels.

Once full replacement is achieved and TSH levels are stable, follow-up measurement of TSH is recommended at annual intervals. It is important to ensure ongoing adherence as patients do not feel any symptomatic difference after missing a few doses of LT4, and this sometimes leads to self-discontinuation.

In patients of normal body weight who are taking ≥200 μg of LT4 daily, an elevated TSH level is often a sign of poor adherence to treatment. This is also the likely explanation for fluctuating TSH levels, despite a constant LT4 dosage. Such patients often have normal or high free T_4 levels, despite an elevated TSH, because they remember to take medication for a few days before testing; this is sufficient to normalize T_4, but not TSH levels. It is important to consider variable adherence because this pattern of thyroid function tests is otherwise suggestive of disorders associated with inappropriate TSH secretion **(Chap. 394)**. Because T_4 has a long half-life (7 days), patients who miss a dose can be advised to take two doses of the skipped tablets at once. Other causes of increased LT4 requirements must be excluded, particularly malabsorption (e.g., celiac disease, small-bowel surgery, atrophic or *Helicobacter pylori*–related gastritis), oral estrogen-containing medications or selective estrogen receptor modulator therapy, ingestion with a meal, and drugs that interfere with T_4 absorption or metabolism such as bile acid sequestrants, ferrous sulfate, calcium supplements, sevelamer, sucralfate, proton pump inhibitors, lovastatin, aluminum hydroxide, rifampicin, amiodarone, carbamazepine, phenytoin, and tyrosine kinase inhibitors.

SUBCLINICAL HYPOTHYROIDISM

Subclinical hypothyroidism refers to biochemical evidence of thyroid hormone deficiency in patients who have few or no apparent clinical features of hypothyroidism. There are no universally accepted recommendations for the management of subclinical hypothyroidism, but LT4 is recommended if the patient is a woman who wishes to conceive or is pregnant or when TSH levels are >10 mIU/L. Most other patients can simply be monitored annually. A trial of treatment may be considered when young or middle-aged patients have symptoms of hypothyroidism or risk of heart disease. It is important to confirm that any elevation of TSH is sustained over a 3-month period before treatment is given. Treatment is administered by starting with a low dose of LT4 (25–50 μg/d) with the goal of normalizing TSH.

SPECIAL TREATMENT CONSIDERATIONS

Rarely, LT4 replacement is associated with pseudotumor cerebri in children. Presentation appears to be idiosyncratic and occurs months after treatment has begun.

Because maternal hypothyroidism may both adversely affect fetal neural development and be associated with adverse gestational outcomes (miscarriage, preterm delivery), thyroid function should be monitored to preserve euthyroidism in women with a history or a high risk of hypothyroidism. Although epidemiologic studies have demonstrated the association of miscarriage and preterm delivery with the presence of thyroid autoantibodies detected either during or prior to gestation in euthyroid women, randomized controlled multicenter trials evaluating LT4 therapy prior to conception in this population have not demonstrated benefit. Because of the known increase in thyroid hormone requirements during pregnancy in hypothyroid women, LT4 therapy should be targeted to maintain a serum TSH in the normal range but <2.5 mIU/L prior to conception.

In women without evidence of thyroid dysfunction, serum TSH decreases in the late first trimester, and if trimester-specific ranges are not available, an appropriate range for 7–12 weeks' gestation can

be approximated by decreasing the upper limit of the nonpregnant reference range by 0.5 mIU/L (~4.0 mIU/L) and the lower limit by 0.4 mIU/L (~0.1 mIU/L). However, it is important to recognize that the normal TSH range in pregnancy for the second and third trimesters is not significantly different from the nonpregnancy reference range. Therefore, when caring for LT4-replaced women with hypothyroidism, thyroid function should be evaluated immediately after pregnancy is confirmed and every 4 weeks during the first half of the pregnancy, with less frequent testing after 20 weeks' gestation (every 6–8 weeks depending on whether LT4 dose adjustment is ongoing). The increment of LT4 dosage increase depends upon the etiology of hypothyroidism, with athyreotic women requiring more (~45%) than those with Hashimoto's who may have some residual thyroid function. Women should increase LT4 from once-daily dosing to nine doses per week as soon as pregnancy is confirmed to anticipate this change. Thereafter, dosage should be closely monitored with a goal TSH in the lower half of the trimester-specific normative range, if available, or <2.5 mIU/L, which allows for reserve if additional LT4 dosage increases are required as pregnancy progresses. After delivery, LT4 doses typically return to prepregnancy levels. Pregnant women should be counseled to separate ingestion of prenatal vitamins and iron supplements from LT4.

Elderly patients may require 20% less thyroxine than younger patients. In the elderly, especially patients with known coronary artery disease, the starting dose of LT4 is 12.5–25 μg/d with similar increments every 2–3 months until TSH is normalized. In some patients, it may be impossible to achieve full replacement despite optimal antianginal treatment. *Emergency surgery* is generally safe in patients with untreated hypothyroidism, although routine surgery in a hypothyroid patient should be deferred until euthyroidism is achieved.

Myxedema coma still has a 20–40% mortality rate, despite intensive treatment, and outcomes are independent of the T_4 and TSH levels. Clinical manifestations include reduced level of consciousness, sometimes associated with seizures, as well as the other features of hypothyroidism (Table 395-3). Hypothermia can reach 23°C (74°F). There may be a history of treated hypothyroidism with poor compliance, or the patient may be previously undiagnosed. Myxedema coma almost always occurs in the elderly and is usually precipitated by factors that impair respiration, such as drugs (especially sedatives, anesthetics, and antidepressants), pneumonia, congestive heart failure, myocardial infarction, gastrointestinal bleeding, or cerebrovascular accidents. Sepsis should also be suspected. Exposure to cold may also be a risk factor. Hypoventilation, leading to hypoxia and hypercapnia, plays a major role in pathogenesis; hypoglycemia and dilutional hyponatremia also contribute to the development of myxedema coma.

LT4 can initially be administered as a single IV bolus of 200–400 μg, which serves as a loading dose, followed by a daily oral dose of 1.6 μg/kg per d, reduced by 25% if administered IV. If a suitable IV preparation is not available, the same initial dose of LT4 can be given by nasogastric tube (although absorption may be impaired in myxedema). Because $T_4 \rightarrow T_3$ conversion is impaired in myxedema coma, there is a rationale for adding liothyronine (T_3) intravenously or via nasogastric tube to LT4 treatment, although excess liothyronine has the potential to provoke arrhythmias. An initial loading dose of 5–20 μg liothyronine should be followed by 2.5–10 μg every 8 h, with lower doses chosen for smaller or older patients and those at cardiovascular risk.

Supportive therapy should be provided to correct any associated metabolic disturbances. External warming is indicated only if the temperature is <30°C, as it can result in cardiovascular collapse (Chap. 477). Space blankets should be used to prevent further heat loss. Parenteral hydrocortisone (50 mg every 6 h) should be administered because there is impaired adrenal reserve in profound hypothyroidism. Any precipitating factors should be treated, including the early use of broad-spectrum antibiotics, pending the exclusion of infection. Ventilatory support with regular blood gas analysis is usually needed during the first 48 h. Hypertonic saline or IV glucose may be needed if there is severe hyponatremia or hypoglycemia; hypotonic IV fluids should be avoided because they may exacerbate water retention secondary to reduced renal perfusion and inappropriate vasopressin secretion. The metabolism of most medications is impaired, and sedatives should be avoided if possible or used in reduced doses. Medication blood levels should be monitored, when available, to guide dosage.

396 Hyperthyroidism and Other Causes of Thyrotoxicosis

Anthony P. Weetman, Susan J. Mandel, J. Larry Jameson

THYROTOXICOSIS

Thyrotoxicosis is defined as the state of thyroid hormone excess and is not synonymous with *hyperthyroidism*, which is the result of excessive thyroid function. However, the major etiologies of thyrotoxicosis are hyperthyroidism caused by Graves' disease, toxic multinodular goiter (MNG), and toxic adenomas. Other causes are listed in Table 396-1.

GRAVES' DISEASE

Epidemiology Graves' disease accounts for 60–80% of thyrotoxicosis. The prevalence varies among populations, reflecting genetic factors and iodine intake (high iodine intake is associated with an increased prevalence of Graves' disease). Graves' disease occurs in up to 2% of women but is one-tenth as frequent in men. The disorder rarely begins before adolescence and typically occurs between 20 and 50 years of age; it also occurs in the elderly.

Pathogenesis As in autoimmune hypothyroidism, a combination of environmental and genetic factors, including polymorphisms in HLA-DR, the immunoregulatory genes *CTLA-4*, *CD25*, *CD40*, *PTPN22*, *FCRL3*, and *CD226*, as well as the gene encoding the thyroid-stimulating hormone (TSH) receptor (TSH-R), contributes to Graves' disease susceptibility. The concordance for Graves' disease in monozygotic twins is 20–30%, compared to <5% in dizygotic twins. Indirect evidence suggests that stress is an important environmental factor, presumably operating through neuroendocrine effects on the immune system. Smoking is a moderate risk factor for Graves' disease and a major risk factor for the development of ophthalmopathy. Sudden increases in iodine intake may precipitate Graves' disease, and there is

TABLE 396-1 Causes of Thyrotoxicosis

Primary Hyperthyroidism
Graves' disease
Toxic multinodular goiter
Toxic adenoma
Functioning thyroid carcinoma metastases
Activating mutation of the TSH receptor
Activating mutation of $G_s\alpha$ (McCune-Albright syndrome)
Struma ovarii
Drugs: iodine excess (Jod-Basedow phenomenon)
Thyrotoxicosis without Hyperthyroidism
Subacute thyroiditis
Silent thyroiditis
Other causes of thyroid destruction: drugs (amiodarone, cytokines, tyrosine kinase inhibitors, immune checkpoint inhibitors), radiation, infarction of adenoma
Ingestion of excess thyroid hormone (thyrotoxicosis factitia) or thyroid tissue
Secondary Hyperthyroidism
TSH-secreting pituitary adenoma
Thyroid hormone resistance syndrome: occasional patients may have features of thyrotoxicosis
Chorionic gonadotropin-secreting tumors[a]
Gestational thyrotoxicosis[a]

[a]Circulating TSH levels are low in these forms of secondary hyperthyroidism.

Abbreviation: TSH, thyroid-stimulating hormone.

TABLE 396-2 Signs and Symptoms of Thyrotoxicosis (Descending Order of Frequency)

SYMPTOMS	SIGNS[a]
Hyperactivity, irritability, dysphoria	Tachycardia; atrial fibrillation in the elderly
Heat intolerance and sweating	Tremor
Palpitations	Goiter
Fatigue and weakness	Warm, moist skin
Weight loss with increased appetite	Muscle weakness, proximal myopathy
Diarrhea	Lid retraction or lag
Polyuria	Gynecomastia
Oligomenorrhea, loss of libido	

[a]Excludes the signs of ophthalmopathy and dermopathy specific for Graves' disease.

a threefold increase in the occurrence of Graves' disease in the postpartum period. Graves' disease may occur during the immune reconstitution phase after highly active antiretroviral therapy (HAART) or alemtuzumab treatment and following treatment with immune checkpoint inhibitors (e.g., nivolumab, pembrolizumab).

The hyperthyroidism of Graves' disease is caused by thyroid-stimulating immunoglobulins (TSIs) that are synthesized by lymphocytes in the thyroid gland as well as in bone marrow and lymph nodes. Such antibodies can be detected by bioassays or by using the more widely available immunoassays (TSH receptor antibodies [TRAb]) that measure whether the patient's serum contains an antibody that can displace either labeled TSH or a monoclonal TSH receptor antibody from the TSH receptor. The presence of TRAb in a patient with thyrotoxicosis implies the existence of TSI, and these assays are useful in monitoring pregnant Graves' patients in whom high levels of TSI can cross the placenta and cause neonatal thyrotoxicosis. Other thyroid autoimmune responses, similar to those in autoimmune hypothyroidism (see above), occur concurrently in patients with Graves' disease. In particular, thyroid peroxidase (TPO) and thyroglobulin (Tg) antibodies occur in up to 80% of cases. Because the coexisting lymphocytic thyroiditis can also affect thyroid function, there is no direct correlation between the level of TSI and thyroid hormone levels in Graves' disease.

Cytokines appear to play a major role in thyroid-associated ophthalmopathy. There is infiltration of the extraocular muscles by activated T cells; the release of cytokines such as interferon γ (IFN-γ), tumor necrosis factor (TNF), and interleukin 1 (IL-1) results in fibroblast activation and increased synthesis of glycosaminoglycans that trap water, thereby leading to characteristic muscle swelling. Late in the disease, there is irreversible fibrosis of the muscles. Increased fat is an additional cause of retrobulbar tissue expansion. The increase in intraorbital pressure can lead to proptosis, diplopia, and optic neuropathy. Although the pathogenesis of thyroid-associated ophthalmopathy is incompletely understood, the TSH-R is a thyroid autoantigen and is expressed in orbital tissues. In addition, aberrant signaling via insulin-like growth factor 1 receptors (IGF-1R) on orbital fibroblasts has also been implicated. These mechanisms are the basis for new monoclonal antibody treatments (e.g., teprotumumab) that reduce the levels of TSH-R/IGF-1R complexes and attenuate signaling.

Clinical Manifestations Signs and symptoms include features that are common to any cause of thyrotoxicosis (Table 396-2) as well as those specific for Graves' disease. The clinical presentation depends on the severity of thyrotoxicosis, the duration of disease, individual susceptibility to excess thyroid hormone, and the patient's age. In the elderly, features of thyrotoxicosis may be subtle or masked, and patients may present mainly with fatigue and weight loss, a condition known as *apathetic thyrotoxicosis*.

Thyrotoxicosis may cause unexplained weight loss, despite an enhanced appetite, due to the increased metabolic rate. Weight gain occurs in 5% of patients, however, because of increased food intake. Other prominent features include hyperactivity, nervousness, and irritability, ultimately leading to a sense of easy fatigability in some patients. Insomnia and impaired concentration are common; apathetic thyrotoxicosis may be mistaken for depression in the elderly. Fine tremor is a frequent finding, best elicited by having patients stretch out their fingers while feeling the fingertips with the palm. Common neurologic manifestations include hyperreflexia, muscle wasting, and proximal myopathy without fasciculation. Chorea is rare. Thyrotoxicosis is sometimes associated with a form of hypokalemic periodic paralysis; this disorder is particularly common in Asian males with thyrotoxicosis, but it occurs in other ethnic groups as well.

The most common cardiovascular manifestation is sinus tachycardia, often associated with palpitations, occasionally caused by supraventricular tachycardia. The high cardiac output produces a bounding pulse, widened pulse pressure, and an aortic systolic murmur and can lead to worsening of angina or heart failure in the elderly or those with preexisting heart disease. Atrial fibrillation is more common in patients >50 years of age. Treatment of the thyrotoxic state alone converts atrial fibrillation to normal sinus rhythm in up to 75% of patients without an underlying cardiac problem.

The skin is usually warm and moist, and the patient may complain of sweating and heat intolerance, particularly during warm weather. Palmar erythema, onycholysis, and, less commonly, pruritus, urticaria, and diffuse hyperpigmentation may be evident. Hair texture may become fine, and diffuse alopecia occurs in up to 40% of patients, persisting for months after restoration of euthyroidism. Gastrointestinal transit time is decreased, leading to increased stool frequency, often with diarrhea and occasionally mild steatorrhea. Women frequently experience oligomenorrhea or amenorrhea; in men, there may be impaired sexual function and, rarely, gynecomastia. The direct effect of thyroid hormones on bone resorption leads to osteopenia in long-standing thyrotoxicosis; mild hypercalcemia occurs in up to 20% of patients, but hypercalciuria is more common. There is a small increase in fracture rate in patients with a previous history of thyrotoxicosis.

In Graves' disease, the thyroid is usually diffusely enlarged to two to three times its normal size. The consistency is firm, but not nodular. There may be a thrill or bruit, best detected at the inferolateral margins of the thyroid lobes, due to the increased vascularity of the gland and the hyperdynamic circulation.

Lid retraction, causing a staring appearance, can occur in any form of thyrotoxicosis and is the result of sympathetic overactivity. However, Graves' disease is associated with specific eye signs that comprise *Graves' ophthalmopathy* (Fig. 396-1*A*). This condition is also called *thyroid eye disease* (TED) because it occurs in the absence

FIGURE 396-1 Features of Graves' disease. ***A.*** Ophthalmopathy in Graves' disease; lid retraction, periorbital edema, conjunctival injection, and proptosis are marked. ***B.*** Thyroid dermopathy over the lateral aspects of the shins. ***C.*** Thyroid acropachy.

of hyperthyroidism in 10% of patients. Most of these individuals have autoimmune hypothyroidism or thyroid antibodies. The onset of Graves' ophthalmopathy occurs within the year before or after the diagnosis of thyrotoxicosis in 75% of patients but can sometimes precede or follow thyrotoxicosis by several years, accounting for some cases of euthyroid ophthalmopathy.

About one-third of patients with Graves' disease have clinical evidence of ophthalmopathy. However, the enlarged extraocular muscles typical of the disease, and other subtle features, can be detected in most patients when investigated by ultrasound or computed tomography (CT) imaging of the orbits. Unilateral signs are found in up to 10% of ophthalmopathy patients. The earliest manifestations of ophthalmopathy are usually a sensation of grittiness, eye discomfort, and excess tearing. About one-third of patients have proptosis, best detected by visualization of the sclera between the lower border of the iris and the lower eyelid, with the eyes in the primary position. Proptosis can be measured using an exophthalmometer. In severe cases, proptosis may cause corneal exposure and damage, especially if the lids fail to close during sleep. Periorbital edema, scleral injection, and chemosis are also frequent. In 5–10% of patients, the muscle swelling is so severe that diplopia results, typically, but not exclusively, when the patient looks up and laterally. The most serious manifestation is compression of the optic nerve at the apex of the orbit, leading to papilledema; peripheral field defects; and, if left untreated, permanent loss of vision.

The "NO SPECS" scoring system to evaluate ophthalmopathy is an acronym derived from the following changes:

0 = **N**o signs or symptoms
1 = **O**nly signs (lid retraction or lag), no symptoms
2 = **S**oft tissue involvement (periorbital edema)
3 = **P**roptosis (>22 mm)
4 = **E**xtraocular muscle involvement (diplopia)
5 = **C**orneal involvement
6 = **S**ight loss

Although useful as a mnemonic, the NO SPECS scheme is inadequate to describe the eye disease fully, and patients do not necessarily progress from one class to another; alternative scoring systems (e.g., the EUGOGO system developed by the European Group on Graves' Orbitopathy) that assess disease activity are preferable for monitoring and treatment purposes. When Graves' eye disease is active and moderate to severe, evaluation and management with an ophthalmologist is indicated, and objective measurements are needed, such as lid-fissure width; corneal staining with fluorescein; evaluation of extraocular muscle function (e.g., Hess chart), intraocular pressure and visual fields, acuity, and color vision; and orbital imaging with CT or magnetic resonance imaging (MRI).

Thyroid dermopathy occurs in <5% of patients with Graves' disease **(Fig. 396-1*B*)**, almost always in the presence of moderate or severe ophthalmopathy. Although most frequent over the anterior and lateral aspects of the lower leg (hence the term *pretibial myxedema*), skin changes can occur at other sites, particularly after trauma. The typical lesion is a noninflamed, indurated plaque with a deep pink or purple color and an "orange skin" appearance. Nodular involvement can occur, and the condition can rarely extend over the whole lower leg and foot, mimicking elephantiasis. *Thyroid acropachy* refers to a form of clubbing found in <1% of patients with Graves' disease **(Fig. 396-1*C*)**. It is so strongly associated with thyroid dermopathy that an alternative cause of clubbing should be sought in a Graves' patient without coincident skin and orbital involvement. Ophthalmopathy, dermopathy, and acropachy have declined in incidence, probably due to better recognition and prompt treatment of the underlying thyroid disease.

Laboratory Evaluation Investigations used to determine the existence and cause of thyrotoxicosis are summarized in **Fig. 396-2**. In Graves' disease, the TSH level is suppressed, and total and unbound thyroid hormone levels are increased. In 2–5% of patients (and more in areas of borderline iodine intake), only T_3 is increased (T_3 toxicosis). The converse state of T_4 toxicosis, with elevated total and unbound T_4 and normal T_3 levels, is occasionally seen when hyperthyroidism is induced by excess iodine, providing surplus substrate for thyroid hormone synthesis. Measurement of TRAb is also useful. Associated abnormalities that may cause diagnostic confusion in thyrotoxicosis include elevation of bilirubin, liver enzymes, and ferritin. Microcytic anemia and thrombocytopenia may occur.

Differential Diagnosis Diagnosis of Graves' disease is straightforward in a patient with biochemically confirmed thyrotoxicosis, diffuse goiter on palpation, ophthalmopathy, and often a personal or family history of autoimmune disorders. TRAb measurement is usually used to confirm the diagnosis of Graves' disease in patients with thyrotoxicosis who lack these features, but the diagnosis can also be established by a radionuclide (^{99m}Tc, ^{123}I, or ^{131}I) scan and uptake of the thyroid, which will distinguish the diffuse, high uptake of Graves' disease from destructive thyroiditis, ectopic thyroid tissue, and factitious thyrotoxicosis, as well as diagnose a toxic adenoma or toxic MNG. Alternatively, color-flow Doppler ultrasonography distinguishes between hyperthyroidism (with increased blood flow) and destructive thyroiditis and avoids using radioactivity. In secondary hyperthyroidism due to a TSH-secreting pituitary tumor, there is also a diffuse goiter. The presence of a nonsuppressed TSH level and the finding of a pituitary tumor on CT or MRI scan suggest this diagnosis.

Clinical features of thyrotoxicosis can mimic certain aspects of other disorders, including panic attacks, mania, pheochromocytoma, and weight loss associated with malignancy. The diagnosis of thyrotoxicosis can be easily excluded if the TSH and unbound T_4 and T_3 levels are normal. A normal TSH also excludes Graves' disease as a cause of diffuse goiter.

Clinical Course Clinical features generally worsen without treatment; mortality was 10–30% before the introduction of satisfactory therapy. Some patients with mild Graves' disease experience spontaneous relapses and remissions. Rarely, there may be fluctuation between hypo- and hyperthyroidism due to changes in the functional activity of TSH-R antibodies. About 15% of patients who enter remission after treatment develop hypothyroidism 10–15 years later because of the destructive autoimmune process.

The clinical course of ophthalmopathy does not follow that of the thyroid disease, although thyroid dysfunction can worsen eye signs. Ophthalmopathy typically worsens over the initial 3–6 months, followed by a plateau phase over the next 12–18 months, and then some

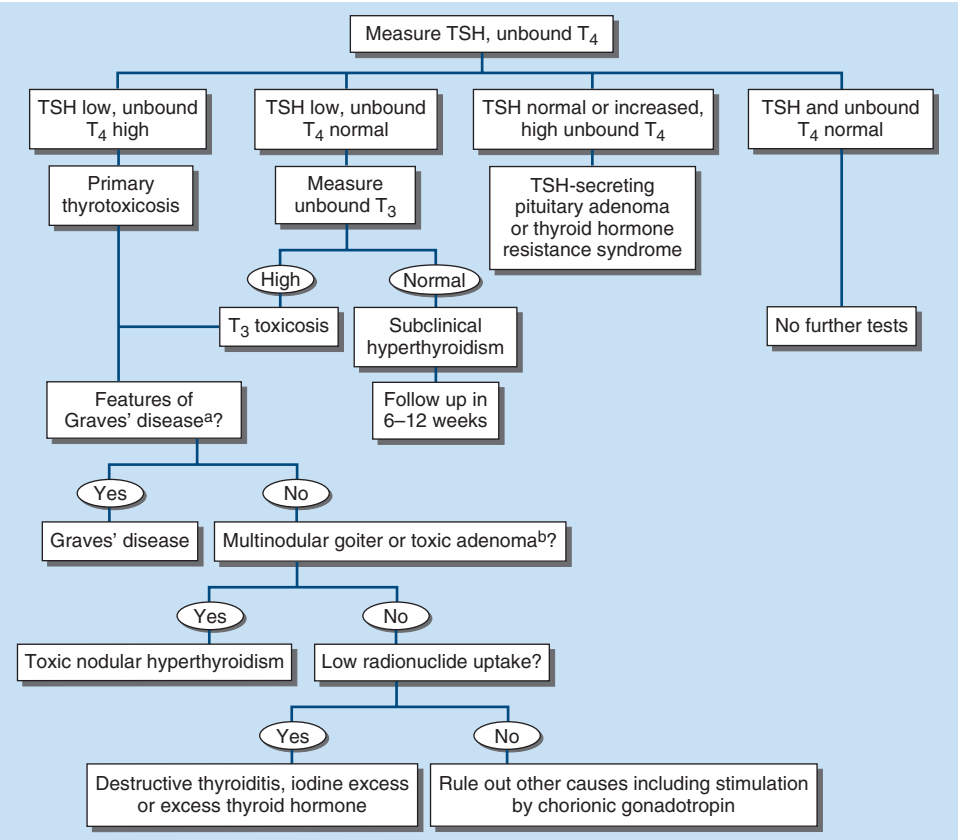

FIGURE 396-2 Evaluation of thyrotoxicosis. [a]Diffuse goiter, positive thyroid peroxidase (TPO) antibodies or thyroid-stimulating hormone (TSH) receptor antibody (TRAb), ophthalmopathy, dermopathy. [b]Can be confirmed by radionuclide scan.

spontaneous improvement, particularly in the soft tissue changes. However, the course is more fulminant in up to 5% of patients, requiring intervention in the acute phase if there is optic nerve compression or corneal ulceration. Diplopia may appear late in the disease due to fibrosis of the extraocular muscles. Radioiodine treatment for hyperthyroidism worsens the eye disease in a small proportion of patients (especially smokers). Antithyroid drugs and surgery have no adverse effects on the clinical course of ophthalmopathy. Thyroid dermopathy, when it occurs, usually appears 1–2 years after the development of Graves' hyperthyroidism; it may improve spontaneously.

TREATMENT

Graves' Disease

The *hyperthyroidism* of Graves' disease is treated by reducing thyroid hormone synthesis, using an antithyroid drug, or reducing the amount of thyroid tissue with radioiodine (^{131}I) treatment or by thyroidectomy. Antithyroid drugs are the predominant initial therapy in many centers in Europe, Latin America, and Japan, whereas radioiodine is more often the first line of treatment in North America. These differences reflect the fact that no single approach is optimal and that patients may require multiple treatments to achieve remission.

The main *antithyroid drugs* are thionamides: propylthiouracil, carbimazole (not available in the United States), and the active metabolite of the latter, methimazole. All inhibit the function of TPO, reducing oxidation and organification of iodide. These drugs also reduce thyroid antibody levels by mechanisms that remain unclear, and they appear to enhance spontaneous rates of remission. Propylthiouracil inhibits deiodination of $T_4 \rightarrow T_3$. However, this effect is of minor benefit, except in the most severe thyrotoxicosis, and is offset by the much shorter half-life of this drug (90 min) compared to methimazole (6 h). Due to the hepatotoxicity of propylthiouracil, the U.S. Food and Drug Administration (FDA) has limited indications for its use to the first trimester of pregnancy, the treatment of thyroid storm, and patients with minor adverse reactions to methimazole. If propylthiouracil is used, monitoring of liver function tests is recommended.

There are many variations of antithyroid drug regimens. The initial dose of carbimazole or methimazole is usually 10–20 mg every 12 h, but once-daily dosing is possible after euthyroidism is restored. Propylthiouracil is given at a dose of 100–200 mg every 6–8 h, and divided doses are usually given throughout the course. Lower doses of each drug may suffice in areas of low iodine intake. The starting dose of an antithyroid drug can be gradually reduced (titration regimen) as thyrotoxicosis improves. Less commonly, high doses may be given combined with levothyroxine (LT4) supplementation (block-replace regimen) to avoid drug-induced hypothyroidism. The titration regimen is often preferred to minimize the dose of antithyroid drug and provide an index of treatment response.

Thyroid function tests and clinical manifestations are reviewed 4–6 weeks after starting treatment, and the dose is titrated based on unbound T_4 levels. Most patients do not achieve euthyroidism until 6–8 weeks after treatment is initiated. TSH levels often remain suppressed for several months and therefore do not provide a sensitive index of treatment response. The usual daily maintenance doses of antithyroid drugs in the titration regimen are 2.5–10 mg of carbimazole or methimazole and 50–100 mg of propylthiouracil. In the block-replace regimen, the initial dose of antithyroid drug is held constant, and the dose of LT4 is adjusted to maintain normal unbound T_4 levels. When TSH suppression is alleviated, TSH levels can also be used to monitor therapy.

Maximum remission rates (30–60%) are achieved by 12–18 months for the titration regimen and are higher in patients in whom TRAb levels are no longer detected than in those with TRAb persistence. For unclear reasons, remission rates appear to vary in different geographic regions. Younger patients, males, smokers, and patients with a history of allergy, severe hyperthyroidism, or large goiters are most likely to relapse when treatment stops, as are those with enduring TRAb, but outcomes are difficult to predict. All patients

should be followed closely for relapse during the first year after treatment and at least annually thereafter. Prolonged treatment for up to 10 years with small doses of an antithyroid drug has been used as an alternative to ablative therapies following relapse.

The common minor side effects of antithyroid drugs are rash, urticaria, fever, and arthralgia (1–5% of patients). These may resolve spontaneously or after substituting an alternative antithyroid drug; rashes may respond to an antihistamine. Rare but major side effects include hepatitis (especially with propylthiouracil; avoid use in children) and cholestasis (methimazole and carbimazole); vasculitis; and, most important, agranulocytosis (<1%). It is essential that antithyroid drugs are stopped and not restarted if a patient develops major side effects. Written instructions should be provided regarding the symptoms of possible agranulocytosis (e.g., sore throat, fever, mouth ulcers) and the need to stop treatment pending an urgent complete blood count to confirm that agranulocytosis is not present. Management of agranulocytosis is described in **Chap. 107**. It is not useful to monitor blood counts prospectively, because the onset of agranulocytosis is idiosyncratic and abrupt.

Propranolol (20–40 mg every 6 h) or longer-acting selective β_1 receptor blockers such as atenolol may be helpful to control adrenergic symptoms, especially in the early stages before antithyroid drugs take effect. Beta blockers are also useful in patients with thyrotoxic periodic paralysis, pending correction of thyrotoxicosis. In consultation with a cardiologist or using a risk score like CHA_2DS_2-VASc, anticoagulation should be considered in all patients with atrial fibrillation; the majority revert spontaneously to sinus rhythm with control of hyperthyroidism, and long-term anticoagulation is not usually needed. Decreased warfarin doses are required when patients are thyrotoxic. If digoxin is used, increased doses are often needed in the thyrotoxic state.

Radioiodine causes progressive destruction of thyroid cells and can be used as initial treatment or for relapses after a trial of antithyroid drugs. There is a small risk of thyrotoxic crisis (see below) after radioiodine, which can be minimized by pretreatment with antithyroid drugs for at least a month before treatment. Antecedent treatment with an antithyroid drug and a beta blocker should be considered for all elderly patients or for those with cardiac problems. Carbimazole or methimazole must be stopped 2–3 days before radioiodine administration to achieve optimum iodine uptake and can be restarted 3–7 days after radioiodine in those at risk of complications from worsening thyrotoxicosis. Propylthiouracil appears to have a prolonged radioprotective effect and should be stopped for a longer period before radioiodine is given, or a larger dose of radioiodine will be necessary.

Efforts to calculate an optimal dose of radioiodine that achieves euthyroidism without a high incidence of relapse or progression to hypothyroidism have not been successful. Some patients inevitably relapse after a single dose because the biologic effects of radiation vary between individuals, and hypothyroidism cannot be uniformly avoided even using accurate dosimetry. A practical strategy is to give a fixed dose based on clinical features, such as the severity of thyrotoxicosis, the size of the goiter (larger goiters need a higher dosage) and the radioiodine uptake (higher uptake decreases the dosage needed). ^{131}I dosage generally ranges between 370 MBq (10 mCi) and 555 MBq (15 mCi). Most authorities favor an approach aimed at thyroid ablation (as opposed to euthyroidism), given that LT4 replacement is straightforward and most patients ultimately progress to hypothyroidism over 5–10 years.

Certain radiation safety precautions are necessary in the first few days after radioiodine treatment, but the exact guidelines vary depending on local protocols. In general, patients need to avoid close, prolonged contact with children and pregnant women for 5–7 days because of possible transmission of residual isotope and exposure to radiation emanating from the gland. Rarely, there may be mild pain due to radiation thyroiditis 1–2 weeks after treatment. Hyperthyroidism can persist for 2–3 months before radioiodine takes full effect. For this reason, β-adrenergic blockers or antithyroid drugs, which can be restarted 5–7 days after radioiodine administration, can be used to control symptoms during this interval. Persistent hyperthyroidism can be treated with a second dose of radioiodine, usually 6 months after the first dose. The risk of hypothyroidism after radioiodine depends on the dosage but is at least 10–20% in the first year and 5% per year thereafter and 5% per year thereafter, with higher rates after ablative treatment. Patients should be informed of this possibility before treatment and require close follow-up during the first year followed by annual thyroid function testing.

Pregnancy and breast-feeding are absolute contraindications to radioiodine treatment, but patients can conceive safely 6 months after treatment. The presence of ophthalmopathy, especially in smokers, requires caution. Prednisone, 0.2–0.5 mg/kg per d (depending on ophthalmopathy severity), at the time of radioiodine treatment, tapered over 6–12 weeks, may prevent exacerbation of ophthalmopathy, but radioiodine should generally be avoided in patients with active moderate-to-severe eye disease. Although many physicians avoid radioiodine in children and adolescents because of the potential risks of malignancy, others have advocated radioiodine use in older children. There is no overall increase in cancer risk after radioiodine. Patients may be advised that the risks are small enough to be indistinguishable from antithyroid drugs or surgery.

Total or near-total thyroidectomy is an option for patients who relapse after antithyroid drugs and prefer this treatment to radioiodine. Some experts recommend surgery in young individuals, particularly when the goiter is very large. Careful control of thyrotoxicosis with antithyroid drugs, followed by potassium iodide (SSKI; 1–2 drops orally tid for 10 days), is needed prior to surgery to avoid thyrotoxic crisis and to reduce the vascularity of the gland. The major complications of surgery—bleeding, laryngeal edema, hypoparathyroidism, and damage to the recurrent laryngeal nerves—are unusual when the procedure is performed by highly experienced surgeons. Recurrence rates in the best series are <2%, but the rate of hypothyroidism is similar to that following radioiodine treatment, especially with the current trend away from subtotal thyroidectomy.

Antithyroid drugs should be used to manage active Graves' disease in *pregnancy.* Because transplacental passage of these drugs may produce fetal hypothyroidism and goiter if the maternal dose is excessive, maternal antithyroid dose titration should target serum free or total T_4 levels at or just above the pregnancy reference range. If available, propylthiouracil should be used until 14–16 weeks' gestation because of the risk of rare cases of methimazole/carbimazole embryopathy, including *aplasia cutis* and other defects, such as choanal atresia and tracheoesophageal fistulae. Because of the potential for teratogenic effects, antithyroid medication should be discontinued in any newly pregnant woman with Graves' disease who is euthyroid on a low dose of methimazole (<5–10 mg/d) or propylthiouracil (<100–200 mg/d), after evaluating recent thyroid function tests, disease history, goiter size, duration of therapy, and TRAb measurement. Following cessation, careful monitoring of maternal thyroid function tests is essential. On the other hand, for women at high risk of developing thyrotoxicosis if antithyroid drugs are discontinued (large goiter, requirement for higher antithyroid drug dosage, elevated TRAb), continued therapy is necessary, with propylthiouracil (if available) administration in the first trimester. Because of its rare association with hepatotoxicity, propylthiouracil should be limited to the first trimester and then maternal therapy should be converted to methimazole (or carbimazole) at a ratio of 15–20 mg of propylthiouracil to 1 mg of methimazole. It is often possible to stop treatment in the last trimester because TSI tend to decline in pregnancy. Nonetheless, the transplacental transfer of these antibodies, if present, at levels three times higher than the normative range may rarely cause *fetal* or *neonatal thyrotoxicosis*. Poor intrauterine growth, a fetal heart rate of >160 beats/min, advanced bone age, fetal goiter, and high levels of maternal TSI after 26 weeks' gestation may herald this complication. Antithyroid drugs given to the mother can be used to treat the fetus and may be needed for 1–3 months after delivery, until the maternal antibodies

disappear from the baby's circulation. The postpartum period is a time of major risk for relapse of Graves' disease. Breast-feeding is safe with low doses of antithyroid drugs. Graves' disease in *children* is usually managed initially with methimazole or carbimazole (avoid propylthiouracil), often given as a course of the titration regimen for at least 3 years. Surgery or radioiodine may be indicated for severe or relapsing disease.

Thyrotoxic crisis, or *thyroid storm*, is rare and presents as a life-threatening exacerbation of hyperthyroidism, accompanied by fever, delirium, seizures, coma, vomiting, diarrhea, and jaundice. The mortality rate due to cardiac failure, arrhythmia, or hyperthermia is high (4–17%) even with treatment. Thyrotoxic crisis is usually precipitated by acute illness (e.g., stroke, infection, trauma, diabetic ketoacidosis), surgery (especially on the thyroid), or radioiodine treatment of a patient with partially treated or untreated hyperthyroidism. Management requires intensive monitoring and supportive care, identification and treatment of the precipitating cause, and measures that reduce thyroid hormone synthesis. Large doses of propylthiouracil (500–1000 mg loading dose and 250 mg every 4 h) should be given orally or by nasogastric tube or per rectum; the drug's inhibitory action on $T_4 \rightarrow T_3$ conversion makes it the antithyroid drug of choice. If not available, methimazole can be used in doses of 20 mg every 6 h. One hour after the first dose of propylthiouracil or methimazole, stable iodide (5 drops SSKI every 6 h) is given to block thyroid hormone synthesis via the Wolff-Chaikoff effect (the delay allows the antithyroid drug to prevent the excess iodine from being incorporated into new hormone). Propranolol should also be given to reduce tachycardia and other adrenergic manifestations (60–80 mg PO every 4 h, or 2 mg IV every 4 h). Although other β-adrenergic blockers can be used, high doses of propranolol decrease $T_4 \rightarrow T_3$ conversion, and the doses can be easily adjusted. Caution is needed to avoid acute negative inotropic effects, but controlling the heart rate is important, as some patients develop a form of high-output heart failure. Short-acting IV esmolol can be used to decrease heart rate while monitoring for signs of heart failure. Additional therapeutic measures include glucocorticoids (e.g., hydrocortisone 300 mg IV bolus, then 100 mg every 8 h), antibiotics if infection is present, cholestyramine to sequester thyroid hormones, cooling, oxygen, and IV fluids.

Mild ophthalmopathy requires no active treatment, because there is usually spontaneous improvement. General measures include meticulous control of thyroid hormone levels, cessation of smoking, and an explanation of the natural history of ophthalmopathy. Discomfort can be relieved with artificial tears (e.g., hypromellose 0.3% or carbomer 0.2% ophthalmic gel), paraffin-based eye ointment, and the use of dark glasses with side frames. Periorbital edema may respond to a more upright sleeping position or a diuretic. Corneal exposure during sleep can be avoided by using patches or taping the eyelids shut. Minor degrees of diplopia improve with prisms fitted to spectacles. Some authorities also advocate selenium 100 μg bid. *Moderate-to-severe ophthalmopathy,* in which the eye disease has sufficient impact on daily life to justify the risks of treatment, is usually treated with IV methylprednisolone (e.g., 500 mg of methylprednisolone once weekly for 6 weeks, then 250 mg once weekly for 6 weeks). This is preferable to oral glucocorticoids. A poor response at 6 weeks generally indicates the need for alternative treatment. Once the eye disease has stabilized, surgery may be indicated for relief of diplopia and correction of appearance. External beam radiotherapy of the orbits has been used for many years, but the efficacy of this therapy remains unclear, and it is best reserved for those who are not responsive to glucocorticoid therapy. Teprotumumab, a monoclonal antibody inhibitor of the IGF-1 receptor, improves proptosis, diplopia, clinical activity score, and quality of life and is recommended as first-line treatment in patients with active moderate-to-severe ophthalmopathy with significant proptosis or diplopia, but use may be limited by availability and cost. Relapse rates are similar to glucocorticoids (30%). Rituximab and tocilizumab are other monoclonal antibodies that have been used as second-line treatment after glucocorticoids. *Sight-threatening ophthalmopathy* due to optic nerve compression or corneal damage is an emergency that requires immediate high-dose IV glucocorticoids (e.g., methylprednisolone 500–1000 mg on alternate days). If there is a poor response after 2 weeks, surgical orbital decompression should be considered by removing bone from the medial and inferior orbital wall, thereby allowing displacement of fat and swollen extraocular muscles. In addition to nerve decompression, proptosis recedes an average of 5 mm, but there may be residual or even worsened diplopia.

Thyroid dermopathy does not usually require treatment, but it can cause cosmetic problems or interfere with the fit of shoes. Surgical removal is not indicated. If necessary, treatment consists of topical, high-potency glucocorticoid ointment under an occlusive dressing or compression dressing. Teprotumumab has been beneficial in some cases.

OTHER CAUSES OF THYROTOXICOSIS

Destructive thyroiditis (subacute or silent thyroiditis) typically presents with a short thyrotoxic phase due to the release of preformed thyroid hormones and catabolism of Tg (see "Subacute Thyroiditis," below). True hyperthyroidism is absent, as demonstrated by a low radionuclide uptake. Circulating Tg levels are typically increased. Other causes of thyrotoxicosis with low or absent thyroid radionuclide uptake include *thyrotoxicosis factitia*, iodine excess, and, rarely, ectopic thyroid tissue, particularly teratomas of the ovary (*struma ovarii*) and functional metastatic follicular carcinoma. Whole-body radionuclide studies can demonstrate ectopic thyroid tissue, and thyrotoxicosis factitia can be distinguished from destructive thyroiditis by the clinical features and low levels of Tg. Amiodarone treatment is associated with thyrotoxicosis in up to 10% of patients, particularly in areas of low iodine intake (see below).

TSH-secreting pituitary adenoma is a rare cause of thyrotoxicosis. It is characterized by the presence of an inappropriately normal or increased TSH level in a patient with hyperthyroidism, diffuse goiter, and elevated T_4 and T_3 levels **(Chap. 392)**. Elevated levels of the α subunit of TSH, released by the TSH-secreting adenoma, support this diagnosis, which can be confirmed by demonstrating the pituitary tumor on MRI or CT scan. A combination of transsphenoidal surgery, sella irradiation, and octreotide may be required to normalize TSH, because many of these tumors are large and locally invasive at the time of diagnosis. Radioiodine or antithyroid drugs can be used to control thyrotoxicosis.

Thyrotoxicosis caused by *toxic MNG* and *hyperfunctioning solitary nodules* is discussed below **(Chap. 396)**.

THYROIDITIS

There are several classification systems to describe the clinical syndromes of thyroiditis. One is based on the onset and duration of disease **(Table 396-3)**; others are based on the absence or presence of pain.

ACUTE THYROIDITIS

Acute thyroiditis is rare and due to suppurative infection of the thyroid. In children and young adults, the most common cause is the presence of a piriform sinus, a remnant of the fourth branchial pouch that connects the oropharynx with the thyroid. Such sinuses are predominantly left-sided. A long-standing goiter and degeneration in a thyroid malignancy are risk factors in the elderly. The patient presents with thyroid pain, often referred to the throat or ears, and a small, tender goiter that may be asymmetric. Fever, dysphagia, and erythema over the thyroid are common, as are systemic symptoms of a febrile illness and lymphadenopathy.

The differential diagnosis of *thyroid pain* includes subacute or, rarely, chronic thyroiditis; hemorrhage into a cyst; malignancy including lymphoma; and, rarely, amiodarone-induced thyroiditis or amyloidosis. However, the abrupt presentation and clinical features of acute thyroiditis rarely cause confusion. The erythrocyte sedimentation rate (ESR) and white cell count are usually increased, but thyroid function is generally normal. Fine-needle aspiration (FNA) biopsy shows infiltration by polymorphonuclear leukocytes; culture of the sample

TABLE 396-3 Causes of Thyroiditis

Acute
Bacterial infection: especially *Staphylococcus, Streptococcus,* and *Enterobacter*
Fungal infection: *Aspergillus, Candida, Coccidioides, Histoplasma,* and *Pneumocystis*
Radiation thyroiditis after ^{131}I treatment
Amiodarone (may also be subacute or chronic)
Subacute
Viral (or granulomatous) thyroiditis
Silent thyroiditis (including postpartum thyroiditis)
Mycobacterial infection
Drug-induced (interferon, amiodarone, tyrosine kinase inhibitors, immune checkpoint inhibitors)
Chronic
Autoimmunity: focal thyroiditis, Hashimoto's thyroiditis, atrophic thyroiditis
Riedel's thyroiditis
Parasitic thyroiditis: echinococcosis, strongyloidiasis, cysticercosis
Traumatic: after palpation

can identify the organism. Caution is needed in immunocompromised patients as fungal, mycobacterial, or *Pneumocystis* thyroiditis can occur in this setting. Antibiotic treatment is guided initially by Gram stain and, subsequently, by cultures of the FNA biopsy. Surgery may be needed to drain an abscess, which can be localized by CT scan or ultrasound. Tracheal obstruction, septicemia, retropharyngeal abscess, mediastinitis, and jugular venous thrombosis may complicate acute thyroiditis but are uncommon with prompt use of antibiotics.

SUBACUTE THYROIDITIS

This is also termed *de Quervain's thyroiditis*, *granulomatous thyroiditis*, or *viral thyroiditis*. Many viruses have been implicated, including mumps, coxsackie, influenza, adenoviruses, and echoviruses. Subacute thyroiditis may also occur with the SARS-CoV-2 illness or after receiving the COVID vaccine. The diagnosis may be overlooked because the symptoms can mimic pharyngitis. Attempts to identify the causative virus in an individual patient are often unsuccessful and do not influence management. The peak incidence occurs at 30–50 years, and women are affected three times more frequently than men.

Pathophysiology The thyroid shows a characteristic patchy inflammatory infiltrate with disruption of the thyroid follicles and multinucleated giant cells within some follicles. The follicular changes progress to granulomas accompanied by fibrosis. Finally, the thyroid returns to normal, usually several months after onset. During the initial phase of follicular destruction, there is release of Tg and thyroid hormones, leading to increased circulating T_4 and T_3 and suppression of TSH **(Fig. 396-3)**. During this destructive phase, radioactive iodine uptake is low or undetectable. After several weeks, the thyroid is depleted of stored thyroid hormone and a phase of hypothyroidism typically occurs, with low unbound T_4 (and sometimes T_3) and moderately increased TSH levels. Radioactive iodine uptake returns to normal or is even increased as a result of the rise in TSH. Finally, thyroid hormone and TSH levels return to normal as the disease subsides.

Clinical Manifestations The patient usually presents with a painful and enlarged thyroid, sometimes accompanied by fever. There may be features of thyrotoxicosis or hypothyroidism, depending on the phase of the illness. Malaise and symptoms of an upper respiratory tract infection may precede the thyroid-related features by several weeks. In other patients, the onset is acute, severe, and without obvious antecedent. The patient typically complains of a sore throat, and examination reveals a small goiter that is exquisitely tender. Pain is often referred to the jaw or ear. Complete resolution is the usual outcome, but late-onset permanent hypothyroidism occurs in 15% of cases, particularly in those with coincidental thyroid autoimmunity. A prolonged course over many months, with one or more relapses, occurs in a small percentage of patients.

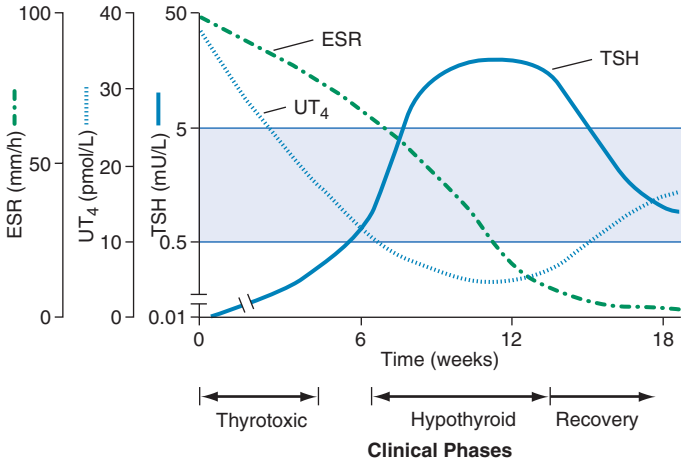

FIGURE 396-3 Clinical course of subacute thyroiditis. The release of thyroid hormones is initially associated with a thyrotoxic phase and suppressed thyroid-stimulating hormone (TSH). A hypothyroid phase then ensues, with low T_4 and TSH levels that are initially low but gradually increase. During the recovery phase, increased TSH levels combined with resolution of thyroid follicular injury lead to normalization of thyroid function, often several months after the beginning of the illness. ESR, erythrocyte sedimentation rate; UT_4, free or unbound T_4.

Laboratory Evaluation As depicted in Fig. 396-3, thyroid function tests characteristically evolve through three distinct phases over about 6 months: (1) thyrotoxic phase, (2) hypothyroid phase, and (3) recovery phase. In the thyrotoxic phase, T_4 and T_3 levels are increased, reflecting their discharge from the damaged thyroid cells, and TSH is suppressed. The T_4/T_3 ratio is lower than in Graves' or thyroid autonomy, in which T_3 is often disproportionately increased. The diagnosis is confirmed by a high ESR and low uptake of radioiodine (<5%) or ^{99m}Tc pertechnetate (as compared to salivary gland pertechnetate concentration). The white blood cell count may be increased, and thyroid antibodies are negative. If the diagnosis is in doubt, FNA biopsy may be useful, particularly to distinguish unilateral involvement from bleeding into a cyst or neoplasm.

TREATMENT

Subacute Thyroiditis

Relatively large doses of aspirin (e.g., 600 mg every 4–6 h) or nonsteroidal anti-inflammatory drugs (NSAIDs) are sufficient to control symptoms in many cases. Generally, gastroprotective medications, such as proton pump inhibitors, are also prescribed. If this treatment is inadequate, or if the patient has marked local or systemic symptoms, glucocorticoids should be given. The usual starting dose is 15–40 mg of prednisone, depending on severity. The dose is gradually tapered over 6–8 weeks, in response to improvement in symptoms and the ESR. If a relapse occurs during glucocorticoid withdrawal, the dosage should be increased and then withdrawn more gradually. Thyroid function should be monitored every 2–4 weeks using TSH and free T_4 levels. Symptoms of thyrotoxicosis improve spontaneously but may be ameliorated by β-adrenergic blockers; antithyroid drugs play no role in treatment of the thyrotoxic phase. LT4 replacement may be needed if the hypothyroid phase is prolonged, but doses should be low enough (50–100 μg daily) to allow TSH-mediated recovery.

SILENT THYROIDITIS

Painless thyroiditis, or "*silent*" *thyroiditis*, occurs in patients with underlying autoimmune thyroid disease and has a clinical course similar to that of subacute thyroiditis. The condition occurs in up to 5% of women 3–6 months after pregnancy and is then termed *postpartum thyroiditis*. Typically, patients have a brief phase of thyrotoxicosis lasting 2–4 weeks, followed by hypothyroidism for 4–12 weeks, and then resolution; often, however, only one phase is apparent. The condition is associated with the presence of TPO antibodies antepartum, and it is

three times more common in women with type 1 diabetes mellitus. As in subacute thyroiditis, the uptake of ^{99m}Tc pertechnetate or radioactive iodine is initially suppressed. In addition to the painless goiter, silent thyroiditis can be distinguished from subacute thyroiditis by a normal ESR and the presence of TPO antibodies. Glucocorticoid treatment is not indicated for silent thyroiditis. Severe thyrotoxic symptoms can be managed with a brief course of propranolol, 20–40 mg three or four times daily. Thyroxine replacement may be needed for the hypothyroid phase but should be withdrawn after 6–9 months, as recovery is the rule. Annual follow-up thereafter is recommended because a proportion of these individuals develop permanent hypothyroidism. The condition may recur in subsequent pregnancies.

DRUG-INDUCED THYROIDITIS

Patients receiving cytokines, such as IFN-α, tyrosine kinase inhibitors, such as sorafenib, and immune checkpoint inhibitors may develop painless thyroiditis. IFN-α, which is used to treat chronic hepatitis B or C and hematologic and skin malignancies, causes thyroid dysfunction in up to 5% of treated patients. It has been associated with painless thyroiditis, hypothyroidism, and Graves' disease and is most common in women with TPO antibodies prior to treatment. Thyroiditis occurs in 5–20% of cancer patients treated with the immune checkpoint inhibitors pembrolizumab or nivolumab. In all cases, treatment is the same as silent thyroiditis. Routine monitoring of thyroid function tests is recommended by the American Society of Clinical Oncology. For discussion of amiodarone, see "Amiodarone Effects on Thyroid Function," below.

CHRONIC THYROIDITIS

Focal thyroiditis is present in 20–40% of euthyroid autopsy cases and is associated with serologic evidence of autoimmunity, particularly the presence of TPO antibodies. The most common clinically apparent cause of chronic thyroiditis is *Hashimoto's thyroiditis*, an autoimmune disorder that often presents as a firm or hard goiter of variable size **(Chap. 395)**. *Riedel's thyroiditis* is a rare disorder that typically occurs in middle-aged women. It presents with an insidious, painless goiter with local symptoms due to compression of the esophagus, trachea, neck veins, or recurrent laryngeal nerves. Dense fibrosis disrupts normal gland architecture and can extend outside the thyroid capsule. Despite these extensive histologic changes, thyroid dysfunction is uncommon. The goiter is hard, nontender, often asymmetric, and fixed, leading to suspicion of a malignancy. Diagnosis requires open biopsy as FNA biopsy is usually inadequate. Treatment is with glucocorticoids, other immunomodulatory treatments, tamoxifen, or surgical relief of compressive symptoms. There is an association between Riedel's thyroiditis and IgG4-related disease causing idiopathic fibrosis at other sites (retroperitoneum, mediastinum, biliary tree, lung, and orbit) **(Chap. 380)**.

SICK EUTHYROID SYNDROME (NONTHYROIDAL ILLNESS)

Any acute, severe illness can cause abnormalities of circulating TSH or thyroid hormone levels in the absence of underlying thyroid disease, making these measurements potentially misleading. The major cause of these hormonal changes is the release of cytokines such as IL-6. Unless a thyroid disorder is strongly suspected, the routine testing of thyroid function should be avoided in acutely ill patients.

The most common hormone pattern in sick euthyroid syndrome (SES), also called nonthyroidal illness (NTI), is a decrease in total and unbound T_3 levels (low T_3 syndrome) with normal levels of T_4 and TSH. The magnitude of the fall in T_3 correlates with the severity of the illness. T_4 conversion to T_3 via peripheral 5′ (outer ring) deiodination is impaired, leading to increased reverse T_3 (rT_3). Since rT_3 is metabolized by 5′ deiodination, its clearance is also reduced. Thus, decreased clearance rather than increased production is the major basis for increased rT_3. Also, T_4 is alternately metabolized to the hormonally inactive T_3 sulfate. It is generally assumed that this low T_3 state is adaptive, because it can be induced in normal individuals by fasting. Teleologically, the fall in T_3 may limit catabolism in starved or ill patients.

Very sick patients may exhibit a dramatic fall in total T_4 and T_3 levels (low T_4 syndrome). With decreased tissue perfusion, muscle and liver expression of the type 3 deiodinase leads to accelerated T_4 and T_3 metabolism. This state has a poor prognosis. Another key factor in the fall in T_4 levels is altered binding to thyroxine-binding globulin (TBG). The commonly used free T_4 assays are subject to artifact when serum binding proteins are low and underestimate the true free T_4 level. Fluctuation in TSH levels also creates challenges in the interpretation of thyroid function in sick patients. TSH levels may range from 0.01 to 0.1 mIU/L in very ill patients, especially with dopamine or glucocorticoid therapy, to >20 mIU/L during the recovery phase of SES. The exact mechanisms underlying the subnormal TSH seen in 10% of sick patients and the increased TSH seen in 5% remain unclear but may be mediated by cytokines including IL-12 and IL-18. However, if the serum TSH is undetectable (<0.01 mIU/L), primary thyroid disease is more likely and endocrine evaluation should be done.

Any severe illness can induce changes in thyroid hormone levels, but certain disorders exhibit a distinctive pattern of abnormalities. Acute liver disease is associated with an initial rise in total (but not unbound) T_3 and T_4 levels due to TBG release; these levels become subnormal with progression to liver failure. A transient increase in total and unbound T_4 levels, usually with a normal T_3 level, is seen in 5–30% of acutely ill psychiatric patients. TSH values may be transiently low, normal, or high in these patients. In the early stage of HIV infection, T_3 and T_4 levels rise, even if there is weight loss. T_3 levels fall with progression to AIDS, but TSH usually remains normal. Renal disease is often accompanied by low T_3 concentrations, but with normal rather than increased rT_3 levels, due to an unknown factor that increases uptake of rT_3 into the liver.

The diagnosis of NTI is challenging. Historic information may be limited, and patients often have multiple metabolic derangements. Useful features to consider include previous history of thyroid disease and thyroid function tests, evaluation of the severity and time course of the patient's acute illness, documentation of medications that may affect thyroid function or thyroid hormone levels, and measurements of rT_3 together with unbound thyroid hormones and TSH. The diagnosis of NTI is frequently presumptive, given the clinical context and pattern of laboratory values; only resolution of the test results with clinical recovery can clearly establish this disorder. Treatment of NTI with thyroid hormone (T_4 and/or T_3) is controversial, but most authorities recommend monitoring the patient's thyroid function tests during recovery, without administering thyroid hormone, unless there is historic or clinical evidence suggestive of hypothyroidism. Sufficiently large randomized controlled trials using thyroid hormone are unlikely to resolve this therapeutic controversy in the near future, because clinical presentations and outcomes are highly variable.

AMIODARONE EFFECTS ON THYROID FUNCTION

Amiodarone is a commonly used type III antiarrhythmic agent **(Chap. 259)**. It is structurally related to thyroid hormone and contains 39% iodine by weight. Thus, typical doses of amiodarone (200 mg/d) are associated with very high iodine intake, leading to greater than 40-fold increases in plasma and urinary iodine levels. Moreover, because amiodarone is stored in adipose tissue, high iodine levels persist for >6 months after discontinuation of the drug. Amiodarone inhibits deiodinase activity, and its metabolites function as weak antagonists of thyroid hormone action. Amiodarone has the following effects on thyroid function: (1) acute, transient suppression of thyroid function; (2) inhibition of T_4 to T_3 conversion causing either euthyroid hyperthyroxinemia or increased dosage requirement in LT4-treated hypothyroid patients; (3) hypothyroidism in patients susceptible to the inhibitory effects of a high iodine load; and (4) thyrotoxicosis that may be caused by either a Jod-Basedow effect from the iodine load, in the setting of MNG or incipient Graves' disease, or a thyroiditis-like condition due to a toxic effect on thyroid follicular cells.

The initiation of amiodarone treatment is associated with a transient decrease of T_4 levels, reflecting the inhibitory effect of iodine on T_4 release. Soon thereafter, most individuals escape from iodide-dependent

suppression of the thyroid (Wolff-Chaikoff effect), and the inhibitory effects on deiodinase activity and thyroid hormone receptor action become predominant. These events lead to the following pattern of thyroid function tests: increased T_4, decreased T_3, increased rT_3, and a transient TSH increase (up to 20 mIU/L). TSH levels normalize or are slightly suppressed within 1–3 months.

The incidence of hypothyroidism from amiodarone varies geographically, apparently correlating with iodine intake. Hypothyroidism occurs in up to 13% of amiodarone-treated patients in iodine-replete countries, such as the United States, but is less common (<6% incidence) in areas of lower iodine intake, such as Italy or Spain. The pathogenesis appears to involve an inability of the thyroid gland to escape from the Wolff-Chaikoff effect in autoimmune thyroiditis. Consequently, amiodarone-associated hypothyroidism is more common in women and individuals with positive TPO antibodies. It is usually unnecessary to discontinue amiodarone for this side effect, because LT4 can be used to normalize thyroid function. TSH levels should be monitored, because T_4 levels are often increased for the reasons described above. In addition, TSH levels need to be monitored in LT4-replaced hypothyroid patients because a dosage increase is often required.

The management of amiodarone-induced thyrotoxicosis (AIT) is complicated by the fact that there are different causes of thyrotoxicosis and because the increased thyroid hormone levels exacerbate underlying arrhythmias and coronary artery disease. Amiodarone treatment causes thyrotoxicosis in 10% of patients living in areas of low iodine intake and in 2% of patients in regions of high iodine intake. There are two major forms of AIT, although some patients have features of both. Type 1 AIT is associated with an underlying thyroid abnormality (preclinical Graves' disease or nodular goiter). Thyroid hormone synthesis becomes excessive as a result of increased iodine exposure (Jod-Basedow phenomenon). Type 2 AIT occurs in individuals with no intrinsic thyroid abnormalities and is the result of drug-induced lysosomal activation leading to destructive thyroiditis with histiocyte accumulation in the thyroid; the incidence rises as cumulative amiodarone dosage increases. Mild forms of type 2 AIT can resolve spontaneously or can occasionally lead to hypothyroidism. Color-flow Doppler ultrasonography shows increased vascularity in type 1 AIT but decreased vascularity in type 2 AIT. Thyroid scintiscans are difficult to interpret in this setting because the high endogenous iodine levels diminish tracer uptake. However, the presence of normal or rarely increased uptake favors type 1 AIT.

In AIT, because of amiodarone's prolonged half-life and storage in adipose tissue, there is no immediate benefit from discontinuing the drug. Treatment studies have reported a similar time course for AIT type 2 resolution whether amiodarone was continued or stopped. Therefore, the decision to discontinue the drug should be based upon the severity of the arrhythmia. High doses of antithyroid drugs can be used in type 1 AIT but are often ineffective. Potassium perchlorate, 500 mg bid, has been used to reduce thyroidal iodide content. Perchlorate treatment has been associated with agranulocytosis, although the risk appears relatively low with short-term use. This drug is also no longer available in many countries. Glucocorticoids (initial dose usually 40–60 mg/d of prednisone) are effective in treating in type 2 AIT. Near-total thyroidectomy rapidly decreases thyroid hormone levels and may be the most effective long-term solution if the patient can undergo the procedure safely.

397 Thyroid Nodular Disease and Thyroid Cancer

Susan J. Mandel, Anthony P. Weetman, J. Larry Jameson

GOITER AND THYROID NODULAR DISEASE

Goiter refers to an enlarged thyroid gland. Biosynthetic defects, iodine deficiency, autoimmune disease, and nodular diseases can each lead to goiter, although by different mechanisms. Biosynthetic defects and iodine deficiency are associated with reduced efficiency of thyroid hormone synthesis, leading to increased thyroid-stimulating hormone (TSH), which stimulates thyroid growth as a compensatory mechanism to overcome the block in hormone synthesis. Graves' disease and Hashimoto's thyroiditis are also associated with goiter. In Graves' disease, the goiter results mainly from the TSH-R–mediated effects of thyroid-stimulating immunoglobulins. The goitrous form of Hashimoto's thyroiditis occurs because of acquired defects in hormone synthesis, leading to elevated levels of TSH and its consequent growth effects. Lymphocytic infiltration and immune system–induced growth factors also contribute to thyroid enlargement in Hashimoto's thyroiditis.

Thyroid nodular disease is characterized by the disordered growth of thyroid cells, which can be either hyperplastic or neoplastic. A patient may have a multinodular goiter (MNG) in which thyroid nodules (generally hyperplastic) replace the majority of the normal thyroid parenchyma; this presentation is more common in areas of borderline iodine deficiency. Or, the thyroid gland may be normal in size and contain discrete thyroid nodules. Because the management of goiter depends on the etiology, the detection of thyroid enlargement on physical examination should prompt further evaluation to identify its cause.

Nodular thyroid disease is common, occurring in about 3–7% of adults when assessed by physical examination. Using ultrasound, nodules are present in up to 50% of adults, with the majority being <1 cm in diameter. Thyroid nodules may be solitary or multiple, and they may be functional or nonfunctional.

DIFFUSE NONTOXIC (SIMPLE) GOITER

Etiology and Pathogenesis When diffuse enlargement of the thyroid occurs in the absence of nodules and hyperthyroidism, it is referred to as a *diffuse nontoxic goiter*. This is sometimes called *simple goiter* and is characterized by the presence of uniform follicles that are filled with colloid. Worldwide, diffuse goiter is most commonly caused by iodine deficiency and is termed *endemic goiter* when it affects >5% of the population. In nonendemic regions, *sporadic goiter* occurs, and the cause is usually unknown. Thyroid enlargement in teenagers is sometimes referred to as *juvenile goiter*. In general, goiter is more common in women than men, probably because of the greater prevalence of underlying autoimmune disease and the increased iodine demands associated with pregnancy.

In *iodine-deficient areas*, thyroid enlargement reflects a compensatory effort to trap iodide and produce sufficient hormone under conditions in which hormone synthesis is relatively inefficient. Somewhat surprisingly, TSH levels are usually normal or only slightly increased, suggesting increased sensitivity to TSH or activation of other pathways that lead to thyroid growth. Iodide appears to have direct actions on thyroid vasculature and may indirectly affect growth through vasoactive substances such as endothelins and nitric oxide. Endemic goiter may also be caused by exposure to environmental *goitrogens* such as cassava root, which contains a thiocyanate; vegetables of the Cruciferae family (known as cruciferous vegetables) (e.g., Brussels sprouts, cabbage, and cauliflower); and milk from regions where goitrogens are present in grass. Although relatively rare, inherited defects in thyroid hormone synthesis lead to a diffuse nontoxic goiter. Abnormalities at each step of hormone synthesis, including iodide transport (sodium/iodide symporter [NIS]), thyroglobulin (Tg) synthesis, organification and coupling (thyroid peroxidase [TPO]), and the regeneration of iodide (dehalogenase), have been described.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

If thyroid function is preserved, most goiters are asymptomatic. Examination of a diffuse goiter reveals a symmetrically enlarged, nontender, generally soft gland without palpable nodules. Goiter is defined, somewhat arbitrarily, as a lateral lobe with a volume greater than the thumb of the individual being examined. On ultrasound, total thyroid volume exceeding 30 mL is considered abnormal. If the thyroid is markedly enlarged, it can cause tracheal or esophageal compression. These features are unusual, however, in the absence of nodular disease and fibrosis. *Substernal goiter* may obstruct the thoracic inlet. *Pemberton's sign* refers to facial and neck congestion due to jugular venous obstruction when the arms are raised above the head, a maneuver that draws the thyroid into the thoracic inlet. Respiratory flow measurements and computed tomography (CT) or magnetic resonance imaging (MRI) should be used to evaluate substernal goiter in patients with obstructive signs or symptoms.

Thyroid function tests should be performed in all patients with goiter to exclude thyrotoxicosis or hypothyroidism. It is not unusual, particularly in iodine deficiency, to find a low total T_4, with normal T_3 and TSH, reflecting enhanced $T_4 \rightarrow T_3$ conversion, as well as preferential T_3 production. A low TSH with a normal free T_3 and free T_4, particularly in older patients, suggests the possibility of thyroid autonomy or undiagnosed Graves' disease, and is termed *subclinical thyrotoxicosis*. The benefit of treatment (typically with radioiodine) in subclinical thyrotoxicosis, versus follow-up and implementing treatment if free T_3 or free T_4 levels become abnormal, is unclear, but treatment is increasingly recommended in the elderly to reduce the risk of atrial fibrillation and bone loss. Low urinary iodine levels (<50 μg/L) support a diagnosis of iodine deficiency. Thyroid scanning is not generally necessary for euthyroid patients. If preformed, scintigraphy demonstrates increased uptake in iodine deficiency and most cases of dyshormonogenesis.

TREATMENT

Diffuse Nontoxic (Simple) Goiter

Iodine replacement induces variable regression of goiter in iodine deficiency, depending on duration and the degree of hyperplasia, with accompanying fibrosis, and autonomous function that may have developed. Surgery is rarely indicated for diffuse goiter. Exceptions include documented evidence of tracheal compression or obstruction of the thoracic inlet, which are more likely to be associated with substernal MNGs (see below). Subtotal or near-total thyroidectomy for these or cosmetic reasons should be performed by an experienced surgeon to minimize complication rates. Surgery should be followed by replacement with levothyroxine (LT4).

NONTOXIC MULTINODULAR GOITER

Etiology and Pathogenesis Depending on the population studied, MNG or the presence of nodules in a thyroid of normal size occurs in up to 12% of adults. MNG should be distinguished from the presence of nodules in a normal-size thyroid gland (see "Approach to the Patient with Thyroid Nodules"). MNG is more common in women than men and increases in prevalence with age. It is more common in iodine-deficient regions but also occurs in regions of iodine sufficiency, reflecting multiple genetic, autoimmune, and environmental influences on the pathogenesis.

There is typically wide variation in nodule size. Histology reveals a spectrum of morphologies ranging from hypercellular, hyperplastic regions to cystic areas filled with colloid. Fibrosis is often extensive, and areas of hemorrhage or lymphocytic infiltration may be seen. Using molecular techniques, most nodules within an MNG are polyclonal in origin, suggesting a hyperplastic response to locally produced growth factors and cytokines. TSH, which is usually not elevated, may play a permissive or contributory role. Monoclonal neoplastic lesions may also occur, reflecting mutations in genes that confer a selective growth advantage to the progenitor cell.

Clinical Manifestations Most patients with nontoxic MNG are asymptomatic and euthyroid. MNG typically develops over many years and is detected on routine physical examination, when an individual notices an enlargement in the neck, or as an incidental finding on imaging. If the goiter is large enough, it can ultimately lead to compressive symptoms including difficulty swallowing, respiratory distress (tracheal compression), or plethora (venous congestion), but these symptoms are uncommon. Symptomatic MNGs are usually large and/or develop fibrotic areas that cause compression. Sudden pain in an MNG is usually caused by hemorrhage into a nodule. Hoarseness, reflecting laryngeal nerve involvement, may suggest malignancy but more commonly is due to others causes such as gastroesophageal reflux.

Diagnosis On examination, thyroid architecture is distorted, and multiple nodules of varying size can be appreciated. Because many nodules are deeply embedded in thyroid tissue or reside in posterior or substernal locations, it is not possible to palpate all nodules. Pemberton's sign, characterized by facial suffusion when the patient's arms are elevated above the head, suggests that the goiter has increased pressure in the thoracic inlet. A TSH level should be measured to exclude subclinical hyper- or hypothyroidism, but thyroid function is usually normal. Tracheal deviation is common, but compression must usually exceed 70% of the tracheal diameter before there is significant airway compromise. Pulmonary function testing can be used to assess the functional effects of compression, which characteristically causes inspiratory stridor. CT or MRI can be used to evaluate the anatomy of the goiter and the extent of substernal extension or tracheal narrowing. A barium swallow may reveal the extent of esophageal compression. The risk of malignancy in MNG is similar to that in solitary nodules. Ultrasonography should be used to identify which nodules should be biopsied based on a combination of size and sonographic pattern **(Fig. 397-1) (Chap. 394)**. For nodules with more suspicious sonographic patterns (e.g., hypoechoic solid nodules with irregular borders), biopsy is recommended at a lower size cutoff than those with less suspicious imaging features (**Figs.** 397-1 and **397-2**).

TREATMENT

Nontoxic Multinodular Goiter

Most nontoxic MNGs can be managed conservatively. T_4 suppression is rarely effective for reducing goiter size and introduces the risk of subclinical or overt thyrotoxicosis, particularly if there is underlying autonomy or if it develops during treatment. Contrast agents and other iodine-containing substances should be avoided because of the risk of inducing the *Jod-Basedow effect*, characterized by enhanced thyroid hormone production by autonomous nodules. Radioiodine has been used when surgery

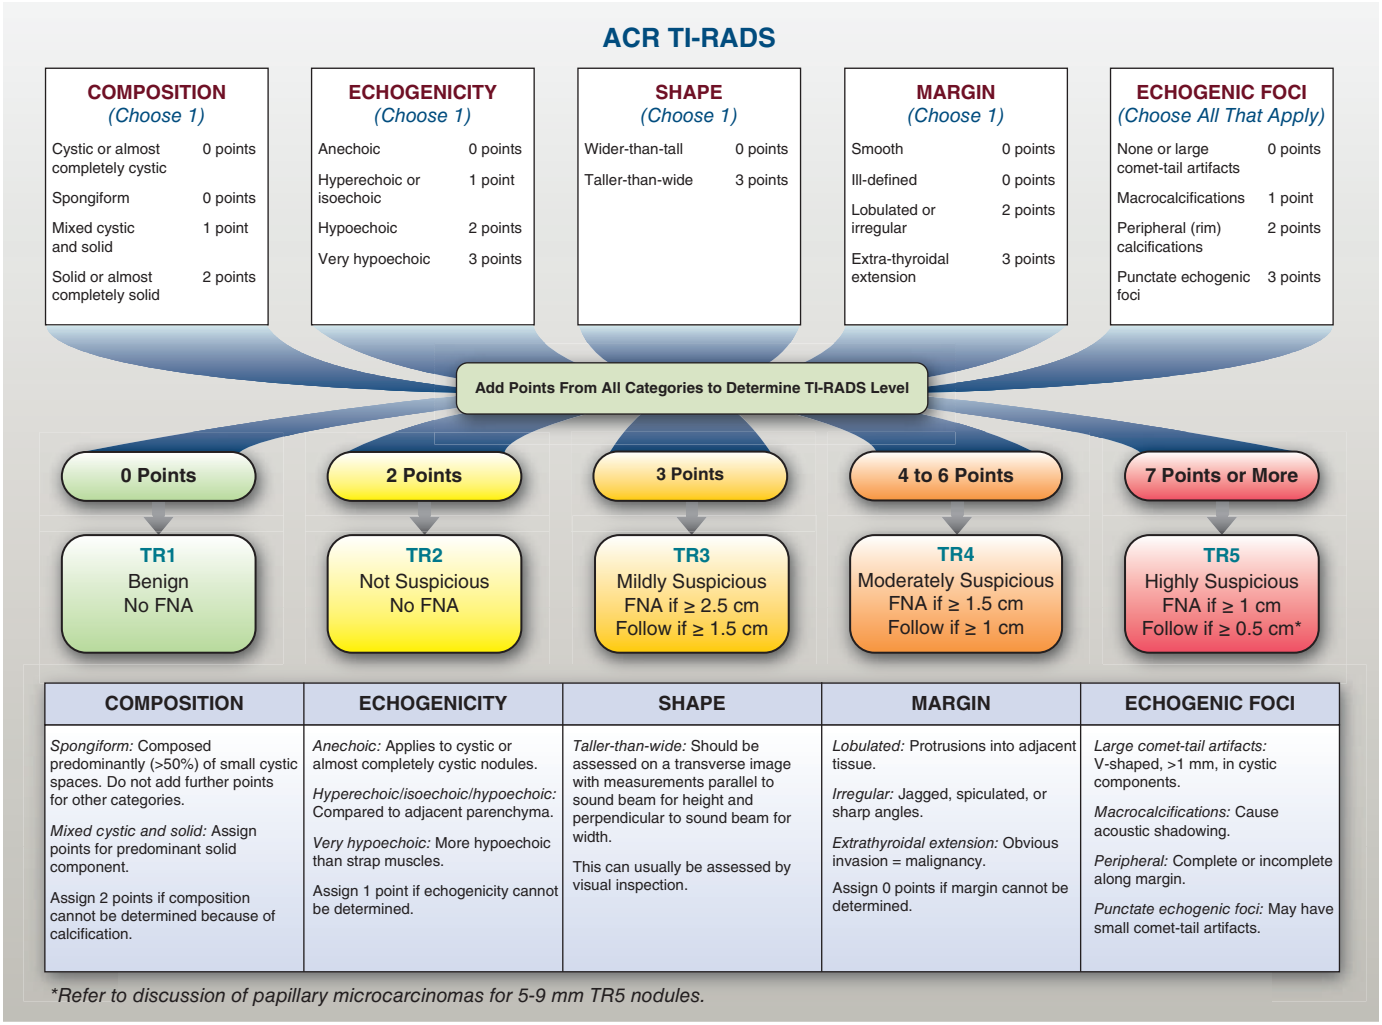

FIGURE 397-1 American College of Radiology (ACR) Thyroid Imaging Reporting and Data System (TI-RADS). TI-RADS is a five-tiered system categorizing the sonographic appearance of thyroid nodules based on increased risk for malignancy. For each level (TR1–5), there are recommendations for both fine-needle aspiration (FNA) minimum size cutoffs and follow-up. *(Reproduced with permission from FN Tessler et al: ACR Thyroid Imaging, Reporting and Data System (TI-RADS): White Paper of the ACR TI-RADS Committee. J Am Coll Radiol 14:587, 2017.)*

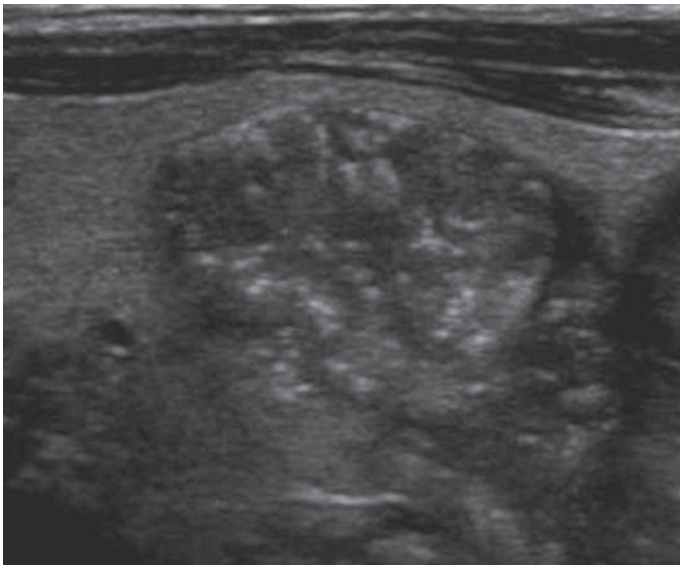
is contraindicated in areas where large nodular goiters are more prevalent (e.g., some areas of Europe and Brazil) because it can decrease MNG volume and may selectively ablate regions of autonomy. Dosage of ^{131}I depends on the size of the goiter and radioiodine uptake but is usually about 3.7 MBq (0.1 mCi) per gram of tissue, corrected for uptake (typical dose 370–1070 MBq [10–29 mCi]). Repeat treatment may be needed, and effectiveness may be increased by concurrent administration of low-dose recombinant TSH (0.1 mg IM). It is possible to achieve a 40–50% reduction in goiter size in most patients. Earlier concerns about radiation-induced thyroid swelling and tracheal compression have diminished, as studies have shown this complication to be rare. When acute compression occurs, glucocorticoid treatment or surgery may be needed. Radiation-induced hypothyroidism is less common than after treatment for Graves' disease. However, posttreatment autoimmune thyrotoxicosis may occur in up to 5% of patients treated for nontoxic MNG. Surgery remains highly effective but is not without risk, particularly in older patients with underlying cardiopulmonary disease.

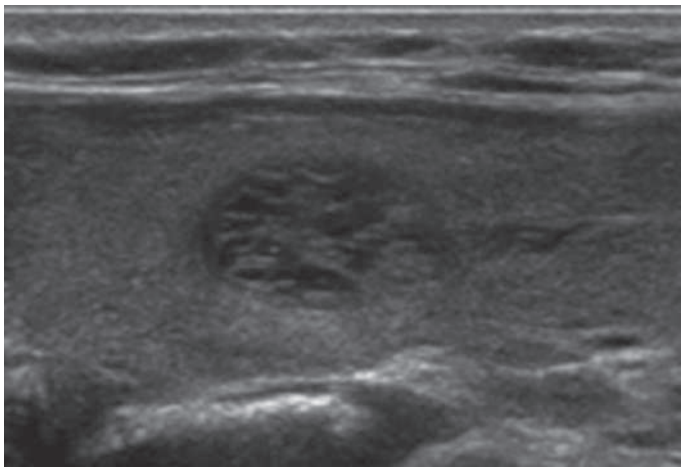
TOXIC MULTINODULAR GOITER

The pathogenesis of toxic MNG appears to be similar to that of nontoxic MNG; the major difference is the presence of functional autonomy in toxic MNG. The molecular basis for autonomy in toxic MNG remains unknown. As in nontoxic goiters, many nodules are polyclonal, whereas others are monoclonal and vary in their clonal origins. Genetic abnormalities known to confer functional autonomy, such as activating TSH-R or $G_s\alpha$ mutations (see below), are not usually found in the autonomous regions of toxic MNG goiter.



In addition to features of goiter, the clinical presentation of toxic MNG includes subclinical or mild overt hyperthyroidism. The patient is usually elderly and may present with atrial fibrillation or palpitations, tachycardia, nervousness, tremor, or weight loss. Recent exposure to iodine, from contrast dyes or other sources, may precipitate or exacerbate thyrotoxicosis. The TSH level is low. The free T_4 level may be normal or minimally increased; T_3 is often elevated to a greater degree than T_4. Thyroid scan shows heterogeneous uptake with multiple regions of increased and decreased uptake; 24-h uptake of radioiodine may not be increased but is usually in the upper normal range in the presence of the low TSH level.

Prior to definitive treatment of the hyperthyroidism, ultrasound imaging should be performed to assess the presence of discrete nodules corresponding to areas of decreased uptake ("cold" nodules) **(Fig. 397-3*A*)**. If present, fine-needle aspiration (FNA) may be indicated based on sonographic patterns and size cutoffs (see "Approach to the Patient with Thyroid Nodules"). The cytology results, if indeterminate or suspicious, may direct the therapy to surgery.



TREATMENT

Toxic Multinodular Goiter

Antithyroid drugs normalize thyroid function and are particularly useful in the elderly or ill patients with limited life span.

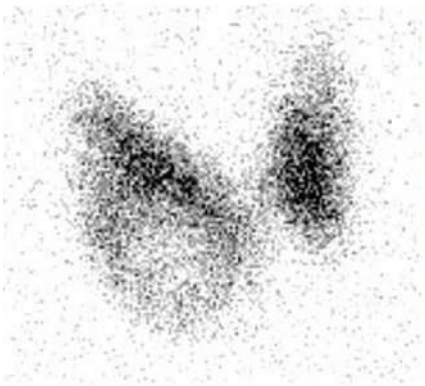
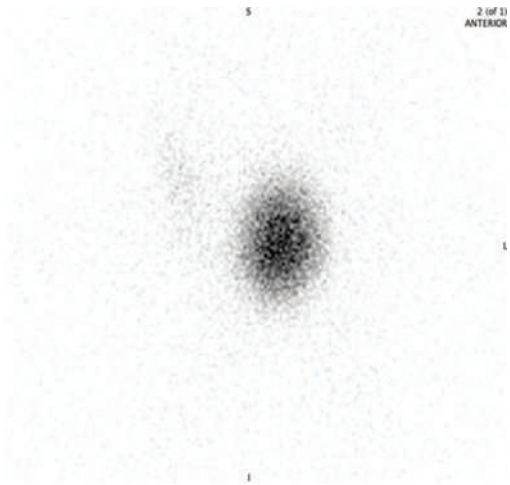
In contrast to Graves' disease, spontaneous remission does not occur, and low-dose antithyroid drug therapy is well tolerated for years. Radioiodine is generally the treatment of choice; it treats areas of autonomy as well as decreasing the mass of the goiter by ablating the functioning nodules. Sometimes, however, a degree of autonomy may persist, presumably because multiple autonomous regions may emerge after others are treated, and further radioiodine treatment may be necessary. Surgery provides definitive treatment of underlying thyrotoxicosis as well as goiter. Patients should be rendered euthyroid using an antithyroid drug before operation.

HYPERFUNCTIONING SOLITARY NODULE



A solitary, autonomously functioning thyroid nodule is referred to as *toxic adenoma*. The pathogenesis of this disorder has been unraveled by demonstrating the functional effects of mutations that stimulate the TSH-R signaling pathway. Most patients with solitary hyperfunctioning nodules have acquired somatic, activating mutations in the TSH-R **(Fig. 397-4)**. These mutations, located primarily in the receptor transmembrane domain, induce constitutive receptor coupling to $G_s\alpha$, increasing cyclic adenosine monophosphate (AMP) levels and leading to enhanced thyroid follicular cell proliferation and function. Less commonly, somatic mutations are identified in $G_s\alpha$. These mutations, which are similar to those seen in McCune-Albright syndrome **(Chap. 424)** or in a subset of somatotrope adenomas **(Chap. 392)**, impair guanosine triphosphate (GTP) hydrolysis, causing constitutive activation of the cyclic AMP signaling pathway. In most series, activating mutations in either the TSH-R or the $G_s\alpha$ subunit genes are identified in >90% of patients with solitary hyperfunctioning nodules.

Thyrotoxicosis is usually mild and is generally only detected when a nodule is >3 cm. The disorder is suggested by a subnormal TSH level; the presence of the thyroid nodule, often large enough to be palpable; and the absence of clinical features suggestive of Graves' disease or other causes of thyrotoxicosis. A thyroid scan provides a definitive diagnostic test, demonstrating focal uptake in the hyperfunctioning nodule and diminished uptake in the remainder of the gland, as activity of the normal thyroid is suppressed.



TREATMENT

Hyperfunctioning Solitary Nodule

Radioiodine ablation is usually the treatment of choice. Because normal thyroid function is suppressed, ^{131}I is concentrated in the

I^{123} scan (anterior view) of right lower pole nonfunctioning "cold" nodule (***A***) in a euthyroid patient and left hyperfunctioning "hot" nodule (***B***) causing thyrotoxicosis with suppression of I^{123} uptake in the extranodular thyroid. *(Courtesy of Dan Pryma.)*

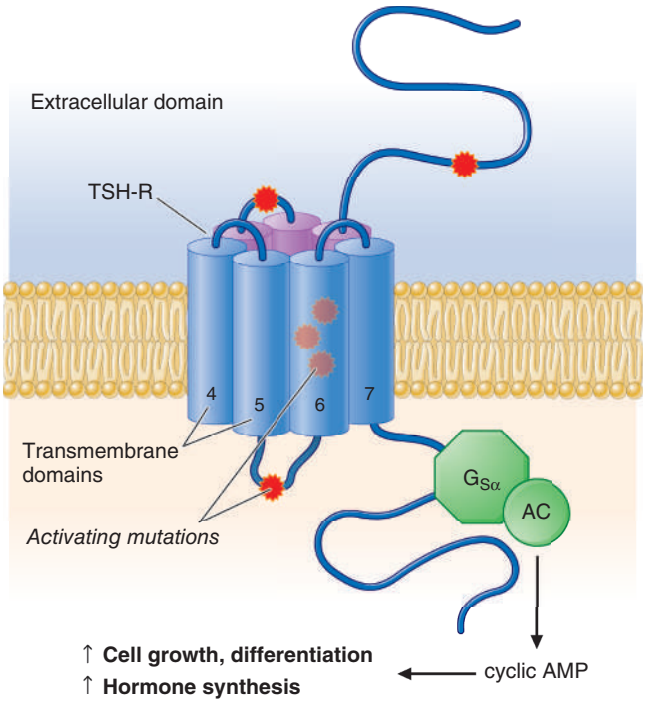

FIGURE 397-4 Activating mutations of the thyroid-stimulating hormone receptor (TSH-R). Mutations (*) that activate TSH-R reside mainly in transmembrane 5 and intracellular loop 3, although mutations have occurred in a variety of different locations. The effect of these mutations is to induce conformational changes that mimic TSH binding, thereby leading to coupling to stimulatory G protein ($G_{s\alpha}$) and activation of adenylate cyclase (AC), an enzyme that generates cyclic AMP.

hyperfunctioning nodule with minimal uptake and damage to normal thyroid tissue. Relatively large radioiodine doses (e.g., 370–1110 MBq [10–29.9 mCi] ^{131}I) have been shown to correct thyrotoxicosis in ~75% of patients within 3 months. Hypothyroidism occurs in <10% of those patients over the next 5 years. Surgical resection is also effective and is usually limited to lobectomy, thereby preserving thyroid function and minimizing risk of hypoparathyroidism or damage to the recurrent laryngeal nerves. Medical therapy using antithyroid drugs and beta blockers can normalize thyroid function but is not an optimal long-term treatment. Using ultrasound guidance, percutaneous radiofrequency ablation has been used successfully in some centers to ablate hyperfunctioning nodules, and this technique has also been used to reduce the size of nonfunctioning thyroid nodules.

BENIGN LESIONS

The various types of benign thyroid nodules are listed in Table 397-1. Benign nodules may be hyperplastic and reflect a combination of both macro- and microfollicular architecture, or they may be neoplastic, encapsulated adenomas that generally have a more monotonous microfollicular pattern. If the adenoma is composed of oncocytic follicular cells arranged in a follicular pattern, this is termed an oncocytic (formerly termed Hürthle cell) adenoma. Hyperplastic nodules generally appear as mixed cystic/solid or spongiform lesions on ultrasound. The definition of spongiform requires the presence of microcystic areas comprising >50% of the nodule volume, with the concept that this microcystic sonographic pattern recapitulates the histology of macrofollicles containing colloid (Fig. 397-2*B*). However, the majority of solid nodules (whether hypo-, iso-, or hyperechoic) are also benign. FNA, usually performed with ultrasound guidance, is the diagnostic procedure of choice to evaluate thyroid nodules (see the "Approach to the Patient with Thyroid Nodules" section). Pure thyroid cysts, <1% of all thyroid growths, consist of colloid and are benign as well. Cysts frequently recur, even after repeated aspiration, and may require surgical excision if they are large. Ethanol ablation to sclerose the cyst has been used successfully for patients who are symptomatic.

TSH suppression with LT4 therapy does not decrease thyroid nodule size in iodine-sufficient populations. However, if there is relative iodine deficiency, both iodine and LT4 therapy have been demonstrated to decrease nodule volume. If LT4 is administered in this situation, the TSH should be maintained at or just below the lower limit of normal, but not frankly suppressed. If the nodule has not decreased in size after 6–12 months of therapy, treatment should be discontinued because little benefit is likely to accrue from long-term treatment; the risk of iatrogenic subclinical thyrotoxicosis should also be considered.

TABLE 397-1 WHO Classification of Thyroid Neoplasms

Developmental abnormalities

1. Thyroglossal duct cyst
2. Other congenital thyroid abnormalities

Follicular cell–derived neoplasms

1. Benign tumors
   a. Thyroid follicular nodular disease
   b. Follicular adenoma
   c. Follicular adenoma with papillary architecture
   d. Oncocytic adenoma of the thyroid
2. Low-risk neoplasms

THYROID CANCER

Thyroid carcinoma is the most common malignancy of the endocrine system. Malignant tumors derived from the follicular epithelium are classified according to histologic features. Differentiated tumors, such as papillary thyroid cancer (PTC) or follicular thyroid cancer (FTC), are often curable, and the prognosis is good for patients identified with early-stage disease. In contrast, anaplastic thyroid cancer (ATC) is aggressive, responds poorly to treatment, and is associated with a bleak prognosis.

Over the past 30 years, the incidence of thyroid cancer has increased from 4.9 to >15 cases per 100,000 individuals in the United States. However, disease-specific mortality has only minimally increased. The increased incidence is predominantly attributable to small T1 papillary cancer tumors (<2 cm) and has led experts to consider that thyroid cancer is being overdiagnosed, suggesting that cancers are being detected that would otherwise be unlikely to harm a patient. The concept of cancer overdiagnosis is predicated upon the presence of a disease reservoir (the autopsy prevalence of PTC is ~25%), activities leading to disease detection (increased diagnostic imaging with incidental detection of nodules), and a mismatch in the directional rate between diagnosis and mortality (thyroid cancer disease-specific mortality not changed in 40 years). Similar trends have been observed worldwide, especially in countries with a higher proportion of privately financed health care, leading to increased resource utilization including imaging. The 20-year disease-specific mortality for low-risk thyroid cancer is 1%. Fortunately, epidemiologic data in the United States document a decrease in new thyroid cancer diagnoses (62,450 cases in 2015 and 43,720 cases in 2023), and this trend correlates with the implementation of evidence-based guidelines that recommend higher size thresholds for nodule FNA.

Current trends in thyroid cancer care focus on (1) avoiding overdiagnosis by limiting FNA by sonographic risk stratification with size cutoffs; (2) limiting surgery, radioiodine, and subsequent surveillance for low-risk tumors; and (3) identifying patients at higher recurrence risk for more aggressive treatment and monitoring. Prognosis is generally worse in older persons (>65 years). Thyroid cancer is twice as common in women as men, but male gender is associated with a worse prognosis. Additional important risk factors include a history of childhood (before age 18) head or neck irradiation, evidence for local tumor fixation or gross metastatic involvement of lymph nodes, and the presence of distant metastases **(Table 397-2)**.

Several unique features of thyroid cancer facilitate its management: (1) thyroid nodules are amenable to biopsy by FNA; (2) iodine radioisotopes can be used to diagnose (^{123}I and ^{131}I) and potentially treat (^{131}I) differentiated thyroid cancer, reflecting the unique uptake of this anion by the thyroid gland; and (3) serum markers allow the detection of residual or recurrent disease, including the use of Tg levels for PTC FTC and oncocytic carcinoma and calcitonin for medullary thyroid cancer (MTC).

CLASSIFICATION

Thyroid neoplasms can arise in each of the cell types that populate the gland, including thyroid follicular cells, calcitonin-producing C cells, lymphocytes, and stromal and vascular elements, as well as metastases from other sites (Table 397-1). The American Joint Committee on Cancer (AJCC) staging system using the tumor, node, metastasis (TNM) classification is most commonly used. This system classifies different types of thyroid cancers (papillary, follicular, poorly differentiated, oncocytic cell, or anaplastic) based upon: 1) tumor size and extrathyroidal invasion; 2) regional lymph node metastases; and 3) distant metastases.[1]

TABLE 397-2 Risk Factors for Thyroid Carcinoma in Patients with Thyroid Nodule from History and Physical Examination

History of head and neck irradiation before the age of 18, including mantle radiation for Hodgkin's disease and brain radiation for childhood leukemia or other cranial malignancies	Family history of papillary thyroid cancer in two or more first-degree relatives, MEN 2, or other genetic syndromes associated with thyroid malignancy (e.g., Cowden's syndrome, familial adenomatous polyposis, Carney complex, PTEN [phosphatase and tensin homolog] hamartoma tumor)
Exposure to ionizing radiation from fallout in childhood or adolescence	Vocal cord paralysis, hoarse voice
Age <20 or >65 years	Nodule fixed to adjacent structures
Rapidly enlarging neck mass	Lateral cervical lymphadenopathy (ipsilateral to the nodule)
Male gender	
^{18}FDG or Ga-68 Dotatate PET avidity	

Abbreviations: FDG, fluorodeoxyglucose; MEN, multiple endocrine neoplasia; PET, positron emission tomography.

PATHOGENESIS AND GENETIC BASIS

Radiation Early studies of the pathogenesis of thyroid cancer focused on the role of external radiation, which predisposes to chromosomal breaks, leading to genetic rearrangements and loss of tumor-suppressor genes. External radiation of the mediastinum, face, head, and neck region was administered in the past to treat an array of conditions, including acne and enlargement of the thymus, tonsils, and adenoids. Radiation exposure increases the risk of benign and malignant thyroid nodules, is associated with multicentric cancers, and shifts the incidence of thyroid cancer to an earlier age group. Radiation from nuclear fallout also increases the risk of thyroid cancer through absorption of radioactive iodine isotopes. Children seem more predisposed to the effects of radiation than adults.

TSH and Growth Factors Many differentiated thyroid cancers express TSH receptors and, therefore, remain responsive to TSH. Higher serum TSH levels, even within normal range, are associated with increased thyroid cancer risk in patients with thyroid nodules. These observations provide the rationale for T_4 suppression of TSH in patients with thyroid cancer. Residual expression of TSH receptors also allows TSH-stimulated uptake of ^{131}I therapy (see below).

Oncogenes and Tumor-Suppressor Genes Thyroid cancers are monoclonal in origin, consistent with the idea that they originate as a consequence of mutations that confer a growth advantage, or resistance to cell death, to a single progenitor cell. In addition to increased rates of proliferation, some thyroid cancers exhibit impaired apoptosis and features that enhance invasion, angiogenesis, and metastasis. Thyroid neoplasms have been analyzed for a variety of genetic alterations, but without clear evidence of an ordered acquisition of somatic mutations as they progress from the benign to the malignant state. On the other hand, certain mutations, such as *RET/PTC* and *PAX8-PPARγ1* rearrangements, are relatively specific for thyroid neoplasia.

As described above, activating mutations of the TSH-R and the $G_s\alpha$ subunit are associated with autonomously functioning nodules. Mutations in the enhancer of zeste homolog 1 (*EZH1*), which plays a role in chromatin remodeling, are also seen in about a quarter of autonomous nodules. Although these mutations induce thyroid cell growth, this type of nodule is almost always benign, likely because they drive differentiation pathways.

Activation of the RET-RAS-BRAF signaling pathway is seen in up to 70% of PTCs, although the types of mutations are heterogeneous. A variety of rearrangements involving the *RET* gene on chromosome 10 bring this receptor tyrosine kinase under the control of other promoters, leading to receptor overexpression. *RET* rearrangements occur in 15% of PTCs in different series and were observed with increased frequency in tumors developing after the Chernobyl radiation accident. Rearrangements in PTC have also occurred for another tyrosine kinase gene, *TRK1*, which is located on chromosome 1. *BRAF* V600E mutations are a common genetic alteration, occurring in up to 60% of PTC. These mutations activate the kinase, which stimulates the mitogen-activated protein kinase (MAPK) cascade. *RAS* mutations, which also stimulate the MAPK cascade, are found in ~15% of thyroid neoplasms (*NRAS* > *HRAS* > *KRAS*), including both PTC follicular variant and FTC. Of note, simultaneous *RET*, *BRAF*, and *RAS* mutations rarely occur in the same tumor, suggesting that activation of the MAPK

[1]RM Tuttle et al: Updated American Joint Committee on Cancer/Tumor-Node-Metastasis Staging System for Differentiated and Anaplastic Thyroid Cancer (Eighth Edition): What changed and why? Thyroid 27:751, 2017.

cascade is critical for tumor development, independent of the step that initiates the cascade. Activation of the phosphatidylinositol 3-kinase (PI3K) pathway, often by deletion of the *PTEN* phosphatase gene, also occurs in both differentiated thyroid cancers.

BRAF and *RAS* mutations also occur in FTCs. In addition, a rearrangement of the thyroid developmental transcription factor PAX8 with the nuclear receptor PPARγ is identified in a significant fraction of FTCs, usually independent of *RAS* pathway mutations. Overall, ~70% of follicular cancers have mutations or genetic rearrangements. Loss of heterozygosity of 3p or 11q, consistent with deletions of tumor-suppressor genes, is also common in FTCs. Upregulation and downregulation of various microRNAs also influence gene expression patterns in both differentiated and dedifferentiated thyroid cancers.

Oncocytic tumors, which contain large numbers of mitochondria, are characterized by mutations in mitochondrial genes, primarily encoding enzymes in the electron transport chain. They also exhibit chromosomal copy number alterations and near haploidization.

Most of the mutations seen in differentiated thyroid cancers have also been detected in ATCs. *TERT* promoter mutations occur in <10% of differentiated PTCs but are more common in ATC. *BRAF* mutations are seen in up to 50% of ATCs. Mutations in *CTNNB1*, which encodes β-catenin, occur in about two-thirds of ATCs, but not in PTC or FTC. Mutations of the tumor-suppressor *P53* also play an important role in the development of ATC. Because *P53* plays a role in cell-cycle surveillance, DNA repair, and apoptosis, its loss may contribute to the rapid acquisition of genetic instability as well as poor treatment responses **(Chap. 77)**.

MTC, when associated with multiple endocrine neoplasia (MEN) type 2, harbors an inherited mutation of the *RET* gene. Unlike the rearrangements of *RET* seen in PTC, the mutations in MEN 2 are point mutations that induce constitutive activity of the tyrosine kinase **(Chap. 400)**. MTC is preceded by hyperplasia of the C cells, raising the likelihood that as-yet-unidentified "second hits" lead to cellular transformation. A subset of ~40% of sporadic MTC contains somatic mutations that activate *RET*.

Molecular diagnostics are being used more commonly in the clinical management of thyroid nodules, particularly to distinguish benign from malignant lesions after FNA and to reduce the number of diagnostic surgeries for indeterminate nodules. These tools are now offered as diagnostic panels by specialized referral laboratories. The panels also distinguish parathyroid and medullary nodules from thyroid follicular cell–derived lesions.

WELL-DIFFERENTIATED THYROID CANCER

Papillary PTC is the most common type of thyroid cancer, accounting for 80–85% of well-differentiated thyroid malignancies. Microscopic PTC is present in up to 25% of thyroid glands at autopsy, but most of these lesions are very small (several millimeters) and are not clinically significant. Characteristic cytologic features of PTC help make the diagnosis by FNA or after surgical resection; these include large, clear nuclei with powdery chromatin (described as an "Orphan Annie eye" appearance) with nuclear grooves and prominent nucleoli. The histologic finding of these cells arranged in either papillary structures or follicles distinguishes the classic and follicular variants of PTC, respectively. There are several subtypes of papillary thyroid cancer. The more differentiated classic and follicular variants are likely to have an indolent course in the absence of angioinvasion or metastatic adenopathy. The aggressive variants (tall cell, columnar cell, hobnail, poorly differentiated) require more intensive therapy and closer follow-up. Recently, a subtype previously known as the encapsulated PTC follicular variant, without capsular or angioinvasion, is no longer considered malignant and has been renamed noninvasive follicular thyroid neoplasm with papillary-like nuclear features (NIFTP).

PTC may be multifocal and invade locally within the thyroid gland as well as through the thyroid capsule and into adjacent structures in the neck. It has a propensity to spread via the lymphatic system but can metastasize hematogenously as well, particularly to bone and lung. Because of the relatively slow growth of the tumor, a significant burden of pulmonary metastases may accumulate, sometimes with remarkably few symptoms. The prognostic implication of lymph node spread depends on the volume of metastatic disease. Micrometastases, defined as <2 mm of cancer in a lymph node, do not affect prognosis. However, gross metastatic involvement of multiple 2- to 3-cm lymph nodes indicates a 25–30% chance of recurrence and may increase mortality in older patients. Most papillary cancers are identified in the early stages (>95% stages I or II) and have an excellent prognosis, with survival curves similar to expected survival **(Fig. 397-5)**. Mortality is markedly increased in stage IV disease, especially in the presence of distant metastases (stage IVB), but this group comprises only about 1% of patients. The treatment of PTC is described below.

Follicular The incidence of FTC varies widely in different parts of the world; it is more common in iodine-deficient regions. Currently, FTC accounts for only about 5% of all thyroid cancers diagnosed in the United States. FTC is difficult to diagnose by FNA because the distinction between benign and malignant follicular neoplasms requires histology because the nuclear features of follicular adenomas and carcinomas do not differ. Rather, follicular carcinoma is diagnosed by the presence of capsular and/or vascular invasion. Follicular carcinomas with only capsular invasion have a very low risk of metastasis, and lobectomy alone suffices. Angioinvasive FTC is more aggressive and may metastasize to bone, lung, and the central nervous system. Mortality rates associated with angioinvasive FTC are less favorable than for PTC, in part because a larger proportion of patients present with stage IV disease. Poor prognostic features include distant metastases, age >55 years, primary tumor size >4 cm, and the presence of marked vascular invasion.

TREATMENT

Surgery for Well-Differentiated Thyroid Cancer

All well-differentiated thyroid cancers >1–1.5 cm (T1b or larger) should be surgically excised. Active surveillance is an option for small (up to 1.5 cm) intrathyroidal micropapillary thyroid cancers without cervical lymph node metastases, extrathyroidal extension, or location near the posterior thyroid capsule (near the recurrent laryngeal nerve). In addition to removing the primary lesion, surgery allows accurate histologic diagnosis and staging. Because there is no compelling evidence that bilateral thyroid surgery improves survival, the initial surgical procedure may be either a unilateral (lobectomy) or bilateral (near-total thyroidectomy) procedure for patients with intrathyroidal cancers >1 cm and <4 cm

(T1b and T2 tumors) in the absence of metastatic disease and after a careful sonographic evaluation for metastatic cervical adenopathy. For patients at high risk for recurrence, bilateral surgery allows administration of radioiodine for remnant ablation and potential treatment of iodine-avid metastases, if indicated, as well as for monitoring of serum Tg levels. Therefore, near-total thyroidectomy is appropriate in the presence of metastases or clinical evidence of extrathyroidal invasion and for most tumors >4 cm. In addition, for patients found to have a high-risk tumor after lobectomy based upon aggressive pathology features (e.g., vascular invasion or a less differentiated subtype), completion surgery should be performed to allow for effective radioiodine administration. Surgical complication rates are acceptably low if the surgeon is highly experienced in the procedure. Preoperative sonography should be performed in all patients to assess the central and lateral cervical lymph node compartments for suspicious adenopathy, which if present, should undergo FNA and be removed, as indicated, at surgery.

TSH SUPPRESSION THERAPY

Because most tumors are still TSH-responsive, LT4 suppression of TSH has been mainstay of thyroid cancer treatment. The degree of TSH suppression should be individualized based on a patient's risk of recurrence. It should be adjusted over time as surveillance blood tests and imaging confirm absence of disease or, alternatively, indicate possible residual/recurrent cancer. For patients at low risk of recurrence, TSH should be maintained in the lower normal limit (0.5–2.0 mIU/L). For patients either at intermediate or high risk of recurrence, TSH levels should be kept to 0.1–0.5 mIU/L and <0.1 mIU/L, respectively, if there are no strong contraindications to mild thyrotoxicosis. TSH should be <0.1 mIU/L for those with known metastatic disease.

RADIOIODINE TREATMENT

After near-total thyroidectomy, <1 g of thyroid tissue remains in the thyroid bed. Postsurgical radioablation of the remnant thyroid eliminates residual normal thyroid, facilitating the use of Tg determinations. In addition, well-differentiated thyroid cancer often incorporates radioiodine, although less efficiently than normal thyroid follicular cells. Radioiodine uptake is determined primarily by expression of the NIS and is stimulated by TSH, requiring expression of the TSH-R. The retention time for radioactivity is influenced by the extent to which the tumor retains differentiated functions such as iodide trapping and organification. Consequently, for patients at higher risk of recurrence and for those with known distant metastatic disease, ^{131}I therapy may provide an adjuvant role and potentially treat residual tumor cells.

Indications Not all patients benefit from radioiodine therapy. Neither recurrence nor survival rates are improved in stage I patients with T1 tumors (≤2 cm) confined to the thyroid. No benefit has been demonstrated for larger (>2 cm but <4 cm) low-risk tumors. However, in higher risk patients (larger tumors, more aggressive variants of papillary cancer, tumor vascular invasion, extrathyroidal invasion, presence of large-volume lymph node metastases), radioiodine may reduce recurrence and may increase survival for older patients.

^{131}I Thyroid Ablation and Treatment As noted above, the decision to use ^{131}I for thyroid ablation should be coordinated with the surgical approach, because radioablation is much more effective when there is minimal remaining normal thyroid tissue. Radioiodine is administered after iodine depletion (patient follows a low-iodine diet for 1–2 weeks) and in the presence of elevated serum TSH levels to stimulate uptake of the isotope into both the remnant and potentially any residual tumor. To achieve high serum TSH levels, there are two approaches. A patient may be withdrawn from thyroid hormone so that endogenous TSH is secreted and, ideally, the serum TSH level is >25 mIU/L at the time of ^{131}I therapy. A typical strategy is to treat the patient for several weeks postoperatively with liothyronine (25 μg qd or bid), followed by thyroid hormone withdrawal for 2 weeks. Alternatively, recombinant human TSH (rhTSH) is administered as two daily consecutive injections (0.9 mg) with administration of ^{131}I 24 h after the second injection. The patient can continue to take LT4 and remains euthyroid. Both approaches have equal success in achieving remnant ablation.

A pretreatment scanning dose of ^{131}I (usually 111 MBq [3 mCi]) or ^{123}I (74 MBq [2 mCi]) can reveal the amount of residual tissue and provides guidance about the dose needed to accomplish ablation. However, because of concerns about radioactive "stunning" that impairs subsequent treatment, there is a trend to avoid pretreatment scanning with ^{131}I and use either ^{123}I or proceed directly to ablation, unless there is suspicion that the amount of residual tissue will alter therapy or that there is distant metastatic disease. In the United States, outpatient doses of up to 6475 MBq (175 mCi) can be given at most centers. The administered dose depends on the indication for therapy, with lower doses of 1100 MBq (30 mCi) given for remnant ablation but higher doses of up to 5500 MBq (150 mCi) reserved for use as adjuvant therapy when residual disease is suspected or present. Whole-body scanning (WBS) following radioiodine treatment is used to confirm the ^{131}I uptake in the remnant and to identify possible metastatic disease.

Surveillance Testing Serum thyroglobulin (Tg) is a sensitive marker of residual/recurrent thyroid cancer after ablation of the residual postsurgical thyroid tissue. Current Tg assays have functional sensitivities as low as 0.1 ng/mL, as opposed to older assays with functional sensitivities of 1–2 ng/mL, reducing the number of patients with truly undetectable serum Tg levels. Because the vast majority of PTC recurrences are in cervical lymph nodes, a neck ultrasound should be performed about 6 months after thyroid ablation; ultrasound has been shown to be more sensitive than WBS in this scenario.

In low-risk patients who have no clinical evidence of residual disease after ablation, negative cervical sonography, and a basal Tg <0.2 ng/mL on LT4, the risk of structural recurrence is <3% at 5 years, and the frequency of follow-up testing can be decreased to annual TSH and Tg testing, with only periodic ultrasound examination. The serum TSH should be maintained in the lower half of the normal range.

The use of WBS for thyroid cancer surveillance is reserved for patients with known iodine-avid metastases or those with elevated serum thyroglobulin levels and negative imaging with ultrasound, chest CT, neck cross-sectional imaging, and positron emission tomography (PET) CT who may require additional ^{131}I therapy.

In addition to radioiodine, external beam radiotherapy is also used to treat gross residual neck disease or specific metastatic lesions, particularly when they cause bone pain or threaten neurologic injury (e.g., vertebral metastases).

New Potential Therapies Kinase inhibitors target pathways known to be active in thyroid cancer, including the RAS, BRAF, RET, EGFR, VEGFR, and angiogenesis pathways. Treatment has been shown to stabilize progressive metastatic disease that is refractory to radioiodine therapy, although only one study has demonstrated improved survival. Given the significant associated toxicities and the need for ongoing therapy, patient selection is critical to limit systemic therapy to those with significant morbidity risk. The American Thyroid Association guidelines recommend active surveillance for asymptomatic patients with metastatic tumors between 1 and 2 cm and then intervention as the rate of tumor growth increases. In addition, based on genetic analyses of metastases, mutation-selective kinase inhibitors are now being used. In addition to multikinase inhibitors, new therapies target tumor-specific mutational changes including *BRAF* V600E point mutations and *NTRK* and *RET* gene fusions. Immune checkpoint inhibitors have also shown efficacy for some thyroid cancers with high tumor mutation burden (TMB-H). Ongoing trials are also exploring whether differentiation protocols, targeting the MAPK pathway, might enhance radioiodine uptake and efficacy.

ANAPLASTIC AND OTHER FORMS OF THYROID CANCER

Anaplastic Thyroid Cancer As noted above, ATC is a poorly differentiated and aggressive cancer. The prognosis is poor, and most patients die within 6 months of diagnosis. Because of the undifferentiated state of these tumors, the uptake of radioiodine is usually negligible, but it can be used therapeutically if there is residual uptake. Chemotherapy has been attempted with multiple agents, including anthracyclines and paclitaxel, but it is usually ineffective. External beam radiation therapy can be attempted and continued if tumors are responsive. Both multitargeted and mutation-directed kinase inhibitors are in clinical trials and may prolong survival by a few months.

Thyroid Lymphoma Lymphoma in the thyroid gland often arises in the background of Hashimoto's thyroiditis. A rapidly expanding thyroid mass suggests the possibility of this diagnosis. Diffuse large-cell lymphoma is the most common type in the thyroid. Biopsies reveal sheets of lymphoid cells that can be difficult to distinguish from small-cell lung cancer or ATC. These tumors are often highly sensitive to external radiation. Surgical resection should be avoided as initial therapy because it may spread disease that is otherwise localized to the thyroid. If staging indicates disease outside of the thyroid, treatment should follow guidelines used for other forms of lymphoma **(Chap. 113)**.

MEDULLARY THYROID CARCINOMA

MTC can be sporadic or familial and accounts for ~5% of thyroid cancers. There are three familial forms of MTC: MEN 2A, MEN 2B, and familial MTC without other features of MEN **(Chap. 400)**. In general, MTC is more aggressive in MEN 2B than in MEN 2A, and familial MTC is more aggressive than sporadic MTC. Elevated serum calcitonin provides a marker of residual or recurrent disease. All patients with MTC should be tested for *RET* mutations, because genetic counseling and testing of family members can be offered to those individuals who test positive for mutations.

The management of MTC is primarily surgical. Prior to surgery, pheochromocytoma should be excluded in all patients with a *RET* mutation. Unlike tumors derived from thyroid follicular cells, these tumors do not take up radioiodine. External radiation treatment and targeted kinase inhibitors may provide palliation in patients with advanced disease **(Chap. 400)**.

APPROACH TO THE PATIENT

Thyroid Nodules

Palpable thyroid nodules are found in ~5% of adults, but the prevalence varies considerably worldwide. Given this high prevalence rate, practitioners may identify thyroid nodules on physical examination. However, the increased usage of diagnostic medical imaging (e.g., carotid ultrasound, cervical spine MRI) has led to an increased frequency of incidental nodule detection, accounting for the majority of patients currently presenting for nodule evaluation. The main goal of this evaluation is to identify, in a cost-effective manner, the small subgroup of individuals with malignant lesions that have the potential to be clinically significant.

Nodules are more common in iodine-deficient areas, in women, and with aging. Most palpable nodules are >1 cm in diameter, but the ability to feel a nodule is influenced by its location within the gland (superficial vs deeply embedded), the anatomy of the patient's neck, and the experience of the examiner. More sensitive methods of detection, such as CT, thyroid ultrasound, and pathologic studies, reveal thyroid nodules in up to 50% of glands in individuals aged >50 years. The presence of these thyroid incidentalomas has led to much debate about how to detect nodules and which nodules to investigate further.

An approach to the evaluation of thyroid nodules detected by either palpation or imaging is outlined in **Fig. 397-6**. Most patients with thyroid nodules have normal thyroid function tests. Nonetheless, thyroid function should be assessed by measuring a TSH level, which may be suppressed by one or more autonomously functioning nodules. If the TSH is suppressed, a radionuclide scan is indicated to determine if the identified nodule is "hot," as lesions with increased uptake are almost never malignant and FNA is unnecessary **(Fig. 397-3*B*)**. Otherwise, the next step in evaluation is performance of a thyroid ultrasound for three reasons: (1) For nodules detected on physical examination, ultrasound will confirm if the palpable nodule is indeed a nodule. About 15% of "palpable" nodules are not confirmed on imaging, and therefore no further evaluation is required. (2) Ultrasound will assess if there are additional nonpalpable nodules for which FNA may be recommended based on imaging features and size. (3) Ultrasound will characterize the imaging pattern of the nodule, which, combined with the nodule's size, facilitates decision-making about FNA. There are several validated risk stratification systems (RSS) for sonographic imaging of thyroid nodules (American College of Radiology [ACR] Thyroid Imaging Reporting and Data System [TI-RADS], American Thyroid Association, European Thyroid Association [EU-TIRADS], among others). These demonstrate consistent risk estimates for thyroid cancer based on certain sonographic patterns. All provide size cutoff recommendations for nodule FNA based on sonographic patterns, with lower size cutoffs for nodules with more suspicious ultrasound patterns, but the specific size cutoff criteria differ among the RSS. Not surprisingly, the RSSs with lower size cutoffs have higher sensitivity and lower specificity for thyroid cancer diagnosis than those with higher cutoffs. Nevertheless, all have been shown to reduce unnecessary FNAs by at least 45%, in part due to the recommendation not to perform FNA for spongiform nodules. ACR TI-RADS is currently the most widely used RSS in the United States, and nodules are classified from TR1 to TR5 (Fig. 397-1).

For example, a spongiform nodule (TR1, Fig. 397-2B) has a <3% chance of cancer, and observation rather than FNA is generally recommended by all RSSs, whereas 10–20% of solid hypoechoic nodules with smooth borders (TR4) are malignant and FNA is recommended at size cutoffs ranging from 1 to 1.5 cm. All the RSSs recommend FNA at 1 cm for the highest suspicion pattern nodule, TR5 (Figs. 397-1 and 397-2A). Given what is known about the prevalence and generally indolent behavior of small thyroid cancers <1 cm, none of the RSSs recommend routine FNA for any nodule <1 cm unless metastatic cervical lymph nodes are present.

FNA biopsy, ideally performed with ultrasound guidance, is the best diagnostic test when performed by physicians familiar with the procedure and when the results are interpreted by experienced cytopathologists. The technique is particularly useful for detecting PTC. However, the distinction between benign and malignant follicular patterned lesions is often not possible using cytology alone because of the absence of characteristic nuclear features in follicular carcinoma. Using the current ultrasound RSS for FNA decision-making, FNA biopsies yield the following spectrum of cytology diagnoses: 50–60% benign, 5% malignant or suspicious for malignancy, 5–7% nondiagnostic or yielding insufficient material for diagnosis, and 25–40% indeterminate. The Bethesda System is now widely used to provide more uniform terminology for reporting thyroid nodule FNA cytology results. This six-tiered classification system (newest version 3) with the respective estimated malignancy rates is shown in **Table 397-3**. Importantly, because NIFTP can only be diagnosed by surgical pathology, NIFTP is included in the malignancy estimates. Specifically, the Bethesda System subcategorized cytology specimens previously labeled as indeterminate into three categories: atypia undetermined significance (AUS), follicular neoplasm (FN), and suspicious for malignancy (SFM).

Cytology results indicative of malignancy generally mandate surgery, after performing preoperative sonography to evaluate the cervical lymph nodes. Nondiagnostic cytology specimens most often result from cystic lesions but may also occur in fibrous long-standing nodules or very vascular nodules where a longer needle

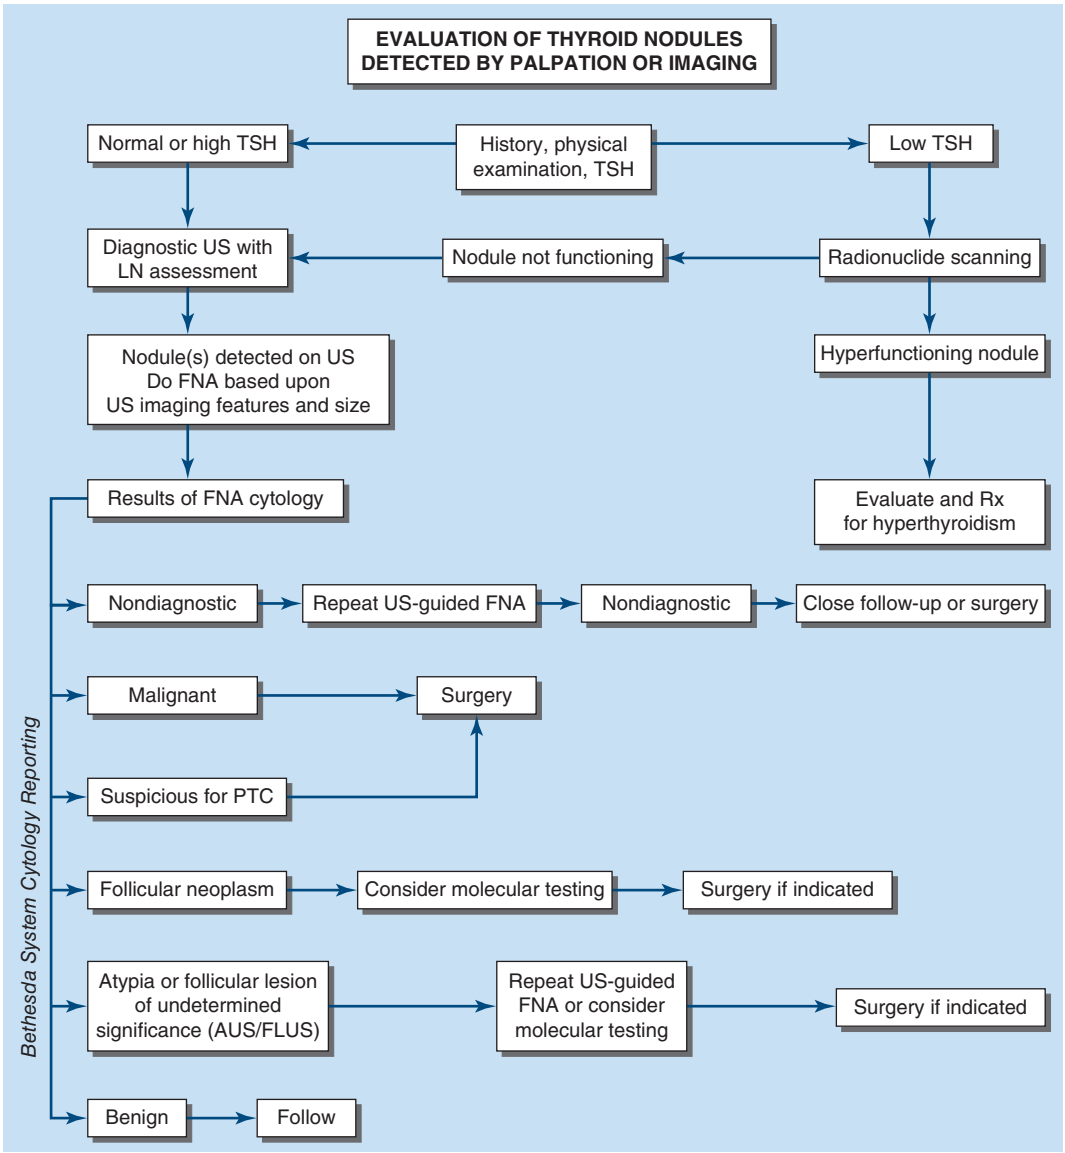

FIGURE 397-6 Approach to the patient with a thyroid nodule. See text and references for details. FNA, fine-needle aspiration; LN, lymph node; PTC, papillary thyroid cancer; Rx, therapy; TSH, thyroid-stimulating hormone; US, ultrasound.

dwell time may result in a hemorrhagic specimen. Ultrasound-guided FNA is indicated when a repeat FNA is necessary. Repeat FNA will yield a diagnostic cytology in ~50% of cases. Given the low false-negative rate of a benign cytology (<3%), benign nodules with a lower suspicion sonographic pattern (TR2, TR3, TR4) can be followed. Those with more worrisome ultrasound features, especially TR5 nodules, should undergo repeat FNA because of a higher likelihood of a missed malignancy. The use of LT4 to suppress serum TSH is not effective in shrinking nodules in iodine-replete populations, and therefore, LT4 suppression should not be used. The three indeterminate cytology classifications introduced by the Bethesda System are associated with different risks of malignancy (Table 397-3). For nodules with suspicious for malignancy cytology, surgery is recommended after ultrasound assessment of cervical lymph nodes. Options to be discussed with the patient include lobectomy versus total thyroidectomy.

On the other hand, the majority of nodules with AUS and FN cytology results are benign; the range of malignancy (ROM) varies from 13 to 34%. The traditional approach for these patients is diagnostic lobectomy for histopathologic diagnosis. Therefore, many patients undergo surgery for benign nodules. Over the past decade, the uncertainty about the ROM for indeterminate cytology nodules has been the driver for the development of molecular testing, which can better differentiate benign from malignant nodules. Based on results from next-generation sequencing, which includes point mutations, small insertions/deletions, and gene fusions, as well as results from microRNA analyses and gene expression, the current validated and commercially available molecular tests combine these techniques with the following two goals: (1) risk stratification of thyroid nodules based on a positive result; and (2) reduction in cancer risk to an acceptable level for nonsurgical surveillance based

TABLE 397-3 Bethesda Classification for Thyroid Cytology Version 3

DIAGNOSTIC CATEGORY	RISK OF MALIGNANCY (INCLUDING NIFTP) MEAN % (RANGE)
I. Nondiagnostic or unsatisfactory	13 (5–20)
II. Benign	4 (2–7)
III. Atypia of unknown significance (AUS)	22 (13–30)
IV. Follicular neoplasm (FN)	30 (23–34)
V. Suspicious for malignancy (SFM)	74 (67–83)
VI. Malignant	97 (97–100)

Abbreviation: NIFTP, noninvasive follicular thyroid neoplasm with papillary-like nuclear features.

on a negative result. Assuming a 25–30% ROM for nodules with indeterminate cytology, the negative predictive values for the currently validated molecular tests are >95%.

The evaluation of a thyroid nodule is stressful for most patients. They are concerned about the possibility of thyroid cancer, whether verbalized or not. It is constructive, therefore, to review the diagnostic approach and to reassure patients when no malignancy is found. When a suspicious lesion or thyroid cancer is identified, the generally favorable prognosis and available treatment options can be reassuring.

398 Disorders of the Adrenal Cortex

Wiebke Arlt, Alessandro Prete

The adrenal cortex produces three classes of corticosteroid hormones: glucocorticoids (e.g., cortisol), mineralocorticoids (e.g., aldosterone), and adrenal androgen precursors (e.g., dehydroepiandrosterone [DHEA]) **(Fig. 398-1)**. Glucocorticoids and mineralocorticoids act through specific nuclear receptors, regulating aspects of the physiologic stress response as well as blood pressure and electrolyte homeostasis. Adrenal androgen precursors are converted in the gonads and peripheral target cells to sex steroids that act via nuclear androgen and estrogen receptors.

Disorders of the adrenal cortex are characterized by deficiency or excess of one or several of the three major corticosteroid classes. Hormone deficiency can be caused by inherited glandular or enzymatic disorders or by destruction of the pituitary or adrenal gland by autoimmune disorders, infection, infarction, or iatrogenic events such as surgery or hormonal suppression. Hormone excess is usually the result of neoplasia, leading to increased production of adrenocorticotropic hormone (ACTH) by the pituitary or neuroendocrine ectopic ACTH-producing cells or increased production of glucocorticoids, mineralocorticoids, or adrenal androgen precursors by adrenal nodules or hyperplasia. Adrenal nodules are increasingly identified incidentally during cross-sectional imaging of the chest or abdomen performed for other reasons.

ADRENAL ANATOMY AND DEVELOPMENT

The normal adrenal glands weigh 6–11 g each. They are located above the kidneys and have their own blood supply. Arterial blood flows initially to the subcapsular region and then meanders from the outer cortical zona glomerulosa through the intermediate zona fasciculata to the inner zona reticularis and eventually to the adrenal medulla. The right adrenal (or suprarenal) vein drains directly into the vena cava, while the left adrenal vein drains into the left renal vein.

During early embryonic development, the adrenals originate from the urogenital ridge and then separate from gonads and kidneys at about the sixth week of gestation. Concordant with the time of sexual differentiation (seventh to ninth week of gestation, **Chap. 402**), the adrenal cortex starts to produce cortisol and the adrenal sex steroid precursor DHEA. The orphan nuclear receptors SF1 (steroidogenic factor 1; encoded by the gene *NR5A1*) and DAX1 (dosage-sensitive sex reversal gene 1; encoded by the gene *NR0B1*), among others, play a crucial role during this period of development, as they regulate a multitude of adrenal genes involved in steroidogenesis.

REGULATORY CONTROL OF STEROIDOGENESIS

Production of glucocorticoids and adrenal androgens is under the control of the hypothalamic-pituitary-adrenal (HPA) axis, whereas mineralocorticoids are regulated by the renin-angiotensin-aldosterone (RAA) system.

Glucocorticoid synthesis is under inhibitory feedback control by the hypothalamus and the pituitary **(Fig. 398-2)**. Hypothalamic release of corticotropin-releasing hormone (CRH) occurs in response to endogenous or exogenous stress. CRH stimulates the cleavage of the 241–amino acid polypeptide proopiomelanocortin (POMC) by pituitary-specific prohormone convertase 1 (PC1), yielding the 39–amino acid peptide ACTH. ACTH is released by the corticotrope cells of the anterior pituitary and acts as the pivotal regulator of adrenal cortisol synthesis, with additional short-term effects on mineralocorticoid and adrenal androgen synthesis. The release of CRH, and subsequently ACTH, occurs in a pulsatile fashion that follows a circadian rhythm under the control of the hypothalamus, specifically its suprachiasmatic nucleus (SCN), with additional regulation by a complex network of cell-specific clock genes. The circadian release of ACTH is mostly regulated by the CRH, but arginine-vasopressin (AVP) also exerts a secretagogue role. Reflecting the pattern of ACTH secretion, adrenal cortisol secretion exhibits a distinct circadian rhythm, starting to rise in the early morning hours prior to awakening, with peak levels in the morning and low levels in the evening **(Fig. 398-3)**.

Diagnostic tests assessing the HPA axis make use of the fact that it is regulated by negative feedback. Glucocorticoid excess is diagnosed by employing a dexamethasone suppression test. Dexamethasone, a potent synthetic glucocorticoid, suppresses CRH/ACTH by binding hypothalamic-pituitary glucocorticoid receptors (GRs) and, therefore, results in downregulation of endogenous cortisol synthesis. Various versions of the dexamethasone suppression test are described in detail in **Chap. 392**. If cortisol production is autonomous (e.g., adrenal nodule), ACTH is already suppressed, and dexamethasone has little additional effect. If cortisol production is driven by an ACTH-producing pituitary adenoma, dexamethasone suppression is ineffective at lower doses but usually induces suppression at higher doses. If cortisol production is driven by an ectopic source of ACTH, the tumors are usually resistant to dexamethasone suppression. Thus, the dexamethasone suppression test is useful to establish the diagnosis of Cushing's syndrome and assist with the differential diagnosis of cortisol excess.

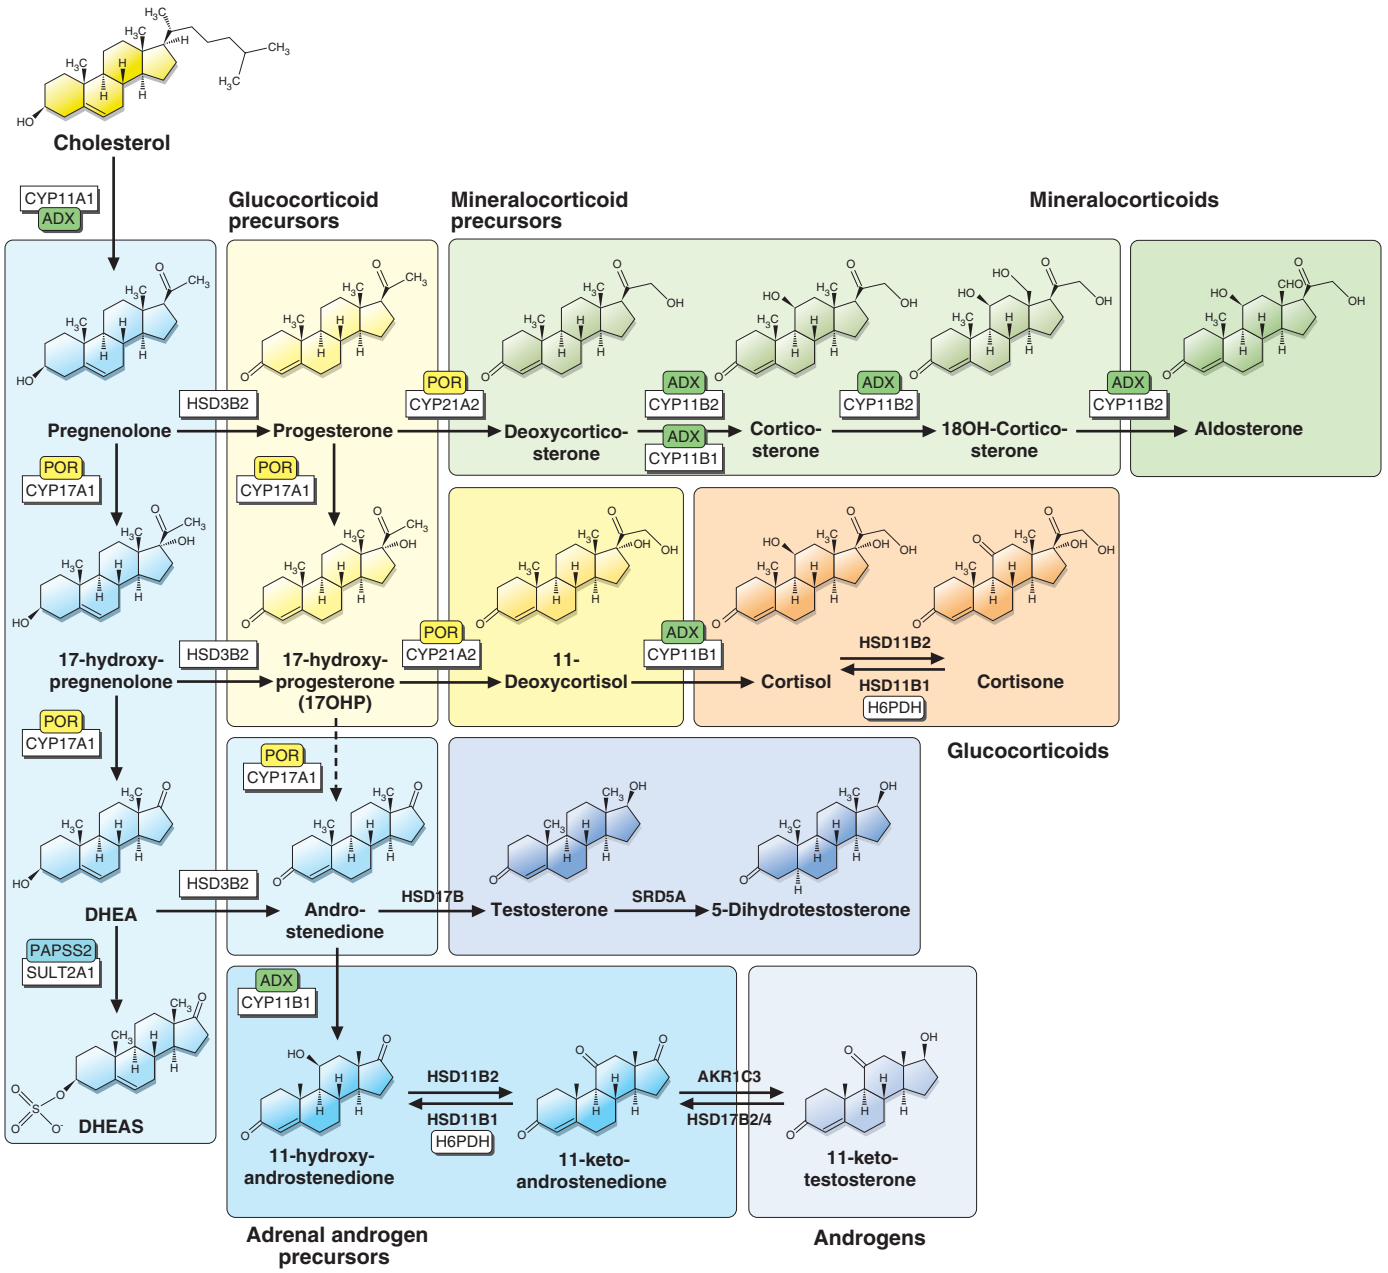

FIGURE 398-1 Adrenal steroidogenesis. ADX, adrenodoxin; AKR1C3, aldo-keto reductase 1C3; CYP11A1, side chain cleavage enzyme; CYP11B1, 11β-hydroxylase; CYP11B2, aldosterone synthase; CYP17A1, 17α-hydroxylase/17,20 lyase; CYP21A2, 21-hydroxylase; DHEA, dehydroepiandrosterone; DHEAS, dehydroepiandrosterone sulfate; H6PDH, hexose-6-phosphate dehydrogenase; HSD11B1, 11β-hydroxysteroid dehydrogenase type 1; HSD11B2, 11β-hydroxysteroid dehydrogenase type 2; HSD17B, 17β-hydroxysteroid dehydrogenase; HSD3B2, 3β-hydroxysteroid dehydrogenase type 2; PAPSS2, PAPS synthase type 2; POR, P450 oxidoreductase; SRD5A, 5α-reductase; SULT2A1, DHEA sulfotransferase.

Conversely, to assess glucocorticoid deficiency, ACTH stimulation of cortisol production is used. The ACTH peptide contains 39 amino acids, but the first 24 are sufficient to elicit a physiologic response. The standard ACTH stimulation test involves the administration of cosyntropin (ACTH 1-24), 250 μg IM or IV, and collection of blood samples at 0, 30, and optionally 60 min for cortisol. A normal response is defined as a cortisol level >15–20 μg/dL (>400–550 nmol/L) 30–60 min after cosyntropin stimulation, with the precise cutoff dependent on the assay used. A low-dose (1 μg cosyntropin IV) version of this test has been advocated; however, it has no superior diagnostic value and is more cumbersome to carry out due to the lack of commercially available preparations of 1 μg cosyntropin. Alternatively, an insulin tolerance test (ITT) can be used to assess adrenal function. It involves injection of insulin to induce hypoglycemia, which represents a strong stress signal that triggers hypothalamic CRH release and activation of the entire HPA axis. The ITT involves administration of regular insulin 0.1 U/kg IV (dose should be lower if hypopituitarism is likely) and collection of blood samples at 0, 30, 60, and 120 min for glucose, cortisol, and growth hormone (GH), if also assessing the GH axis. Oral or IV glucose is administered after the patient has achieved symptomatic hypoglycemia (usually plasma glucose <40 mg/dL). A normal response is defined as a cortisol >20 μg/dL and GH >5.1 μg/L, again with assay-specific cutoff variability. The ITT requires careful clinical monitoring and sequential measurements of glucose. It is contraindicated in patients with coronary disease, cerebrovascular disease, or seizure disorders, which has made the cosyntropin test the commonly accepted first-line test. The overnight metyrapone test is alternatively used in some centers: metyrapone—a drug blocking the conversion of 11-deoxycortisol to cortisol by 11β-hydroxylase (see treatment of Cushing's syndrome)—is administered orally at midnight (2500 mg or 30 mg/kg). In healthy individuals, the decrease in cortisol stimulates CRH and ACTH production, resulting in an increase in 11-deoxycortisol. A normal response consists of an early morning serum 11-deoxycortisol concentration >287 nmol/L (10 μg/dL). The use of home-waking salivary cortisone as a measure of adrenal cortisol reserve looks highly promising and represents a potential alternative noninvasive test that can be undertaken at home.

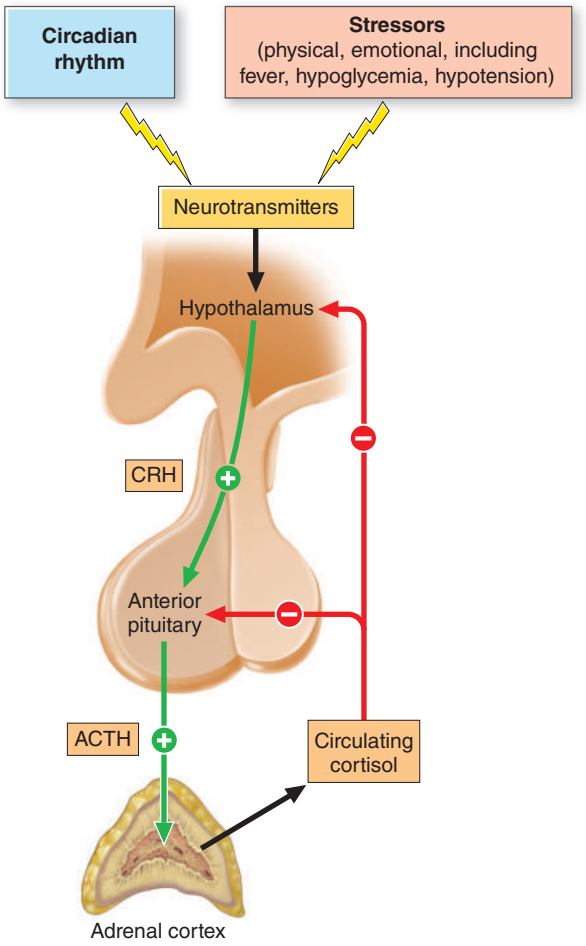

FIGURE 398-2 Regulation of the hypothalamic-pituitary-adrenal (HPA) axis. ACTH, adrenocorticotropic hormone; CRH, corticotropin-releasing hormone.

Mineralocorticoid production is controlled by the RAA regulatory cycle, which is initiated by the release of the enzyme renin from the juxtaglomerular cells in the kidney, resulting in cleavage of hepatic angiotensinogen to angiotensin I (Fig. 398-4). The angiotensin-converting enzyme (ACE) cleaves angiotensin I to angiotensin II, which binds and activates the angiotensin II receptor type 1 (AT1 receptor [AT1R]), resulting in increased adrenal aldosterone production and vasoconstriction. Aldosterone enhances renal sodium retention and potassium excretion resulting in volume expansion and increased renal perfusion, which in turn regulates renin release. Because mineralocorticoid synthesis is primarily under the control of the RAA system, hypothalamic-pituitary damage does not significantly impact the capacity of the adrenal to synthesize aldosterone.

Similar to the HPA axis, the assessment of the RAA system can be used for diagnostic purposes. If mineralocorticoid excess is present, there is a counterregulatory downregulation of plasma renin (see below for testing). Conversely, in mineralocorticoid deficiency, plasma renin is markedly increased. Physiologically, oral or IV sodium loading results in suppression of aldosterone, a response that is attenuated or absent in patients with autonomous mineralocorticoid excess.

STEROID HORMONE BIOSYNTHESIS, METABOLISM, AND ACTION

ACTH stimulation is required for the initiation of steroidogenesis. The ACTH receptor MC2R (melanocortin 2 receptor) interacts with the MC2R-accessory protein MRAP, and the complex is transported to the adrenocortical cell membrane, where it binds to ACTH (Fig. 398-5). ACTH stimulation generates cyclic AMP (cAMP), which upregulates the protein kinase A (PKA) signaling pathway. Inactive PKA is a tetramer of two regulatory and two catalytic subunits that is dissociated by cAMP into a dimer of two regulatory subunits bound to cAMP and two free and active catalytic subunits. PKA activation impacts steroidogenesis in three distinct ways: (1) increases the import of cholesterol esters; (2) increases the activity of hormone-sensitive lipase, which cleaves cholesterol esters to cholesterol for import into the mitochondrion; and (3) increases the availability and phosphorylation of CREB (cAMP response element binding), a transcription factor that enhances transcription of CYP11A1 and other enzymes required for glucocorticoid synthesis.

Adrenal steroidogenesis occurs in a zone-specific fashion, with mineralocorticoid synthesis occurring in the outer zona glomerulosa, glucocorticoid synthesis in the zona fasciculata, and adrenal androgen biosynthesis in the inner zona reticularis serving as precursors for both classic and 11-oxygenated androgens (Fig. 398-1). All steroidogenic pathways require cholesterol import into the mitochondrion, a process initiated by the action of the steroidogenic acute regulatory (StAR) protein, which shuttles cholesterol from the outer to the inner mitochondrial membrane. The majority of steroidogenic enzymes are cytochrome P450 (CYP) enzymes, which are either located in the mitochondrion (side chain cleavage enzyme, CYP11A1; 11β-hydroxylase, CYP11B1; aldosterone synthase, CYP11B2) or in the endoplasmic reticulum membrane (17α-hydroxylase, CYP17A1; 21-hydroxylase, CYP21A2; aromatase, CYP19A1). These enzymes require electron donation via specific redox cofactor enzymes, P450 oxidoreductase (POR), and adrenodoxin/adrenodoxin reductase (ADX/ADR) for the microsomal and mitochondrial CYP enzymes, respectively. In addition, the short-chain dehydrogenase 3β-hydroxysteroid dehydrogenase type 2 (3β-HSD2), also termed Δ4, Δ5 isomerase, plays a major role in adrenal steroidogenesis.

The cholesterol side chain cleavage enzyme CYP11A1 generates pregnenolone. Glucocorticoid synthesis requires conversion of pregnenolone to progesterone by 3β-HSD2, followed by conversion to 17-hydroxyprogesterone (17OHP) by CYP17A1, further hydroxylation at carbon 21 by CYP21A2, and eventually, 11β-hydroxylation by CYP11B1 to generate active cortisol (Fig. 398-1). Mineralocorticoid synthesis also requires progesterone, which is first converted to deoxycorticosterone (DOC) by CYP21A2 and then converted via corticosterone and 18-hydroxycorticosterone to aldosterone in three steps catalyzed by CYP11B2. For adrenal androgen synthesis, pregnenolone undergoes conversion by CYP17A1, which uniquely catalyzes two enzymatic reactions. Via its 17α-hydroxylase activity, CYP17A1

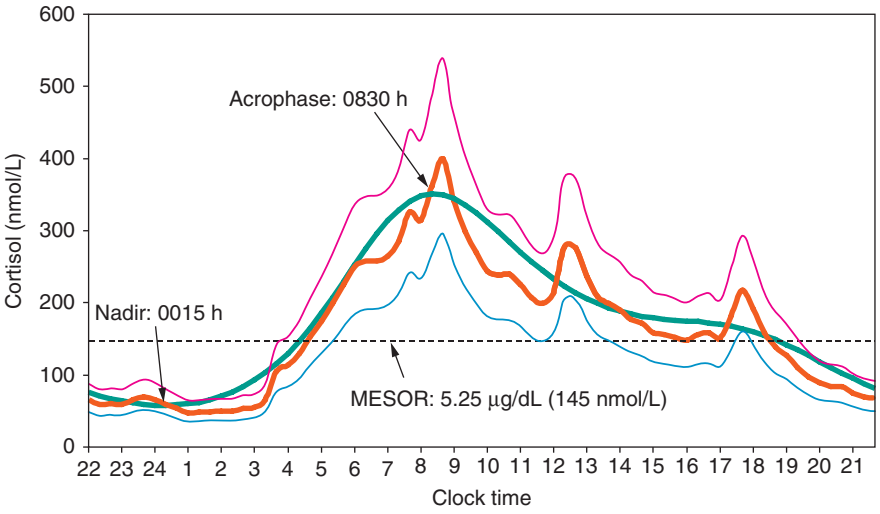

FIGURE 398-3 Physiologic cortisol circadian rhythm. Circulating cortisol concentrations (geometrical mean ± standard deviation values and fitted cosinor) drop under the rhythm-adjusted mean (MESOR) in the early evening hours, with nadir levels around midnight and a rise in the early morning hours; peak levels are observed ~8:30 A.M. (acrophase). *(Reproduced with permission from M Debono et al: Modified-release hydrocortisone to provide circadian cortisol profiles. J Clin Endocrinol Metab 94:1548, 2009.)*

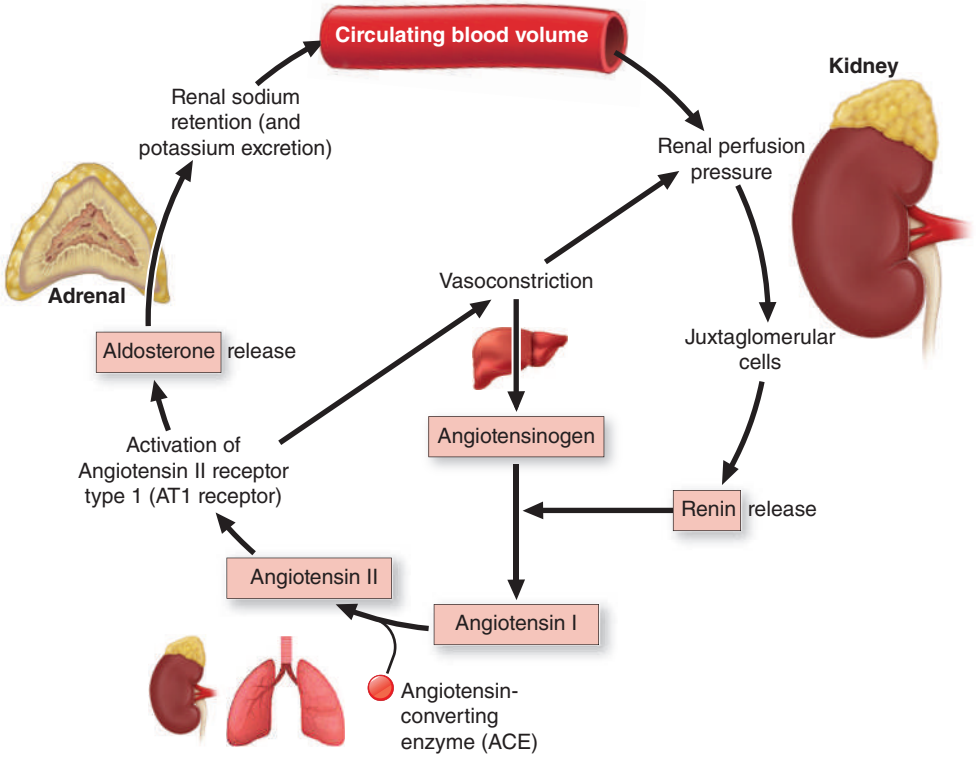

FIGURE 398-4 Regulation of the renin-angiotensin-aldosterone (RAA) system.

converts pregnenolone to 17-hydroxypregnenolone, followed by generation of the universal sex steroid precursor DHEA via CYP17A1 17,20 lyase activity. The majority of DHEA is secreted by the adrenal in the form of its sulfate ester, DHEAS, generated by DHEA sulfotransferase (SULT2A1). DHEA is converted to androstenedione, which can be activated to testosterone or channeled into the 11-oxygenated androgen pathway by 11β-hydroxylation (CYP11B1).

Following its release from the adrenal, cortisol circulates in the bloodstream mainly bound to cortisol-binding globulin (CBG) and, to a lesser extent, to albumin, with only a minor fraction circulating as free, unbound hormone. Free cortisol is thought to enter cells directly, not requiring active transport. In addition, in a multitude of peripheral target tissues of glucocorticoid action, including adipose, liver, muscle, and brain, cortisol is generated from inactive cortisone within the cell by the enzyme 11β-hydroxysteroid dehydrogenase type 1 (11β-HSD1) (Fig. 398-6). Thereby, 11β-HSD1 functions as a tissue-specific prereceptor regulator of glucocorticoid action. For the conversion of inactive cortisone to active cortisol, 11β-HSD1 requires nicotinamide adenine

dinucleotide phosphate (NADPH [reduced form]), which is provided by the enzyme hexose-6-phosphate dehydrogenase (H6PDH). Like the catalytic domain of 11β-HSD1, H6PDH is located in the lumen of the endoplasmic reticulum and converts glucose-6-phosphate (G6P) to 6-phosphogluconate (6PGL), thereby regenerating $NADP^+$ to NADPH, which drives the activation of cortisol from cortisone by 11β-HSD1.

In the cytosol of target cells, cortisol binds and activates the GR, which results in dissociation of heat shock proteins (HSPs) from the receptor and subsequent dimerization (Fig. 398-6). Cortisol-bound GR dimers translocate to the nucleus and activate glucocorticoid response elements (GREs) in the DNA sequence, thereby enhancing transcription of glucocorticoid-regulated genes (GR transactivation). However, cortisol-bound GR can also form heterodimers with transcription factors such as AP-1 or nuclear factor-κB (NF-κB), resulting in transrepression of proinflammatory genes, a mechanism of major importance for the anti-inflammatory action of glucocorticoids. It is important to note that corticosterone also exerts glucocorticoid activity, albeit much weaker than cortisol itself. However, in rodents, corticosterone is the major glucocorticoid, and in patients with 17-hydroxylase deficiency, lack of cortisol can be compensated for by higher concentrations of corticosterone that accumulates as a consequence of the enzymatic block.

Cortisol is inactivated to cortisone by the microsomal enzyme 11β-hydroxysteroid dehydrogenase type 2 (11β-HSD2) **(Fig. 398-7)**, mainly in the kidney, but also in the colon, salivary glands, and other mineralocorticoid target tissues. Cortisol and aldosterone bind the mineralocorticoid receptor (MR) with equal affinity; however, cortisol circulates in the bloodstream at about a 1000-fold higher concentration. Thus, only rapid inactivation of cortisol to cortisone by 11β-HSD2 prevents MR activation by excess cortisol, thereby acting as a tissue-specific modulator of the MR pathway. In addition to cortisol and aldosterone, DOC (Fig. 398-1) also exerts mineralocorticoid activity. DOC accumulation due to 11β-hydroxylase deficiency or due to tumor-related excess production can result in mineralocorticoid excess.

Aldosterone synthesis in the adrenal zona glomerulosa cells is driven by the enzyme aldosterone synthase (CYP11B2). The binding of angiotensin II to the AT1 receptor causes glomerulosa cell membrane depolarization by increasing intracellular sodium through inhibition of sodium-potassium (Na^+/K^+) ATPase enzymes as well as potassium channels. This drives an increase in intracellular calcium by opening voltage-dependent calcium channels or inhibition of calcium (Ca^{2+}) ATPase enzymes. Consequently, the calcium signaling pathway is triggered, resulting in upregulation of CYP11B2 transcription **(Fig. 398-8)**.

Analogous to cortisol action via the GR, aldosterone (or cortisol) binding to the MR in the kidney tubule cell dissociates the HSP-receptor complex, allowing homodimerization of the MR and translocation of the hormone-bound MR dimer to the nucleus (Fig. 398-7). The activated MR enhances transcription of the epithelial sodium channel (ENaC) and serum glucocorticoid-inducible kinase 1 (SGK-1). In the cytosol, interaction of ENaC with Nedd4 prevents cell surface expression of ENaC. However, SGK-1 phosphorylates serine residues within the Nedd4 protein, reduces the interaction between Nedd4 and ENaC, and consequently, enhances the trafficking of ENaC to the cell surface, where it mediates sodium retention at the expense of potassium extrusion through the renal outer medullary potassium channel (ROMK) channel.

CUSHING'S SYNDROME

(See also Chap. 392) Cushing's syndrome reflects a constellation of clinical features that result from chronic exposure to excess glucocorticoids of any etiology. The disorder can be ACTH-dependent (e.g., pituitary corticotrope adenoma, ectopic secretion of ACTH by nonpituitary tumor) or ACTH-independent (e.g., adrenocortical adenoma, adrenocortical carcinoma [ACC], nodular adrenal hyperplasia), as well as iatrogenic (e.g., administration of exogenous glucocorticoids to treat various inflammatory conditions). The term *Cushing's disease* refers specifically to Cushing's syndrome caused by a pituitary corticotrope adenoma.

Epidemiology Iatrogenic (or exogenous) Cushing's syndrome is by far the most common etiology, considering that around 1% of the population uses chronic glucocorticoid treatments for their anti-inflammatory and immunosuppressive properties. On the contrary, endogenous Cushing's syndrome is generally considered a rare disease; it occurs with an incidence of 1.8–3.2 per million population per year. However, it is debated whether mild cortisol excess may be more prevalent among patients with features of Cushing's such as centripetal obesity, type 2 diabetes, and osteoporotic vertebral fractures, recognizing that these are relatively nonspecific and common in the population.

Etiology In the overwhelming majority of patients with endogenous Cushing's syndrome, the underlying cause is an ACTH-producing pituitary neuroendocrine tumor, i.e., a corticotrope adenoma **(Table 398-1)**, as initially described by Harvey Cushing in 1912. Cushing's disease more frequently affects women, with the exception of prepubertal cases, where it is more common in boys. By contrast, ectopic

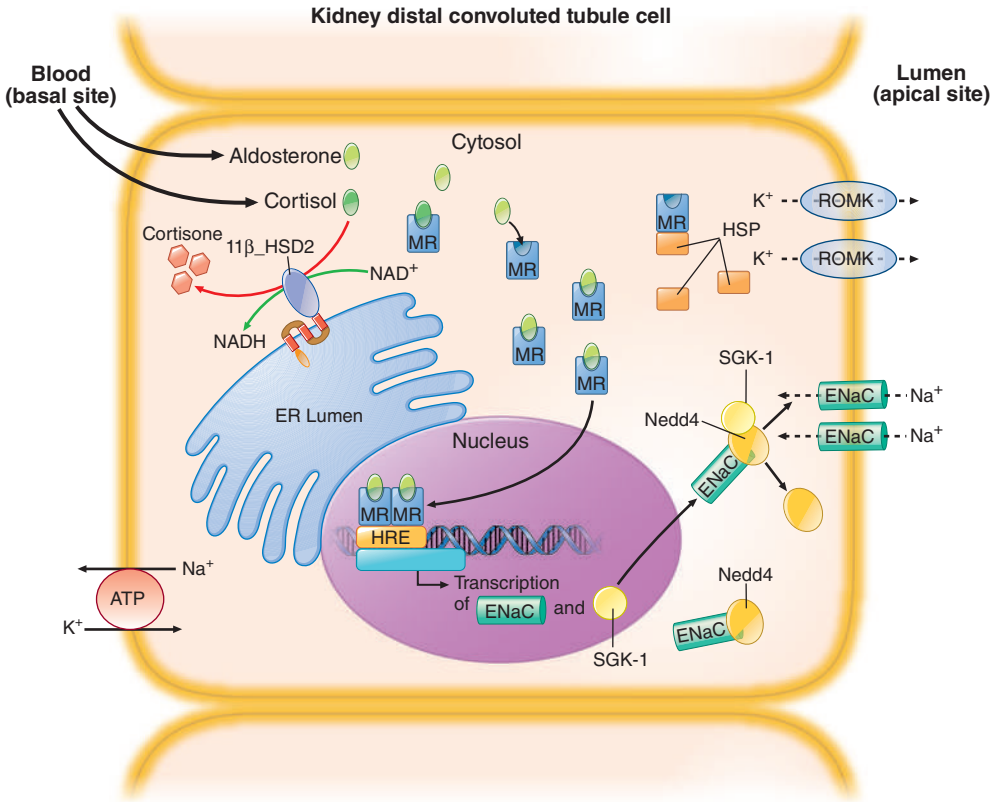

FIGURE 398-7 Prereceptor inactivation of cortisol and mineralocorticoid receptor action. ENaC, epithelial sodium channel; HRE, hormone response element; Na^+/K^+-ATPase, sodium-potassium adenosine triphosphatase; NADH, nicotinamide adenine dinucleotide; ROMK, renal outer medullary potassium channel; SGK-1, serum glucocorticoid-inducible kinase-1.

ACTH syndrome is more frequently identified in men. Only 10% of patients with Cushing's syndrome have a primary, adrenal cause of their disease (i.e., autonomous cortisol excess independent of ACTH), and most of these patients are women.

In at least 90% of patients with Cushing's disease, ACTH excess is caused by a corticotrope pituitary microadenoma, often only a few millimeters in diameter. Pituitary macroadenomas (i.e., tumors >1 cm in size) are found in only 5–10% of patients and may have invasive features and affect the optic chiasm and the cavernous sinuses. Pituitary corticotrope adenomas usually occur sporadically but very rarely can be found in the context of multiple endocrine neoplasia type 1 (MEN 1) **(Chap. 400)**, MEN 4, familial isolated pituitary adenomas, Carney complex, DICER 1 syndrome, and Lynch syndrome. Pituitary adenomas causative of Cushing's disease frequently harbor activating somatic variants in the *USP8* gene, encoding the deubiquitinating enzyme ubiquitin-specific protease 8, which lead to constitutive activation of epidermal growth factor (EGF) signaling and consequent upregulated expression of the ACTH precursor POMC. *USP8* mutations are found in 11–62% of corticotrope adenomas and more frequently in adults and women with Cushing's disease. Less frequently, somatic variants of the glucocorticoid receptor gene (*NR3C1*), *BRAF*, *USP48*, and *TP53* are observed in the tumor tissue of *USP8* wild-type Cushing's disease cases.

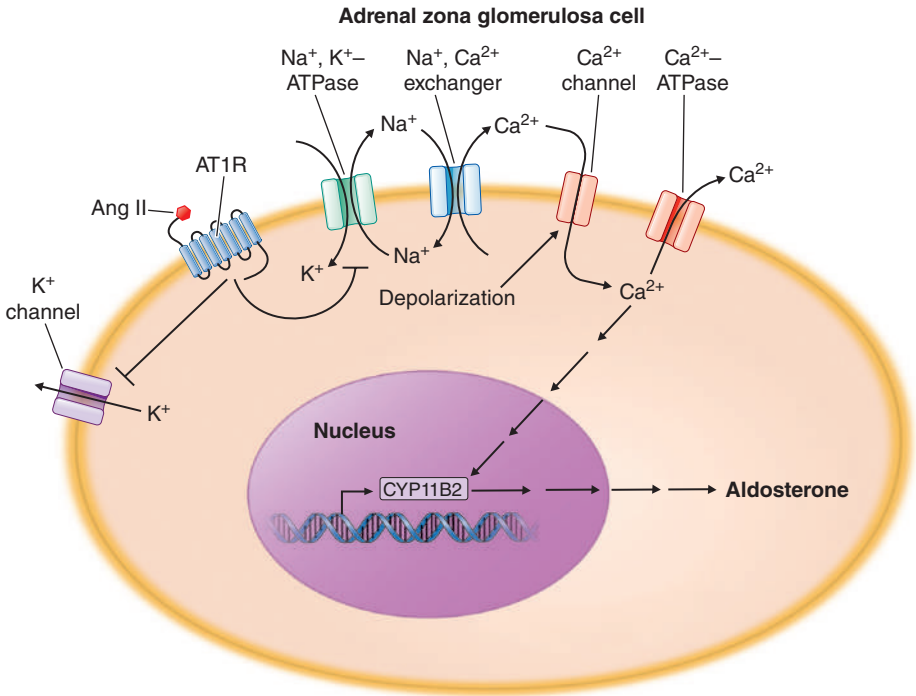

FIGURE 398-8 Regulation of adrenal aldosterone synthesis. Ang II, angiotensin II; AT1R, angiotensin II receptor type 1; CYP11B2, aldosterone synthase.

Ectopic ACTH production is predominantly caused by occult carcinoid tumors, most frequently in the lung, but also in the thymus or pancreas. Because of their small size, these tumors are often difficult to locate. Advanced small-cell lung cancer can cause ectopic ACTH production. In rare cases, ectopic CRH and/or ACTH production has been found to originate from medullary thyroid carcinoma or pheochromocytoma, the latter co-secreting catecholamines and ACTH.

The majority of patients with endogenous ACTH-independent cortisol excess harbor a cortisol-producing adrenal adenoma, and

TABLE 398-1 Causes of Endogenous Cushing's Syndrome

	FEMALE:MALE RATIO	%
ACTH-Dependent Cushing's Syndrome		**90**
Cushing's disease (= ACTH-producing pituitary adenoma)	4:1	75
Ectopic ACTH syndrome (due to ACTH secretion by bronchial or pancreatic carcinoid tumors, small-cell lung cancer, medullary thyroid carcinoma, pheochromocytoma, and others)	1:1	15
ACTH-Independent Cushing's Syndrome	**4:1**	**10**
Adrenocortical adenoma		5–10
Adrenocortical carcinoma		1
Rare causes: macronodular adrenal hyperplasia; primary pigmented nodular adrenal disease (micro- and/or macronodular); McCune-Albright syndrome		<1

Abbreviation: ACTH, adrenocorticotropic hormone.

TABLE 398-2 Signs and Symptoms of Cushing's Syndrome

BODY COMPARTMENT/ SYSTEM	SIGNS AND SYMPTOMS
Body fat	Weight gain, central obesity, rounded face, fat pad on back of neck ("buffalo hump")
Skin	Facial plethora, thin and brittle skin, easy bruising, broad and purple stretch marks, acne, hirsutism
Bone	Osteopenia, osteoporosis (vertebral fractures), decreased linear growth in children
Muscle	Weakness, proximal myopathy (prominent atrophy of gluteal and upper leg muscles with difficulty climbing stairs or getting up from a chair)
Cardiovascular system	Hypertension, hypokalemia, edema, atherosclerosis
Metabolism	Glucose intolerance/diabetes, dyslipidemia
Reproductive system	Decreased libido; in women, amenorrhea (due to cortisol-mediated inhibition of gonadotropin release)
Central nervous system	Irritability, emotional lability, depression, insomnia and disrupted sleep, sometimes cognitive defects; in severe cases, paranoid psychosis
Blood and immune system	Increased susceptibility to infections, increased white blood cell count, eosinopenia, hypercoagulation with increased risk of deep vein thrombosis and pulmonary embolism

activating somatic mutations in the PKA catalytic subunit *PRKACA* have been identified as the cause of disease in 40% of these tumors. Somatic inactivating defects of *PRKAR1A*, encoding one of the regulatory subunits of PKA, and *GNAS*, encoding the stimulatory G protein alpha subunit 1 GNAS-1 (guanine nucleotide-binding protein alpha stimulating activity polypeptide 1), have been observed less frequently in unilateral cortisol-producing adenomas. ACCs may also cause ACTH-independent cortisol excess and are often large, with excess production of several corticosteroid classes.

A rare but notable cause of adrenal cortisol excess is primary bilateral macronodular adrenal hyperplasia (PBMAH) with low circulating ACTH but with evidence for autocrine stimulation of cortisol production via intra-adrenal ACTH production. These hyperplastic nodules are often also characterized by aberrant expression of G protein–coupled receptors not usually found in the adrenal, including receptors for luteinizing hormone, vasopressin, serotonin, interleukin 1, catecholamines, or gastric inhibitory peptide (GIP), the cause of food-dependent Cushing's. Activation of these receptors results in upregulation of PKA signaling, as physiologically occurs with ACTH, with a subsequent increase in cortisol production. A combination of germline and somatic mutations in the tumor-suppressor gene *ARMC5* have been identified as a prevalent cause of Cushing's due to bilateral macronodular adrenal hyperplasia; these patients often present with biochemical evidence of Cushing's but lack specific clinical signs, which develop slowly over decades and accelerate cardiovascular risk. Constitutively activating *PRKACA* mutations and inactivating *KDM1A* variants (lysine-specific histone demethylase 1A) can also be a rare cause of bilateral macronodular adrenal hyperplasia, the latter associated with GIP-dependent Cushing's syndrome. Bilateral macronodular adrenal hyperplasia with cortisol excess has also been described in other familial syndromes: MEN 1, hereditary leiomyomatosis and renal cell cancer (*FH* gene), and familial adenomatous polyposis (*APC* gene).

Germline mutations in *PRKAR1A* are found in patients with primary pigmented nodular adrenal disease (PPNAD) as part of *Carney's complex*, an autosomal dominant multiple neoplasia condition associated with cardiac and cutaneous myxomas, hyperlentiginosis, Sertoli cell tumors, ovarian tumors, breast tumors, thyroid nodules, Schwannomas, and PPNAD. PPNAD can present as micronodular or macronodular hyperplasia, or both. Phosphodiesterases can influence intracellular cAMP and can thereby impact PKA activation. Mutations in *PDE11A* and *PDE8B* have been identified in patients with bilateral adrenal hyperplasia and Cushing's, with and without evidence of PPNAD.

Another rare cause of ACTH-independent Cushing's is *McCune-Albright syndrome*, also associated with polyostotic fibrous dysplasia, unilateral café-au-lait spots, and precocious puberty. McCune-Albright syndrome is caused by *GNAS* activating mutations (Table 398-1; **Chap. 424**).

Clinical Manifestations Glucocorticoids affect almost all cells of the body; thus, signs of cortisol excess impact multiple physiologic systems **(Table 398-2)**, with upregulation of gluconeogenesis, lipolysis, and protein catabolism causing the most prominent features. In addition, excess glucocorticoid secretion overcomes the ability of 11β-HSD2 to rapidly inactivate cortisol to cortisone in the kidney, thereby exerting mineralocorticoid actions, manifest as hypertension, hypokalemia, and edema. Excess glucocorticoids also interfere with central regulatory systems, leading to suppression of gonadotropins with subsequent hypogonadism and amenorrhea and suppression of the hypothalamic-pituitary-thyroid axis, resulting in decreased thyroid-stimulating hormone (TSH) secretion.

The majority of clinical signs and symptoms observed in Cushing's syndrome are relatively nonspecific and include features such as obesity, diabetes, diastolic hypertension, hirsutism, and depression that are commonly found in patients who do not have Cushing's. Therefore, careful clinical assessment is an important aspect of evaluating suspected cases. A diagnosis of Cushing's should be considered when several clinical features are found in the same patient, particularly when more specific features are found or manifest at an unusual age, e.g., osteoporosis in a young patient. Distinct features include thinning and fragility of the skin, with easy bruising and broad (>1 cm), purplish striae **(Fig. 398-9)**, and signs of proximal myopathy, which becomes most obvious when trying to stand up from a chair without the use of hands or when climbing stairs. Clinical manifestations of Cushing's do not differ substantially among the different causes of Cushing's. In ectopic ACTH syndrome, hyperpigmentation of the knuckles, scars, or skin areas exposed to increased friction can be observed (Fig. 398-9) and is caused by stimulatory effects of excess ACTH and other POMC cleavage products on melanocyte pigment production. Furthermore, patients with ectopic ACTH syndrome, and some with ACC as the cause of Cushing's, may have a more rapid onset and progression of clinical signs and symptoms, namely edema, hypokalemia, and hypertension.

Patients with Cushing's syndrome can be acutely endangered by deep vein thrombosis, with subsequent pulmonary embolism, due to a hypercoagulable state associated with cortisol excess. The majority of patients also experience psychiatric symptoms, mostly in the form of anxiety or depression, but acute paranoid or depressive psychosis may occur. Even after cure, long-term health may be affected by persistently impaired health-related quality of life and increased risk of cardiovascular disease and osteoporosis with vertebral fractures, depending on the duration and degree of exposure to significant cortisol excess.

FIGURE 398-9 Clinical features of Cushing's syndrome. ***A.*** Note central obesity and broad, purple stretch marks (***B.*** close-up). ***C.*** Note thin and brittle skin in an elderly patient with Cushing's syndrome. ***D.*** Hyperpigmentation of the knuckles in a patient with ectopic adrenocorticotropic hormone (ACTH) excess.

Diagnosis The most important first step in the management of patients with suspected Cushing's syndrome is to establish the correct diagnosis. Most mistakes in clinical management, leading to unnecessary imaging or surgery, are made because the diagnostic protocol is not followed **(Fig. 398-10)**. This protocol requires establishing the diagnosis of Cushing's beyond doubt prior to employing any tests used for the differential diagnosis of the condition. In principle, after excluding exogenous glucocorticoid use as the cause of clinical signs and symptoms, suspected cases should be tested if there are multiple and progressive features of Cushing's, particularly features with a potentially higher discriminatory value. Exclusion of cortisol excess is also indicated in patients with incidentally discovered adrenal masses.

A diagnosis of Cushing's can be considered as established if the results of several tests are consistently suggestive of Cushing's. These tests may include increased 24-h urinary free cortisol excretion in three separate collections, failure to appropriately suppress morning serum cortisol after overnight exposure to dexamethasone, and evidence of loss of diurnal cortisol secretion with high levels of serum or salivary cortisol at midnight, the time of the physiologically lowest secretion (Fig. 398-10). Factors potentially affecting the outcome of these diagnostic tests have to be excluded such as incomplete 24-h urine collection or rapid inactivation of dexamethasone due to concurrent intake of CYP3A4-inducing drugs (e.g., antiepileptics, rifampicin). Concurrent intake of oral contraceptives that raise CBG and thus total cortisol can cause failure to suppress after dexamethasone. If in doubt, testing should be repeated after 4–6 weeks off oral estrogens. Patients with pseudo-Cushing states, e.g., alcohol-related nonneoplastic hypercortisolism or associated with major depression or morbid obesity, as well as those with cyclic Cushing's syndrome, may require further testing to safely confirm or exclude the diagnosis of Cushing's. In addition, the biochemical assays employed can affect the test results, with specificity representing a common problem with antibody-based assays for the measurement of urinary free cortisol. These assays have been greatly improved by the introduction of highly specific tandem mass spectrometry.

Differential Diagnosis The evaluation of patients with confirmed Cushing's should be carried out by an endocrinologist and begins with the differential diagnosis of ACTH-dependent and ACTH-independent cortisol excess (Fig. 398-10). Generally, plasma ACTH levels are suppressed in cases of autonomous adrenal cortisol excess, consequent to enhanced negative feedback to the hypothalamus and pituitary. By contrast, patients with ACTH-dependent Cushing's have normal or increased plasma ACTH, with very high levels being found in some patients with ectopic ACTH syndrome. Importantly, imaging should only be used after it is established whether the cortisol excess is ACTH-dependent or ACTH-independent because nodules in the pituitary or the adrenal are a common finding in the general population. In patients with confirmed ACTH-independent excess, adrenal imaging is indicated **(Fig. 398-11)**, preferably using an unenhanced computed tomography (CT) scan. This allows assessment of adrenal morphology and also the determination of tumor density, i.e., the attenuation value measured in Hounsfield units (HUs), which helps to distinguish between benign and malignant adrenal lesions (note, this only applies to unenhanced CT; postcontrast CT does not convey this information).

For ACTH-dependent cortisol excess **(Chap. 392)**, a magnetic resonance image (MRI) of the pituitary is the investigation of choice, but it may not show an abnormality in up to 40% of cases because of small tumors below the sensitivity of detection. Characteristically, pituitary corticotrope adenomas fail to enhance following gadolinium administration on T1-weighted MRI images. In all cases of confirmed ACTH-dependent Cushing's, further tests are required for the differential diagnosis of pituitary Cushing's disease and ectopic ACTH syndrome. These tests exploit the fact that most pituitary corticotrope adenomas still display regulatory features, including residual ACTH suppression by high-dose glucocorticoids and responsiveness to CRH or desmopressin, a synthetic analog of vasopressin. In contrast, ectopic sources of ACTH are typically resistant to dexamethasone suppression and unresponsive to CRH or desmopressin (Fig. 398-10). However, it should be noted that a small minority of ectopic ACTH-producing

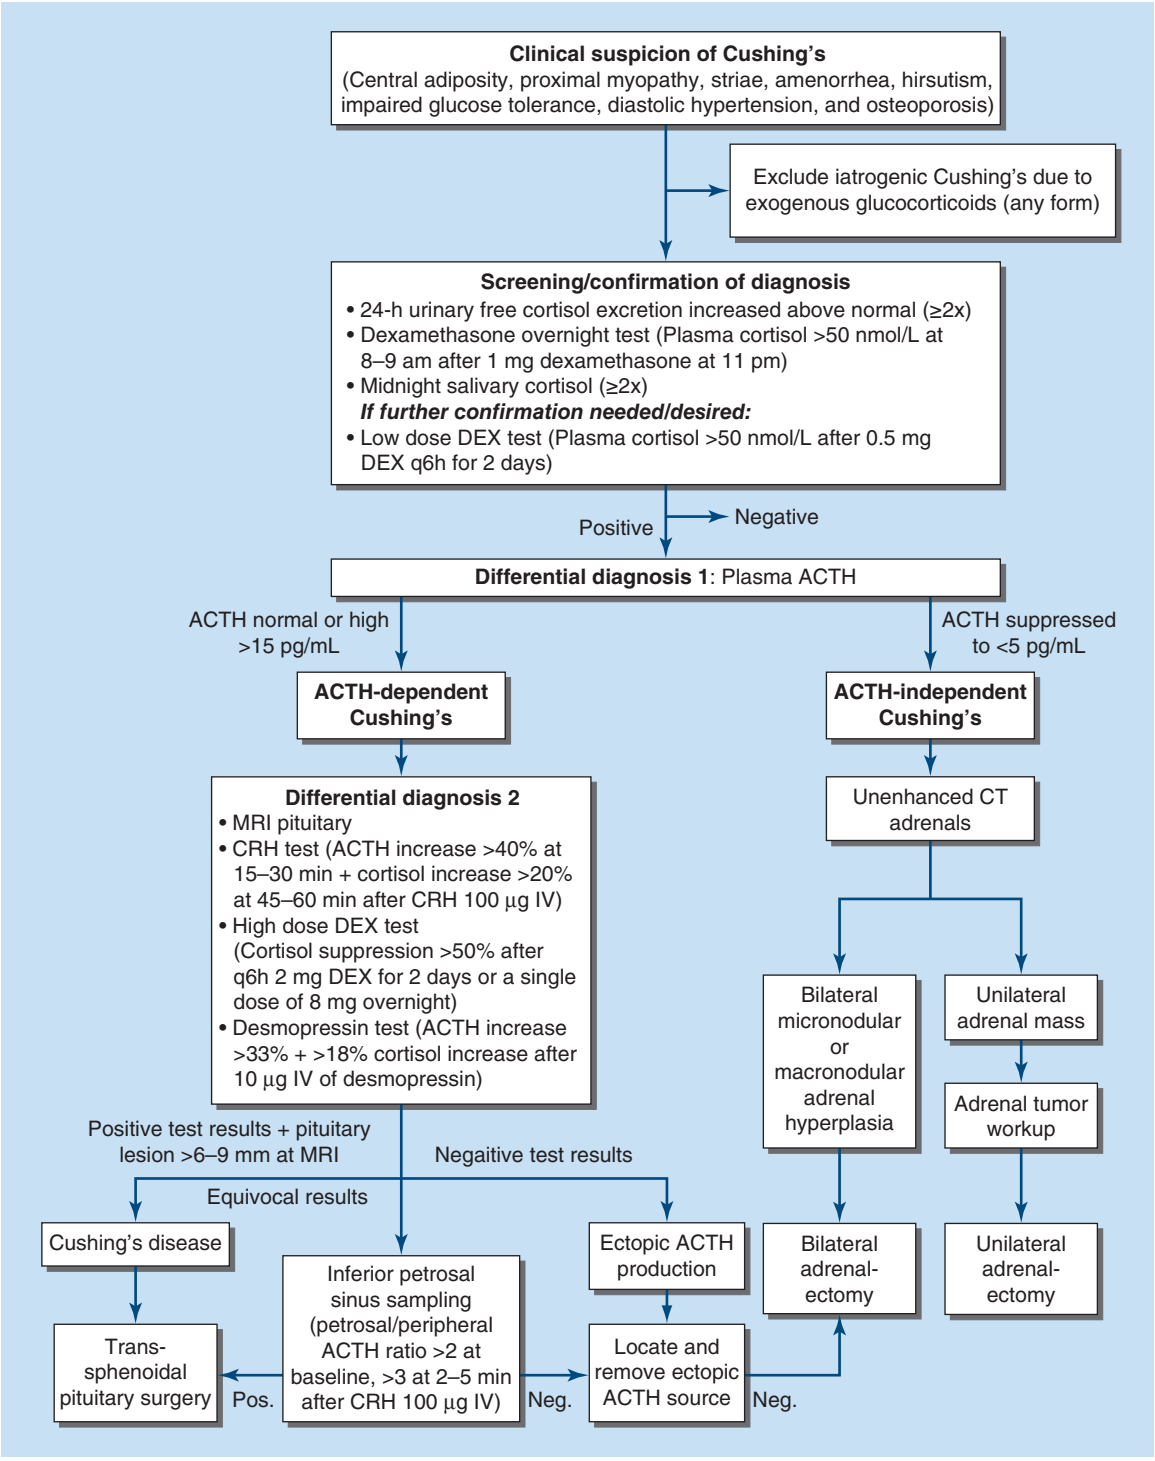

FIGURE 398-10 Management of the patient with suspected Cushing's syndrome. ACTH, adrenocorticotropic hormone; CRH, corticotropin-releasing hormone; CT, computed tomography; DEX, dexamethasone; MRI, magnetic resonance imaging.

tumors exhibit dynamic responses similar to pituitary corticotrope tumors. If the tests show discordant results or if there is any other reason for doubt, the differential diagnosis can be further clarified by performing bilateral inferior petrosal sinus sampling (IPSS) with concurrent blood sampling for ACTH in the right and left inferior petrosal sinus and a peripheral vein. An increased central/peripheral plasma ACTH ratio >2 at baseline and >3 at 2–5 min after CRH injection is indicative of Cushing's disease (Fig. 398-10), with very high sensitivity and specificity. Of note, the results of the IPSS cannot be reliably used for lateralization (i.e., prediction of the location of the tumor within the pituitary) because there is broad interindividual variability in the venous drainage of the pituitary region. Importantly, no cortisol-lowering agents should be used prior to IPSS.

If the differential diagnostic testing indicates ectopic ACTH syndrome, then further imaging should include high-resolution, fine-cut CT scanning of the chest and abdomen for scrutiny of the lung, thymus, and pancreas. If no lesions are identified, an MRI of the chest can be considered because carcinoid tumors usually show high signal intensity on T2-weighted images. Furthermore, octreotide scintigraphy and ^{68}Ga DOTATATE positron emission tomography (PET)/CT can be helpful in some cases because ectopic ACTH-producing tumors often express somatostatin receptors. Depending on the suspected cause, patients with ectopic ACTH syndrome should also undergo blood sampling for fasting gut hormones, chromogranin A, calcitonin, and biochemical exclusion of pheochromocytoma.

TREATMENT

Cushing's Syndrome

Overt Cushing's is associated with a poor prognosis if left untreated. In ACTH-independent disease, treatment consists of surgical removal of the adrenal tumor or nodular hyperplasia. For benign tumors, a minimally invasive laparoscopic approach can be used, whereas for those suspected of malignancy, an open approach is preferred.

In Cushing's disease, the treatment of choice is selective removal of the pituitary corticotrope tumor, usually via an endoscopic transsphenoidal approach. This results in an initial cure rate of 60–80% when performed by a highly experienced surgeon, although remission rates are much lower (12–70%) in patients presenting with larger or invasive tumors. Even after initial remission following surgery, long-term follow-up is important because late relapse occurs in a significant number of patients. If pituitary disease persists after surgery or recurs after initial remission, there are several options including second surgery, fractionated radiotherapy, stereotactic radiosurgery, pharmacologic therapy, and bilateral adrenalectomy. These options need to be applied in a highly individualized fashion.

In some patients with very severe, overt Cushing's (e.g., difficult-to-control hypokalemic hypertension, acute psychosis, or life-threatening infections), it may be necessary to introduce medical therapy to rapidly control the cortisol excess during the period leading up to surgery, which also can help to alleviate hypercoagulability and, thus, operative risk. Similarly, patients with metastasized, glucocorticoid-producing carcinomas may require long-term antiglucocorticoid drug treatment. In the case of ectopic ACTH syndrome, in which the tumor cannot be located, one must carefully weigh whether drug treatment or bilateral adrenalectomy is the most appropriate choice, with the latter facilitating immediate cure but requiring life-long corticosteroid replacement. In this instance, it is paramount to ensure regular imaging follow-up for identification of the ectopic ACTH source.

Oral agents with established efficacy in Cushing's syndrome are osilodrostat, metyrapone, ketoconazole, levoketoconazole, and mifepristone. Osilodrostat and metyrapone inhibit cortisol synthesis at the level of 11β-hydroxylase (Fig. 398-1). The antimycotic drug ketoconazole, and its stereoisomer levoketoconazole, inhibit the early steps of steroidogenesis. Mifepristone is a GR blocker, hence mitigating the effects of cortisol excess on target tissues. Typical starting doses are 1–2 mg bid for osilodrostat (maximum daily dose, 60 mg), 500 mg tid for metyrapone (maximum daily dose, 6 g), 200 mg tid for ketoconazole (maximum daily dose, 1200 mg), 150 mg bid for levoketoconazole (maximum daily dose, 1200 mg), and 300 mg for mifepristone (maximum daily dose, 1200 mg). Mitotane, a derivative of the insecticide o,p'DDD, is an adrenolytic agent that is also effective for reducing cortisol. Because of its side effect profile, it is most commonly used in the context of ACC, but low-dose treatment (500–1000 mg/d) has also been used in benign Cushing's. In severe cases of cortisol excess, etomidate, an agent that potently blocks 11β-hydroxylase and aldosterone synthase, can be used to rapidly lower cortisol. It is administered by continuous IV infusion in low, nonanesthetic doses. For Cushing's disease, the subcutaneous or intramuscular administration of pasireotide, a somatostatin receptor agonist, represents another therapeutic option, if surgical cure cannot be achieved. The dopamine agonist cabergoline is also used off-label to treat certain patients with Cushing's disease, especially those with mild cortisol excess and/or residual tumor due to the potential for tumor shrinkage.

After the successful removal of an ACTH- or cortisol-producing tumor, the HPA axis will remain suppressed. Thus, hydrocortisone replacement needs to be initiated at the time of surgery and slowly tapered following recovery, to allow physiologic adaptation to normal cortisol levels. Depending on the degree and duration of cortisol excess, the HPA axis may require many months or even years to resume normal function and sometimes does not recover. Generally, ectopic ACTH syndrome shows the best recovery rate (80%; median time to recovery 7 months) and adrenal Cushing's has the lowest (40%; median time to recovery 30 months), with Cushing's disease intermediate (60%; median time to recovery 17 months).

PRIMARY MINERALOCORTICOID EXCESS

Epidemiology Following the first description of a patient with an aldosterone-producing adrenal adenoma (*Conn's syndrome*), mineralocorticoid excess was thought to represent a rare cause of hypertension. However, in studies systematically screening all patients with hypertension, a much higher prevalence is now recognized, ranging from 5 to 12%. The prevalence is higher when patients are preselected for hypokalemic hypertension or drug-resistant hypertension.

Etiology The most common cause of primary (i.e., adrenal) mineralocorticoid excess is primary aldosteronism, reflecting excess production of aldosterone by the adrenal zona glomerulosa. Traditionally, the main subtypes of the disease are bilateral primary aldosteronism due to bilateral micronodular adrenal hyperplasia (the most common form) and unilateral aldosterone-producing adenoma (Conn's syndrome) (Table 398-3). Although recent evidence has shown that primary aldosteronism exists on a spectrum blurring the line between bilateral and unilateral forms, their binary distinction underpins clinical management because unilateral forms are amenable to potentially curative surgery, whereas mineralocorticoid receptor antagonist therapy is the treatment of choice for bilateral forms. Somatic mutations in channels and enzymes responsible for increasing sodium and calcium influx in adrenal zona glomerulosa cells have been identified as prevalent causes of aldosterone-producing adrenal adenomas (Table 398-3) and, in the case of germline mutations, also of familial forms of primary aldosteronism. Sporadic bilateral adrenal hyperplasia as a cause of mineralocorticoid excess is usually micronodular but can also contain larger nodules that might be mistaken for a unilateral adenoma. Genetic forms of primary aldosteronism, which account for up to 6% of cases, should be suspected in patients with severe hypertension diagnosed

TABLE 398-3 Causes of Primary Mineralocorticoid Excess

CAUSES OF PRIMARY MINERALOCORTICOID EXCESS	MECHANISM	%
Sporadic Primary Aldosteronism		**94–99**
Adrenal (Conn's) adenoma	Autonomous aldosterone excess can be caused by somatic (intratumor) mutations in the potassium channel GIRK4 (encoded by *KCNJ5*; identified as cause of disease in 40–70% of aldosterone-producing adenomas and associated with overproduction of hybrid steroids). Further causes include somatic mutations affecting the α-subunit of the Na^+/K^+-ATPase (encoded by *ATP1A1*), the plasma membrane calcium-transporting ATPase 3 (encoded by *ATP2B3*), the voltage-gated calcium channel CaV1.3 and CaV3.2 (encoded by *CACNA1D* and *CACNA1H*, respectively), and the ClC-2 chloride channel (encoded by *CLCN2*). All mutations result in the upregulation of CYP11B2 and hence aldosterone synthesis. Rarely, somatic mutations affecting β-catenin (encoded by *CTNNB1*) have been observed alone or in combination with *CACNA1D* mutations and are presumed to promote an increase in the number of aldosterone-producing cells.	30–40
Bilateral adrenal hyperplasia	Bilateral autonomous aldosterone excess due to aldosterone-producing diffuse hyperplasia and/or multiple aldosterone-producing micronodules. *CACNA1D* somatic mutations have been described in 58% of aldosterone-producing micronodules of patients with bilateral aldosterone excess who underwent unilateral adrenalectomy as a nonstandard treatment.	60–70
Familial Primary Aldosteronism		**1–6**
Type 1 (also known as glucocorticoid-remediable hyperaldosteronism or dexamethasone-suppressible hyperaldosteronism)	Autosomal dominant. Crossover between the *CYP11B1* and *CYP11B2* genes results in ACTH-driven aldosterone production. Characterized by severe hypertension in childhood or young adults (often <20 years), with a high risk of cardiovascular events including hemorrhagic stroke at a young age due to ruptured intracranial aneurysm. Analysis of adrenal steroidogenesis shows overproduction of hybrid steroids.	
Type 2	Autosomal dominant. The most common form (1–6% of adults with primary aldosteronism). Due to germline *CLCN2* mutations. Variable phenotypic presentation, which typically includes early-onset hypertension.	
Type 3	Autosomal dominant. Germline *KCNJ5* mutations. Characterized by severe early-onset hypertension (<20 years) with massive bilateral macronodular adrenal hyperplasia. Analysis of adrenal steroidogenesis shows overproduction of hybrid steroids.	
Type 4	Autosomal dominant. Germline *CACNA1H* mutations. Characterized by severe early-onset hypertension (<20 years), which can be associated with developmental disorders in some cases.	
Primary aldosteronism, seizures, and neurologic abnormalities (PASNA)	De novo *CACNA1D* mutations. Characterized by childhood-onset hypertension, seizures, neurologic abnormalities, congenital hyperinsulinism, and cardiac abnormalities.	
Other Causes (Rare)		**<1**
Syndrome of apparent mineralocorticoid excess (SAME)	Mutations in *HSD11B2* result in lack of renal inactivation of cortisol to cortisone, leading to excess activation of the MR by cortisol (inhibition of 11β-hydroxysteroid dehydrogenase type 2 by excess licorice ingestion can have similar effects).	
Cushing's syndrome	Cortisol excess overcomes the capacity of HSD11B2 to inactivate cortisol to cortisone, consequently flooding the MR.	
Glucocorticoid resistance	Upregulation of cortisol production due to GR mutations results in flooding of the MR by cortisol.	
Adrenocortical carcinoma	Autonomous aldosterone and/or DOC excess.	
Congenital adrenal hyperplasia	Accumulation of DOC due to mutations in *CYP11B1* or *CYP17A1*.	
Progesterone-induced hypertension	Progesterone acts as an abnormal ligand due to mutations in the MR gene.	
Liddle's syndrome	Mutant ENaC β or γ subunits resulting in reduced degradation of ENaC keeping the membrane channel in open conformation for longer, enhancing mineralocorticoid action.	

Abbreviations: ACTH, adrenocorticotropic hormone; DOC, deoxycorticosterone; ENaC, epithelial sodium channel; GR, glucocorticoid receptor; HSD11B2, 11β-hydroxysteroid dehydrogenase type 2; MR, mineralocorticoid receptor.

during childhood or young adulthood (Table 398-3). In rare instances, primary aldosteronism is caused by an ACC. Carcinomas should be considered in younger patients and in those with larger tumors because benign aldosterone-producing adenomas usually measure <2 cm in diameter.

A rare cause of aldosterone excess is glucocorticoid-remediable aldosteronism (GRA), or type 1 familial primary aldosteronism, which is caused by a chimeric gene resulting from the crossover of promoter sequences between the *CYP11B1* and *CYP11B2* genes that are involved in glucocorticoid and mineralocorticoid synthesis, respectively (Fig. 398-1). This rearrangement brings *CYP11B2* transcription under the control of ACTH receptor signaling; consequently, aldosterone production is regulated by ACTH rather than by renin. The family history can be helpful because there may be evidence for dominant transmission of hypertension. Recognition of the disorder is important because it can be associated with early-onset hypertension and strokes. In addition, glucocorticoid suppression can reduce aldosterone production. The adrenal glands of patients with GRA produce high levels of the hybrid steroids 18-oxocortisol and 18-hydroxycortisol due to the coexistence of CYP11B1 and CYP11B2 enzymatic activities in the same steroidogenic cells, which are normally segregated to the zona fasciculata and glomerulosa, respectively. Similarly, high hybrid steroid levels are observed in patients with aldosterone-producing adenomas harboring somatic *KCNJ5* mutations (encoding the potassium channel GIRK4) and type 3 familial primary aldosteronism due to germline *KCNJ5* mutations (Table 398-3). Hybrid steroids are produced by normal adrenal glands in very low concentrations and can therefore be measured in the blood and urine to identify these conditions.

Other rare causes of primary mineralocorticoid excess are listed in Table 398-3. An important cause is excess binding and activation of the MR by a steroid other than aldosterone. Cortisol acts as a potent mineralocorticoid if it escapes efficient inactivation to cortisone by 11β-HSD2 in the kidney (Fig. 398-7). This can be caused by inactivating mutations in the *HSD11B2* gene resulting in the syndrome of apparent mineralocorticoid excess (SAME) that characteristically manifests with severe hypokalemic hypertension in childhood. However, milder mutations may cause normokalemic hypertension manifesting in adulthood (type II SAME). Inhibition of 11β-HSD2 by excess licorice ingestion also results in hypokalemic hypertension, as does overwhelming of 11β-HSD2 conversion capacity by cortisol excess in Cushing's syndrome. DOC also binds and activates the MR and can cause hypertension if its circulating concentrations are increased. This can arise through autonomous DOC secretion by an ACC, but also when DOC accumulates as a consequence of an adrenal enzymatic block, as seen in congenital adrenal hyperplasia (CAH) due to CYP11B1 (11β-hydroxylase) or CYP17A1 (17α-hydroxylase) deficiency (Fig. 398-1). Progesterone can cause hypokalemic hypertension in rare individuals who harbor a MR mutation that enhances binding and activation by progesterone; physiologically, progesterone normally exerts antimineralocorticoid activity. Finally, excess mineralocorticoid activity can be caused by mutations in the β or γ subunits of the ENaC, disrupting its interaction with Nedd4 (Fig. 398-7), and thereby decreasing receptor internalization and degradation. The constitutively active ENaC drives hypokalemic hypertension, resulting in an autosomal dominant disorder termed *Liddle's syndrome*.

Clinical Manifestations Excess activation of the MR leads to potassium depletion and increased sodium retention, with the latter causing an expansion of extracellular and plasma volume. Increased ENaC activity also results in hydrogen depletion, which can cause metabolic alkalosis. Aldosterone also has direct effects on the vascular system, where it increases cardiac remodeling and decreases compliance. Aldosterone excess may cause direct damage to the myocardium and the kidney glomeruli, in addition to secondary damage due to systemic hypertension.

The clinical hallmark of mineralocorticoid excess is hypokalemic hypertension; however, only 10–40% of patients with primary aldosteronism exhibit hypokalemia. Serum sodium tends to be normal due to the concurrent fluid retention, which in some cases can lead to peripheral edema. Hypomagnesemia is also a common finding. Hypokalemia can be exacerbated by thiazide drug treatment, which leads to increased delivery of sodium to the distal renal tubule, thereby driving potassium excretion. Severe hypokalemia can be associated with polyuria, glucose intolerance, muscle weakness, overt proximal myopathy, or even arrhythmias, rhabdomyolysis, and hypokalemic paralysis. Severe alkalosis contributes to muscle cramps and, in severe cases, can cause tetany.

Of note, patients with primary aldosteronism show increased rates of osteoporosis, type 2 diabetes, and cognitive dysfunction. A significant proportion of patients with primary aldosteronism suffer from concurrent mild autonomous cortisol secretion (MACS), a constellation also termed *Connshing syndrome*.

Diagnosis Diagnostic screening for mineralocorticoid excess is not currently recommended for all patients with hypertension but should be restricted to those who exhibit hypertension associated with drug resistance, hypokalemia, an adrenal mass, onset of disease before the age of 40 years, or family history of primary aldosteronism **(Fig. 398-12)**. The accepted screening test is concurrent measurement of plasma renin and aldosterone with subsequent calculation of the aldosterone-renin ratio (ARR) (Fig. 398-12); serum potassium needs to be normalized prior to testing. Stopping antihypertensive medication can be cumbersome, particularly in patients with severe hypertension. Thus, for practical purposes, in the first instance, the patient can remain on the usual antihypertensive medications, with the exception that MR antagonists need to be ceased at least 4–6 weeks prior to ARR measurement. The remaining antihypertensive drugs may also affect the outcome of ARR testing (e.g., beta-blocker treatment can cause false-positive results and ACE/AT1R inhibitors can cause false-negative results in milder cases and may have to be discontinued for 2–4 weeks in case of repeat testing) **(Table 398-4)**. The decision to arrange washout from potentially interfering medications should be individualized.

Current international guidelines suggest a positive ARR screening result is >750 pmol/L per ng/mL per hour, with a concurrently high normal or increased aldosterone (Fig. 398-12). However, lower ARR cutoffs are routinely used in clinical practice since it is increasingly recognized that milder forms of primary aldosteronism may otherwise be missed. Another consideration is that if one relies on the ARR only, the likelihood of a false-positive ARR becomes greater when renin levels are very low. The characteristics of the biochemical assays are also important. Some labs measure plasma renin activity, whereas others measure plasma renin concentrations. Antibody-based assays for the measurement of serum aldosterone lack the reliability of tandem mass spectrometry assays, but these are not yet ubiquitously available.

Diagnostic confirmation of mineralocorticoid excess in a patient with a positive ARR screening result should be undertaken by an endocrinologist as the tests lack optimized validation. The most straightforward is the saline infusion test, which involves the IV administration of 2 L of physiologic saline over a 4-h period. Failure of aldosterone to suppress <170 pmol/L (6 ng/dL) in the seated position or <140 pmol/L (5 ng/dL) in the recumbent position is indicative of autonomous mineralocorticoid excess. Alternative tests are the oral sodium loading test (300 mmol NaCl/d for 3 days) or the fludrocortisone suppression test (0.1 mg q6h with 30 mmol NaCl q8h for 4 days); the latter can be difficult because of the risk of profound hypokalemia and increased hypertension. In patients with overt hypokalemic hypertension, strongly positive ARR, and concurrently increased aldosterone levels, confirmatory testing is usually not necessary.

Differential Diagnosis and Treatment After the diagnosis of hyperaldosteronism is established, the next step is to use adrenal imaging to further assess the cause. Fine-cut CT scanning of the adrenal region is the method of choice because it provides excellent visualization of adrenal morphology, and most aldosterone-producing adenomas are <2 cm. CT will readily identify larger tumors suspicious of malignancy but may miss lesions <5 mm. The differentiation between bilateral micronodular hyperplasia and a unilateral adenoma is only required if a surgical approach is feasible and desired. Consequently, selective adrenal vein sampling (AVS) should only be carried out in

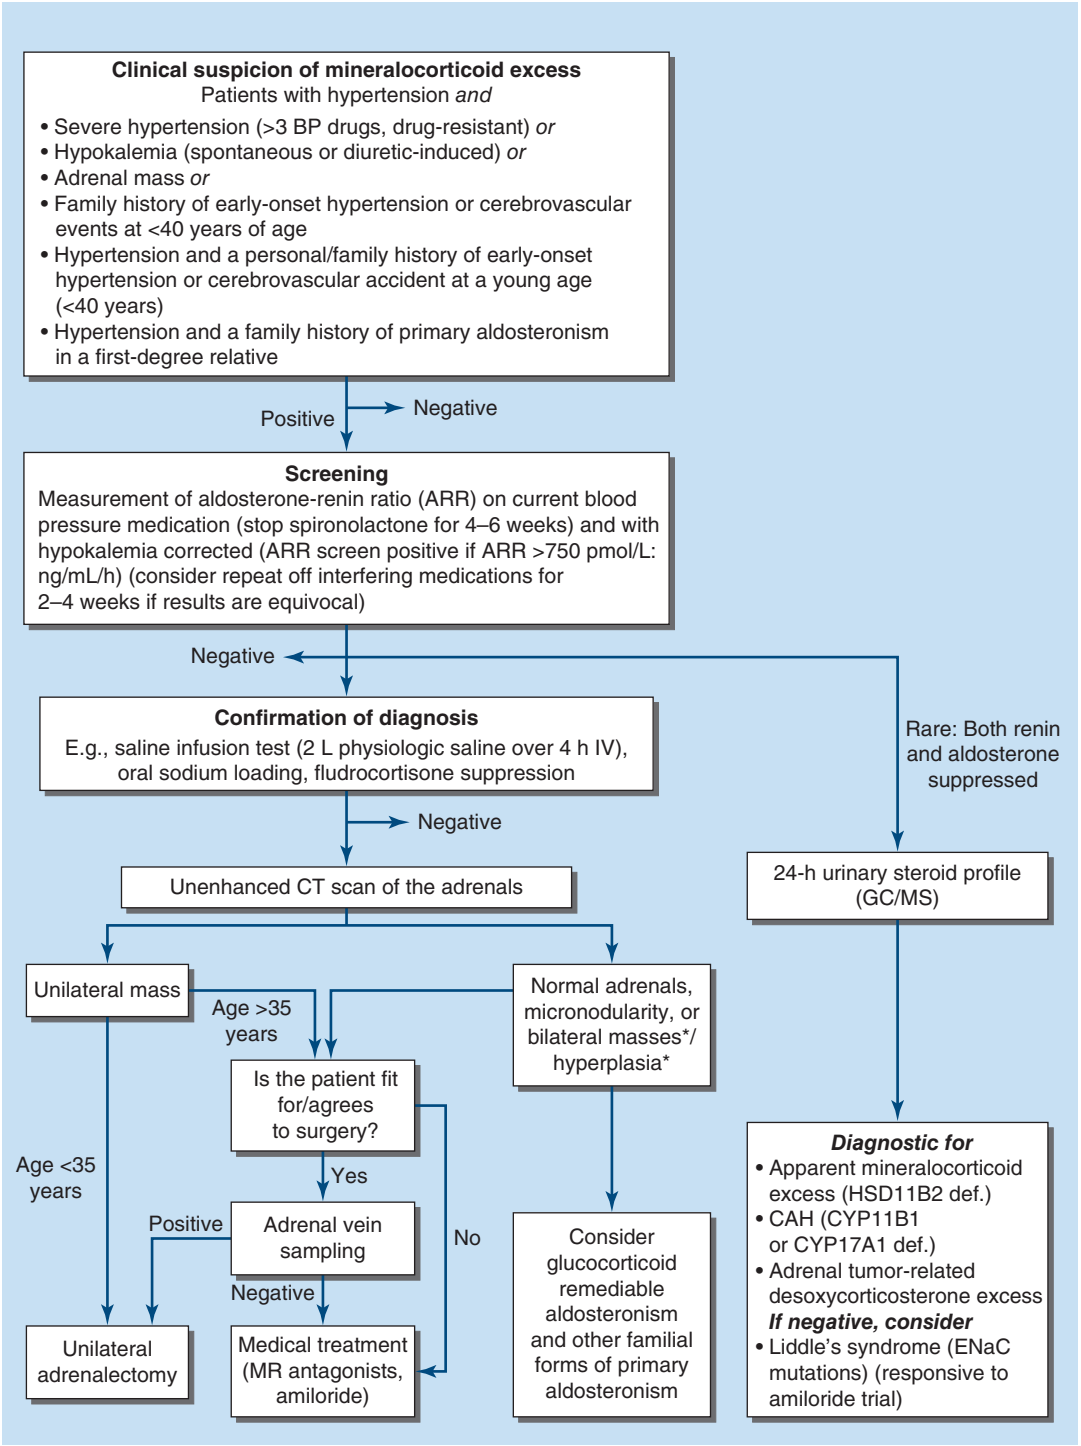

FIGURE 398-12 Management of patients with suspected mineralocorticoid excess. Perform adrenal tumor workup (see Fig. 398-13). TABLE 398-4 Effects of Medications and Other Conditions on the Aldosterone-Renin Ratio (ARR)

EFFECT ON THE ARR	ANTIHYPERTENSIVE DRUGS	OTHER MEDICATIONS	OTHER CONDITIONS
Possible *false-negative* results (due to increase of renin and/or aldosterone)	MR antagonists; diuretics; DHP-calcium antagonists; ACE inhibitors; AT1R blockers; aliskiren[a]	SGLT2 inhibitors; SSRIs	Hypokalemia; dietary salt restriction; malignant hypertension; renovascular hypertension; pregnancy
Possible *false-positive* results (due to reduction of renin and/or aldosterone)	β-Blockers; clonidine; α-methyldopa; aliskiren[a]	NSAIDs; estrogen-containing oral contraceptives	Impaired renal function with hyperkalemia; luteal phase of the menstrual cycle in premenopausal women
Negligible effect	Non-DHP-calcium antagonists; α_1-adrenergic receptor antagonists; hydralazine	/	/

[a]The direct renin inhibitor aliskiren can cause false-negative results if the direct renin concentration is measured, as it causes a reduction of plasma renin activity.

Abbreviations: ACE, angiotensin-converting enzyme; AT1R, angiotensin II receptor type 1; DHP, dihydropyridine; MR, mineralocorticoid receptor; NSAID, nonsteroidal anti-inflammatory drug; SGLT2, sodium-glucose cotransporter 2; SSRI, selective serotonin reuptake inhibitor.

surgical candidates with either no obvious lesion on CT or evidence of a unilateral lesion but with age >35 years because the latter patients have a higher likelihood of harboring a coincidental, endocrine-inactive adrenal adenoma (Fig. 398-12). AVS is used to compare aldosterone levels in the inferior vena cava and between the right and left adrenal veins. AVS requires concurrent measurement of cortisol to document the correct placement of the catheter in the adrenal veins and should demonstrate a cortisol gradient >2–3 in baseline conditions between the vena cava and each adrenal vein. Lateralization is confirmed by an aldosterone/cortisol ratio that is at least twofold higher on one side than the other in baseline conditions. AVS is a complex procedure that requires a highly skilled interventional radiologist. Even then, the right adrenal vein can be difficult to cannulate correctly, which, if not achieved, invalidates the procedure. There is also no agreement as to whether the two adrenal veins should be cannulated simultaneously or successively and whether ACTH stimulation enhances the diagnostic value of AVS. Recently, PET-CT with a labeled form of metomidate, a methyl analogue of etomidate that binds to both CYP11B1 and CYP11B2, has been validated as a noninvasive alternative to AVS. [^{11}C] metomidate PET-CT with dexamethasone pretreatment to suppress CYP11B1 activity can differentiate unilateral from bilateral forms of primary aldosteronism and has similar performance to AVS in predicting biochemical and clinical success following adrenalectomy.

Patients <35 years with confirmed primary aldosteronism, a unilateral lesion on CT, and no clinical suspicion of familial forms can go straight to surgery, which is also indicated in patients with confirmed lateralization documented by a valid AVS procedure or [^{11}C]metomidate PET-CT. Laparoscopic adrenalectomy is the preferred approach. Patients who are not surgical candidates, or with evidence of bilateral hyperplasia based on CT or AVS, should be treated medically (Fig. 398-12). Medical treatment, which can also be considered prior to surgery to avoid postsurgical hypoaldosteronism, consists primarily of the MR antagonist spironolactone. It can be started at 12.5–50 mg daily and titrated up to a maximum of 400 mg/d to control blood pressure and normalize potassium. Side effects include menstrual irregularity, decreased libido, and gynecomastia. The more selective MR antagonist eplerenone can also be used. Doses start at 25 mg bid, and it can be titrated up to 200 mg/d. Another useful drug is the potassium-sparing diuretic amiloride (5–10 mg bid).

In patients with normal adrenal morphology and family history of early-onset, severe hypertension, a diagnosis of GRA should be considered and can be evaluated using genetic testing. Treatment of GRA consists of administering dexamethasone, using the lowest dose possible to control blood pressure. Some patients also require additional MR antagonist treatment.

The diagnosis of non-aldosterone-related mineralocorticoid excess is based on documentation of suppressed renin and suppressed aldosterone in the presence of hypokalemic hypertension. This testing is best carried out by employing urinary steroid metabolite profiling by gas chromatography/mass spectrometry (GC/MS). An increased free cortisol over free cortisone ratio is suggestive of SAME and can be treated with dexamethasone. Steroid profiling by GC/MS also detects the steroids associated with CYP11B1 and CYP17A1 deficiency or the irregular steroid secretion pattern in a DOC-producing ACC (Fig. 398-12). If the GC/MS profile is normal, Liddle's syndrome should be considered. It is very sensitive to amiloride treatment but will not respond to MR antagonist treatment because the defect is due to a constitutively active ENaC.

APPROACH TO THE PATIENT: INCIDENTALLY DISCOVERED ADRENAL MASS

Epidemiology Incidentally discovered adrenal masses, commonly termed adrenal "incidentalomas," are common, with a prevalence of 2–5% in the general population as documented in CT and autopsy series. The prevalence increases with age, with 1% of 40-year-olds and 7% of 70-year-olds harboring an adrenal mass. The widespread use of cross-sectional imaging has also increased the recognized prevalence.

Etiology Most solitary adrenal tumors are monoclonal neoplasms. Several genetic syndromes, including MEN 1 (*MEN1*), MEN 2 (*RET*), Carney's complex (*PRKAR1A*), McCune-Albright (*GNAS1*), Li Fraumeni (*TP53*), Lynch (*MLH1*, *MSH2*, *MSH6*, *PMS2*, *EPCAM*), and familial adenomatous polyposis (*APC*) can have adrenocortical tumors as one of their features. On the other hand, Von-Hippel-Lindau disease (*VHL*), MEN 2, paraganglioma syndrome type 1/4/5 (*SDHD*/*SDHB*/*SDHA*), neurofibromatosis type 1 (*NF1*), and hereditary leiomyomatosis and renal cell cancer (*FH*) are among the genetic syndromes associated with pheochromocytomas.

TABLE 398-5 Classification of Unilateral Adrenal Masses

MASS	APPROXIMATE PREVALENCE (%)
Benign	
Adrenocortical adenoma	
Endocrine-inactive	40–70
Cortisol-producing (mild autonomous cortisol secretion)	20–50
Aldosterone-producing	2–5
Cortisol-producing (overt Cushing's syndrome)	1–4
Pheochromocytoma	1–5
Adrenal myelolipoma	3-6
Adrenal ganglioneuroma	1
Adrenal cyst and pseudocyst	1
Adrenal hematoma/hemorrhagic infarction	<1
Adrenal hemangioma	<0.1
Indeterminate	
Adrenocortical oncocytoma	<1
Malignant	
Metastases (most frequent: breast, lung)	3–7
Adrenocortical carcinoma	0.4–4
Malignant pheochromocytoma	<1
Adrenal neuroblastoma	<0.1
Lymphomas (including primary adrenal lymphoma)	<0.1

Note: Bilateral adrenal enlargement/masses may be caused by congenital adrenal hyperplasia, bilateral macronodular hyperplasia, bilateral hemorrhage (due to antiphospholipid syndrome or sepsis-associated Waterhouse-Friderichsen syndrome), granuloma, amyloidosis, or infiltrative disease including tuberculosis.

Up to 50% of adrenal nodules are hormonally active, due to a cortisol- or aldosterone-producing adrenocortical adenoma or a pheochromocytoma associated with catecholamine excess (Table 398-5). ACC is rare but is the cause of an adrenal mass in up to 4% of patients. However, metastases originating from another solid tissue tumor are an additional cause of adrenal incidentaloma and account for up to 40% of adrenal masses in patients undergoing imaging for tumor staging or follow-up monitoring (Table 398-5).

Differential Diagnosis and Treatment Patients with an adrenal mass >1 cm require a diagnostic evaluation. Two key questions need to be addressed: (1) Does the tumor autonomously secrete hormones that could have a detrimental effect on health? (2) Is the adrenal mass benign or malignant?

Hormone secretion by an adrenal mass occurs along a continuum, with a gradual increase in clinical manifestations in parallel with hormone levels. Exclusion of catecholamine excess from a pheochromocytoma arising from the adrenal medulla is a mandatory part of the diagnostic workup of lipid-poor masses (Fig. 398-13). In case of hypertension, primary aldosteronism should be ruled out. Overproduction of adrenal androgen precursors, DHEA and its sulfate, is rare and most frequently seen in the context of ACC, as are increased levels of steroid precursors such as 17OHP. Cortisol excess is the most observed hormonal abnormality in adrenal masses, ranging from rare clinically overt Cushing's syndrome to much more prevalent MACS (early-morning cortisol >50 nmol/L [1.8 μg/dL] after overnight administration of dexamethasone 1 mg in the absence of clinical features of Cushing's). Patients with MACS may exhibit one or more components of the metabolic syndrome (e.g., obesity, type 2 diabetes, hypertension,

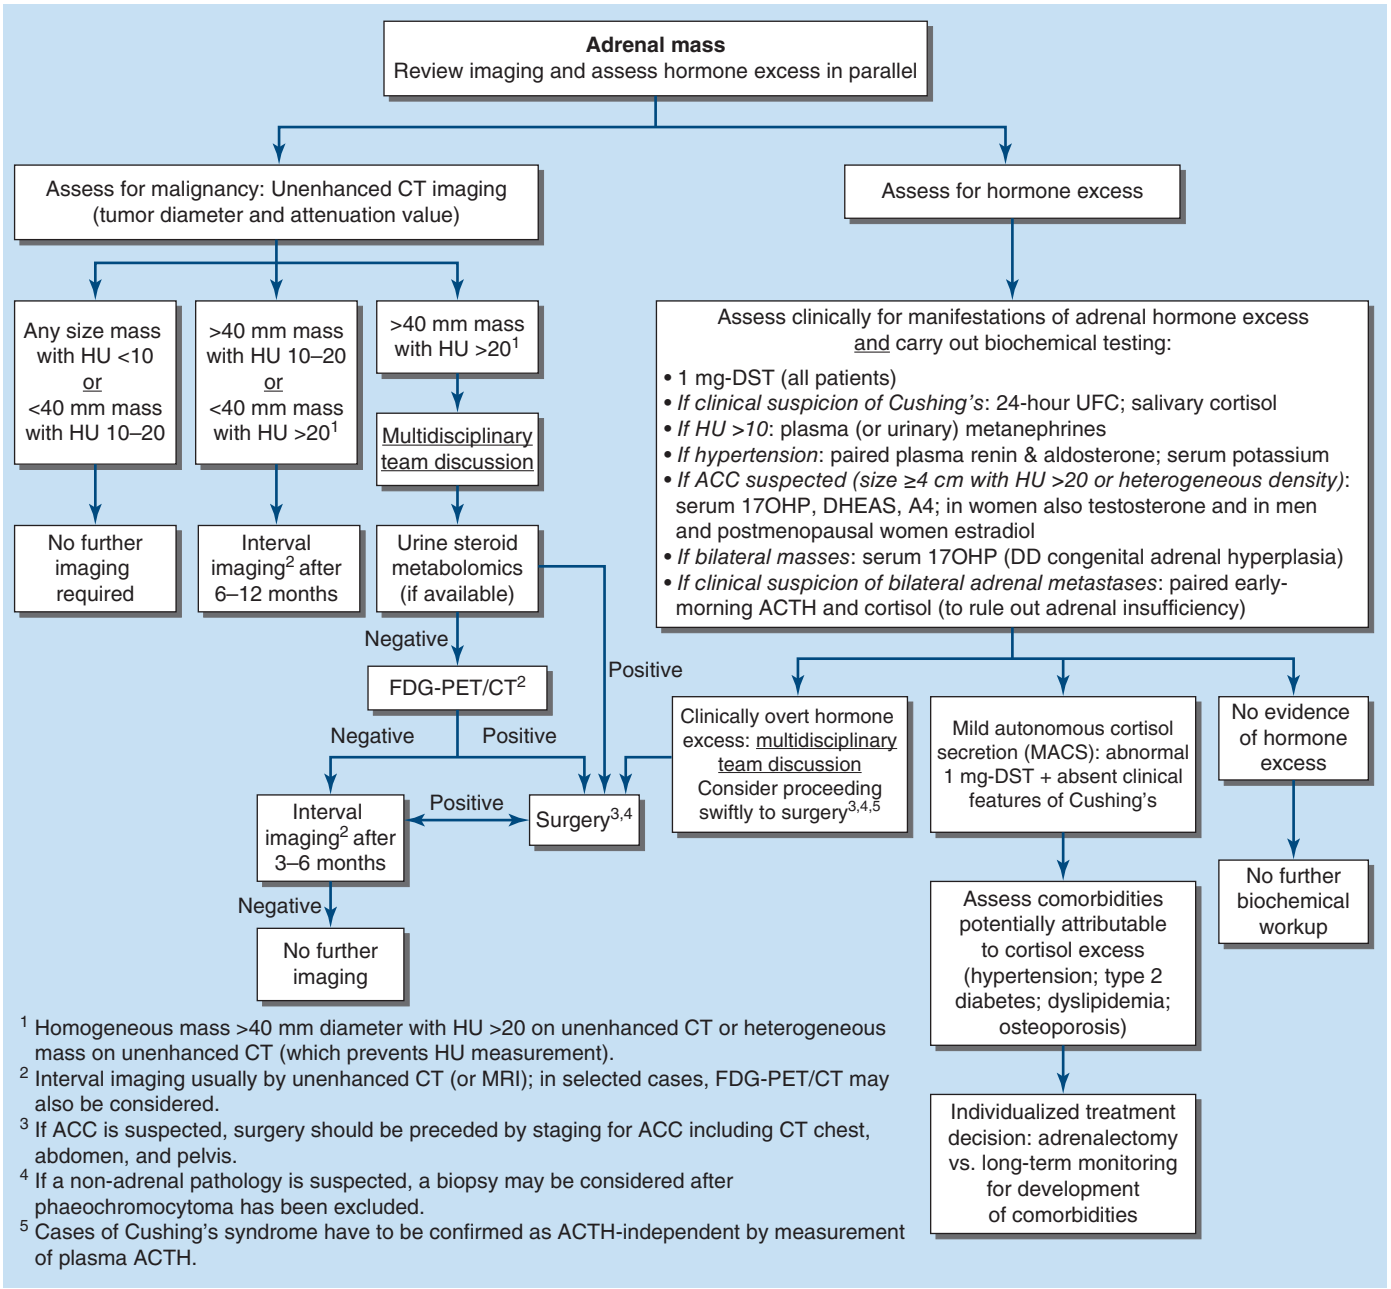

FIGURE 398-13 Management of the patient with an incidentally discovered adrenal mass. This pathway is primarily designed for adrenal incidentalomas; in adrenal nodules identified by screening or staging for an extra-adrenal primary malignancy, the likelihood of a metastasis needs to be considered when arranging further imaging or a biopsy. ACC, adrenocortical carcinoma; ACTH, adrenocorticotropic hormone; CT, computed tomography; DD, differential diagnosis; DHEAS, dehydroepiandrosterone sulfate; 1 mg-DST, 1 mg dexamethasone overnight suppression test; FDG-PET, fluorodeoxyglucose positron emission tomography; HU, Hounsfield Units; 17-OHP, 17-hydroxyprogesterone; MACS, mild autonomous cortisol excess secretion; MRI, magnetic resonance imaging; UFC, urinary free cortisol.

dyslipidemia), osteoporosis, increased risk of cardiovascular events, frailty, and impaired quality of life, and have increased mortality risk. There is an ongoing debate about the optimal treatment for these patients, which includes adrenalectomy or conservative management with long-term monitoring and treatment of comorbidities potentially attributable to the cortisol excess.

For the differentiation of benign from malignant adrenal masses, imaging is relatively sensitive, although specificity is suboptimal. Unenhanced CT is the procedure of choice for imaging the adrenal glands (Fig. 398-11). A diagnosis of ACC, pheochromocytoma, and benign adrenal myelolipoma becomes more likely with increasing diameter of the adrenal mass. However, size alone is of poor predictive value, with only 80% specificity for the differentiation of benign from malignant masses when using a 4-cm cutoff. Metastases are rare but are found with similar frequency in adrenal masses of all sizes. The tumor attenuation value on unenhanced CT is of high diagnostic value, as many adrenocortical adenomas are lipid rich and thus present with low attenuation values (i.e., densities of <20 HUs). However, similar numbers of adrenocortical adenomas are lipid poor and present with higher HUs, making it difficult to differentiate them from ACCs, as well as pheochromocytomas, both of which invariably have high attenuation values (i.e., densities >20 HU on precontrast scans). Generally, benign lesions are rounded and homogenous, whereas most malignant lesions appear lobulated and inhomogeneous. Pheochromocytoma and adrenomyelolipoma may also exhibit lobulated and inhomogeneous features. MRI also allows for the visualization of the adrenal glands with somewhat lower resolution than CT. However, because it does not involve exposure to ionizing radiation, it is preferred in children, young adults, and during pregnancy. MRI has a valuable role in the characterization of indeterminate adrenal lesions using chemical shift analysis, with malignant tumors rarely showing loss of signal on opposed-phase MRI; however, this may also be observed in a proportion of benign

adrenocortical adenomas, and chemical shift analysis results usually are similar to those obtained by measuring tumor attenuation on unenhanced CT. The evidence base for the utility of fluorodeoxyglucose (FDG)-PET was initially scarce but is now expanding, with recent data indicating that a lack of FDG uptake reliably indicates a benign adrenocortical mass; however, care has to be taken in patients with a history of extra-adrenal cancer as adrenal metastases arising from those sometimes do not take up FDG, i.e., as typically seen in renal cell carcinoma. Adrenocortical carcinoma is invariably FDG avid; however, specificity is poor, with many benign adrenal adenomas also taking up FDG.

Fine-needle aspiration (FNA) or CT-guided biopsy of an adrenal mass is very rarely indicated. FNA of a pheochromocytoma can cause a life-threatening hypertensive crisis. FNA of an ACC violates the tumor capsule and can cause needle track metastasis. FNA should only be considered in a patient with a history of nonadrenal malignancy and a newly detected adrenal mass, after careful exclusion of pheochromocytoma, and if the outcome will influence therapeutic management. It is important to recognize that in 25% of patients with a previous history of nonadrenal malignancy, a newly detected mass on CT is not a metastasis. While FNA can diagnose extra-adrenal malignancies, it has very limited ability to differentiate between benign and malignant adrenocortical lesions and hence should not be used for the diagnosis of ACC.

Adrenal masses associated with confirmed hormone excess or suspected malignancy are usually treated surgically (Fig. 398-13) or, if adrenalectomy is not feasible or desired, with medication. Preoperative exclusion of glucocorticoid excess is particularly important for the prediction of postoperative suppression of the contralateral adrenal gland, which requires glucocorticoid replacement peri- and postoperatively. Adrenal masses of any size with normal endocrine biochemistry at diagnosis and an attenuation value of <10 HU on unenhanced CT can be considered benign (malignancy rate <0.5%) and do not require further follow-up (Fig. 398-13). This similarly applies to adrenal masses <4 cm in diameter and an attenuation value of 10–20 HU. In adrenal masses <4 cm and >20 HU attenuation as well as in masses >4 cm and 10–20 HU, the likelihood of malignancy is still very low (<5%) and can be mitigated by arranging for interval imaging (Fig. 398-13). The overwhelming majority of risk of malignancy applies to adrenal masses >4 cm with an attenuation >20 HU, and these masses require swift attention (Fig. 398-13), with a 50% risk of underlying malignancy. The risk of adrenocortical carcinoma is higher in young patients (<40 years), whereas metastases of extra-adrenal primaries occur at all ages. In adrenal masses with suspicious imaging findings (>4 cm and >20 HU), surgery and/or biopsy are feasible options; however, the latter will still result in unnecessary surgery for many benign tumors. A recently introduced diagnostic test, urine steroid metabolomics, has a twofold higher positive predictive value than imaging in detecting adrenocortical carcinoma, based on a distinct "malignant steroid fingerprint" with accumulating precursor steroid metabolites in 24-h urine.

ADRENOCORTICAL CARCINOMA

ACC is a rare malignancy with an annual incidence of 1–2 per million population. ACC is generally considered a highly malignant tumor; however, it presents with broad interindividual variability with regard to biologic characteristics and clinical behavior. Somatic mutations in the tumor-suppressor gene *TP53* are found in 25% of apparently sporadic ACC. Germline *TP53* mutations are the cause of the Li-Fraumeni syndrome associated with multiple solid organ cancers including ACC and are found in 25% of pediatric ACC cases; the *TP53* mutation R337H is found in almost all pediatric ACC in Brazil. Other genetic changes identified in ACC include germline mutations of genes affecting DNA mismatch repair (Lynch syndrome), *PRKAR1A* (Carney complex), *MEN1*, *APC* (familial adenomatous polyposis), and somatic alterations in the Wnt/β-catenin pathway and in the insulin-like growth factor 2 (IGF2) cluster. IGF2 overexpression is found in 90% of ACCs.

Patients with large adrenal tumors suspicious of malignancy should be managed by a multidisciplinary specialist team, including an endocrinologist, an oncologist, a surgeon, a radiologist, and a histopathologist. FNA is not indicated in suspected ACC: first, cytology and also histopathology of a core biopsy cannot differentiate between benign and malignant primary adrenal masses; second, FNA violates the tumor capsule and may even cause needle canal metastasis. Even when the entire tumor specimen is available, the histopathologic differentiation between benign and malignant adrenocortical lesions is a diagnostic challenge. The most common histopathologic classification is the Weiss score, taking into account high nuclear grade; mitotic rate (>5/high-power field [HPF]); atypical mitosis; <25% clear cells; diffuse architecture; and presence of necrosis, venous invasion, and invasion of sinusoidal structures and tumor capsule. The presence of three or more elements suggests ACC. However, FNA is a feasible option if looking for metastases of an extra-adrenal primary or other adrenal tumor entities, such as ganglioneuroma.

TABLE 398-6 Classification System for Staging of Adrenocortical Carcinoma

ENSAT STAGE	TNM STAGE	TNM DEFINITIONS
I	T1,N0,M0	T1, tumor ≤5 cm N0, no positive lymph node M0, no distant metastases
II	T2,N0,M0	T2, tumor >5 cm N0, no positive lymph node M0, no distant metastases
III	T1–T2,N1,M0 T3–T4,N0–N1,M0	N1, positive lymph node(s) M0, no distant metastases T3, tumor infiltration into surrounding tissue T4, tumor invasion into adjacent organs *or* venous tumor thrombus in vena cava or renal vein
IV	T1–T4,N0–N1,M1	M1, presence of distant metastases

Abbreviations: ENSAT, European Network for the Study of Adrenal Tumors; TNM, tumor, node, metastasis.

Although 60–70% of ACCs show biochemical evidence of steroid overproduction, in many patients, this is not clinically apparent due to the relatively inefficient steroid production by the adrenocortical cancer cells. Excess production of glucocorticoids and adrenal androgen precursors are most common and indicative of malignancy.

Tumor staging at ACC diagnosis **(Table 398-6)** has important prognostic implications and requires scanning of the chest and abdomen for local organ invasion, lymphadenopathy, and metastases. Intravenous contrast medium is necessary for maximum sensitivity for hepatic metastases. An adrenal origin may be difficult to determine on standard axial CT imaging if the tumors are large and invasive, but CT reconstructions and MRI are more informative **(Fig. 398-14)** using multiple planes and different sequences. Vascular and adjacent organ invasion is diagnostic of malignancy. 18-Fluoro-2-deoxy-D-glucose PET (18-FDG-PET) is highly sensitive for the detection of malignancy and can be used to detect small metastases or local recurrence that may not be obvious on CT (Fig. 398-14). However, FDG-PET has limited specificity and therefore cannot be used for differentiating benign from malignant adrenal lesions. Metastasis in ACC most frequently occurs to liver and lung.

There is no established grading system for ACC, and the Weiss score carries no prognostic value; the most important prognostic histopathologic parameter is the Ki67 proliferation index, with Ki67 <10% indicative of slow to moderate growth velocity, whereas a Ki67 ≥10% is associated with poor prognosis including high risk of recurrence and rapid progression.

Cure of ACC can only be achieved by early detection and complete surgical removal. Capsule violation during primary surgery, metastasis at diagnosis, and primary treatment in a nonspecialist center and by a nonspecialist surgeon are major determinants of poor survival. If the primary tumor invades adjacent organs, en bloc removal of kidney and spleen should be considered to reduce the risk of recurrence, and regional lymph node dissection may further reduce this risk. Surgery

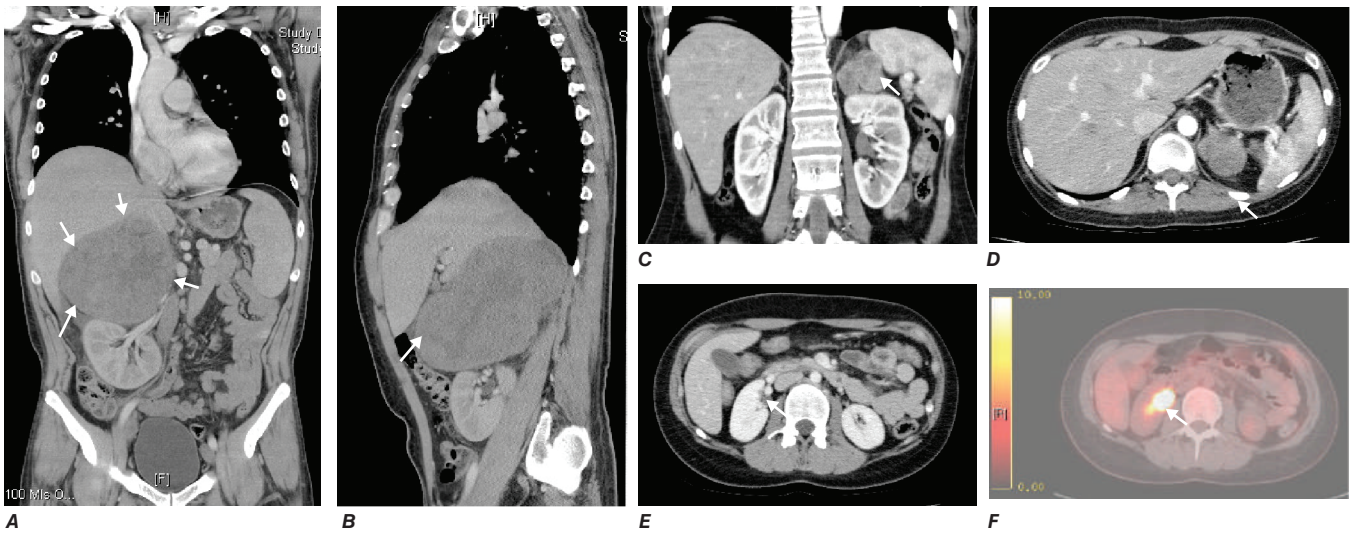

FIGURE 398-14 Imaging in adrenocortical carcinoma (ACC). Magnetic resonance imaging scan with (***A***) frontal and (***B***) lateral views of a right ACC that was detected incidentally. Computed tomography (CT) scan with (***C***) coronal and (***D***) transverse views depicting a right-sided ACC. Note the irregular border and inhomogeneous structure. CT scan (***E***) and positron emission tomography/CT (***F***) visualizing a peritoneal metastasis of an ACC in close proximity to the right kidney (*arrow*).

can also be considered in a patient with metastases if there is severe tumor-related hormone excess. This indication needs to be carefully weighed against surgical risk, including thromboembolic complications, and the resulting delay in the introduction of other therapeutic options. Patients with confirmed ACC and successful removal of the primary tumor should receive adjuvant treatment with mitotane (o,p'DDD), particularly in patients with a high risk of recurrence as determined by European Network for the Study of Adrenal Tumors (ENSAT) stage III and IV or Ki67 proliferation index ≥10%. Adjuvant mitotane should be continued for at least 2 years, if side effects are tolerated. Regular monitoring of plasma mitotane levels is mandatory (therapeutic range 14–20 mg/L; neurotoxic complications more frequent at >20 mg/L). Mitotane is usually started at 500 mg tid, with stepwise increases to a maximum dose of 2000 mg tid in days (high-dose saturation) or weeks (low-dose saturation) as tolerated. Once therapeutic range plasma mitotane levels are achieved, the dose can be tapered to maintenance doses mostly ranging from 1000 to 1500 mg tid. Mitotane treatment results in disruption of cortisol synthesis and thus requires glucocorticoid replacement; glucocorticoid replacement dose should be at least double of that usually used in adrenal insufficiency (i.e., 40–60 mg daily in two to three divided doses) because mitotane induces hepatic CYP3A4 activity, resulting in rapid inactivation of glucocorticoids. Mitotane also increases circulating CBG, thereby decreasing the available free cortisol fraction. Single metastases can be addressed surgically or with radiofrequency ablation as appropriate. If the tumor recurs or progresses during mitotane treatment, cytotoxic chemotherapy should be considered; the established first-line chemotherapy regimen is the combination of cisplatin, etoposide, and doxorubicin plus continuing mitotane. Painful bone metastasis responds to irradiation. Overall survival in ACC is still poor, with 5-year survival rates of 30–40% and a median survival of 15 months in metastatic ACC.

ADRENAL INSUFFICIENCY

Epidemiology The prevalence of well-documented, permanent adrenal insufficiency is 5 in 10,000 in the general population. Hypothalamic-pituitary origin of the disease is most frequent, with a prevalence of 3 in 10,000, whereas primary adrenal insufficiency has a prevalence of 2 in 10,000. Approximately one-half of the latter cases are acquired, mostly caused by autoimmune destruction of the adrenal glands; the other one-half are genetic, most commonly caused by distinct enzymatic blocks in adrenal steroidogenesis affecting glucocorticoid synthesis (i.e., CAH).

Adrenal insufficiency arising from suppression of the HPA axis consequent to exogenous glucocorticoid treatment is much more common, occurring in 0.5–2% of the population in developed countries.

Etiology *Primary adrenal insufficiency* is most commonly caused by autoimmune adrenalitis. Isolated autoimmune adrenalitis accounts for 30–40%, whereas 60–70% develop adrenal insufficiency as part of autoimmune polyglandular syndromes (APSs) **(Chap. 400)** **(Table 398-7)**. APS1, also termed APECED (autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy), is the underlying cause in 10% of patients affected by APS. APS1 is transmitted in an autosomal recessive manner and is caused by mutations in the autoimmune regulator gene *AIRE*. Associated autoimmune conditions overlap with those seen in APS2 but may also include total alopecia, primary hypoparathyroidism, and, in rare cases, lymphoma. APS1 patients invariably develop chronic mucocutaneous candidiasis, usually manifested in childhood and preceding adrenal insufficiency by years or decades. The much more prevalent APS2 is of polygenic inheritance, with confirmed associations with the *HLA-DR3* gene region in the major histocompatibility complex and distinct gene regions involved in immune regulation (*CTLA-4, PTPN22, CLEC16A*). Coincident autoimmune disease most frequently includes thyroid autoimmune disease, vitiligo, and premature ovarian failure. Less commonly, additional features may include type 1 diabetes and pernicious anemia caused by vitamin B_{12} deficiency.

X-linked adrenoleukodystrophy has an incidence of 1:20,000 males and is caused by mutations in the *X-ALD* gene encoding the peroxisomal membrane transporter protein ABCD1; its disruption results in the accumulation of very-long-chain (>24 carbon atoms) fatty acids. Approximately 50% of cases manifest in early childhood with rapidly progressive white matter disease (cerebral adrenoleukodystrophy); 35% present during adolescence or in early adulthood with neurologic features indicative of myelin and peripheral nervous system involvement (adrenomyeloneuropathy [AMN]). In the remaining 15%, adrenal insufficiency is the sole manifestation of disease. Of note, distinct mutations manifest with variable penetrance and phenotypes within affected families.

Rarer causes of adrenal insufficiency involve the destruction of the adrenal glands as a consequence of infection, hemorrhage, or infiltration (Table 398-7); tuberculous adrenalitis is still a frequent cause of disease in developing countries. Adrenal metastases rarely cause adrenal insufficiency, and this occurs only with bilateral, bulky metastases.

Inborn causes of primary adrenal insufficiency other than CAH are rare, causing <1% of cases. However, their elucidation provides important insights into adrenal gland development and physiology. Mutations causing primary adrenal insufficiency (Table 398-7) include factors regulating adrenal development and steroidogenesis (DAX-1, SF-1), cholesterol synthesis, import and cleavage (DHCR7, StAR, CYP11A1), elements of the adrenal ACTH response pathway (MC2R, MRAP) (Fig. 398-5), and factors involved in redox regulation (NNT, TXNRD2) and DNA repair (MCM4, CDKN1C).

TABLE 398-7 Causes of Primary Adrenal Insufficiency

DIAGNOSIS	GENE	ASSOCIATED FEATURES
Autoimmune polyglandular syndrome 1 (APS1)	*AIRE*	Hypoparathyroidism, chronic mucocutaneous candidiasis, other autoimmune disorders, rarely lymphomas
Autoimmune polyglandular syndrome 2 (APS2)	Associations with HLA-DR3, CTLA-4	Hypothyroidism, hyperthyroidism, premature ovarian failure, vitiligo, type 1 diabetes mellitus, pernicious anemia
Isolated autoimmune adrenalitis	Associations with HLA-DR3, CTLA-4	
Congenital adrenal hyperplasia (CAH)	*CYP21A2, CYP11B1, CYP17A1, HSD3B2, POR*	See Table 398-10 (see also **Chap. 402**)
Congenital lipoid adrenal hyperplasia (CLAH)	*STAR, CYP11A1*	46,XY DSD, gonadal failure (see also **Chap. 402**)
Adrenal hypoplasia congenita (AHC)	*NR0B1 (DAX-1), NR5A1 (SF-1)*	46,XY DSD, gonadal failure (see also **Chap. 402**)
Adrenoleukodystrophy (ALD), adrenomyeloneuropathy (AMN)	*ABCD1*	Demyelination of central nervous system (ALD) or spinal cord and peripheral nerves (AMN)
Familial glucocorticoid deficiency	*MC2R*	Tall stature
	MRAP	None
	STAR	None
	NNT	None
	TXNRD2	None
	MCM4	Growth retardation, natural killer cell deficiency
Triple A syndrome	*AAAS*	Alacrima, achalasia, neurologic impairment
Smith-Lemli-Opitz syndrome	*SLOS*	Cholesterol synthesis disorder associated with mental retardation, craniofacial malformations, growth failure
Kearns-Sayre syndrome	Mitochondrial DNA deletions	Progressive external ophthalmoplegia, pigmentary retinal degeneration, cardiac conduction defects, gonadal failure, hypoparathyroidism, type 1 diabetes,
IMAGe syndrome	*CDKN1C*	Intrauterine growth retardation, metaphyseal dysplasia, genital anomalies
MIRAGE syndrome	*SAMD9*	Myelodysplasia, infection, restriction of growth, genital phenotypes, and enteropathy
Sphingosine-1-phosphate lyase deficiency	*SGPL1*	Steroid-resistant nephrotic syndrome, immunodeficiency, neurologic defects, ichthyosis, primary hypothyroidism, cryptorchidism
Adrenal infections		Tuberculosis, HIV, CMV, cryptococcosis, histoplasmosis, coccidioidomycosis
Adrenal infiltration		Metastases, lymphomas, sarcoidosis, amyloidosis, hemochromatosis
Adrenal hemorrhage		Meningococcal sepsis (Waterhouse-Friderichsen syndrome), primary antiphospholipid syndrome
Drug-induced		Mitotane, aminoglutethimide, abiraterone, trilostane, etomidate, ketoconazole, levoketoconazole, osilodrostat, suramin, mifepristone (RU486), interferon-alpha, immune checkpoint inhibitors (rare)
Bilateral adrenalectomy		E.g., in the management of Cushing's syndrome or after bilateral nephrectomy

Abbreviations: AIRE, autoimmune regulator; CMV, cytomegalovirus; DSD, disordered sex development; MC2R, ACTH receptor; MCM4, mini chromosome maintenance-deficient 4 homologue; MRAP, MC2R-accessory protein; NNT, nicotinamide nucleotide transhydrogenase.

Secondary (or central) adrenal insufficiency is the consequence of dysfunction of the hypothalamic-pituitary component of the HPA axis **(Table 398-8)**. Excluding iatrogenic suppression, the overwhelming majority of cases are caused by pituitary or hypothalamic tumors or their treatment by surgery or irradiation **(Chap. 392)**. Rarer causes include pituitary apoplexy, either as a consequence of an infarcted pituitary adenoma or transient reduction in the blood supply of the pituitary during surgery or after rapid blood loss associated with parturition, also termed Sheehan's syndrome. Isolated ACTH deficiency is rarely caused by autoimmune disease or pituitary infiltration (Table 398-8). Mutations in the ACTH precursor POMC or in factors regulating pituitary development are genetic causes of ACTH deficiency (Table 398-8).

Clinical Manifestations In principle, the clinical features of primary adrenal insufficiency (Addison's disease) are characterized by the loss of both glucocorticoid and mineralocorticoid secretion **(Table 398-9)**. In secondary adrenal insufficiency, only glucocorticoid deficiency is present, as the adrenal itself is intact and thus still amenable to regulation by the RAA system. Adrenal androgen secretion is disrupted in both primary and secondary adrenal insufficiency (Table 398-9). Hypothalamic-pituitary disease can lead to additional clinical manifestations due to involvement of other endocrine axes (thyroid, gonads, GH, prolactin) or visual impairment with bitemporal hemianopia caused by chiasmal compression. It is important to recognize that iatrogenic adrenal insufficiency caused by exogenous glucocorticoid suppression of the HPA axis may result in all symptoms associated with glucocorticoid deficiency (Table 398-9), if exogenous glucocorticoids are stopped abruptly. However, patients will appear clinically cushingoid as a result of the preceding overexposure to glucocorticoids.

Chronic adrenal insufficiency manifests with relatively nonspecific signs and symptoms, such as fatigue and loss of energy, often resulting in delayed or missed diagnoses (e.g., as depression or anorexia). A distinguishing feature of primary adrenal insufficiency is hyperpigmentation, which is caused by excess ACTH stimulation of melanocytes. Hyperpigmentation is most pronounced in skin areas exposed to increased friction or shear stress and is increased by sunlight **(Fig. 398-15)**. Conversely, in secondary adrenal insufficiency, the skin has an alabaster-like paleness due to lack of ACTH secretion.

Hyponatremia is a characteristic biochemical feature in primary adrenal insufficiency and is found in 80% of patients at presentation. Hyperkalemia is present in 40% of patients at initial diagnosis. Hyponatremia is primarily caused by mineralocorticoid deficiency but can also occur in secondary adrenal insufficiency due to diminished inhibition of antidiuretic hormone (ADH) release by cortisol, resulting in mild syndrome of inappropriate secretion of antidiuretic hormone (SIADH). Glucocorticoid deficiency also results in slightly increased TSH concentrations that normalize within days to weeks after initiation of glucocorticoid replacement.

TABLE 398-8 Causes of Secondary Adrenal Insufficiency

DIAGNOSIS	GENE	ASSOCIATED FEATURES
Pituitary tumors (endocrine active and inactive adenomas, very rare: carcinoma)		Depending on tumor size and location: visual field impairment (bilateral hemianopia), hyperprolactinemia, secondary hypothyroidism, hypogonadism, growth hormone deficiency
Other mass lesions affecting the hypothalamic-pituitary region		Craniopharyngioma, meningioma, ependymoma, metastases
Pituitary irradiation		Radiotherapy administered for pituitary tumors, brain tumors, or craniospinal irradiation in leukemia
Autoimmune hypophysitis		Often associated with pregnancy; may present with panhypopituitarism or isolated ACTH deficiency; can be associated with autoimmune thyroid disease, more rarely with vitiligo, premature ovarian failure, type 1 diabetes, pernicious anemia
Pituitary apoplexy/ hemorrhage		Hemorrhagic infarction of large pituitary adenomas or pituitary infarction consequent to traumatic major blood loss (e.g., surgery or pregnancy: Sheehan's syndrome)
Pituitary infiltration		Tuberculosis, actinomycosis, sarcoidosis, histiocytosis X, granulomatosis with polyangiitis (Wegener's), metastases
Drug-induced		Chronic glucocorticoid excess (endogenous or exogenous), immune check point inhibitors, opioids, interferon alpha, ribavirin, megestrol acetate
Congenital isolated ACTH deficiency	*TBX19* (Tpit)	
Combined pituitary hormone deficiency (CPHD)	*PROP-1*	Progressive development of CPHD in the order GH, PRL, TSH, LH/FSH, ACTH
	HESX1	CPHD and septo-optic dysplasia
	LHX3	CPHD and limited neck rotation, sensorineural deafness
	LHX4	CPHD and cerebellar abnormalities
	SOX3	CPHD and variable mental retardation
Proopiomelanocortin (POMC) deficiency	*POMC*	Early-onset obesity, red hair pigmentation

Abbreviations: ACTH, adrenocorticotropic hormone; GH, growth hormone; LH/FSH, luteinizing hormone/follicle-stimulating hormone; PRL, prolactin; TSH, thyroid-stimulating hormone.

TABLE 398-9 Signs and Symptoms of Adrenal Insufficiency

Signs and Symptoms Caused by Glucocorticoid Deficiency
Fatigue, lack of energy
Weight loss, anorexia
Myalgia, joint pain
Fever
Normochromic anemia, lymphocytosis, eosinophilia
Slightly increased TSH (due to loss of feedback inhibition of TSH release)
Hypoglycemia (more frequent in children)
Low blood pressure, postural hypotension
Hyponatremia (due to loss of feedback inhibition of AVP release)
Signs and Symptoms Caused by Mineralocorticoid Deficiency (Primary Adrenal Insufficiency Only)
Abdominal pain, nausea, vomiting
Dizziness, postural hypotension
Salt craving
Low blood pressure, postural hypotension
Increased serum creatinine (due to volume depletion)
Hyponatremia
Hyperkalemia
Signs and Symptoms Caused by Adrenal Androgen Deficiency
Lack of energy
Dry and itchy skin (in women)
Loss of libido (in women)
Loss of axillary and pubic hair (in women)
Other Signs and Symptoms
Hyperpigmentation (primary adrenal insufficiency only) (due to excess of proopiomelanocortin [POMC]-derived peptides)
Alabaster-colored pale skin (secondary adrenal insufficiency only) (due to deficiency of POMC-derived peptides)

Abbreviations: AVP, arginine vasopressin; TSH, thyroid-stimulating hormone.

Acute adrenal insufficiency, also termed adrenal crisis, usually occurs after a prolonged period of nonspecific complaints and is more frequently observed in patients with primary adrenal insufficiency, due to the loss of both glucocorticoid and mineralocorticoid secretion. Postural hypotension may progress to hypovolemic shock. Adrenal insufficiency may mimic features of acute abdomen with abdominal tenderness, nausea, vomiting, and fever. In some cases, the primary presentation may resemble neurologic disease, with decreased responsiveness progressing to stupor and coma. An adrenal crisis can be triggered by an intercurrent illness, surgical or other stress, or increased glucocorticoid inactivation (e.g., hyperthyroidism). Prospective data indicate 8.3 adrenal crises and 0.5 adrenal crisis–related deaths per 100 patient-years.

Diagnosis The diagnosis of adrenal insufficiency is established by the short cosyntropin test, a safe and reliable tool with excellent predictive diagnostic value **(Fig. 398-16)**. The cutoff for failure is usually defined at cortisol levels of <450–500 nmol/L (16–18 μg/dL) sampled 30–60 min after ACTH stimulation; the exact cutoff is dependent on the locally available assay, with generally lower cutoffs for mass spectrometry–based assays. During the early phase of HPA disruption (e.g., within 4 weeks of pituitary insufficiency), patients may still respond to exogenous ACTH stimulation. In this circumstance, the ITT is an alternative choice but is more invasive and should be carried out only under a specialist's supervision (see above). Induction of hypoglycemia is contraindicated in individuals with diabetes mellitus, cardiovascular disease, or history of seizures. Random serum cortisol measurements are of limited diagnostic value because baseline cortisol levels may be coincidentally low due to the physiologic diurnal rhythm of cortisol secretion (Fig. 398-3). Similarly, many patients with secondary adrenal insufficiency have relatively normal baseline cortisol levels but fail to mount an appropriate cortisol response to ACTH, which can only be revealed by stimulation testing. Importantly, tests to establish the diagnosis of adrenal insufficiency should never delay treatment. Thus, in a patient with suspected adrenal crisis, it is reasonable to draw baseline cortisol levels, provide replacement therapy, and defer formal stimulation testing until a later time.

Once adrenal insufficiency is confirmed, measurement of plasma ACTH is the next step, with increased or inappropriately low levels defining primary and secondary origin of disease, respectively (Fig. 398-16). In primary adrenal insufficiency, increased plasma renin will confirm the presence of mineralocorticoid deficiency. At initial presentation, patients with primary adrenal insufficiency should undergo screening for steroid autoantibodies as a marker of autoimmune adrenalitis. If these tests are negative, adrenal imaging by CT is indicated to investigate possible hemorrhage, infiltration, or masses. In male patients with negative autoantibodies in the plasma, very-long-chain fatty acids should be measured to exclude X-ALD. Patients with inappropriately low ACTH, in the presence of confirmed cortisol deficiency, should undergo hypothalamic-pituitary imaging by MRI. Features suggestive of preceding pituitary apoplexy, such as sudden-onset severe headache or history of previous head trauma, should be carefully explored, particularly in patients with no obvious MRI lesion.

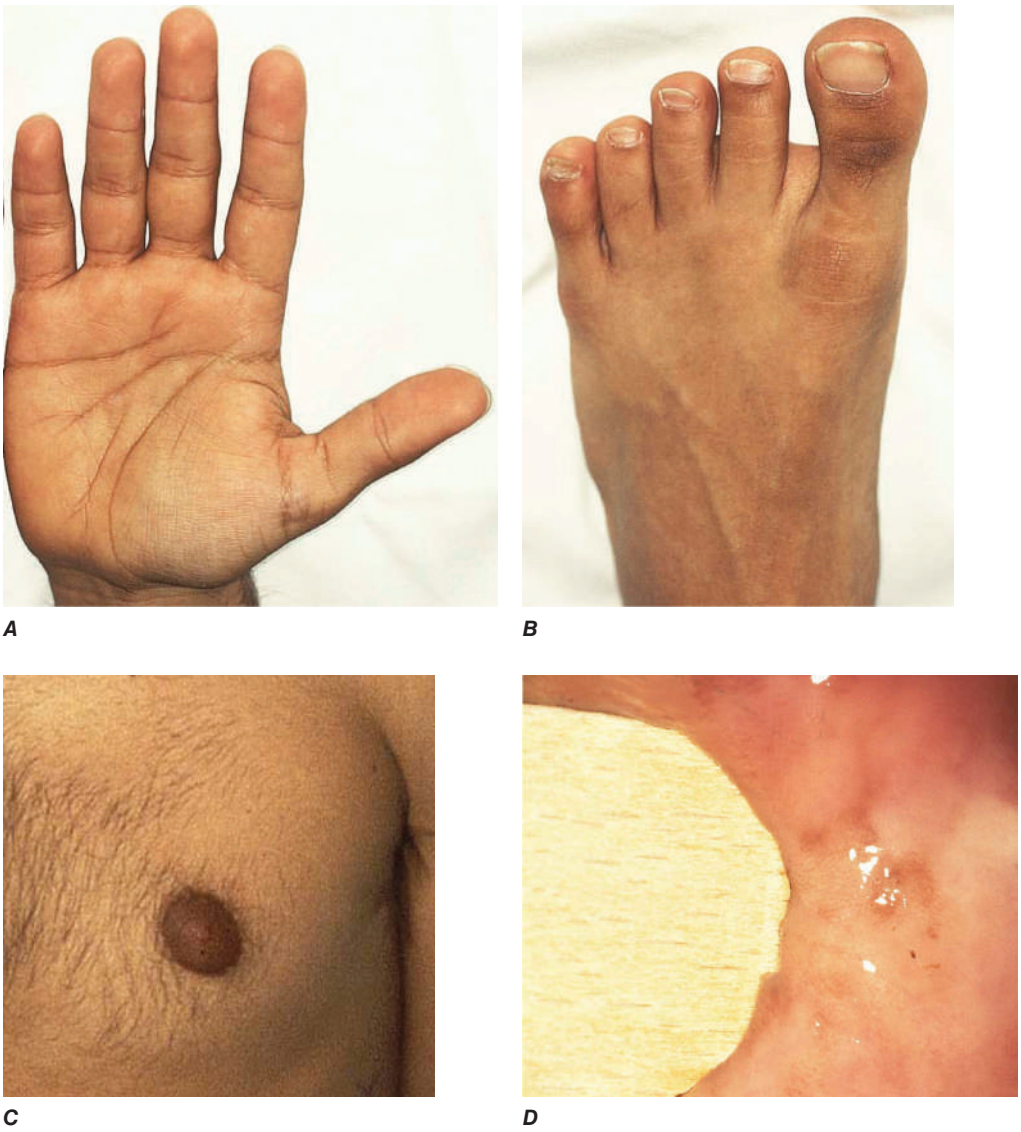

FIGURE 398-15 Clinical features of Addison's disease. Note the hyperpigmentation in areas of increased friction including (***A***) palmar creases, (***B***) dorsal foot, (***C***) nipples and axillary region, and (***D***) patchy hyperpigmentation of the oral mucosa.

TREATMENT

Acute Adrenal Insufficiency

Acute adrenal insufficiency requires immediate initiation of rehydration, usually carried out by saline infusion at initial rates of 1 L/h with continuous cardiac monitoring. Glucocorticoid replacement should be initiated by bolus injection of 100 mg hydrocortisone, followed by the administration of 200 mg hydrocortisone over 24 h, preferably by continuous infusion or alternatively by bolus IV or IM injections. Mineralocorticoid replacement can be initiated once the daily hydrocortisone dose has been reduced to <50 mg because at higher doses hydrocortisone provides sufficient stimulation of MRs.

Glucocorticoid replacement for the treatment of chronic adrenal insufficiency should be administered at a dose that replaces the physiologic daily cortisol production, which is usually achieved by the oral administration of 15–25 mg hydrocortisone in two to three divided doses. Pregnancy may require an increase in hydrocortisone dose by 50% during the last trimester. In all patients, at least one-half of the daily dose should be administered in the morning upon awakening. Long-acting glucocorticoids such as prednisolone or dexamethasone are not preferred because they result in increased glucocorticoid exposure due to extended GR activation at times of physiologically low cortisol secretion. There are no well-established dose equivalencies, but as a guide, equipotency can be assumed for 1 mg hydrocortisone, 1.6 mg cortisone acetate, 0.2 mg prednisolone, 0.25 mg prednisone, and 0.025 mg dexamethasone. Currently available standard glucocorticoid preparations fail to mimic the physiologic cortisol secretion rhythm (Fig. 398-3). However, this is overcome by recent modified release hydrocortisone preparations, with promising results emerging from the treatment of patients with primary adrenal insufficiency due to congenital adrenal hyperplasia.

Monitoring of glucocorticoid replacement is mainly based on the history and examination for signs and symptoms suggestive of glucocorticoid over- or underreplacement, including assessment of body weight and blood pressure. Plasma ACTH, 24-h urinary free cortisol, or serum cortisol day curves reflect whether hydrocortisone has been taken or not but do not convey reliable information about replacement quality. In patients with isolated primary adrenal insufficiency, monitoring should include screening for autoimmune thyroid disease, and female patients should be made aware of the possibility of premature ovarian failure. Supraphysiologic glucocorticoid treatment with doses equivalent to 30 mg hydrocortisone or more will affect bone metabolism, and these patients should undergo regular bone mineral density evaluation. All patients with adrenal insufficiency need to be instructed about the requirement for stress-related glucocorticoid dose adjustments. These generally consist of doubling the routine oral glucocorticoid dose in the case of intercurrent illness with fever and bed rest and the need for immediate IV or IM injection of 100 mg hydrocortisone followed

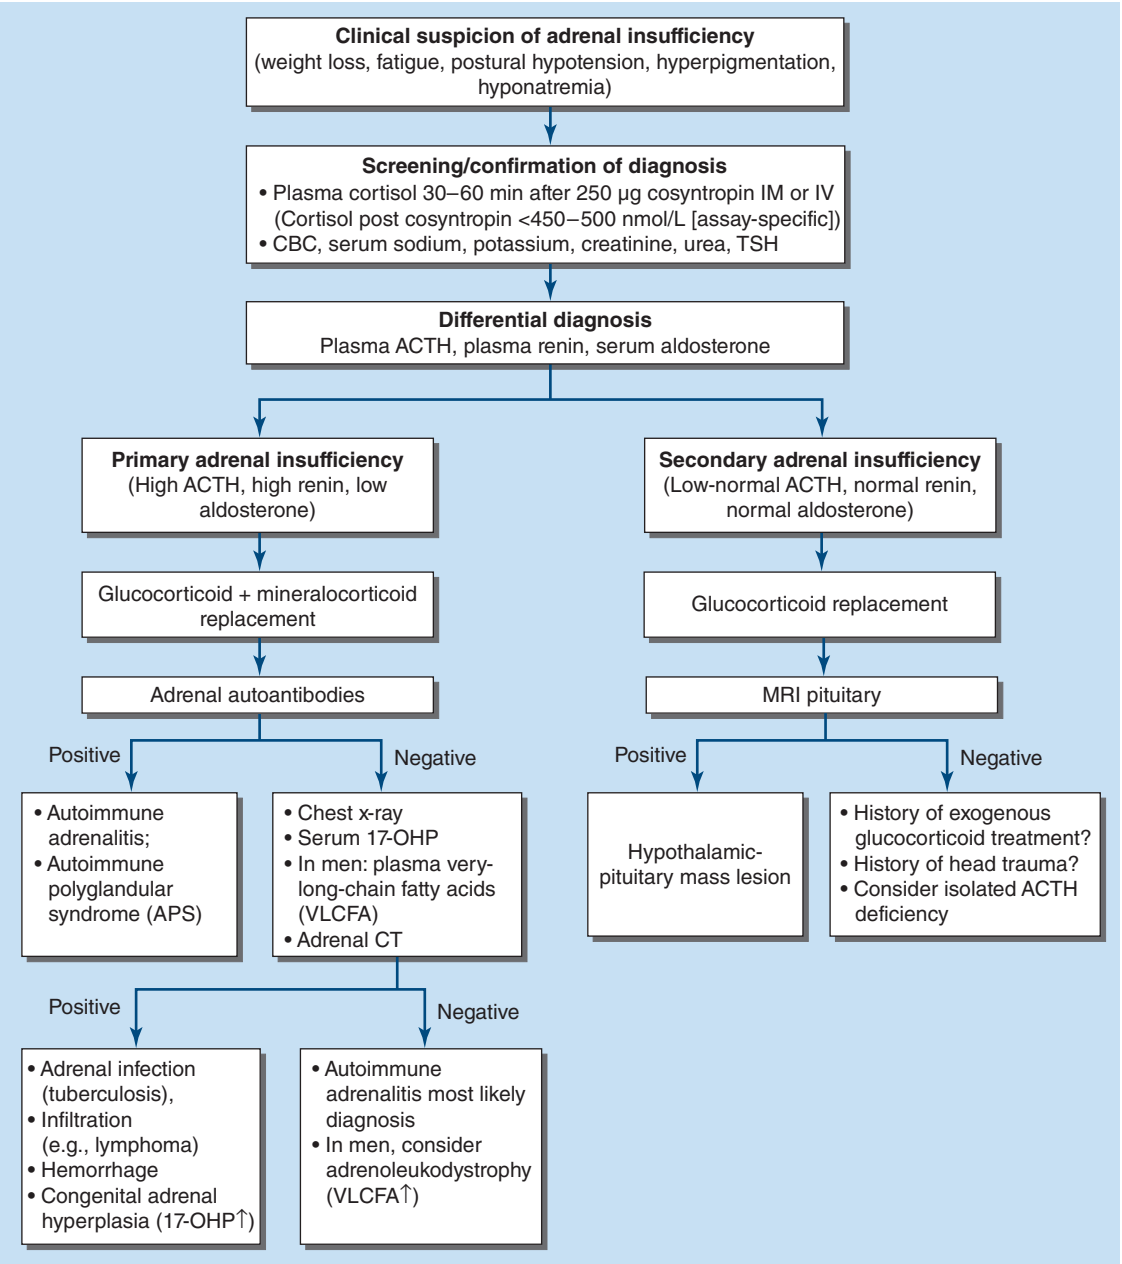

FIGURE 398-16 Management of the patient with suspected adrenal insufficiency. ACTH, adrenocorticotropic hormone; CBC, complete blood count; CT, computed tomography; MRI, magnetic resonance imaging; 17-OHP, 17-hydroxyprogesterone; PRA, plasma renin activity; TSH, thyroid-stimulating hormone.

by intravenous infusion of 200 mg hydrocortisone/24 h in cases of prolonged vomiting, surgery, or trauma. All patients, but in particular those living or traveling in regions with delayed access to acute health care, should carry a hydrocortisone self-injection emergency kit, in addition to their usual steroid emergency cards and bracelets, and should receive training in its use.

Mineralocorticoid replacement in primary adrenal insufficiency should be initiated at a dose of 100–150 µg fludrocortisone. The adequacy of treatment can be evaluated by measuring blood pressure, sitting and standing, to detect a postural drop indicative of hypovolemia. In addition, serum sodium, potassium, and plasma renin should be measured regularly. Renin levels should be kept in the upper normal reference range. Changes in glucocorticoid dose may also impact on mineralocorticoid replacement as cortisol also binds the MR; 40 mg of hydrocortisone is equivalent to 100 µg of fludrocortisone. It is important to note that prednisone and prednisolone have reduced mineralocorticoid activity and dexamethasone has none. In patients living or traveling in areas with hot or tropical weather conditions, the fludrocortisone dose should be increased by 50–100 µg during the summer. Mineralocorticoid dose may also need to be adjusted during pregnancy due to the anti-mineralocorticoid activity of progesterone, but this is less often required than hydrocortisone dose adjustment. Plasma renin cannot serve as a monitoring tool during pregnancy because renin rises physiologically during gestation.

Adrenal androgen replacement is an option in patients with lack of energy, despite optimized glucocorticoid and mineralocorticoid replacement. It may also be indicated in women with features of androgen deficiency, including loss of libido. Adrenal androgen replacement can be achieved by once-daily administration of 25–50 mg DHEA. Treatment is monitored by measurement of DHEAS, androstenedione, testosterone, and sex hormone–binding globulin (SHBG) 24 h after the last DHEA dose.

GLUCOCORTICOID-INDUCED ADRENAL INSUFFICIENCY

A possible unwanted effect of glucocorticoid treatment is suppression of the hypothalamic-pituitary-adrenal axis. Glucocorticoid-induced adrenal insufficiency (GI-AI) can be observed with any route of

exogenous administration, including oral, topical, inhaled, intranasal, and intraarticular. Factors affecting the risk of GI-AI include the duration of glucocorticoid therapy, mode of administration, glucocorticoid dose and potency, concomitant drugs that interfere with glucocorticoid metabolism, and individual susceptibility. Up to half of long-term oral glucocorticoid users (0.5–1.8% of the general population in Western countries) develop GI-AI: patients treated with supraphysiologic doses for longer than 3–4 weeks carry the highest risk, whereas short-term therapy is generally safe. GI-AI has been described in around 8% of inhaled glucocorticoid users, but the risk increases substantially (21–27%) when high doses are used and for treatment duration >1 year. GI-AI has also been reported in approximately half of patients receiving intra-articular steroid injections, but evidence in this population is very limited. The use of multiple glucocorticoid formulations at the same time and the concomitant administration of strong cytochrome P450 3A4 inhibitors, which include several antibiotics, antifungals, and the protease inhibitor ritonavir, are among the factors dramatically increasing the risk of developing GI-AI. Ritonavir is the most reported offending medication, used as part of antiviral combinations to treat HIV infection, hepatitis C infection, and COVID-19. Other drugs that can increase the risk are opioids, which can also blunt the HPA axis response.

Clinicians who prescribe glucocorticoids should educate patients about the different aspects of glucocorticoid therapy, including the risk of GI-AI. If glucocorticoids are no longer required for the control of the underlying disease and the treatment duration is <3–4 weeks, glucocorticoids can be stopped abruptly. Conversely, patients on long-term treatment should be tapered down gradually until approaching a physiologic dose (e.g., 3–5 mg of prednisone). Patients who have developed a dependence on supraphysiologic glucocorticoid doses can develop withdrawal symptoms during tapering including malaise, fatigue, nausea, muscle and joint pain, and sleep and mood disturbances. Symptoms can be severe, and patients can sometimes benefit from a temporary increase in their glucocorticoid dose and a subsequent slower taper. Once a physiologic glucocorticoid dose has been achieved, patients should be tested for HPA axis recovery through an early-morning serum cortisol measurement, which provides information on the likelihood of GI-AI. There are no established cortisol cutoffs, which are influenced by the assay used and other factors including concurrent major stress and altered CBG levels leading to falsely elevated (e.g., oral estrogens, pregnancy) or falsely reduced (e.g., advanced liver cirrhosis, nephrotic syndrome) cortisol levels. Current international guidelines suggest that an early-morning cortisol <150 nmol/L (or 5 μg/dL) is highly suggestive of GI-AI, whereas values >300 nmol/L (or 10 μg/dL) are in keeping with HPA axis recovery. For indeterminate values, cosyntropin stimulation may be considered. Several clinicians do not routinely measure cortisol levels in patients tapering glucocorticoids; in such cases, patients must be educated and closely monitored for clinical manifestations of adrenal insufficiency, and biochemical testing should be swiftly arranged if there are any clinical concerns.

Patients with established GI-AI must be treated as any other patient with secondary adrenal insufficiency. Other than daily glucocorticoid replacement, patients should receive stress dose coverage when they are exposed to stress to avoid acute adrenal insufficiency. Mineralocorticoid therapy is not required due to preserved aldosterone production.

CONGENITAL ADRENAL HYPERPLASIA

(See also Chap. 402) CAH is caused by mutations in genes encoding steroidogenic enzymes involved in glucocorticoid synthesis (*CYP21A2, CYP17A1, HSD3B2, CYP11B1*) or in the cofactor enzyme P450 oxidoreductase that serves as an electron donor to CYP21A2 and CYP17A1 (Fig. 398-1). Invariably, patients affected by CAH exhibit glucocorticoid deficiency. Depending on the exact step of enzymatic block, they may also have excess production of mineralocorticoids or deficient production of sex steroids (Table 398-10). The diagnosis of CAH is readily established by measurement of the steroids accumulating before the distinct enzymatic block, either in serum or in urine, preferably by the use of mass spectrometry–based assays (Table 398-10).

Mutations in *CYP21A2* are the most prevalent cause of CAH, responsible for 90–95% of cases. 21-Hydroxylase deficiency disrupts glucocorticoid and mineralocorticoid synthesis (Fig. 398-1), resulting in diminished negative feedback via the HPA axis. This leads to increased pituitary ACTH release, which drives increased synthesis of adrenal androgen precursors and subsequent androgen excess. The degree of impairment of glucocorticoid and mineralocorticoid secretion depends on the severity of mutations. Major loss-of-function mutations result in combined glucocorticoid and mineralocorticoid deficiency (classic CAH, neonatal presentation), whereas less severe mutations affect glucocorticoid synthesis only (simple virilizing CAH, neonatal or early childhood presentation). The mildest mutations result in the least severe clinical phenotype, nonclassic CAH, usually presenting during adolescence and early adulthood and with preserved glucocorticoid production.

Androgen excess is present in all patients and manifests with broad phenotypic variability, ranging from severe virilization of the external genitalia in neonatal girls (e.g., 46,XX disordered sex development [DSD]) to hirsutism and oligomenorrhea resembling a polycystic ovary syndrome phenotype in young women with nonclassic CAH. In countries without neonatal screening for CAH, boys with classic CAH usually present with life-threatening adrenal crisis in the first few weeks of life (salt-wasting crisis); a simple-virilizing genotype manifests with precocious pseudo-puberty and advanced bone age in early childhood, whereas men with nonclassic CAH are usually detected only through family screening.

Glucocorticoid treatment is more complex than for other causes of primary adrenal insufficiency as it not only needed to replace missing glucocorticoids but also to control the increased ACTH drive and subsequent androgen excess. Current treatment is hampered by the lack of glucocorticoid preparations that mimic the diurnal cortisol secretion profile, resulting in a prolonged period of ACTH stimulation and subsequent androgen production during the early morning hours. In childhood, optimization of growth and pubertal development are important goals of glucocorticoid treatment, in addition to prevention of adrenal crisis and treatment of 46,XX DSD. In adults, the focus shifts

TABLE 398-10 Variants of Congenital Adrenal Hyperplasia

VARIANT	GENE	IMPACT ON STEROID SYNTHESIS	DIAGNOSTIC MARKER STEROIDS IN SERUM (AND URINE)
21-Hydroxylase deficiency (21OHD)	*CYP21A2*	Glucocorticoid deficiency, mineralocorticoid deficiency, adrenal androgen excess	17-Hydroxyprogesterone, 21-deoxycortisol (pregnanetriol, 17-hydroxypregnanolone, pregnanetriolone)
11β-Hydroxylase deficiency (11OHD)	*CYP11B1*	Glucocorticoid deficiency, mineralocorticoid excess, adrenal androgen excess	11-deoxycortisol, 11-deoxycorticosterone (tetrahydro-11-deoxycortisol, tetrahydro-11-deoxycorticosterone)
17α-Hydroxylase deficiency (17OHD)	*CYP17A1*	(Glucocorticoid deficiency), mineralocorticoid excess, androgen deficiency	11-Deoxycorticosterone, corticosterone, pregnenolone, progesterone (tetrahydro-11-deoxycorticosterone, tetrahydrocorticosterone, pregnenediol, pregnanediol)
3β-Hydroxysteroid dehydrogenase deficiency (3bHSDD)	*HSD3B2*	Glucocorticoid deficiency, (mineralocorticoid deficiency), adrenal androgen excess (females and males), gonadal androgen deficiency (males)	17-Hydroxypregnanolone (pregnanetriol)
P450 oxidoreductase deficiency (PORD)	*POR*	Glucocorticoid deficiency, (mineralocorticoid excess), prenatal androgen excess and postnatal androgen deficiency, skeletal malformations	Pregnenolone, progesterone, 17-hydroxyprogesterone (pregnanediol, pregnanetriol)

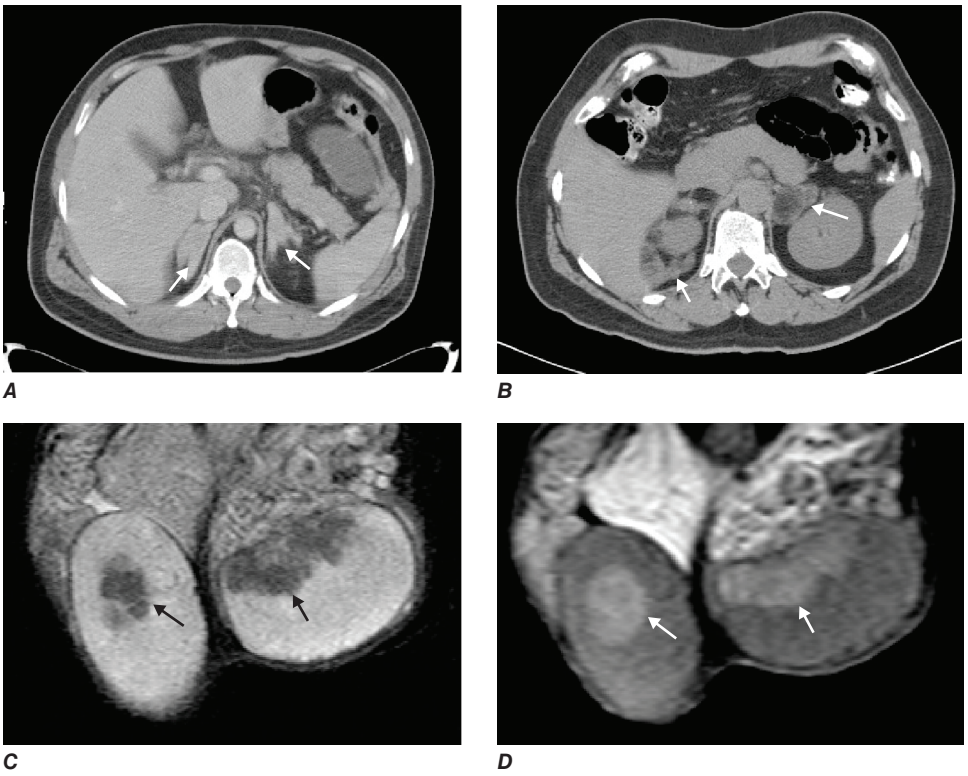

FIGURE 398-17 Imaging in congenital adrenal hyperplasia (CAH). Reisch.)*

to preserving fertility and preventing side effects of glucocorticoid overtreatment, namely, the metabolic syndrome and osteoporosis. Fertility can be compromised in women due to oligomenorrhea/amenorrhea with chronic anovulation as a consequence of androgen excess. Men may develop testicular adrenal rest tissue (TART) **(Fig. 398-17)** consisting of hyperplastic cells with shared adrenal and gonadal characteristics located in the rete testis, which should not be confused with testicular tumors. TART can compromise sperm production and induce testicular fibrosis that may be irreversible.

TREATMENT

Congenital Adrenal Hyperplasia

Hydrocortisone is a good treatment option for the prevention of adrenal crisis, but longer acting prednisolone may be needed to control androgen excess. In children, hydrocortisone is given in divided doses at 1–1.5 times the normal cortisol production rate (~10–13 mg/m^2 per day). In adults, if hydrocortisone does not suffice, intermediate-acting glucocorticoids (e.g., prednisone) may be given, using the lowest dose necessary to suppress excess androgen production. For achieving fertility, dexamethasone treatment may be required but should only be given for the shortest possible time period to limit adverse metabolic side effects. The recent introduction of modified and delayed-release hydrocortisone, which mimics the endogenous physiologic cortisol release pattern, is promising, providing effective control of steroid precursor excess while the daily hydrocortisone dose is lower than required for immediate-release hydrocortisone. An oral corticotropin-releasing factor antagonist, Crinecerfont, has shown efficacy to reduce glucocorticoid replacement doses needed to suppress adrenal androgens.

Biochemical monitoring should include androstenedione and testosterone, aiming for the normal sex-specific reference range. 17OHP is a useful marker of overtreatment, indicated by 17OHP levels within the normal range of healthy controls. Glucocorticoid overtreatment may suppress the hypothalamic-pituitary-gonadal axis. Thus, treatment needs to be carefully titrated against clinical features of disease control. Stress-dose glucocorticoids should be given at double or triple the daily dose for surgery, acute illness, or severe trauma. Poorly controlled CAH can result in adrenocortical hyperplasia, which gave the disease its name, and may present as macronodular hyperplasia subsequent to long-standing ACTH excess (Fig. 398-17). The nodular areas can develop autonomous adrenal androgen production and may be unresponsive to glucocorticoid treatment. The prevalence of adrenomyelolipomas is increased in CAH; these are benign but can require surgical intervention due to lack of self-limiting growth.

Mineralocorticoid requirements change during life and are higher in children, explained by relative mineralocorticoid resistance that diminishes with ongoing maturation of the kidney. Children with CAH usually receive mineralocorticoid and salt replacement. However, young adults with CAH should undergo reassessment of their mineralocorticoid reserve. Plasma renin should be regularly monitored and kept within the upper half of the normal reference range.

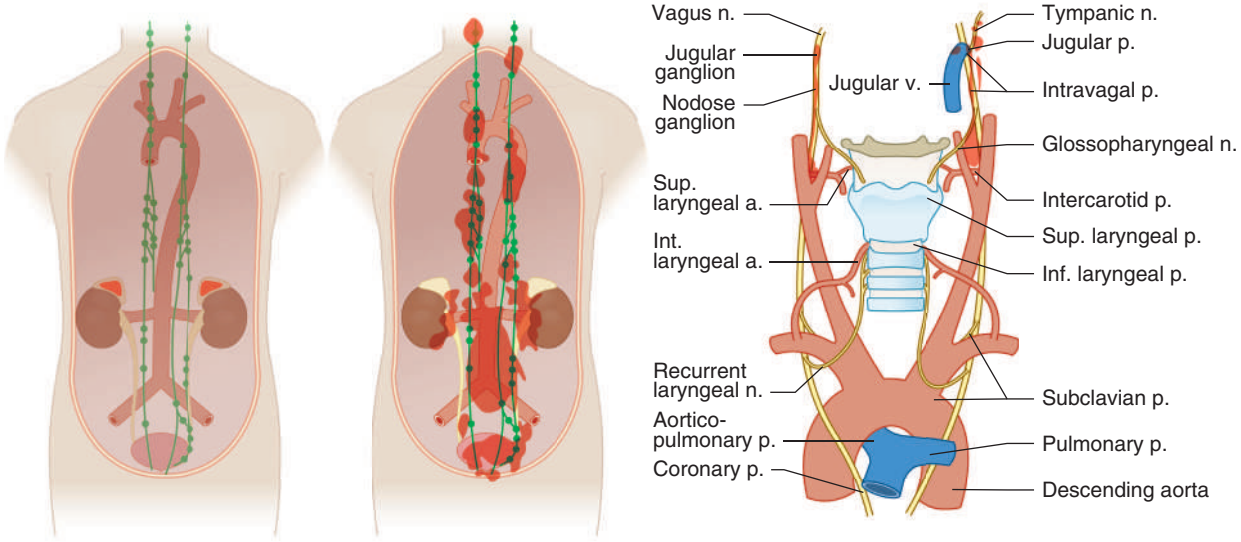
399 Pheochromocytoma

Frederic Castinetti,
Hartmut P. H. Neumann

Pheochromocytomas and paragangliomas (PPGLs) are catecholamine-producing tumors derived from the sympathetic or parasympathetic nervous system. These tumors may arise sporadically or be inherited as features of multiple endocrine neoplasia type 2 (MEN 2), von Hippel–Lindau (VHL) disease, or several other pheochromocytoma-associated syndromes. The diagnosis of pheochromocytomas identifies a potentially correctable cause of hypertension, and their removal can prevent hypertensive crises that can be lethal. The clinical presentation is variable, ranging from an adrenal incidentaloma to a hypertensive crisis with associated cerebrovascular or cardiac complications. Given the wide range of clinical signs, diagnosis may be delayed for years.

EPIDEMIOLOGY



The incidence of PPGL ranges from 0.04 to 0.95 cases per 100,000 per year, with a gradual increase over time probably due to genetic familial screening, changes in imaging modalities, and more frequent diagnosis as an incidentaloma. About ~0.1% of hypertensive patients harbor a pheochromocytoma. The mean age at diagnosis is ~40 years, although the tumors can be detected from early childhood, particularly when genetically determined, until late in life. The classic "rule of tens" for pheochromocytomas states that ~10% are bilateral, 10% are extra-adrenal, and 10% are metastatic.

ETIOLOGY AND PATHOGENESIS

PPGLs are well-vascularized tumors that arise from cells derived from the sympathetic (e.g., adrenal medulla or sympathetic trunk) or parasympathetic (e.g., carotid body, glomus tympanicum, glomus jugulare, glomus vagale) paraganglia **(Fig. 399-1)**. The name *pheochromocytoma* reflects the formerly used black-colored staining caused by chromaffin oxidation of catecholamines. The World Health Organization (WHO) applies the term *pheochromocytoma* to adrenal tumors (usually secreting) and the term *paraganglioma* to tumors at all other sites including head and neck, thoracic, extra-adrenal retroperitoneal, and pelvic sites.

The etiology of sporadic PPGLs is unknown. However, 25–33% of patients have an inherited condition, including germline mutations in the classically recognized *RET* (*re*arranged during *t*ransfection), *VHL, NF1* (neurofibromatosis type 1), *SDHB, SDHC,* and *SDHD* (subunits of SDH) genes or in the more recently recognized *SDHA, SDHAF2, TMEM127* (transmembrane protein 127), *MAX* (myc-associated factor X), *FH* (fumarate hydratase), *PDH1, PDH2* (pyruvate dehydrogenase), *HIF1α* and *HIF2α* (hypoxia-inducible factor), *MDH2* (malate dehydrogenase), *KIF1Bβ* (kinesin family member), *IDH1*, (isocitrate dehydrogenase 1), *SLC25A11* (oxoglutarate/malate), *H-RAS* (transforming protein p21), and *DNMTA3* (DNA methyltransferase 3 alpha) genes. Biallelic gene inactivation, a characteristic of tumor-suppressor genes, has been demonstrated for the *VHL, NF1, SDHx, TMEM127, MAX, FH, PDH1, PDH2, MDH2*, and *KIF1Bβ* genes. In contrast, *RET* is a protooncogene, and mutations activate receptor tyrosine kinase activity. Succinate dehydrogenase (SDH) is an enzyme of the Krebs cycle and the mitochondrial respiratory chain. The VHL protein is a component of a ubiquitin E3 ligase. *VHL* mutations reduce protein degradation, resulting in upregulation of components involved in cell-cycle progression, glucose metabolism, and oxygen sensing.

In addition to germline mutations, somatic mutations have been observed in >20 genes, broadly grouped into three different clusters of pathogenetically relevant genes: cluster 1, the pseudohypoxia group comprising mainly the genes *SDHx* (subunits of SDH), *FH*, *VHL*, and *HIF2A*; cluster 2, the kinase signaling group (*RET*, *NF1*, *TMEM127*, *MAX*, *HRAS, KIF1Bβ, PDH*); and cluster 3, the Wnt signaling group (*CSDE1*, *MAML3*).

TABLE 399-1 Clinical Features Associated with Pheochromocytoma, Listed by Frequency of Occurrence

1. Headaches	10. Weight loss
2. Profuse sweating	11. Paradoxical response to antihypertensive drugs
3. Palpitations and tachycardia	12. Polyuria and polydipsia
4. Hypertension, sustained or paroxysmal	13. Constipation
5. Anxiety and panic attacks	14. Orthostatic hypotension
6. Pallor	15. Dilated cardiomyopathy
7. Nausea	16. Erythrocytosis
8. Abdominal pain	17. Elevated blood sugar
9. Weakness	18. Hypercalcemia

CLINICAL FEATURES

Its clinical presentation is so variable that pheochromocytoma has been termed "the great masquerader" (Table 399-1). Among the presenting manifestations, episodes of palpitation, headache, and profuse sweating are typical, and these manifestations constitute a classic triad that is seen in roughly a third of patients with pheochromocytoma. The presence of all three manifestations in association with hypertension makes pheochromocytoma a likely diagnosis. However, a pheochromocytoma can be asymptomatic for years or can be identified through imaging screening in a patient presenting with a hereditary syndrome. Some tumors grow to a considerable size before patients note symptoms.

The dominant sign is hypertension. Classically, patients have episodic hypertension, but sustained hypertension is also common. Catecholamine crises can lead to heart failure, pulmonary edema, arrhythmias, and intracranial hemorrhage. During episodes of hormone release, which can occur at widely divergent intervals, patients are anxious and pale, and they experience tachycardia and palpitations. These paroxysms generally last <1 h and may be precipitated by surgery, positional changes, exercise, pregnancy, urination (particularly with bladder pheochromocytomas), and various medications (e.g., tricyclic antidepressants, opiates, metoclopramide). Patients may present with true panic attacks that may be mistakenly attributed to psychiatric illness.

DIAGNOSIS

The diagnosis is based on documentation of catecholamine excess by biochemical testing and localization of the tumor by imaging. These two criteria are of equal importance, although measurement of catecholamines or metanephrines (their methylated metabolites) is traditionally the first step in diagnosis.

Biochemical Testing PPGLs synthesize and store catecholamines, which include norepinephrine (noradrenaline), epinephrine (adrenaline), and dopamine. Elevated plasma and urinary levels of catecholamines and metanephrines form the cornerstone of diagnosis. The characteristic fluctuations in the hormonal activity of tumors result in considerable variation in serial catecholamine measurements. However, most tumors continuously leak O-methylated metabolites, which are detected by measurement of metanephrines.

Catecholamines and metanephrines can be measured by different methods, including high-performance liquid chromatography, enzyme-linked immunosorbent assay, and liquid chromatography/mass spectrometry. When pheochromocytoma is suspected on clinical grounds (i.e., when values are three times the upper limit of normal), this diagnosis is highly likely regardless of the assay used. However, as summarized in Table 399-2, the sensitivity and specificity of available biochemical tests vary greatly, and these differences are important in assessing patients with borderline elevations of different compounds. Urinary tests for metanephrines (total or fractionated) and catecholamines are widely available and are used commonly for initial evaluation. Among these tests, those for the fractionated metanephrines and catecholamines are the most sensitive. Plasma tests are more convenient and include measurements of catecholamines and metanephrines. Measurements of plasma metanephrines are the most sensitive and are less susceptible to false-positive elevations from stress, including venipuncture. Although the incidence of false-positive test results has been reduced by the introduction of newer assays, physiologic stress responses and medications that increase catecholamine levels still can confound testing. Because the tumors are relatively rare, borderline elevations are likely to represent false-positive results. In this circumstance, it is important to exclude dietary or drug-related factors (withdrawal of levodopa or use of sympathomimetics, diuretics, tricyclic antidepressants, alpha and beta blockers) that might cause false-positive results and then to repeat testing.

TABLE 399-2 Biochemical and Imaging Methods Used for Diagnosis of Pheochromocytoma and Paraganglioma

DIAGNOSTIC METHOD	SENSITIVITY	SPECIFICITY
24-h urinary tests		
Catecholamines	+++	+++
Fractionated metanephrines	++++	++
Total metanephrines	+++	++++
Plasma tests		
Catecholamines	+++	++
Free metanephrines	++++	+++
Imaging		
CT	++++	+++
MRI	++++	+++
MIBG scintigraphy	++	++++
Somatostatin receptor scintigraphy[a]	++	++
^{18}Fluoro-DOPA PET/CT	++++	++++
^{68}Gallium-DOTATOC or DOTATATE PET/CT	++++	++++

[a]Values are particularly high in head and neck paragangliomas.

Abbreviations: CT, computed tomography; MIBG, metaiodobenzylguanidine; MRI, magnetic resonance imaging; PET/CT, positron emission tomography plus CT. For the biochemical tests, the ratings correspond globally to sensitivity and specificity rates as follows: ++, <85%; +++, 85–95%; and ++++, >95%.

Diagnostic Imaging A variety of methods have been used to localize PPGLs (Table 399-2, Figs. 399-2, 399-3, and 399-4). Computed tomography (CT) and magnetic resonance imaging (MRI) are similar in sensitivity and should be performed with contrast. T2-weighted MRI with gadolinium contrast is optimal for detecting pheochromocytomas and is somewhat better than CT for imaging extra-adrenal PPGLs. About 5% of adrenal incidentalomas, which usually are detected by CT or MRI, prove to be pheochromocytomas upon endocrinologic evaluation, but the presence of pheochromocytomas is unlikely if unenhanced CT reveals an attenuation of <10 Hounsfield units (HU).

Tumors also can be localized by procedures using radioactive tracers, including ^{131}I- or ^{123}I-metaiodobenzylguanidine (MIBG) scintigraphy, ^{18}F-DOPA positron emission tomography (PET), ^{68}Ga-DOTATATE PET, or ^{18}F-fluorodeoxyglucose (FDG) PET (Fig. 399-2*B* and 399-4*A* and *B*). For PET-CT with both ^{68}Ga-DOTATATE and ^{18}F-DOPA, the sensitivity and specificity are very high (>95%). These agents are particularly useful in the documentation of hereditary syndromes but also in metastatic pheochromocytoma, because uptake is exhibited also in paragangliomas and metastases.

Pathology PPGLs are found at the classical sites of the adrenal medulla (Fig. 399-2) and paraganglia (Fig. 399-3). Histologically, the tumors often show a characteristic "Zellballen" pattern, consisting of nests of neuroendocrine chief cells with peripheral glial-like sustentacular cells. However, a broad spectrum of architectural and cytologic features can be seen. Immunohistochemistry is positive for chromogranin and synaptophysin in the chief cells and S-100 in the sustentacular cells (Fig. 399-5*A–D*). Increasingly, staining with antibodies against the proteins encoded by susceptibility genes for hereditary pheochromocytomas, such as SDHB, is used to histologically demonstrate defects of these proteins, thereby making germline mutations more likely (Fig. 399-5*E* and *F*).

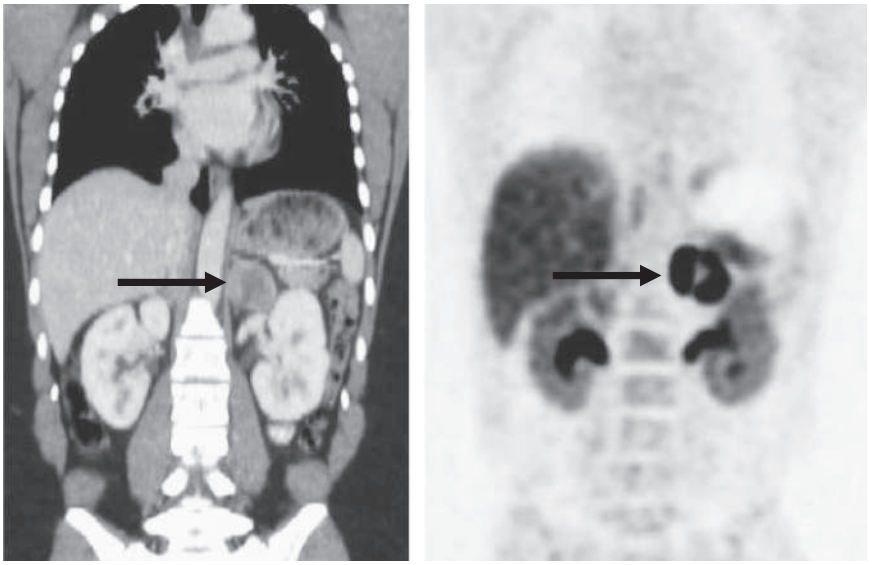

FIGURE 399-2 Typical pheochromocytoma (adrenal unilateral). *A.* Magnetic resonance imaging. ***B.*** ^{18}F-DOPA positron emission tomography (PET). Tumor marked by *arrows*. *(Part A was provided courtesy of Dr. Tobias Krauss, Freiburg. Part B was provided courtesy of Dr. Juri Ruf, Freiburg.)*

Differential Diagnosis When the possibility of a pheochromocytoma is being entertained, other disorders to consider include essential hypertension, anxiety attacks, use of cocaine or amphetamines, mastocytosis or carcinoid syndrome (usually without hypertension), intracranial lesions, clonidine withdrawal, autonomic epilepsy, and factitious crises (usually from use of sympathomimetic amines). When an asymptomatic adrenal mass is identified, likely diagnoses other than pheochromocytoma include a nonfunctioning adrenal adenoma, an aldosteronoma, and a cortisol-producing adenoma (Cushing's syndrome).

TREATMENT

Complete tumor removal, the ultimate therapeutic goal, can be achieved by partial or total adrenalectomy. It is important to preserve the normal adrenal cortex in order to prevent Addison's disease, particularly in hereditary disorders in which bilateral pheochromocytomas are most likely. Preoperative preparation of the patient has to be considered, and blood pressure should be consistently <160/90 mmHg. Classically, blood pressure has been controlled by α-adrenergic blockers (oral phenoxybenzamine, 0.5–4 mg/kg of body weight). Because patients are volume-constricted, liberal salt intake and hydration are necessary to avoid severe orthostasis. Oral prazosin or intravenous phentolamine can be used to manage paroxysms while adequate alpha blockade is awaited. Beta blockers (e.g., 10 mg of propranolol three or four times per day) should not be used as first-line treatment because of the risk of increased hypertension. Other antihypertensives, such as calcium channel blockers

Part E was provided courtesy of Dr. Kurt Werner Schmid, Essen.)*

or angiotensin-converting enzyme inhibitors, have also been used effectively.

Surgery should be performed by teams of surgeons and anesthesiologists with experience in the management of pheochromocytomas. Blood pressure can be labile during surgery, particularly at the outset of intubation or when the tumor is manipulated. Nitroprusside infusion is useful for intraoperative hypertensive crises, and hypotension usually responds to volume infusion. The latter side effect can, however, be avoided in normotensive pheochromocytoma patients by having only standby intraoperative nitroprusside, which has been shown to be safe and avoids postoperative hypotension often caused by alpha blockers. The long-lasting guideline for obligatory preoperative treatment with alpha blockers is under discussion and seemingly not needed.

Minimally invasive techniques (laparoscopy or retroperitoneoscopy) have become the standard approaches in pheochromocytoma surgery. They are associated with fewer complications, a faster recovery, and optimal cosmetic results. Extra-adrenal abdominal and most thoracic pheochromocytomas can also be removed endoscopically. In this setting, adrenal sparing surgery should be considered. Postoperatively, catecholamine normalization should be documented. An adrenocorticotropic hormone (ACTH) test should be used to exclude cortisol deficiency when bilateral adrenal cortex–sparing surgery has been performed.

Head and neck paragangliomas are a challenge for surgeons, since damage of adjacent tissue, mainly vessels or cranial nerves II, VII, IX, X, XI, and XII, is a frequent permanent side effect. Careful consideration of best management is important, and radiotherapy may be an alternative, especially for large head and neck paragangliomas. Tympanic paragangliomas are symptomatic early, and most of these tumors can easily be resected, with subsequent improvement of hearing and alleviation of tinnitus. Asymptomatic paraganglial tumors, now often detected in patients with hereditary tumors and their relatives, are challenging to manage. Watchful waiting strategies have been introduced, but they should consider any genetic syndrome, such as *SDHB*, that might be associated with a higher degree of malignancy (see below).

METASTATIC PHEOCHROMOCYTOMA

About 5–10% of PPGLs are metastatic. The diagnosis of malignant pheochromocytoma is problematic. The typical histologic criteria of cellular atypia, presence of mitoses, and invasion of vessels or adjacent tissues are insufficient for the diagnosis of malignancy in pheochromocytoma. Size >5 cm, high pheochromocytoma of the adrenal gland scaled score (PASS) and grading system for adrenal pheochromocytoma and paraganglioma (GAPP) score, and SDHB-positive status have been considered as markers of risk of recurrence, but they remain controversial. Thus, the term *malignant pheochromocytoma* has been replaced by *metastatic pheochromocytoma* as suggested by the WHO and is restricted to tumors with lymph node or distant metastases, the latter most commonly found by nuclear medicine imaging in lungs, bone, or liver locations, suggesting a vascular pathway of spread (Fig. 399-4*B*). Because hereditary syndromes are associated with multifocal tumor sites, these features should be anticipated in patients with germline mutations, especially of *SDHB, SDHD, VHL,* and *RET.* However, distant metastases also occur in these syndromes, especially in carriers of *SDHB* mutations.

Treatment of metastatic pheochromocytoma or paraganglioma is challenging. Options include tumor mass reduction, alpha blockers for symptoms, chemotherapy including tyrosine kinase inhibitors, nuclear medicine radiotherapy, and stereotactic radiation. Nuclear medicine therapy is the treatment of choice for scintigraphically documented metastases, preferably with ^{131}I-MIBG in 100–300 mCi doses over 3–6 cycles, or somatostatin receptor ligands, e.g., DOTATOC labeled with yttrium-90 or lutetium-177. Averbuch's chemotherapy protocol includes dacarbazine (600 mg/m^2 on days 1 and 2), cyclophosphamide (750 mg/m^2 on day 1), and vincristine (1.4 mg/m^2 on day 1), all repeated every 21 days for 3–6 cycles. Palliation (stable disease to shrinkage) is achieved in about one-half of patients. Due to increasing insights in the genetics of pheochromocytoma and their molecular pathways, new targeted chemotherapeutic options such as sunitinib and temozolomide are under investigation. The prognosis of metastatic pheochromocytoma or paraganglioma is variable, with 5-year survival rates of 30–60%.

PHEOCHROMOCYTOMA IN PREGNANCY

Pheochromocytomas occasionally are diagnosed in pregnancy and can be very challenging to manage. The pathogenesis of adrenergic crises during pregnancy in previously asymptomatic women might be linked to human chorionic gonadotropin (hCG)-induced stimulation of epinephrine production by pheochromocytoma, as some of these express luteinizing hormone/chorionic gonadotropin (LHCG) receptors. Endoscopic removal, preferably in the fourth to sixth month of gestation, is possible and can be followed by uneventful childbirth. Regular screening in families with inherited pheochromocytomas provides an opportunity to identify and remove such tumors in women of reproductive age.

PHEOCHROMOCYTOMA-ASSOCIATED SYNDROMES

About 25–33% of patients with a PPGL have an inherited syndrome. At diagnosis, patients with inherited syndromes are a mean of ~15 years younger than patients with sporadic tumors.

The best-known pheochromocytoma-associated syndrome is the autosomal dominant disorder MEN 2 **(Chap. 400)**. Both types of MEN 2 (2A and 2B) are caused by mutations in *RET*, which encodes a tyrosine kinase. The locations of *RET* mutations correlate with the age of disease onset, the aggressiveness, and the type of MEN 2 **(Chap. 400)**. MEN 2A is characterized by medullary thyroid carcinoma (MTC), pheochromocytoma, and hyperparathyroidism. MEN 2B also includes MTC (more aggressive than in MEN 2A), pheochromocytoma, and multiple mucosal neuromas, marfanoid habitus, and other developmental disorders, although it typically lacks hyperparathyroidism. MTC is found in virtually all patients with MEN 2, but pheochromocytoma occurs in only ~50% of these patients. Nearly all pheochromocytomas in MEN 2 are benign and located in the adrenals, often bilaterally. Pheochromocytoma may be symptomatic before the diagnosis of MTC is made. Prophylactic thyroidectomy is being performed in many carriers of *RET* mutations, and the recommended age to perform thyroidectomy usually depends on the mutation and/or the level of calcitonin; pheochromocytomas should be excluded before any surgery in these patients.

VHL is an autosomal dominant disorder that predisposes to retinal and cerebellar hemangioblastomas, which also occur in the brainstem and spinal cord **(Fig. 399-6)**. Other important features of VHL are clear cell renal carcinomas, pancreatic neuroendocrine tumors, endolymphatic sac tumors of the inner ear, cystadenomas of the epididymis and broad ligament, and multiple pancreatic or renal cysts. Although the *VHL* gene can be inactivated by all types of mutations, patients with pheochromocytoma predominantly have missense mutations. About 20–30% of patients with VHL have pheochromocytomas, but in some families, the incidence can reach 90%. The recognition of pheochromocytoma as a VHL-associated feature provides an opportunity to diagnose retinal, central nervous system, renal, and pancreatic tumors at a stage when effective treatment may still be possible.

NF1 was the first described pheochromocytoma-associated syndrome. The *NF1* gene functions as a tumor suppressor by regulating the Ras signaling cascade. Classic features of neurofibromatosis include multiple neurofibromas, café au lait spots, axillary freckling of the skin, and Lisch nodules of the iris. Pheochromocytomas occur in only ~1% of these patients and are located predominantly in the adrenals. Metastatic pheochromocytoma is not uncommon in NF1.

The *paraganglioma syndromes* (PGLs) have been classified by genetic analyses of families with head and neck paragangliomas. The susceptibility genes encode subunits of the enzyme SDH, a component in the Krebs cycle and the mitochondrial electron transport chain. SDH is formed by four subunits (A–D). Mutations of *SDHA* (PGL5), *SDHB* (PGL4), *SDHC* (PGL3), *SDHD* (PGL1), and *SDHAF2* (PGL2) predispose to the PGLs. The transmission of the disease in carriers of

SDHA, *SDHB*, and *SDHC* germline mutations is autosomal dominant. In contrast, in virtually all *SDHD* and *SDHAF2* families, only the progeny of affected fathers develops tumors if they inherit the mutation. PGL1 is most common, followed by PGL4; PGL2, PGL3, and PGL5 are rare. Adrenal, extra-adrenal abdominal, and thoracic pheochromocytomas, which are components of PGL1, PGL4, and PGL5, are rare in PGL3 and absent in PGL2 (Fig. 399-4*A*). About one-third of patients with PGL4 develop metastases, which is the highest rate in pheochromocytoma-associated syndromes. However, the penetrance of the disease is usually low, raising questions about the optimal way to monitor asymptomatic carriers on a long-term basis. Other syndromes with metastatic pheochromocytomas are mainly VHL, NF1, and PGL1.

Other familial pheochromocytoma has been attributed to hereditary, mainly adrenal tumors in patients with germline mutations in the genes *TMEM127* and *MAX*. Transmission is also autosomal dominant, and mutations of *MAX*, like those of *SDHD,* cause tumors only if inherited from the father. Pituitary neuroendocrine tumors have been described as an association with *SDHx* (pituitary adenoma and pheochromocytoma/paraganglioma 3PA syndrome) as well as *MAX* mutations (MEN 5), but they seem to occur very rarely.

GENETIC SCREENING OF PATIENTS WITH PHEOCHROMOCYTOMA OR PARAGANGLIOMA

Universal germline panel testing is now the gold standard to characterize the genetic factors involved in PPGL. It usually identifies a genetic etiology in up to 30% of the cases. This rate can be even higher in patients with early age of onset, extra-adrenal location, multiple tumors, metastatic tumors, or family history of PPGL. Effective preventive medicine for pheochromocytoma and pheochromocytoma-associated diseases requires management according to identified germline mutations in susceptibility genes **(Table 399-3)**. Because of the relatively high prevalence of familial syndromes among patients who present with pheochromocytoma or paraganglioma, it is useful to identify germline mutations even in patients without a known family history. Despite the use of a universal germline panel testing performed for all patients with a PPGL, a first step remains to search for clinical features of inherited syndromes and to obtain an in-depth, multigenerational family history. Each of these syndromes exhibits autosomal dominant transmission with variable penetrance, but a proband with a mother affected by paraganglial tumors is not predisposed to PLG1 and PGL2 (*SDHD* and *SDHAF2* mutation carrier). Cutaneous neurofibromas, café au lait spots, and axillary freckling suggest neurofibromatosis. Germline mutations in *NF1* have nearly never been reported in patients with sporadic pheochromocytomas. Thus, *NF1* testing is not needed in the absence of other clinical features of neurofibromatosis. A personal or family history of MTC or an elevation of serum calcitonin strongly suggests MEN 2 and should prompt testing for *RET* mutations. A history of visual impairment or tumors of the cerebellum, brainstem, spinal cord, or the kidney suggests the possibility of VHL. A personal and/or family history of head and neck paraganglioma suggests PGL1 or PGL4. Of note, sequencing protocols may not detect large deletions of one or more exons.

TABLE 399-3 Patterns of Occurrence in Inherited Pheochromocytoma and Paraganglioma–Associated Syndromes

MUTATED GENE	ADRENAL TUMORS	HEAD AND NECK TUMORS	EXTRA-ADRENAL RETROPERITONEAL OR PELVIC TUMORS	THORACIC TUMORS	MULTIPLE TUMORS	BILATERAL ADRENAL TUMORS	METASTATIC TUMORS	FAMILY HISTORY IN PROBANDS FOR COMPONENTS OF THE GIVEN SYNDROME

VHL	+++++	<+	+	+	++++	+++	+	++++
TMEM127	+++++	+	+	+	++	++	<+	+

Note: Frequencies in percentage (<+: 0–4%; +: 5–19%; ++: 20–39%; +++: 40–59%; ++++: 60–79%; +++++: 80–100%) of clinical characteristics of pheochromocytomas/paragangliomas of patients with germline mutations of the genes *MAX, NF1, RET, SDHA, SDHB, SDHC, SDHD, VHL*, and *TMEM127*; for other genes, the data are too limited to include in this summary.

A single adrenal pheochromocytoma in a patient with an otherwise unremarkable history may still be associated with mutations of *VHL, RET, SDHB*, or *SDHD* (in decreasing order of frequency). Two-thirds of extra-adrenal tumors are associated with one of these syndromes, and multifocal tumors occur with decreasing frequency in carriers of *RET, SDHD, VHL*, *SDHB*, and *MAX* mutations. About 30% of head and neck paragangliomas are associated with germline mutations of one of the SDH subunit genes (most often *SDHD*) and are rare in carriers of *VHL, RET, MAX*, and *TMEM127* mutations. Immunohistochemistry is helpful in the preselection of hereditary pheochromocytoma. Negative immunostaining with antibodies to SDHB (Fig. 399-5*F*), TMEM127, and MAX may predict mutations of the *SDHx* (PGL1-5), *TMEM127*, and *MAX* genes, respectively.

Once the underlying syndrome is diagnosed, the benefit of genetic testing can be extended to relatives. For this purpose, it is necessary to identify the germline mutation in the proband and, after genetic counseling, to perform DNA sequence analyses of the responsible gene in relatives to determine whether they are affected. Other family members may benefit when individuals who carry a germline mutation are biochemically screened for paraganglial tumors.

FUTURE PERSPECTIVES

About 15% of sporadic PPGLs present with recurrence, including some ocurring >10 years after initial management; this rate is higher in genetically determined PPGL. Defining the clinical outcome of a PPGL remains difficult, and machine learning models including several factors might be helpful in the future to personalize the follow-up of these patients. The recent American Joint Committee on Cancer tumor-node-metastasis classification could help select patients at risk of recurrence. The pathogenesis of PPGL remains imperfectly understood, and as for other endocrine tumors, microenvironment and immune cells might influence PPGL aggressiveness or metastatic behavior; they could also constitute some new therapeutic targets in the future.

400 Multiple Endocrine Neoplasia Syndromes

Rajesh V. Thakker

Multiple endocrine neoplasia (MEN) is characterized by a predilection for tumors involving two or more endocrine glands. Five major forms of MEN are recognized and referred to as MEN types 1–5 (MEN 1–5) **(Table 400-1)**. Each type of MEN is inherited as an autosomal dominant syndrome or may occur sporadically, that is, without a family history. However, this distinction between familial and sporadic forms is often difficult because family members with the disease may have died before symptoms developed. In addition to MEN 1–5, at least six other syndromes are associated with multiple endocrine and other organ neoplasias (MEONs) **(Table 400-2)**. These MEONs include the hyperparathyroidism-jaw tumor (HPT-JT) syndrome, Carney complex, von Hippel–Lindau disease **(Chap. 399)**, neurofibromatosis

TABLE 400-1 Multiple Endocrine Neoplasia (MEN) Syndromes

TYPE (CHROMOSOMAL LOCATION)	TUMORS (ESTIMATED PENETRANCE)	GENE AND MOST FREQUENTLY MUTATED CODONS
MEN 1 (11q13)	Parathyroid adenoma (90%)	*MEN1*
	Enteropancreatic tumor (30–70%)	83/84, 4-bp del (≈4%)
	• Gastrinoma (>50%)	119, 3-bp del (≈3%)
	• Insulinoma (10–30%)	209-211, 4-bp del (≈8%)
	• Nonfunctioning and PPoma (20–55%)	418, 3-bp del (≈4%)
	• Glucagonoma (<3%)	514-516, del or ins (≈7%)
	• VIPoma (<1%)	Intron 4 ss (≈10%)
	Pituitary adenoma (15–50%)	
	• Prolactinoma (60%)	
	• Somatotrophinoma (25%)	
	• Corticotrophinoma (<5%)	
	• Nonfunctioning (<5%)	
	Associated tumors	
	• Adrenal cortical tumor (20–70%)	
	• Pheochromocytoma (<1%)	
	• Bronchopulmonary NET (2%)	
	• Thymic NET (2%)	
	• Gastric NET (10%)	
	• Lipomas (>33%)	
	• Angiofibromas (85%)	
	• Collagenomas (70%)	
	• Meningiomas (8%)	
MEN 2 (10 cen-10q11.2)		
MEN 2A	MTC (90%)	*RET*
	Pheochromocytoma (>50%)	634, e.g., Cys → Arg (~85%)
	Parathyroid adenoma (10–25%)	
MTC only	MTC (100%)	*RET* 618, missense (>50%)
MEN 2B (also known as MEN 3)	MTC (>90%)	*RET* 918, Met → Thr (>95%)
	Pheochromocytoma (>50%)	
	Associated abnormalities (40–50%)	
	• Mucosal neuromas	
	• Marfanoid habitus	
	• Medullated corneal nerve fibers	
	• Megacolon	
MEN 4 (12p13)	Parathyroid adenoma[a]	*CDKN1B*; no common mutations identified to date
	Pituitary adenoma[a]	
	Reproductive organ tumors[a] (e.g., testicular cancer, neuroendocrine cervical carcinoma)	
	?Adrenal + renal tumors[a]	
MEN5 (14q23.3)	Pheochromocytoma[a]	*MAX*; no common mutations identified to date
	Pituitary adenoma[a]	
	Parathyroid adenomas?[a]	
	Neural crest tumors (e.g., ganglioneuroma, neuroblastoma)	
	(other tumors? – renal cell carcinoma, renal oncocytoma, pancreatic NETs, chondrosarcoma)	

[a]Insufficient numbers reported to provide prevalence information.

Note: Autosomal dominant inheritance of the MEN syndromes has been established.

Abbreviations: del, deletion; ins, insertion; MTC, medullary thyroid cancer; NET, neuroendocrine tumor; PPoma, pancreatic polypeptide–secreting tumor; VIPoma, vasoactive intestinal polypeptide–secreting tumor.

TABLE 400-2 Multiple Endocrine and Other Organ Neoplasia (MEON) Syndromes

DISEASE[a]	GENE PRODUCT	CHROMOSOMAL LOCATION
Hyperparathyroidism-jaw tumor (HPT-JT)	Parafibromin	1q31.2
Carney complex		
CNC1	PRAKAR1A	17q24.2
CNC2	?[b]	2p16
von Hippel–Lindau disease (VHL)	pVHL (elongin)	3p25
Neurofibromatosis type 1 (NF1)	Neurofibromin	17q11.2
Cowden's syndrome (CWS)		
CWS1	PTEN	10q23.31
CWS2	SDHB	1p36.13
CWS3	SDHD	11q23.1
CWS4	KLLN	10q23.31
CWS5	PIK3CA	3q26.32
CWS6	AKT1	14q32.33
CWS7	SEC23B	20p11.23
McCune-Albright syndrome (MAS)	$G_s\alpha$	20q13.32

[a]The inheritance for these disorders is autosomal dominant, except MAS, which is due to mosaicism that results from the postzygotic somatic cell mutation of the *GNAS1* gene, encoding $G_s\alpha$. [b]?, unknown.

type 1 **(Chap. 95)**, Cowden's syndrome (CWS), and McCune-Albright syndrome (MAS) **(Chap. 424)**; all of these are inherited as autosomal dominant disorders, except for MAS, which is caused by mosaic expression of a postzygotic somatic cell mutation (Table 400-2).

A diagnosis of a MEN or MEON syndrome may be established in an individual by one of three criteria: (1) clinical features (two or more of the associated tumors [or lesions] in an individual); (2) familial pattern (one of the associated tumors [or lesions] in a first-degree relative of a patient with a clinical diagnosis of the syndrome); and (3) genetic analysis (a germline mutation in the associated gene in an individual, who may be clinically affected or asymptomatic). Mutational analysis in MEN and MEON syndromes is helpful in clinical practice to (1) confirm the clinical diagnosis; (2) identify family members who harbor the mutation and require screening for relevant tumor detection and early/appropriate treatment; and (3) identify the ~50% of family members who do not harbor the germline mutation and can, therefore, be alleviated of the anxiety of developing associated tumors. This latter aspect also helps to reduce health care costs by reducing the need for unnecessary biochemical and radiologic investigations.

MULTIPLE ENDOCRINE NEOPLASIA TYPE 1

Clinical Manifestations MEN type 1 (MEN 1), which is also referred to as Wermer's syndrome, is characterized by the triad of tumors involving the parathyroids, pancreatic islets, and anterior pituitary. In addition, adrenal cortical tumors, carcinoid tumors usually of the foregut, meningiomas, facial angiofibromas, collagenomas, and lipomas may also occur in some patients with MEN 1. Combinations of the affected glands and their pathologic features (e.g., hyperplastic adenomas of the parathyroid glands) may differ in members of the same family and even between identical twins. In addition, a nonfamilial (e.g., sporadic) form occurs in 8–14% of patients with MEN 1, and molecular genetic studies have confirmed the occurrence of de novo mutations of the *MEN1* gene in ~10% of patients with MEN 1. The prevalence of MEN 1 is ~0.25% based on randomly chosen postmortem studies but is 1–18% among patients with primary hyperparathyroidism, 16–38% among patients with pancreatic islet tumors, and <3% among patients with pituitary tumors. The disorder affects all age groups, with a reported age range of 5–81 years, with clinical and biochemical manifestations developing in the vast majority by the fifth decade. The clinical manifestations of MEN 1 are related to the sites of tumors and their hormonal products. In the absence of treatment, endocrine tumors are associated with an earlier

TABLE 400-3 Biochemical and Radiologic Screening in Multiple Endocrine Neoplasia Type 1

TUMOR	AGE TO BEGIN (YEARS)	BIOCHEMICAL TEST (PLASMA OR SERUM) ANNUALLY	IMAGING TEST (TIME INTERVAL)
Parathyroid	8	Calcium, PTH	None
Pancreatic NETs			
Gastrinoma	20	Gastrin (± gastric pH)	None
Insulinoma	5	Fasting glucose, insulin	None
Other pancreatic NET	<10	Chromogranin A; pancreatic polypeptide, glucagon, vasoactive intestinal peptide	MRI, CT, or EUS (annually)
Anterior pituitary	5	Prolactin, IGF-I	MRI (every 3 years)
Adrenal	<10	None unless symptoms or signs of functioning tumor and/or tumor >1 cm identified on imaging	MRI or CT (annually with pancreatic imaging)
Thymic and bronchial carcinoid	15	None	CT or MRI (every 1–2 years)

Abbreviations: CT, computed tomography; EUS, endoscopic ultrasound; IGF-I, insulin-like growth factor I; MRI, magnetic resonance imaging; NET, neuroendocrine tumor; PTH, parathyroid hormone.

Source: Data from PJ Newey, RV Thakker: Role of multiple endocrine neoplasia type 1 mutational analysis in clinical practice. Endocr Pract 17, 2011 and RV Thakker: Multiple endocrine neoplasia type 1 (MEN1). Translational Endocrinology and Metabolism, Vol 2. Chevy Chase, MD: The Endocrine Society; 2011.

mortality in patients with MEN 1, with a 50% probability of death by the age of 50 years. The cause of death is usually a malignant tumor, often from a pancreatic neuroendocrine tumor (NET) or foregut carcinoid. In addition, the treatment outcomes of patients with MEN 1–associated tumors are not as successful as those in patients with non–MEN 1 tumors. This is because MEN 1–associated tumors, with the exception of pituitary NETs, are usually multiple, making it difficult to achieve a successful surgical cure. Occult metastatic disease is also more prevalent in MEN 1, and the tumors may be larger, more aggressive, and resistant to treatment.

Parathyroid Tumors **(See also Chap. 422)** Primary hyperparathyroidism occurs in ~90% of patients and is the most common feature of MEN 1. Patients may have asymptomatic hypercalcemia or vague symptoms associated with hypercalcemia (e.g., polyuria, polydipsia, constipation, malaise, or dyspepsia). Nephrolithiasis and osteitis fibrosa cystica (less commonly) may also occur. Biochemical investigations reveal hypercalcemia, usually in association with elevated circulating parathyroid hormone (PTH) **(Table 400-3)**. The hypercalcemia is usually mild, and severe hypercalcemia or parathyroid cancer is a rare occurrence. Additional differences in the primary hyperparathyroidism of patients with MEN 1, as opposed to those without MEN 1, include an earlier age at onset (20–25 vs 55 years) and an equal male-to-female ratio (1:1 vs 1:3). Preoperative imaging (e.g., neck ultrasound with ^{99m}Tc-sestamibi parathyroid scintigraphy) is of limited benefit because all parathyroid glands may be affected, and neck exploration may be required irrespective of preoperative localization studies.

TREATMENT

Parathyroid Tumors

Surgical removal of the abnormally overactive parathyroids in patients with MEN 1 is the definitive treatment, and most specialist centers recommend performing a subtotal (e.g., removal of 3.5 glands) parathyroidectomy. Minimally invasive parathyroidectomy is not recommended because all four parathyroid glands are usually affected with multiple adenomas or hyperplasia. Surgical experience should be taken into account given the variability in pathology in MEN 1. Calcimimetics (e.g., cinacalcet), which act via the calcium-sensing receptor, have been used to treat primary hyperparathyroidism in some patients when surgery is unsuccessful or contraindicated.

Pancreatic Tumors **(See also Chap. 89)** The incidence of pancreatic islet cell tumors, which are NETs, in patients with MEN 1 ranges from 30 to 80% in different series. Most of these tumors (Table 400-1) produce excessive amounts of hormone (e.g., gastrin, insulin, glucagon, vasoactive intestinal polypeptide [VIP]) and are associated with distinct clinical syndromes, although some are nonfunctioning or nonsecretory. These pancreatic islet cell tumors have an earlier age at onset in patients with MEN 1 than in patients without MEN 1.

Gastrinoma Gastrin-secreting tumors (gastrinomas) are associated with marked gastric acid production and recurrent peptic ulcerations, a combination referred to as Zollinger-Ellison syndrome. Gastrinomas occur more often in patients with MEN 1 who are aged >30 years. Recurrent severe multiple peptic ulcers, which may perforate, and cachexia are major contributors to the high mortality. Patients with Zollinger-Ellison syndrome may also suffer from diarrhea and steatorrhea. The diagnosis is established by demonstration of an elevated fasting serum gastrin concentration in association with increased basal gastric acid secretion (Table 400-3). However, the diagnosis of Zollinger-Ellison syndrome may be difficult in hypercalcemic MEN 1 patients because hypercalcemia can also cause hypergastrinemia. Ultrasonography, endoscopic ultrasonography, computed tomography (CT), nuclear magnetic resonance imaging (MRI), selective abdominal angiography, venous sampling, and somatostatin receptor scintigraphy (SRS) are helpful in localizing the tumor prior to surgery. Gastrinomas represent >50% of all pancreatic NETs in patients with MEN 1, and ~20% of patients with gastrinomas will be found to have MEN 1. Gastrinomas, which may also occur in the duodenal mucosa, are the major cause of morbidity and mortality in patients with MEN 1.

TREATMENT

Gastrinoma

Medical treatment of patients with MEN 1 and Zollinger-Ellison syndrome is directed toward reducing basal acid output to <10 mmol/L. Parietal cell H^+-K^+-adenosine triphosphatase (ATPase) inhibitors (e.g., omeprazole or lansoprazole) reduce acid output and are the drugs of choice for gastrinomas. Some patients may also require additional treatment with the histamine H_2 receptor antagonists cimetidine or ranitidine. The role of surgery in the treatment of gastrinomas in patients with MEN 1 is controversial. The goal of surgery is to reduce the risk of distant metastatic disease and improve survival. For a nonmetastatic gastrinoma situated in the pancreas, surgical excision is often effective. However, the risk of hepatic metastases increases with tumor size, such that 25–40% of patients with pancreatic NETs >4 cm develop hepatic metastases, and 50–70% of patients with tumors 2–3 cm in size have lymph node metastases. Survival in MEN 1 patients with gastrinomas <2.5 cm in size is 100% at 15 years, but 52% at 15 years, if metastatic disease is present. The presence of lymph node metastases does not appear to adversely affect survival. Surgery for gastrinomas that are >2–2.5 cm has been recommended, because the disease-related survival in these patients is improved following surgery. In addition, duodenal gastrinomas, which occur more frequently in patients with MEN 1, have been treated successfully with surgery. However,

in most patients with MEN 1, gastrinomas are multiple or extrapancreatic, and with the exception of duodenal gastrinomas, surgery is rarely successful. For example, the results of one study revealed that only ~15% of patients with MEN 1 were free of disease immediately after surgery, and at 5 years, this number had decreased to ~5%; the respective outcomes in patients without MEN 1 were better, at 45 and 40%. Given these findings, most specialists recommend a nonsurgical management for gastrinomas in MEN 1, except as noted earlier for smaller, isolated lesions. Treatment of disseminated gastrinomas is difficult. Chemotherapy with streptozotocin and 5-fluorouracil; hormonal therapy with octreotide or lanreotide, which are human somatostatin analogues (SSAs); selected internal radiation therapy (SIRT); radiofrequency ablation; peptide radio receptor therapy (PRRT); hepatic artery embolization; administration of human leukocyte interferon; and removal of all resectable tumor have been successful in some patients.

Insulinoma These β islet cell insulin-secreting tumors represent 10–30% of all pancreatic tumors in patients with MEN 1. Patients with an insulinoma present with hypoglycemic symptoms (e.g., weakness, headaches, sweating, faintness, seizures, altered behavior, weight gain) that typically develop after fasting or exertion and improve after glucose intake. The most reliable test is a supervised 72-h fast. Biochemical investigations reveal increased plasma insulin concentrations in association with hypoglycemia (Table 400-3). Circulating concentrations of C peptide and proinsulin, which are also increased, are useful in establishing the diagnosis. It also is important to demonstrate the absence of sulfonylureas in plasma and urine samples obtained during the investigation of hypoglycemia (Table 400-3). Surgical success is greatly enhanced by preoperative localization by endoscopic ultrasonography, CT scanning, or celiac axis angiography. Additional localization methods may include preoperative and perioperative percutaneous transhepatic portal venous sampling, selective intraarterial stimulation with hepatic venous sampling, and intraoperative direct pancreatic ultrasonography. Insulinomas occur in association with gastrinomas in 10% of patients with MEN 1, and the two tumors may arise at different times. Insulinomas occur more often in patients with MEN 1 who are aged <40 years, and some arise in individuals aged <20 years. In contrast, in patients without MEN 1, insulinomas generally occur in those aged >40 years. Insulinomas may be the first manifestation of MEN 1 in 10% of patients, and ~4% of patients with insulinomas will have MEN 1.

TREATMENT

Insulinoma

Medical treatment, which consists of frequent carbohydrate meals and diazoxide or octreotide, is not always successful, and surgery is the optimal treatment. Surgical treatment, which ranges from enucleation of a single tumor to a distal pancreatectomy or partial pancreatectomy, has been curative in many patients. Chemotherapy (streptozotocin, 5-fluorouracil, and doxorubicin), PRRT (e.g., with ^{177}Lu-DOTATATE), or hepatic artery embolization has been used for metastatic disease.

Glucagonoma These glucagon-secreting pancreatic NETs occur in <3% of patients with MEN 1. The characteristic clinical manifestations of a skin rash (necrolytic migratory erythema), weight loss, anemia, and stomatitis may be absent. The tumor may have been detected in an asymptomatic patient with MEN 1 undergoing pancreatic imaging or by the finding of glucose intolerance and hyperglucagonemia.

TREATMENT

Glucagonoma

Surgical removal of the glucagonoma is the treatment of choice. However, treatment may be difficult because ~50–80% of patients have metastases at the time of diagnosis. Medical treatment with SSAs (e.g., octreotide or lanreotide) or chemotherapy with streptozotocin and 5-fluorouracil has been successful in some patients, and hepatic artery embolization has been used to treat metastatic disease.

Vasoactive Intestinal Peptide (VIP) Tumors (VIPomas) VIPomas have been reported in only a few patients with MEN 1. This clinical syndrome is characterized by watery diarrhea, hypokalemia, and achlorhydria (WDHA syndrome), which is also referred to as the Verner-Morrison syndrome, or the VIPoma syndrome. The diagnosis is established by excluding laxative and diuretic abuse, confirming a stool volume in excess of 0.5–1.0 L/d during a fast, and documenting a markedly increased plasma VIP concentration.

TREATMENT

VIPomas

Surgical management of VIPomas, which are mostly located in the tail of the pancreas, can be curative. However, in patients with unresectable tumor, SSAs, such as octreotide and lanreotide, may be effective. Streptozotocin with 5-fluorouracil may be beneficial, along with hepatic artery embolization for the treatment of metastases.

Pancreatic Polypeptide-Secreting Tumors (PPomas) and Nonfunctioning Pancreatic NETs PPomas are found in a large number of patients with MEN 1. No pathologic sequelae of excessive polypeptide (PP) secretion are apparent, and the clinical significance of PP is unknown. Many PPomas may have been unrecognized or classified as nonfunctioning pancreatic NETs, which likely represent the most common enteropancreatic NET associated with MEN 1 **(Fig. 400-1)**. The absence of both a clinical syndrome and specific biochemical abnormalities may result in a delayed diagnosis of nonfunctioning pancreatic NETs, which are associated with a worse prognosis than other functioning tumors, including insulinoma and gastrinoma. The optimum screening method and its timing interval for nonfunctioning pancreatic NETs remain to be established. At present, endoscopic ultrasound likely represents the most sensitive method of detecting small pancreatic tumors, but SRS is the most reliable method for detecting metastatic disease (Table 400-3).

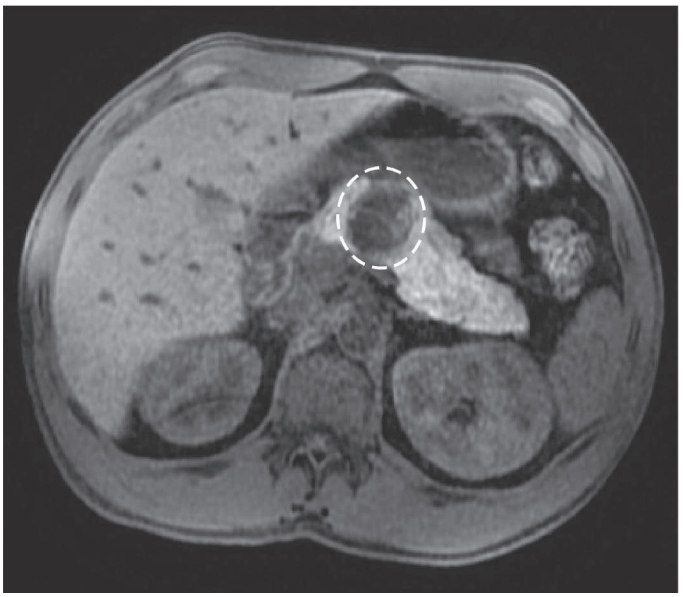

FIGURE 400-1 Pancreatic nonfunctioning neuroendocrine tumor (NET) in a 32-year-old patient with multiple endocrine neoplasia type 1 (MEN 1). An abdominal magnetic resonance imaging (MRI) scan revealed a low-intensity >3.0 cm (anteroposterior maximal diameter) tumor within the body of pancreas. There was no evidence of invasion of adjacent structures or metastases. The tumor is indicated by *white dashed circle*.

TREATMENT

PPomas and Nonfunctioning Pancreatic NETs

The management of nonfunctioning pancreatic NETs in the asymptomatic patient is controversial. One recommendation is to undertake surgery irrespective of tumor size after biochemical assessment is complete. Alternatively, other experts recommend surgery based on tumor size, using either >1 cm or >2 cm at different centers. Pancreatoduodenal surgery is successful in removing the tumors in 80% of patients, but >40% of patients develop complications, including diabetes mellitus, frequent steatorrhea, early and late dumping syndromes, and other gastrointestinal symptoms. However, ~50–60% of patients treated surgically survive >5 years. When considering these recommendations, it is important to consider that occult metastatic disease (e.g., tumors not detected by imaging investigations) is likely to be present in a substantial proportion of these patients at the time of presentation. Inhibitors of tyrosine kinase receptors (TKRs) and of the mammalian target of rapamycin (mTOR) signaling pathway have been reported to be effective in treating pancreatic NET metastases and in doubling the progression-free survival time. Additional treatments for metastatic disease include PRRT using ^{177}Lu-DOTATATE, chemotherapy, radiofrequency ablation, transarterial chemoembolization, and SIRT.

Other Pancreatic NETs NETs secreting growth hormone–releasing hormone (GHRH), GHRHomas, have been reported rarely in patients with MEN 1. It is estimated that ~33% of patients with GHRHomas have other MEN 1–related tumors. GHRHomas may be diagnosed by demonstrating elevated serum concentrations of growth hormone and GHRH. More than 50% of GHRHomas occur in the lung, 30% occur in the pancreas, and 10% are found in the small intestine. Somatostatinomas secrete somatostatin, a peptide that inhibits the secretion of a variety of hormones, resulting in hyperglycemia, cholelithiasis, low acid output, steatorrhea, diarrhea, abdominal pain, anemia, and weight loss. Although 7% of pancreatic NETs secrete somatostatin, the clinical features of somatostatinoma syndrome are unusual in patients with MEN 1.

Pituitary Tumors **(See also Chap. 392)** Pituitary tumors occur in 15–50% of patients with MEN 1 (Table 400-1), and ~75% of these are microadenomas (<1 cm diameter). The tumors occur as early as 5 years of age or as late as the ninth decade. MEN 1 pituitary adenomas are more frequent in women than men, in whom they are often macroadenomas (>1 cm diameter). There are no specific histologic parameters that differentiate between MEN 1 and non–MEN 1 pituitary tumors. Approximately 60% of MEN 1–associated pituitary tumors secrete prolactin, <25% secrete growth hormone, 5% secrete adrenocorticotropic hormone (ACTH), and the remainder appear to be nonfunctioning, with some secreting glycoprotein subunits (Table 400-1). However, pituitary tumors derived from MEN 1 patients may exhibit immunoreactivity to several hormones. In particular, there is a greater frequency of somatolactotrope tumors. Prolactinomas are the first manifestation of MEN 1 in ~15% of patients, whereas somatotrope tumors occur more often in patients aged >40 years. Fewer than 3% of patients with anterior pituitary tumors will have MEN 1. Clinical manifestations are similar to those in patients with sporadic pituitary tumors without MEN 1 and depend on the hormone secreted and the size of the pituitary tumor. Thus, patients may have symptoms of hyperprolactinemia (e.g., amenorrhea, infertility, and galactorrhea in women, or impotence and infertility in men) or have features of acromegaly or Cushing's disease. In addition, enlarging pituitary tumors may compress adjacent structures such as the optic chiasm or normal pituitary tissue, causing visual disturbances and/or hypopituitarism. In asymptomatic patients with MEN 1, periodic biochemical monitoring of serum prolactin and insulin-like growth factor 1 (IGF-1) levels, as well as MRI of the pituitary, can lead to early identification of pituitary tumors (Table 400-3). In patients with abnormal results, hypothalamic-pituitary testing should characterize the nature of the pituitary lesion and its effects on the secretion of other pituitary hormones.

TREATMENT

Pituitary Tumors

Treatment of pituitary tumors in patients with MEN 1 consists of therapies similar to those used in patients without MEN 1 and includes appropriate medical therapy (e.g., bromocriptine or cabergoline for prolactinoma; or octreotide or lanreotide for somatotrope tumors) or selective transsphenoidal adenomectomy, if feasible, with radiotherapy reserved for residual unresectable tumor tissue.

Associated Tumors Patients with MEN 1 may also develop carcinoid tumors, adrenal cortical tumors, facial angiofibromas, collagenomas, thyroid tumors, and lipomatous tumors.

Carcinoid Tumors **(See also Chap. 89)** Carcinoid tumors occur in >3% of patients with MEN 1 (Table 400-1). The carcinoid tumor may be located in the bronchi, gastrointestinal tract, pancreas, or thymus. At the time of diagnosis, most patients are asymptomatic and do not have clinical features of the carcinoid syndrome. Importantly, no hormonal or biochemical abnormality (e.g., plasma chromogranin A) is consistently observed in individuals with thymic or bronchial carcinoid tumors. Thus, screening for these tumors is dependent on radiologic imaging. The optimum method for screening has not been established. Low-dose CT and MRI are sensitive for detecting thymic and bronchial tumors (Table 400-3), although repeated CT scanning raises concern about exposure to repeated doses of ionizing radiation. Octreotide scintigraphy may also reveal some thymic and bronchial carcinoids, although there is insufficient evidence to recommend its routine use. Gastric carcinoids, of which the type II gastric enterochromaffin-like (ECL) cell carcinoids (ECLomas) are associated with MEN 1 and Zollinger-Ellison syndrome, may be detected incidentally at the time of gastric endoscopy for dyspeptic symptoms in MEN 1 patients. These tumors, which may be found in >10% of MEN 1 patients, are usually multiple and sized <1.5 cm. Bronchial carcinoids in patients with MEN 1 occur predominantly in women (male-to-female ratio, 1:4). In contrast, thymic carcinoids in European patients with MEN 1 occur predominantly in men (male-to-female ratio, 20:1), with cigarette smokers having a higher risk for these tumors; thymic carcinoids in Japanese patients with MEN 1 have a less marked sex difference (male-to-female ratio 2:1). The course of thymic carcinoids in MEN 1 appears to be particularly aggressive. The presence of thymic tumors in patients with MEN 1 is associated with a median survival after diagnosis of ~9.5 years, with 70% of patients dying as a direct result of the tumor.

TREATMENT

Carcinoid Tumors

If resectable, surgical removal of carcinoid tumors is the treatment of choice. For patients with unresectable tumors and those with metastatic disease, treatment with SSAs, radiotherapy, chemotherapeutic agents (e.g., fluorouracil, temozolomide, cisplatin, etoposide), mTOR inhibitors (e.g., everolimus), or PRRT therapy has resulted in symptom improvement and regression of some tumors. Little is known about the malignant potential of gastric type II ECLomas, but treatment with SSAs has resulted in regression of these ECLomas.

Adrenocortical Tumors **(See also Chap. 398)** Asymptomatic adrenocortical tumors occur in 20–70% of patients with MEN 1 depending on the radiologic screening methods used (Table 400-1). Most of these tumors, which include cortical adenomas, hyperplasia, multiple adenomas, nodular hyperplasia, cysts, and carcinomas, are nonfunctioning. Indeed, <10% of patients with enlarged adrenal glands have hormonal hypersecretion, with primary hyperaldosteronism and ACTH-independent Cushing's syndrome being encountered most commonly. Occasionally, hyperandrogenemia may occur in association with adrenocortical carcinoma. Pheochromocytoma in association

with MEN 1 is rare. Biochemical investigation (e.g., plasma renin and aldosterone concentrations, low-dose dexamethasone suppression test, urinary catecholamines, and/or metanephrines) should be undertaken in those with symptoms or signs suggestive of functioning adrenal tumors or in those with tumors >1 cm. Adrenocortical carcinoma occurs in ~1% of MEN 1 patients but increases to >10% for adrenal tumors >1 cm.

TREATMENT

Adrenocortical Tumors

Consensus has not been reached about the management of MEN 1–associated nonfunctioning adrenal tumors, because the majority are benign. However, the risk of malignancy increases with size, particularly for tumors with a diameter >4 cm. Indications for surgery for adrenal tumors include size >4 cm in diameter, atypical or suspicious radiologic features (e.g., increased Hounsfield unit on unenhanced CT scan) and size of 1–4 cm in diameter, or significant measurable growth over a 6-month period. The treatment of functioning (e.g., hormone-secreting) adrenal tumors is similar to that for tumors occurring in non–MEN 1 patients.

Meningioma Central nervous system (CNS) tumors, including ependymomas, schwannomas, and meningiomas, have been reported in MEN 1 patients (Table 400-1). Meningiomas are found in <10% of patients with other clinical manifestations of MEN 1 (e.g., primary hyperparathyroidism) for >15 years. The majority of meningiomas are not associated with symptoms, and 60% do not enlarge. The treatment of MEN 1–associated meningiomas is similar to that in non–MEN 1 patients.

Lipomas Subcutaneous lipomas occur in >33% of patients with MEN 1 (Table 400-1) and are frequently multiple. In addition, visceral, pleural, or retroperitoneal lipomas may occur in patients with MEN 1. Management is conservative. However, when surgically removed for cosmetic reasons, they typically do not recur.

Facial Angiofibromas and Collagenomas The occurrence of multiple facial angiofibromas in patients with MEN 1 may range from >20 to >90%, and occurrence of collagenomas may range from 0 to >70% (Table 400-1). These cutaneous findings may allow presymptomatic diagnosis of MEN 1 in the relatives of a patient with MEN 1. Treatment for these cutaneous lesions is usually not required.

Thyroid Tumors Thyroid tumors, including adenomas, colloid goiters, and carcinomas, have been reported to occur in >25% of patients with MEN 1. However, the prevalence of thyroid disorders in the general population is high, and it has been suggested that the association of thyroid abnormalities in patients with MEN 1 may be incidental. The treatment of thyroid tumors in MEN 1 patients is similar to that for non–MEN 1 patients.

Genetics and Screening The *MEN1* gene is located on chromosome 11q13 and consists of 10 exons, which encode a 610–amino acid protein, menin, that regulates transcription, genome stability, cell division, and proliferation. The pathophysiology of MEN 1 follows the Knudson two-hit hypothesis with a tumor-suppressor role for menin. Inheritance of a germline *MEN1* mutation predisposes an individual to developing a tumor that arises following a somatic mutation, which may be a point mutation or more commonly a deletion, leading to loss of heterozygosity (LOH) in the tumor DNA. The germline mutations of the *MEN1* gene are scattered throughout the entire 1830-bp coding region and splice sites, and there is no apparent correlation between the location of *MEN1* mutations and clinical manifestations of the disorder, in contrast with the situation in patients with MEN 2 (Table 400-1). More than 10% of *MEN1* germline mutations arise de novo and may be transmitted to subsequent generations. Some families with MEN 1 mutations develop parathyroid tumors as the sole endocrinopathy, and this condition is referred to as familial isolated hyperparathyroidism (FIHP). However, between 5 and 25% of patients with MEN 1 do not harbor germline mutations or deletions of the *MEN1* gene. Such patients with MEN 1–associated tumors but without *MEN1* mutations may represent phenocopies or have mutations involving other genes. Other genes associated with MEN 1–like features include *CDKN1B*, which encodes p27kip1; mutations result in MEN4 (see below) (Table 400-1). Mutations in *CDC73*, which encodes parafibromin, result in the HPT-JT syndrome; mutations in the calcium-sensing receptor gene (*CaSR*) result in familial benign hypocalciuric hypercalcemia (FBHH); mutations in *MAX*, which encodes Myc-associated factor X, result in MEN5, and mutations in the aryl hydrocarbon receptor interacting protein gene (*AIP*), a tumor suppressor located on chromosome 11q13, are associated with familial isolated pituitary adenomas (FIPA). Genetic testing to determine the *MEN1* mutation status in symptomatic family members within a MEN 1 kindred, as well as in all index cases (e.g., patients) with two or more endocrine tumors, is advisable. If a *MEN1* mutation is not identified in the index case with two or more endocrine tumors, clinical and genetic tests for other disorders such as HPT-JT syndrome, FBHH, FIPA, MEN 2, or MEN 4 should be considered because these patients may represent phenocopies for MEN 1.

The current guidelines recommend that *MEN1* mutational analysis should be undertaken in (1) an index case with two or more MEN 1–associated endocrine tumors (e.g., parathyroid, pancreatic, or pituitary tumors); (2) asymptomatic first-degree relatives of a known *MEN1* mutation carrier; and (3) first-degree relatives of a *MEN1* mutation carrier with symptoms, signs, or biochemical or radiologic evidence for one or more MEN 1–associated tumors. In addition, *MEN1* mutational analysis should be considered in patients with suspicious or atypical MEN 1. This would include individuals with parathyroid adenomas before the age of 30 years or multigland parathyroid disease; individuals with gastrinoma or multiple pancreatic NETs at any age; or individuals who have two or more MEN 1–associated tumors that are not part of the classical triad of parathyroid, pancreatic islet, and anterior pituitary tumors (e.g., parathyroid tumor plus adrenal tumor). Family members, including asymptomatic individuals who have been identified to harbor a *MEN1* mutation, will require biochemical and radiologic screening (Table 400-3). In contrast, relatives who do not harbor the *MEN1* mutation have a risk of developing MEN 1–associated endocrine tumors that is similar to that of the general population; thus, relatives without the *MEN1* mutation do not require repeated screening.

Mutational analysis in asymptomatic individuals should be undertaken at the earliest opportunity and, if possible, in the first decade of life because tumors have developed in some children by the age of 5 years. Appropriate biochemical and radiologic investigations (Table 400-3) aimed at detecting the development of tumors should then be undertaken in affected individuals. Mutant gene carriers should undergo biochemical screening at least once per annum and also have baseline pituitary and abdominal imaging (e.g., MRI or CT), which should then be repeated at 1- to 3-year intervals (Table 400-3). Screening should commence after 5 years of age and should continue for life because the disease may develop as late as the eighth decade. The screening history and physical examination elicit the symptoms and signs of hypercalcemia; nephrolithiasis; peptic ulcer disease; neuroglycopenia; hypopituitarism; galactorrhea and amenorrhea in women; acromegaly; Cushing's disease; and visual field loss and the presence of subcutaneous lipomas, angiofibromas, and collagenomas. Biochemical screening should include measurements of serum calcium, PTH, gastrointestinal hormones (e.g., gastrin, insulin with a fasting glucose, glucagon, VIP, PP), chromogranin A, prolactin, and IGF-1 in all individuals. More specific endocrine function tests should be undertaken in individuals who have symptoms or signs suggestive of a specific clinical syndrome. Biochemical screening for the development of MEN 1 tumors in asymptomatic members of families with MEN 1 is of great importance to reduce morbidity and mortality from the associated tumors.

MULTIPLE ENDOCRINE NEOPLASIA TYPE 2 AND TYPE 3

Clinical Manifestations MEN type 2 (MEN 2), which is also called Sipple's syndrome, is characterized by the association of medullary

[a]Data from American Thyroid Association Guidelines Task Force, RT Kloos et al: Medullary thyroid cancer: management guidelines of the American Thyroid Association. Thyroid 19:565, 2009 and revised from SA Wells Jr et al: Revised American Thyroid Association guidelines for the management of medullary thyroid carcinoma. Thyroid 25:567, 2015. [b]Risk for early development of metastasis and aggressive growth of medullary thyroid cancer: +++, highest; ++, high; and + moderate. [c]Mutations associated with MEN 2A (or medullary thyroid carcinoma only). [d]Timing of surgery to be based on elevation of serum calcitonin and/or joint discussion with pediatrician, surgeon, and parent/family. Later surgery may be appropriate if serum calcitonin and neck ultrasound are normal. [e]Presence of pheochromocytoma must be excluded prior to any surgical intervention and also in women with *RET* mutation who are planning pregnancy or are pregnant. [f]Surgery earlier than 5 years based on elevation of serum calcitonin. Optimal timing of surgery should be decided by the surgeon and pediatrician, in consultation with the child's parent. [g]Mutations associated with MEN 2B (MEN 3). [h]Not required because PHPT is not a feature of MEN 2B (MEN 3).

Abbreviations: ASAP, as soon as possible; MEN, multiple endocrine neoplasia; PHPT, primary hyperparathyroidism.

thyroid carcinoma (MTC), pheochromocytomas, and parathyroid tumors (Table 400-1). Three clinical variants of MEN 2 are recognized: MEN 2A, MEN 2B, and MTC only. MEN 2A, which is often referred to as MEN 2, is the most common variant. In MEN 2A, MTC is associated with pheochromocytomas in 50% of patients (may be bilateral) and with parathyroid tumors in 20% of patients. MEN 2A may rarely occur in association with Hirschsprung's disease, caused by the absence of autonomic ganglion cells in the terminal hindgut, resulting in colonic dilatation, severe constipation, and obstruction. MEN 2A may also be associated with cutaneous lichen amyloidosis, which is a pruritic lichenoid lesion that is usually located on the upper back. MEN 2B, which is also referred to as MEN 3, represents 5% of all cases of MEN 2 and is characterized by the occurrence of MTC and pheochromocytoma in association with a Marfanoid habitus; mucosal neuromas of the lips, tongue, and eyelids; medullated corneal fibers; and intestinal autonomic ganglion dysfunction leading to multiple diverticulae and megacolon. Parathyroid tumors do not usually occur in MEN 2B. MTC only (FMTC) is a variant in which MTC is the sole manifestation of the syndrome. However, the distinction between FMTC and MEN 2A is difficult and should only be considered if there are at least four family members aged >50 years who are affected by MTC but not pheochromocytomas or primary hyperparathyroidism. All of the MEN 2 variants are due to mutations of the rearranged during transfection (*RET*) protooncogene, which encodes a TKR. Moreover, there is a correlation between the locations of *RET* mutations and MEN 2 variants. Thus, ~95% of MEN 2A patients have mutations involving the cysteine-rich extracellular domain, with mutations of codon 634 accounting for ~85% of MEN 2A mutations; FMTC patients also have mutations of the cysteine-rich extracellular domain, with most mutations occurring in codon 618. In contrast, ~95% of MEN 2B/MEN 3 patients have mutations of codon 918 of the intracellular tyrosine kinase domain (Table 400-1 and **Table 400-4**).

Medullary Thyroid Carcinoma MTC is the most common feature of MEN 2A and MEN 2B and occurs in almost all affected individuals. MTC represents 5–10% of all thyroid gland carcinomas, and 20% of MTC patients have a family history of the disorder. The use of *RET* mutational analysis to identify family members at risk for hereditary forms of MTC has altered the presentation of MTC from that of symptomatic tumors to a preclinical disease for which prophylactic thyroidectomy (Table 400-4) is undertaken to improve the prognosis and ideally result in cure. However, in patients who do not have a known family history of MEN 2A, FMTC, or MEN 2B, and therefore have not had *RET* mutational analysis, MTC may present as a palpable mass in the neck, which may be asymptomatic or associated with symptoms of pressure or dysphagia in >15% of patients. Diarrhea occurs in 30% of patients and is associated either with elevated circulating concentrations of calcitonin or tumor-related secretion of serotonin and prostaglandins. Some patients may also experience flushing. In addition, ectopic ACTH production by MTC may cause Cushing's syndrome. The diagnosis of MTC relies on the demonstration of hypercalcitoninemia (>90 pg/mL in the basal state); stimulation tests using IV pentagastrin (0.5 mg/kg) and or calcium infusion (2 mg/kg) are rarely used now, reflecting improvements in the assay for calcitonin. Neck ultrasonography with fine-needle aspiration of the nodules can confirm the diagnosis. Radionucleotide thyroid scans may reveal MTC tumors as "cold" nodules. Radiography may reveal dense irregular calcification within the involved portions of the thyroid gland and in lymph nodes involved with metastases. Positron emission tomography (PET) may help to identify the MTC and metastases **(Fig. 400-2)**. Metastases of MTC usually occur to the cervical lymph nodes in the early stages and to the mediastinal nodes, lung, liver, trachea, adrenal, esophagus, and bone in later stages. Elevations in serum calcitonin concentrations are often the first sign of recurrence or persistent disease, and the serum calcitonin doubling time is useful for determining prognosis. MTC can have an aggressive clinical course, with early metastases and death in ~10% of patients. A family history of aggressive MTC or MEN 2B may be elicited.

TREATMENT

Medullary Thyroid Carcinoma

Individuals with *RET* mutations who do not have clinical manifestations of MTC should be offered prophylactic surgery between the ages of <1 and 5 years. The timing of surgery will depend on the type of *RET* mutation and its associated risk for early development, metastasis, and aggressive growth of MTC (Table 400-4). Such patients should have a total thyroidectomy with a systematic central neck dissection to remove occult nodal metastasis, although the value of undertaking a central neck dissection has been subject to debate. Prophylactic thyroidectomy, with lifelong thyroxine replacement, has dramatically improved outcomes in patients with MEN 2 and MEN 3, such that ~90% of young patients with *RET* mutations who had a prophylactic thyroidectomy have no evidence of persistent or recurrent MTC at 7 years after surgery. In patients with clinically evident MTC, a total thyroidectomy with bilateral central resection is recommended, and an ipsilateral lateral neck dissection should be undertaken if the primary tumor is >1 cm in size or there is evidence of nodal metastasis in the central neck. Surgery is the only curative therapy for MTC. The 10-year survival in patients with metastatic MTC is ~20%. For inoperable MTC or metastatic disease, TKR inhibitors (e.g., vandetanib, cabozantinib, selpercatinib) have improved the progression-free survival times. Among these, selpercatinib is more selective for the RET kinase and is most effective. PRRT with ^{177}Lu-DOTATATE has been reported to be beneficial for metastatic MTCs that were found by SRS to express somatostatin receptors. Other types of chemotherapy are of limited efficacy, but radiotherapy may help to palliate local disease.

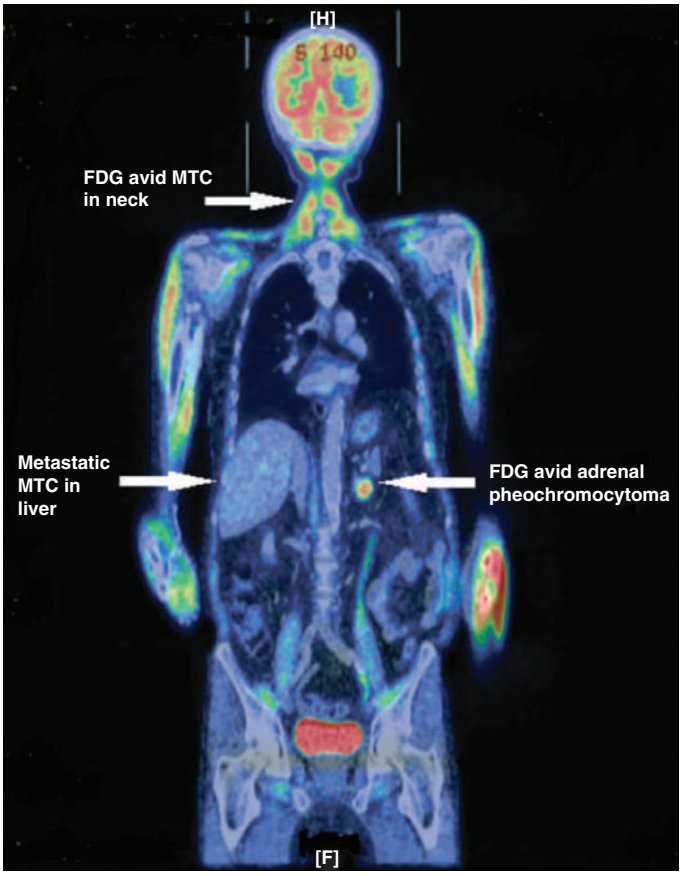

FIGURE 400-2 Fluorodeoxyglucose (FDG) positron emission tomography scan in a patient with multiple endocrine neoplasia type 2A, showing medullary thyroid cancer (MTC) with hepatic and skeletal (left arm) metastasis and a left adrenal pheochromocytoma. Note the presence of excreted FDG compound in the bladder. *(Reproduced with permission from A Naziat et al: Confusing genes: A patient with MEN2A and Cushing's disease. Clin Endocrinol (Oxf) 78:966, 2013.)*

Pheochromocytoma (See also Chap. 399) These noradrenaline- and adrenaline-secreting tumors occur in >50% of patients with MEN 2A and MEN 2B and are a major cause of morbidity and mortality. Patients may have symptoms and signs of catecholamine secretion (e.g., headaches, palpitations, sweating, poorly controlled hypertension), or they may be asymptomatic with detection through biochemical screening based on a history of familial MEN 2A, MEN 2B, or MTC. Pheochromocytomas in patients with MEN 2A and MEN 2B differ significantly in distribution when compared with patients without MEN 2A and MEN 2B. Extra-adrenal pheochromocytomas, which occur in 10% of patients without MEN 2A and MEN 2B, are observed rarely in patients with MEN 2A and MEN 2B. Malignant pheochromocytomas are much less common in patients with MEN 2A and MEN 2B. The biochemical and radiologic investigation of pheochromocytoma in patients with MEN 2A and MEN 2B is similar to that in non–MEN 2 patients and includes the measurement of plasma (obtained from supine patients) and urinary free fractionated metanephrines (e.g., normetanephrine and metanephrines measured separately), CT or MRI scanning, radionuclide scanning with meta-iodo-(^{123}I or ^{131}I)-benzyl guanidine (MIBG), and PET using (^{18}F)-fluorodopamine or (^{18}F)-fluoro-2-dexoxy-D-glucose (Fig. 400-2).

TREATMENT

Pheochromocytoma

Surgical removal of pheochromocytoma, using α and β adrenoreceptor blockade before and during the operation, is the recommended treatment. Other antihypertensive agents, including calcium channel blockers, are sometimes required for adequate blood pressure control. Endoscopic adrenal-sparing surgery, which decreases postoperative morbidity, hospital stay, and expense, as opposed to open surgery, has become the method of choice.

Parathyroid Tumors (See also Chap. 422) Parathyroid tumors occur in 10–25% of patients with MEN 2A. However, >50% of these patients do not have hypercalcemia. The presence of abnormally enlarged parathyroids, which are unusually hyperplastic, is often seen in the normocalcemic patient undergoing thyroidectomy for MTC. The biochemical investigation and treatment of hypercalcemic patients with MEN 2A is similar to that of patients with MEN 1.

Genetics and Screening To date, ~50 different *RET* mutations have been reported, and these are located in exons 5, 8, 10, 11, 13, 14, 15, and 16. *RET* germline mutations are detected in >95% of MEN 2A, FMTC, and MEN 2B families, with Cys634Arg being most common in MEN 2A, Cys618Arg being most common in FMTC, and Met918Thr being most common in MEN 2B (Tables 400-1 and 400-4). Between 5 and 10% of patients with MTC or MEN 2A–associated tumors have de novo *RET* germline mutations, and ~50% of patients with MEN 2B have de novo *RET* germline mutations. These de novo *RET* germline mutations always occur on the paternal allele. Approximately 5% of patients with sporadic pheochromocytoma have a germline *RET* mutation, but such germline *RET* mutations do not appear to be associated with sporadic primary hyperparathyroidism. Thus, *RET* mutational analysis should be performed in (1) all patients with MTC who have a family history of tumors associated with MEN 2, FMTC, or MEN 3, such that the diagnosis can be confirmed and genetic testing offered to asymptomatic relatives; (2) all patients with MTC and pheochromocytoma without a known family history of MEN 2 or MEN 3; (3) all patients with MTC, but without a family history of MEN 2, FMTC, or MEN 3, because these patients may have a de novo germline *RET* mutations; (4) all patients with bilateral pheochromocytoma; and (5) patients with unilateral pheochromocytoma, particularly if this occurs with increased calcitonin levels.

Screening for MEN 2/MEN 3–associated tumors in patients with *RET* germline mutations should be undertaken annually and include serum calcitonin measurements, a neck ultrasound for MTC, plasma (or 24-h urinary) fractionated metanephrines for pheochromocytoma, and albumin-corrected serum calcium or ionized calcium with PTH for primary hyperparathyroidism. In patients with MEN 2–associated *RET* mutations, screening for MTC should begin by 1–5 years, for pheochromocytoma by 11–16 years, and for primary hyperparathyroidism by 11–16 years of age (Table 400-4).

MULTIPLE ENDOCRINE NEOPLASIA TYPE 4

Clinical Manifestations Patients with MEN 1–associated tumors, such as parathyroid adenomas, pituitary adenomas, and pancreatic NETs, occurring in association with gonadal, adrenal, renal, and thyroid tumors have been reported to have mutations of the gene encoding the 196–amino acid cyclin-dependent kinase inhibitor (CK1) p27 kip1 (*CDKN1B*). Such families with MEN 1–associated tumors and *CDKN1B* mutations are designated to have MEN 4 (Table 400-1). The investigations and treatments for the MEN 4–associated tumors are similar to those for MEN 1 and non–MEN 1 tumors.

Genetics and Screening To date, 50 MEN patients (from <20 kindreds) with mutations of *CDKN1B*, which is located on chromosome 12p13, have been reported, and all of these are predicted to result in a loss of function. These MEN 4 patients may represent ~3% of the 5–10% of patients with MEN 1 who do not have mutations of the *MEN1* gene. Germline *CDKN1B* mutations may rarely be found in patients with sporadic (i.e., nonfamilial) forms of primary hyperparathyroidism.

MULTIPLE ENDOCRINE NEOPLASIA TYPE 5

Clinical Manifestations Two kindreds in whom multiple endocrine tumors were associated with heterozygous germline *MAX* mutations have been reported. Although *MAX* mutations have been described in rare cases of hereditary pheochromocytoma and paraganglioma, the occurrence of these tumors in these kindreds was also

associated with pituitary adenomas, parathyroid adenomas, and non-endocrine tumors including chondrosarcoma, lung adenocarcinoma, ganglioneuroma, and neuroblastoma. Additional tumors reported in patients with germline *MAX* mutations include pancreatic NETs, renal oncocytomas, and renal carcinoma.

Genetics and Screening The *MAX* gene is located on chromosome 14q23.3 and encodes the ubiquitously expressed MYC-associated factor X transcription factor, which is presumed to act as a tumor suppressor. The spectrum of clinical manifestations associated with germline *MAX* mutations and MEN 5 remains to be fully defined, although most patients appear to have development of early-onset pheochromocytoma.

HYPERPARATHYROIDISM-JAW TUMOR SYNDROME (SEE ALSO CHAP. 422)

Clinical Manifestations Hyperparathyroidism-jaw tumor (HPT-JT) syndrome is an autosomal dominant disorder characterized by the development of parathyroid tumors (15% are carcinomas) and fibro-osseous jaw tumors. In addition, some patients may also develop Wilms' tumors, renal cysts, renal hamartomas, renal cortical adenomas, renal cell carcinoma (RCC), pancreatic adenocarcinomas, uterine tumors, testicular mixed germ cell tumors with a major seminoma component, and Hürthle cell thyroid adenomas. The parathyroid tumors may occur in isolation and without any evidence of jaw tumors, and this may cause confusion with other hereditary hypercalcemic disorders, such as MEN 1. However, genetic testing to identify the causative mutation will help to establish the correct diagnosis. The investigation and treatment for HPT-JT–associated tumors are similar to those in non-HPT-JT patients, except that early parathyroidectomy is advisable because of the increased frequency of parathyroid carcinoma.

Genetics and Screening The gene that causes HPT-JT is located on chromosome 1q31.2 and encodes a 531–amino acid protein, parafibromin (Table 400-2). Parafibromin is also referred to as cell division cycle protein 73 (CDC73) and has a role in transcription. Genetic testing in families helps to identify mutation carriers who should be periodically screened for the development of tumors (Table 400-5).

VON HIPPEL–LINDAU DISEASE (SEE ALSO CHAP. 399)

Clinical Manifestations von Hippel–Lindau (VHL) disease is an autosomal dominant disorder characterized by hemangioblastomas of the retina and CNS; cysts involving the kidneys, pancreas, and epididymis; RCC; pheochromocytomas; and pancreatic islet cell tumors. The retinal and CNS hemangioblastomas are benign vascular tumors that may be multiple; those in the CNS may cause symptoms by compressing adjacent structures and/or increasing intracranial pressure. In the CNS, the cerebellum and spinal cord are the most frequently involved sites. The renal abnormalities consist of cysts and carcinomas, and the lifetime risk of RCC in VHL is 70%. The endocrine tumors in VHL consist of pheochromocytomas and pancreatic islet cell tumors. The clinical presentation of pheochromocytoma in VHL disease is similar to that in sporadic cases, except that there is a higher frequency of bilateral or multiple tumors, which may involve extra-adrenal sites in VHL disease. The most frequent pancreatic lesions in VHL are multiple cyst-adenomas, which rarely cause clinical disease. However, nonsecreting pancreatic islet cell tumors occur in <10% of VHL patients, who are usually asymptomatic. The pancreatic tumors in these patients are often detected by regular screening using abdominal imaging. Pheochromocytomas should be investigated and treated as described earlier for MEN 2. The pancreatic islet cell tumors frequently become malignant, and early surgery is recommended.

Genetics and Screening The *VHL* gene, which is located on chromosome 3p26-p25, is widely expressed in human tissues and encodes a 213–amino acid protein (pVHL) (Table 400-2). A wide variety of germline *VHL* mutations have been identified. *VHL* acts as a tumor-suppressor gene. A correlation between the type of mutation and the clinical phenotype has been reported; large deletions and protein-truncating mutations are associated with a low incidence of pheochromocytomas, whereas some missense mutations in VHL patients are associated with pheochromocytoma (referred to as VHL type 2C). Other missense mutations may be associated with hemangioblastomas and RCC but not pheochromocytoma (referred to as VHL type 1), whereas distinct missense mutations are associated with hemangioblastomas, RCC, and pheochromocytoma (VHL type 2B). VHL type 2A, which refers to the occurrence of hemangioblastomas and pheochromocytoma without RCC, is associated with rare missense mutations. The basis for these complex genotype-phenotype relationships remains to be elucidated. One major function of pVHL, which is also referred to as elongin, is to downregulate the expression of vascular endothelial growth factor (VEGF) and other hypoxia-inducible mRNAs. Thus, pVHL, in complex with other proteins, regulates the expression of hypoxia-inducible factors (HIF-1 and HIF-2) such that loss of functional pVHL leads to a stabilization of the HIF protein complexes, resulting in VEGF overexpression and tumor angiogenesis. Screening for the development of pheochromocytomas and pancreatic islet cell tumors is as described earlier for MEN 2 and MEN 1, respectively (Tables 400-3 and 400-4).

TABLE 400-5 HPT-JT Screening Guidelines

TUMOR[a]	TEST	FREQUENCY[b]
Parathyroid	Serum Ca, PTH	6–12 months
Ossifying jaw fibroma	Panoramic jaw x-ray with neck shielding[c]	5 years
Renal	Abdominal MRI[c,d]	5 years
Uterine	Ultrasound (transvaginal or transabdominal) and additional imaging ± D&C if indicated[e]	Annual

[a]Screening for most common HPT-JT–associated tumors is considered. Assessment for other reported tumor types may be indicated (e.g., pancreatic, thyroid, testicular tumors). [b]Frequency of repeating test after baseline tests performed. [c]X-rays and imaging involving ionizing radiation should ideally be avoided to minimize risk of generating subsequent mutations. [d]Ultrasound scan recommended if MRI unavailable. [e]Such selective pelvic imaging should be considered after obtaining a detailed menstrual history.

Abbreviations: Ca, calcium; D&C, dilation and curettage; HPT-JT, hyperparathyroidism-jaw tumor syndrome; MRI, magnetic resonance imaging; PTH, parathyroid hormone.

NEUROFIBROMATOSIS

Clinical Manifestations Neurofibromatosis type 1 (NF1), which is also referred to as von Recklinghausen's disease, is an autosomal dominant disorder characterized by the following manifestations: neurologic (e.g., peripheral and spinal neurofibromas); ophthalmologic (e.g., optic gliomas and iris hamartomas such as Lisch nodules); dermatologic (e.g., café au lait macules); skeletal (e.g., scoliosis, macrocephaly, short stature, pseudoarthrosis); vascular (e.g., stenoses of renal and intracranial arteries); and endocrine (e.g., pheochromocytoma, carcinoid tumors, precocious puberty). Neurofibromatosis type 2 (NF2) is also an autosomal dominant disorder but is characterized by the development of bilateral vestibular schwannomas (acoustic neuromas) that lead to deafness, tinnitus, or vertigo. Some patients with NF2 also develop meningiomas, spinal schwannomas, peripheral nerve neurofibromas, and café au lait macules. Endocrine abnormalities are not found in NF2 and are associated solely with NF1. Pheochromocytomas, carcinoid tumors, and precocious puberty occur in ~1% of patients with NF1, and growth hormone deficiency has also been reported. The features of pheochromocytomas in NF1 are similar to those in non-NF1 patients, with 90% of tumors being located within the adrenal medulla and the remaining 10% at an extra-adrenal location, which often involves the para-aortic region. Primary carcinoid tumors are often periampullary and may also occur in the ileum but rarely in the pancreas, thyroid, or lungs. Hepatic metastases are associated with symptoms of the carcinoid syndrome, which include flushing, diarrhea, bronchoconstriction, and tricuspid valve disease.

Precocious puberty is usually associated with the extension of an optic glioma into the hypothalamus with resultant early activation of gonadotropin-releasing hormone secretion. Growth hormone deficiency has also been observed in some NF1 patients, who may or may not have optic chiasmal gliomas, but it is important to note that short stature is frequent in the absence of growth hormone deficiency in patients with NF1. The investigation and treatment for tumors are similar to those undertaken for each respective tumor type in non-NF1 patients.

Genetics and Screening The *NF1* gene, which is located on chromosome 17q11.2 and acts as a tumor suppressor, consists of 60 exons that span >350 kb of genomic DNA (Table 400-2). Mutations in *NF1* are of diverse types and are scattered throughout the exons. The NF1 gene product is the protein neurofibromin, which has homologies to the p120GAP (GTPase activating protein) and acts on p21ras by converting the active GTP bound form to its inactive GDP form. Mutations of *NF1* impair this downregulation of the p21ras signaling pathways, which in turn results in abnormal cell proliferation. Screening for the development of pheochromocytomas and carcinoid tumors is as described earlier for MEN 2 and MEN 1, respectively (Tables 400-3 and 400-4).

CARNEY COMPLEX

Clinical Manifestations Carney complex (CNC) is an autosomal dominant disorder characterized by spotty skin pigmentation (usually of the face, labia, and conjunctiva), myxomas (usually of the eyelids and heart, but also the tongue, palate, breast, and skin), psammomatous melanotic schwannomas (usually of the sympathetic nerve chain and upper gastrointestinal tract), and endocrine tumors that involve the adrenals, Sertoli cells, somatotropes, thyroid, and ovary. Cushing's syndrome, the result of primary pigmented nodular adrenal disease (PPNAD), is the most common endocrine manifestation of CNC and may occur in one-third of patients. Patients with CNC and Cushing's syndrome often have an atypical appearance by being thin (as opposed to having truncal obesity). In addition, they may have short stature, muscle and skin wasting, and osteoporosis. These patients often have levels of urinary free cortisol that are normal or increased only marginally. Cortisol production may fluctuate periodically with days or weeks of hypercortisolism; this pattern is referred to as "periodic Cushing's syndrome." Patients with Cushing's syndrome usually have loss of the circadian rhythm of cortisol production. Acromegaly, the result of a somatotrope tumor, affects ~10% of patients with CNC. Testicular tumors may also occur in one-third of patients with CNC. These may either be large-cell calcifying Sertoli cell tumors, adrenocortical rests, or Leydig cell tumors. The Sertoli cell tumors occasionally may be estrogen-secreting and lead to precocious puberty or gynecomastia. Some patients with CNC have been reported to develop thyroid follicular tumors, ovarian cysts, or breast duct adenomas.

Genetics and Screening CNC type 1 (CNC1) is due to mutations of the protein kinase A (PKA) regulatory subunit 1 α (R1α) (*PRAKAR1A*), a tumor suppressor, whose gene is located on chromosome 17q.24.2 (Table 400-2). The gene causing CNC type 2 (CNC2) is located on chromosome 2p16 and has not yet been identified. It is interesting to note, however, that some tumors do not show LOH of 2p16 but instead show genomic instability, suggesting that this CNC gene may not be a tumor suppressor. Screening and treatment of these endocrine tumors are similar to those described earlier for patients with MEN 1 and MEN 2 (Tables 400-3 and 400-4).

COWDEN'S SYNDROME

Clinical Manifestations Multiple hamartomatous lesions, especially of the skin, mucous membranes (e.g., buccal, intestinal, colonic), breast, and thyroid, are characteristic of Cowden's syndrome (CWS), which is an autosomal dominant disorder. Thyroid abnormalities occur in two-thirds of patients with CWS, and these usually consist of multinodular goiters or benign adenomas, although <10% of patients may have a follicular thyroid carcinoma. Breast abnormalities occur in >75% of patients and consist of either fibrocystic disease or adenocarcinomas. The investigation and treatment for CWS tumors are similar to those undertaken for non-CWS patients.

Genetics and Screening CWS is genetically heterogenous, and seven types (CWS1–7) are recognized (Table 400-2). CWS1 is due to mutations of the phosphate and tensin homologue deleted on chromosome 10 (*PTEN*) gene, located on chromosome 10q23.31. CWS2 is caused by mutations of the succinate dehydrogenase subunit B (*SDHB*) gene, located on chromosome 1p36.13; and CWS3 is caused by mutations of the *SDHD* gene, located on chromosome 11q13.1. *SDHB* and *SDHD* mutations are also associated with pheochromocytoma. CWS4 is caused by hypermethylation of the Killin (*KLLN*) gene, the promoter of which shares the same transcription site as *PTEN* on chromosome 10q23.31. CWS5 is caused by mutations of the phosphatidylinositol 3-kinase catalytic alpha (*PIK3CA*) gene on chromosome 3q26.32. CWS6 is caused by mutations of the V-Akt murine thymoma viral oncogene homolog 1 (*AKT1*) gene on chromosome 14q32.33, and CWS7 is caused by mutations of the saccharomyces cerevisiae homology of B (*SEC23B*) gene on chromosome 20p11.23. Screening for thyroid abnormalities entails neck ultrasonography and fine-needle aspiration with analysis of cell cytology.

MCCUNE-ALBRIGHT SYNDROME (SEE ALSO CHAP. 424)

Clinical Manifestations McCune-Albright syndrome (MAS) is characterized by the triad of polyostotic fibrous dysplasia, which may be associated with hypophosphatemic rickets; café au lait skin pigmentation; and peripheral precocious puberty. Other endocrine abnormalities include thyrotoxicosis, which may be associated with a multinodular goiter, somatotrope tumors, and Cushing's syndrome (due to adrenal tumors). Investigation and treatment for each endocrinopathy are similar to those used in patients without MAS.

Genetics and Screening MAS is a disorder of mosaicism that results from postzygotic somatic cell mutations of the G protein α-stimulating subunit ($G_s\alpha$), encoded by the *GNAS1* gene, located on chromosome 20q13.32 (Table 400-2). The $G_s\alpha$ mutations, which include Arg201Cys, Arg201His, Glu227Arg, or Glu227His, are activating and are found only in cells of the abnormal tissues. Screening for hyperfunction of relevant endocrine glands and development of hypophosphatemia, which may be associated with elevated serum fibroblast growth factor 23 (FGF23) concentrations, is undertaken in MAS patients.

401 Autoimmune Polyendocrine Syndromes

Peter A. Gottlieb, Aaron W. Michels

Polyglandular deficiency syndromes have been given many different names, reflecting the wide spectrum of disorders that have been associated with these syndromes and the heterogeneity of their clinical presentations. The name used in this chapter for this group of disorders is *autoimmune polyendocrine syndrome* (APS). In general, these disorders are divided into two major categories, APS type 1 (APS-1) and APS type 2 (APS-2). Some groups have further subdivided APS-2 into APS type 3 (APS-3) and APS type 4 (APS-4) depending on the type of autoimmunity involved. For the most part, this additional classification does not clarify our understanding of disease pathogenesis or prevention of complications in individual patients. Importantly, there are many nonendocrine disease associations included in these syndromes, suggesting that although the underlying autoimmune disorder predominantly involves endocrine targets, it does not exclude other tissues. The disease associations found in APS-1 and APS-2 are summarized in Table 401-1. Understanding these syndromes and their disease manifestations can lead to early diagnosis and treatment of additional disorders in patients and their family members.

TABLE 401-1 Disease Associations with Autoimmune Polyendocrine Syndromes

AUTOIMMUNE POLYENDOCRINE SYNDROME TYPE 1	AUTOIMMUNE POLYENDOCRINE SYNDROME TYPE 2	OTHER AUTOIMMUNE POLYENDOCRINE DISORDERS
Endocrine	**Endocrine**	IPEX (immune dysfunction polyendocrinopathy X-linked)
Addison's disease	Addison's disease	Thymic tumors
Hypoparathyroidism	Type 1 diabetes	Anti-insulin receptor antibodies
Hypogonadism	*Graves' disease or autoimmune thyroiditis*	POEMS syndrome
Graves' disease or autoimmune thyroiditis	*Hypogonadism*	Insulin autoimmune syndrome (Hirata's syndrome)
Type 1 diabetes		Adult combined pituitary hormone deficiency (CPHD) with anti-Pit1 autoantibodies
		Kearns-Sayre syndrome
		DIDMOAD syndrome
Nonendocrine	**Nonendocrine**	Congenital rubella associated with thyroiditis and/or diabetes
Mucocutaneous candidiasis	Celiac disease, dermatitis herpetiformis	
Chronic active hepatitis	Pernicious anemia	
Pernicious anemia	Vitiligo	
Vitiligo	*Alopecia*	
Asplenism	*Myasthenia gravis*	
Ectodermal dysplasia	*IgA deficiency*	
Alopecia	*Parkinson's disease*	
Malabsorption syndromes	*Idiopathic thrombocytopenia*	
IgA deficiency		

Abbreviations: DIDMOAD, *d*iabetes *i*nsipidus, *d*iabetes *m*ellitus, progressive bilateral *o*ptic *a*trophy, and sensorineural *d*eafness; POEMS, *p*olyneuropathy, *o*rganomegaly, *e*ndocrinopathy, *M*-protein, and *s*kin changes.

Note: Italics denote less common disorders.

APS-1

APS-1 (Online Mendelian Inheritance in Man [OMIM] 240300) has also been called autoimmune polyendocrinopathy–candidiasis–ectodermal dystrophy (APECED). Mucocutaneous candidiasis, hypoparathyroidism, and Addison's disease form the three major components of this disorder. However, as summarized in Table 401-1, many other organ systems can be involved over time. APS-1 is rare, with <500 cases reported in the literature.

The classical form of APS-1 is an autosomal recessive disorder caused by mutations in the *AIRE* gene (autoimmune regulator gene) found on chromosome 21. This gene is most highly expressed in thymic medullary epithelial cells (mTECs) where it controls the expression of tissue-specific self-antigens (e.g., insulin). Deletion of this regulator leads to decreased expression of tissue-specific self-antigens and is hypothesized to allow autoreactive T cells to avoid central deletion, which normally occurs during T-cell maturation in the thymus. The *AIRE* gene is also expressed in epithelial cells found in peripheral lymphoid organs, but its role in these extrathymic cells remains controversial. To date, >100 mutations have been described in this gene, and there is a higher frequency within certain ethnic groups including Iranian Jews, Sardinians, Finns, Norwegians, and Irish. Recently, several autosomal dominant mutations have been identified and are localized primarily in the PHD1 domain of the *AIRE* gene, rather than the CARD region, where the autosomal recessive mutations have been found. Individuals with this nonclassical form of APS-1 may have a later onset of symptoms and less aggressive disease, without the full spectrum of autoimmune components being expressed.

Clinical Manifestations Classical APS-1 develops very early in life, often in infancy (Table 401-2). Chronic mucocutaneous candidiasis without signs of systemic disease is often the first manifestation. It affects the mouth and nails more frequently than the skin and esophagus. Chronic oral candidiasis can result in atrophic disease with areas suggestive of leukoplakia, which can pose a risk for future carcinoma. The etiology is associated with anticytokine autoantibodies (anti-interleukin [IL] 17A, IL-17F, and IL-22) related to T helper (T_H) 17 T cells and depressed production of these cytokines by peripheral blood mononuclear cells. Hypoparathyroidism usually develops next, followed by adrenal insufficiency. The time from development of one component of the disorder to the next can be many years, and the order of disease appearance is variable.

Chronic candidiasis is nearly always present and is not very responsive to treatment. Hypoparathyroidism is found in >85% of cases, and Addison's disease is found in nearly 80%. Gonadal failure appears to affect women more than men (70 vs 25%, respectively), and hypoplasia of the dental enamel also occurs frequently (77% of patients).

TABLE 401-2 Comparison of APS-1 and APS-2

APS-1	APS-2
Early onset: infancy	Later onset
Siblings often affected and at risk	Multigenerational
Equivalent sex distribution	Females > males affected
Monogenic: *AIRE* gene, chromosome 21, autosomal recessive	Polygenic: *HLA, MICA, PTNP22, CTLA4*
Not HLA associated for entire syndrome, some specific component risk	DR3/DR4 associated; other HLA class III gene associations noted
Autoantibodies to type 1 interferons and IL-17 and IL-22	No autoantibodies to cytokines
Autoantibodies to specific target organs	Autoantibodies to specific target organs
Asplenism	No defined immunodeficiency
Mucocutaneous candidiasis	Association with other nonendocrine immunologic disorders like myasthenia gravis and idiopathic thrombocytopenic purpura

Abbreviations: APS, autoimmune polyendocrine syndrome; HLA, human leukocyte antigen; IL, interleukin.

Other endocrine disorders that occur less frequently include type 1 diabetes (23%) and autoimmune thyroid disease (18%). Nonendocrine manifestations that present less frequently include alopecia (40%), vitiligo (26%), intestinal malabsorption (18%), pernicious anemia (31%), chronic active hepatitis (17%), and nail dystrophy. An unusual and debilitating manifestation of the disorder is the development of refractory diarrhea/obstipation that may be related to autoantibody-mediated destruction of enterochromaffin or enterochromaffin-like cells. The incidence rates for many of these disorders peak in the first or second decade of life, but the individual disease components continue to emerge over time. Therefore, prevalence rates may be higher than originally reported.

Diagnosis The diagnosis of APS-1 is usually made clinically when two of the three major component disorders are found in an individual patient. Siblings of individuals with APS-1 should be considered affected even if only one component disorder has been detected due to the known inheritance of the syndrome. Genetic analysis of the *AIRE* gene should be undertaken to identify mutations. Detection of anti–interferon α and anti–interferon ω antibodies can identify nearly 100% of cases with APS-1. The autoantibody arises independent of the type of *AIRE* gene mutation and is not found in other autoimmune disorders.

Diagnosis of each underlying disorder should be done based on their typical clinical presentations **(Table 401-3)**. Mucocutaneous candidiasis may present throughout the gastrointestinal tract, and it may be detected in the oral mucosa or from stool samples. Evaluation by a gastroenterologist to examine the esophagus for candidiasis or secondary stricture may be merited based on symptoms. Other gastrointestinal manifestations of APS-1, including malabsorption and obstipation, may also bring these young patients to the attention of gastroenterologists for first evaluation. Specific physical examination findings of hyperpigmentation, vitiligo, alopecia, tetany, and signs of hyper- or hypothyroidism should be considered as signs of development of component disorders.

The development of disease-specific autoantibody assays can help confirm disease and also detect risk for future disease. For example, where possible, detection of anticytokine antibodies to IL-17 and IL-22 would confirm the diagnosis of mucocutaneous candidiasis due to APS-1. The presence of anti-21-hydroxylase antibody or anti-17-hydroxylase antibody (which may be found more commonly in adrenal insufficiency associated with APS-1) would confirm the presence or risk for Addison's disease. Other autoantibodies found in type 1 diabetes (e.g., anti-GAD65), pernicious anemia, and other component conditions should be screened for on a regular basis (6- to 12-month intervals depending on the age of the subject).

Laboratory tests, including a complete metabolic panel, phosphorous and magnesium, thyroid-stimulating hormone (TSH), adrenocorticotropic hormone (ACTH; morning), hemoglobin A_{1c}, plasma vitamin B_{12} level, and complete blood count with peripheral smear looking for Howell-Jolly bodies (asplenism), should also be performed at these time points. Detection of abnormal physical findings or test results should prompt subsequent examinations of the relevant organ system (e.g., presence of Howell-Jolly bodies indicates need for ultrasound of spleen).

TABLE 401-3 Clinical Features and Recommended Follow-Up for APS-1 and APS-2

COMPONENT DISEASE	RECOMMENDED EVALUATION
APS-1	
Addison's disease	Sodium, potassium, ACTH, cortisol, 21- and 17-hydroxylase autoantibodies
Diarrhea	History
Ectodermal dysplasia	Physical examination
Hypoparathyroidism	Serum calcium, phosphate, PTH
Hepatitis	Liver function tests
Hypothyroidism/Graves' disease	TSH; thyroid peroxidase and/or thyroglobulin autoantibodies and anti-TSH receptor Ab
Male hypogonadism	FSH/LH, testosterone
Malabsorption	Physical examination, anti-IL-17 and anti-IL-22 autoantibodies
Mucocutaneous candidiasis	Physical examination, mucosal swab, stool samples
Obstipation	History
Ovarian failure	FSH/LH, estradiol
Pernicious anemia	CBC, vitamin B_{12} levels
Splenic atrophy	Blood smear for Howell-Jolly bodies; platelet count; ultrasound if positive
Type 1 diabetes	Glucose, hemoglobin A_{1c}, diabetes-associated autoantibodies (insulin, GAD65, IA-2, ZnT8)
APS-2	
Addison's disease	21-Hydroxylase autoantibodies, ACTH stimulation testing if positive
Alopecia	Physical examination
Autoimmune hyper- or hypothyroidism	TSH; thyroid peroxidase and/or thyroglobulin autoantibodies, anti-TSH receptor Ab
Celiac disease	Transglutaminase autoantibodies; small intestine biopsy if positive
Cerebellar ataxia	Dictated by signs and symptoms of disease
Chronic inflammatory demyelinating polyneuropathy	Dictated by signs and symptoms of disease
Hypophysitis	Dictated by signs and symptoms of disease, anti-Pit1 autoantibody
Idiopathic heart block	Dictated by signs and symptoms of disease
IgA deficiency	IgA level
Myasthenia gravis	Dictated by signs and symptoms of disease, antiacetylcholinesterase Ab
Myocarditis	Dictated by signs and symptoms of disease
Pernicious anemia	Anti–parietal cell autoantibodies
	CBC, vitamin B_{12} levels if positive
Serositis	Dictated by signs and symptoms of disease
Stiff man syndrome	Dictated by signs and symptoms of disease
Vitiligo	Physical examination, NALP-1 polymorphism

Abbreviations: Ab, antibody; ACTH, adrenocorticotropic hormone; APS, autoimmune polyendocrine syndrome; CBC, complete blood count; FSH, follicle-stimulating hormone; IL, interleukin; LH, luteinizing hormone; PTH, parathyroid hormone; TSH, thyroid-stimulating hormone.

TREATMENT

APS-1

Therapy of individual disease components is carried out as outlined in other relevant chapters. Replacement of deficient hormones (e.g., adrenal, pancreas, ovaries/testes) will treat most of the endocrinopathies noted. Several unique issues merit special emphasis. Adrenal insufficiency can be masked by primary hypothyroidism by prolonging the half-life of cortisol. The caveat therefore is that replacement therapy with thyroid hormone can precipitate an adrenal crisis in an undiagnosed individual. Hence, all patients with hypothyroidism and the possibility of APS should be screened for adrenal insufficiency to allow treatment with glucocorticoids prior to the initiation of thyroid hormone replacement. Treatment of mucocutaneous candidiasis with ketoconazole in an individual with subclinical adrenal insufficiency may also precipitate adrenal crisis. Furthermore, mucocutaneous candidiasis may be difficult to eradicate entirely. Severe cases of disease involvement may require systemic immunomodulatory therapy, but this is not commonly needed.

APS-2

APS-2 (OMIM 269200) is more common than APS-1, with a prevalence of 1–2 in 100,000. It has a gender bias and occurs more often in

female patients, with a ratio of at least 3:1 compared to male patients. In contrast to APS-1, APS-2 often has its onset in adulthood, with a peak incidence between 20 and 60 years of age. It shows a familial, multigenerational heritage (Table 401-2). The presence of two or more of the following endocrine deficiencies in the same patient defines the presence of APS-2: primary adrenal insufficiency (Addison's disease; 50–70%), Graves' disease or autoimmune thyroiditis (15–69%), type 1 diabetes mellitus (T1D; 40–50%), and primary hypogonadism. Frequently associated autoimmune conditions include celiac disease (3–15%), myasthenia gravis, vitiligo, alopecia, serositis, and pernicious anemia. These conditions occur with increased frequency in affected patients but are also found in their family members (Table 401-3).

Genetic Considerations The overwhelming risk factor for APS-2 has been localized to the genes in the human lymphocyte antigen (HLA) complex on chromosome 6. Primary adrenal insufficiency in APS-2, but not APS-1, is strongly associated with both HLA-DR3 and HLA-DR4. Other class I and class II genes and alleles, such as HLA-B8, HLA-DQ2 and HLA-DQ8, and HLA-DR subtypes such as *DRB1*04:04*, appear to contribute to organ-specific disease susceptibility **(Table 401-4)**. HLA-B8- and HLA-DR3-associated illnesses include selective IgA deficiency, juvenile dermatomyositis, dermatitis herpetiformis, alopecia, scleroderma, autoimmune thrombocytopenia purpura, hypophysitis, metaphyseal osteopenia, and serositis.

Several other immune genes have been proposed to be associated with Addison's disease and therefore with APS-2 (Table 401-3). The "5.1" allele of a major histocompatibility complex (MHC) gene is an atypical class I HLA molecule MIC-A. The MIC-A5.1 allele has a very strong association with Addison's disease that is not accounted for by linkage disequilibrium with DR3 or DR4. Its role is complicated because certain HLA class I genes can offset this effect. *PTPN22* codes for a polymorphism in a protein tyrosine phosphatase, which acts on intracellular signaling pathways in both T and B lymphocytes. It has been implicated in T1D, Addison's disease, and other autoimmune conditions. *CTLA4* is a receptor on the T-cell surface that modulates the activation state of the cell as part of the signal 2 pathway (i.e., binding to CD80/86 on antigen presenting cells). Polymorphisms of this gene appear to cause downregulation of the cell surface expression of the receptor, leading to decreased T-cell activation and proliferation. This appears to contribute to Addison's disease and potentially other components of APS-2. Allelic variants of the IL-2Rα are linked to development of T1D and autoimmune thyroid disease and could contribute to the phenotype of APS-2 in certain individuals.

Diagnosis When one of the component disorders is present, a second associated disorder occurs more commonly than in the general population (Table 401-3). There is controversy as to which tests to use and how often to screen individuals for disease. A strong family history of autoimmunity should raise suspicion in an individual with an initial component diagnosis. The development of a rarer form of autoimmunity, such as Addison's disease, should prompt more extensive screening for other linked disorders, as ~50% of Addison's disease patients develop another autoimmune disease during their lifetime.

Circulating autoantibodies, as previously discussed, can precede the development of clinical disease by many years but would allow the clinician to follow the patient and identify the disease onset at its earliest time point (Tables 401-3 and 401-4). For each of the endocrine components of the disorder, appropriate autoantibody assays are listed and, if positive, should prompt physiologic testing to diagnose clinical or subclinical disease. For Addison's disease, antibodies to 21-hydroxylase antibodies are highly diagnostic for risk of adrenal insufficiency. However, individuals may take many years to develop overt symptoms of hypoadrenalism. Screening of 21-hydroxylase antibody–positive patients can be performed measuring morning ACTH and cortisol on a yearly basis. Rising ACTH values over time or low morning cortisol in association with signs or symptoms of adrenal insufficiency should prompt testing via the cosyntropin stimulation test **(Chap. 398)**. T1D can be screened for by measuring autoantibodies directed against insulin, GAD65, IA-2, and ZnT8. Risk for progression to disease is based on the number of antibodies (≥2 islet autoantibodies with normal glucose tolerance is now defined as stage 1 of T1D as the lifetime risk for developing clinical symptoms is nearly 100%) and metabolic factors (impaired oral glucose tolerance test). Many efforts are ongoing and underway to screen relatives of T1D patients and those in the general population for islet autoantibodies to identify individuals with

TABLE 401-4 APS-2 and Other Polyendocrine Disorder Associations

DISEASE	HLA ASSOCIATION	INITIATING FACTOR	MECHANISM	AUTOANTIGEN
Graves' disease	DR3	Iodine Anti-CD52	Antibody	TSH receptor
Myasthenia gravis	DR3, DR7	Thymoma Penicillamine	Antibody	Acetylcholine receptor
Anti-insulin receptor	?	SLE or other autoimmune disease	Antibody	Insulin receptor
Hypoparathyroidism	?	?	Antibody	Cell surface inhibitor
Insulin autoimmune syndrome	DR4, DRB1*0406	Methimazole Sulfhydryl-containing drugs	Antibody	Insulin
Celiac disease	DQ2/DQ8	Gluten diet	T cell	Transglutaminase
Type 1 diabetes	DR3/DR4 DQ2/DQ8	? Congenital rubella	T cell	Insulin, GAD65, IA-2, ZnT8, IGRP
Addison's disease	DR3/DR4 DRB1*0404	Unknown	T cell	21-Hydroxylase P450-5cc
Thyroiditis	DR3/DQB1*0201 DQA1*0301	Iodine Interferon α	T cell	Thyroglobulin Thyroid peroxidase
Pernicious anemia	?	?	T cell	Intrinsic factor H+/K+ ATPase
Vitiligo	?	Melanoma Antigen Immunization	?	Melanocyte
Chromosome dysgenesis–trisomy 21 and Turner's syndrome	DQA1*0301	?	?	Thyroid, islet, transglutaminase
Hypophysitis	?	Pit-1, TDRD6	?	Pituitary, Pit-1

Abbreviations: APS, autoimmune polyendocrine syndrome; SLE, systemic lupus erythematosus; TSH, thyroid-stimulating hormone.

preclinical disease who may elect to have treatment with teplizumab, anti-CD3 monoclonal antibody, to delay the clinical onset of diabetes.

Screening tests for thyroid disease can include anti–thyroid peroxidase (TPO) or anti-thyroglobulin autoantibodies or anti-TSH receptor antibodies for Graves' disease. Yearly measurements of TSH can then be used to follow these individuals. Celiac disease can be screened for using the anti–tissue transglutaminase (tTg) antibody test. For those <20 years of age, testing every 1–2 years should be performed, whereas less frequent testing is indicated after the age of 20 because the majority of individuals who develop celiac disease have the antibody earlier in life. Positive tTg antibody test results should be confirmed on repeat testing, followed by small-bowel biopsy to document pathologic changes of celiac disease. Many patients have asymptomatic celiac disease that is nevertheless associated with osteopenia and impaired growth. If left untreated, symptomatic celiac disease has been reported to be associated with an increased risk of gastrointestinal malignancy, especially lymphoma, and osteoporosis later in life.

The knowledge of the particular disease associations should guide other autoantibody or laboratory testing. A complete history and physical examination should be performed every 1–3 years including complete blood count, metabolic panel, TSH, and vitamin B_{12} levels to screen for most of the possible abnormalities. More specific tests should be based on specific findings from the history and physical examination.

TREATMENT

APS-2

With the exception of Graves' disease, the management of each endocrine component of APS-2 involves hormone replacement and is covered in detail in the chapters on adrenal **(Chap. 398)**, thyroid **(Chap. 394)**, gonadal **(Chaps. 403 and 404)**, and parathyroid diseases **(Chap. 422)**. As noted for APS-1, adrenal insufficiency can be masked by primary hypothyroidism and should be considered and treated as discussed above. In patients with T1D, decreasing insulin requirements or hypoglycemia, without obvious secondary causes, may indicate the emergence of adrenal insufficiency. Hypocalcemia in APS-2 patients is more likely due to malabsorption, potentially from undiagnosed celiac disease, than hypoparathyroidism.

Immunotherapy for autoimmune endocrine disease has been reserved for T1D, for the most part, reflecting the lifetime burden of the disease for the individual patient and society. Although several immunotherapies (e.g., modified anti-CD3, rituximab, abatacept, alefacept, low-dose antithymocyte globulin, TNF-α inhibitors, and JAK inhibitors) can prolong the honeymoon phase of T1D, none has achieved long-term success. Notably, the anti-CD3 monoclonal antibody (teplizumab) does delay the onset of clinical diabetes by an average of 3 years when administered to individuals with stage 2 T1D (e.g., those with autoantibodies and impaired glucose tolerance) and is now approved for clinical use in the United States. Active basic and clinical research using novel therapies and combinations may change the treatment landscape of this disease and other autoimmune conditions that share similar pathways.

IMMUNE CHECKPOINT INHIBITOR–INDUCED ENDOCRINE AUTOIMMUNITY

Therapies that block immune checkpoints, such as programmed cell death protein 1 (PD-1), its ligand (PD-L1), or CTLA-4, are beneficial immunotherapies for many advanced-stage cancers. These immune checkpoint inhibitors (ICIs) block negative immune regulation, thereby allowing for an immune response directed against tumor cells. However, immune-related adverse events also occur, especially autoimmunity directed toward self-tissues. ICI-induced T1D, thyroid disease, hypophysitis, and adrenal insufficiency have all been reported with these therapies and in combination. Hypothyroidism occurs in ~10% and T1D in 1–2% of those receiving monoclonal antibodies directed against PD-1 or PD-L1, and hypophysitis and adrenal insufficiency occur in <1% of treated patients. These autoimmune side effects can develop during or after therapy, mostly within a few weeks to months following the start of therapy. ICI-induced T1D has a very rapid onset, presents with diabetic ketoacidosis, is permanent, and requires lifelong exogenous insulin therapy for treatment. There is a strong genetic association, with HLA-DR4 being present in ~70% of patients, and islet autoantibodies may be present at diagnosis. The pathogenesis is immune mediated as T lymphocyte infiltration has been documented in the pancreatic islets of an ICI-T1D patient. Determining the mechanisms of autoimmune disease development following ICI therapies and developing biomarkers to stratify risk for autoimmune side effects prior to therapy are active areas of research.

IPEX

*I*mmune dysregulation, *p*olyendocrinopathy, *e*nteropathy, and *X*-linked disease (IPEX; OMIM 304790) is a rare X-linked recessive disorder. The disease onset is in infancy and is characterized by severe enteropathy, T1D, and skin disease, as well as variable association with several other autoimmune disorders. Many infants die within the first days of life, but the course is variable, with some children surviving for 12–15 years. Early onset of T1D, often at birth, is highly suggestive of the diagnosis because nearly 80% of IPEX patients develop T1D. Although treatment of the individual disorders can temporarily improve the situation, treatment of the underlying immune deficiency is required and includes immunosuppressive therapy generally followed by hematopoietic stem cell transplantation. Transplantation is the only life-saving form of therapy and can be fully curative by normalizing the imbalanced immune system found in this disorder.

IPEX is caused by mutations in the *FOXP3* gene, which is also mutated in the Scurfy mouse, an animal model that shares much of the same phenotype of IPEX patients. The FOXP3 transcription factor is expressed in regulatory T cells designated CD4+CD25+FOXP3+ (Treg). Lack of this factor causes a profound deficiency of this Treg population and results in rampant autoimmunity due to the lack of peripheral tolerance normally provided by these cells. Certain mutations may lead to varying forms of expression of the full syndrome, and there are rare cases where the *FOXP3* gene is intact but other genes involved in this pathway (e.g., CD25, IL-2Rα) may be causative. Future therapy with autologous CD4+ T cells transfected with a functioning *FOXP3* gene may offer a better long-term outcome than has been seen in those treated with stem cell transplantation.

THYMIC TUMORS

Thymomas and thymic hyperplasia are associated with several autoimmune diseases, with the most common being myasthenia gravis (44%) and red cell aplasia (20%). Graves' disease, T1D, and Addison's disease may also be associated with thymic tumors. Patients with myasthenia gravis and thymoma may have unique anti–acetylcholine receptor autoantibodies. Most thymomas lack AIRE expression within the thymoma, and this could be a potential factor in the development of autoimmunity. In support of this concept, thymoma is the one other disease with "frequent" development of anticytokine antibodies and mucocutaneous candidiasis in adults. The majority of tumors are malignant, and temporary remissions of the autoimmune condition can occur with resection of the tumor.

ANTI-INSULIN RECEPTOR ANTIBODIES

This is a very rare disorder where severe insulin resistance (type B) is caused by the presence of anti-insulin receptor antibodies. It is associated with acanthosis nigricans, which can also be associated with other forms of less severe insulin resistance. About one-third of patients have an associated autoimmune illness such as systemic lupus erythematosus or Sjögren's syndrome. Therefore, the presence of antinuclear antibodies, elevated erythrocyte sedimentation rate, hyperglobulinemia, leukopenia, and hypocomplementemia may accompany

the presentation. The presence of anti-insulin receptor autoantibodies leads to marked insulin resistance, requiring >100,000 units of insulin to be given daily with only partial control of hyperglycemia. Patients can also have severe hypoglycemia due to partial activation of the insulin receptor by the antibody. The course of the disease is variable, and several patients have had spontaneous remissions. A therapeutic approach that targets B lymphocytes, including rituximab, cyclophosphamide, and pulse steroids, has been validated in follow-on case reports to induce remission of the disease.

INSULIN AUTOIMMUNE SYNDROME (HIRATA'S SYNDROME)

The insulin autoimmune syndrome, associated with Graves' disease and methimazole therapy (or other sulfhydryl-containing medications), is of particular interest due to a remarkably strong association with a specific HLA haplotype. Such patients with elevated titers of anti-insulin antibodies frequently present with hypoglycemia. In Japan, the disease is restricted to HLA-DR4-positive individuals with DRB1*04:06, while Caucasian patients predominantly have *DRB1*04:03* (which is related to *DRB1*04:06*). In Hirata's syndrome, the anti-insulin antibodies are often polyclonal. Discontinuation of the medication generally leads to resolution of the syndrome over time. There are very rare cases of insulin autoimmune syndrome not associated with sulfhydryl-containing medications that result in profound, life-threatening hypoglycemia. Treatment involves treating the underlying condition that causes anti-insulin antibodies, such as a B lymphocyte lymphoma (tend to have monoclonal insulin antibodies) or systemic lupus erythematosus. As hypoglycemia is profound when elevated titers of high-affinity insulin antibodies bind secreted insulin and then release it into circulation, treatment that begins with high-dose glucocorticoids and rituximab to target B lymphocytes has been shown to be effective.

POEMS SYNDROME

POEMS (*p*olyneuropathy, *o*rganomegaly, *e*ndocrinopathy, *M*-protein, and *s*kin changes; also known as Crow-Fukase syndrome; OMIM 192240) patients usually present with a progressive sensorimotor polyneuropathy, diabetes mellitus (50%), primary gonadal failure (70%), and a plasma cell dyscrasia with sclerotic bony lesions. Associated findings can be hepatosplenomegaly, lymphadenopathy, and hyperpigmentation. Patients often present in the fifth to sixth decade of life and have a median survival after diagnosis of <3 years. The syndrome is assumed to be secondary to circulating immunoglobulins, but patients have excess vascular endothelial growth factor as well as elevated levels of other inflammatory cytokines such as IL-1β, IL-6, and tumor necrosis factor α. Patients have been treated with thalidomide, and more recently lenalidomide, leading to a decrease in vascular endothelial growth factor. Hyperglycemia responds to small, subcutaneous doses of insulin. The hypogonadism is due to primary gonadal disease with elevated plasma levels of follicle-stimulating hormone and luteinizing hormone. Temporary resolution of the features of POEMS, including normalization of blood glucose, may occur after radiotherapy for localized plasma cell lesions of bone or after chemotherapy, lenalidomide and dexamethasone, or autologous stem cell transplantation.

OTHER DISORDERS

Other diseases can exhibit polyendocrine deficiencies, including Kearns-Sayre syndrome, DIDMOAD syndrome (*d*iabetes *i*nsipidus, *d*iabetes *m*ellitus, progressive bilateral *o*ptic *a*trophy, and sensorineural *d*eafness; also termed Wolfram's syndrome), Down's syndrome or trisomy 21 (OMIM 190685), Turner's syndrome (monosomy X, 45,X0), and congenital rubella.

Kearns-Sayre syndrome (OMIM 530000) is a rare mitochondrial DNA disorder characterized by myopathic abnormalities leading to ophthalmoplegia and progressive weakness in association with several endocrine abnormalities, including hypoparathyroidism, primary gonadal failure, diabetes mellitus, and hypopituitarism. Crystalline mitochondrial inclusions are found in muscle biopsy specimens, and such inclusions have also been observed in the cerebellum. Antiparathyroid antibodies have not been described; however, antibodies to the anterior pituitary gland and striated muscle have been identified, and the disease may have autoimmune components. These mitochondrial DNA mutations occur sporadically and do not appear to be associated with a familial syndrome.

Wolfram's syndrome (OMIM 222300, chromosome 4; OMIM 598500, mitochondrial) is a rare autosomal recessive disease that is also called DIDMOAD. Neurologic and psychiatric disturbances are prominent in most patients and can cause severe disability. The disease is caused by defects in the *Wolfram syndrome 1* (*WFS1*) gene, which encodes a 100-kDa transmembrane protein that has been localized to the endoplasmic reticulum and is found in neuronal and neuroendocrine tissue. Its expression induces ion channel activity with a resultant increase in intracellular calcium and may play an important role in intracellular calcium homeostasis. Wolfram's syndrome appears to be a slowly progressive neurodegenerative process, and there is nonautoimmune selective destruction of the pancreatic beta cells. Diabetes mellitus with an onset in childhood is usually the first manifestation. Diabetes mellitus and optic atrophy are present in all reported cases, but expression of the other features is variable. Treatments targeting endoplasmic reticulum dysfunction are being tested and may be a bridge until gene therapy can be developed to treat the most severely affected cases.

Down's syndrome, or trisomy 21 (OMIM 190685), is associated with the development of T1D, thyroiditis, and celiac disease. Patients with Turner's syndrome also appear to be at increased risk for the development of thyroid disease and celiac disease. It is recommended to screen patients with trisomy 21 and Turner's syndrome for associated autoimmune diseases on a regular basis.

GLOBAL CONSIDERATIONS

Identification of these syndromes requires access to central laboratories with the ability to detect unique autoantibodies and to sequence the specific genes that may underlie these disorders. Early recognition of the clinical features of these disorders and timely referral and/or consultation with tertiary care centers to confirm the diagnosis and initiate therapy are important to improving outcomes. The *AIRE* recessive gene mutations found in APS-1 were originally described in high frequency in several populations including Finns, Iranian Jews, Sardinians, Norwegians, and Irish. Although individuals from many other countries have now been found to have these mutations and the newly identified dominant *AIRE* gene mutations, understanding the frequency in the background population may raise the clinician's level of suspicion for these rare disorders. Hirata's syndrome was originally reported in Japanese populations but also may be found in other populations, as noted.

402 Sex Development

Courtney Finlayson, J. Larry Jameson, John C. Achermann

Sex development begins in utero but continues into young adulthood with the achievement of sexual maturity and reproductive capability. The major determinants of sex development can be divided into three components: chromosomal sex, gonadal sex (sex determination), and phenotypic sex (sex differentiation) (Fig. 402-1). Variations at each of these stages can result in differences (or disorders) of sex development (DSDs) (Table 402-1). In the newborn period, ~1 in 5000 babies undergo investigation because of atypical or ambiguous genitalia. Urgent assessment is indicated, because some causes such as congenital adrenal hyperplasia (CAH) can be associated with life-threatening adrenal crises. An experienced multidisciplinary team is important for counseling, planning appropriate investigations, discussing long-term well-being, supporting parents, and providing clear communication about the diagnosis and management options. DSDs can also present at other ages and to a range of health professionals, including with either absent puberty, primary amenorrhea, or androgenization in the teen years (Table 402-2). Other forms of gonadal dysfunction (e.g., Klinefelter syndrome [KS], Turner syndrome [TS]) often are diagnosed later in life by internists. Because DSDs are associated with a variety of psychological, reproductive, and potential medical consequences, an open dialogue must be established between the patient and health care providers to ensure continuity and attention to these issues across the life span. Gender variance and gender dysphoria are more common among some individuals with DSD than in the general population, though not high. Thus, attention to and comfort discussing gender identity is important. Support groups also have a valuable role to play for many patients and families.

Care of individuals with DSDs should be holistic, often involving medical, psychosocial, and urogynecologic expertise, while acknowledging that the best way to care for individuals with DSD is not always clear and should be individualized. There are many controversies, particularly concerning whether genitoplasty or prophylactic gonadectomy in selected conditions should be performed for infants and young children prior to the age of consent. Accepted nomenclature is also controversial. Previous terms such as *intersex* and *hermaphrodite* were changed by the 2006 Consensus Statement to *disorder of sex development* and *ovotesticular DSD*. The term "disorder" is often considered negative and stigmatizing and thus has shifted toward *difference of sex development*, but no term is universally accepted.

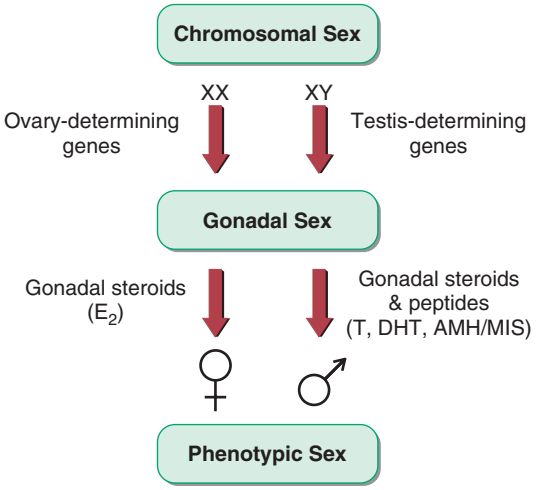

FIGURE 402-1 Sex development can be divided into three major components: chromosomal sex, gonadal sex, and phenotypic sex. AMH, anti-müllerian hormone also known as Müllerian-inhibiting substance, MIS; DHT, dihydrotestosterone; T, testosterone.

SEX DEVELOPMENT

Chromosomal sex, defined by a karyotype, describes the X and/or Y chromosome complement (46,XY; 46,XX) established at the time of fertilization. The presence of a normal Y chromosome determines that testis development will occur even in the presence of multiple X chromosomes (e.g., 47,XXY). Loss of an X chromosome impairs gonad development (45,X or 45,X/46,XY mosaicism). Fetuses with no X chromosome (45,Y) are not viable.

Gonadal sex refers to the histologic and functional characteristics of gonadal tissue as testis or ovary. The embryonic gonad is initially "bipotential" and can develop into either a testis or an ovary (Fig. 402-2). Testis development is initiated by expression of the gene *SRY* (sex-determining region on the Y chromosome) (from ~42 days after conception). Disruption of *SRY* prevents testis development in 46,XY individuals, whereas translocation of *SRY* in 46,XX individuals induces testis development and a male phenotype. SRY regulates *SOX9* (*SRY*-related HMG-box gene 9), leading to expression of a cascade of genes involved in testis development, including in Sertoli cell maturation and Leydig cell differentiation/steroidogenesis. Disruption of some of these genes can influence both the development of the testis and other organs, such as kidney (*WT1*), adrenal/spleen (*SF1*, *NR5A1*), brain (*PPP1R12A*), or heart (*GATA4*). Chromosomal segment duplications (e.g., Xp21 containing *DAX1*/*NR0B1*) can also impair testis development, revealing the sensitivity of testis-determining pathway to gene dosage effects.

Ovarian development is not a "passive" process. Many specific genes are expressed during early ovary development, some of which may repress testis development (e.g., WNT4, R-spondin-1) (Fig. 402-2). Once the ovary has formed, additional factors are required for normal follicular development (e.g., follicle-stimulating hormone [FSH] receptor). Steroidogenesis in the ovary requires the development of follicles that contain granulosa cells and theca cells surrounding the oocytes (Chap. 404). Thus, there is relatively limited ovarian steroidogenesis until puberty.

Germ cells also develop in a sex dimorphic manner. In the developing ovary, primordial germ cells (PGCs) show marked proliferation and enter meiosis, whereas they undergo mitotic arrest in the developing testis. Approximately 7 million germ cells are present in the fetal ovary toward the end of the second trimester, and 1 million remain at birth. Only 400 are ovulated during a woman's reproductive life span (Chap. 404).

Phenotypic sex refers to the structures of the external and internal genitalia and secondary sex characteristics. In early gestation, internal and external genitalia are initially similar in both sexes ("indifferent"). Sex-specific development occurs as a result of hormone action (Fig. 402-3). The developing testis releases anti-müllerian hormone (AMH; also known as müllerian-inhibiting substance [MIS]) from Sertoli cells and testosterone from Leydig cells. AMH acts through specific receptors to cause regression of the müllerian structures from 60–80 days after conception. At ~60–140 days after conception, testosterone supports the maintenance of wolffian structures, including the epididymides, vasa deferentia, and seminal vesicles. Testosterone is the precursor for dihydrotestosterone (DHT), a potent androgen that promotes development of the external genitalia, including the penis and scrotum (60–100 days, and thereafter) (Fig. 402-3). The urogenital sinus develops into the prostate and prostatic urethra in the male and into the urethra and lower portion of the vagina in the female. The genital tubercle becomes the glans penis in the male and the clitoris in the female. The urogenital swellings form the scrotum or the labia majora, and the urethral folds fuse to form the shaft of the penis and the male urethra or the labia minora. In the female, wolffian ducts regress and the müllerian ducts form the fallopian tubes, uterus, and upper segment of the vagina. A female phenotype will develop in the

TABLE 402-1 Classification of Differences (Disorders) of Sex Development (DSDs)

SEX CHROMOSOME DSD	46,XY DSD (SEE TABLE 402-3)	46,XX DSD (SEE TABLE 402-4)
47,XXY (Klinefelter syndrome and variants)	**Gonadal (testis) development**	**Gonadal (ovary) development**
45,X (Turner syndrome and variants)	Complete or partial gonadal dysgenesis	Gonadal dysgenesis
45,X/46,XY mosaicism (mixed gonadal dysgenesis)	Impaired fetal Leydig cell function	Ovotesticular DSD
46,XX/46,XY (chimerism/mosaicism)	Ovotesticular DSD	Testicular DSD
	Testis regression	**Androgen excess**
	Disruption in androgen synthesis or action	Fetal
	Disruption of androgen biosynthesis	3β-Hydroxysteroid dehydrogenase II (*HSD3B2*)
	LH receptor (*LHCGR*)	21-Hydroxylase (*CYP21A2*)
	Smith-Lemli-Opitz syndrome (*DHCR7*)	P450 oxidoreductase (*POR*)
	Steroidogenic acute regulatory (*StAR*) protein	11β-Hydroxylase (*CYP11B1*)
	Cholesterol side-chain cleavage (*CYP11A1*)	Fetoplacental
	3β-Hydroxysteroid dehydrogenase II (*HSD3B2*)	Aromatase deficiency (*CYP19A1*)
	17α-Hydroxylase/17,20-lyase (*CYP17A1*)	Oxidoreductase deficiency (*POR*)
	P450 oxidoreductase (*POR*)	Maternal
	Cytochrome b5 (*CYB5A*)	Maternal virilizing tumors (e.g., luteomas)
	17β-Hydroxysteroid dehydrogenase III (*HSD17B3*)	Androgenic drugs
	5α-Reductase II (*SRD5A2*)	**Others include:**
	Aldo-keto reductase 1C2 (*AKR1C2*)	Syndromic associations (e.g., cloacal anomalies)
	Disruption of androgen action	Müllerian agenesis/hypoplasia (e.g., MRKH)
	Androgen insensitivity syndrome	Uterine abnormalities (e.g., MODY5)
	Others include:	Vaginal atresia (e.g., McKusick-Kaufman)
	Syndromic associations of male genital development	Labial adhesions
	Associated with fetal growth restriction	
	Persistent müllerian duct syndrome	
	Vanishing testis syndrome	
	Isolated hypospadias	
	Congenital hypogonadotropic hypogonadism	
	Cryptorchidism	
	Environmental influences

absence of the gonad, but estrogen is needed for maturation of the uterus and breast at puberty.

The prenatal hormone environment is likely one of many factors influencing aspects of gender identity and behavior. This is an area of ongoing research and is beyond the scope of this chapter.

DIFFERENCES OF CHROMOSOMAL SEX

Variations in sex chromosome number and structure can present as DSDs (e.g., 45,X/46,XY). KS (47,XXY) and TS (45,X) do not usually present with genital ambiguity but are associated with gonadal dysfunction (Table 402-3).

KLINEFELTER SYNDROME (47,XXY) (SEE ALSO CHAP. 403)

Pathophysiology The classic form of KS (47,XXY) occurs after meiotic nondisjunction of the sex chromosomes during gametogenesis (40% during spermatogenesis, 60% during oogenesis). Other forms of aneuploidy have similar features to KS (including mosaic 46,XY/47,XXY, 48,XXYY, and 48,XXXY) but are less common. KS has an incidence of at least 1 in 1000 men, but ~75% of cases are not diagnosed. Of those diagnosed, historically only 10% were identified prepubertally. However, noninvasive prenatal testing is leading to increased early detection.

TABLE 402-2 Presentation of Differences of Sex Development (DSD) at Different Stages of Life

PRESENTATION	FEATURES	PROFESSIONAL	EXAMPLES
Prenatal	Karyotype-phenotype discordance	Obstetrician; fetal medicine	Many
Neonatal	Atypical genitalia	Obstetrician; neonatal medicine	Many
	Salt-losing crisis	Pediatrician	CAH *(CYP21A2)*
Childhood	Hernia	Surgeon	CAIS
	Androgenization	Endocrinologist	CAH *(CYP21A2, CYP11B1)*
	Poor growth	Pediatrician	Turner, 45,X/46,XY
	Associated features	Oncologist/nephrologist	Wilms' tumor
Puberty	Androgenization	Endocrinologist	17β-HSD, 5α-reductase, SF1
	Estrogenization	Endocrinologist	Ovotestis
	Absent puberty	Endocrinologist	Gonadal dysgenesis, CAH *(CYP17A1)*, Turner
Post-puberty	Amenorrhea	Gynecologist	CAIS
Adult	Infertility	Andrologist	Klinefelter, 45,X/46,XY, SF1

Abbreviations: CAH, congenital adrenal hyperplasia; CAIS, complete androgen insensitivity syndrome; 17β-HSD, 17β-hydroxysteroid dehydrogenase deficiency; SF1, steroidogenic factor 1 (*NR5A1*).

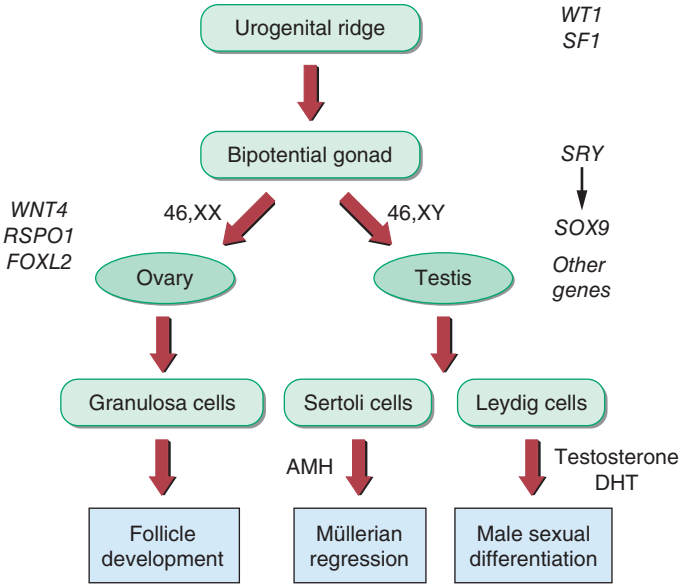

FIGURE 402-2 The genetic regulation of gonadal development. See text for additional genes involved. AMH, anti-müllerian hormone (müllerian-inhibiting substance); DHT, dihydrotestosterone; *FOXL2*, forkhead transcription factor L2; *RSPO1*, R-spondin 1; *SF1*, steroidogenic factor 1 (also known as NR5A1); *SOX9*, *SRY*-related HMG-box gene 9; *SRY*, sex-determining region on the Y chromosome; *WNT4*, wingless-type MMTV integration site 4; *WT1*, Wilms' tumor–related gene 1.

Clinical Features KS is most commonly characterized by small testes, infertility, gynecomastia, tall stature/increased leg length, and hypogonadism in phenotypic males. At birth, most infants with KS do not have clinical features, although there are higher rates of cryptorchidism and hypospadias. Most patients present in puberty with arrested pubertal development caused by testicular insufficiency. Others are diagnosed after puberty, based on low androgens, gynecomastia, or infertility. Testes are small and firm (median length 2.5 cm [4 mL volume]; almost always <3.5 cm [12 mL]) and typically seem inappropriately small for the degree of androgenization. Biopsies are not usually necessary but typically reveal seminiferous tubule hyalinization and azoospermia. Other clinical features of KS are listed in Table 402-3. Plasma concentrations of FSH and luteinizing hormone (LH) are increased in most adults with 47,XXY, and plasma testosterone is decreased (50–75%), reflecting primary gonadal insufficiency. Estradiol is often increased, resulting in gynecomastia (Chap. 403). Those with mosaic forms of KS have less severe clinical features, have larger testes, and sometimes achieve spontaneous fertility.

TREATMENT

Klinefelter Syndrome

Growth, endocrine function, and bone mineralization should be monitored, especially from adolescence. Educational and psychological support is important for many individuals with KS.

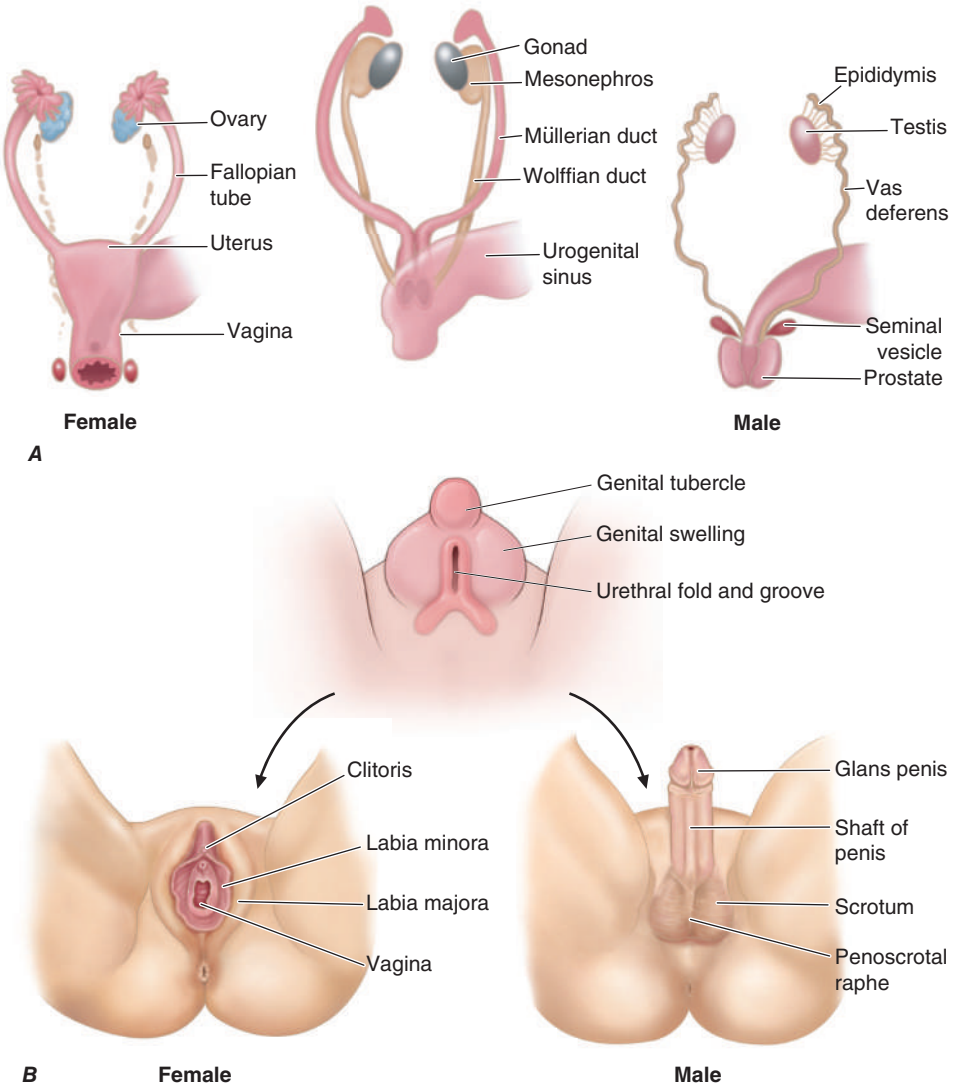

FIGURE 402-3 Sex development. ***A.*** Internal urogenital tract. ***B.*** External genitalia.

TABLE 402-3 Possible Associated Clinical Features of Sex Chromosome Variations

DISORDER	COMMON CHROMOSOMAL COMPLEMENT	GONAD	GENITALIA		BREAST DEVELOPMENT
			EXTERNAL	INTERNAL	
Klinefelter syndrome	47,XXY or 46,XY/47,XXY	Hyalinized testes	Male	Male	Increased incidence of gynecomastia
	Clinical Features				
	Small testes, azoospermia, decreased facial and axillary hair, decreased libido, tall stature and increased leg length, decreased penile length, increased risk of breast tumors, thromboembolic disease, learning difficulties, anxiety, speech delay and decreased verbal IQ, obesity, diabetes mellitus, metabolic syndrome, varicose veins, hypothyroidism, systemic lupus erythematosus, epilepsy				
Turner syndrome	45,X or 45,X/46,XX	Streak gonad or immature ovary	Female	Hypoplastic female	Immature female
	Clinical Features				
	Infancy: lymphedema, web neck, shield chest, low-set hairline, cardiac defects and coarctation of the aorta, urinary tract malformations, and horseshoe kidney				
	Childhood: short stature, cubitus valgus, short neck, short fourth metacarpals, hypoplastic nails, micrognathia, scoliosis, otitis media and sensorineural hearing loss, ptosis and amblyopia, multiple nevi and keloid formation, autoimmune thyroid disease, visuospatial learning difficulties				
	Adulthood: absent puberty and primary amenorrhea, hypertension, obesity, dyslipidemia, impaired glucose tolerance and insulin resistance, autoimmune thyroid disease, cardiovascular disease, aortic root dilation, osteoporosis, inflammatory bowel disease, chronic hepatic dysfunction, increased risk of colon cancer, hearing loss				
45,X/46,XY mosaicism	45,X/46,XY	Testis or streak gonad	Variable	Variable	Usually male
	Clinical Features				
	Short stature, increased risk of gonadal tumors, some Turner syndrome features				
Ovotesticular DSD	46,XX/46,XY	Testis and ovary or ovotestis	Variable	Variable	Gynecomastia
	Clinical Features				
	Possible increased risk of gonadal tumors				

Abbreviation: DSD, difference of sex development.

Androgen supplementation improves virilization, libido, energy, hypofibrinolysis, and bone mineralization in men with low testosterone levels but may occasionally worsen gynecomastia (Chap. 403). Gynecomastia can be treated by surgical reduction if it causes concern (Chap. 403). Fertility has been achieved by using in vitro fertilization in men with oligospermia or with intracytoplasmic sperm injection (ICSI) after retrieval of spermatozoa by testicular sperm extraction techniques (Chap. 403). Long-term monitoring of men with KS is important given the increased risk of breast cancer, cardiovascular disease, metabolic syndrome, osteoporosis, and autoimmune disorders. Because most men with KS are never diagnosed, it is important that all internists consider this diagnosis in men with such features.

TURNER SYNDROME (GONADAL DYSGENESIS; 45,X)

Pathophysiology TS is caused by complete or partial loss of one X chromosome and affects ~1 in 2500 women. Approximately one-half of women with TS have a 45,X karyotype, ~20% have 45,X/46,XX mosaicism, and the remainder have structural abnormalities of the X chromosome, or Y chromosome material. The clinical features of TS likely result at least in part from haploinsufficiency of X chromosomal genes (especially in the pseudoautosomal region), but the exact mechanisms remain poorly understood.

Clinical Features TS is characterized by female-typical external genitalia, short stature, hypergonadotropic hypogonadism, infertility, and other phenotypic features (Table 402-3). Infants may present with lymphedema, nuchal folds, low hairline, or left-sided cardiac defects or later in childhood with unexplained growth failure or delayed puberty. Although limited spontaneous pubertal development occurs in up to 30% of girls with TS (10%, 45,X; 60%, 45,X/46,XX) and up to 20% have menarche, the vast majority of women with TS develop complete ovarian insufficiency. Therefore, this diagnosis should be considered in all women who present with primary or secondary amenorrhea and elevated gonadotropin levels.

TREATMENT

Turner Syndrome

The management of girls and women with TS requires a multidisciplinary approach to address many potentially affected organ systems according to TS practice guidelines. Individuals require long-term monitoring by an experienced cardiologist to follow congenital heart defects (CHDs) (30%) (bicuspid aortic valve, 30–50%; coarctation of the aorta, 30%; aortic root dilation, 5%), antibiotic prophylaxis for dental or surgical procedures, and serial magnetic resonance imaging (MRI) of aortic root dimensions, as progressive aortic root dilation is associated with increased risk of aortic dissection. Individuals found to have congenital renal and urinary tract malformations (30%) are at risk for urinary tract infections, hypertension, and nephrocalcinosis. Hypertension can occur independently of cardiac and renal malformations and should be monitored and treated as in other patients with essential hypertension. Regular assessment of thyroid function, weight, dentition, hearing, speech, vision, and educational issues should be performed during childhood. Counseling about long-term growth and fertility issues should be provided. Patient support groups are active throughout the world and can play an invaluable role.

Short stature is common, and untreated final height rarely exceeds 150 cm in nonmosaic 45,X TS. Recombinant growth hormone is used to increase adult height. Girls with evidence of ovarian insufficiency require estrogen replacement to induce breast and uterine development, support growth, and maintain bone mineralization. Most physicians now initiate low-dose estrogen therapy to induce puberty at an age-appropriate time (~11 years). Doses of estrogen are increased gradually to allow development over a 2- to 4-year period. Progestins are added later to regulate withdrawal bleeds. A very small percentage of women with TS have had spontaneous pregnancy, whereas others have achieved successful pregnancy after ovum donation and in vitro fertilization, but the risks of cardiac complications are high, and expert counseling and

management are needed. The existence of Y chromosome material in individuals with TS increases the risk for germ cell tumors, and gonadectomy has traditionally been advised. Increasingly, it is recommended that this decision also weigh potential for gonadal function and the importance of autonomous decision-making. Long-term follow-up of women with TS includes careful surveillance of sex hormone replacement and reproductive function, bone mineralization, cardiac function and aortic root dimensions, blood pressure, weight and glucose tolerance, hepatic and lipid profiles, thyroid function, celiac disease screening, skin examination, and hearing. This service is provided by a dedicated TS clinic in some centers.

45,X/46,XY MOSAICISM

The phenotype of individuals with 45,X/46,XY mosaicism (sometimes called *mixed gonadal dysgenesis*) can vary considerably. Some have a predominantly female phenotype (see TS above). Most 45,X/46,XY individuals have a male phenotype and testes, and the diagnosis is made incidentally after amniocentesis or during investigation of infertility. In practice, most newborns referred for assessment have atypical genitalia and variable somatic features. There is often marked asymmetry, with a streak gonad and hemiuterus on one side and a partially descended dysgenetic testis and hemiscrotum on the other side. Many children are raised as boys, but in some children, sex designation (whether to raise the baby as male or female) must be decided by parents and the multidisciplinary team. There is an increased risk of germ cell cancer (GCC), up to 35% in intraabdominal gonads, so prophylactic removal of intraabdominal gonads is usually considered. Individuals raised as males often have hypospadias surgery and removal of dysgenetic or streak gonads if the gonads cannot be brought down into the scrotum. Scrotal testes can be preserved but require regular examination for tumor development and sonography (and possibly biopsy) at the time of puberty. Testosterone supplementation may be required in puberty or adulthood if low testosterone is detected. Potential associated features (e.g., cardiac, renal) should be monitored according to TS guidelines. Infertility is typical, but non-azoospermia or focal spermatogenesis has been reported, highlighting the importance of individualized approaches to management.

OVOTESTICULAR DSD

Ovotesticular DSD (OTDSD) is a condition in which an individual has both ovarian and testicular tissue, either by having both an ovary and a testis or by having an ovotestis. Most individuals with this diagnosis have a 46,XX karyotype (especially in individuals of African ancestry), although 46,XX/46,XY chimerism and very rarely a 46,XY karyotype is also possible. OTDSD usually presents with atypical genitalia at birth and sometimes breast development, cyclical hematuria, and/or phallic development at puberty. Progressive regression of the ovarian and/or testicular component can occur over time. Gender identity varies in OTDSD but often aligns with assigned sex. Risk of GCC is also elevated in OTDSD (~3%). Infertility is typical (especially in 46,XX testes with no Y chromosome), but births have occurred via ovum or sperm from individuals with other forms of OTDSD.

DIFFERENCES OF GONADAL AND PHENOTYPIC SEX

Differences of gonadal and phenotypic sex can result in reduced androgen production or action in individuals with a 46,XY karyotype (46,XY DSD) or excess androgen production in individuals with a 46,XX karyotype (46,XX DSD) (Table 402-1). These conditions cover a spectrum of phenotypes ranging from phenotypic females with a Y chromosome to phenotypic males with a 46,XX karyotype to individuals with atypical genitalia. Karyotype is a useful starting investigation for diagnosis with basic biochemical profiling. High-throughput genetic testing can help in reaching a definitive diagnosis.

46,XY DSD

Underandrogenization of the 46,XY fetus reflects defects in androgen production or action. It can result from disruption of testis development, defects of androgen synthesis, or resistance to testosterone and DHT (Table 402-1).

Disruption of Testis Development • TESTICULAR DYSGENESIS *Complete gonadal dysgenesis* (CGD, *Swyer's syndrome*) is associated with streak gonads, müllerian structures (due to insufficient AMH/MIS secretion), and a complete absence of androgenization. Phenotypic females with this condition usually present because of absent pubertal development and are found to have a 46,XY karyotype. Serum sex steroids, AMH/MIS, and inhibin B are low, and LH and FSH are elevated. Individuals with CGD typically identify as female. The risk of GCC is high, and intraabdominal gonads should be removed. In contrast, patients with *partial gonadal dysgenesis* (PGD, *dysgenetic testes*) may produce enough MIS to regress the uterus and sufficient testosterone for partial androgenization and, therefore, usually present in the newborn period with atypical genitalia, highlighting the spectrum of features that are typically seen with many DSDs.

Testicular dysgenesis can result from disruption of testis-promoting genes (e.g., *WT1*, *SF1*, *SRY*, *SOX9*, *MAP3K1*, *DHH*, *DHX37*, and others) or, rarely, duplication of chromosomal loci containing "antitestis" genes (e.g., *DAX1*) **(Table 402-4)**. Among these, deletions or mutations of *SRY* and heterozygous mutations of *SF1* (*NR5A1*) or *DHX37* appear to be most common but still account collectively for <30% of cases. Associated clinical features may be present (Table 402-4). A family history of DSD, hypospadias, infertility, or early menopause is important because variations in some genes (e.g., *SF1*/*NR5A1*, *SOX8*) can be associated with a range of reproductive phenotypes. *SF1* variants are sometimes inherited from a mother in a sex-limited dominant manner (which can mimic X-linked inheritance), and a woman may later develop primary ovarian insufficiency because of the effect of *SF1* on the ovary. Gender identity can be variable in PGD. Dysgenetic testes have an increased risk of GCC. For descended testes, monitoring via physical examination is appropriate. If testes are intraabdominal and not able to be brought down, they may be removed to prevent GCC (risk up to 35% if intraabdominal). Dysgenetic testes may or may not produce sufficient testosterone for puberty. In those who identify as male, testosterone replacement may be needed. In those who identify as female, estrogen replacement will be needed for female-typical pubertal development and ongoing sex steroid requirements. *Absent (vanishing) testis syndrome* (*bilateral anorchia*) reflects regression of the testis during development. The absence of müllerian structures indicates adequate secretion of AMH early in utero. Usually, androgenization of the external genitalia is normal. The etiology is often unknown but sometimes associated with pathogenic variants in *DHX37*. These individuals can be offered testicular prostheses and androgen replacement in adolescence and typically identify as male.

Disruption of Androgen Synthesis Defects in the pathway that regulates androgen synthesis **(Fig. 402-4)** cause underandrogenization of the 46,XY fetus (Table 402-1). Müllerian regression is unaffected because Sertoli cell function is preserved, and no uterus is found. These conditions can present with a spectrum of genital appearances, ranging from female-typical external genitalia or clitoromegaly in some individuals to penoscrotal hypospadias or a small phallus in others.

LH RECEPTOR Pathogenic variants in the LH receptor (LHCGR) cause Leydig cell hypoplasia and testosterone insufficiency due to LH resistance.

STEROIDOGENIC ENZYME PATHWAYS Mutations in *steroidogenic acute regulatory protein* (*StAR*) and *CYP11A1* affect both adrenal and gonadal steroidogenesis (Fig. 402-4) **(Chap. 398)**. Affected individuals (46,XY) usually have severe early-onset salt-losing adrenal failure and a female phenotype, although later-onset milder variants are increasingly reported. Defects in *3β-hydroxysteroid dehydrogenase type 2* (*HSD3B2*) also cause adrenal insufficiency in severe cases, but the accumulation of dehydroepiandrosterone (DHEA) has a mild androgenizing effect, resulting in atypical genitalia or hypospadias. Salt loss occurs in many but not all children. Patients with CAH due to *17α-hydroxylase (CYP17A1) deficiency* have variable underandrogenization and develop hypertension and hypokalemia due to the potent salt-retaining effects

TABLE 402-4 Selected Genetic Causes of 46,XY Differences of Sex Development (DSDs)

GENE	INHERITANCE	GONAD	UTERUS	EXTERNAL GENITALIA	ASSOCIATED FEATURES
Disruption of Testis Development					
WT1	AD	Dysgenetic testis	+/–	Female or ambiguous	Wilms' tumor, renal abnormalities, gonadal tumors (WAGR, Denys-Drash and Frasier syndromes)
SF1/NR5A1	AR/AD (SL)	Dysgenetic testis/ Leydig dysfunction	+/–	Female, ambiguous or male	Primary adrenal failure (rare); hyposplenia (common); primary ovarian insufficiency in female (46,XX) relatives
SRY	Y	Dysgenetic testis or ovotestis	+/–	Female or ambiguous	
SOX9	AD	Dysgenetic testis or ovotestis	+/–	Female or ambiguous	Campomelic dysplasia
DHX37	AD	Dysgenetic testis	+/–	Female, ambiguous or male	Testicular regression syndrome
Other causes of testicular dysgenesis include: *DMRT1*, *CBX2*, *MAP3K1*, *SOX8*, *ZNRF3*, *GATA4*/*ZFPM2* (congenital heart disease), *DHH* (neuropathy), *ARX* (X-linked lissencephaly), *TSPYL1* (sudden infant death), *MYRF* (diaphragmatic hernia), *ESR2/NR3A2*, *SAMD9* (MIRAGE syndrome), *ATRX* (blood), *PPP1R12A* (brain, gastrointestinal), *MAMLD1*, dupXp21, dup1p35, del9p24, del10q23, and in several other congenital syndromes					
Disruption of Androgen Synthesis					
LHCGR	AR	Testis	–	Female, ambiguous or micropenis	Leydig cell hypoplasia
DHCR7	AR	Testis	–	Variable	Smith-Lemli-Opitz syndrome: coarse facies, second-third toe syndactyly, failure to thrive, developmental delay, cardiac and visceral abnormalities
STAR	AR	Testis	–	Female or ambiguous	Congenital lipoid adrenal hyperplasia (primary adrenal insufficiency)
CYP11A1	AR	Testis	–	Female or ambiguous	Primary adrenal insufficiency
HSD3B2	AR	Testis	–	Ambiguous	CAH, primary adrenal insufficiency ± salt loss, partial androgenization due to ↑ DHEA
CYP17A1	AR	Testis	–	Female or ambiguous	CAH, hypertension due to ↑ corticosterone and 11-deoxycorticosterone, except in isolated 17,20-lyase deficiency
CYB5A	AR	Testis	–	Ambiguous	Apparent isolated 17,20-lyase deficiency; methemoglobinemia
POR	AR	Testis	–	Ambiguous or male	Mixed features of 21-hydroxylase deficiency and 17α-hydroxylase/17,20-lyase deficiency, sometimes associated with Antley-Bixler craniosynostosis
HSD17B3	AR	Testis	–	Female or ambiguous	Partial androgenization at puberty, ↑ androstenedione-to-testosterone ratio
SRD5A2	AR	Testis	–	Ambiguous or micropenis	Partial androgenization at puberty, ↑ testosterone-to-dihydrotestosterone ratio
AKR1C2 (*AKR1C4*)	AR	Testis	–	Female or ambiguous	Decreased fetal DHT production
Disruption of Androgen Action					
Androgen receptor	X	Testis	–	Female, ambiguous, micropenis or normal male	Phenotypic spectrum from complete androgen insensitivity syndrome (female external genitalia) and partial androgen insensitivity (ambiguous) to normal male genitalia and infertility

Abbreviations: AD, autosomal dominant; *AKR1C2*, aldo-keto reductase family 1 member 2; AR, autosomal recessive; *ARX*, aristaless related homeobox, X-linked; CAH, congenital adrenal hyperplasia; *CBX2*, chromobox homologue 2; *CYB5A*, cytochrome b5; *CYP11A1*, P450 cholesterol side-chain cleavage; *CYP17A1*, cytochrome P450 family 17 subfamily A member 1; *DAX1*, dosage sensitive sex-reversal, adrenal hypoplasia congenita on the X chromosome, gene 1; DHEA, dehydroepiandrosterone; *DHCR7*, sterol 7 δ reductase; *DHH*, desert hedgehog; *DMRT1*,doublesex and mab3-related transcription factor 1; *GATA4*, GATA binding protein 4; *HSD17B3*, 17β-hydroxysteroid dehydrogenase type 3; *HSD3B2*, 3β-hydroxysteroid dehydrogenase type 2; *LHR*, LH receptor; *MAP3K1*, mitogen-activated protein kinase kinase kinase 1; MIRAGE, myelodysplasia, infection, restriction of growth, adrenal hypoplasia, genital phenotypes, and enteropathy; *MYRF*, myelin regulatory factor; POR, P450 oxidoreductase; *SF1*, steroidogenic factor 1; SL, sex-limited; *SOX8*, *SRY*-related HMG-box gene 8; *SOX9*, *SRY*-related HMG-box gene 9; *SRD5A2*, 5α-reductase type 2; *SRY*, sex-related gene on the Y chromosome; *StAR*, steroidogenic acute regulatory protein; *TSPYL1*, testis-specific Y-encoded-like protein 1; WAGR, Wilms' tumor, aniridia, genitourinary anomalies, and mental retardation; *WNT4*, wingless-type mouse mammary tumor virus integration site, 4; *WT1*, Wilms' tumor–related gene 1; *ZFPM2*, zinc finger protein, multitype 2; *ZNRF3*, zinc and ring finger 3.

of corticosterone and 11-deoxycorticosterone. Patients with complete loss of 17α-hydroxylase function often present as phenotypic females who do not enter puberty and are found to have inguinal testes and hypertension in adolescence. Some mutations in *CYP17A1* selectively impair 17,20-lyase activity without altering 17α-hydroxylase activity, leading to underandrogenization without mineralocorticoid excess and hypertension. Disruption of the coenzyme, *cytochrome b5* (*CYB5A*), can present similarly, and methemoglobinemia is usually present. Mutations in *P450 oxidoreductase* (*POR*) affect multiple steroidogenic enzymes, leading to reduced androgen production and a biochemical pattern of apparent combined 21-hydroxylase and 17α-hydroxylase deficiency, sometimes with skeletal abnormalities (Antley-Bixler craniosynostosis). Defects in *17β-hydroxysteroid dehydrogenase type 3* (*HSD17B3*) and *5α-reductase type 2* (*SRD5A2*) interfere with the synthesis of testosterone and DHT, respectively. These conditions are characterized by minimal or absent androgenization in utero, but some phallic development can occur during adolescence due to the action of other enzyme isoforms. Individuals with 5α-reductase type 2 deficiency have normal wolffian structures and usually do not develop significant breast tissue. At puberty, the increase in testosterone may lead to virilizing features despite DHT deficiency. DHT gel can improve prepubertal phallic growth in patients raised as male. Prevention of testosterone exposure (by gonadectomy or pubertal suppression) in adolescence and estrogen replacement at puberty can be considered in individuals who identify as female. Disruption of alternative pathways to fetal DHT production might also present with 46,XY DSD (*AKR1C2*/*AKR1C4*).

Disruption of Androgen Action • **ANDROGEN INSENSITIVITY SYNDROME** Pathogenic variants in the androgen receptor cause resistance to androgen (testosterone, DHT) action or the *androgen insensitivity syndrome* (*AIS*). AIS is a spectrum of disorders that affects

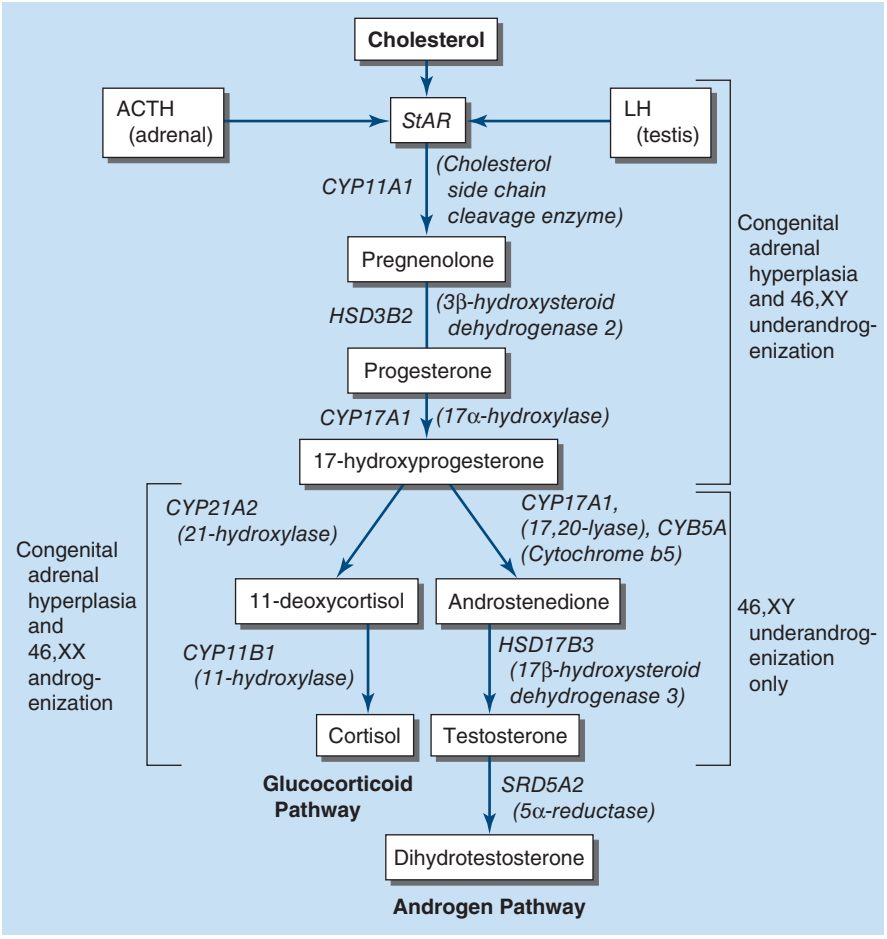

FIGURE 402-4 Simplified overview of glucocorticoid and androgen synthesis pathways. Defects in *CYP21A2* and *CYP11B1* shunt steroid precursors into the androgen pathway and cause androgenization of the 46,XX fetus. Testosterone is synthesized in the testicular Leydig cells and converted to dihydrotestosterone peripherally. Defects in enzymes involved in androgen synthesis result in underandrogenization of the 46,XY fetus. ACTH, adrenocorticotropic hormone; LH, luteinizing hormone; *StAR*, steroidogenic acute regulatory protein.

at least 1 in 100,000 46,XY individuals. Because the androgen receptor is X-linked, only 46,XY offspring are affected. The condition is usually inherited from a mother who carries the sequence variant but can also arise de novo. XY individuals with *complete AIS* (formerly called *testicular feminization syndrome*) have a female phenotype, normal breast development (due to aromatization of testosterone), a short vagina but no uterus (because AMH/MIS production is normal), sometimes scanty pubic and axillary hair, and typically a female gender identity and sex role behavior. Gonadotropins can be variable, but testosterone is usually elevated and AMH/MIS levels in childhood are normal or high. CAIS sometimes presents as inguinal hernias (containing testes) in childhood or more often with primary amenorrhea in late adolescence. In the past, gonadectomy was recommended early in childhood. Increasingly, risk of tumor development is weighed against potential for endogenous hormone function. Thus gonadectomy is often delayed and gonads are left in situ until breast development is complete. Subsequently, the adolescent or young adult should be counseled about the risk of malignancy and the option for gonadectomy (with estrogen replacement), especially because early detection of premalignant changes by imaging or biomarkers is currently not possible. The use of graded dilators in adolescence or young adulthood is often sufficient to dilate the vagina for sexual activity.

Partial AIS (*Reifenstein's syndrome*) results from androgen receptor mutations that maintain residual function. Patients often present in infancy with penoscrotal hypospadias and undescended testes and with gynecomastia at the time of puberty. Gender identity can be variable. At puberty, testes produce testosterone with variable phenotypic development. For those who identify as male, high-dose testosterone has been given to support development if puberty does not progress, but long-term data are limited. For those raised as female, testosterone effects at puberty can be prevented (by pubertal suppression) and female-typical puberty induced with estrogen. They also have an increased risk of GCC, again raising the question of if and when to perform gonadectomy. *Azoospermia* and male-factor infertility also have been described in association with mild loss-of-function mutations in the androgen receptor. Androgen resistance without AR variants is called type 2 AIS (e.g., *DAAM2*).

OTHER DISORDERS AFFECTING 46,XY MALES

Persistent müllerian duct syndrome is the presence of a uterus in an otherwise phenotypic male. This condition can result from pathogenic variants in AMH or its receptor (AMHR2). *Isolated hypospadias* occurs in ~1 in 250 males. Many less severe cases are idiopathic. However, evidence of penoscrotal hypospadias, poor phallic development, bilateral cryptorchidism, and/or other clinical features requires investigation for an underlying DSD (e.g., partial gonadal dysgenesis, partial defect in testosterone action, or even severe forms of 46,XX CAH) or one of many DSD/hypospadias-associated syndromes. Unilateral undescended testes (cryptorchidism) affect >3% of boys at birth. Orchidopexy should be considered if the testis has not descended by 6–9 months of age. Bilateral cryptorchidism occurs less frequently and should raise suspicion of gonadotropin deficiency or DSD. *Syndromic associations* and *intrauterine growth retardation* also occur relatively frequently in association with impaired testicular function or target tissue responsiveness, but the underlying etiology of many of these conditions is unknown except in specific syndromes (e.g., MIRAGE [myelodysplasia, infection, restriction of growth, adrenal hypoplasia, genital phenotypes, and enteropathy], IMAGe [intrauterine growth restriction, metaphyseal dysplasia, adrenal hypoplasia congenita, and genitourinary abnormalities]).

46,XX DSD

Androgenization (virilization) of the 46,XX fetus occurs when the gonad (ovary) contains androgen-secreting testicular tissue or after increased androgen exposure, which is usually adrenal in origin (Table 402-1).

46,XX Testicular DSD Testicular tissue can develop in 46,XX testicular DSD (46,XX males) most often following translocation of *SRY*. This may be diagnosed with karyotype/phenotype discordance or later in life during evaluation for hypogonadism or infertility. Individuals with this condition develop testes with normal testosterone production, leading to external male phenotype in utero, and produce AMH/MIS to regress müllerian structures. They have azoospermia due to lack of the AZF region of the Y chromosome. Progressive testicular regression and hypogonadism are common. Gender identity is typically male.

46,XX OTDSD Ovotestes (or testes) can also develop in individuals with a 46,XX karyotype following upregulation of *SOX9* or *SOX3* or defects in *RSPO1*, *NR2F2*, *WT1*, or *SF1*/*NR5A1* (Table 402-5). OTDSD is discussed above under "Differences of Chromosomal Sex."

Increased Androgen Exposure • 21-HYDROXYLASE DEFICIENCY (CONGENITAL ADRENAL HYPERPLASIA) The *classic form* of 21-hydroxylase deficiency (21-OHD) is the most common cause of CAH (Chap. 398), and it is the most common cause of androgenization in chromosomal 46,XX children (incidence around 1 in 15,000

TABLE 402-5 Selected Genetic Causes of 46,XX Differences of Sex Development (DSDs)

GENE	INHERITANCE	GONAD	UTERUS	EXTERNAL GENITALIA	ASSOCIATED FEATURES
Testicular/Ovotesticular DSD					
SRY	Translocation	Testis or ovotestis	–	Male or ambiguous	
SF1/NR5A1 (codon 92)	AD	Testis or ovotestis	+/–	Male or ambiguous	
Other causes of testicular/ovotesticular DSD include: *COUP-TF2/NR2F2* (congenital heart disease), *RSPO1* (palmar plantar hyperkeratosis, squamous cell skin carcinoma), *WNT4* (SERKAL syndrome), *WT1* (in zinc finger 4), dysregulation/duplication of *SOX3* (Xq27) and *SOX9* (dup17q24)					
Increased Androgen Synthesis					
HSD3B2	AR	Ovary	+	Clitoromegaly	CAH, primary adrenal insufficiency, mild androgenization due to ↑ DHEA
CYP21A2	AR	Ovary	+	Ambiguous	CAH, phenotypic spectrum from severe salt-losing forms associated with adrenal insufficiency to simple virilizing forms with compensated adrenal function, ↑ 17-hydroxyprogesterone
POR	AR	Ovary	+	Ambiguous or female	Mixed features of 21-hydroxylase deficiency and 17α-hydroxylase/17,20-lyase deficiency, sometimes associated with Antley-Bixler craniosynostosis
CYP11B1	AR	Ovary	+	Ambiguous	CAH, hypertension due to ↑ 11-deoxycorticosterone
CYP19	AR	Ovary	+	Ambiguous	Maternal virilization during pregnancy, absent breast development at puberty

Abbreviations: ACTH, adrenocorticotropin; AD, autosomal dominant; AR, autosomal recessive; CAH, congenital adrenal hyperplasia; *COUP-TF2*, chicken ovalbumin upstream promoter transcription factor 2; *CYP11B1*, 11β-hydroxylase; *CYP19*, aromatase; *CYP21A2*, 21-hydroxylase; DHEA, dehydroepiandrosterone; *HSD3B2*, 3β-hydroxysteroid dehydrogenase type 2; *POR*, P450 oxidoreductase; *RSPO1*, R-spondin 1; SERKAL, sex reversion, kidneys, adrenal and lung dysgenesis; *SF1*, steroidogenic factor 1; *SOX3*, *SRY*-related HMG-box gene 3; *SOX9*, *SRY*-related HMG-box gene 9; *SRY*, sex-related gene on the Y chromosome; *WT1*, Wilms' tumor–related gene 1.

live births) (Table 402-5). Affected individuals are homozygous or compound heterozygous for severely disruptive sequence variants in the gene (*CYP21A2*) encoding the enzyme 21-hydroxylase. Impaired 21-hydroxylase activity prevents adrenal glucocorticoid and mineralocorticoid synthesis, thus shunting steroid precursors into the androgen synthesis pathway (Fig. 402-4). Increased androgen synthesis in utero causes androgenization of the 46,XX fetus in the first trimester. Atypical genitalia are usually seen at birth, with varying degrees of clitoral enlargement and labial fusion.

A salt-wasting crisis usually manifests between 5 and 21 days of life and is a potentially life-threatening event that requires urgent fluid resuscitation and steroid treatment. Thus, a diagnosis of 21-OHD should be considered in any baby with atypical genitalia with bilateral nonpalpable gonads. Males (46,XY) with 21-OHD have no genital abnormalities at birth but are equally susceptible to adrenal insufficiency and salt-losing crises. Excess androgen production can cause gonadotropin-independent precocious puberty in males with 21-OHD.

Nonclassic 21-OHD is discussed in **Chap. 398**.

TREATMENT

Congenital Adrenal Hyperplasia

Acute salt-wasting crises require fluid resuscitation, IV hydrocortisone, and correction of hypoglycemia. Once the patient is stabilized, glucocorticoids must be given to correct the cortisol insufficiency and suppress adrenocorticotropic hormone (ACTH) stimulation, thereby preventing further virilization, rapid skeletal maturation, and the development of polycystic ovaries. Mineralocorticoid replacement may be needed. Salt supplements may be required in early life. In childhood, treatment is also titrated carefully to prevent impairment of linear growth. In the future, different forms of glucocorticoid replacement and multimodal therapies may improve treatment options. **See Chap. 398 for detailed discussion of hormone replacement.**

Individuals with 46,XX CAH due to classic 21-OHD historically often underwent genitoplasty in infancy, but if and when these procedures should be performed is debated. Concerns have arisen about the importance of assent/consent by the individual for genital surgery, potential long-term side effects related to sexual function and ability to achieve orgasm, and the increased incidence of non-female gender identity. Surgical options include vaginoplasty and clitoroplasty. When vaginoplasty is performed in infancy, surgical revision or vaginal dilation may still be needed in adolescence or adulthood and, if deferred, may be necessary for menstrual flow or intercourse. Current clinical practice guidelines can vary in different countries, including supporting parents to defer surgery or for individuals to have no surgery. Women with 21-OHD frequently develop polycystic ovaries and have subfertility. The latter occurs due to multiple factors including anatomic barriers, hormone imbalances, and psychological effects of the condition. Preconception genetic counseling is recommended. Due to concerns about fetal neurologic development, prenatal treatment with dexamethasone to prevent androgenization of a fetus is currently not recommended unless in a study protocol that allows long-term follow-up of all children treated.

The treatment of other forms of CAH (including in 46,XY individuals) includes mineralocorticoid and glucocorticoid replacement for salt-losing conditions (e.g., *StAR*, *CYP11A1*, *HSD3B2*), suppression of ACTH drive with glucocorticoids in disorders associated with hypertension (e.g., *CYP11B1*), and appropriate sex hormone replacement in adolescence and adulthood, when necessary.

OTHER CAUSES Increased androgen synthesis can also occur in CAH due to defects in *POR*, *11β-hydroxylase* (*CYP11B1*), and *3β-hydroxysteroid dehydrogenase type 2* (*HSD3B2*) and with mutations in the genes encoding *aromatase* (*CYP19A1*). Increased androgen exposure in utero can occur with maternal virilizing tumors, luteomas, and ingestion of androgenic compounds.

OTHER DISORDERS AFFECTING 46,XX FEMALES

Congenital absence of the vagina occurs in association with *müllerian agenesis* or *hypoplasia* as part of the Mayer-Rokitansky-Kuster-Hauser (MRKH) syndrome. This diagnosis should be considered in otherwise phenotypic females with primary amenorrhea. Associated features include renal (agenesis) and cervical spinal abnormalities.

LONG-TERM FOLLOW-UP

Whether a DSD is diagnosed during childhood or adulthood, many individuals will require ongoing care. Medical care may include hormone replacement, optimization of bone health, screening related to other associated clinical features, and care for infertility or sterility. There is increasing attention to fertility preservation and investigational gonadal tissue cryopreservation in the pediatric and young adult population, which may allow for increased fertility potential in adulthood. More frequently, individuals retain gonadal tissue at

increased risk for germ cell cancer, requiring monitoring and potential gonadectomy. Long-term urogynecologic follow-up may be needed. Psychosocial and psychosexual evaluation and management are also important, particularly to address the reported increased rates of mental health symptoms and poorer quality of life sometimes related to social relationships.

GLOBAL CONSIDERATIONS

The approach to an individual with atypical genitalia or another DSD requires cultural sensitivity, as the concepts of sex and gender vary widely around the world. Rare genetic DSDs can occur more frequently in specific populations (e.g., *5α-reductase type 2* in the Dominican Republic). Different forms of CAH also show ancestral and geographic variability. In many countries, appropriate biochemical or genetic tests may not be readily available, and access to appropriate forms of treatment and support may be limited.

403 Disorders of the Testes and Male Reproductive System

Shalender Bhasin, J. Larry Jameson

The male reproductive system regulates sex differentiation, androgenization, and the hormonal changes that accompany puberty, ultimately leading to spermatogenesis and fertility. Under the control of the pituitary hormones—luteinizing hormone (LH) and follicle-stimulating hormone (FSH)—the Leydig cells of the testes produce testosterone and germ cells are nurtured by Sertoli cells to divide, differentiate, and mature into sperm. During embryonic development, testosterone and dihydrotestosterone (DHT) induce the wolffian duct and virilization of the external genitalia. During puberty, testosterone promotes somatic growth and the development of secondary sex characteristics. In the adult, testosterone is necessary for spermatogenesis, libido and normal sexual function, and maintenance of muscle and bone mass. This chapter focuses on the physiology of the testes and disorders associated with decreased androgen production, which may be caused by gonadotropin deficiency or by primary testis dysfunction. Infertility occurs in ~5% of men and is increasingly amenable to treatment by hormone replacement or by using sperm transfer techniques. **For further discussion of sexual dysfunction, disorders of the prostate, and testicular cancer, see Chaps. 409, 92, and 93, respectively.**

DEVELOPMENT AND STRUCTURE OF THE TESTIS

The fetal testis develops from a single bipotential progenitor cell population in the undifferentiated gonad after expression of a genetic cascade that is initiated by the gene encoding SRY (sex-related gene on the Y chromosome) **(Chap. 402)**. SRY, whose expression is regulated by histone modification and DNA methylation, induces differentiation of Sertoli cells, which surround germ cells and, together with peritubular myoid cells, form testis cords that will later develop into seminiferous tubules. Sertoli cells direct the differentiation of fetal germ cells into spermatogenic precursors. Fetal Leydig cells and endothelial cells migrate into the gonad from the adjacent mesonephros but may also arise from interstitial cells that reside between testis cords. Fetal Leydig cells atrophy after birth and do not contribute to the origin of adult Leydig cells, which originate from undifferentiated progenitor cells that appear in the testis after birth and acquire full steroidogenic function during puberty. Testosterone produced by the fetal Leydig cells supports the growth and differentiation of Wolffian duct structures that develop into the epididymis, vas deferens, and seminal vesicles. Testosterone is also converted to DHT (see below), which induces formation of the prostate and the external male genitalia, including the penis, urethra, and scrotum. The development of the germ cells is dependent on normally functioning Sertoli and Leydig cells and cannot occur without them; in contrast, the somatic cells can develop and function without the germ cells. Testicular descent through the inguinal canal is controlled in part by Leydig cell production of insulin-like factor 3 (INSL3), which along with testosterone, acts through their cognate receptors—relaxin/insulin-like family peptide receptor 2 (*RXFP2*) and androgen receptor (AR)—to guide the inguinoscrotal descent of the testes. Sertoli cells produce Müllerian inhibiting substance (MIS), which causes regression of the Müllerian structures, including the fallopian tube, uterus, and upper segment of the vagina.

NORMAL MALE PUBERTAL DEVELOPMENT

Puberty commonly refers to the maturation of the reproductive axis, initiation of gametogenesis, rhythmic sex hormone secretion, and the development of secondary sex characteristics. In addition to reproductive hormones, it requires a coordinated response of multiple hormonal systems including metabolic signals (e.g., leptin), as well as the adrenal and growth hormone (GH, IGF-1) axes **(Fig. 403-1)**. The development of secondary sex characteristics is initiated by *adrenarche*, which usually occurs between 6 and 8 years of age when the adrenal gland begins to produce greater amounts of androgens from the zona reticularis, the principal site of dehydroepiandrosterone (DHEA) production. The sex maturation process is accelerated by the activation of the hypothalamic-pituitary axis and the production of gonadotropin-releasing hormone (GnRH). The GnRH pulse generator in the infundibular

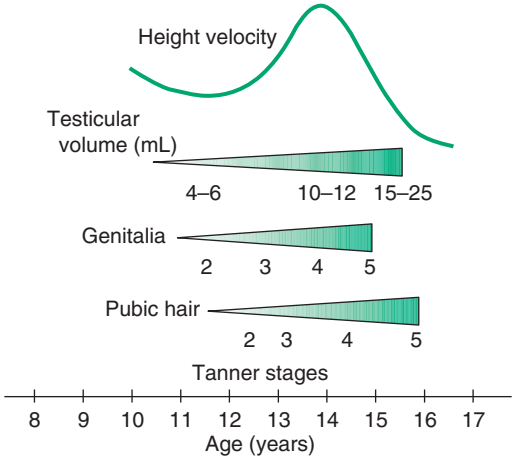

FIGURE 403-1 Pubertal events in males. Sexual maturity ratings for genitalia and pubic hair and divided into five stages.

nucleus is active during fetal life and early infancy but is restrained until the early stages of puberty by a neuroendocrine brake imposed by the inhibitory actions of glutamate and γ-aminobutyric acid (GABA) in the mediobasal hypothalamus and neuropeptide Y. Kisspeptin 1 (kiss1), neurokinin B, dynorophin (KNDy) neurons in the arcuate nucleus and possibly other kiss1 neurons in the anteroventral periventricular nucleus (AVPV), and neurons producing neuropeptide Y (NPY), agouti-related protein (AgRP), pro-opiomelanocortin (POMC), and cocaine and amphetamine-regulated transcript (CART) play an important role in the control of puberty. The Kisspeptin pathway plays a critical role in puberty. Individuals with mutations of G protein-coupled kisspeptin receptor fail to enter puberty. Infusion of the Kiss1 is sufficient to induce premature puberty in nonhuman primates. Kisspeptin signaling plays an important role in mediating the feedback action of sex steroids on gonadotropin secretion and in regulating the tempo of sexual maturation at puberty. The metabolic control of puberty is mediated via the action of leptin secreted by adipocytes, and by neurons expressing NPY and AgRP, and by POMC and CART expressing neurons that transmit the energy sensing signals communicated by leptin to the Kiss1 neurons. *MKRN3*, an imprinted gene encoding makorin ring finger protein 3, serves as an upstream inhibitor of GnRH secretion and plays an important role in directing the onset of puberty. Leptin plays a permissive role in the resurgence of GnRH secretion at the onset of puberty, as leptin-deficient individuals also fail to enter puberty **(Chap. 413)**. The adipocyte hormone leptin, the gut hormone ghrelin, neuropeptide Y, AgRP, CART, and kiss 1 integrate the signals originating in energy stores and metabolic tissues and control the onset of puberty through regulation of GnRH secretion. Energy deficit and excess and metabolic stress are associated with disturbed reproductive maturation and timing of puberty.

The early stages of puberty are characterized by nocturnal surges of LH and FSH. Growth of the testes is usually the first clinical sign of puberty, reflecting an increase in seminiferous tubule volume. Increasing levels of testosterone deepen the voice and stimulate muscle growth. Conversion of testosterone to DHT leads to growth of the external genitalia and pubic hair. DHT also stimulates prostate and facial hair growth and initiates recession of the temporal hairline. The growth spurt occurs at a testicular volume of ~10–12 mL. GH increases early in puberty and is stimulated in part by the rise in gonadal steroids. GH increases the level of insulin-like growth factor 1 (IGF-1), which enhances linear bone growth. The prolonged pubertal exposure to gonadal steroids (mainly estradiol) ultimately induces epiphyseal closure and limits further bone growth.

REGULATION OF TESTICULAR FUNCTION

REGULATION OF THE HYPOTHALAMIC-PITUITARY-TESTIS AXIS IN ADULT MAN

Pulsatile secretion of GnRH in the hypothalamus is regulated by kisspeptin, neurokinin B (NKB), and dynorphin (DYN) **(Fig. 403-2)** that are co-expressed within the KNDy neurons in the arcuate nucleus and are important regulators of mammalian reproduction. Kisspeptin binds to the kisspeptin (GPR54) receptors in the cell bodies of the GnRH neurons as well as in the GnRH nerve terminals in the median eminence to induce pulsatile GnRH secretion into the portal blood. As a component of this autocrine/paracrine loop, NKB released by the KNDy neurons activates NK3R to stimulate kisspeptin release. KNDy neurons also produce dynorphin A, which inhibits basal as well as NKB-stimulated kisspeptin release through the mediation of K-type opioid receptor. Exogenous opioids suppress LH and FSH and inhibit LH pulsatility likely by mimicking the effects of DYN, an endogenous opioid peptide that acts primarily through the κ-opioid receptor (KOR). The negative feedback effects of testosterone, estradiol, and progesterone are mediated through KNDy neurons in the preoptic area by inhibition of kisspeptin release. Mutations in the genes encoding NKB, tachykinin 3 (TAC3), or its receptor (TACR3) are associated with hypogonadotrophic hypogonadism.

Hypothalamic GnRH regulates the production of the pituitary gonadotropins LH and FSH (Fig. 403-2). GnRH is released in discrete

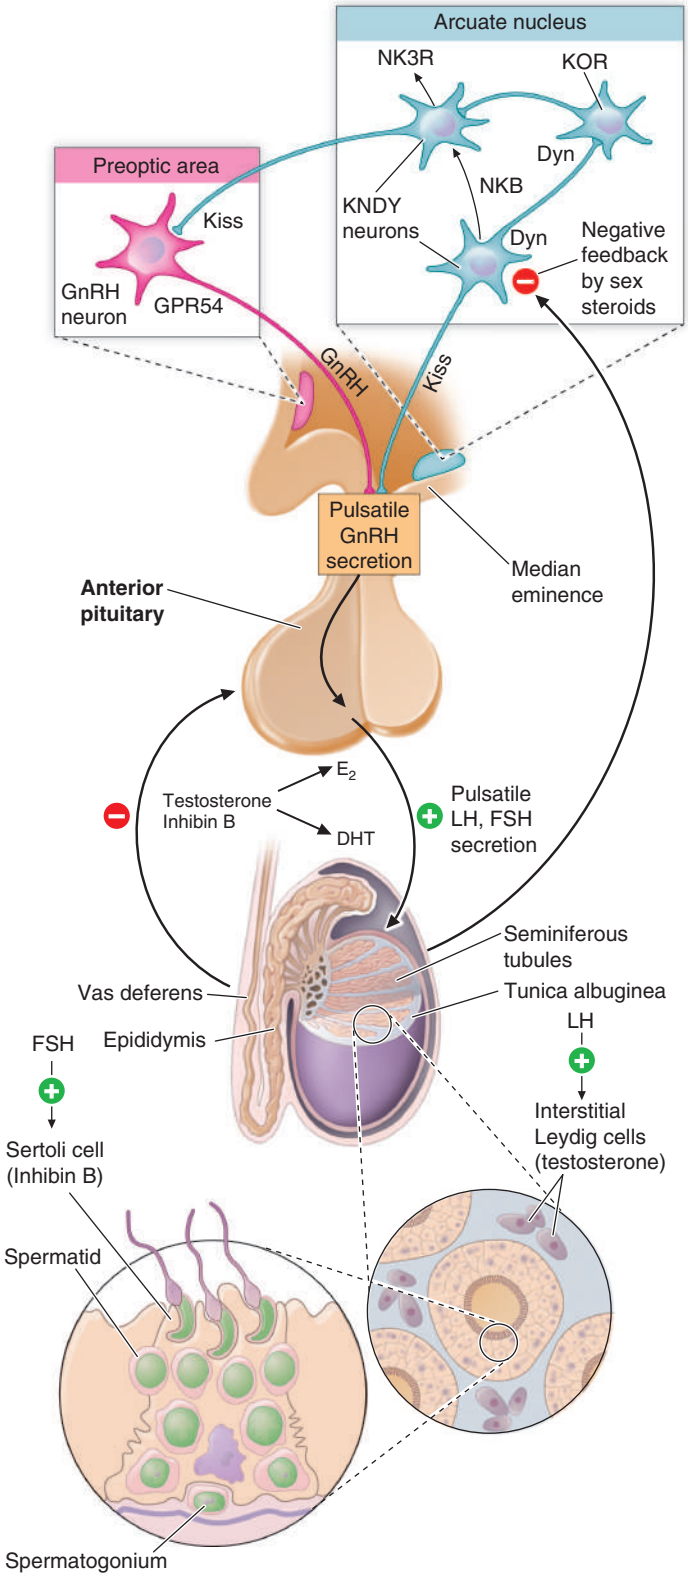

FIGURE 403-2 Hypothalamic-pituitary-gonadotropin axis, structure of testis, seminiferous tubule. DHT, dihydrotestosterone; Dyn, dynorphin A; E_2, 17β-estradiol; FSH, follicle-stimulation hormone; GnRH, gonadotropin-releasing hormone; KISSR, G protein–coupled receptor 54 for kisspeptin; Kiss, kisspeptin; KNDY, kisspeptin, neurokinin B, dynorphin neurons; KOR, K-type opioid receptor; LH, luteinizing hormone; NKB, neurokinin B; NK3R, neurokinin 3 receptor.

pulses approximately every 2 h, resulting in corresponding pulses of LH and FSH. These dynamic hormone pulses account in part for the wide variations in LH and testosterone, even within the same individual. LH acts primarily on the Leydig cell to stimulate testosterone synthesis. The regulatory control of androgen synthesis is modulated by dynamic integration of the feedforward elements exerted on the testis by LH

and FSH and the feedback exerted by testosterone and estrogen on both the hypothalamus and the pituitary. FSH acts on the Sertoli cell to regulate spermatogenesis and the production of inhibin B, which acts to selectively suppress pituitary FSH. Despite these somewhat distinct Leydig and Sertoli cell–regulated pathways, testis function is integrated at several levels: GnRH regulates both gonadotropins; spermatogenesis requires high levels of testosterone; and numerous paracrine interactions between Leydig, Sertoli, and germ cells are necessary for normal testis function.

THE LEYDIG CELL: ANDROGEN SYNTHESIS

LH binds to its transmembrane G protein–coupled receptor to activate the adenylyl cyclase/cyclic AMP/protein kinase A pathway. Stimulation of the LH receptor induces *st*eroid *a*cute *r*egulatory (StAR) protein, along with several steroidogenic enzymes involved in androgen synthesis. LH receptor mutations cause Leydig cell hypoplasia or agenesis, underscoring the importance of this pathway for Leydig cell development and function. The rate-limiting process in testosterone synthesis is the transport of intracellular cholesterol to the inner mitochondrial membrane by a protein complex that contains the steroidogenic acute regulatory (StAR) protein and a translocator protein (TSPO), previously called peripheral benzodiazepine receptor protein. Mutations of the StAR protein are associated with congenital lipoid adrenal hyperplasia, a rare form of congenital adrenal hyperplasia (CAH) characterized by very low adrenal and gonadal steroids. The major enzymatic steps involved in testosterone synthesis are summarized in **Fig. 403-3**. After cholesterol transport into the mitochondrion, the formation of pregnenolone, catalyzed by CYP11A1 (side chain cleavage enzyme) and auxiliary electron transferring proteins, is a limiting enzymatic step. The 17α-hydroxylase and the 17,20-lyase

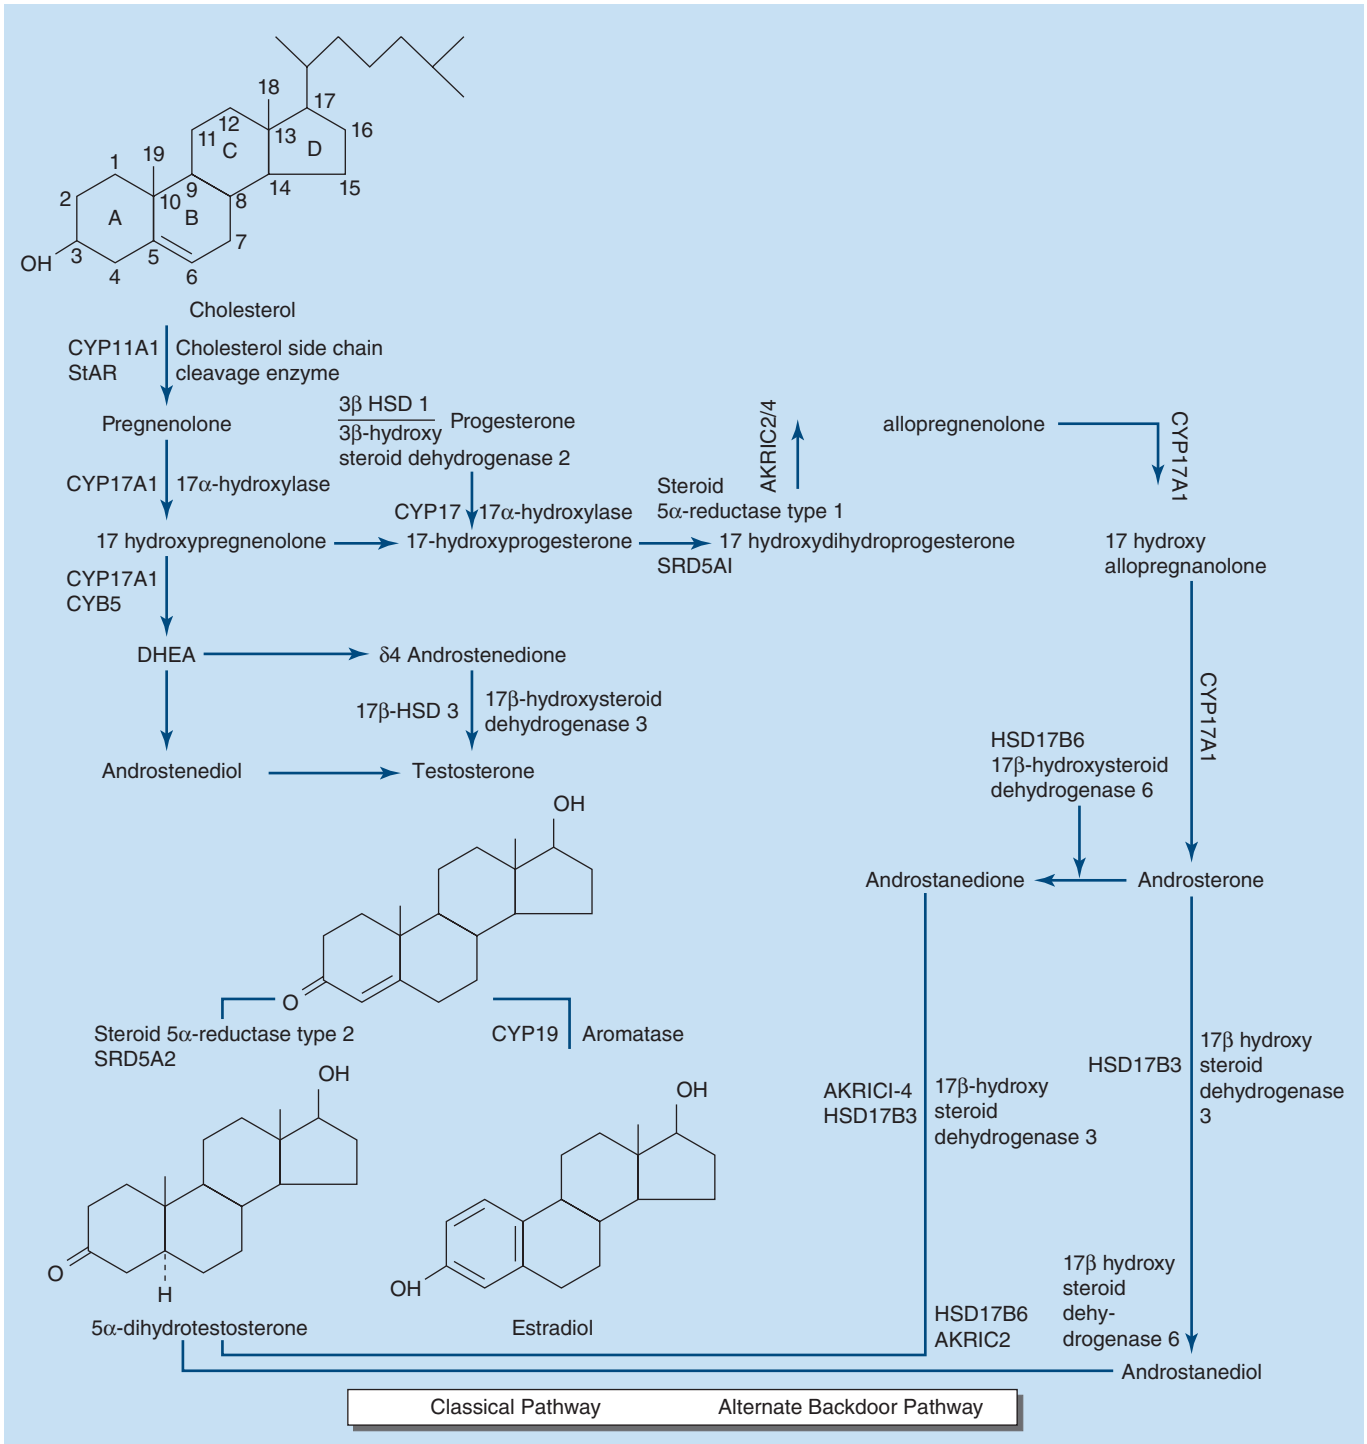

FIGURE 403-3 The biochemical pathway in the conversion of 27-carbon sterol cholesterol to androgens and estrogens.

reactions are catalyzed by a single enzyme, CYP17A1; posttranslational modification (phosphorylation) of this enzyme and the presence of specific enzyme cofactors, such as cytochrome B, confer 17,20-lyase activity selectively in the testis and zona reticularis of the adrenal gland. Although CYP17A1 is able to catalyze the conversion of progesterone to 17α-hydroxyprogesterone, most of δ4-androstenedione in humans is derived from the conversion of 17α-hydroxypregnenolone to DHEA in the δ5 pathway and further conversion of DHEA to δ4-androstenedione. Abiraterone is a dual inhibitor of 17α-hydroxylase and 17,20-lyase activities, which play an important role in androgen synthesis in castration-resistant prostate cancers. Testosterone can be converted to the more potent DHT by a family of steroid 5α-reductase enzymes, and it is aromatized to estradiol by CYP19 (aromatase). At least two isoforms of steroid 5α-reductase, SRD5A1 and SRD5A2, have been described; most known patients with 5α-reductase deficiency have had mutations in SRD5A2, the predominant form in the prostate and the skin. Finasteride predominantly inhibits SRD5A2, whereas dutasteride is a dual inhibitor of both SRD5A1 and SRD5A2. DHT can also be derived through the backdoor pathway in which 17α-hydroxyprogesterone is converted to androsterone and eventually to DHT. Recent reports of mutations in the *AKR1C2/4* genes in undervirilized 46,XY individuals suggest that the backdoor pathway for DHT formation, which was originally described in the tammar wallaby, is active in the human fetal testis. The placental progesterone serves as a substrate for the synthesis of androsterone via the backdoor pathway, which is then converted to DHT in the genital tubercle.

Testosterone Transport and Metabolism In males, 95% of circulating testosterone is derived from testicular production (3–10 mg/d). Direct secretion of testosterone by the adrenal and the peripheral conversion of androstenedione to testosterone collectively account for another 0.5 mg/d of testosterone. Only a small amount of DHT (70 μg/d) is secreted directly by the testis; most circulating DHT is derived from peripheral conversion of testosterone. Most of the daily production of estradiol (~45 μg/d) in men is derived from aromatase-mediated peripheral conversion of testosterone and androstenedione.

Circulating testosterone is bound predominantly to sex hormone–binding globulin (SHBG) and albumin **(Fig. 403-4)** and, to a lesser extent, to cortisol-binding globulin (CBG) and orosomucoid (also known as α_1 acid glycoprotein). SHBG binds testosterone with much greater affinity than albumin, CBG, and orosomucoid. The binding proteins regulate the transport and bioavailability of testosterone. SHBG circulates as a dimer, and testosterone's binding to SHBG involves intermonomeric allostery such that neither the conformation nor the binding affinity of the two monomers is equivalent. Similarly, estradiol binding to SHBG involves bidirectional, intermonomeric allostery that changes the distribution of both monomers among various energy and conformational states. Intermonomeric allostery offers a mechanism to extend the binding range of SHBG and regulate hormone bioavailability as sex hormone concentrations vary widely during life. Albumin contains multiple, allosterically coupled binding sites for testosterone. Testosterone shares these binding sites on albumin with free fatty acids. Commonly used drugs such as ibuprofen and some antibiotics can displace testosterone from albumin under various physiologic states or disease conditions, affecting its bioavailability. SHBG concentrations are decreased by androgens, obesity, diabetes mellitus, hypothyroidism, nephrotic syndrome, and genetic factors. Conversely, polymorphisms in the SHBG gene, estrogen administration, hyperthyroidism, chronic inflammatory illnesses, infections such as HIV or hepatitis B and C, aging, and the use of some anticonvulsants are associated with high SHBG concentrations.

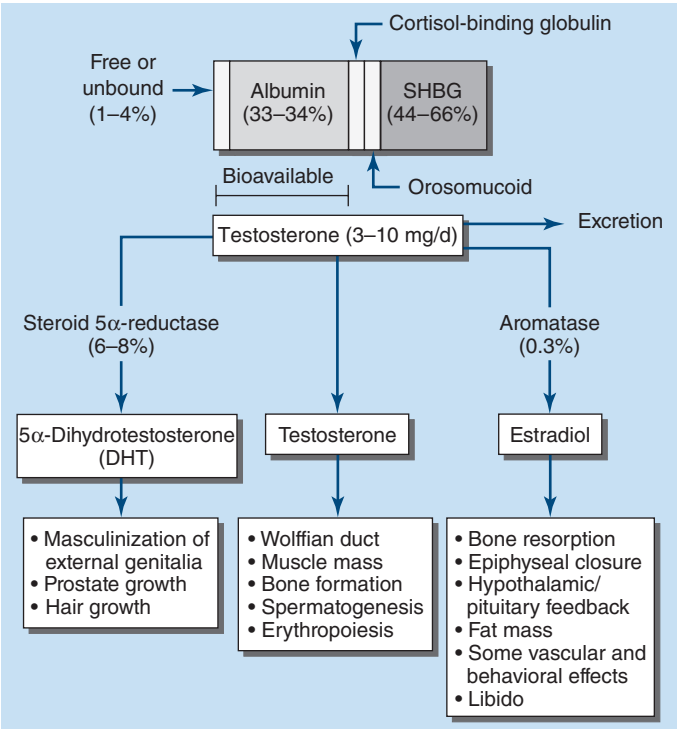

FIGURE 403-4 Androgen metabolism and actions. SHBG, sex hormone–binding globulin.

Testosterone is metabolized predominantly in the liver, although some degradation occurs in peripheral tissues, particularly the prostate and the skin. In the liver, testosterone is converted by a series of enzymatic steps that involve 5α and 5β-reductases, 3α- and 3β-hydroxysteroid dehydrogenases, and 17β-hydroxysteroid dehydrogenase into androsterone, etiocholanolone, DHT, and 3α-androstanediol. These compounds undergo glucuronidation or sulfation before being excreted by the kidneys. Polymorphisms of these enzymes are associated with altered testosterone metabolism and circulating testosterone levels.

Mechanism of Androgen Action Testosterone exerts its biologic effects by either binding to androgen receptor (AR) directly or after its conversion to its metabolites, DHT, and 11-ketotestosterone. 11-Ketotestosterone and 11-ketoandrostenedione are 11-oxygenated steroids and potent androgens that are produced in the testes, adrenals, and some peripheral tissues by the action of CYP11B1 and CYP11B2. DHT is converted in some tissues by 3β-hydroxysteroid dehydrogenase to 5α-androstane-3β,17β-diol, which is a high-affinity ligand and agonist of estrogen receptor β. 5α-DHT can also be converted by 3α-hydroxysteroid dehydrogenase in some cell types to 5α-androstane-3α,17β-diol, a modulator of $GABA_A$ receptors. Testosterone also is aromatized by CYP19 to 17β estradiol, a ligand for estrogen receptor, that can be further converted in tissues to catechol estrogens by addition of hydroxyl groups at C2 and C4 that are inhibitors of the catecholamine methyltransferase and affect angiogenesis and cell proliferation **(Fig. 403-5)**. 16-Hydroestradiol levels have been associated with breast cancer risk in women. The actions of testosterone on the Wolffian structures, skeletal muscle, erythropoiesis, and bone in men do not require its obligatory conversion to DHT. However, the conversion of testosterone to DHT is necessary for the masculinization of the urogenital sinus and genital tubercle but is not obligatory for mediating its effects on the muscle, bone, or hematopoiesis. Aromatization of testosterone to estradiol mediates additional effects of testosterone on bone resorption, epiphyseal closure, sexual desire, vascular endothelium, and fat.

The AR is structurally related to the nuclear receptors for estrogen, glucocorticoids, and progesterone **(Chap. 389)**. The AR, a 919–amino acid protein with a molecular mass of ~110 kDa, is encoded by a gene on the long arm of the X chromosome. A polymorphic region in the amino terminus of the receptor, which contains a variable number of glutamine and glycine repeats, modifies the transcriptional activity of the receptor. The ligand binding to the AR induces conformational changes that dissociates it from heat shock protein and allows the recruitment and assembly of tissue-specific cofactors and causes it to translocate into the nucleus, where it binds to specific androgen response elements in the DNA or other transcription factors already bound to DNA. Thus, the AR is a ligand-activated transcription factor that regulates the expression of androgen-dependent genes in a tissue-specific manner. Some

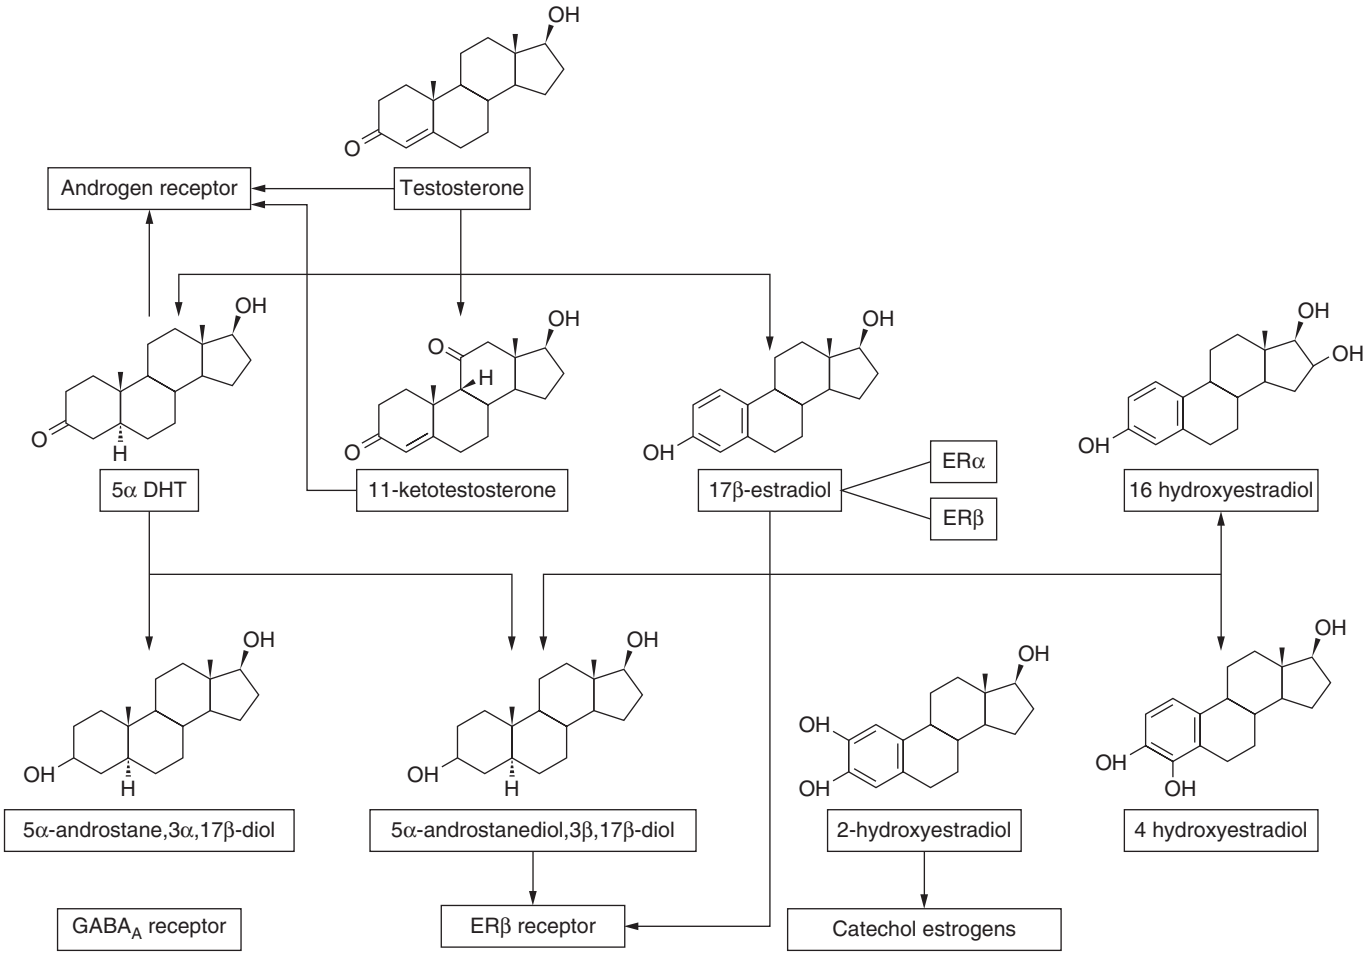

FIGURE 403-5 Testosterone as an androgen and precursor of other steroids with diverse actions. DHT, dihydrotestosterone; ERα, estrogen receptor α; Eαβ, estrogen receptor β.

androgen effects, such as those on the smooth muscle, may be mediated by nongenomic AR signal transduction pathways. The nongenomic actions of testosterone involve direct activation of kinase signaling cascades such as the Src tyrosine kinase that activates the epidermal growth factor receptor and induces the downstream mitogen-activated protein kinase cascade (RAF, MEK, and ERK), resulting in increased transcription of the cyclic AMP response element binding protein transcription factor-regulated genes. Some effects of testosterone on cell proliferation and autophagy require the mediation of GPRC6A. Testosterone and DHT improve penile blood flow and erections by rapid nongenomic endothelial-dependent (increased nitric oxide production) and endothelium-independent inhibition of l-type calcium channels and/or activation of potassium channels in the vascular smooth muscle.

THE SEMINIFEROUS TUBULES: SPERMATOGENESIS

The seminiferous tubules are convoluted, closed loops that empty into the rete testis, a network of progressively larger efferent ducts that ultimately form the epididymis (Fig. 403-2). The seminiferous tubules total ~600 m in length and compose about two-thirds of testis volume. The walls of the tubules are formed by polarized Sertoli cells that are apposed to peritubular myoid cells. Tight junctions between Sertoli cells create the blood-testis barrier. Germ cells compose the majority of the seminiferous epithelium (~60%) and are intimately embedded within the cytoplasmic extensions of the Sertoli cells, which function as "nurse cells." Germ cells progress through characteristic stages of mitotic and meiotic divisions. A pool of type A spermatogonia serve as stem cells capable of self-renewal. Primary spermatocytes are derived from type B spermatogonia and undergo meiosis before progressing to spermatids that undergo spermiogenesis (a differentiation process involving chromatin condensation, acquisition of an acrosome, elongation of cytoplasm, and formation of a tail) and are released from Sertoli cells as mature spermatozoa. The complete differentiation process into mature sperm requires 74 days. Peristaltic-type action by peritubular myoid cells transports sperm into the efferent ducts. The spermatozoa spend an additional 21 days in the epididymis, where they undergo further maturation and capacitation. The normal adult testes produce >100 million sperm per day.

Naturally occurring mutations in FSHβ or in the FSH receptor confirm an important, but not essential, role for this pathway in spermatogenesis. Females with mutations in FSHβ or the FSH receptor are hypogonadal and infertile because ovarian follicles do not mature; males with these mutations exhibit variable degrees of reduced spermatogenesis, presumably because of impaired Sertoli cell function. Because Sertoli cells produce inhibin B, an inhibitor of FSH, seminiferous tubule damage (e.g., by radiation) causes a selective increase of FSH. Testosterone reaches very high concentrations locally in the testis and is essential for spermatogenesis. The cooperative actions of FSH and testosterone are important in the progression of meiosis and spermiation. In the prepubertal testis, testosterone alone is insufficient for completion of spermatogenesis; however, in men with postpubertal onset of gonadotropin deficiency, human chorionic gonadotropin (hCG) or recombinant LH can reinitiate spermatogenesis without FSH. FSH and testosterone regulate germ cell survival via the intrinsic and extrinsic apoptotic mechanisms. FSH may also play an important role in supporting spermatogonia. Gonadotropin-regulated testicular RNA helicase (GRTH/DDX25), a testis-specific gonadotropin/androgen-regulated RNA helicase, is present in germ cells and Leydig cells and may be an important factor in the paracrine regulation of germ cell development. Several cytokines and growth factors are also involved in the regulation of spermatogenesis by paracrine and autocrine mechanisms.

The human Y chromosome contains two pseudoautosomal regions that are located at the two tips of Y chromosome and can recombine with homologous regions of the X chromosome **(Fig. 403-6)**. The genes

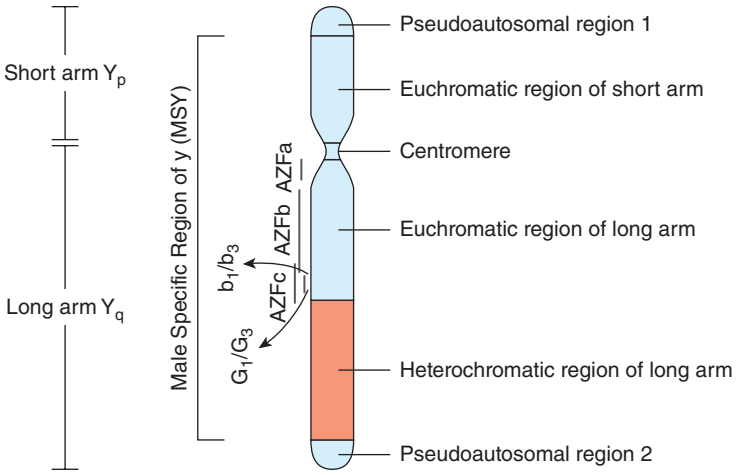

FIGURE 403-6 Structure of the Y chromosome relevant for spermatogenesis.

in the pseudoautosomal regions are involved in cell signaling, transcriptional regulation, and mitochondrial function. Mutations of genes in pseudoautosomal region 1 are associated with mental disorders and short stature. The euchromatic part of the Y chromosome that does not recombine with the X chromosome is referred to as the male-specific region of the Y chromosome (MSY) and contains X-transposed sequences that have 99% homology with the X chromosome, single-copy genes or pseudogene homologues of X-linked genes, and ampliconic sequences that are organized in large palindromes. The MSY contains nine families of Y-specific multicopy genes; many of these Y-specific genes are testis-specific and necessary for spermatogenesis.

Nonallelic homologous recombination between highly homologous repeated sequences in the MSY region renders the Y chromosome susceptible to microdeletions. Microdeletions in four major nonoverlapping subregions of the Y chromosome—AZFa, AZFb, AZFbc, and AZFc—which contain many spermatogenic genes, are associated with oligospermia or azoospermia. Microdeletions involving the AZFc region are the most common Y microdeletions in infertile men. Several partial deletions of the AZFc region have been described including the gr/gr deletion, which is associated with infertility among Caucasian men in Europe and the Western Pacific region, whereas the b2/b3 deletion is associated with male infertility in African and Dravidian men. Approximately 6 to 15% of infertile men with nonobstructive azoospermia or severe oligozoospermia harbor a Y microdeletion. Complete deletions of the AZFa and AZFb subregions are typically associated with Sertoli cells only and azoospermia and a poor prognosis for sperm retrieval. In contrast, AZFc subregion microdeletions are typically associated with oligozoospermia and higher success rates for sperm retrieval.

TREATMENT

Male Factor Infertility

Treatment options for male factor infertility have expanded greatly in recent years. Secondary hypogonadism is highly amenable to treatment with pulsatile GnRH or gonadotropins (see below). Assisted reproductive technologies, such as in vitro fertilization (IVF) and intracytoplasmic sperm injection (ICSI), have provided new opportunities for patients with primary testicular failure and disorders of sperm transport. Choice of initial treatment options depends on sperm concentration and motility. Expectant management should be attempted initially in men with mild male factor infertility (sperm count of 15–20 × 10^6/mL and normal motility). Treatment of moderate male factor infertility (10–15 × 10^6/mL and 20–40% motility) should begin with intrauterine insemination alone or in combination with treatment of the female partner with clomiphene or gonadotropins, but it may require IVF with or without ICSI. For men with a severe defect (sperm count of <10 × 10^6/mL, 10% motility), IVF with ICSI or donor sperm has become the treatment of choice. Yq microdeletions will be transmitted through ICSI from the affected father to his male offspring if sperm carrying the Yq microdeletion is used.

CLINICAL AND LABORATORY EVALUATION OF MALE REPRODUCTIVE FUNCTION

HISTORY AND PHYSICAL EXAMINATION

The history should focus on developmental stages such as puberty and linear growth, as well as androgen-dependent events such as early morning erections, frequency and intensity of sexual thoughts, and frequency of masturbation or intercourse. Although libido and the overall frequency of sexual acts are decreased in androgen-deficient men, young hypogonadal men can achieve erections in response to visual erotic stimuli. Men with acquired androgen deficiency often report decreased energy, low mood, and less commonly hot flushes.

The physical examination should focus on secondary sex characteristics such as hair growth, gynecomastia, testicular volume, prostate, and height and body proportions. *Eunuchoid proportions* are defined as an arm span >2 cm greater than height and suggest that androgen deficiency occurred before epiphyseal fusion. Hair growth in the face, axilla, chest, and pubic regions is androgen-dependent; however, changes may not be noticeable unless androgen deficiency is severe and prolonged. Ethnicity also influences the intensity of hair growth (Chap. 406). Testicular volume is measured by using a Prader orchidometer. Testes range from 3.5 to 5.5 cm in length, which corresponds to a volume of 12–25 mL. Advanced age does not influence testicular size, although the consistency becomes less firm. Because of its possible role in infertility, the presence of varicocele should be sought by palpation while the patient is standing; it is more common on the left side. Patients with Klinefelter syndrome have markedly reduced testicular volumes (1–2 mL). In congenital hypogonadotropic hypogonadism, testicular volumes provide a good index of the degree of gonadotropin deficiency and the likelihood of response to gonadotropin therapy.

GONADOTROPIN AND INHIBIN MEASUREMENTS

LH and FSH are measured using two-site immunoradiometric, immunofluorometric, or chemiluminescent assays, which have very low cross-reactivity with other pituitary glycoprotein hormones and hCG and have sufficient sensitivity to measure the low levels present in patients with hypogonadotropic hypogonadism. In men with a low testosterone level, an LH level can distinguish primary (high LH) versus secondary (low or inappropriately normal LH) hypogonadism. An elevated LH level indicates a primary defect at the testicular level, whereas a low or inappropriately normal LH level suggests a defect at the hypothalamic-pituitary level. LH pulses occur about every 1–3 h in normal men. Thus, gonadotropin levels fluctuate, and samples should be pooled or repeated when results are equivocal. FSH is less pulsatile than LH because it has a longer half-life. Selective increase in FSH suggests damage to the seminiferous tubules. Inhibin B, a Sertoli cell product that suppresses FSH, is reduced with seminiferous tubule damage. Inhibin B is a dimer with α-β_B subunits and is measured by two-site immunoassays.

GnRH Stimulation Testing The GnRH test is performed by measuring LH and FSH concentrations at baseline and at 30 and 60 min after intravenous administration of 100 μg of GnRH. A minimally acceptable response is a twofold LH increase and a 50% FSH increase. In the prepubertal period or with severe GnRH deficiency, the gonadotrope may not respond to a single bolus of GnRH; in these patients, GnRH responsiveness may be restored by chronic, pulsatile GnRH administration. With the availability of sensitive and specific LH assays, GnRH stimulation testing is used rarely.

TESTOSTERONE ASSAYS

Total Testosterone Total testosterone includes both unbound and protein-bound testosterone and is measured by radioimmunoassays, immunometric assays, or liquid chromatography tandem mass

spectrometry (LC-MS/MS). LC-MS/MS involves extraction of serum by organic solvents, separation of testosterone from other steroids by high-performance liquid chromatography and mass spectrometry, and quantitation of unique testosterone fragments by mass spectrometry. LC-MS/MS provides accurate and precise measurements of testosterone levels even in the low range and has emerged as the method of choice for testosterone measurement. The use of LC-MS/MS for the measurement of testosterone in laboratories that have been certified by the Centers for Disease Control and Prevention's (CDC) Hormone Standardization Program for Testosterone (HoST) can ensure that testosterone measurements are accurate and calibrated to an international standard. Serum testosterone levels fluctuate because of its pulsatile, diurnal, and circannual secretory rhythms. Testosterone is generally lower in the late afternoon, or after eating a meal, and is reduced by acute illness. The harmonized normal range for total testosterone, measured using LC-MS/MS in nonobese populations of European and American men aged 19–39 years, is 264–916 ng/dL. This harmonized reference range can be applied to values from laboratories that are certified by the CDC's HoST program.

Alterations in SHBG levels due to aging, obesity, diabetes mellitus, hyperthyroidism, some types of medications, chronic illness, or genetic factors can affect total testosterone levels. Heritable factors contribute substantially to the population-level variation in testosterone levels. Genome-wide association studies have revealed polymorphisms in the SHBG gene as well as other loci that are uniquely associated with total and bioavailable testosterone levels, but not with SHBG levels, as important contributors to variation in testosterone levels.

Measurement of Unbound Testosterone Levels Most circulating testosterone is bound to SHBG and to albumin; only 2.0–4.0% of circulating testosterone is unbound, or "free." Free testosterone should ideally be measured by equilibrium dialysis under standardized conditions using an accurate and reliable assay for total testosterone. The unbound testosterone concentration also can be calculated from total testosterone, SHBG, and albumin concentrations. Recent research has shown that testosterone binding to SHBG is a multistep process that involves complex allosteric interactions between the two binding sites within the SHBG dimer; a novel ensemble allosteric model of testosterone's binding to SHBG dimers provides good estimates of free testosterone concentrations. The previous law-of-mass-action equations based on linear models of testosterone binding to SHBG used assumptions that have been shown to be erroneous. Tracer analogue methods are relatively inexpensive and convenient, but they are inaccurate. The term *bioavailable testosterone* refers to unbound testosterone plus testosterone bound loosely to albumin and reflects the concept that albumin-bound testosterone can dissociate at the capillary level, especially in tissues with long transit time, such as the liver and the brain. *Bioavailable testosterone* can be determined by the ammonium sulfate precipitation method. However, the measurements of bioavailable testosterone using the ammonium sulfate precipitation are technically challenging, susceptible to imprecision, and not recommended.

hCG Stimulation Test The hCG stimulation test is performed by administering a single injection of 1500–4000 IU of hCG intramuscularly and measuring testosterone levels at baseline and 24, 48, 72, and 120 h after hCG injection. An alternative regimen involves three injections of 1500 units of hCG on 3 successive days and measuring testosterone levels 24 h after the last dose. An acceptable response to hCG is a doubling of the testosterone concentration in adult men. In prepubertal boys, an increase in testosterone to >150 ng/dL indicates the presence of testicular tissue. No response may indicate an absence of testicular tissue or marked impairment of Leydig cell function. Measurement of Anti-Mullerian hormone, a Sertoli cell product, is also used to detect the presence of testes in prepubertal boys with cryptorchidism.

SEMEN ANALYSIS

Semen analysis is the most important step in the evaluation of male infertility. Samples are collected by masturbation following abstinence for 2–3 days. Semen volumes and sperm concentrations vary considerably among fertile men, and several samples may be needed before concluding that the results are abnormal. Analysis should be performed within an hour of collection. Using semen samples from >4500 men in 14 countries, whose partners had a time to pregnancy of <12 months, the World Health Organization (WHO) has generated the following one-sided reference limits for semen parameters: semen volume, 1.5 mL; total sperm number, 39 million per ejaculate; sperm concentration, 15 million per mL; vitality, 58% live; progressive motility, 32%; total (progressive + nonprogressive) motility, 40%; and morphologically normal forms, 4.0%. Some men with low sperm counts are fertile. Some studies suggest that sperm counts have declined in recent decades. A variety of tests for sperm function can be performed in specialized laboratories, but these add relatively little to the treatment options.

TESTICULAR BIOPSY

Testicular biopsy is useful in some patients with oligospermia or azoospermia as an aid in diagnosis and in assessing the feasibility of treatment. Fine-needle aspiration biopsy is performed under local anesthesia to aspirate tissue for histology. Alternatively, open biopsies can be performed under local or general anesthesia when more tissue is required. A normal biopsy in an azoospermic man with a normal FSH level suggests obstruction of the vas deferens, which may be correctable surgically. Biopsies are also used to harvest sperm for ICSI and to classify disorders such as hypospermatogenesis (all stages present but in reduced numbers), germ cell arrest (usually at primary spermatocyte stage), and Sertoli cell–only syndrome (absent germ cells) or hyalinization (sclerosis with absent cellular elements).

Testing for Y Chromosome Microdeletions Testing for Y chromosome microdeletions is indicated in infertile men with nonobstructive azoospermia or severe oligozoospermia (sperm density < 5 million/mL). Y chromosome microdeletions are detected by extracting DNA from peripheral blood leukocytes and using polymerase chain reaction (PCR) analysis of a small number of sequence-tagged sites on the Y chromosome (typically sY84 and sY86 in AZFa region, sY127 and SY134 in AZFb region, and sY254 and sY255 in AZFc region). Because these Y chromosome markers account for only a small fraction of the 23 million base pairs on the Y chromosome, a negative test does not exclude microdeletions in other subregions of the Y chromosome.

DISORDERS OF SEXUAL DIFFERENTIATION

See Chap. 402.

DISORDERS OF PUBERTY

The onset and tempo of puberty vary greatly in the general population and are affected by genetic, nutritional, and environmental factors. Although the mean age for reaching Tanner stage 2 in boys is 11.5 years, the range is much wider (9–14 years). A substantial fraction of the variance in the timing of puberty is explained by heritable factors. The timing of pubertal onset is highly correlated within families and between twins. Genome-wide association studies for age of menarche in girls and age of voice deepening in boys have identified nearly 400 independent loci in girls and boys. Over the past century, the age of onset of puberty has fallen by 3 years and this secular trend towards earlier onset of puberty has continued during the past decade, in part due to improved nutrition as well as increasing obesity rates in children.

PRECOCIOUS PUBERTY

Precocious puberty in boys is defined by progressive testicular enlargement (>4 mL) before 9 years of age associated with acceleration of linear growth and bone age. Earlier onset of puberty is associated with increased risk of breast and endometrial cancer, cardiovascular disease, hypertension, type 2 diabetes, hair pigmentation, and shorter life span.

Isosexual precocity refers to premature sexual development consistent with phenotypic sex and includes features such as the development of facial hair and phallic growth. Isosexual precocity is divided into gonadotropin-dependent and gonadotropin-independent causes of androgen excess (Table 403-1). *Heterosexual precocity* refers to the premature development of estrogenic features in boys, such as breast development.

TABLE 403-1 Causes of Precocious or Delayed Puberty in Boys

I. Precocious puberty
- A. Gonadotropin-dependent
  1. Idiopathic
  2. CNS tumors such as hypothalamic hamartoma, optic glioma, arachnoid cysts, astrocytoma, ependymoma, or tunerous sclerosis
  3. Inflammatory and infectious lesions
  4. Mutations in genes that regulate GnRH secretion, such as kisspeptin (*KISS1*), kisspeptin receptor (*KISS1R*), and makorin ring finger protein 3 (*MKRN3*)
- B. Gonadotropin-independent
  1. Congenital adrenal hyperplasia
  2. hCG-secreting tumor
  3. McCune-Albright syndrome
  4. Activating LH receptor mutations (familial male-limited precocious puberty)
  5. Exogenous androgens
  6. Androgen producing tumors of the adrenal or the testis

II. Delayed puberty
- A. Constitutional delay of growth and puberty
- B. Systemic disorders
  1. Chronic disease
  2. Malnutrition
  3. Eating disorders
- C. CNS tumors and their treatment (radiotherapy and surgery)
- D. Hypothalamic-pituitary causes of pubertal failure (low gonadotropins)
  1. Congenital disorders associated with GnRH or gonadotropin deficiency (Table 403-2)
  2. Acquired disorders
     a. Pituitary tumors
     b. Hyperprolactinemia
     c. Infiltrative disorders, such as hemochromatosis
- E. Gonadal causes of pubertal failure (elevated gonadotropins)
  1. Klinefelter syndrome
  2. Bilateral undescended testes
  3. Orchitis
  4. Chemotherapy or radiotherapy
  5. Anorchia
- F. Androgen insensitivity

Abbreviations: CNS, central nervous system; GnRH, gonadotropin-releasing hormone; hCG, human chronic gonadotropin; LH, luteinizing hormone.

Gonadotropin-Dependent Precocious Puberty This disorder, also called *central precocious puberty* (CPP), is less common in boys than in girls. It is caused by premature activation of the GnRH pulse generator, sometimes because of central nervous system (CNS) lesions such as hypothalamic hamartomas, but it is often idiopathic. CPP is characterized by gonadotropin levels that are inappropriately elevated for age and LH and FSH responses to GnRH typical of those seen in postpubertal boys or adults. Magnetic resonance imaging (MRI) should be performed to exclude a mass, structural defect, infection, or inflammatory process. Mutations in *MKRN3*, an imprinted gene encoding makorin ring finger protein 3, that serves as an upstream inhibitor of GnRH secretion and is expressed only from the paternally inherited allele, have been associated with CPP. Loss-of-function mutations in *MKRN3* remove the brake that restrains pulsatile GnRH secretion, resulting in precocious puberty. Additional activating mutations in kisspeptin and kisspeptin receptor and loss-of-function mutations in delta-like homolog (*DLK1*) have been identified in patients with CPP.

Gonadotropin-Independent Precocious Puberty In boys with gonadotropin-independent precocious puberty, circulating androgens are increased but gonadotropins are low. This group of disorders includes hCG-secreting tumors; CAH; sex steroid–producing tumors of the testis, adrenal, and ovary; accidental or deliberate exogenous sex steroid administration; hypothyroidism; and activating mutations of the LH receptor or $G_s\alpha$ subunit.

Familial Male-Limited Precocious Puberty Also called *testotoxicosis*, familial male-limited precocious puberty is an autosomal dominant disorder caused by activating mutations in the LH receptor, leading to constitutive stimulation of the cyclic AMP pathway and testosterone production. Clinical features include premature androgenization in boys, linear growth acceleration in early childhood, and advanced bone age followed by premature epiphyseal fusion. Testosterone is elevated, and LH is suppressed. Treatment options include inhibitors of testosterone synthesis (e.g., ketoconazole, abiraterone, medroxyprogesterone acetate), AR antagonists (e.g., flutamide and bicalutamide), and aromatase inhibitors (e.g., anastrozole).

MCCUNE-ALBRIGHT SYNDROME This is a sporadic disorder caused by somatic (postzygotic) activating mutations in the $G_s\alpha$ subunit that links G protein–coupled receptors to intracellular signaling pathways **(Chap. 424)**. The mutations impair the guanosine triphosphatase activity of the $G_s\alpha$ protein, leading to ligand-independent signaling of the G_s-coupled receptor, constitutive activation of adenylyl cyclase, and stimulation of testosterone production. In addition to sexual precocity, affected individuals may have autonomy in the adrenals, pituitary, and thyroid glands. *Café au lait* spots are characteristic skin lesions that reflect the onset of the somatic mutations in melanocytes during embryonic development. Constitutive $G_s\alpha$ activation in the postnatal multipotent skeletal stem cells leads to the formation of immature woven bone and replacement of the bone marrow with fibrotic stroma (polyostotic fibrous dysplasia). Treatment is similar to that in patients with activating LH receptor mutations. Bisphosphonates have been used to treat bone lesions.

CONGENITAL ADRENAL HYPERPLASIA Boys with CAH who are not well controlled with glucocorticoid suppression of adrenocorticotropic hormone (ACTH) can develop premature virilization because of excessive androgen production by the adrenal gland **(Chaps. 398 and 402)**. LH is low, and the testes are small. Some children with CAH, who are poorly controlled with glucocorticoid treatment, may develop gonadotropin-dependent precocious puberty with early maturation of the hypothalamic-pituitary-gonadal axis, elevated gonadotropins, and testicular growth. Similar development of gonadotropin-dependent precocious puberty has been reported in children with androgen-secreting tumors or other conditions associated with androgen excess, likely due to androgen-induced skeletal maturation. Adrenal rests may develop within the testis of poorly controlled patients with CAH because of chronic ACTH stimulation; adrenal rests do not require surgical removal and regress with effective glucocorticoid therapy.

Heterosexual Sexual Precocity Breast enlargement in prepubertal boys can result from familial aromatase excess, estrogen-producing tumors in the adrenal gland, Sertoli cell tumors in the testis, marijuana smoking, or exogenous estrogens or androgens. Occasionally, germ cell tumors that secrete hCG can be associated with breast enlargement due to excessive stimulation of estrogen production (see "Gynecomastia," below).

APPROACH TO THE PATIENT

Precocious Puberty

After verification of precocious development, serum testosterone, LH, and FSH levels should be measured to determine whether gonadotropins are increased in relation to chronologic age (gonadotropin-dependent) or whether sex steroid secretion is occurring independent of LH and FSH (gonadotropin-independent). In children with gonadotropin-dependent precocious puberty, CNS lesions should be excluded by history, neurologic examination, and MRI scan of the head. If an organic cause is not found, one is left with the diagnosis of idiopathic central precocious puberty. Patients with high testosterone but suppressed LH concentrations have gonadotropin-independent precocious puberty; in these patients,

DHEA sulfate (DHEAS) and 17α-hydroxyprogesterone should be measured. High levels of testosterone and 17α-hydroxyprogesterone suggest the possibility of CAH due to 21α-hydroxylase or 11β-hydroxylase deficiency. If testosterone and DHEAS are elevated, adrenal tumors should be excluded by obtaining a computed tomography (CT) scan of the adrenal glands. Patients with elevated testosterone but without increased 17α-hydroxyprogesterone or DHEAS should undergo evaluation of the testis by palpation and ultrasound to exclude a Leydig cell neoplasm. Activating mutations of the LH receptor or $G_s\alpha$ subunit should be considered in children with gonadotropin-independent precocious puberty in whom CAH, androgen abuse, and adrenal and testicular neoplasms have been excluded.

TREATMENT

Precocious Puberty

In patients with a known cause (e.g., a CNS lesion or a testicular tumor), therapy should be directed toward the underlying disorder. In patients with idiopathic CPP, treatment with long-acting GnRH analogues is indicated in boys showing rapid pubertal progression, who are more advanced in pubertal development (e.g., Tanner stage 3 or greater genital development) and experiencing rapid linear growth or psychological distress. GnRH analogues suppress gonadotropins and testosterone, halt early pubertal development, delay accelerated bone maturation, prevent early epiphyseal closure, promote final height gain, and mitigate the psychosocial consequences of early pubertal development without causing osteoporosis. The treatment is most effective for increasing final adult height if it is initiated before age 6. Puberty resumes after discontinuation of the GnRH analogue. Counseling is an important aspect of the overall treatment strategy.

In children with gonadotropin-independent precocious puberty, inhibitors of steroidogenesis, such as ketoconazole or abiraterone, AR antagonists, and aromatase inhibitors have been used empirically. Long-term treatment with spironolactone (a weak androgen antagonist) and ketoconazole also has been reported to normalize growth rate and bone maturation and to improve predicted height in small, nonrandomized trials in boys with familial male-limited precocious puberty. Aromatase inhibitors, such as testolactone and letrozole, have been used as adjuncts to antiandrogen therapy for children with familial male-limited precocious puberty, CAH, and McCune-Albright syndrome. More potent novel inhibitors of testosterone synthesis, such as abiraterone, have not been systematically evaluated in boys with gonadotropin-independent precocious puberty.

DELAYED PUBERTY

Puberty is considered delayed in boys if it has not ensued by age 14, an age that is 2–2.5 standard deviations above the mean for healthy children. Pubertal delay is not necessarily pathologic and may be a variant of normal pubertal development in some children. Delayed puberty has been associated with lower peak bone mass, higher risk for metabolic and cardiovascular disorders, and lower risk for breast and endometrial cancer in women.

Delayed puberty is more common in boys than in girls. There are four main categories of delayed puberty: (1) self-limited delayed puberty (previously called constitutional delay of puberty) (~60% of cases); (2) functional hypogonadotropic hypogonadism caused by systemic illness, malnutrition, or eating disorders (~20% of cases); (3) hypogonadotropic hypogonadism caused by congenital or acquired defects in the hypothalamic-pituitary region (~10% of cases); and (4) hypogonadism secondary to primary gonadal failure (~15% of cases) (Table 403-1). The self-limited delayed puberty is the most common cause that accounts for nearly two-thirds of boys and one-third of girls with delayed puberty. The self-limited puberty clusters in families and displays a complex inheritance pattern, having an autosomal dominant pattern of inheritance in some families, but autosomal recessive, X-linked, or bilineal pattern in other families. Self-limited delayed puberty and congenital hypogonadotropic hypogonadism share similarities in their clinical presentation but differ in their clinical course and treatment. In boys with self-limited delayed puberty, pubertal progression will occur eventually, while in those with congenital hypogonadotropin hypogonadism, hormone treatment will be needed to induce secondary sex characteristics. Genetic studies of patients with congenital hypogonadotropic hypogonadism have identified >65 genes that are involved in regulating one or more of the following: (1) development and migration of GnRH neurons (e.g., *ANOS1, PROK2, PROK2R, FGFR1, FGF8, FGF17, WDR11,* and *CHD7*); (2) regulation of GnRH secretion (*KISS1, KISS1R, TAC3,* and *TACR3*); and (3) GnRH function (e.g., *GNRH1, RNRHR*). The mutations in some of these genes are associated with dysmorphic features or occur as a part of a syndromic constellation that can facilitate their identification. Some of the genes associated with self-limited delayed puberty are found uniquely in kindreds of children with this disorder, while others are similar to those found in families with congenital hypogonadotropic hypogonadism. Furthermore, 10 to 20% of children with congenital hypogonadotropic hypogonadism may experience spontaneous restoration of GnRH and gonadotropin secretion in adulthood.

Functional hypogonadotropic hypogonadism is more common in girls than in boys. Permanent causes of congenital hypogonadotropic hypogonadism or primary testicular failure are identified in <25% of boys with delayed puberty.

APPROACH TO THE PATIENT

Delayed Puberty

History of systemic illness, eating disorders, excessive exercise, social and psychological problems, and abnormal patterns of linear growth during childhood should be verified. Boys with pubertal delay may have accompanying emotional and physical immaturity relative to their peers, which can be a source of anxiety. Physical examination should focus on height; arm span; weight; visual fields; and secondary sex characteristics, including hair growth, testicular volume, phallic size, and scrotal reddening and thinning. Testicular size >2.5 cm generally indicates that the child has entered puberty.

The main diagnostic challenge is to distinguish those with self-limited delayed puberty, who will progress through puberty at a later age, from those with congenital hypogonadotropic hypogonadism as both conditions present with low testosterone and low gonadotropin levels, delayed bone age and short stature. Pituitary priming by pulsatile GnRH is required before LH and FSH are synthesized and secreted normally. Thus, blunted responses to exogenous GnRH can be seen in patients with self-limited delayed puberty, congenital hypogonadotropic hypogonadism, or pituitary disorders. On the other hand, low-normal basal gonadotropin levels or a normal response to exogenous GnRH is consistent with an early stage of puberty, which is often heralded by nocturnal GnRH secretion. The presence of micropenis or history of cryptorchidism are more suggestive of congenital hypogononadotropic hypogonadism. However, self-limited delayed puberty remains a diagnosis of exclusion that requires ongoing evaluation until the onset of puberty and the growth spurt.

TREATMENT

Delayed Puberty

A major challenge in the treatment of children with delayed puberty is to determine whether and when to initiate hormonal treatment. Reassurance without hormonal treatment is appropriate for many individuals with presumed self-limited delayed puberty. However, the impact of delayed growth and pubertal progression on a child's social relationships and school performance should be weighed.

Boys with self-limited delayed puberty are less likely to achieve their full genetic height potential and have reduced total body bone mass as adults, mainly due to narrow limb bones and vertebrae as a result of impaired periosteal expansion during puberty. Furthermore, the time of onset of puberty is negatively associated with bone mineral content and density in boys at skeletal maturity. Judicious use of testosterone therapy in carefully selected boys with self-limited delayed puberty can induce pubertal induction and progression and promote short-term growth without compromising final height, and when administered with an aromatase inhibitor, it may improve final height.

If therapy is considered appropriate, it can begin with 25–50 mg of testosterone enanthate or testosterone cypionate every 2–4 weeks or by using a 2.5-mg testosterone patch or 25-mg testosterone gel. Because aromatization of testosterone to estrogen is obligatory for mediating androgen effects on epiphyseal fusion, concomitant treatment with aromatase inhibitors may allow attainment of greater final adult height. Testosterone treatment should be interrupted after 6 months to determine if endogenous LH and FSH secretion have ensued. Other causes of delayed puberty should be considered when there are associated clinical features or when boys do not enter puberty spontaneously after a year of observation or treatment.

Boys with confirmed congenital hypogonadotropic hypogonadism require an earlier institution of hormonal treatment than those with self-limited delayed puberty. Optimization of future fertility potential may require initial treatment with hCG to induce development of secondary sex characteristics as well as spermatogenesis to enable harvesting and cryopreservation of sperm.

DISORDERS OF THE MALE REPRODUCTIVE AXIS DURING ADULTHOOD

HYPOGONADOTROPIC HYPOGONADISM

Because LH and FSH are trophic hormones for the testes, impaired secretion of these pituitary gonadotropins results in secondary hypogonadism, which is characterized by low testosterone in the setting of low or inappropriately normal LH and FSH. Hypogonadotropic hypogonadism can be classified into congenital and acquired disorders. Congenital disorders most commonly involve GnRH deficiency, which leads to gonadotropin deficiency. Acquired disorders are more common than congenital disorders and may result from sellar mass lesions, infiltrative diseases of the hypothalamus or pituitary, drugs, nutritional or psychiatric disorders, or systemic diseases. Those with the most severe congenital gonadotropin deficiency have complete absence of pubertal development, and, in some cases, hypospadias, undescended testes, and micropenis. Patients with congenital or prepubertal onset of partial gonadotropin deficiency have delayed or arrested sex development. The 24-h LH secretory profiles are heterogeneous in patients with hypogonadotropic hypogonadism, reflecting variable abnormalities of LH pulse frequency or amplitude. In severe cases, basal LH is low, and there are no LH pulses. A smaller subset of patients has low-amplitude LH pulses or markedly reduced pulse frequency. Occasionally, only sleep-entrained LH pulses occur, reminiscent of the pattern seen in the early stages of puberty.

Congenital Disorders Associated with Gonadotropin Deficiency **(See Chap. 391)** Congenital hypogonadotropic hypogonadism is a heterogeneous group of disorders characterized by decreased gonadotropin secretion and testicular dysfunction either due to impaired function of the GnRH pulse generator or the gonadotrope. The disorders characterized by GnRH deficiency represent a family of monogenic or oligogenic disorders whose phenotype spans a wide spectrum. Some individuals with GnRH deficiency may suffer from complete absence of pubertal development, while others may manifest varying degrees of gonadotropin deficiency and pubertal delay, and a subset that carries the same mutations as their affected family members may even have normal reproductive function. In ~10% of men with congenital isolated hypogonadotropic hypogonadism (IHH), reversal of gonadotropin deficiency may occur in adult life after sex steroid therapy. Also, a small fraction of men with IHH may present with testosterone deficiency and infertility in adult life after having gone through apparently normal pubertal development. Nutritional, emotional, or metabolic stress may unmask gonadotropin deficiency and reproductive dysfunction (e.g., hypothalamic amenorrhea) in some patients who harbor mutations in the candidate genes but who previously had normal reproductive function. Oligogenicity and gene-gene and gene-environment interactions may contribute to variations in clinical phenotype.

Mutations in >60 genes involved in the development and migration of GnRH neurons (e.g., *ANOS1, PROK2, PROK2R, FGFR1, FGF8, FGF17, WDR11, CHD7*), GnRH secretion (*KISS1, KISS1R, TAC3, TACR3*), or GnRH function (e.g., *GNRH1, RNRHR*) have been linked to congenital IHH. The genetic defect remains elusive in nearly two-thirds of cases. Familial hypogonadotropic hypogonadism can be transmitted as an X-linked (20%), autosomal recessive (30%), or autosomal dominant (50%) trait. Some individuals with IHH have sporadic mutations in the same genes that cause inherited forms of the disorder. The genetic defects associated with GnRH deficiency can be classified as anosmic (Kallmann syndrome) or normosmic **(Table 403-2)**, although the occurrence of both anosmic and normosmic forms of GnRH deficiency in the same families suggests commonality of pathophysiologic mechanisms. *Kallmann syndrome*, the anosmic form

Abbreviations: ACTH, adrenocorticotropic hormone; AD, autosomal dominant; AR, autosomal recessive; *CCDC141*, coiled-coil domain containing 141; CHARGE syndrome, eye coloboma, heart defects, choanal atresia, growth and developmental retardation, genitourinary anomalies, ear anomalies; CPHD, combined pituitary hormone deficiency; *DAX1*, dosage-sensitive sex-reversal, adrenal hypoplasia congenita, X chromosome; *DCC*, deleted in colon cancer; *DMXL2*, DMX like 2; *DUSP6*, dual specificity phosphatase 6; *FGFR1*, fibroblast growth factor receptor 1; *FGF17*, fibroblast growth factor 17; *FSHβ*, follicle-stimulating hormone β-subunit; *FLRT3*, fibronectin like domain containing leucine rich transmembrane protein 3; GH, growth hormone; *GLCE*, glucuronic acid epimerase; *GNRHR*, gonadotropin-releasing hormone receptor; *GPR54*, G protein–coupled receptor 54; *HESX1*, homeobox gene expressed in embryonic stem cells 1; *IGSF10*, immunoglobulin superfamily member 10; *KAL1*, Kallmann syndrome interval gene 1, also known as anosmin 1; *KISS1*, kisspeptin 1; *KLB*, klotho-1; *LEP*, leptin; *LEPR*, leptin receptor; *LHX3*, LIM homeobox gene 3; *LHβ*, luteinizing hormone β-subunit; *NELF*, nasal embryonic luteinizing hormone–releasing hormone factor; *NSMF*, NMDA receptor synaptonuclear signaling and neuronal migration factor; *NR0B1*, nuclear receptor subfamily 0, group B, member 1; *NTN1*, netrin-1; *OTUD4*, OUT domain containing protein 4; *PCSK1*, proprotein convertase subtilisin/kexin type 1; *PLXNA1, plexin A1; PNPLA6*, patatin-like phospholipase domain-containing protein 6; *PC1*, prohormone convertase 1; *PROK2*, prokineticin 2; *PROKR2*, prokineticin 2 receptor; *PROP1*, prophet of pit 1; *RNF216*, ring finger protein 216; *POLR3B*, polymerase III RNA subunit B; *SEMA3A, semaphorin 3A; SEMA7A, semaphorin 7A; SEMA3E, semoaphorin 3E; SF1*, steroidogenic factor 1; *SPRY4*, sprouty RTK signaling antagonist 4; *STUB1*, srip 1 homologous and U box containing protein 1; *TUBB3*, tubulin beta 3; *IL17RD*, interleukin 17 receptor D.

of GnRH deficiency, can result from mutations in one or more neurodevelopmental genes associated with olfactory bulb morphogenesis or the migration of GnRH neurons from their origin in the region of the olfactory placode, along the scaffold established by the olfactory nerves, through the cribriform plate into their final location into the preoptic region of the hypothalamus. Thus, mutations in *KAL1*, NMDA receptor synaptonuclear signaling and neuronal migration factor (*NSMF*), genes involved in fibroblast growth factor (FGF) signaling (*FGF8*, *FGFR1*, *FGF17*, *IL17RD*, *DUSP6*, *SPRY4*, and *FLRT3*), *NELF*, genes involved in *PROK* signaling (*PROK2* and *PROK2R*), *WDR11*, *SOX10*, *TUBB3 SEMA3*, *HS6ST1*, *CHD7*, and *FEZF1* have been described in patients with Kallmann syndrome; among these mutations in *ANOS1*, *CHD7*, *FGF8*, *FGFR1*, *PRROK2*, and *PROLR2* are the most common. An X-linked form of IHH is caused by mutations in the *ANOS1* gene,

which encodes anosmin, a protein that mediates the migration of neural progenitors of the olfactory bulb and GnRH-producing neurons. These individuals have GnRH deficiency and variable combinations of anosmia or hyposmia. Proteins such as those involved in FGF and prokineticin signaling and *KAL1*, which account for the great majority of Kallmann syndrome cases, interact with heparin sulfate glycosaminoglycan compounds within the extracellular matrix in supporting GnRH neuronal migration. Mutations in the *FGFR1* gene cause an autosomal dominant form of hypogonadotropic hypogonadism that clinically resembles Kallmann syndrome; mutations in its putative ligand, the *FGF8* gene product, have also been associated with IHH. Craniofacial tissues and olfactory ensheathing cells also play important roles in neurogenesis and migration of the GnRH neurons, and additional proteins that regulate these cell types may also be involved in the pathogenesis of Kallmann syndrome. The co-occurrence of tooth anomalies, cleft palate, craniofacial anomalies, pigmentation, and neurologic defects in patients with Kallmann syndrome suggests that the syndrome may be a part of the spectrum of neurocristopathies. Other dysmorphic features associated with some forms of IHH include renal agenesis, hearing loss, synkinesia, short metacarpals, eye movement abnormalities, cerebellar ataxia, and dental agenesis. The presence of these dysmorphic features can offer clues to the underlying genetic abnormality and guide genetic testing.

Normosmic GnRH deficiency results from defects in pulsatile GnRH secretion, its regulation, or its action on the gonadotrope and has been associated with mutations in *GnRHR, GNRH1, KISS1R, TAC3, TACR3, NROB1* (*DAX1*), leptin, or leptin receptor. Some mutations, such as those in *PROK2, PROKR2, NSMF, FGFR1, FGF8, SEMA3A, WDR11*, and *CHD7*, have been associated with both anosmic and normosmic forms of IHH; it is possible that these genes are involved in GnRH neuronal migration as well in regulation of GnRH secretion. *GnRHR* mutations, the most frequent identifiable cause of normosmic IHH, account for ~40% of autosomal recessive and 10% of sporadic cases of hypogonadotropic hypogonadism. These patients have decreased LH response to exogenous GnRH. Some receptor mutations alter GnRH binding affinity, allowing apparently normal responses to pharmacologic doses of exogenous GnRH, whereas other mutations may alter signal transduction downstream of hormone binding. Mutations of the *GnRH1* gene have also been reported in patients with hypogonadotropic hypogonadism, although they are rare. The G protein–coupled receptor *KISS1R* (*GPR54*) and its cognate ligand, kisspeptin (*KISS1*), are important regulators of sexual maturation in primates. Recessive mutations in *GPR54* cause gonadotropin deficiency without anosmia. The genes encoding NKB (*TAC3*), which is involved in preferential activation of GnRH release in early development, and its receptor (*TAC3R*) have been implicated in some families with normosmic IHH. The tachykinin pathway plays an important role in GnRH activation during "mini-puberty" as well as in puberty. Prokineticin 2 (PROK2) and its receptor (PROK2R) are highly expressed in the olfactory ventricle and subventricular zone of the lateral ventricle and are associated with neurogenesis of the olfactory bulbs and the migration of the olfactory neuronal cells. Mutations in the *CHD7* gene that encodes for the chromodomain helicase DNA binding protein 7 causes CHARGE syndrome characterized by eye coloboma, heart anomalies, choanal atresia, growth and developmental retardation, genitourinary anomalies, hypogonadism, and ear abnormalities. X-linked hypogonadotropic hypogonadism also occurs in *adrenal hypoplasia congenita*, a disorder caused by mutations in the *DAX1* gene, which encodes a nuclear receptor in the adrenal gland and reproductive axis. Adrenal hypoplasia congenita is characterized by absent development of the adult zone of the adrenal cortex, leading to neonatal adrenal insufficiency. Puberty usually does not occur or is arrested, reflecting variable degrees of gonadotropin deficiency. Although sexual differentiation is normal, some patients have testicular dysgenesis and impaired spermatogenesis despite gonadotropin replacement. Less commonly, adrenal hypoplasia congenita, sex reversal, and hypogonadotropic hypogonadism can be caused by mutations of steroidogenic factor 1 (SF1). Rarely, recessive mutations in the *LHβ* or *FSHβ* genes have been described in patients with selective deficiencies of these gonadotropins.

A number of homeodomain transcription factors are involved in the development and differentiation of the specialized hormone-producing cells within the pituitary gland (Table 403-2). Patients with mutations of *PROP1* have combined pituitary hormone deficiency that includes GH, prolactin (PRL), thyroid-stimulating hormone (TSH), LH, and FSH, but not ACTH. *LHX3* mutations cause combined pituitary hormone deficiency in association with cervical spine rigidity. *HESX1* mutations cause septo-optic dysplasia and combined pituitary hormone deficiency. Mutations of *ARNT1*, inherited as an autosomal recessive disorder, are associated with diabetes insipidus; ACTH, GH, LH, and FSH deficiency; anterior pituitary hypoplasia; hypoplastic frontal and temporal lobes; thin corpus callosum; prominent forehead; and retrognathia. Patients with *SOX2* mutations can have gonadotropin deficiency, variable deficiencies of TSH and ACTH, pituitary hypoplasia, microphthalmia, and intellectual disability.

Prader-Willi syndrome (PWS) is a genomic imprinting disorder caused by deletions of the proximal portion of the paternally derived chromosome 15q11-15q13 region, which contains a bipartite imprinting center (65–75%); uniparental disomy of the maternal alleles (20–30%); or mutations of the genes/loci involved in imprinting (1–3%) **(Chap. 479)**. The imprinting gene implicated in PWS is a ubiquitin pathway gene known as *UBE3A*, for which the maternal allele is normally expressed while the paternal allele is silenced. PWS is characterized by obesity, hypotonic musculature, intellectual disability, hypogonadism, short stature, and small hands and feet. Some of the major manifestations of PWS may be due to reduced expression of prohormone convertase 1.

Laurence-Moon syndrome is an autosomal recessive disorder characterized by obesity, hypogonadism, mental retardation, polydactyly, and retinitis pigmentosa. Recessive mutations of leptin, or its receptor, cause severe obesity and pubertal arrest, apparently because of hypothalamic GnRH deficiency **(Chap. 413)**.

Acquired Hypogonadotropic Disorders • SEVERE ILLNESS, STRESS, MALNUTRITION, AND EXERCISE These may cause reversible gonadotropin deficiency. Although gonadotropin deficiency and reproductive dysfunction are well documented in these conditions in women, men exhibit similar but less pronounced responses. Unlike women, most male runners and other endurance athletes have normal gonadotropin and sex steroid levels, despite low body fat and frequent intensive exercise. Testosterone levels fall at the onset of illness and recover during recuperation. The magnitude of gonadotropin suppression generally correlates with the severity of illness. Although hypogonadotropic hypogonadism is the most common cause of testosterone deficiency in patients with acute illness, some have elevated levels of LH and FSH, which suggests primary gonadal dysfunction. The pathophysiology of reproductive dysfunction during acute illness is unknown but likely involves the combined effects of reductive stress, inflammation, cytokines, and/or glucocorticoid effects. There is a high frequency of low testosterone levels in patients with chronic illnesses such as HIV infection, end-stage renal disease, chronic obstructive lung disease, and many types of cancer and in patients receiving glucocorticoids. About 20% of HIV-infected men with low testosterone levels have elevated LH and FSH levels; these patients presumably have primary testicular dysfunction. The remaining 80% have either normal or low LH and FSH levels; these men have a central hypothalamic-pituitary defect or a dual defect involving both the testis and the hypothalamic-pituitary centers. Muscle wasting is common in chronic diseases associated with hypogonadism, which also leads to debility, poor quality of life, and adverse outcome of disease.

Men using opioids for relief of cancer or noncancerous pain or because of addiction often have suppressed testosterone and LH levels and high prevalence of sexual dysfunction and osteoporosis; the degree of suppression is dose-related and particularly severe with long-acting opioids such as methadone. Exogenous opioids bind to the κ-opioid receptors on the KNDy neurons, suppress GnRH secretion, and alter the sensitivity to feedback inhibition by gonadal steroids. Heavy marijuana use has been associated with reduced sperm density, motility, morphology, and capacitation, and increased risk of subfertility.

The effects of marijuana use on circulating testosterone levels have been inconsistent in humans. Gynecomastia observed in marijuana users can be caused by plant estrogens in crude preparations. Androgen deprivation therapy in men with prostate cancer has been associated with increased risk of bone fractures, diabetes mellitus, cardiovascular events, fatigue, sexual dysfunction, tender gynecomastia, and poor quality of life.

OBESITY In men with mild to moderate obesity, SHBG levels decrease in proportion to the degree of obesity, resulting in lower total testosterone levels. However, free testosterone levels usually remain within the normal range. SHBG production in the liver is inhibited by hepatic lipids and by tumor necrosis factor α and interleukin 1, but it is not affected by insulin. Thus, the low SHBG levels seen in obesity and diabetes are likely the result of low-grade inflammation and the increased amount of hepatic lipids rather than high insulin levels. Inflammation and gliosis in the pituitary, hypothalamic leptin resistance, and increased estradiol levels because of aromatization of testosterone to estradiol in adipose tissue may impair hypothalamic-pituitary function; obesity also may directly affect testicular function. Weight gain in adult men can accelerate the rate of age-related decline in testosterone levels. Weight loss is associated with reversal of these abnormalities including an increase in total and free testosterone levels and a decrease in estradiol levels.

HYPERPROLACTINEMIA **(See also Chap. 392)** Elevated PRL levels are associated with hypogonadotropic hypogonadism. PRL inhibits hypothalamic GnRH secretion either directly or through modulation of tuberoinfundibular dopaminergic pathways and also attenuates LH and FSH response to GnRH. A PRL-secreting tumor may also destroy the surrounding gonadotropes by invasion or compression of the pituitary stalk. Treatment with dopamine agonists reverses gonadotropin deficiency, although there may be a delay relative to PRL suppression.

SELLAR MASS LESIONS Neoplastic and nonneoplastic lesions in the hypothalamus or pituitary can directly or indirectly affect gonadotrope function. In adults, pituitary adenomas constitute the largest category of space-occupying lesions affecting gonadotropin and other pituitary hormone production. Pituitary adenomas that extend into the suprasellar region can impair GnRH secretion and mildly increase PRL secretion (usually <50 μg/L) because of impaired tonic inhibition by dopaminergic pathways. These tumors that cause hyperprolactinemia by stalk compression should be distinguished from prolactinomas, which typically are associated with higher PRL levels. The presence of diabetes insipidus suggests the possibility of a craniopharyngioma, infiltrative disorder, or other hypothalamic lesions **(Chap. 393)**.

HEMOCHROMATOSIS **(See also Chap. 426)** Both the pituitary and testis can be affected by excessive iron deposition. However, the pituitary defect is the predominant lesion in most patients with hemochromatosis and hypogonadism. The diagnosis of hemochromatosis is suggested by the association of characteristic skin discoloration, hepatic enlargement or dysfunction, diabetes mellitus, arthritis, cardiac conduction defects, hypogonadism, and increased serum ferritin (>300 ng/mL for men) and transferrin saturation (>45%, threshold varies in different guidelines).

PRIMARY TESTICULAR CAUSES OF HYPOGONADISM

Common causes of primary testicular dysfunction include Klinefelter syndrome, uncorrected cryptorchidism, cancer chemotherapy, radiation to the testes, trauma, torsion, infectious orchitis, HIV infection, anorchia syndrome, and myotonic dystrophy. Primary testicular disorders may be associated with impaired spermatogenesis, decreased androgen production, or both. **See Chap. 402 for disorders of testis development, androgen synthesis, and androgen action.**

Klinefelter Syndrome **(See also Chap. 402)** Klinefelter syndrome is the most common chromosomal disorder associated with 47,XXY karyotype, testicular dysfunction, and male infertility. It occurs in about 1 in 600 live-born males. Azoospermia is the rule in men with Klinefelter syndrome who have the 47,XXY karyotype due to the progressive loss of 47,XXY spermatogonial stem cells; however, men with mosaicism (46,XY/47,XXY) and even some with 47,XXY karyotype may have germ cells, especially at a younger age. The clinical phenotype of Klinefelter syndrome can be variable, possibly because of mosaicism, polymorphisms in AR gene, the parental origin of the X chromosome, X-linked copy number variations, gene-dosage effects in conjunction with X chromosome inactivation, variable testosterone levels, and variable changes in the transcriptome and methylome in various tissues. Testicular histology shows hyalinization of seminiferous tubules and germ cell aplasia. However, spermatogenesis can be observed in a small number of tubules from which sperm can be harvested during testicular sperm extraction for IVF. Although their function is impaired, the number of Leydig cells appears to increase. Testosterone is decreased and estradiol is increased, leading to clinical features of undervirilization and gynecomastia. Men with Klinefelter syndrome are at increased risk of systemic lupus erythematosus, Sjögren's syndrome, breast cancer, diabetes mellitus, osteoporosis, non-Hodgkin's lymphoma, and some types of lung cancers and at reduced risk of prostate cancer. Periodic mammography for breast cancer surveillance is recommended for men with Klinefelter syndrome. Fertility can be achieved by intracytoplasmic injection of sperm retrieved surgically from the testes of men with Klinefelter syndrome, including some men with nonmosaic form of Klinefelter syndrome. Although sperm retrieval in adolescence for fertility preservation offers no benefit over harvesting in adulthood, fertility counseling, including the potential for sperm retrieval, should be offered prior to starting testosterone replacement therapy. The karyotypes 48,XXXY and 49,XXXXY are associated with a more severe phenotype, increased risk of congenital malformations, and lower intelligence than 47,XXY individuals.

Cryptorchidism Cryptorchidism occurs when there is incomplete descent of the testis from the abdominal cavity into the scrotum. About 1–4% of full-term and 30% of premature male infants have at least one undescended testis at birth, but descent is usually complete by the first few weeks of life. Fifty percent of undescended testes at birth will descend spontaneously within the first 6–18 months of life. Consequently, the incidence of cryptorchidism is <1% by 9 months of age. Cryptorchidism should be distinguished from retractile testes that can be pulled down into the scrotum during physical examination and require no treatment.

Testosterone and insulin-like 3 (*INSL3*) and their cognate receptors, androgen receptor and relaxin/insulin-like family peptide receptor 2 (*RXFP2*), regulate the development and growth of the fetal gubernaculum-cremaster muscle complex and the inguinoscrotal descent of the testes. Mutations in *INSL3* and *RXFP2* have been found in some patients with nonsyndromic cryptorchidism. However, genome-wide association studies have not found a consistent relation of nonsyndromic cryptorchidism with any single locus, suggesting complex, multilocus genetic susceptibility.

Cryptorchidism is associated with increased risk of malignancy, infertility, inguinal hernia, and torsion. Unilateral cryptorchidism, even when corrected before puberty, is associated with decreased sperm count, possibly reflecting unrecognized damage to the fully descended testis or other genetic factors. Surgical correction is usually performed between 6 and 18 months of age depending on the location of the testes, the child's body size, and parental preference. Epidemiologic, clinical, and molecular evidence supports the idea that cryptorchidism, hypospadias, impaired spermatogenesis, and testicular cancer may be causally related to common genetic and environment perturbations and are components of the testicular dysgenesis syndrome.

Acquired Testicular Defects *Viral orchitis* may be caused by the mumps virus, echovirus, lymphocytic choriomeningitis virus, and group B arboviruses. Orchitis occurs in as many as one-fourth of adult men with mumps; the orchitis is unilateral in about two-thirds and bilateral in the remainder. Orchitis usually develops a few days after the onset of parotitis but may precede it. The testis may return to normal size and function or undergo atrophy. Semen analysis returns to normal for three-fourths of men with unilateral involvement but for only one-third of men with bilateral orchitis. *Trauma*, including testicular torsion, can also cause secondary

atrophy of the testes. The exposed position of the testes in the scrotum renders them susceptible to both thermal and physical trauma, particularly in men with hazardous occupations.

The late-term adverse effects of cancer treatment on reproductive health have emerged as an important concern among cancer survivors. Many professional cancer societies have published guidelines on the fertility preservation in patients with cancer and strongly endorsed consideration of fertility preservation measures prior to initiation of cancer treatment. The testes are sensitive to *radiation damage* due to the direct effects of ionized radioactive particles as well as indirect effects of free radicals generated from water. Radiation doses <1.0 Gy are associated with only a transient decline in sperm density; doses between 1.0 and 2.0 Gy are associated with temporary azoospermia, and doses >2.0 Gy are generally associated with permanent azoospermia. Leydig cells are relatively resistant to the effects of radiation and only doses >20 Gy are associated with Leydig cell dysfunction and increased FSH and LH levels. Permanent testosterone deficiency in adult men is uncommon after therapeutic radiation; however, most boys given direct testicular radiation therapy for acute lymphoblastic leukemia have permanently low testosterone levels. Direct testicular radiation and whole-body radiation before bone marrow transplantation pose the greatest risk of permanent testicular damage.

Combination chemotherapy for acute leukemia, Hodgkin's disease, and testicular and other cancers may impair Leydig cell function and cause infertility. The degree of gonadal dysfunction depends on the type of chemotherapeutic agent and the dose and duration of therapy. Because of the high response rates and the young age of these men, infertility and testosterone deficiency have emerged as important long-term complications of cancer chemotherapy. Cyclophosphamide, procarbazine, ifosfamide, busulfan, chlorambucil, chlormethine cisplatin, carboplatin, and doxorubicin are associated with moderate to high risk of infertility. Azoospermia is uncommon with cyclophosphamide equivalent doses of <4000 mg/m^2, and higher doses of alkylating agents are generally associated with varying degree of damage to germ cells. The outcomes of assisted reproductive technologies in cancer survivors using cryopreserved sperm collected prior to cancer treatment are similar to those in infertile men who do not have cancer. A smaller subset of cancer survivors treated with large doses of alkylating agents may also suffer from testosterone deficiency and sexual dysfunction.

Drugs interfere with testicular function by several mechanisms, including inhibition of testosterone synthesis (e.g., ketoconazole, abiraterone, GnRH agonists and antagonists), blockade of androgen action (e.g., spironolactone), increased estrogen (e.g., marijuana), and toxic effects on spermatogenesis (e.g., chemotherapy).

Alcohol, when consumed in small to moderate amounts, modestly increases testosterone levels, but ingestion of large quantities decreases testosterone, independent of liver disease or malnutrition. Chronic ethanol use in large amounts lowers testosterone levels by inducing inflammation and reductive stress and by its effects on the hypothalamus, pituitary, and liver.

The occupational and recreational history should be evaluated in all men with infertility because of the toxic effects of many *chemical agents* on spermatogenesis. Known environmental hazards include pesticides (e.g., vinclozolin, dicofol, atrazine), sewage contaminants (e.g., ethinyl estradiol in birth control pills, surfactants such as octylphenol, nonylphenol), plasticizers (e.g., phthalates), flame retardants (e.g., polychlorinated biphenyls, polybrominated diphenol ethers), industrial pollutants (e.g., heavy metals such as cadmium and lead, dioxins, polycyclic aromatic hydrocarbons), microwaves, and ultrasound. In some populations, sperm density is said to have declined by as much as 40% in the past 50 years. Environmental estrogens or antiandrogens may be partly responsible.

Sperm antibodies can cause isolated male infertility. In some instances, these antibodies are secondary phenomena resulting from duct obstruction or vasectomy. Granulomatous diseases can affect the testes, and testicular atrophy occurs in 10–20% of men with lepromatous leprosy because of direct tissue invasion by the mycobacteria. The tubules are involved initially, followed by endarteritis and destruction of Leydig cells.

Systemic disease can cause primary testis dysfunction in addition to suppressing gonadotropin production. In cirrhosis, a combined testicular and pituitary abnormality leads to decreased testosterone production independent of the direct toxic effects of ethanol. Impaired hepatic extraction of adrenal androstenedione leads to extraglandular conversion to estrone and estradiol, which partially suppresses LH. Testicular atrophy and gynecomastia are present in approximately one-half of men with cirrhosis. In chronic renal failure, testosterone synthesis and sperm production decrease despite elevated gonadotropins. The elevated LH level is due to reduced clearance. About one-fourth of men with renal failure have hyperprolactinemia. Improvement in testosterone production with hemodialysis is incomplete, but successful renal transplantation may return testicular function to normal. Testicular atrophy is present in one-third of men with sickle cell anemia. The defect may be at either the testicular or the pituitary level, although hypogonadotropic hypogonadism is more common. Sperm density can decrease temporarily after acute febrile illness in the absence of a change in testosterone production. Infertility in men with celiac disease is associated with a hormonal pattern typical of androgen resistance, namely, elevated testosterone and LH levels.

Neurologic diseases such as myotonic dystrophy, spinobulbar muscular atrophy (Kennedy's disease), and spinal cord injury are often associated with associated with impaired testicular function. In myotonic dystrophy, small testes may be associated with impairment of both spermatogenesis and Leydig cell function. Spinobulbar muscular atrophy (Kennedy's disease) is caused by an expansion of the glutamine repeat tract in the amino-terminal region of the AR; this expansion impairs function of the AR. Men with spinobulbar muscular atrophy often have undervirilization and infertility as a late manifestation. Spinal cord injury that causes paraplegia is often associated with low testosterone levels and may cause persistent defects in spermatogenesis; some patients retain the capacity for penile erection and ejaculation.

ANDROGEN INSENSITIVITY SYNDROMES

Mutations in the AR cause resistance to the action of testosterone and DHT. These X-linked mutations are associated with variable degrees of defective male phenotypic development and undervirilization **(Chap. 402)**. Although not technically hormone-insensitivity syndromes, two genetic disorders associated with mutations in the steroid 5α-reductase type 2 or the *CYP19* (aromatase) gene impair testosterone conversion to active sex steroids. Mutations in the *SRD5A2* gene, which encodes the steroid 5α-reductase type 2, prevent the conversion of testosterone to DHT, which is necessary for the normal development of the male external genitalia. Mutations in the *CYP19* gene, which encodes aromatase, prevent testosterone conversion to estradiol. Males with *CYP19* mutations have delayed epiphyseal fusion, tall stature, eunuchoid proportions, visceral adiposity, and osteoporosis, consistent with evidence from an estrogen receptor–deficient individual that these testosterone actions are mediated via estrogen.

GYNECOMASTIA

Gynecomastia refers to enlargement of the male breast. It is caused by excess estrogen action and is usually the result of an increased estrogen/androgen ratio. True gynecomastia is associated with glandular breast tissue that is >4 cm in diameter and often tender. Glandular tissue enlargement should be distinguished from excess adipose tissue: glandular tissue is firmer and contains fibrous-like cords. Gynecomastia occurs as a normal physiologic phenomenon in the newborn (due to transplacental transfer of maternal and placental estrogens), during puberty (high estrogen-to-androgen ratio in early stages of puberty), and with aging (increased fat tissue and increased aromatase activity along with the age-related decline in testosterone levels), but it can also result from pathologic conditions associated with testosterone deficiency or estrogen excess. The prevalence of gynecomastia increases with age and body mass index (BMI), likely because of increased aromatase activity in adipose tissue. Medications that alter androgen metabolism or action may also cause gynecomastia. The relative risk of breast cancer is increased in men with gynecomastia, although the absolute risk is relatively small.

PATHOLOGIC GYNECOMASTIA

Any cause of *androgen deficiency* can lead to gynecomastia, reflecting an increased estrogen/androgen ratio, as estrogen synthesis still occurs by aromatization of residual adrenal and gonadal androgens. Gynecomastia is a characteristic feature of Klinefelter syndrome **(Chap. 402)**. *Androgen insensitivity* disorders also cause gynecomastia. Androgen deprivation therapy using GnRH analogues with and without androgen receptor blockers in men with prostate cancer is often associated with painful breast enlargement. *Excess estrogen production* may be caused by tumors, including Leydig cell tumors; Sertoli cell tumors in isolation or in association with Peutz-Jeghers syndrome or Carney complex; granulosa cell tumors; and adrenal tumors producing estrogen precursors. Tumors that produce hCG, including some testicular germ cell tumors, stimulate Leydig cell estrogen synthesis. *Increased conversion of androgens to estrogens* can be a result of increased availability of substrate (androstenedione) for extraglandular estrogen formation (CAH, hyperthyroidism, and most feminizing adrenal tumors) or of diminished catabolism of androstenedione (liver disease) so that estrogen precursors are shunted to aromatase in peripheral sites. Obesity is associated with increased aromatization of androgen precursors to estrogens. Extraglandular aromatase activity can also be increased in tumors of the liver or adrenal gland or rarely as an inherited disorder. Several families with *increased peripheral aromatase activity* inherited as an autosomal dominant or as an X-linked disorder have been described. In some families with this disorder, a chimeric CYP19 due to an inversion in chromosome 15q21.2-3 causes the *CYP19* gene to be activated by the regulatory elements of contiguous genes (e.g., transient receptor potential cation channel subfamily M member 7 [*TRPM7*], *TMOD3*, or *FLJ14957*), resulting in excessive estrogen production in the fat and other extragonadal tissues. The familial aromatase excess syndrome due to *CYP19* mutation or chromosomal rearrangement is characterized by pre- or peripubertal onset of gynecomastia, advanced bone age, short adult height due to premature epiphyseal closure, and hypogonadotropic hypogonadism. Peutz-Jeghers syndrome is characterized by intestinal hamartomas, mucocutaneous pigmentation, calcifying Sertoli cell tumors, premature epiphyseal closure, and prepubertal gynecomastia due to increased aromatization. Hyperthyroidism is associated with elevated SHBG levels, which increase the free estradiol–to–free testosterone ratio even though total testosterone and estradiol levels are often normal. *Drugs* can cause gynecomastia by acting directly as estrogenic substances (e.g., oral contraceptives, phytoestrogens, digitalis) or inhibiting androgen synthesis (e.g., GnRH agonists, ketoconazole) or action (e.g., spironolactone, AR blockers such as enzalutamide); for many drugs, such as cimetidine, imatinib, or some antiretroviral drugs for HIV, the precise mechanism is unknown. Unintentional exposure to estrogenic agents in skin care products has been reported as a cause of gynecomastia in prepubertal children.

Because up to two-thirds of pubertal boys and about half of hospitalized men have palpable glandular tissue that is benign, detailed investigation or intervention is not indicated in all men presenting with gynecomastia **(Fig. 403-7)**. In addition to the extent of gynecomastia, recent onset, rapid growth, tender tissue, and occurrence in a lean subject should prompt more extensive evaluation. This should include a careful drug history, examination of the testes, assessment

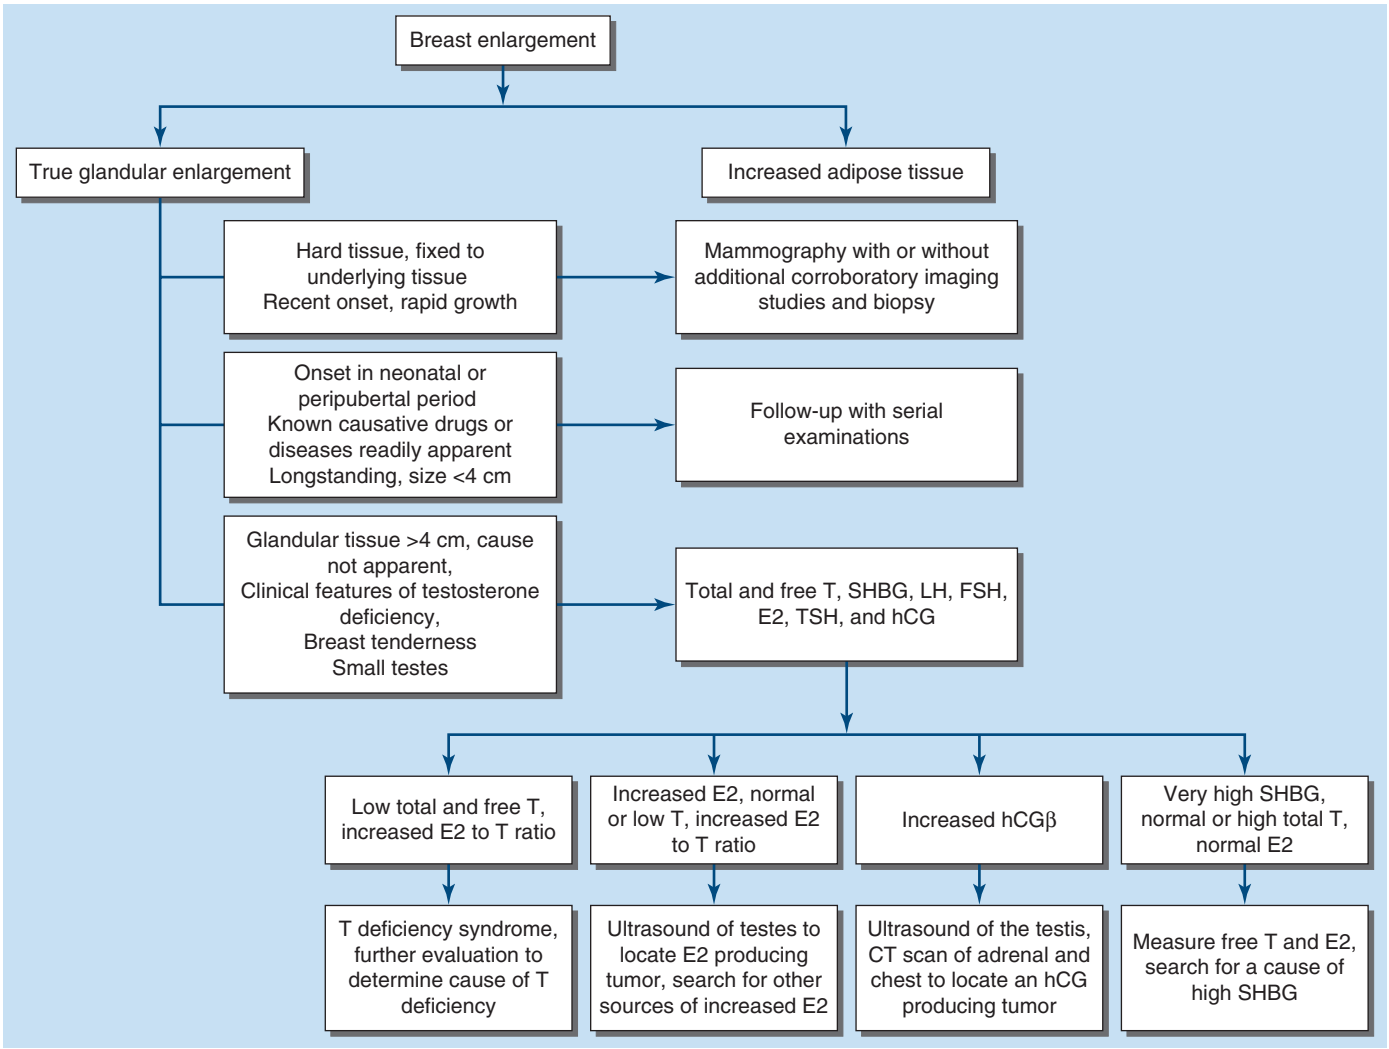

FIGURE 403-7 Evaluation of gynecomastia. E_2, 17β-estradiol; FSH, follicle-stimulating hormones; hCGβ, human chorionic gonadotropin β; LH, luteinizing hormone; T, testosterone.

of virilization, evaluation of liver function, and hormonal measurements including testosterone, estradiol, estrone, androstenedione, LH, and hCG. Markedly elevated estradiol concentrations along with suppressed LH should prompt a search for a testicular or adrenal estrogen-secreting tumor. A karyotype should be obtained in men with very small testes to exclude Klinefelter syndrome. Despite extensive evaluation, the etiology is established in only a small proportion of patients.

TREATMENT

Gynecomastia

When the primary cause can be identified and corrected shortly after the onset of gynecomastia, breast enlargement usually subsides over several months. However, if gynecomastia is of long duration, surgery is the most effective therapy. Indications for surgery include severe psychological distress, continued growth or tenderness, failure to respond to medical therapy, or suspected malignancy. In patients who have painful gynecomastia and in whom surgery cannot be performed, treatment with antiestrogens such as tamoxifen (20 mg/d) can reduce pain and breast tissue size in over half the patients. The estrogen receptor antagonists tamoxifen and raloxifene have been reported in small trials to reduce breast size in men with pubertal gynecomastia, although complete regression of breast enlargement is unusual with the use of estrogen receptor antagonists. Aromatase inhibitors can be effective in the early proliferative phase of the disorder. However, in a randomized trial in men with established gynecomastia, anastrozole proved no more effective than placebo in reducing breast size. Tamoxifen is effective in prevention and treatment of breast enlargement and breast pain in men with prostate cancer who are receiving androgen deprivation therapy. Long-standing gynecomastia is usually not responsive to drug therapy and requires mammoplasty if it is associated with pain and distress.

AGING-RELATED CHANGES IN MALE REPRODUCTIVE FUNCTION

A number of cross-sectional and longitudinal studies (e.g., the Baltimore Longitudinal Study of Aging, the Framingham Heart Study, the Massachusetts Male Aging Study, and the European Male Aging Study [EMAS]) have established that testosterone concentrations decrease with advancing age. This age-related decline starts in the third decade of life and progresses slowly; the rate of decline in testosterone concentrations is greater in men with obesity, chronic illness, and in those taking medications. Because SHBG concentrations are higher in older men than in younger men, free or bioavailable testosterone concentrations decline with aging to a greater extent than total testosterone concentrations. The age-related decline in testosterone is due to defects at all levels of the hypothalamic-pituitary-testicular axis: pulsatile GnRH secretion is attenuated, LH response to GnRH is reduced, and testicular response to LH is impaired. However, the gradual rise of LH with aging suggests that testis dysfunction is the main cause of declining androgen levels. The term *andropause* has been used to denote age-related decline in testosterone concentrations; this term is a misnomer because there is no discrete time when testosterone concentrations decline abruptly.

Several epidemiologic studies, such as the Framingham Heart Study, the EMAS, and the Study of Osteoporotic Fractures in Men (MrOS), that used mass spectrometry for measuring testosterone levels have reported ~10% prevalence of low testosterone levels in middle-aged and older men; the prevalence of unequivocally low testosterone and sexual symptoms in men aged 40–70 years in the EMAS was 2.1% and increased with age from 0.1% for men aged 40–49 years of age to 5.1% for those aged 70–79 years. Low total and bioavailable testosterone concentrations have been associated with decreased sexual desire, decreased appendicular skeletal muscle mass and strength, decreased self-reported physical function, higher whole body and visceral fat mass and insulin resistance, and increased risk of type 2 diabetes, coronary artery disease, and all-cause mortality. An analysis of signs and symptoms in older men in the EMAS revealed a syndromic association of sexual symptoms with total testosterone levels <320 ng/dL and free testosterone levels <64 pg/mL in community-dwelling older men.

Two placebo-controlled randomized trials—the Testosterone Trials (TTrials) and the Testosterone Replacement Therapy for Assessment of Long-Term Vascular Events and efficacy Response in Hypogonadal Men (TRAVERSE) study—have provided important information about the efficacy and safety of testosterone replacement therapy (TRT) in middle-aged and older men with hypogonadism. In these and other randomized trials, TRT of men with hypogonadism consistently improved sexual activity and sexual desire and alleviated hypogonadal symptoms. TRT also improves mood and energy level. TRT increases hemoglobin levels and corrects anemia in a greater proportion of middle-aged and older men with hypogonadism who have unexplained anemia, compared to placebo. Testosterone treatment significantly increases vertebral as well as femoral volumetric and areal bone mineral density and estimated bone strength. Testosterone treatment does not improve memory or other measures of cognition in men who do not have cognitive deficits. Testosterone treatment increases lean body mass, maximal voluntary muscle strength and muscle power, and self-reported mobility, and reduces whole body and visceral fat mass. In men with hypogonadism, testosterone treatment has not been shown to prevent progression from prediabetes to diabetes or induce glycemic remission in those with diabetes. In systematic reviews of randomized controlled trials, testosterone therapy of healthy older men with low or low-normal testosterone levels was associated with greater increments in lean body mass, grip strength, and self-reported physical function than that associated with placebo.

Neither the testosterone trials nor a randomized trial of the effects of testosterone on atherosclerosis progression in aging men (TEAAM trial) with low or low normal testosterone levels found significant differences between testosterone and placebo arms in the rates of change in either the coronary artery calcium scores or the common carotid artery intima-media thickness. However, in the TTrials, testosterone treatment was associated with a significantly greater increase in coronary artery noncalcified plaque volume, as measured by coronary artery computed tomography angiography. Neither of the trials was long enough or large enough to determine the effects of TRT on prostate or major adverse cardiovascular events.

The TRAVERSE trial compared the effects of TRT and placebo on major adverse cardiovascular events (MACE) in middle-aged and older men with hypogonadism and either preexisting cardiovascular disease (CVD) or increased risk of CVD. During a mean follow-up period of 33 months, the incidence of MACE did not differ between the testosterone and placebo groups. Testosterone treatment was associated with higher incidence of venous thromboembolism and atrial fibrillation than placebo. The incidences of high-grade prostate cancer (Gleason grade 4+3 or higher) or any prostate cancer, acute urinary retention, invasive surgical procedures for benign prostatic hyperplasia, and initiation of new pharmacologic therapy for benign prostatic hyperplasia were low and did not differ between the testosterone and placebo groups. Testosterone treatment was associated with significantly greater increase in serum prostate-specific antigen (PSA) level in the first 12 months of testosterone but the rate of change in PSA after 12 months of treatment was similar in the testosterone and placebo-treated men. Testosterone treatment did not worsen lower urinary tract symptoms. Testosterone treatment, by increasing PSA levels, could increase the risk of referral for prostate biopsy and detection of low-grade prostate cancer.

Population screening of all older men for low testosterone levels is not recommended, and testing should be restricted to men who have symptoms or signs attributable to androgen deficiency. Testosterone therapy is not recommended for all older men with low testosterone levels. In older men with significant symptoms of testosterone deficiency who have unequivocally low testosterone levels, testosterone treatment should be individualized based on consideration of the burden of symptoms, the presence of comorbid conditions that may increase the risk of harm from testosterone treatment, the risks versus benefits of treatment and monitoring, and clinician and patient values (see "Testosterone Replacement," below).

Testicular morphology, semen production, and fertility are maintained up to a very old age in men. Although concern has been expressed about age-related increases in germ cell mutations and impairment of DNA repair mechanisms, there is no clear evidence that the frequency of chromosomal aneuploidy is increased in the sperm of older men. However, the incidence of autosomal dominant diseases, such as achondroplasia, polyposis coli, Marfan syndrome, and Apert syndrome, increases in the offspring of men who are advanced in age, consistent with transmission of sporadic missense mutations. Advanced paternal age may be associated with increased rates of de novo mutations, which may contribute to an increased risk of neurodevelopmental diseases such as schizophrenia and autism. The somatic mutations in male germ cells that enhance the proliferation of germ cells could lead to within-testis expansion of mutant clonal lines, thus favoring the propagation of germ cells carrying these pathogenic mutations and increasing the risk of mutations in the offspring of older fathers (the "selfish spermatogonial selection" hypothesis).

APPROACH TO THE PATIENT

Testosterone Deficiency

Hypogonadism is often characterized by decreased sex drive, reduced frequency of sexual activity, inability to maintain erections, fatigue, low mood, hot flushes, reduced beard growth, loss of muscle mass, decreased testicular size, and gynecomastia. Erectile dysfunction and testosterone deficiency are two distinct clinical disorders that can coexist in middle-aged and older men. Some, but not all, patients with erectile dysfunction have testosterone deficiency. Thus, it is useful to evaluate men presenting with erectile dysfunction for testosterone deficiency. Except when extreme, these clinical features of testosterone deficiency may be difficult to distinguish from changes that occur with normal aging. Moreover, testosterone deficiency may develop gradually. When symptoms or clinical features suggest possible testosterone deficiency, the laboratory evaluation is initiated by the measurement of total testosterone in a fasting specimen, preferably in the morning using a reliable assay, such as LC-MS/MS, that has been calibrated to an international testosterone standard **(Fig. 403-8)**. A consistently low total testosterone level below the lower limit of the normal male range, measured by an LC-MS/MS assay in a CDC-certified laboratory, in association with symptoms, is evidence of testosterone deficiency. An early-morning testosterone level >400 ng/dL makes the diagnosis of androgen deficiency unlikely. In men with testosterone levels between 200 and 400 ng/dL, the total testosterone level should be repeated, and a free testosterone level should be measured. In older men and in patients with other clinical states that are associated with alterations in SHBG levels, a direct measurement of free testosterone level by equilibrium dialysis is needed to diagnose testosterone deficiency.

When testosterone deficiency has been confirmed by the consistently low testosterone concentrations, LH should be measured to determine whether the patient has primary (high LH) or secondary (low or inappropriately normal LH) hypogonadism. Elevated LH and FSH levels indicate a defect at the testicular level. Common causes of primary testicular failure include Klinefelter syndrome, HIV infection, uncorrected cryptorchidism, cancer chemotherapeutic agents, radiation, surgical orchiectomy, or prior infectious orchitis. A karyotype should be performed in men with low testosterone and elevated LH to diagnose Klinefelter syndrome. Men who have a low testosterone but "inappropriately normal" or low LH levels have secondary hypogonadism; their defect resides at the hypothalamic-pituitary level. Common causes of acquired secondary hypogonadism include space-occupying lesions of the sella,

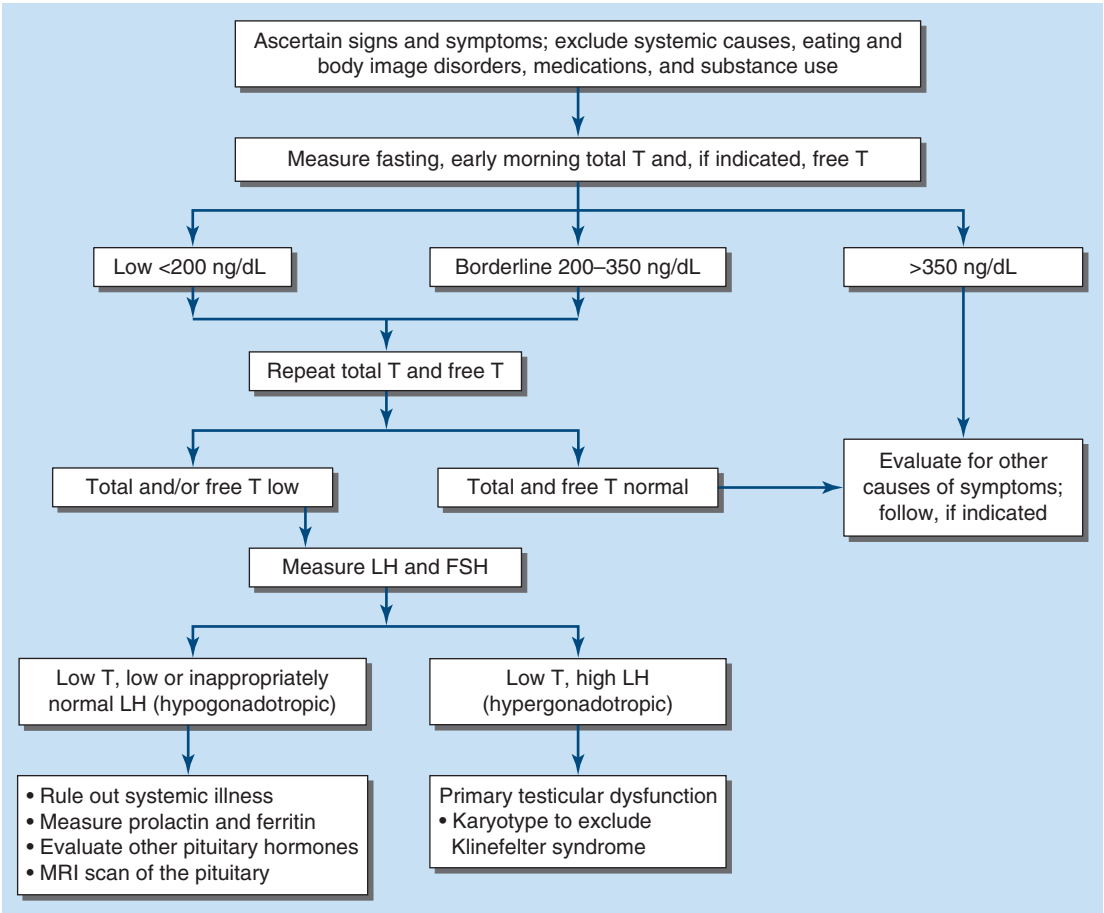

FIGURE 403-8 Evaluation of hypogonadism. FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; LH, luteinizing hormone; T, testosterone.

hyperprolactinemia, chronic illness, hemochromatosis, excessive exercise, and the use of anabolic-androgenic steroids, opioids, marijuana, glucocorticoids, and alcohol. Measurement of PRL and MRI scan of the hypothalamic-pituitary region can help exclude the presence of a space-occupying lesion. Patients in whom known causes of hypogonadotropic hypogonadism have been excluded are classified as having IHH. It is not unusual for congenital causes of hypogonadotropic hypogonadism, such as Kallmann syndrome, to be diagnosed in young adults.

TREATMENT

Testosterone Deficiency

GONADOTROPINS

Gonadotropin therapy is used to establish or restore fertility in patients with gonadotropin deficiency of any cause. Several gonadotropin preparations are available. Human menopausal gonadotropin (hMG; purified from the urine of postmenopausal women) contains 75 IU of FSH and 75 IU of LH per vial. hCG (purified from the urine of pregnant women) has minimal FSH activity and resembles LH in its ability to stimulate testosterone production by Leydig cells. Recombinant LH is also available, but its half-life is relatively short (10 h). Treatment is usually begun with hCG alone. If hCG alone does not induce spermatogenesis, hMG is added to promote the FSH-dependent stages of spermatid development. Recombinant human FSH (hFSH) is available and is indistinguishable from purified urinary hFSH in its biologic activity and pharmacokinetics in vitro and in vivo, although the mature β subunit of recombinant hFSH has seven fewer amino acids. Recombinant hFSH is available in ampoules containing 75 IU (~7.5 μg FSH), which accounts for >99% of protein content. Once spermatogenesis is restored using combined FSH and LH therapy, hCG alone is often sufficient to maintain spermatogenesis.

Although a variety of treatment regimens are used, 1500 IU of hCG administered intramuscularly three times weekly is a reasonable starting dose. Testosterone levels should be measured 6–8 weeks later and 48–72 h after the hCG injection; the hCG dose should be adjusted to achieve testosterone levels in the mid-normal range. Sperm counts should be monitored on a monthly basis. It may take several months for spermatogenesis to be restored; therefore, it is important to forewarn patients about the potential length and expense of the treatment and to provide conservative estimates of success rates. If testosterone levels are in the mid-normal range but the sperm concentrations are low after 6 months of therapy with hCG alone, FSH should be added. This can be done by using hMG, highly purified urinary hFSH, or recombinant hFSH. A common practice is to start with the addition of 75 IU FSH three times each week in conjunction with the hCG injections. If sperm densities are still low after 3 months of combined treatment, the FSH dose should be increased to 150 IU. Occasionally, it may take ≥18–24 months for spermatogenesis to be restored.

The two best predictors of the success of gonadotropin therapy in hypogonadotropic men are testicular volume at presentation and time of onset of gonadotropin deficiency. In general, men with testicular volumes >8 mL have better response rates than those who have testicular volumes <4 mL. Patients who develop gonadotropin deficiency after puberty experience higher success rates than those who have never undergone pubertal changes. Spermatogenesis can usually be reinitiated by hCG alone, with high rates of success for men with postpubertal onset of hypogonadotropism. The presence of a primary testicular abnormality, such as cryptorchidism, will attenuate testicular response to gonadotropin therapy. Prior testosterone therapy does not preclude subsequent response to gonadotropin therapy, although some studies suggest that it may attenuate response to subsequent gonadotropin therapy.

TESTOSTERONE REPLACEMENT

TRT is indicated to restore testosterone levels to normal and correct features of testosterone deficiency in men with hypogonadism. TRT induces secondary sex characteristics; improves libido and overall sexual activity; relieves symptoms of hypogonadism; improves mood and energy level; increases skeletal muscle mass, muscle strength and power, and some measures of physical function; hemoglobin and hematocrit; and volumetric and areal bone mineral density; corrects the mild anemia associated with testosterone deficiency; and decreases fat mass. The benefits of TRT have only been proven in men with confirmed hypogonadism, as demonstrated by testosterone levels that are below the lower limit of normal and one or more symptoms of hypogonadism.

Testosterone is available in a variety of formulations with distinct pharmacokinetics **(Table 403-3)**. Testosterone serves as a prohormone and is converted to 17β-estradiol by aromatase and to 5α-DHT by steroid 5α-reductase. Therefore, when evaluating testosterone formulations, it is important to consider whether the formulation being used can achieve physiologic estradiol and DHT concentrations, in addition to normal testosterone concentrations. The current recommendation is to restore testosterone levels to the mid-normal range.

Oral Derivatives of Testosterone Testosterone is well absorbed after oral administration but is quickly degraded during the first pass through the liver. Therefore, it is difficult to achieve sustained blood levels of testosterone after oral administration of crystalline testosterone. 17α-Alkylated derivatives of testosterone (e.g., 17α-methyl testosterone, oxandrolone, fluoxymesterone) are relatively resistant to hepatic degradation and can be administered orally; however, because of the potential for hepatotoxicity, including cholestatic jaundice, peliosis, and hepatocellular neoplasms, these formulations should not be used for testosterone replacement. Hereditary angioedema due to C1 esterase deficiency is the only exception to this general recommendation; in this condition, oral 17α-alkylated androgens are useful because they stimulate hepatic synthesis of the C1 esterase inhibitor.

Injectable Forms of Testosterone The esterification of testosterone at the 17β-hydroxy position makes the molecule hydrophobic and extends its duration of action. The slow release of testosterone ester from an oily depot in the muscle accounts for its extended duration of action. The longer the side chain, the greater is the hydrophobicity of the ester and longer the duration of action. Thus, testosterone enanthate, cypionate, and undecanoate with longer side chains have longer durations of action than testosterone propionate. Within 24 h after intramuscular administration of 200 mg testosterone enanthate or cypionate, testosterone levels rise into the high-normal or supraphysiologic range and then gradually decline into the hypogonadal range over the next 2 weeks. A bimonthly regimen of testosterone enanthate or cypionate therefore results in peaks and troughs in testosterone levels that may be accompanied by changes in a patient's mood, sexual desire, and energy level; weekly administration of testosterone enanthate or cypionate can reduce these variations in testosterone levels during the dosing interval. The kinetics of testosterone enanthate and cypionate are similar. Estradiol and DHT levels are normal if testosterone replacement is physiologic.

A long-acting testosterone undecanoate in oil, administered at an initial priming dose of 750 mg intramuscularly followed by a second dose of 750 mg 4 weeks later, and then at a maintenance dose of 750 mg every 10 weeks, maintains serum testosterone, estradiol, and DHT in the normal male range and corrects symptoms of testosterone deficiency in a majority of treated men. Its relative drawbacks are the large injection volume and the risk of pulmonary oil microembolism (POME) reaction in a small proportion of patients.

Testosterone Gel Several transdermal testosterone gels, such as Androgel, Testim, Fortesta, and Axiron, and some generic versions, when applied topically to the skin in appropriate doses (Table 403-3), can maintain total and free testosterone concentrations in the normal range in men with hypogonadism. The current

TABLE 403-3 Clinical Pharmacology of Some Testosterone Formulations

FORMULATION	REGIMEN	PHARMACOKINETIC PROFILE	DHT AND E2	ADVANTAGES	DISADVANTAGES
T enanthate or cypionate	140–200 mg IM q2wk or 70–100 mg/wk	After a single IM injection, serum T levels rise into the supraphysiologic range, then decline gradually into the low-normal or the hypogonadal range by the end of the dosing interval	DHT and E2 levels rise in proportion to the increase in T levels; T:DHT and T:E2 ratios do not change	Corrects symptoms of testosterone deficiency; relatively inexpensive if self-administered; flexibility of dosing	Requires IM injection; peaks and valleys in serum T levels that are associated with fluctuations in patient's mood, energy level, and sex drive
Topical T gels	Available in sachets, tubes, and pumps	When used in appropriate doses, these topical formulations restore serum T and E2 levels to the physiologic male range	Serum DHT levels and DHT:T ratio are higher in hypogonadal men treated with the transdermal gels than in healthy eugonadal men	Corrects symptoms of testosterone deficiency, ease of application, good skin tolerability	Potential of transfer to a female partner or child by direct skin-to-skin contact; skin irritation in a small proportion of treated men; moderately high DHT levels; considerable interindividual and intraindividual variation in on-treatment testosterone levels
T pellets	Several pellets implanted SC; dose and regimen vary with formulation	Serum T peaks at 1 month and then is sustained in normal range for 3–4 months, depending on formulation	T:DHT and T:E2 ratios do not change	Corrects symptoms of testosterone deficiency	Requires surgical incision for insertions; pellets may extrude spontaneously
Oral T undecanoate (TU)	Two different formulations of oral testosterone are available each taken orally bid with food	TU formulated in a self-emulsifying drug delivery system that includes hydrophilic and lipophilic excipients to enable the solubilization of TU and its absorption through the lymphatics after oral ingestion with a typical meal. After each administration, serum T levels rise and return to baseline by 12 h. When administered at the recommended dose, average serum T levels are maintained in the normal range in a majority of treated men	High DHT:T ratio	Convenience of oral administration	High DHT:T ratio
Injectable long-acting TU in oil	U.S. regimen 750 mg IM, followed by 750 mg at 4 weeks, and 750 mg every 10 weeks	When administered at the recommended dose, serum T levels are maintained in the normal range in a majority of treated men	DHT and E2 levels rise in proportion to the increase in T levels; T:DHT and T:E2 ratios do not change	Corrects symptoms of testosterone deficiency; requires infrequent administration	Requires IM injection of a large volume; serious pulmonary oil microembolism (POME) reactions, characterized by cough, dyspnea, throat tightening, chest pain, dizziness, and syncope, and episodes of anaphylaxis have been reported to occur during or immediately after the injection in a very small number of patients; patients should be watched for POME reaction for 30 min after each injection
Intranasal T	2 actuations of the metered-dose pump (11 mg) applied into the nostrils 3 times daily	Restores T into the normal male range	T:DHT and T:E2 ratio in the physiologic range		Requires 3 times daily application; nasal irritation, epistaxis, nasopharyngitis

Abbreviations: DHT, dihydrotestosterone; E2, estradiol; T, testosterone.

recommendations are to begin with an initial U.S. Food and Drug Administration–recommended dose and adjust the dose based on testosterone and hematocrit levels. The advantages of the testosterone gel include the ease of application. A major concern is the potential for transfer of the gel to a sexual partner or to children who may come in close contact with the patient. The ratio of DHT to testosterone concentrations is higher in men treated with the testosterone gel than in healthy men. Also, there is considerable intra- and interindividual variation in serum testosterone levels in men treated with the transdermal gel due to variations in transdermal absorption and plasma clearance of testosterone. Therefore, monitoring of serum testosterone levels and multiple dose adjustments are required to achieve and maintain testosterone levels in the target range.

Pellets of crystalline testosterone can be inserted in the subcutaneous tissue through a small skin incision. Testosterone is released by surface erosion of the implanted pellets and absorbed into the systemic circulation, and testosterone levels can be maintained in the normal range for 3–4 months. Potential drawbacks include the need for skin incision for insertion and removal and spontaneous extrusions and fibrosis at the insertion.

Testosterone undecanoate, formulated in a self-emulsifying drug delivery system that includes hydrophilic and lipophilic excipients to enable its solubilization in the gut, is absorbed through the lymphatics after oral ingestion with a fatty meal and is spared the first-pass degradation in the liver. After each administration, serum testosterone levels rise and return to baseline by 12 h. When administered at the recommended dose, average serum testosterone levels are maintained in the normal range in a majority of treated men, but DHT-to-testosterone ratios are higher in men with hypogonadism treated with oral testosterone undecanoate, as compared to eugonadal men.

An intranasal testosterone gel is available as a metered-dose pump and is administered typically at a starting dose of 11 mg testosterone in the form of two pump actuations, one in each nostril three times daily. Formulation-specific adverse effects include rhinorrhea, nasal discomfort, epistaxis, nasopharyngitis, and nasal scab.

Novel Androgen Formulations Selective AR modulators (SARMs) are a class of AR ligands that bind the AR and display tissue-selective actions. A number of nonsteroidal SARMs that act as

agonists on the muscle and bone and that spare the prostate to varying degrees have advanced to phase 3 human trials. Nonsteroidal SARMs do not serve as substrates for either the steroid 5α-reductase or the CYP19 (aromatase). SARM binding to AR induces specific conformational changes in the AR protein, which then modulates protein–protein interactions between AR and its coregulators, resulting in tissue-specific regulation of gene expression. SARMs that are strong agonists for the muscle, bone, and sexual function and antagonists for the prostate may be valuable in treating men with prostate cancer who are receiving androgen deprivation therapy. 7α-Methyl-19-nortestosterone is an androgen that cannot be 5α-reduced; therefore, compared to testosterone, it has relatively greater agonist activity in muscle and gonadotropin suppression but lesser activity on the prostate.

Pharmacologic Uses of Androgens Androgens and SARMs are being evaluated as anabolic therapies for functional limitations associated with aging and chronic illness. Testosterone supplementation increases skeletal muscle mass, maximal voluntary strength, and muscle power in healthy men, hypogonadal men, older men with low testosterone levels, HIV-infected men with weight loss, and men receiving glucocorticoids. These anabolic effects of testosterone are related to testosterone dose and circulating concentrations. Systematic reviews have confirmed that testosterone therapy of HIV-infected men with weight loss promotes improvements in body weight, lean body mass, muscle strength, and depression indices, leading to the recommendation that testosterone may be considered as an adjunctive therapy in HIV-infected men who are experiencing unexplained weight loss and who have low testosterone levels. It is unknown whether testosterone therapy of older men with functional limitations is safe and effective in improving physical function and reducing disability.

Testosterone administration induces hypertrophy of both type 1 and 2 fibers and increases satellite cell (muscle progenitor cells) and myonuclear number. Androgens promote the differentiation of mesenchymal, multipotent progenitor cells into the myogenic lineage and inhibit their differentiation into the adipogenic lineage. Testosterone binding to AR promotes the association of liganded AR with β-catenin and its translocation into the nucleus where it binds TCF-4 and activates Wnt-target genes, including follistatin, which blocks signaling through the transforming growth factor β pathway, thereby promoting myogenic differentiation of muscle progenitor cells. Testosterone may have additional effects on satellite cell replication and polyamine pathway, which may contribute to an increase in skeletal muscle mass.

Other indications for androgen therapy are in selected patients with anemia due to bone marrow failure (an indication largely supplanted by erythropoietin) and hereditary angioedema.

Recommended Regimens for Testosterone Replacement Therapy Testosterone esters are administered typically at doses of 70–100 mg intramuscularly every week or 140–200 mg every 2 weeks. Testosterone undecanoate is administered at an initial dose of 750 mg followed 4 weeks later by a second injection of 750 mg and then 750 mg every 10 weeks. Testosterone gels are typically applied over a covered area of skin at initial doses that vary with the formulation. Patients should wash their hands after gel application and keep the area of gel application covered with clothing to minimize the risk of gel transfer to another person. Oral testosterone undecanoate is taken with meals at a starting dose of 237 mg twice daily. Intranasal testosterone is administered as a spray in each nostril three times a day (33 mg/d).

Evaluating Efficacy of Testosterone Replacement Therapy The goals of TRT are to restore serum testosterone levels into the mid-normal range for healthy young men, correct symptoms of hypogonadism, and induce and maintain secondary sex characteristics. Testosterone should be measured 3 months after initiating therapy to assess adequacy of therapy. There is substantial interindividual variability in serum testosterone levels, especially with transdermal gels, presumably due to genetic differences in testosterone clearance and substantial variation in transdermal absorption. In patients who are treated with testosterone enanthate or cypionate, testosterone levels should be 350–550 ng/dL 1 week after the injection. If testosterone levels are outside this range, adjustments should be made either in the dose or in the interval between injections. In men on transdermal testosterone patch or gel, testosterone levels should be in the mid-normal range (400–750 ng/dL) 4–12 h after application. If testosterone levels are outside this range, the dose should be adjusted. Multiple dose adjustments are often necessary to achieve testosterone levels in the desired therapeutic range.

Restoration of sexual function, induction and maintenance of secondary sex characteristics, well-being, and maintenance of muscle and bone health are important objectives of TRT. The patient should be asked about sexual desire and activity, the presence of early morning erections, and the ability to achieve and maintain erections adequate for sexual intercourse. The hair growth in response to androgen replacement is variable and depends on ethnicity. Men with prepubertal onset of testosterone deficiency who begin testosterone therapy in their late twenties or thirties may find it difficult to adjust to their newly found sexuality and may benefit from counseling. If the patient has a sexual partner, the partner should be included in counseling because of the dramatic physical and sexual changes that occur with TRT.

Contraindications for Testosterone Administration Testosterone administration is contraindicated in men with prostate or breast cancer **(Table 403-4)**. Testosterone therapy should not be administered without further urologic evaluation to men with a palpable prostate nodule or induration, a PSA >3 ng/mL, or severe lower urinary tract symptoms (American Urological Association lower urinary tract symptom score >19). Testosterone should not be administered to men with a hypercoagulable condition, baseline hematocrit ≥50%, severe untreated obstructive sleep apnea, or uncontrolled or poorly controlled congestive heart failure, or with myocardial infarction, stroke, or acute coronary syndrome in the preceding 4 months.

Monitoring Potential Adverse Experiences The clinical effectiveness and safety of TRT should be assessed 3–6 months after initiating testosterone therapy and annually thereafter **(Table 403-5)**. Potential adverse effects include acne, oiliness of skin, erythrocytosis, venous thromboembolism, breast tenderness, leg edema, and increased risk of detection of prostate events. In addition, there may be formulation-specific adverse effects such as skin irritation with transdermal patch; risk of gel transfer to a sexual partner with testosterone gels; pain and mood fluctuation with injectable testosterone esters; cough and injection site pain with long-acting

TABLE 403-4 Conditions in Which Testosterone Administration Should not be Used or Used with Increased Caution

Conditions in which testosterone administration is associated with very high risk of serious adverse outcomes:
Metastatic prostate cancer
Some types of breast cancers
Thrombophilia
Conditions in which testosterone administration is associated with moderate to high risk of adverse outcomes and should be used with increased caution and only after further evaluation
Undiagnosed prostate nodule or induration
PSA >3
Erythrocytosis (hematocrit >50%)
Severe lower urinary tract symptoms associated with benign prostatic hypertrophy as indicated by American Urological Association/International prostate symptom score >19
Uncontrolled or poorly controlled congestive heart failure
Myocardial infarction, stroke, or acute coronary syndrome in the preceding 4 months

Abbreviation: PSA, prostate-specific antigen.

TABLE 403-5 Monitoring Men Receiving Testosterone Therapy

1. Evaluate the patient 3–6 months after treatment initiation and then annually to assess whether symptoms have responded to treatment and whether the patient is suffering from any adverse effects.
2. Monitor testosterone level 3–6 months after initiation of testosterone therapy:
   - Therapy should aim to raise average serum testosterone level into the mid-normal range (~400–750 ng/dL).
     - Injectable testosterone enanthate or cypionate: Measure serum testosterone level midway between injections. If testosterone is >750 ng/dL (26.2 nmol/L) or <400 ng/dL (14.0 nmol/L), adjust dose or frequency.
     - Transdermal gels and solution: Assess testosterone level 2–12 h after patient has been on treatment for at least 2 weeks; adjust dose to achieve serum testosterone level in the mid-normal range (400–750 ng/dL).
     - Testosterone pellets: Measure testosterone levels at the end of the dosing interval. Adjust the number of pellets and/or the dosing interval to achieve serum testosterone levels in the normal range.
     - Oral testosterone undecanoate: Measure testosterone levels 6–8 h after an oral dose.
     - Injectable testosterone undecanoate: Measure serum testosterone level just prior to each subsequent injection and adjust the dosing interval to maintain serum testosterone in mid-normal range.
3. Check hematocrit at baseline, at 3–6 months, and then annually. If hematocrit is >54%, stop therapy until hematocrit decreases to a safe level; evaluate the patient for hypoxia and sleep apnea; reinitiate therapy with a reduced dose.
4. Measure bone mineral density of lumbar spine and/or femoral neck after 1–2 years of testosterone therapy in hypogonadal men with osteoporosis or low trauma fracture, consistent with regional standard of care.
5. In men aged ≥55 years, perform digital rectal examination and check PSA level before initiating treatment, at 3–6 months, and then in accordance with guidelines for prostate cancer screening depending on the age and race of the patient.
6. Obtain urologic consultation if there is:
   - An increase in serum PSA concentration >1.4 ng/mL within the first 12 months after starting testosterone treatment, confirmed by repeating the test.
   - A PSA level >4 ng/mL any time during treatment, confirmed by repeating the test.
   - Detection of a prostatic abnormality on digital rectal examination.
   - Severe lower urinary tract symptoms
7. Evaluate formulation-specific adverse effects at each visit:
   - Injectable testosterone esters (enanthate, cypionate, and undecanoate): Ask about fluctuations in mood or libido, and rarely cough after injections.
   - Testosterone gels: Advise patients to cover the application sites with a shirt and to wash the skin with soap and water before having skin-to-skin contact because testosterone gels leave a testosterone residue on the skin that can be transferred to a woman or child who might come in close contact. Serum testosterone levels are maintained when the application site is washed 4–6 h after application of the testosterone gel.
   - Testosterone undecanoate injection: Observe patients for POME reaction for 30 min after each injection.
   - Testosterone pellets: Look for signs of infection, fibrosis, or pellet extrusion.
   - Intranasal testosterone: Look for signs of nasal irritation or scab.

Abbreviations: AUA/IPSS, American Urological Association International Prostate Symptom Score; POME, pulmonary oil microembolism; PSA, prostate-specific antigen.

testosterone undecanoate; and nasal irritation, epistaxis, and nasal scab with intranasal formulation. In the TRAVERSE trial, a randomized controlled trial of TRT in middle-aged and older men with hypogonadism, TRT was associated with increased risk of atrial fibrillation, acute kidney injury, and bone fractures.

Hemoglobin Levels Administration of testosterone to men with hypogonadism is typically associated with only a small (~3%) increase in hemoglobin levels, due to direct effects of testosterone on hematopoietic progenitors in the bone marrow, stimulation of erythropoietin, suppression of hepcidin, and increased iron availability for erythropoiesis. The magnitude of hemoglobin increase during TRT is greater in older men than younger men and in men who have sleep apnea, a significant smoking history, or chronic obstructive lung disease or who live at high altitude. The frequency of erythrocytosis is higher in men with hypogonadism treated with injectable testosterone esters than in those treated with transdermal formulations, presumably due to the higher testosterone dose delivered by the typical regimens of testosterone esters. Erythrocytosis is a frequent adverse event reported in testosterone trials in middle-aged and older men and is also the most frequent cause of treatment discontinuation in these trials. If hematocrit rises above 54%, testosterone therapy should be stopped until hematocrit has fallen to <50%. After evaluation of the patient for hypoxia and sleep apnea, testosterone therapy may be reinitiated at a lower dose.

Prostate and Serum PSA Levels TRT increases prostate volume to the size seen in age-matched controls. In the TRAVERSE trial, the incidences of high-grade or any prostate cancer were low and did not differ between the testosterone- and placebo-treated men. The incidences of acute urinary retention, invasive surgical procedure for benign prostatic hyperplasia, prostate biopsy, or initiation of new pharmacologic therapy for benign prostatic hyperplasia also were similar in the testosterone and placebo groups. Testosterone treatment did not worsen lower urinary tract symptoms. There is no evidence that TRT causes prostate cancer. However, testosterone treatment can exacerbate preexisting metastatic prostate cancer. Many older men harbor microscopic foci of cancer in their prostates. It is not known whether long-term TRT will induce these microscopic foci to grow into clinically significant cancers.

PSA levels are lower in testosterone-deficient men and increase after initiation of TRT. An increase in PSA levels after starting TRT can lead to urologic referral, increased risk of prostate biopsy, and detection of a low-grade prostate cancer that is common among middle-aged and older men. Increments in PSA levels after testosterone supplementation in androgen-deficient men are generally <0.5 ng/mL, and increments >1.0 ng/mL over a 3- to 6-month period are unusual. The 90% confidence interval for the change in PSA values in men with benign prostatic hyperplasia, measured 3–6 months apart, is 1.4 ng/mL. Therefore, the Endocrine Society expert panel suggested that an increase in PSA >1.4 ng/mL in the first year after starting TRT, if confirmed, should lead to urologic evaluation. There is considerable test-retest variability in PSA measurements. Therefore, PSA elevations after starting TRT should be confirmed by repeating the PSA test no sooner than 4 weeks after the first test. PSA level >4 ng/mL at any time during treatment, if confirmed by repeat testing, requires further urologic evaluation. Because prostate biopsy has the potential for harm (infection, bleeding, and diagnosis of a low-grade prostate cancer), the institution of PSA monitoring and urologic referral for a prostate biopsy should be a shared decision of the patient and the clinician.

Cardiovascular Risk In 2015, the U.S. Food and Drug Administration (FDA), because of concerns about the cardiovascular risk of TRT, required the testosterone manufacturers to conduct a randomized controlled trial to compare the effects of TRT versus placebo on cardiovascular events. The TRAVERSE trial, a large prospective randomized controlled trial, conducted in response to the FDA's requirement, has provided strong evidence that testosterone treatment does not increase the risk of major cardiovascular events (death due to cardiovascular cause, nonfatal myocardial infarction, or nonfatal stroke) relative to placebo treatment in middle-aged and older men with hypogonadism and preexisting cardiovascular disease or increased risk of cardiovascular disease during a mean follow-up duration of 33 months. The incidence of a secondary composite cardiovascular endpoint that included death due to cardiovascular cause, nonfatal myocardial infarction, nonfatal stroke, or coronary revascularization procedure also did not differ between the testosterone and placebo groups. Testosterone-treated men experienced higher rates of venous thromboembolic events, nonfatal arrythmias clinical bone fractures, and acute kidney injury than placebo-treated men. The TRAVERSE trial also found a small

but statistically significantly greater increase in blood pressure in the testosterone than in the placebo group, similar to the findings of some other studies.

Androgen Use by Athletes and Recreational Bodybuilders The illicit use of androgenic-anabolic steroids (AAS) to enhance athletic performance first surfaced in the 1950s among powerlifters and spread rapidly to other sports, professional as well as high school athletes, and recreational bodybuilders. In the early 1980s, the use of AAS spread beyond the athletic community into the general population, and now, as many as 3–4 million Americans—most of them men—have likely used these compounds. Most AAS users are not athletes, but rather recreational weightlifters, almost all men, who use these drugs to look lean and more muscular. A subset of AAS users suffers from muscle dysmorphia, a form of body image disorder characterized by excessive preoccupation with leanness and muscularity and poor functioning in social and occupational life. A secular transformation of idealized body image toward greater muscularity and leanness has contributed to increasing prevalence of body image disorders and the use of muscle-building anabolic drugs in young men.

The most commonly used AAS include testosterone esters, nandrolone, trenbolone, stanozolol, methandienone, boldenone, and methenolone. AAS users generally use large doses of multiple steroids in cycles, a practice known as stacking. AAS users may also typically use other drugs that are perceived to be muscle building or performance enhancing, such as human GH; erythropoiesis-stimulating agents; insulin; stimulants such as amphetamine, clenbuterol, cocaine, ephedrine, and thyroxine; and drugs perceived to reduce adverse effects such as hCG, aromatase inhibitors, or estrogen antagonists. Recent years have witnessed increasing use of unapproved nonsteroidal SARMs and GH secretagogues purchased from internet sites.

Most of the information about the adverse effects of AAS has emerged from case reports, uncontrolled studies, or clinical trials that used replacement doses of testosterone. The adverse event data from clinical trials using physiologic replacement doses of testosterone have been extrapolated unjustifiably to AAS users, who may administer 10–100 times the replacement doses of testosterone over many years, to support the claim that AAS use is safe and manageable. The adverse events associated with AAS use may be due to AAS themselves, concomitant use of other drugs, high-risk behaviors, and host characteristics that may render these individuals more susceptible to AAS use or to other high-risk behaviors.

Four categories of adverse events associated with AAS abuse are of particular concern: cardiovascular events, psychiatric disorders, prolonged suppression of the hypothalamic-pituitary-testicular axis, and potential neurotoxicity. The high rates of premature mortality observed in AAS users are alarming. One Finnish study reported 4.6 times the risk of death among elite powerlifters compared with age-matched men from the general population. The causes of death among powerlifters included suicides, myocardial infarction, and liver failure. A retrospective review of patient records in Sweden also reported higher standardized mortality ratios for AAS users than for nonusers and increased death rates due to suicide, homicide, and accidents. High doses of AAS may induce proatherogenic dyslipidemia, accelerate atherogenesis, increase thrombosis risk via effects on clotting factors and platelets, and induce vasospasm through their effects on vascular nitric oxide. Long-term AAS use may be associated with myocardial hypertrophy and fibrosis. Myocardial tissue of powerlifters using AAS has been shown to be infiltrated with fibrous tissue and fat droplets. Current AAS users display significantly reduced left ventricular systolic and diastolic function compared to previous users and nonusers. Additionally, studies using CT angiography have reported higher coronary artery plaque volume in AAS users than in nonusers. Lifetime AAS dose is strongly associated with coronary atherosclerotic burden. Power athletes using AAS often have short QT intervals but increased QT dispersion, which may predispose them to ventricular arrhythmias.

Unlike replacement doses of testosterone, which are associated with only a small decrease in high-density lipoprotein (HDL) cholesterol and little or no effect on total cholesterol, low-density lipoprotein (LDL) cholesterol, and triglyceride levels, supraphysiologic doses of testosterone and orally administered 17α-alkylated, nonaromatizable AAS are associated with marked reductions in HDL cholesterol and increases in LDL cholesterol.

Some AAS users develop hypomanic and manic symptoms (irritability, aggressiveness, reckless behavior, and occasional psychotic symptoms, sometimes associated with violence) during AAS exposure, and depression, sometimes associated with suicidality, during AAS withdrawal. Users may also be susceptible to other forms of illicit drug use.

Long-term AAS use suppresses LH, FSH, and testosterone levels and spermatogenesis. Men who have used AAS for more than a few months experience marked suppression of the hypothalamic-pituitary-testicular (HPT) axis after stopping AAS that may be associated with sexual dysfunction, fatigue, infertility, depressed mood, and even suicidality. In some long-term AAS users, recovery of the HPT axis may take a long time, may be incomplete, or may never occur. The symptoms of testosterone deficiency caused by AAS withdrawal may cause some men to revert back to using AAS, leading to continued use and AAS dependence. As many as 30% of AAS users develop a syndrome of AAS dependence, characterized by long-term AAS use despite adverse medical and psychiatric effects. AAS withdrawal hypogonadism has emerged as an important cause of androgen deficiency, accounting for a substantial fraction of testosterone prescriptions in many men's health clinics; therefore, AAS use should be considered in the differential diagnosis of hypogonadism in young men.

Supraphysiologic doses of testosterone may also impair insulin sensitivity. Orally administered androgens also have been associated with insulin resistance and diabetes.

AAS users are more likely to engage in high-risk behaviors such as unsafe injection practices and have increased rates of incarceration that may render them at increased risk of HIV and hepatitis B and C. AAS users are more likely to report high-risk unprotected anal sex than nonusers.

Elevated liver enzymes, cholestatic jaundice, hepatic neoplasms, and peliosis hepatis have been reported with oral, 17α-alkylated AAS. AAS use may cause muscle hypertrophy without compensatory adaptations in tendons, ligaments, and joints, thus increasing the risk of tendon, ligament, and joint injuries. Upper extremity tendon ruptures are observed predominantly among weightlifters who use AAS. AAS use is associated with acne, baldness, and increased body hair.

APPROACH TO THE PATIENT

Androgenic-Anabolic Steroids Use

The suspicion of AAS use should be raised by increased hemoglobin and hematocrit levels, suppressed LH and FSH and testosterone levels, low HDL cholesterol and SHBG levels, and low testicular volume and sperm density in a person who looks highly muscular. In AAS users seeking medical attention, evaluation using the Appearance and Performance Enhancing Drug Use Schedule (APEDUS), a validated semi-structured interview, is sufficient to assess the associated body image or eating disorder, psychiatric symptoms, and the use of AAS and other substances; formal testing for AAS usually is rarely needed in clinical practice. History of AAS use should be obtained in all young men being evaluated for hypogonadism. As AAS use is often associated with the use of other substances, a urine dug screen for other substances is helpful in guiding treatment. If needed, accredited laboratories use gas chromatography–mass spectrometry or liquid chromatography–tandem mass spectrometry to detect anabolic steroid abuse. High-resolution mass spectrometry and tandem mass spectrometry have improved the sensitivity of

detecting AAS use. Illicit testosterone use is detected generally by the measurement of urinary testosterone-to-epitestosterone ratio and further confirmed by the ^{13}C:^{12}C ratio in testosterone using isotope ratio combustion mass spectrometry. Exogenous testosterone administration increases urinary testosterone glucuronide excretion and consequently the testosterone-to-epitestosterone ratio. Ratios >6 are highly suggestive of exogenous testosterone use but can also reflect genetic variation. Genetic variations in uridine diphospho-glucuronyltransferase 2B17 (*UGT2B17*), the major enzyme for testosterone glucuronidation, affect the testosterone-to-epitestosterone ratio. Synthetic testosterone has a lower ^{13}C:^{12}C ratio than endogenously produced testosterone, and these differences in ^{13}C:^{12}C ratio can be detected by isotope ratio combustion mass spectrometry, which is used to confirm exogenous testosterone use in individuals with a high testosterone-to-epitestosterone ratio.

The treatment of AAS use disorder requires a multidisciplinary team that includes an endocrinologist or an internist to treat the AAS withdrawal hypogonadism and other medical problems; a mental health expert to treat the substance use disorder and depressive symptoms and to address suicide risk and body image disorder; and sometimes a social worker for care coordination. In patients who are willing to stop or who have already stopped AAS use, the initial step is to restore the hypothalamic-pituitary-gonadal axis by administering either clomiphene (or its enantiomer trans enclomiphene), a partial estrogen agonist, at an initial dose of 50 mg daily or hCG at a dose of 1000–2000 IU three times weekly. Some men may not respond to clomiphene and may require hCG. AAS users also need evaluation and treatment of the underlying body image disorder. Mirror exposure therapy in which the patient stands in front of a mirror and describes his body appearance to the mental health provider has been moderately efficacious in small, randomized trials. Body dysmorphia may require cognitive-behavioral therapy or pharmacotherapy using selective serotonin uptake inhibitors or tricyclic antidepressants.

404 Disorders of the Female Reproductive System

Janet E. Hall, Anuja Dokras

The female reproductive system regulates the hormonal changes responsible for puberty and adult reproductive function. Normal reproductive function in women requires the dynamic integration of hormonal signals from the hypothalamus, pituitary, and ovary, resulting in repetitive cycles of follicle development, ovulation, and preparation of the endometrial lining of the uterus for implantation should conception occur.

For further discussion of related topics, see the following chapters: amenorrhea and pelvic pain **(Chap. 405)**, infertility and contraception **(Chap. 408)**, menopause **(Chap. 407)**, disorders of sex development **(Chap. 402)**, and disorders of the male reproductive system **(Chap. 403)**.

DEVELOPMENT OF THE OVARY AND EARLY FOLLICULAR GROWTH

The ovary orchestrates the development and release of a mature oocyte and secretes hormones (e.g., estrogen, progesterone, inhibins A and B, relaxin) that play critical roles in a variety of target tissues, including breast, bone, and uterus, in addition to the hypothalamus and pituitary. To achieve these functions in repeated monthly cycles, the ovary undergoes some of the most dynamic changes of any organ in the body. Primordial germ cells can be identified by the third week of gestation, and their migration to the genital ridge is complete by 6 weeks of gestation. Germ cells persist within the genital ridge, are then referred to as *oogonia*, and are essential for induction of ovarian development. In patients with 45,X Turner syndrome, primordial germ cells proliferate and migrate to the genital ridge but do not persist because their survival requires pregranulosa cells that are dependent on the presence of both X chromosomes **(Chap. 402)**.

The germ cell population expands, and starting at ~8 weeks of gestation, oogonia begin to enter prophase of the first meiotic division and become primary oocytes. Entry into meiosis provides some degree of protection from programmed cell death. It also allows the oocyte to be surrounded by a single layer of flattened granulosa cells to form a primordial follicle. Granulosa cells are derived from mesonephric cells that migrate into the ovary early in its development, pushing the germ cells to the periphery. Although there is evidence that both oocyte-like cells and follicle-like structures can form from embryonic stem cells in culture, there is no clear evidence that this occurs in vivo, and thus, the ovary appears to contain a nonrenewable pool of germ cells. Through

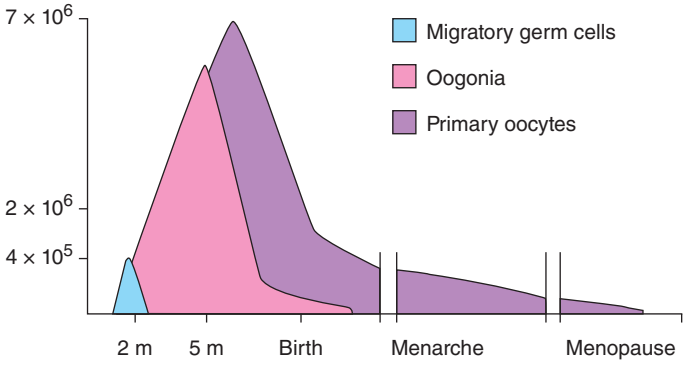

FIGURE 404-1 Ovarian germ cell number is maximal at mid-gestation and decreases precipitously thereafter.

the combined processes of mitosis, meiosis, and atresia, the population of oogonia reaches its maximum of 6–7 million by 20 weeks in the fetus, after which there is a progressive loss of both oogonia and primordial follicles through the process of atresia. At birth, oogonia are no longer present in the ovary, and only 1–2 million germ cells remain in the form of primordial follicles **(Fig. 404-1)**. The oocyte persists in prophase of the first meiotic division until just before ovulation, when meiosis resumes.

The quiescent primordial follicles are recruited to further growth and differentiation through a highly regulated process that limits the size of the developing cohort to ensure that folliculogenesis can continue throughout the reproductive life span. Transformation of primordial follicles to form primary follicles **(Fig. 404-2)** is characterized by growth of the oocyte and the transition from squamous to cuboidal granulosa cells. The theca interna cells that surround the developing follicle begin to form as the primary follicle grows. Acquisition of a zona pellucida by the oocyte, and the presence of several layers of surrounding cuboidal granulosa cells, further surrounded by theca cells, mark the development of secondary follicles. It is at this stage that granulosa cells develop follicle-stimulating hormone (FSH), estradiol, and androgen receptors and communicate with one another through the development of gap junctions.

Bidirectional signaling between the germ cells and the somatic cells in the ovary is a necessary component underlying the maturation of the oocyte and the capacity for hormone secretion. Members of the transforming growth factor beta (TGF-β) family of proteins are involved in this bidirectional signaling; oocyte-derived growth differentiation factor 9 (GDF-9) and bone morphogenic protein-15 (BMP-15), also known as GDF-9b, are required for migration of pregranulosa and pretheca cells to the outer surface of the developing follicle initial follicle formation. GDF-9 is also required for formation of secondary follicles, as are granulosa cell–derived KIT ligand (KITL) and the forkhead transcription factor (FOXL2). A significant number of genes have been identified that are required for development of the normal complement of oogonia in the ovary, initial follicle development, and resistance to follicle loss; all are candidates for premature ovarian insufficiency (POI), and mutations in >50 genes have been identified in patients with POI, with even more that have been associated with an earlier age at natural menopause.

DEVELOPMENT OF A MATURE FOLLICLE

The early stages of follicle growth are primarily driven by intraovarian factors. Further maturation to the preovulatory stage, including the resumption of meiosis in the oocyte, requires the combined stimulus of FSH and luteinizing hormone (LH) **(Figs. 404-2 and 404-3)**. Recruitment from the resting pool of secondary follicles, termed *cyclic recruitment*, requires the direct action of FSH, whereas anti-müllerian hormone (AMH) produced from small growing preantral follicles restrains this effect of FSH, controlling the number of follicles entering the actively growing pool. Accumulation of follicular fluid between the layers of granulosa cells creates an antrum that divides the granulosa cells into two functionally distinct groups: mural cells that line the follicle wall and cumulus cells that surround the oocyte (Fig. 404-3). As the follicle develops into a preovulatory, or Graffian, follicle, mural granulosa cells in proximity to theca cells express the greatest steroidogenic activity. Cumulus cells surround the oocyte and express mammalian target of rapamycin (mTOR), which regulates cellular metabolism and increases the transfer of nutrients to the oocyte. In addition to its role in normal development of the müllerian system, the WNT signaling pathway is required for normal antral follicle development and may also play a role in ovarian steroidogenesis. Recruitment to the small antral stage generally occurs over several cycles with further growth to follicle sizes of >4–7 mm in waves during a single cycle. However, recruitment over a single cycle can occur as evidenced by a normal follicular phase length in gonadotropin-releasing hormone (GnRH)-deficient women in response to a first cycle of treatment with a physiologic regimen of pulsatile GnRH administration and normalization of FSH and LH. A single dominant follicle emerges from the growing follicle pool within the first 5–7 days after the onset of menses, while the majority of follicles

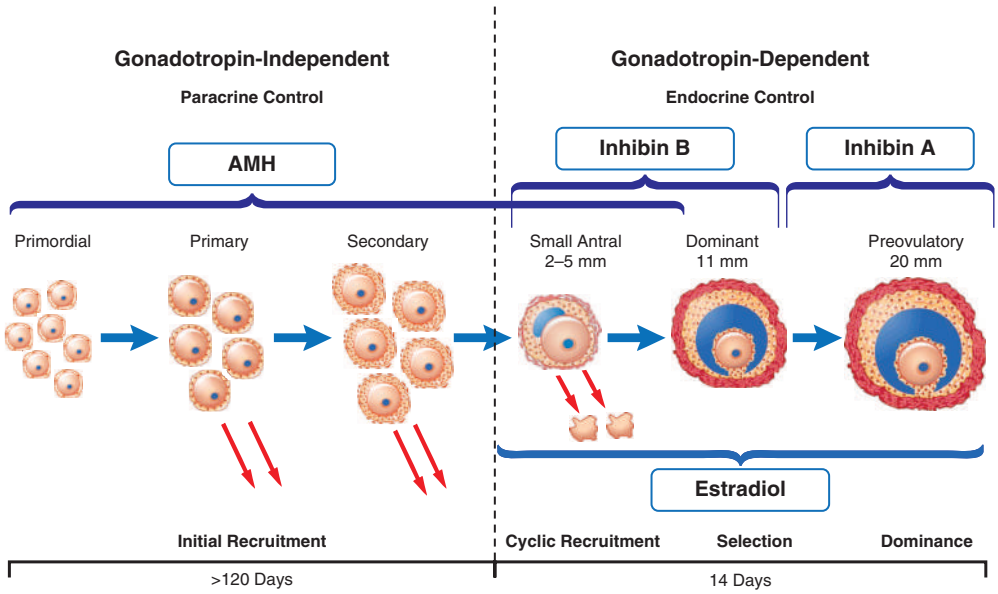

FIGURE 404-2 Gonadotropin-independent and gonadotropin-dependent ovarian follicle development that ultimately results in ovulation of a mature oocyte. AMH, anti-müllerian hormone. *(Reproduced with permission from Donna Jeanne Corcoran.)*

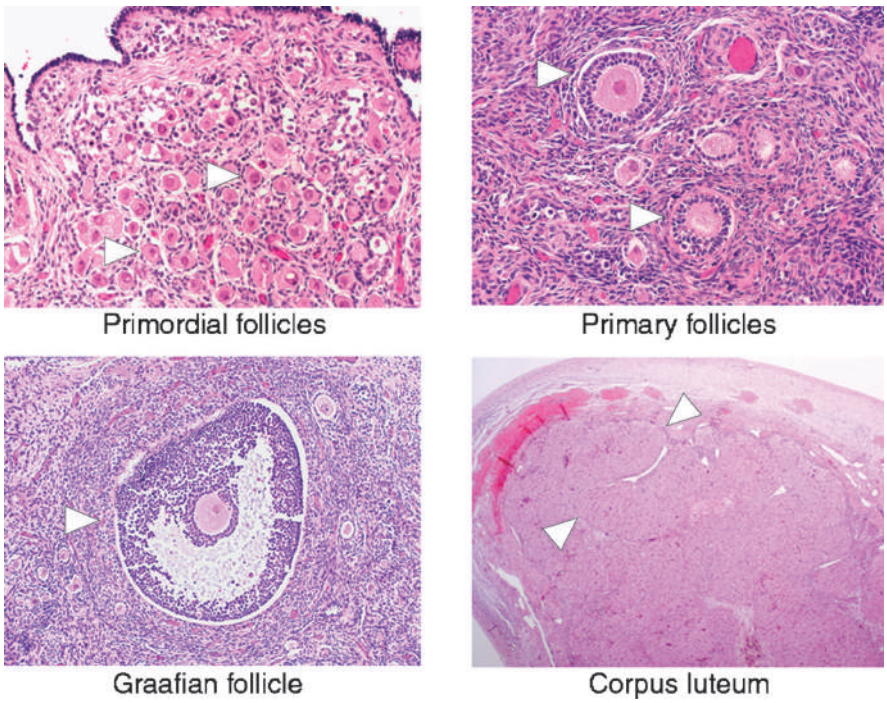

FIGURE 404-3 Development of ovarian follicles. The Graafian follicle is also known as a tertiary or preovulatory follicle. *(Courtesy of JH Eichhorn and D Roberts, Massachusetts General Hospital; with permission.)*

fall off their growth trajectory and become atretic. Autocrine actions of activin and BMP-6, derived from the granulosa cells, and paracrine actions of GDF-9, BMP-15, BMP-6, and Gpr149, derived from the oocyte, are involved in granulosa cell proliferation and modulation of FSH responsiveness. Differential exposure to these factors, and to vascular endothelial growth factor (VEGF), can alter vascular density and permeability, likely explaining the mechanism whereby a given follicle is selected for continued growth to the preovulatory stage. The dominant follicle can be distinguished by its size, evidence of granulosa cell proliferation, large number of FSH receptors, high aromatase activity, and elevated concentrations of estradiol and inhibin A in follicular fluid. In addition, secretion of estradiol and inhibin from the dominant follicle inhibits FSH and the growth of other follicles.

The dominant follicle undergoes rapid expansion during the 5–6 days prior to ovulation, reflecting granulosa cell proliferation and accumulation of follicular fluid. FSH induces LH receptors on the granulosa cells, and the preovulatory, or Graafian, follicle moves to the outer ovarian surface in preparation for ovulation. The LH surge triggers the resumption of meiosis, the suppression of granulosa cell proliferation, and the induction of cyclooxygenase 2 (COX-2), prostaglandins, the progesterone receptor (PR), and the epidermal growth factor–like growth factors amphiregulin, epiregulin, betacellulin, and neuroregulin 1, all of which are required for ovulation. Ovulation requires production of extracellular matrix, leading to expansion of the cumulus cell population that surrounds the oocyte and the controlled expulsion of the egg and follicular fluid. Both progesterone and prostaglandins (induced by the ovulatory stimulus) are essential for this process, as are members of the matrix metalloproteinase family. After ovulation, luteinization of theca and granulosa cells is induced by LH in conjunction with the acquisition of a rich vascular network in response to VEGF and basic fibroblast growth factor (FGF). Traditional regulators of central reproductive control, GnRH and its receptor (GnRHR), as well as kisspeptin, are also produced in the ovary and may be involved in corpus luteum function.

REGULATION OF OVARIAN FUNCTION

HYPOTHALAMIC AND PITUITARY SECRETION

GnRH neurons derive from cells in the olfactory placode and, to a lesser extent, the neural crest. They migrate into the brain across the cribriform plate along with the olfactory neurons which then form the olfactory bulb, while the GnRH neurons continue their journey to the hypothalamus. The importance of the initial migratory pathway into the brain is evidenced in patients born without a nose (bosma arhinia microphthalmia syndrome) who lack olfactory foramina in the cribriform plate and are both anosmic and have hypogonadotropic hypogonadism. Studies in these and other GnRH-deficient patients who fail to undergo puberty have provided insights into genes that control the ontogeny and function of GnRH neurons **(Fig. 404-4)**. *ANOS1* (also known as *KAL1*), *FGF8/FGFR1*,

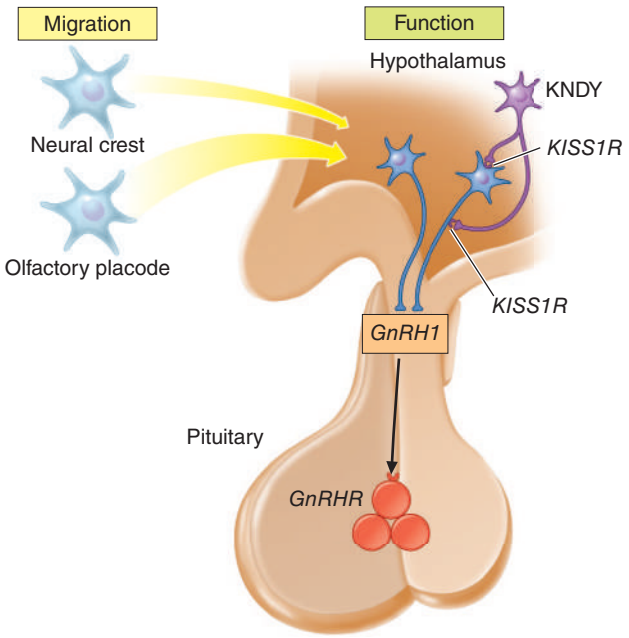

FIGURE 404-4 Genetic studies in patients with congenital forms of hypogonadotropic hypogonadism have expanded our understanding of the development and migration of gonadotropin-releasing hormone (GnRH) neurons from the olfactory placode and possibly the neural crest to the hypothalamus as well as the upstream regulation of GnRH secretion by kisspeptin (*KISS1*), neurokinin B (*TAC3*), and dynorphin (*Dyn*), which are co-expressed in the KNDY neurons. GnRHR, GnRH receptor.

PROK2/PROKR2, *NSMF*, *HS6SD1*, and *CDH7*, among a host of others **(Chap. 403)**, have been implicated in the migration of GnRH neurons to the hypothalamus, whereas *KISS*, *TAC3*, *Dyn*, and their receptors are involved in the upstream regulation of GnRH secretion. Approximately 7000 GnRH neurons, scattered throughout the medial basal hypothalamus, establish contacts with capillaries of the pituitary portal system in the median eminence. GnRH is secreted into the pituitary portal system in discrete pulses to stimulate synthesis and secretion of LH and FSH from pituitary gonadotropes, which comprise ~10% of cells in the pituitary **(Chap. 390)**. Functional connections of GnRH neurons with the portal system are established by the end of the first trimester, coinciding with the production of pituitary gonadotropins. Thus, like the ovary, the hypothalamic and pituitary components of the reproductive system are present before birth. However, the high levels of estradiol and progesterone produced by the placenta suppress hypothalamic-pituitary stimulation of ovarian hormonal secretion in the fetus.

After birth and the loss of placenta-derived steroids, gonadotropin levels rise. FSH levels are much higher in girls than in boys. The rise in FSH in girls results in circulating estradiol and inhibin B in what has been termed the mini-puberty of infancy, but without terminal follicle maturation or ovulation. Studies that have identified mutations in *TAC3*, which encodes neurokinin B, and its receptor, *TAC3R*, in patients with GnRH deficiency indicate that both are involved in control of GnRH secretion and may be particularly important at this early stage of development. By 12–20 months of age, the reproductive axis is again suppressed, and a period of relative quiescence persists until puberty **(Fig. 404-5)**. At the onset of puberty, pulsatile GnRH secretion induces pituitary gonadotropin production. In the early stages of puberty, LH and FSH secretion are apparent only during sleep, but as puberty develops, pulsatile LH secretion, a faithful marker of GnRH secretion, occurs throughout the day and night.

The mechanisms responsible for the childhood quiescence and pubertal reactivation of the reproductive axis remain incompletely understood. GnRH neurons in the hypothalamus respond to both excitatory and inhibitory factors. Increased sensitivity to the inhibitory influence of gonadal steroids has long been implicated in the inhibition of GnRH secretion during childhood but has not been definitively established in the human. Metabolic signals, including adipocyte-derived leptin, play a permissive role in reproductive function but are not sufficient to induce puberty **(Chap. 413)**.

Studies of patients with isolated GnRH deficiency reveal that mutations in the G protein–coupled receptor 54 (*GPR54*) gene (now known as *KISS1R*) preclude the onset of puberty. Kisspeptin, the ligand for this receptor, is derived from the parent peptide, kisspeptin-1 (*KISS1*), and is a potent stimulant for GnRH release. The tachykinin 3 gene (*TAC3*), which encodes neurokinin-B (NKB), stimulates GnRH secretion through kisspeptin signaling, while dynorphin (*Dyn*), which acts mainly through kappa opioid receptors, plays an inhibitory role in GnRH control. *TAC3* and *Dyn* are frequently co-expressed with *KISS1* in KNDy neurons of the median eminence that project to GnRH neurons. This system is intimately involved in both estrogen and progesterone negative feedback regulation of GnRH secretion as well as metabolic and stress signaling to the reproductive axis. Kisspeptin release is pulsatile, and secretion is generated by alternate stimulation and inhibition of kisspeptin by NKB and Dyn, respectively. While pulsatility is an intrinsic property of GnRH neurons, the current model suggests that pulsatile secretion of GnRH is coordinated by pulsatile kisspeptin secretion, with potential input from upstream glutaminergic neurons.

A role for kisspeptin in the onset of puberty is suggested by upregulation of *KISS1* and *KISS1R* transcripts in the hypothalamus at the time of puberty. The onset of puberty may occur via a switch from epigenetic repression to epigenetic activation in kisspeptin neurons. Two imprinted genes that were initially identified in families with central precocious puberty, *MKRN3* and *DLK1*, may be involved in this switch given their known functions and their association with age at onset of menarche in a large cohort of women.

While short-term infusion of kisspeptin restored LH pulsatility in patients with hypothalamic amenorrhea and hyperprolactinemia, there is also evidence that tachyphylaxis occurs, potentially limiting its use as a treatment for these conditions.

RFamide-related peptides (RFRPs) are the mammalian orthologues of gonadotropin inhibitory hormone (GnIH), which was initially discovered in the quail. In lower animal species, these peptides decrease gonadal function and sexual motivation in addition to increasing feeding behavior and mediating the inhibitory actions of stress on reproduction. While RFRP-1 and RFRP-3 neurons send axonal projections to GnRH neurons in humans and RFRPs are secreted into the pituitary portal system, further studies are required to determine their potential physiologic role in the human.

OVARIAN STEROIDS

Ovarian steroid-producing cells do not store hormones but produce them in response to FSH and LH during the normal menstrual cycle. The sequence of steps and the enzymes involved in the synthesis of steroid hormones are similar in the ovary, adrenal, and testis. However, the enzymes required to catalyze specific steps are compartmentalized and may not be abundant or even present in all cell types. Within the developing ovarian follicle, estrogen synthesis from cholesterol requires close integration between theca and granulosa cells—the two-cell model for steroidogenesis **(Fig. 404-6)**. FSH receptors are confined to the granulosa cells, whereas LH receptors are restricted to the theca

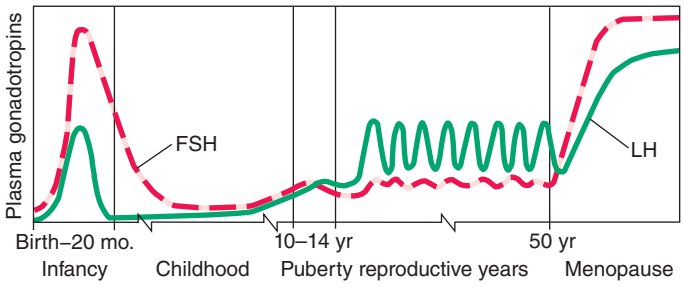

FIGURE 404-5 Follicle-stimulating hormone (FSH) and luteinizing hormone (LH) are increased during the neonatal years but go through a period of childhood quiescence before increasing again during puberty. Gonadotropin levels are cyclic during the reproductive years and increase dramatically with the loss of negative feedback that accompanies menopause.

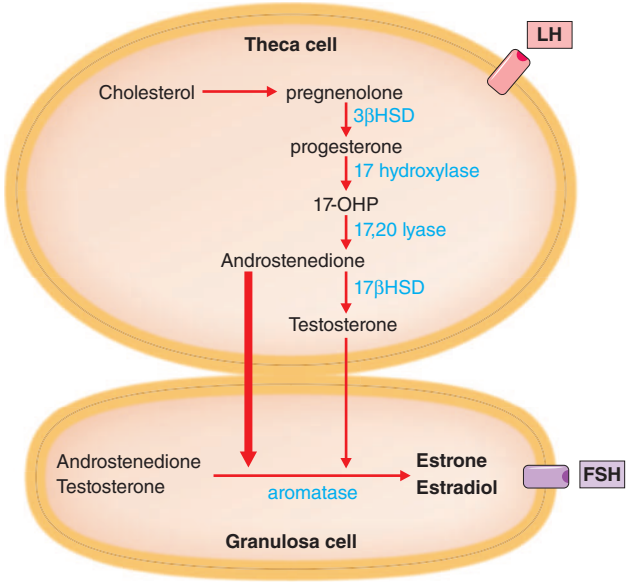

FIGURE 404-6 Estrogen production in the ovary requires the cooperative function of the theca and granulosa cells under the control of luteinizing hormone (LH) and follicle-stimulating hormone (FSH). HSD, hydroxysteroid dehydrogenase; OHP, hydroxyprogesterone.

cells until the late stages of follicular development, when they are also found on granulosa cells. The theca cells surrounding the follicle are highly vascularized and use cholesterol, derived primarily from circulating lipoproteins, as the starting point for the synthesis of androstenedione and testosterone under the control of LH. There is some evidence that 11-oxo-androgens, which are generally thought to be produced only in the adrenal, may also be produced to some degree in the ovary. These steroid precursors cross the basal lamina to the granulosa cells, which receive no direct blood supply. The mural granulosa cells are particularly rich in aromatase and, under the control of FSH, produce estradiol, the primary steroid secreted from the follicular phase ovary and the most potent estrogen. Theca cell–produced androstenedione and, to a lesser extent, testosterone are also secreted into peripheral blood, where they can be converted to dihydrotestosterone in skin and to estrogens in adipose tissue. The hilar interstitial cells of the ovary are functionally similar to Leydig cells and are also capable of secreting androgens. Stromal cells proliferate in response to androgens (as in polycystic ovary syndrome [PCOS]) but do not secrete androgens. However, high levels of androgens may be produced by luteinized theca cells within the stroma in women with hyperthecosis.

Development of the rich capillary network following rupture of the follicle at the time of ovulation makes it possible for large molecules such as low-density lipoprotein (LDL) to reach the luteinized granulosa and theca lutein cells. As in the follicle, both cell types are required for steroidogenesis in the corpus luteum. The luteinized granulosa cells are the main source of progesterone production, whereas the smaller theca lutein cells produce 17-hydroxyprogesterone and androgenic substrates for aromatization to estradiol by the luteinized granulosa cells. Production of estrogen metabolites by the corpus luteum plays a significant role in maintenance of the vascularization required for its function. LH is critical for formation and maintenance of corpus luteum structure and function. LH and human chorionic gonadotropin (hCG) bind to a common receptor; thus, in conception cycles, hCG produced upon fertilization rescues the declining function of the corpus luteum, maintaining steroid and peptide secretion for the first 10 weeks of pregnancy. hCG is commonly used for luteal phase support in the treatment of infertility.

Steroid Hormone Actions Both estrogen and progesterone play critical roles in the expression of secondary sexual characteristics in women **(Chap. 389)**. Estrogen promotes development of the ductule system in the breast, whereas progesterone is responsible for glandular development. In the reproductive tract, estrogens create a receptive environment for fertilization and support pregnancy and parturition through carefully coordinated changes in the endometrium, thickening of the vaginal mucosa, thinning of the cervical mucus, and uterine growth and contractions. Progesterone induces secretory activity in the estrogen-primed endometrium, increases the viscosity of cervical mucus, and inhibits uterine contractions. Both gonadal steroids play critical roles in negative and positive feedback of gonadotropin secretion. Progesterone also increases basal body temperature, which is used clinically as a marker of ovulation.

The vast majority of circulating estrogens and androgens are carried in the blood bound to carrier proteins, which restrain their free diffusion into cells and prolong their clearance, serving as a reservoir. High-affinity binding proteins include sex hormone–binding globulin (SHBG), which binds androgens with somewhat greater affinity than estrogens, and corticosteroid-binding globulin (CBG), which also binds progesterone. Modulations in binding protein levels by insulin, androgens, and estrogens contribute to high bioavailable testosterone levels in PCOS and to high circulating total estrogen and progesterone levels during pregnancy.

Estrogens act primarily through binding to the nuclear receptors, estrogen receptors (ER) α and β. Transcriptional coactivators and co-repressors modulate ER action **(Chap. 389)**. Both ER subtypes are present in the hypothalamus, pituitary, ovary, and reproductive tract. Although ERα and ERβ exhibit some functional redundancy, there is also a high degree of specificity, particularly in expression within cell types. For example, ERα functions in ovarian theca cells, whereas ERβ is critical for granulosa cell function. There is also evidence for membrane-initiated signaling by estrogen. Similar signaling mechanisms pertain for progesterone with evidence of transcriptional regulation through PR-A and PR-B protein isoforms, as well as rapid membrane signaling.

OVARIAN PEPTIDES

Inhibin was initially isolated from gonadal fluids based on its ability to selectively inhibit FSH secretion from pituitary cells. Inhibin is a heterodimer composed of an α subunit and a βA or βB subunit to form inhibin A or inhibin B, both of which are secreted from the ovary. Activin is a homodimer of inhibin β subunits with the capacity to stimulate the synthesis and secretion of FSH. Inhibins and activins are members of the TGF-β superfamily of growth and differentiation factors. During the purification of inhibin, follistatin, an unrelated monomeric protein that inhibits FSH secretion, was discovered. Within the pituitary, follistatin inhibits FSH secretion indirectly by binding and neutralizing activin.

Inhibin B is constitutively secreted from the granulosa cells of small antral follicles, and its serum levels increase in conjunction with granulosa cell proliferation during recruitment of secondary follicles under the control of FSH (Fig. 404-2). Inhibin B is an important inhibitor of FSH, independent of estradiol, during the menstrual cycle. Inhibin A is present in both granulosa and theca cells and is secreted by the dominant follicle. Inhibin A is also present in luteinized granulosa cells and is a major secretory product of the corpus luteum. Synthesis and secretion of inhibin A are directly controlled by FSH and LH. Although activin is also secreted from the ovary, the excess of follistatin in serum, combined with its nearly irreversible binding of activin, make it unlikely that ovarian activin plays an endocrine role in FSH regulation. However, there is evidence that activin plays an autocrine/paracrine role in the ovary in germ cell survival, follicle assembly, and inhibition of androgen production, in addition to its intrapituitary role in modulation of FSH production.

AMH (also known as müllerian-inhibiting substance) is important in ovarian biology in addition to the function from which it derived its name (i.e., promotion of the degeneration of the müllerian system during embryogenesis in the male). AMH is produced by granulosa cells from small preantral and early antral follicles (Fig. 404-2) and is a marker of ovarian reserve with advantages over inhibin B because of its relative stability across the menstrual cycle. AMH inhibits FSH in the recruitment of primordial follicles into the follicle pool and counters FSH stimulation of aromatase expression. AMH levels increase during puberty, are highest in the early twenties, and decrease markedly by menopause. AMH is increased in PCOS in conjunction with the abundance of small follicles in this disorder.

Gonadotropin surge attenuating factor (GnSAF) is an ovarian factor that attenuates GnRH-induced gonadotropin secretion. Its role is not yet fully understood, but there is an inverse relationship between GnSAF and follicle size, suggesting that its primary role involves the early stages of follicle development rather than curtailing the gonadotropin surge as its name implies.

Relaxin is produced primarily by the theca lutein cells of the corpus luteum. Both relaxin and its receptor, encoded by the gene *RXFP1*, are highly expressed in the uterus during the peri-implantation period and its primary role appears to be in promoting decidualization and vascularization of the endometrium prior to implantation. Relaxin was named for its ability to suppress myometrial contractility in pigs and rodents, but it does not appear to exert this activity in women.

HORMONAL INTEGRATION OF THE NORMAL MENSTRUAL CYCLE

The sequence of changes responsible for mature reproductive function is coordinated through a series of negative and positive feedback loops that alter pulsatile GnRH secretion, the pituitary response to GnRH, and the relative secretion of LH and FSH from gonadotropes **(Fig. 404-7)**. The frequency and amplitude of pulsatile GnRH secretion differentially modulate the synthesis and secretion of LH and FSH. Slow GnRH pulse frequencies favor FSH synthesis, whereas increased

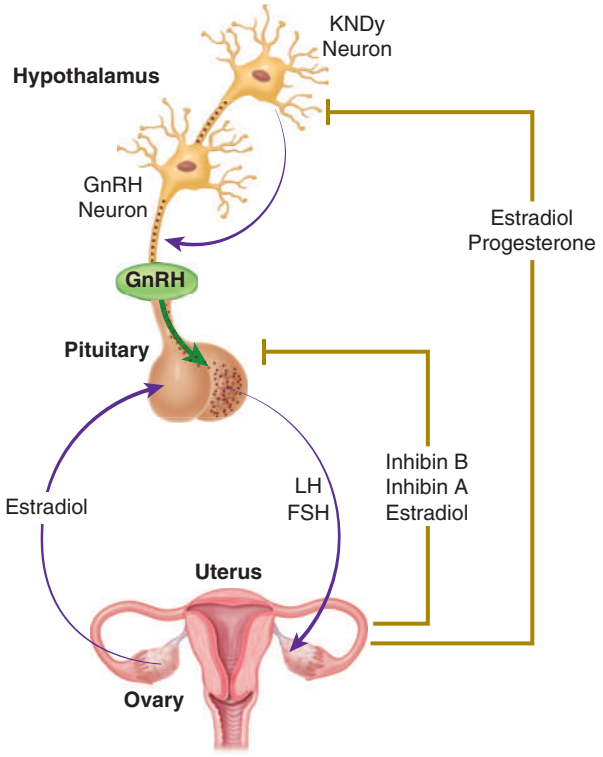

FIGURE 404-7 The reproductive system in women is critically dependent on both negative feedback of gonadal steroids and inhibin to modulate follicle-stimulating hormone (FSH) secretion and on estrogen positive feedback to generate the preovulatory luteinizing hormone (LH) surge. GnRH, gonadotropin-releasing hormone.

GnRH pulse frequency and amplitude favor LH synthesis. FSH synthesis is also controlled by the activin-inhibin-follistatin system within the pituitary. Activin is produced in both pituitary gonadotropes and folliculostellate cells and stimulates the synthesis and secretion of FSH through autocrine-paracrine mechanisms that are modulated by follistatin, which is also produced in folliculostellate cells. Inhibins function as potent antagonists of activins through sequestration of the activin receptors. Although inhibin is expressed in the pituitary, gonadal inhibin is the principal source of feedback inhibition of FSH.

For the majority of the cycle, the reproductive system functions in a classic endocrine negative feedback mode. Estradiol and progesterone inhibit GnRH secretion, acting through kisspeptin and dynorphin in the KNDy neurons, while the inhibins act at the pituitary to selectively inhibit FSH synthesis and secretion (Fig. 404-7). Estradiol also contributes to negative feedback at the pituitary with an effect that is greater for FSH than LH. This tightly regulated negative feedback control of FSH is critical for development of the single mature follicle that characterizes normal reproductive cycles in women. In addition to these negative feedback controls, the menstrual cycle is uniquely dependent on estrogen-induced positive feedback to produce an LH surge that is essential for ovulation of a mature follicle. Estrogen negative feedback in women occurs primarily at the hypothalamus with a small pituitary contribution, whereas estrogen positive feedback occurs at the pituitary in women with upregulation of GnRH signaling and responsiveness. In women, hypothalamic GnRH secretion plays a permissive role in generating the preovulatory gonadotropin surge, a mechanism that differs significantly from that in rodents and other species that rely on seasonal and circadian cues, in which a surge of GnRH also occurs.

THE FOLLICULAR PHASE

The follicular phase is characterized by *cyclic recruitment* of a cohort of secondary follicles and the ultimate selection of a preovulatory follicle **(Figs.** 404-2 **and 404-8)**. The follicular phase begins, by convention, on the first day of menses. However, follicle recruitment is initiated by the rise in FSH that begins in the late luteal phase of the previous cycle in conjunction with the loss of negative feedback of gonadal steroids and likely inhibin A. The fact that an ~20% increase in FSH is

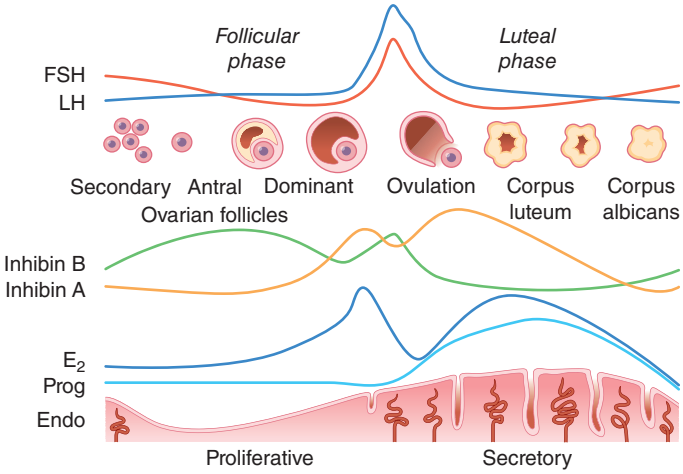

FIGURE 404-8 Relationship between gonadotropins, follicle development, gonadal secretion, and endometrial changes during the normal menstrual cycle. E_2, estradiol; Endo, endometrium; FSH, follicle-stimulating hormone; LH, luteinizing hormone; Prog, progesterone.

adequate for follicular recruitment speaks to the marked sensitivity of the resting follicle pool to FSH. The resultant granulosa cell proliferation is responsible for increasing early follicular phase levels of inhibin B. Inhibin B, in conjunction with rising levels of estradiol and inhibin A, restrains FSH secretion during this critical period such that only a single follicle matures in the vast majority of cycles. The increased risk of multiple gestation associated with the higher levels of FSH characteristic of advanced maternal age or with exogenous gonadotropin administration in the treatment of infertility attests to the importance of the precise negative feedback regulation of FSH that is necessary for monofollicular development. With further growth of the dominant follicle, estradiol and inhibin A increase. Increasing levels of estradiol across the follicular phase are responsible for proliferative changes in the endometrium. Acquisition of FSH-induced LH receptors on granulosa cells allows LH to complete the final stages of maturation of the preovulatory follicle, leading to secretion of low levels of progesterone and 17α-hydroxyprogesterone.

The exponential rise in estradiol in the mid-late luteal phase results in positive feedback on the pituitary gonadotropes, leading to generation of an LH surge (and a smaller FSH surge). The low levels of progesterone secreted from the peri-ovulatory follicle are not required for the gonadotropin surge but appear to play a role in its timing. The LH surge may precede follicle rupture by 24–36 h, during which time the oocyte uncouples from the granulosa cells, and genes involved in inflammation and tissue remodeling are induced. Further alterations in steroidogenesis accompany luteinization of theca and granulosa cells.

THE LUTEAL PHASE

The luteal phase begins with the formation of the corpus luteum from the ruptured follicle (Fig. 404-8). Progesterone, 17α-hydroxyprogesterone, and inhibin A are produced from the luteinized granulosa cells. The granulosa-lutein cells continue to aromatize androgen precursors derived from theca-lutein cells, producing estradiol. The combined actions of estrogen and progesterone, as well as relaxin, are responsible for the secretory changes in the endometrium that are necessary for implantation. The corpus luteum is supported by LH but has a finite life span. Both the progesterone-induced decrease in LH pulse frequency and diminished postreceptor signaling are likely to contribute to the demise of the corpus luteum. The progressive decline in hormonal support of the endometrium results in inflammation, local hypoxia and ischemia, and subsequent vascular changes with release of cytokines, cell death, and shedding of the endometrium.

If conception occurs, hCG produced by the trophoblast binds to LH receptors on the corpus luteum, maintaining steroid hormone production and preventing involution of the corpus luteum until the luteal-placental shift in hormone production that occurs 6–10 weeks after conception.

CLINICAL ASSESSMENT OF OVARIAN FUNCTION

Menstrual bleeding should become regular within 2–4 years of menarche, although anovulatory and irregular cycles are common before that. For the remainder of adult reproductive life, the cycle length counted from the first day of menses to the day preceding subsequent menses is ~28 days, with a range of 25–35 days. However, cycle-to-cycle variability for an individual woman is ±2 days. Luteal phase length is relatively constant between 12 and 14 days in normal cycles; thus, the major variability in cycle length is due to variations in follicular phase length. The duration of menstrual bleeding in ovulatory cycles varies between 4 and 6 days. There is a gradual shortening of cycle length with age such that women aged >35 years have cycles that are shorter than during their younger reproductive years. Anovulatory cycles increase as women approach menopause, and bleeding patterns may be erratic.

Women who report regular monthly bleeding generally have ovulatory cycles, but several other clinical signs can be used to assess the likelihood of ovulation. Some women experience *mittelschmerz*, described as midcycle pelvic discomfort that is thought to be caused by the rapid expansion of the dominant follicle at the time of ovulation. A constellation of premenstrual moliminal symptoms such as bloating, breast tenderness, mood changes, and food cravings often occur several days before menses in ovulatory cycles, but their absence cannot be used as evidence of anovulation. Methods that can be used to determine whether ovulation occurred include a serum progesterone level >3 ng/mL ~7 days after ovulation, an increase in basal body temperature of 0.24°C (>0.5°F) in the second half of the cycle due to the thermoregulatory effect of progesterone, or detection of the urinary LH surge using ovulation predictor kits, although the mere presence of an apparent LH surge does not guarantee that ovulation will occur. However, because ovulation occurs ~36 h after the LH surge, urinary LH can be helpful in timing intercourse to coincide with ovulation.

Ultrasound can be used to detect the growth of the fluid-filled antrum of the developing follicle and to assess endometrial thickness in response to increasing estradiol levels in the follicular phase. It can also be used to provide evidence of ovulation by documenting collapse of the dominant follicle and/or the presence of a corpus luteum as well as the characteristic echogenicity of the secretory endometrium of the luteal phase.

PUBERTY

NORMAL PUBERTAL DEVELOPMENT IN GIRLS

The first menstrual period (*menarche*) occurs relatively late in the series of developmental milestones that characterize normal pubertal development. Menarche is preceded by the appearance of pubic and then axillary hair (*adrenarche*) as a result of maturation of the zona reticularis in the adrenal gland and increased adrenal androgen secretion, particularly dehydroepiandrosterone (DHEA). The triggers for adrenarche remain unknown but may involve increases in body mass index, as well as in utero and neonatal factors. Menarche is also preceded by breast development (*thelarche*). The breast is exquisitely sensitive to the very low levels of estrogen that result from peripheral conversion of adrenal androgens and the low levels of estrogen secreted from the ovary early in pubertal maturation. This estrogen sensitivity also explains why infants occasionally develop breast tissue in response to endogenous or environmental estrogens. Breast development precedes the appearance of pubic and axillary hair in ~60% of girls. The interval between the onset of breast development and menarche is ~2 years. There has been a gradual decline in the age of puberty attributed to improved nutrition, however more recent changes indicate a decline in the age of thelarche but not menarche which is associated with obesity. In the United States, menarche occurs at an average age of 12.5 years.

Much of the variation in the timing of puberty is due to genetic factors. Heritability estimates from twin studies range between 50 and 80%. Adrenarche and thelarche occur ~1 year earlier in black girls compared with white girls, although the difference in the timing of menarche is less pronounced. Genome-wide association studies have identified over a hundred genes associated with pubertal timing in boys and girls, attesting to the high degree of coordination of this reproductive and growth milestone. These findings include genes involved in GnRH secretion (e.g., *TACR3,* and the maternally imprinted gene, *MKRN3*, that has been associated with familial precocious puberty), pituitary development and function (e.g., *POU1F1*), hormone synthesis and bioactivity (e.g., *STARD4, ESR1, RXRG*), gonadal feedback (e.g., *INHBA, ESR1*), and energy homeostasis and growth, including *LIN28B*, a sentinel puberty gene, which is a potent regulator of microRNA processing.

Other important hormonal changes also occur in conjunction with puberty. Growth hormone (GH) levels increase early in puberty, stimulated in part by the pubertal increase in estrogen secretion. GH increases insulin-like growth factor-1 (IGF-1), which enhances linear growth. The growth spurt is generally less pronounced in girls than in boys, with a peak growth velocity of ~7 cm/year. Linear growth is ultimately limited by closure of epiphyses in the long bones as a result of prolonged exposure to estrogen. Puberty is also associated with mild insulin resistance.

DISORDERS OF PUBERTY

The differential diagnosis of precocious and delayed puberty is similar in boys **(Chap. 403)** and girls. However, there are differences in the timing of normal puberty and differences in the relative frequency of specific disorders in girls compared with boys.

Precocious Puberty Traditionally, precocious puberty has been defined as the development of secondary sexual characteristics before the age of 8 in girls based on data from Marshall and Tanner in British girls studied in the 1960s. More recent studies led to recommendations that girls be evaluated for precocious puberty if breast development or pubic hair is present at <7 years of age for white girls or <6 years for black girls; however, these guidelines have not been widely accepted in favor of careful follow-up in all girls presenting at <8 years.

Precocious puberty in girls is most often centrally mediated **(Table 404-1)**, resulting from early activation of the hypothalamic-pituitary-ovarian axis. It is characterized by pulsatile LH secretion (which is initially associated with deep sleep) and an enhanced LH and FSH response to exogenous GnRH or a GnRH agonist (two- to threefold stimulation) **(Table 404-2)**. True precocity is marked by advancement in bone age of >2 standard deviations, a recent history of growth acceleration, and progression of secondary sexual characteristics.

TABLE 404-1 Differential Diagnosis of Precocious Puberty

CENTRAL (GnRH DEPENDENT)	PERIPHERAL (GnRH INDEPENDENT)
Idiopathic	Congenital adrenal hyperplasia
CNS tumors	Estrogen-producing tumors
Hamartomas	Adrenal tumors
Astrocytomas	Ovarian tumors
Adenomyomas	Gonadotropin/hCG-producing tumors
Gliomas	Exogenous exposure to estrogen or androgen or lavender or tea-tree oil
Germinomas	McCune-Albright syndrome
CNS infection	Aromatase excess syndrome
Genetic, i.e., *KISS1, KISS1R, MKRN3, DLK1*	
Head trauma	
Iatrogenic	
Radiation	
Chemotherapy	
Surgical	
CNS malformation	
Arachnoid or suprasellar cysts	
Septo-optic dysplasia	
Hydrocephalus	

Abbreviations: CNS, central nervous system; *DLK1,* delta-like 1 homolog gene; GnRH, gonadotropin-releasing hormone; hCG, human chorionic gonadotropin; *KISS1,* kisspeptin gene; *KISS1R,* kisspeptin receptor gene; *MKRN3,* makorin ring finger protein 3 gene.

Abbreviations: ACTH, adrenocorticotropic hormone; DHEAS, dehydroepiandrosterone sulfate; FSH, follicle-stimulating hormone; GnRH, gonadotropin-releasing hormone; hCG, human chorionic gonadotropin; IGF-1, insulin-like growth factor 1; IGFBP-3, IGF-binding protein 3; LH, luteinizing hormone; MRI, magnetic resonance imaging; TSH, thyroid-stimulating hormone; T_4, thyroxine.

In girls, centrally mediated precocious puberty (CPP) is categorized as idiopathic in ~85% of cases; however, neurogenic causes must be considered. Loss-of-function mutations in *MKRN3* and *DLK1*, both of which are imprinted genes, have been reported in familial CPP. Activating mutations in *KISS1*, *KISS1R*, and *PROKR2* have also been found in a small number of patients with CPP. However, the frequency of these mutations is insufficient to justify their use in routine clinical testing. GnRH agonists that induce pituitary desensitization are the mainstay of treatment to prevent premature epiphyseal closure and preserve adult height, as well as to manage psychosocial repercussions of precocious puberty.

Peripherally mediated precocious puberty does not involve activation of the hypothalamic-pituitary-ovarian axis and is characterized by suppressed gonadotropins in the presence of elevated estradiol. Management of peripheral precocious puberty involves treating the underlying disorder (Table 404-1) and limiting the effects of gonadal steroids using aromatase inhibitors, inhibitors of steroidogenesis, and ER blockers. It is important to be aware that central precocious puberty can also develop in girls whose precocity was initially peripherally mediated, as in McCune-Albright syndrome and congenital adrenal hyperplasia.

Incomplete and intermittent forms of precocious puberty may also occur. For example, premature breast development are common in girls before the age of 2 years, with no further progression and without significant advancement in bone age, estrogen production, or compromised height. Premature adrenarche can also occur in the absence of progressive pubertal development, but it must be distinguished from late-onset congenital adrenal hyperplasia and androgen-secreting tumors, in which case it may be termed *heterosexual precocity*. Premature adrenarche may be associated with obesity, hyperinsulinemia, and the subsequent predisposition to PCOS.

Delayed Puberty Delayed puberty (Table 404-3) is defined as the absence of secondary sexual characteristics by age 13 in girls. The diagnostic considerations are very similar to those for primary amenorrhea (Chap. 405). Between 25 and 40% of delayed puberty in girls is of ovarian origin, with Turner syndrome accounting for the majority of such patients. Delayed puberty may occur in the setting of systemic illnesses, including celiac disease and chronic renal disease, and endocrinopathies such as diabetes and hypothyroidism. In addition, girls appear to be particularly susceptible to the adverse effects of decreased energy balance resulting from exercise, dieting, and/or eating disorders, and thus, functional hypothalamic amenorrhea (HA) can present with primary amenorrhea. Together, these reversible conditions account for ~25% of delayed puberty in girls. Congenital hypogonadotropic hypogonadism in girls or boys can be caused by mutations in several different genes or combinations of genes (Fig. 404-4, Chap. 391, Table 404-3).

Abbreviations: CHD7, chromodomain-helicase-DNA-binding protein 7; CNS, central nervous system; *FGF8,* fibroblast growth factor 8; *FGFR1,* fibroblast growth factor 1 receptor; *FSH*β, follicle-stimulating hormone β chain; *FSHR,* FSH receptor; *GNRHR,* gonadotropin-releasing hormone receptor; *HESX1,* homeobox, embryonic stem cell expressed 1; *HS6ST1,* heparin sulfate 6-O sulfotransferase 1; IHH, idiopathic hypogonadotropic hypogonadism; KAL, Kallmann; *KISS1,* kisspeptin 1; *KISSR1,* KISS1 receptor; *LHR,* luteinizing hormone receptor; *NSMF,* NMDA receptor synaptonuclear signaling and neuronal migration factor; *PROK2,* prokineticin 2; *PROKR2,* prokineticin receptor 2; *PROP1,* prophet of Pit1, paired-like homeodomain transcription factor; *SEMA3A,* semaphorin-3A; *WDR11,* WD repeat-containing protein 11.

Approximately 50% of girls with congenital hypogonadotropic hypogonadism, with or without anosmia, have a history of some degree of breast development, and 10% report one to two episodes of vaginal bleeding. Family studies suggest that genes identified in association with absent puberty may also cause delayed puberty, and recent reports have further suggested that a genetic susceptibility to environmental stresses such as diet and exercise may account for at least some cases of functional HA, including in girls who present with primary amenorrhea. Although neuroanatomic causes of delayed puberty are considerably less common in girls than in boys, it is always important to rule these out in the setting of primary hypogonadotropic hypogonadism.

405 Menstrual Disorders and Pelvic Pain

Janet E. Hall, Anuja Dokras

Menstrual dysfunction can signal an underlying abnormality that may have long-term health consequences. Although frequent or prolonged bleeding usually prompts a woman to seek medical attention, infrequent or absent bleeding may seem less troubling, and the patient may not bring it to the attention of the physician. Thus, a focused menstrual history is a critical part of every encounter with a female patient. Pelvic pain is a common complaint that may relate to an abnormality of the reproductive organs but also may be of gastrointestinal, urinary tract, or musculoskeletal origin. Depending on its cause, pelvic pain may require urgent surgical attention. Recent guidelines no longer recommend routine pelvic examination in asymptomatic, average-risk women other than periodic cervical cancer screening. However, pelvic examination is an important part of the evaluation of amenorrhea, abnormal uterine bleeding, and pelvic pain.

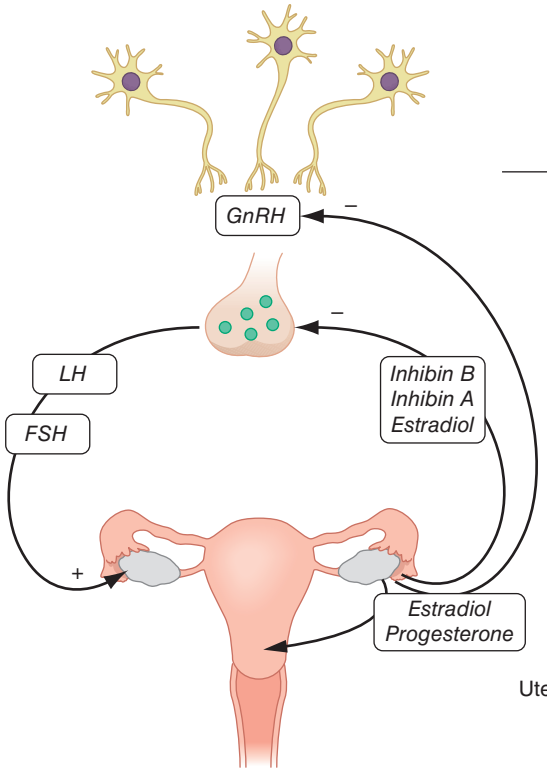
MENSTRUAL DISORDERS

DEFINITION AND PREVALENCE

Amenorrhea refers to the absence of menstrual periods and is classified as *primary* if menstrual bleeding has never occurred in the absence of hormonal treatment or *secondary* if menstrual periods cease for 3–6 months. Primary amenorrhea is a rare disorder that occurs in <1% of the female population. However, between 3 and 5% of women experience at least 3 months of secondary amenorrhea in any specific year. There is no evidence that race or ethnicity influences the prevalence of amenorrhea. However, because of the importance of adequate nutrition for normal reproductive function, both the age at menarche and the prevalence of secondary amenorrhea vary significantly in different parts of the world.

Abnormal uterine bleeding (AUB) has replaced the term dysfunctional uterine bleeding and describes irregularities in the menstrual cycle involving frequency, cyclicity, duration, and volume of flow outside of pregnancy. A menstrual cycle typically occurs every 21–35 days, lasting between 4 and 7 days, with up to 80 mL of blood loss. Variations in any of these parameters constitutes a diagnosis of AUB, with up to one-third of women between menarche and menopause experiencing these symptoms. The acronym PALM-COEIN, which was developed to describe the etiologies for AUB, includes the structural causes (polyp, adenomyosis, leiomyoma [submucosal or other myoma], and malignancy and hyperplasia) and nonstructural causes (coagulopathy, ovulatory dysfunction, endometrial, iatrogenic, and not yet classified). Oligo- and anovulation are most frequently associated with polycystic ovary syndrome (PCOS).

Primary Amenorrhea The absence of menarche (the first menstrual period) by age 16 has been used traditionally to define primary amenorrhea. However, other factors, such as growth, secondary sexual characteristics, and the presence of cyclic pelvic pain, also influence the age at which primary amenorrhea should be investigated. Recent studies suggest that puberty is occurring at an earlier age, particularly in obese girls. However, it is important to note that these data reflect earlier breast development alone with minimal change in the age of menarche. Thus, an evaluation for amenorrhea should be initiated by age 15 or 16 in the presence of normal growth and secondary sexual characteristics; age 13 in the absence of secondary sexual characteristics or if height is less than the third percentile; age 12 or 13 in the presence of breast development and cyclic pelvic pain; or within 2 years of breast development if menarche has not occurred.



Secondary Amenorrhea or Oligomenorrhea Irregular cycles are relatively common for up to 3 years after menarche and for 1–2 years before the final menstrual period. In the intervening years, menstrual cycle length is ~28 days. Cycle-to-cycle variability in an individual woman who is ovulating consistently is generally +/− 2 days. Pregnancy should be excluded early in any evaluation of menstrual irregularity. However, many women occasionally miss a single period. Three months of secondary amenorrhea, or 6 months in women with previously irregular cycles, should prompt an evaluation, as should a history of intermenstrual intervals >35 or <21 days or bleeding that persists for >7 days.

DIAGNOSIS

Pregnancy is the most common cause of amenorrhea and must be excluded in all cases, regardless of patient history. Evaluation of menstrual dysfunction depends on understanding the interrelationships between the four critical components of the reproductive tract: (1) the hypothalamus, (2) the pituitary, (3) the ovaries, and (4) the uterus and outflow tract **(Fig. 405-1; Chap. 404)**. This system is maintained by complex negative and positive feedback loops involving the ovarian steroids (estradiol and progesterone) and peptides (inhibin B and inhibin A) and the hypothalamic (gonadotropin-releasing hormone [GnRH]) and pituitary (follicle-stimulating hormone [FSH] and luteinizing hormone [LH]) components of this system (Fig. 405-1).

Disorders of menstrual function fall into two main categories: disorders of the uterus and outflow tract and disorders of ovulation. Many of the conditions that cause primary amenorrhea are congenital but go unrecognized until the time of normal puberty (e.g., genetic, chromosomal, and anatomic abnormalities). All causes of secondary amenorrhea also can cause primary amenorrhea.

Disorders of the Uterus or Outflow Tract Abnormalities of the uterus and outflow tract typically present as primary amenorrhea. In patients with normal pubertal development and a blind vagina,

	Primary	Secondary
Hypothalamus	28%	36%
Pituitary	2%	15%
PCOS	8%	30%
Ovary	43%	12%
Uterus/outflow tract	19%	7%

FIGURE 405-1 Role of the hypothalamic-pituitary-gonadal axis in the etiology of amenorrhea. Gonadotropin-releasing hormone (GnRH) secretion from the hypothalamus stimulates follicle-stimulating hormone (FSH) and luteinizing hormone (LH) secretion from the pituitary to induce ovarian folliculogenesis and steroidogenesis. Ovarian secretion of estradiol and progesterone controls the shedding of the endometrium, resulting in menses, and, in combination with the inhibins, provides feedback regulation of the hypothalamus and pituitary to control secretion of FSH and LH. The prevalence of amenorrhea resulting from abnormalities at each level of the reproductive system (hypothalamus, pituitary, ovary, uterus, and outflow tract) varies depending on whether amenorrhea is primary or secondary. PCOS, polycystic ovarian syndrome.

the differential diagnosis includes *obstruction* by a transverse vaginal septum or imperforate hymen; *müllerian agenesis* (Mayer-Rokitansky-Kuster-Hauser syndrome), which can be caused by mutations in the *WNT4* gene, and *androgen insensitivity syndrome* (AIS), which is an X-linked recessive disorder that accounts for ~10% of all cases of primary amenorrhea (Chap. 403). Patients with AIS have a 46,XY karyotype, but because of the lack of androgen receptor responsiveness, those with complete AIS lack features of androgenization and have female external genitalia. The absence of pubic and axillary hair distinguishes them clinically from patients with müllerian agenesis, as does a testosterone level in the male range. The rare patient with 5α reductase type 2 enzyme deficiency has a similar presentation but undergoes virilization at the time of puberty. *Asherman's syndrome* presents as secondary amenorrhea or hypomenorrhea and results from partial or complete obliteration of the uterine cavity by adhesions that prevent normal growth and shedding of the endometrium. Curettage performed for pregnancy complications accounts for >90% of cases; genital tuberculosis is an important cause in regions where it is endemic.

TREATMENT

Disorders of the Uterus or Outflow Tract

Obstruction of the outflow tract usually presents as dysmenorrhea or lower abdominal cyclic pain with no menses. Evaluation of the patient includes a medical history, physical examination including a perineal examination, and ultrasound imaging. In many cases, a magnetic resonance imaging (MRI) scan can more accurately identify the reproductive tract anomaly prior to surgery. It is important that surgery be performed as soon as the diagnosis is made as the risk of endometriosis is increased with retrograde menstrual flow. *Müllerian agenesis* may require surgical intervention to allow sexual intercourse, although vaginal dilatation is adequate in some patients. In these patients, because ovarian function is normal, assisted reproductive techniques can be used with a surrogate carrier. More recently, there have been a few cases of successful uterine transplantation in women with müllerian agenesis. AIS (Chap. 402) requires gonadectomy because there is risk of gonadoblastoma in the dysgenetic gonads, although surgery is generally delayed until after breast development and the pubertal growth spurt. Estrogen replacement is indicated after gonadectomy, and vaginal dilatation may be required to allow sexual intercourse.

Disorders of Ovulation Once uterus and outflow tract abnormalities have been excluded, other causes of amenorrhea involve disorders of ovulation. The differential diagnosis is based on the results of initial tests, including a pregnancy test, an FSH level (to determine whether the cause is likely to be ovarian or central), and assessment of hyperandrogenism (Fig. 405-2).

HYPOGONADOTROPIC HYPOGONADISM Low estrogen levels in combination with normal or low levels of LH and FSH are seen with anatomic, genetic, or functional abnormalities that interfere with hypothalamic GnRH secretion or normal pituitary responsiveness to GnRH. Although relatively uncommon, tumors and infiltrative diseases should be considered in the differential diagnosis of hypogonadotropic hypogonadism (Chap. 392). These disorders may present with primary or secondary amenorrhea. They may occur in association with other features suggestive of hypothalamic or pituitary dysfunction, such as short stature, diabetes insipidus, galactorrhea, and headache. Hypogonadotropic hypogonadism also may be seen after cranial irradiation. In the postpartum period, amenorrhea occurs normally in association with breast feeding but may also be caused by pituitary necrosis (Sheehan's syndrome) or lymphocytic hypophysitis. Because reproductive dysfunction is commonly associated with hyperprolactinemia from neuroanatomic lesions or medications, prolactin should be measured in all patients with hypogonadotropic hypogonadism (Chap. 392).

Isolated hypogonadotropic hypogonadism (IHH) occurs in women, although it is three times more common in men. IHH generally presents with primary amenorrhea, although 50% have some degree of

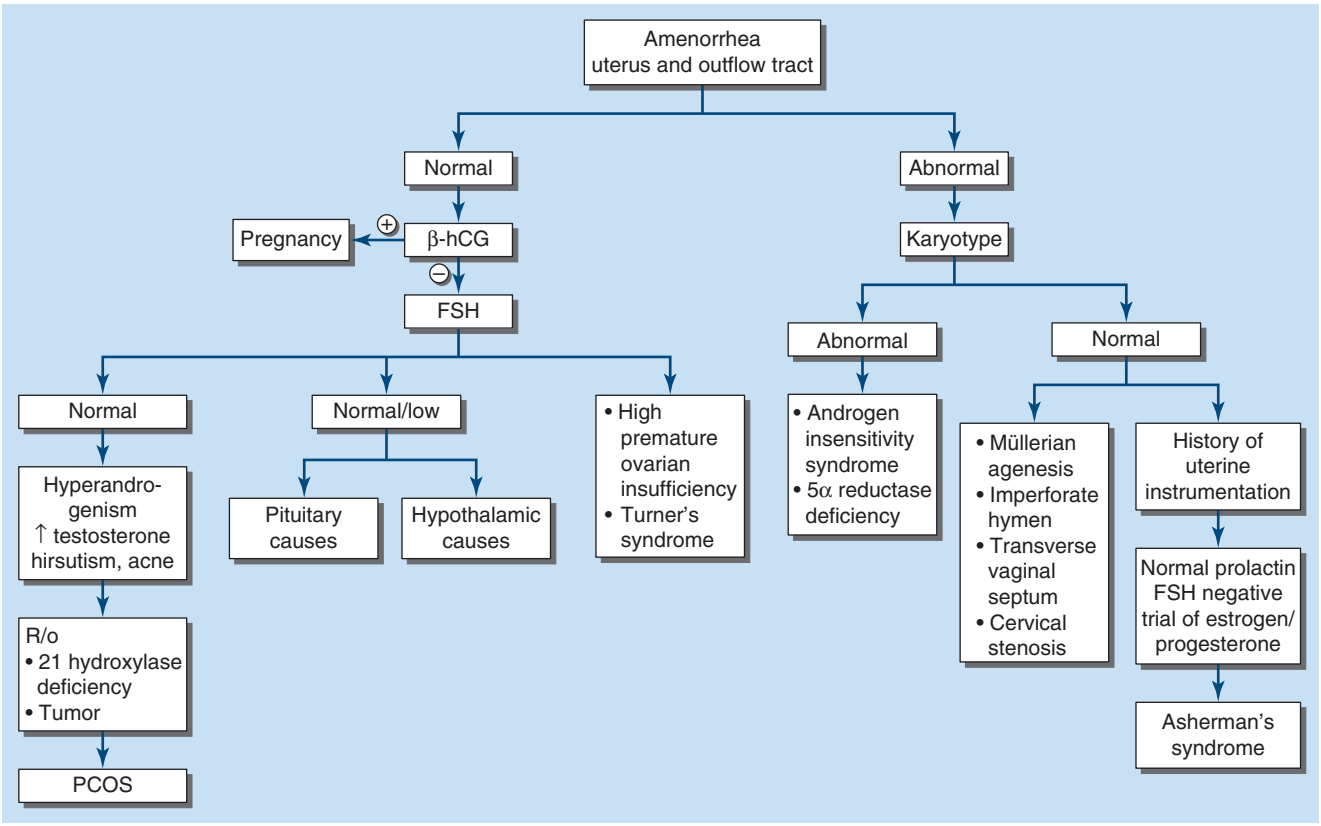


FIGURE 405-2 Algorithm for evaluation of amenorrhea. β-hCG, β-human chorionic gonadotropin; FSH, follicle-stimulating hormone; GYN, gynecologist; MRI, magnetic resonance imaging; PRL, prolactin; R/O, rule out; TSH, thyroid-stimulating hormone.

breast development, and ~10% report one to two menses. IHH is associated with anosmia in half of women (termed Kallmann's syndrome). Genetic causes of IHH have been identified in ~50% of patients **(Chaps. 403 and 404)**.

Functional hypothalamic amenorrhea (HA) is a diagnosis of exclusion of other causes of hypogonadotropic hypogonadism including chronic diseases (type 1 diabetes, celiac disease, hyperthyroidism, Cushing's syndrome) and use of opioids, glucocorticoids, or psychotropic medications that increase prolactin levels. Functional HA is most commonly associated with conditions causing a mismatch between energy expenditure and energy intake and/or significant stress leading to increased corticotropin-releasing hormone (CRH), suppression of GnRH, and decreased thyrotropin-releasing hormone (TRH) input. Variants in genes associated with IHH may increase susceptibility to these environmental inputs, accounting in part for the clinical variability in this disorder. Metabolic and stress signaling is transduced to the reproductive axis, at least in part, through leptin signaling from the periphery and via hypothalamic kisspeptin, neurokinin B, and dynorphin control of GnRH. The diagnosis of HA generally can be made on the basis of a careful history, a physical examination, and the demonstration of low levels of gonadotropins and normal prolactin levels. Eating disorders, excessive exercise, and chronic disease must be specifically excluded. An atypical history, headache, signs of other hypothalamic dysfunction, or hyperprolactinemia, even if mild, necessitates cranial MRI to exclude a neuroanatomic cause. Up to 10% of women with HA may have some features of PCOS (irregular menses, increased ovarian volume with polycystic appearing ovaries, higher anti-müllerian hormone [AMH] levels, and slightly elevated androgen levels).

HYPERGONADOTROPIC HYPOGONADISM Ovarian failure is considered premature when it occurs in women <40 years old and accounts for ~10% of secondary amenorrhea. *Primary ovarian insufficiency* (POI) has replaced the terms *premature menopause* and *premature ovarian failure* in recognition of the continuum of impaired ovarian function encompassed by this disorder. Ovarian insufficiency is associated with the loss of negative feedback restraint on the hypothalamus and pituitary, resulting in increased FSH and LH levels. FSH is a better marker of ovarian failure because of loss of negative feedback effects of both estradiol and the inhibins and because its levels are less variable than those of LH. AMH levels will also be low in patients with POI. As with natural menopause, POI may wax and wane, and serial measurements may be necessary to establish the diagnosis. The presentation may include irregular menses or complete cessation of menses, hot flashes, and vaginal dryness.

Once the diagnosis of POI has been established, further evaluation is indicated because of other health problems that may be associated with POI. Although POI is most commonly of unknown cause, it also occurs in association with a variety of chromosomal abnormalities (most often Turner's syndrome), autoimmune polyglandular failure syndromes, and other rare disorders. Radiotherapy and chemotherapy may reduce ovarian reserve, with effects on both the oocytes and the supporting granulosa cells. New approaches, including ovarian, oocyte, and embryo cryopreservation, should be offered to women of reproductive age prior to gonadotoxic chemotherapy or pelvic radiation treatment. The recognition that early ovarian insufficiency occurs in premutation carriers of the fragile X syndrome is important because of the increased risk of severe intellectual disability in male children with *FMR1* mutations. Thus, follow-up testing should include a karyotype in all POI patients, serum anti-cortical and 21-hydroxylase antibodies (specific but not sensitive for subsequent adrenal insufficiency), thyroid function and thyroid peroxidase antibodies, *FMR1* premutation screening, and assessment of bone mineral density. Ovarian biopsy is not indicated. Although the number of genetic causes of POI is increasing, routine testing for mutations other than *FMR1* is currently not recommended.

Hypergonadotropic hypogonadism occurs rarely in other disorders, such as mutations in the FSH or LH receptors. Aromatase deficiency and 17α-hydroxylase deficiency are associated with decreased estrogen and elevated gonadotropins and with hyperandrogenism and

hypertension, respectively. Gonadotropin-secreting tumors in women of reproductive age generally present with high, rather than low, estrogen levels and cause ovarian hyperstimulation or dysfunctional bleeding.

TREATMENT

Hypo- and Hypergonadotropic Causes of Amenorrhea

Amenorrhea almost always is associated with chronically low levels of estrogen, whether it is caused by hypogonadotropic hypogonadism or ovarian insufficiency. Development of secondary sexual characteristics requires gradual titration of estradiol replacement with eventual addition of progestin. Hormone replacement with either low-dose estrogen/progesterone regimens or oral contraceptive pills is recommended until the usual age of menopause for bone and cardiovascular protection. In women with functional HA or anorexia nervosa, hormone replacement alone may not be sufficient to restore or maintain bone density. A more long-term multidisciplinary approach including behavioral health professionals is essential. Patients with hypogonadotropic hypogonadism who are interested in fertility require treatment with both exogenous FSH and LH. Patients with POI can consider oocyte donation, which has a high rate of success in this population, although its use in women with Turner's syndrome is limited by increased cardiovascular risk in pregnancy.

POLYCYSTIC OVARY SYNDROME The diagnosis of PCOS is made in adult women using the updated Rotterdam criteria (published in the 2023 international guidelines). These include irregular menses (<8 menses per year), clinical or biochemical hyperandrogenism (elevated total or free testosterone, modified Ferriman-Gallwey score >4–6 depending on ethnicity, see **Chap. 406**), and polycystic-appearing ovaries on ultrasound (≥20 antral follicles or ovarian volume ≥10 cm^3 in at least one ovary) or elevated AMH. The presence of two of the three criteria will confirm the diagnosis, resulting in different phenotypes, namely, hyperandrogenic or non-hyperandrogenic. PCOS is a diagnosis of exclusion, and other etiologies for irregular menses and hyperandrogenism should be excluded (hypothyroidism, hyperprolactinemia, adrenal sources for hyperandrogenism). Diagnosis in adolescents may be difficult to establish, and it is recommended to wait at least 3 years after menarche before confirming the diagnosis. In adolescents, the diagnosis is based on irregular menses and hyperandrogenism criteria only, as the ultrasound and AMH criteria are not established for this age group. Lean oligo-ovulatory patients with PCOS generally have high LH levels in the presence of normal to low levels of FSH and estradiol, although given the pulsatility of LH secretion, a random serum LH/FSH ratio is not included in the diagnostic criteria. The prevalence of obesity is high in PCOS and significantly increases the risk of comorbidities including metabolic syndrome, type 2 diabetes, dyslipidemia, hypertension, and cardiovascular disease. Frequent anovulation results in irregular menses and increased risk of endometrial hyperplasia and endometrial cancer (two- to sixfold increased risk). Abnormalities in GnRH pulsatility result in elevated LH levels resulting in increased production of ovarian androgens. Insulin resistance, especially in skeletal muscle and adipose tissue, also contributes to increased insulin-stimulated ovarian androgen production. An alternate source of androgens, namely 11-oxygenated androgens, may also be elevated in this population. Genome-wide association studies in diverse populations and PCOS phenotypes have identified several loci (~19) associated with PCOS, and cluster analyses suggest the presence of reproductive and metabolic abnormalities. Symptoms generally begin in adolescence and are modified by obesity and age, such that by the fourth decade of life, most women with PCOS will have regular menses and normal serum androgens. There is a high prevalence of depression and anxiety disorders, as well as disordered eating and body image distress. PCOS is also associated with an increased risk of obstructive sleep apnea and metabolic dysfunction-associated steatotic liver disease (MDSLD), independent of body mass index (BMI).

TREATMENT

Polycystic Ovary Syndrome

The first-line treatment of women with PCOS not attempting pregnancy is combined hormonal contraceptives to regulate menstrual cycles and decrease serum androgens by increasing sex hormone–binding globulin levels. Although serum androgens decrease by 2–3 months after initiating hormonal therapy, it may take longer to observe the beneficial effects on hirsutism and acne. Patients should be prescribed hormonal contraceptives containing the lowest effective dose of estrogen, either in a cyclic or continuous manner. If there is an inadequate response to hormonal contraceptives after 6 months for management of hyperandrogenic symptoms, antiandrogens, such as spironolactone and flutamide, can be considered **(Chap. 406)**. Endometrial protection can also be achieved with the use of progestins (medroxyprogesterone acetate,10 mg, or Prometrium [progesterone], 200 mg daily for 10–14 days at least every 3 months, or a levonorgestrel intrauterine device [IUD]). All women with PCOS should be screened for obesity, hypertension, glycemic control, depression, and anxiety at the time of diagnosis and then at regular intervals. Overweight and obese women should also have a fasting lipid profile at the time of diagnosis. Lifestyle management should be recommended in all women with PCOS, and metformin should be considered for prevention of cardiometabolic risk factors in those with overweight and obesity **(Chap. 420)**. Women with PCOS are at an increased risk of early miscarriage, gestational diabetes, gestational hypertension, preeclampsia, and preterm birth. Lifestyle management and prepregnancy counseling should be offered prior to attempting pregnancy **(Chap. 408)**. Letrozole, an aromatase inhibitor, is the first-line treatment for ovulation induction followed by clomiphene citrate, a selective estrogen response modulator, with or without metformin. Injectable gonadotropins can be used judiciously by experienced practitioners to induce monofollicular growth as PCOS increases the risk of hyperstimulation. Metformin can be used as an adjunct with diet and exercise for obese women with PCOS or for treatment of diabetes or impaired glucose tolerance, as in non-PCOS patients. However, metformin alone is not recommended for endometrial protection or treatment of hyperandrogenic symptoms, infertility, pregnancy loss, or prevention of gestational diabetes.

PELVIC PAIN

The mechanisms that cause pelvic pain are similar to those that cause abdominal pain **(Chap. 16)** and include inflammation of the parietal peritoneum, obstruction of hollow viscera, vascular disturbances, and pain originating in the abdominal wall. Pelvic pain may reflect pelvic disease per se but also may reflect extrapelvic disorders that refer pain to the pelvis. In up to 60% of cases, pelvic pain can be attributed to gastrointestinal problems, including appendicitis, cholecystitis, infections, intestinal obstruction, diverticulitis, and inflammatory bowel disease. Urinary tract and musculoskeletal disorders are also common causes of pelvic pain.

APPROACH TO THE PATIENT

Pelvic Pain

As with all types of abdominal pain, the first priority is to identify life-threatening conditions (shock, peritoneal signs) that may require emergent surgical management. The possibility of pregnancy should be identified as soon as possible by menstrual history and β-human chorionic gonadotropin (β-hCG) testing. A thorough history that includes the type, location, radiation, and recurrence can help identify the cause of acute pelvic pain. Specific associations

with vaginal bleeding, sexual activity, defecation, urination, movement, or eating should be specifically sought. Determination of whether the pain is acute versus chronic and cyclic versus noncyclic will direct further investigation (Table 405-1). However, disorders that cause cyclic pain occasionally may cause noncyclic pain, and the converse is also true.

ACUTE PELVIC PAIN

Pelvic inflammatory disease (PID) refers to infection of the upper genital tract and may present with a spectrum of symptoms. In the acute setting, the most common presentation is bilateral lower abdominal pain of recent onset that may be exacerbated with sexual activity. Risk factors for PID include age <25 years and history of multiple sexual partners, sexually transmitted infections (STIs), or recent uterine procedures. However, any sexually active woman can be at risk for PID. PID associated with tubo-ovarian abscess or peritonitis may present with severe pain, fever, and peritoneal signs. Abnormal uterine bleeding may occur in about one-third of patients. Cervical motion tenderness, uterine and adnexal pain, and vaginal discharge are common findings on pelvic examination. The presence of right upper quadrant pain is suggestive of perihepatitis (Fitz-Hugh–Curtis syndrome).

The diagnosis of PID is established based on symptoms and clinical examination and can be aided by a wet mount preparation of vaginal discharge and nucleic acid amplification tests for *Chlamydia trachomatis* and *Neisseria gonorrhoeae*. Of note, a presumptive clinical diagnosis is sufficient to prescribe treatment even in the absence of positive test results, as PID can occur due to other vaginal and enteric pathogens. Pelvic imaging can be obtained based on symptoms, findings of the pelvic examination, or if there is lack of response to therapy. With public health efforts to control STIs, the incidence and severity of PID have declined in the United States and Europe; however, this is not the case in the developing world. Subclinical PID with its attendant risks of infertility and ectopic pregnancy remains a significant problem worldwide. Public health and professional organizations recommend annual testing for *C. trachomatis* in all sexually active women <25 years old and both *C. trachomatis* and *N. gonorrhoeae* in all women at increased risk. *Adnexal pathology* can present acutely and may be due to rupture, bleeding, or torsion of ovarian cysts or, much less commonly, the fallopian tubes. Rupture of an ovarian cyst may be diagnosed based on the acute presentation in a reproductive-age woman and pelvic ultrasound findings of a simple, collapsed or hemorrhagic cyst, with or without free fluid in the pelvis. Ovarian torsion typically presents as acute onset of unilateral, intermittent pain and is a diagnosis of exclusion unless absent blood flow to the ovary is demonstrated via Doppler ultrasound imaging. Neoplasms of the ovary or fallopian tube are much less common causes of acute pain.

Ectopic pregnancy represents 1–2% of all pregnancies and most commonly occurs in the fallopian tubes. It may present with acute lower abdominal pain, hemodynamic instability, and peritoneal signs. The index of suspicion should be high in any reproductive-age woman presenting with abdominal pain or vaginal bleeding irrespective of current use of contraception. Risk factors for an ectopic pregnancy include history of tubal disease, pelvic infection, tubal surgery, previous ectopic pregnancy, infertility, smoking, and current use of IUD, although a large proportion may have no risk factors. Rupture of the fallopian tube remains a life-threatening emergency; the incidence depends on access to care but is ~18% in developed countries. Diagnosis of an ectopic pregnancy can be established by assessing the patient's menstrual history and symptoms, measuring a single or serial β-hCG levels, and performing pelvic ultrasound imaging. β-hCG levels typically double every 48 h in early first trimester, and 99% of viable intrauterine pregnancies are associated with an increase in hCG levels of at least 53% in 2 days. The discriminatory zone refers to β-hCG values above which the landmarks of a normal intrauterine pregnancy should be seen on ultrasound (1500–3000 IU/mL). Absence of an intrauterine pregnancy and presence of an adnexal mass or free fluid increase the likelihood of an ectopic pregnancy. *Threatened abortion* may also present with amenorrhea, abdominal pain, and vaginal bleeding with no cervical dilation in the setting of an intrauterine pregnancy with cardiac activity in the first trimester of pregnancy. Although more common than ectopic pregnancy, it is rarely associated with systemic signs. *Uterine pathology* includes endometritis, and less frequently, degenerating leiomyomas (fibroids) present with acute pain. Endometritis often is associated with vaginal bleeding and systemic signs of infection. It occurs in the setting of STIs, uterine instrumentation, or postpartum infection.

TABLE 405-1 Gynecologic Causes of Pelvic Pain

TREATMENT

Acute Pelvic Pain

Treatment of acute pelvic pain depends on the suspected etiology but may require surgical or medical intervention. Immediate treatment of PID is indicated upon diagnosis, even if the diagnosis is presumed or the symptoms are mild, due to long-term complications resulting in increased risk of ectopic pregnancy and infertility. Treatment in patients eligible for outpatient management includes 250 mg IM ceftriaxone and a 14-day course of oral doxycycline 100 mg twice daily. If the presentation is acute with high fever, nausea, vomiting, severe abdominal pain, or presence of tubo-ovarian abscess, inpatient therapy is recommended (Chap. 141). Conservative management is an important consideration for *ovarian cysts*, if torsion is not suspected, to avoid unnecessary surgery and associated risks of reduced fertility due to cystectomy or adhesions. If surgery is performed, it is preferable to perform a cystectomy, removing the cyst wall and leaving the remaining ovary, in a reproductive-age woman. Combined hormonal contraceptives are recommended in women with a history of recurrent ovarian cyst formation. Surgical treatment may be required for *ectopic pregnancies* when the patient presents with acute pain, is hemodynamically unstable, or has signs of intraperitoneal bleeding. The choice of salpingectomy versus salpingostomy is based on patient's presentation, desire for future child-bearing, and prior pelvic infections. Clinically stable women presenting with unruptured ectopic pregnancies may be appropriate for treatment with methotrexate, which is effective in ~90% of cases when multiple doses are used. Threatened abortion is managed conservatively even in the presence of a subchorionic hemorrhage. The treatment of endometritis is similar to PID. Pain from a degenerating fibroid, if visualized on pelvic sonography, can be managed with nonsteroidal anti-inflammatory drugs (NSAIDs).

CHRONIC PELVIC PAIN

Chronic pelvic pain is a complex condition resulting from gynecologic, urologic, or gastrointestinal organs and contributes to significant frustration and burden of disease. Common gynecologic conditions contributing to chronic pain are endometriosis, fibroids, adenomyosis, and adnexal pathology. In addition to a detailed history and physical exam, the evaluation of chronic pelvic pain typically includes a pelvic ultrasound. As causes other than those related to the female reproductive system are common, referral should be made to other specialists,

as appropriate. Neuromuscular and psychosomatic etiologies should also be considered.

Some women experience discomfort at the time of ovulation (*mittelschmerz* or *ovulation pain*). The pain can be quite intense but is generally of short duration. The mechanism is thought to involve rapid expansion of the dominant follicle, although it also may be caused by peritoneal irritation by follicular fluid released at the time of ovulation.

Dysmenorrhea typically refers to the crampy lower abdominal midline discomfort that begins with the onset of menstrual bleeding and gradually decreases over 12–72 h. It may be associated with nausea, diarrhea, fatigue, and headache and occurs in 60–93% of adolescents, beginning with the establishment of regular ovulatory cycles. Its prevalence decreases after pregnancy and can be treated effectively with hormonal contraceptives. *Primary dysmenorrhea* results, in a majority of cases, from hormone-dependent prostaglandin (PG) pathway mechanisms that cause intense uterine contractions, decreased blood flow, and increased peripheral nerve hypersensitivity, resulting in pain. However, variability in response to cyclooxygenase inhibitors suggests that PG-independent pathways, such as platelet activating factor, may also mediate inflammation. *Secondary dysmenorrhea* refers to pain caused by underlying pelvic pathology.

Endometriosis results from the presence of endometrial glands and stroma outside the uterus. These deposits of ectopic endometrium respond to hormonal stimulation and may be associated with dysmenorrhea, painful intercourse, and painful bowel movements. On pelvic exam, adnexal tenderness may be present or tender nodules may be palpated along the uterosacral ligaments. Pain associated with endometriosis can be cyclic or continuous, and the stage/severity of endometriosis, as determined by laparoscopy, does not always correlate with the extent of pain. Transvaginal pelvic ultrasound is part of the initial workup and may detect an endometrioma within the ovary. Additional sonographic techniques can be used to identify deep endometriosis including nonmobile ovaries and rectovaginal or bladder nodules. The CA-125 level may be increased, but it has low negative predictive value. Pelvic MRI has higher sensitivity and specificity for diagnosis of endometriosis. Diagnostic laparoscopy is performed when patients do not respond adequately to empiric treatment and is considered the gold standard for diagnosis. If endometriosis is detected, the severity can be staged and the endometriotic lesions ablated or excised.

Large *fibroids* can cause chronic pelvic pain or pressure, and submucosal fibroids may be associated with dysmenorrhea. *Other secondary causes* of dysmenorrhea include adenomyosis, a condition caused by the presence of ectopic endometrial glands and stroma within the myometrium. Chronic PID may be associated with ongoing pelvic pain and is associated with tuberculosis or actinomycosis. *Pelvic congestion syndrome* is associated with pelvic varicosities with low blood flow, resulting in pelvic venous congestion. However, this is no clear evidence to indicate that this finding is associated with chronic pelvic pain.

TREATMENT

Chronic Pelvic Pain

DYSMENORRHEA

Local application of heat, exercise, sexual activity, a vegetarian diet, use of vitamins D, B_1, B_6, and E and fish oil, acupuncture, and yoga have all been suggested to be of benefit, but studies are not adequate to provide recommendations. However, NSAIDs are very effective and provide >80% sustained response rates. Ibuprofen, naproxen, ketoprofen, mefenamic acid, and nimesulide are all superior to placebo. For best response, treatment should be initiated prior to the onset of menses and continued for at least 2–3 days. Combined or progestin-only hormonal contraceptives taken cyclically or continuously effectively reduce symptoms of dysmenorrhea.

ENDOMETRIOSIS

Combined hormonal contraceptives or continuous progestin (either orally, implants, or a levonorgestrel IUD) is used for the treatment of endometriosis. Evidence of an endometrioma on ultrasound imaging can be medically managed and does not require surgical removal unless it increases in size or there is persistent pain. Patients who do not respond to medical management and laparoscopic resection of endometriotic lesions can be offered GnRH agonist suppression with add-back therapy or aromatase inhibitors.

FIBROIDS

Chronic pain and dysmenorrhea associated with *fibroids* can be managed medically or surgically depending on the number and location of fibroids and associated symptoms. The U.S. Food and Drug Administration (FDA) approved the first two oral treatments for uterine fibroids (elagolix with estradiol/norethindrone acetate and relugolix with estradiol/norethindrone acetate), and the selective progesterone receptor modulator ulipristal acetate was withdrawn in Europe and Canada. Medical management includes oral hormonal contraceptives, tranexamic acid, NSAIDs, progestins, IUDs, and GnRH agonists and antagonists. Surgical management includes myomectomy, endometrial ablation/myolysis, radiofrequency volumetric thermal ablation, laparoscopic ablation, or hysterectomy. Chronic pain and dysmenorrhea associated with adenomyosis can be managed with combined hormonal treatment, levonorgestrel IUD, or hysterectomy after child-bearing is complete.

406 Hirsutism

David A. Ehrmann

DEFINING HIRSUTISM

Body hair can be categorized as either *vellus* (fine, soft, and not pigmented) or *terminal* (long, coarse, and pigmented). Approximately 10% of reproductive-age women have hirsutism, defined by the presence of excessive terminal hair growth. Hirsutism is most often idiopathic or the consequence of androgen excess associated with polycystic ovary

TABLE 406-1 Causes of Hirsutism

Cyclosporine
Valproic acid
Ovotesticular disorders of sex development

syndrome (PCOS). Less frequently, it results from adrenal androgen overproduction as occurs in nonclassic congenital adrenal hyperplasia (CAH) **(Table 406-1)**.

Virilization refers to a condition that may the result from benign hyperplasia of ovarian theca and stroma cells (e.g., *hyperthecosis*); it may also be a harbinger of a serious underlying condition, such as an ovarian or adrenal neoplasm. In women with virilization, androgen levels are sufficiently high to cause deepening of the voice, breast atrophy, increased muscle bulk, clitoromegaly, and increased libido. Cutaneous manifestations commonly associated with hirsutism include acne and hair thinning or pattern hair loss (androgenic alopecia).

HAIR FOLLICLE GROWTH AND DIFFERENTIATION

The number of hair follicles remains unchanged over the life span, but follicle size and the type of hair can change in response to numerous factors, particularly androgens. Androgens are necessary for terminal hair and sebaceous gland development and mediate differentiation of pilosebaceous units (PSUs) into a terminal hair follicle and/or a sebaceous gland. In the former case, androgens transform the vellus hair into a terminal hair; in the latter case, the sebaceous component proliferates and the hair remains vellus.

There are three phases in the cycle of hair growth: (1) *anagen* (growth phase), (2) *catagen* (involution phase), and (3) *telogen* (rest phase). Depending on the body site, hormonal regulation may play an important role in the hair growth cycle. Hair growth on the face, chest, upper abdomen, and back typically requires elevated androgen concentrations. However, there is only a modest correlation between androgen levels and the quantity of hair growth. This is due to the fact that hair growth from the follicle also depends on local growth factors, and the variability in end-organ (PSU) sensitivity to androgens. Genetic factors and ethnic background also influence hair growth. Androgen excess in women may result in hair thinning or loss because androgens cause scalp hairs to spend less time in the anagen phase.

In general, dark-haired individuals tend to be more hirsute than blond or fair individuals. Asians and Native Americans have relatively sparse hair in regions sensitive to high androgen levels, whereas people of Mediterranean descent are more hirsute.

CLINICAL ASSESSMENT

Historic elements relevant to the assessment of hirsutism include the age at onset and rate of progression of hair growth and associated symptoms or signs (e.g., menstrual irregularity and acne). Depending on the cause, excess hair growth typically is first noted during the second and third decades of life. The growth is usually slow but progressive. Sudden development and rapid progression of hirsutism suggest the possibility of an androgen-secreting neoplasm, in which case virilization may also be present.

The age at onset of menstrual cycles (menarche) and the pattern of the menstrual cycle should be ascertained. Menses may be irregular in the first 2 years after menarche; oligomenorrhea (<8 cycles per calendar year) thereafter is more likely to result from ovarian than adrenal androgen excess. Associated symptoms such as galactorrhea should prompt evaluation for hyperprolactinemia **(Chap. 392)** or possibly hypothyroidism **(Chap. 394)**. Hypertension, striae, easy bruising, and centripetal weight gain suggest hypercortisolism (Cushing's syndrome; **Chap. 398**). Rarely, patients with acromegaly present with hirsutism. Medications such as phenytoin, minoxidil, and cyclosporine may be associated with androgen-*independent* excess hair growth (i.e., hypertrichosis). A family history of infertility and/or hirsutism may indicate inherited disorders such as nonclassic CAH **(Chap. 398)**.

Physical examination should include measurement of height and weight and calculation of body mass index (BMI). A BMI >25 kg/m^2 is indicative of excess weight for height, and values >30 kg/m^2 are often seen in association with hirsutism, probably the result of increased conversion of androgen precursors to testosterone. Notation should be made of blood pressure, as adrenal causes may be associated with hypertension. Cutaneous signs sometimes associated with androgen excess and insulin resistance include acanthosis nigricans and skin tags.

An objective clinical assessment of hair distribution and quantity is central to the evaluation in any woman presenting with concerns about excessive hair growth. This assessment permits the distinction between hirsutism and hypertrichosis and provides a baseline reference point to gauge the response to treatment. A simple and commonly used method to grade hair growth is the modified scale of Ferriman and Gallwey **(Fig. 406-1)**, in which each of nine androgen-sensitive sites is graded from 0 (no hair growth) to 4 (hair growth typically seen in adult men). Although it is normal for most women to have some hair growth in androgen-sensitive sites, ~95% of non-Hispanic white and African American women have a score <8 on this scale. Scores >8 suggest excess androgen-mediated hair growth, a finding that should be assessed further by means of hormonal evaluation (see below). Asian and Native American women are less likely to manifest hirsutism, and the only cutaneous evidence of androgen excess may be pustular acne and thinning scalp hair.

HORMONAL EVALUATION

Androgens are secreted by the ovaries and adrenal glands in response to their respective tropic hormones: luteinizing hormone (LH) and adrenocorticotropic hormone (ACTH). Testosterone is the principal circulating steroid involved in the etiology of hirsutism; other steroids that may contribute to the development of hirsutism include androstenedione and dehydroepiandrosterone (DHEA) and its sulfated form (DHEAS). The ovaries and adrenal glands normally contribute about equally to testosterone production. Approximately half of the total testosterone originates from direct glandular secretion, and the remainder is derived from the peripheral conversion of androstenedione and DHEA **(Chap. 393)**.

Testosterone is the most important circulating androgen, but it is a precursor hormone in mediating hirsutism. Testosterone is converted to dihydrotestosterone (DHT) by the enzyme 5α-reductase, which is

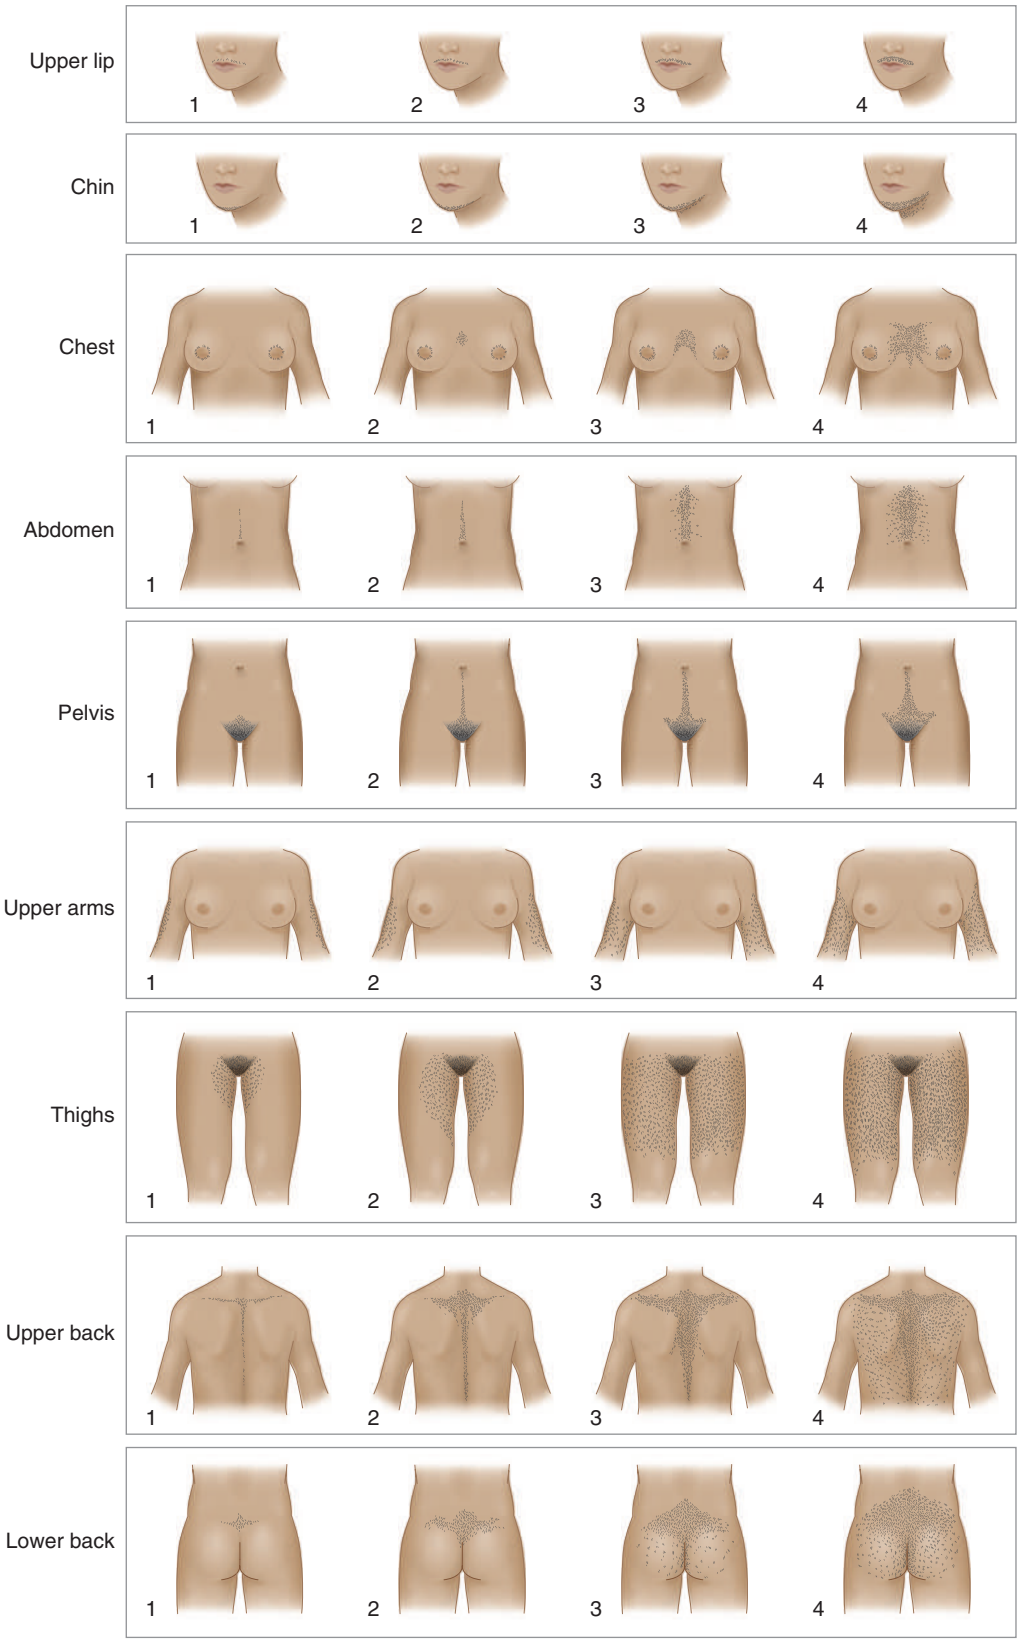

FIGURE 406-1 Hirsutism scoring scale of Ferriman and Gallwey. The nine body areas that have androgen-sensitive areas are graded from 0 (no terminal hair) to 4 (frankly virile) to obtain a total score. A normal hirsutism score is <8. *(Modified with permission from LJ DeGroot, JL Jameson: Endocrinology, 5th ed. Philadelphia, PA: Saunders; 2006.)*

located in the PSU. DHT is more potent than testosterone as it has a higher affinity for, and slower dissociation from, the androgen receptor. The local production of DHT allows it to serve as the primary mediator of androgen action at the level of the PSU. There are two isoenzymes of 5α-reductase: type 2 is found in the prostate gland and in hair follicles, and type 1 is found primarily in sebaceous glands.

One approach to the evaluation and treatment of hirsutism is depicted in Fig. 406-2. In addition to measuring blood levels of testosterone and DHEAS, it is often important to measure the level of free (or unbound) testosterone, i.e., the fraction of testosterone that is not bound to its carrier protein, sex hormone–binding globulin (SHBG). Unbound testosterone is biologically available for conversion to DHT

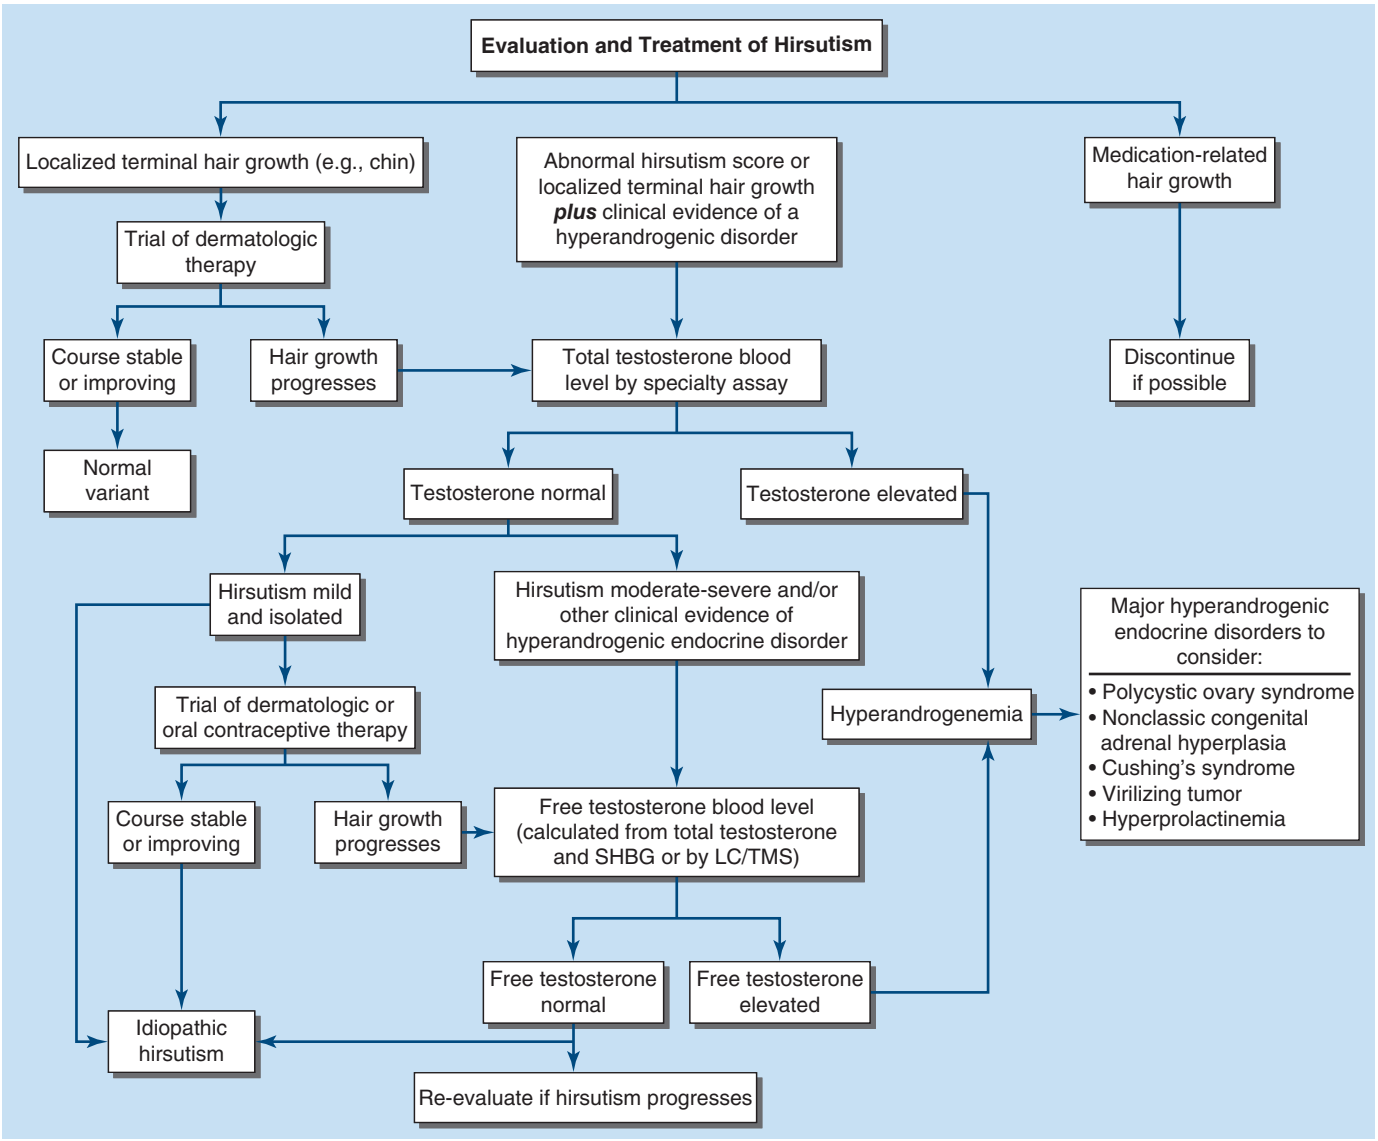

FIGURE 406-2 Algorithm for the evaluation and treatment of hirsutism. LC/TMS, liquid chromatography/tandem mass spectrometry; SHBG, sex hormone–binding globulin. *(Reproduced with permission from KA Martin et al: Evaluation and treatment of hirsutism in premenopausal women: An endocrine society clinical practice guideline. J Clin Endocrinol Metab 103:1233, 2018.)*

and binding to androgen receptors. Both hyperinsulinemia and androgen excess decrease hepatic production of SHBG, resulting in levels of total testosterone within the high-normal range, whereas the unbound hormone is elevated more substantially. Although there is a decline in ovarian testosterone production after menopause, ovarian estrogen production decreases to an even greater extent, and the concentration of SHBG is reduced. Consequently, there is an increase in the relative proportion of unbound testosterone, and it may exacerbate hirsutism after menopause.

A baseline plasma total testosterone level >12 nmol/L (>3.5 ng/mL) usually indicates an androgen-producing tumor, whereas a level >7 nmol/L (>2 ng/mL) is suggestive of tumor but may also be observed in women with hyperthecosis. A basal DHEAS level >18.5 μmol/L (>7000 μg/L) suggests an adrenal tumor. Although DHEAS has been proposed as a "marker" of predominant adrenal androgen excess, it is not unusual to find modest elevations in DHEAS among women with PCOS. Computed tomography (CT) or magnetic resonance imaging (MRI) should be used to localize an adrenal mass, and transvaginal ultrasound usually suffices to identify an ovarian mass if clinical evaluation and hormonal levels suggest these possibilities.

PCOS is the most common cause of ovarian androgen excess **(Chap. 404)**. An increased ratio of LH to follicle-stimulating hormone (FSH) is characteristic in carefully studied patients with PCOS. However, because of the pulsatile nature of gonadotropin secretion, a random measurement of LH and FSH may be misleading and is not recommended. Transvaginal ultrasound classically shows enlarged ovaries, increased stroma, and multiple "cysts" in women with PCOS. These so-called cysts are, in fact, preantral and early antral follicles that result from abnormal follicular maturation. "Cystic" ovaries also may be found in women with hypothalamic amenorrhea **(Chap. 404)** and even among women without clinical or laboratory features of PCOS. Thus, ultrasonography is often not needed to diagnose PCOS given its relatively low specificity and its high degree of operator dependence.

Because adrenal androgens are readily suppressed by low doses of glucocorticoids, the dexamethasone androgen-suppression test may broadly distinguish ovarian from adrenal androgen overproduction. A blood sample is obtained before and after the administration of dexamethasone (0.5 mg orally every 6 h for 4 days). An adrenal source is suggested by suppression of unbound testosterone into the normal range; incomplete suppression suggests ovarian androgen excess. An overnight 1-mg dexamethasone suppression test, with measurement of 8:00 A.M. serum cortisol, is useful when there is clinical suspicion of Cushing's syndrome **(Chap. 398)**.

Nonclassic CAH is most commonly due to 21-hydroxylase deficiency but also can be caused by autosomal recessive defects in other steroidogenic enzymes necessary for adrenal corticosteroid synthesis **(Chap. 398)**. Because of the enzyme defect, the adrenal gland cannot secrete glucocorticoids (especially cortisol) efficiently. This results in diminished negative feedback inhibition of ACTH, leading to

compensatory adrenal hyperplasia and the accumulation of steroid precursors that subsequently are converted to androgen. Deficiency of 21-hydroxylase can be reliably excluded by determining a morning 17-hydroxyprogesterone level <6 nmol/L (<2 μg/L) (drawn in the follicular phase). Alternatively, 21-hydroxylase deficiency can be diagnosed by measurement of 17-hydroxyprogesterone 1 h after the administration of 250 μg of synthetic ACTH (cosyntropin) intravenously.

TREATMENT

Hirsutism

Treatment of hirsutism may be accomplished pharmacologically or by mechanical means of hair removal. Nonpharmacologic treatments should be considered in all patients either as the only treatment or as an adjunct to drug therapy.

Nonpharmacologic treatments include (1) bleaching, (2) removal of the hair from the skin surface by shaving or with chemical treatments, and (3) depilatory (removal of the hair including the root) such as plucking, waxing, electrolysis, laser, and intense pulsed light (IPL). Despite perceptions to the contrary, shaving does not increase the rate or density of hair growth. Chemical depilatory treatments may be useful for mild hirsutism that affects only limited skin areas, although they can cause skin irritation. Wax treatment removes hair temporarily but is uncomfortable. Electrolysis is effective for more permanent hair removal, particularly in the hands of a skilled electrologist. Laser and IPL are used to treat large areas of pigmented, terminal hair. Light of specific wavelength, duration, and energy is absorbed by melanin in the hair shaft and follicle leading to photothermolysis. Properly delivered, this treatment delays hair regrowth and causes permanent hair removal in many patients.

Pharmacologic therapy is directed at interrupting one or more of the steps in the pathway of androgen synthesis and action: (1) suppression of adrenal and/or ovarian androgen production, (2) enhancement of androgen-binding to plasma-binding proteins, particularly SHBG, (3) impairment of the peripheral conversion of androgen precursors to active androgen, and (4) inhibition of androgen action at the target tissue level. Attenuation of hair growth is typically not evident until 4–6 months after initiation of medical treatment and, in most cases, leads to only a modest reduction in hair growth.

Combination estrogen-progestin therapy in the form of an oral contraceptive is usually the first-line endocrine treatment for hirsutism and acne, after dermatologic management. The estrogenic component of most oral contraceptives currently in use is either ethinyl estradiol or mestranol. The suppression of LH leads to reduced production of ovarian androgens. The reduced androgen levels also result in a dose-related increase in SHBG, thus lowering the fraction of unbound plasma testosterone. Estrogens also have a direct, dose-dependent suppressive effect on sebaceous cell function.

The choice of a specific oral contraceptive should be predicated on the progestational component, as progestins vary in their suppressive effect on SHBG levels and in their androgenic potential. Ethynodiol diacetate has relatively low androgenic potential, whereas progestins such as norgestrel and levonorgestrel are particularly androgenic, as judged from their attenuation of the estrogen-induced increase in SHBG. Norgestimate exemplifies the newer generation of progestins that are virtually "nonandrogenic." Drospirenone, an analogue of spironolactone that has both antimineralocorticoid and antiandrogenic activities, is often used as a progestational agent in combination with ethinyl estradiol, although concern remains about is prothrombotic effects.

Oral contraceptives are contraindicated in women with a history of thromboembolic disease and women with increased risk of breast or other estrogen-dependent cancers (Chap. 407). There is a relative contraindication to the use of oral contraceptives in smokers and those with hypertension or a history of migraine headaches. Improvements in hirsutism are typically in the range of 20%, but there may be an arrest of further progression of hair growth. In most trials, estrogen-progestin therapy alone improves the extent of acne by an average of 50%. The effect on hair growth may not be evident for 6 months, and the maximum effect may require 9–12 months owing to the length of the hair growth cycle

Because oral contraceptives are efficacious and have fewer side effects, they are recommended over glucocorticoids as first-line treatment of hirsutism in CAH. If the response to oral contraceptives is inadequate, glucocorticoids may be used. The lowest effective dose of glucocorticoid should be used (e.g., dexamethasone [0.2–0.5 mg] or prednisone [5–10 mg]) taken at bedtime to achieve maximal suppression by inhibiting the nocturnal surge of ACTH.

Cyproterone acetate is the prototypic antiandrogen. It acts mainly by competitive inhibition of the binding of testosterone and DHT to the androgen receptor. In addition, it may enhance the metabolic clearance of testosterone by inducing hepatic enzymes. Although not available for use in the United States, cyproterone acetate is widely used in Canada, Mexico, and Europe. Cyproterone (50–100 mg) is given on days 1–15, and ethinyl estradiol (50 μg) is given on days 5–26 of the menstrual cycle. Side effects include irregular uterine bleeding, nausea, headache, fatigue, weight gain, and decreased libido.

Spironolactone, which usually is used as a mineralocorticoid antagonist, is also a weak antiandrogen. It is almost as effective as cyproterone acetate when used at high enough doses (100–200 mg daily). Patients should be monitored intermittently for hyperkalemia or hypotension, though these side effects are uncommon. Pregnancy should be avoided because of the risk of feminization of a male fetus. Spironolactone can also cause menstrual irregularity. It often is used in combination with an oral contraceptive, which suppresses ovarian androgen production and helps prevent pregnancy.

Flutamide is a potent nonsteroidal antiandrogen that is effective in treating hirsutism, but concerns about the induction of hepatocellular dysfunction preclude its use. Finasteride is a competitive inhibitor of 5α-reductase type 2. Beneficial effects on hirsutism have been reported, but the predominance of 5α-reductase type 1 in the PSU appears to account for its limited efficacy. Finasteride would also be expected to impair sexual differentiation in a male fetus, and it should not be used in women who may become pregnant. Although studies of dutasteride are limited in number, it appears that this agent may have efficacy in treating scalp hair thinning and loss as well as hirsutism. Dutasteride differs from finasteride as it targets both 5α-reductase types 1 and 2.

Ultimately, the choice of any specific agent(s) must be tailored to the unique needs of the patient being treated. As noted previously, pharmacologic treatments for hirsutism should be used in conjunction with nonpharmacologic approaches. It is also helpful to review the pattern of female hair distribution in the normal population to dispel unrealistic expectations.

407 Menopause and Postmenopausal Hormone Therapy

JoAnn E. Manson, Shari S. Bassuk

Menopause is the permanent cessation of menstruation due to loss of ovarian follicular function. It is diagnosed retrospectively after 12 months of amenorrhea. The average age at menopause is 51 years among U.S. women. *Perimenopause* refers to the time period preceding menopause, when fertility wanes and menstrual cycle irregularity increases, until the first year after cessation of menses. The onset of perimenopause precedes the final menses by 2–8 years, with a mean duration of 4 years. Smoking accelerates the menopausal transition by 2 years.

Although the peri- and postmenopausal transitions share many symptoms, the physiology and clinical management of the two differ. Low-dose oral contraceptives have become a therapeutic mainstay in perimenopause, whereas postmenopausal hormone therapy (HT) has been a common method of symptom alleviation after menstruation ceases.

PERIMENOPAUSE

PHYSIOLOGY

Ovarian mass and fertility decline sharply after age 35 and even more precipitously during perimenopause; depletion of primary follicles, a process that begins before birth, occurs steadily until menopause (Chap. 404). In perimenopause, intermenstrual intervals shorten significantly (typically by 3 days) as a result of an accelerated follicular phase. Follicle-stimulating hormone (FSH) levels rise because of altered folliculogenesis and reduced inhibin secretion. In contrast to the consistently high FSH and low estradiol levels seen in menopause, perimenopause is characterized by "irregularly irregular" hormone levels. The propensity for anovulatory cycles can produce a hyperestrogenic, hypoprogestagenic environment that may account for the increased incidence of endometrial hyperplasia or carcinoma, uterine polyps, and leiomyoma observed among women of perimenopausal age. Mean serum levels of selected ovarian and pituitary hormones during the menopausal transition are shown in Fig. 407-1. With transition into menopause, estradiol levels fall markedly, whereas estrone levels are relatively preserved, a pattern reflecting peripheral aromatization of adrenal and ovarian androgens. Levels of FSH increase more than those of luteinizing hormone, presumably because of the loss of inhibin as well as estrogen feedback.

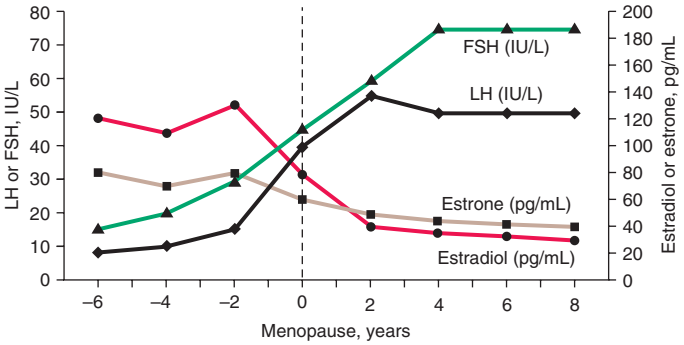

FIGURE 407-1 Mean serum levels of ovarian and pituitary hormones during the menopausal transition. FSH, follicle-stimulating hormone; LH, luteinizing hormone. *(Data from G Rannevik et al: A longitudinal study of the perimenopausal transition: Altered profiles of steroid and pituitary hormones, SHBG and bone mineral density. Maturitas 21:103, 1995.)*

DIAGNOSTIC TESTS

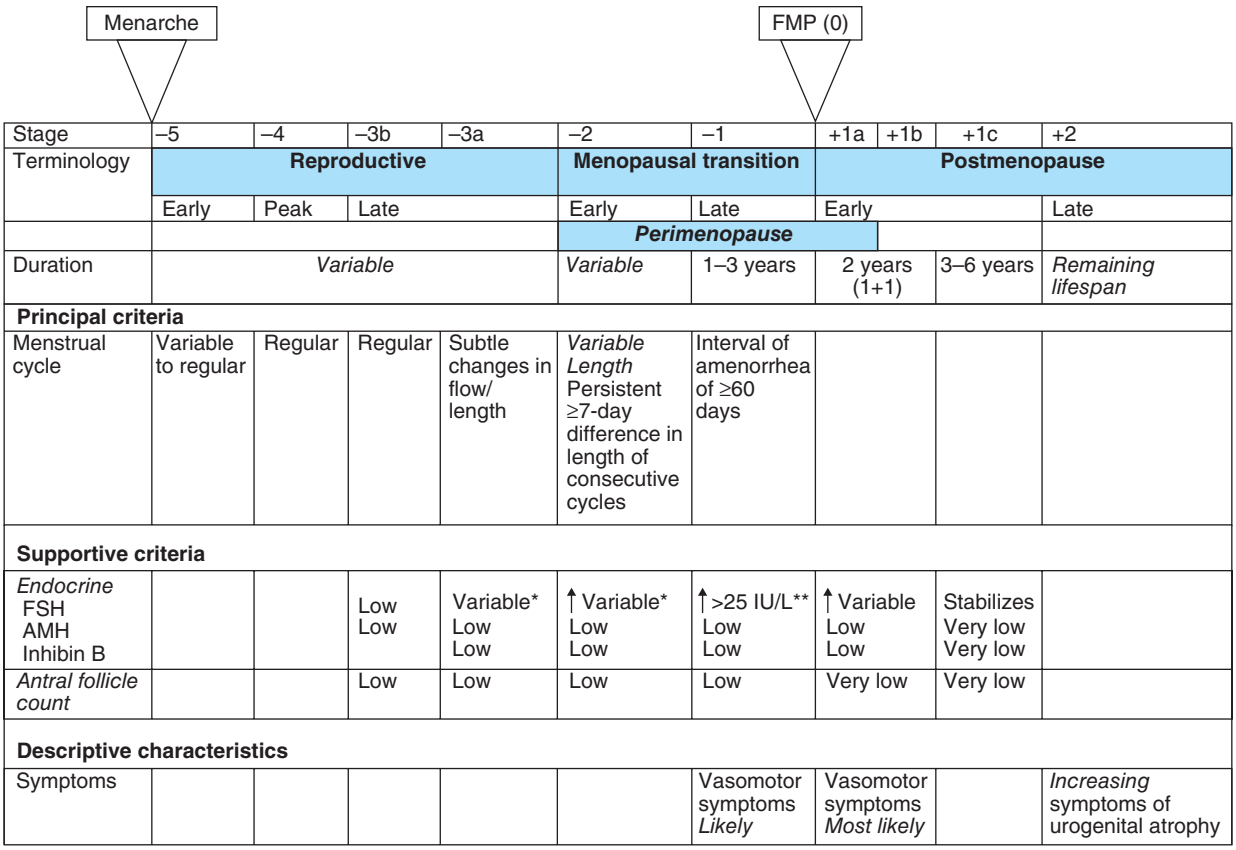
The Stages of Reproductive Aging Workshop +10 (STRAW+10) classification provides a comprehensive framework for the clinical assessment of ovarian aging. As shown in Fig. 407-2, menstrual cycle characteristics are the principal criteria for characterizing the menopausal transition, with biomarker measures as supportive criteria. Because of their extreme intraindividual variability, FSH and estradiol levels are imperfect diagnostic indicators of perimenopause in menstruating women. However, a consistently low FSH level in the early follicular phase (days 2–5) of the menstrual cycle does not support a diagnosis of perimenopause, while levels >25 IU/L in a random blood sample are characteristic of the late menopause transition. FSH measurement can also aid in assessing fertility; levels of <20 IU/L, 20 to <30 IU/L, and ≥30 IU/L measured on day 3 of the cycle indicate a good, fair, and poor likelihood of achieving pregnancy, respectively. Anti-müllerian hormone and inhibin B may also be useful for assessing reproductive aging.

SYMPTOMS

Determining whether symptoms that develop in midlife are due to ovarian senescence or to other age-related changes is difficult. There is strong evidence that the menopausal transition can cause hot flashes, night sweats, irregular bleeding, and vaginal dryness, and there is moderate evidence that it can cause sleep disturbances in some women. There is inconclusive or insufficient evidence that ovarian aging is a major cause of mood swings, depression, impaired memory or concentration, somatic symptoms, urinary incontinence, or sexual dysfunction. In one U.S. study, nearly 60% of women reported hot flashes in the 2 years before their final menses. Symptom intensity, duration, frequency, and effects on quality of life are highly variable.

TREATMENT

Perimenopause



PERIMENOPAUSAL THERAPY

For women with irregular or heavy menses or hormone-related symptoms that impair quality of life, low-dose combined oral contraceptives are a staple of therapy. Static doses of estrogen and progestin (e.g., 20 μg of ethinyl estradiol and 1 mg of norethindrone acetate daily for 21 days each month) can eliminate vasomotor symptoms and restore regular cyclicity. Oral contraceptives provide other benefits, including protection against ovarian and endometrial cancers and increased bone density, although it is not clear whether use during perimenopause decreases fracture risk later in life. Moreover, the contraceptive benefit is important, given that the unintentional pregnancy rate among women in their forties rivals that of adolescents. Contraindications to oral contraceptive use include cigarette smoking, liver disease, a history of thromboembolism or cardiovascular disease, breast cancer, or unexplained vaginal bleeding. Progestin-only formulations (e.g., 0.35 mg of norethindrone daily) or medroxyprogesterone (Depo-Provera) injections (e.g., 150 mg IM every 3 months) may provide an alternative for the treatment of perimenopausal menorrhagia in women who smoke or have cardiovascular risk factors. Although progestins neither regularize cycles nor reduce the number of bleeding days, they reduce the volume of menstrual flow.

Nonhormonal strategies to reduce menstrual flow include the use of nonsteroidal anti-inflammatory agents such as mefenamic acid (an initial dose of 500 mg at the start of menses, then 250 mg qid for 2–3 days) or, when medical approaches fail, endometrial ablation. It should be noted that menorrhagia requires an evaluation to rule out uterine disorders. Transvaginal ultrasound with saline enhancement is useful for detecting leiomyomata or polyps, and endometrial aspiration can identify hyperplastic changes.

TRANSITION TO MENOPAUSE

For sexually active women using contraceptive hormones to alleviate perimenopausal symptoms, the question of when and if to

Stage	–5	–4	–3b	–3a	–2	–1	+1a	+1b	+1c	+2

Menopause 19:387, 2012.)*

switch to HT must be individualized. Doses of estrogen and progestogen (either synthetic progestins or natural forms of progesterone) in HT are lower than those in oral contraceptives and have not been documented to prevent pregnancy. Although a 1-year absence of spontaneous menses reliably indicates ovulation cessation, it is not possible to assess the natural menstrual pattern while a woman is taking an oral contraceptive. Women willing to switch to a barrier method of contraception should do so; if menses occur spontaneously, oral contraceptive use can be resumed. The average age of final menses among relatives can serve as a guide for when to initiate this process, which can be repeated yearly until menopause has occurred.

MENOPAUSE AND POSTMENOPAUSAL HT

One of the most complex health care decisions facing women is whether to use postmenopausal HT. Once prescribed primarily to relieve vasomotor symptoms, HT has been promoted as a strategy to forestall various disorders that accelerate after menopause, including osteoporosis and cardiovascular disease. In 2000, nearly 40% of postmenopausal women aged 50–74 in the United States had used HT. This widespread use occurred despite the paucity of conclusive data, until recently, on the health consequences of such therapy. Although many women rely on their health care providers for a definitive answer to the question of whether to use postmenopausal hormones, balancing the benefits and risks for an individual patient is challenging.

Although observational studies suggest that HT prevents cardiovascular and other chronic diseases, the apparent benefits may result at least in part from differences between women who opt to take postmenopausal hormones and women who do not. Those choosing HT tend to be healthier, have greater access to medical care, are more compliant with prescribed treatments, and maintain a more health-promoting lifestyle. Randomized trials, which eliminate these confounding factors, have not consistently confirmed the benefits found in observational studies. Indeed, the largest HT trial to date, the Women's Health Initiative (WHI), which examined >27,000 postmenopausal women aged 50–79 (mean age, 63) for an average of 5–7 years, was stopped early because of an overall unfavorable benefit-risk ratio in the estrogen-progestin arm and an excess risk of stroke that was not offset by a reduced risk of coronary heart disease (CHD) in the estrogen-only arm.

The following summary offers a decision-making guide based on a synthesis of currently available evidence. Prevention of cardiovascular disease is eliminated from the equation due to lack of evidence for such benefits in randomized clinical trials.

BENEFITS AND RISKS OF POSTMENOPAUSAL HT

See Table 407-1.

Definite Benefits • **SYMPTOMS OF MENOPAUSE** Compelling evidence, including data from randomized clinical trials, indicates that estrogen therapy is highly effective for controlling vasomotor and genitourinary symptoms. Alternative approaches, including the use of antidepressants (such as paroxetine mesylate, 7.5 mg/d; venlafaxine, 37.5–75 mg/d; desvenlafaxine, 100 mg/d; fluoxetine, 20–30 mg/d; sertraline, 50–100 mg/d; citalopram, 10–30 mg/d; and escitalopram, 10–20 mg/d); the neurokinin-3 receptor antagonist fezolinetant (45 mg/d); the γ-aminobutyric acid analogue gabapentin (300 mg nightly, up to 900 mg in divided doses); and the antispasmodic anticholinergic oxybutynin (2.5–5 mg twice per day) may also alleviate vasomotor symptoms, although they are less effective than HT. Evidence is inconsistent on the efficacy of pregabalin (75–150 mg/d twice per day) and clonidine (oral, 0.1–1 mg/d, or transdermal, 0.1–0.3 mg weekly). Paroxetine mesylate and fezolinetant are the only nonhormonal drugs approved

TABLE 407-1 Benefits and Risks of Postmenopausal Hormone Therapy in the Overall Study Population of Women aged 50–79 Years in the Intervention Phase of the Women's Health Initiative (WHI) Estrogen-Progestin and Estrogen-Alone Trials[a]

		ESTROGEN-PROGESTIN		ESTROGEN ALONE	
OUTCOME	EFFECT	RELATIVE BENEFIT OR RISK	ABSOLUTE BENEFIT OR RISK[b]	RELATIVE BENEFIT OR RISK	ABSOLUTE BENEFIT OR RISK[b]
Definite Benefits					
Symptoms of menopause	Definite improvement	↓65–90% decreased risk[c]		↓65–90% decreased risk[c]	
Osteoporosis	Definite increase in bone mineral density and decrease in fracture risk	↓33% decreased risk for hip fracture	6 fewer cases (11 vs 17) of hip fracture	↓33% decreased risk for hip fracture	6 fewer cases (13 vs 19) of hip fracture
Definite Risks[h]					
Endometrial cancer	Definite increase in risk with estrogen alone (see below for estrogen-progestin)	See below	See below		4.6 excess cases (observational studies)
Pulmonary embolism	Definite increase in risk	↑98% increased risk	9 excess cases (18 vs 9)	↑35% increased risk (n.s.)	4 excess cases (14 vs 10)
Deep-vein thrombosis	Definite increase in risk	↑87% increased risk	11.5 excess cases (25 vs 14)	↑48% increased risk	7.5 excess cases (23 vs 15)
Breast cancer	Definite increase in risk with long-term use (≥5 years) of estrogen-progestin	↑24% increased risk	8.5 excess cases (43 vs 35)	↓21% decreased risk (n.s.)	7 fewer cases (28 vs 35)
Gallbladder disease	Definite increase in risk	↑57% increased risk	47 excess cases (131 vs 84)	↑55% increased risk	58 excess cases (164 vs 106)
Probable or Uncertain Risks and Benefits[h]					
Coronary heart disease[d]	Probable increase in risk among older women and women many years past menopause; possible decrease in risk or no effect in younger or recently menopausal women[e]	↑18% increased risk (n.s.)	6 excess cases (41 vs 35)	No increase in risk	No difference in risk
Myocardial infarction	Significant interaction by age group for estrogen alone, with reduced risk in younger—but not older—women (*p* for trend by age = .02)	↑24% increased risk (n.s.)	6 excess cases (35 vs 29)	No increase in risk[e]	No difference in risk[e]
Stroke	Probable increase in risk	↑37% increased risk	9 excess cases (33 vs 24)	↑35% increased risk	11 excess cases (45 vs 34)
Ovarian cancer	Probable increase in risk with long-term use (≥5 years)	↑41% increased risk (n.s.)	1 excess case (5 vs 4)	Not available	Not available
Endometrial cancer	Probable decrease in risk with estrogen-progestin during long-term follow-up (see above for estrogen alone)	↓33% decreased risk[f]	3 fewer cases (7 vs 10)	See above	See above
Urinary incontinence	Probable increase in risk	↑49% increased risk	549 excess cases (1661 vs 1112)	↑61% increased risk	852 excess cases (2255 vs 1403)
Colorectal cancer	Probable decrease in risk with estrogen-progestin; possible increase in risk in older women with estrogen alone (*p* for trend by age = .02 for estrogen alone)	↓38% decreased risk	6.5 fewer cases (10 vs 17)	No increase or decrease in risk[e]	No difference in risk[e]
Type 2 diabetes	Probable decrease in risk	↓19% decreased risk	16 fewer cases (72 vs 88)	↓14% decreased risk	21 fewer cases (134 vs 155)
Dementia (age ≥65)	Increase in risk in older women (but inconsistent data from observational studies and randomized trials)	↑101% increased risk	23 excess cases (46 vs 23)	↑47% increased risk (n.s.)	15 excess cases (44 vs 29)
Total mortality	Possible increase in risk among older women and women many years past menopause; possible decrease in risk or no effect in younger or recently menopausal women (*p* for trend by age <.05 for both trials combined)	No increase in risk	No difference in risk	No increase in risk[e]	No difference in risk[e]
Global index[g]	Probable increase in risk or no effect among older women and women many years past menopause; possible decrease in risk or no effect in younger or recently menopausal women (*p* for trend by age = .02 for estrogen alone)	↑12% increased risk	20.5 excess cases (189 vs 168)	No increase in risk[e]	No difference in risk[e]

[a]The estrogen-progestin arm of the WHI assessed 5.6 years of conjugated equine estrogens (0.625 mg/d) plus medroxyprogesterone acetate (2.5 mg/d) versus placebo. The estrogen-alone arm of the WHI assessed 7.1 years of conjugated equine estrogens (0.625 mg/d) versus placebo. [b]Number of cases per 10,000 women per year. [c]The WHI was not designed to assess the effect of hormone therapy (HT) on menopausal symptoms. Data from other randomized trials suggest that HT reduces risk for menopausal symptoms by 65–90%. [d]*Coronary heart disease* is defined as nonfatal myocardial infarction or coronary death. [e]There was a significant interaction by age; that is, the association between HT and the specified outcome was different in younger women and older women. [f]This is the risk reduction that was observed during a cumulative 13-year follow-up period (5.6 years of treatment plus 8.2 years of postintervention observation). [g]The *global index* is a composite outcome representing the first event for each participant from among the following: coronary heart disease, stroke, pulmonary embolism, breast cancer, colorectal cancer, endometrial cancer (estrogen-progestin arm only), hip fracture, and death. Because participants can experience more than one type of event, the global index cannot be derived by a simple summing of the component events. [h]Includes some outcomes where results were divergent between the estrogen-progestin arm and the estrogen-alone arm.

Abbreviation: n.s., not statistically significant.

by the U.S. Food and Drug Administration for treatment of vasomotor symptoms. Bazedoxifene, an estrogen agonist/antagonist, in combination with conjugated estrogens has also received approval for this use. Cognitive behavioral therapy and clinical hypnosis have been shown in randomized trials to help with vasomotor symptom management. The consumption of phytoestrogens, including soy isoflavones, may be effective in women who are able to metabolize the isoflavone daidzein to the biologically active metabolite equol. Weight loss, mindfulness-based stress reduction, and stellate ganglion block are also promising strategies, although more trials are needed. For genitourinary syndrome of menopause, the efficacy of low-dose vaginal estrogen is similar to that of oral or transdermal estrogen; oral ospemifene and vaginal prasterone are additional options.

OSTEOPOROSIS (See also Chap. 423)

Bone density By reducing bone turnover and resorption rates, estrogen slows the aging-related bone loss experienced by most postmenopausal women. More than 50 randomized trials have demonstrated that postmenopausal estrogen therapy, with or without a progestogen, rapidly increases bone mineral density at the spine by 4–6% and at the hip by 2–3% and that those increases are maintained during treatment.

Fractures Data from observational studies indicate a 50–80% lower risk of vertebral fracture and a 25–30% lower risk of hip, wrist, and other peripheral fractures among current estrogen users; addition of a progestogen does not appear to modify this benefit. In the WHI, 5–7 years of either combined estrogen-progestin or estrogen-only therapy was associated with a 33% reduction in hip fractures and 25–30% fewer total fractures among a population unselected for osteoporosis. Bisphosphonates (such as alendronate, 10 mg/d or 70 mg once per week; risedronate, 5 mg/d or 35 mg once per week; ibandronate, 2.5 mg/d or 150 mg once per month or 3 mg every 3 months IV; or zoledronic acid, 5 mg once per year IV) and denosumab (60 mg twice per year SC) increase bone mass density by reducing bone resorption and have been shown in randomized trials to decrease fracture rates. Other treatment options include bazedoxifene in combination with conjugated estrogens; the selective estrogen receptor modulator (SERM) raloxifene (60 mg/d); and parathyroid hormone (teriparatide, 20 μg/d SC). Unlike estrogen, these alternative therapies do not appear to have adverse effects on the endometrium or breast. Increased weight-bearing and resistance exercise; adequate calcium intake (1000–1200 mg/d through diet or supplements in two or three divided doses); and adequate vitamin D intake (600–1000 IU/d) may also reduce the risk of osteoporosis-related fractures. According to a 2011 report by the Institute of Medicine (now the National Academy of Medicine), 25-hydroxyvitamin D blood levels of ≥50 nmol/L are sufficient for bone-density maintenance and fracture prevention. The Fracture Risk Assessment (FRAX®) score, an algorithm that combines an individual's bone-density score with age and other risk factors to predict her 10-year risk of hip and major osteoporotic fracture, may be of use in guiding decisions about pharmacologic treatment (see *www.sheffield.ac.uk/FRAX/*).

Definite Risks

• **ENDOMETRIAL CANCER (WITH ESTROGEN ALONE)** A combined analysis of 30 observational studies found a tripling of endometrial cancer risk among short-term users (1–5 years) of unopposed estrogen and a nearly 10-fold increased risk among long-term users (≥10 years). These findings are supported by results from the randomized Postmenopausal Estrogen/Progestin Interventions (PEPI) trial, in which 24% of women assigned to unopposed estrogen for 3 years developed atypical endometrial hyperplasia—a premalignant lesion—as opposed to only 1% of women assigned to placebo. Use of a progestogen, which opposes the effects of estrogen on the endometrium, eliminates these risks and may even reduce risk (see later).

VENOUS THROMBOEMBOLISM A meta-analysis of observational studies found that current oral estrogen use was associated with a 2.5-fold increase in risk of venous thromboembolism in postmenopausal women. A meta-analysis of randomized trials, including the WHI, found a 2.1-fold increase in risk. Results from the WHI indicate a nearly twofold increase in risk of pulmonary embolism and deep-vein thrombosis with estrogen-progestin and a 35–50% increase in these risks with estrogen-only therapy. Transdermal estrogen, taken alone or with certain progestogens (micronized progesterone or pregnane derivatives), appears to be a safer alternative with respect to thrombotic risk.

BREAST CANCER (WITH ESTROGEN-PROGESTIN) An increased risk of breast cancer has been found among current or recent estrogen users in observational studies; this risk is directly related to duration of use. In contrast to findings for endometrial cancer, combined estrogen-progestin regimens appear to increase breast cancer risk more than estrogen alone. In a 2019 meta-analysis of 58 observational studies (108,647 breast cancer cases) published between 1992 and 2017, the relative risks (RRs) for incident breast cancer with current use of estrogen-progestin for 1–4, 5–9, 10–14, and ≥15 years were 1.60 (95% confidence interval [CI], 1.52–1.69), 1.97 (95% CI, 1.90–2.04), 2.26 (95% CI, 2.16–2.36), and 2.51 (95% CI, 2.35–2.68), respectively, compared with never use. The corresponding statistics for incident breast cancer with current use of estrogen alone were 1.17 (1.10–1.26), 1.22 (1.17–1.28), 1.43 (1.37–1.50), and 1.58 (1.51–1.66), respectively. Data from randomized trials also indicate that estrogen-progestin raises breast cancer risk. In the WHI, women assigned to receive combination hormones for an average of 5.6 years were 24% more likely to develop breast cancer than women assigned to placebo, but 7.1 years of estrogen-only therapy did not increase risk. Indeed, the WHI showed a trend toward a reduction in breast cancer risk with estrogen alone, although it is unclear whether this finding would pertain to formulations of estrogen other than conjugated equine estrogens or to treatment durations of >7 years. In the Heart and Estrogen/Progestin Replacement Study (HERS), combination therapy for 4 years was associated with a 27% increase in breast cancer risk. Although the latter finding was not statistically significant, the totality of evidence strongly implicates estrogen-progestin therapy in breast carcinogenesis.

Some observational data suggest that the length of the interval between menopause onset and HT initiation may influence the association between such therapy and breast cancer risk, with a "gap time" of <3–5 years conferring a higher HT-associated breast cancer risk. (This pattern of findings contrasts with that for CHD, as discussed later in this chapter.) However, this association remains inconclusive and may be a spurious finding attributable to higher rates of screening mammography and thus earlier cancer detection in HT users than in nonusers, especially in early menopause. Indeed, in the WHI trial, relative risk (RRs) for HT and breast cancer risk did not differ among women 50–59, those 60–69, and those 70–79 years of age at trial entry. (There was insufficient power to examine finer age categories.) Additional research is needed to clarify the issue.

GALLBLADDER DISEASE Large observational studies report a two- to threefold increased risk of gallstones or cholecystectomy among postmenopausal women taking oral estrogen. In the WHI, women randomized to estrogen-progestin or estrogen alone were ~55% more likely to develop gallbladder disease than those assigned to placebo. Risks were also increased in HERS. Transdermal HT might be a safer alternative, but further research is needed.

Probable or Uncertain Risks and Benefits

• **CORONARY HEART DISEASE/STROKE** Until recently, HT had been enthusiastically recommended as a possible cardioprotective agent. In the past three decades, multiple observational studies suggested, in the aggregate, that estrogen use leads to a 35–50% reduction in CHD incidence among postmenopausal women. The biologic plausibility of such an association is supported by data from randomized trials demonstrating that exogenous estrogen lowers plasma low-density lipoprotein (LDL) cholesterol levels and raises high-density lipoprotein (HDL) cholesterol levels by 10–15%. Administration of estrogen also favorably affects lipoprotein(a) levels, LDL oxidation, endothelial vascular function, fibrinogen, and plasminogen activator inhibitor 1. However, estrogen therapy has unfavorable effects on other biomarkers of cardiovascular risk: it boosts triglyceride levels; promotes coagulation via factor VII, prothrombin fragments 1 and 2, and fibrinopeptide A elevations; and raises levels of the inflammatory marker C-reactive protein.

Randomized trials of estrogen or combined estrogen-progestin in women with preexisting cardiovascular disease have not confirmed the benefits reported in observational studies. In HERS (a secondary-prevention trial designed to test the efficacy and safety of estrogen-progestin therapy with regard to clinical cardiovascular outcomes), the 4-year incidence of coronary death and nonfatal myocardial infarction was similar in the active-treatment and placebo groups, and a 50% increase in risk of coronary events was noted during the first year among participants assigned to the active-treatment group. Although it is possible that progestin may mitigate estrogen's benefits, the Estrogen Replacement and Atherosclerosis (ERA) trial indicated that angiographically determined progression of coronary atherosclerosis was unaffected by either opposed or unopposed estrogen treatment. Moreover, no cardiovascular benefit was found in the Papworth Hormone Replacement Therapy Atherosclerosis Study, a trial of transdermal estradiol with and without norethindrone; the Women's Estrogen for Stroke Trial (WEST), a trial of oral 17β-estradiol; or the Estrogen in the Prevention of Reinfarction Trial (ESPRIT), a trial of oral estradiol valerate. Thus, in clinical trials, HT has not proved effective for the secondary prevention of cardiovascular disease in postmenopausal women.

Primary-prevention trials also suggest an early increase in cardiovascular risk and an absence of cardioprotection with postmenopausal HT. In the WHI, women assigned to 5.6 years of estrogen-progestin therapy were 18% more likely to develop CHD (defined in primary analyses as nonfatal myocardial infarction or coronary death) than those assigned to placebo, although this risk elevation was not statistically significant. However, during the trial's first year, there was a significant 80% increase in risk, which diminished in subsequent years (p for trend by time = .03). In the estrogen-only arm of the WHI, no overall effect on CHD was observed during the 7.1 years of the trial or in any specific year of follow-up. This pattern of results was similar to that for the outcome of total myocardial infarction.

However, a closer look at available data suggests that timing of initiation of HT may critically influence the association between such therapy and CHD. Estrogen may slow early stages of atherosclerosis but have adverse effects on advanced atherosclerotic lesions. It has been hypothesized that the prothrombotic and proinflammatory effects of estrogen manifest themselves predominantly among women with subclinical lesions who initiate HT well after the menopausal transition, whereas women with less arterial damage who start HT early in menopause may derive cardiovascular benefit because they have not yet developed advanced lesions. Data from experiments in nonhuman primates and from some randomized trials in humans support this concept. Conjugated estrogens had no effect on the extent of coronary artery plaque in cynomolgus monkeys assigned to receive estrogen alone or combined with progestin starting 2 years (~6 years in human terms) after oophorectomy and well after the establishment of atherosclerosis. However, administration of exogenous hormones immediately after oophorectomy, during the early stages of atherosclerosis, reduced the extent of plaque by 70%. In the Early versus Late Intervention Trial with Estradiol (ELITE), a 6-year trial among 643 healthy postmenopausal women that was designed to test whether effects of estrogen on the development and progression of atherosclerosis depend on age at initiation of therapy, oral 17β-estradiol administered with or without vaginal micronized progesterone significantly slowed carotid atherosclerotic progression in women within 6 years of menopause onset (mean age, 55.4 years) but not in women >10 years past menopause onset (mean age, 65.4 years) (p for interaction = .007). On the other hand, in the Kronos Early Estrogen Prevention Study (KEEPS), a 4-year trial among 729 healthy postmenopausal women within 3 years of menopause onset at trial entry (mean age, 53 years), neither oral conjugated estrogens nor transdermal estradiol, administered with oral micronized progesterone, affected carotid atherosclerotic progression. However, the low prevalence of this endpoint in the overall study population may have curtailed power to detect a treatment difference.

Lending further credence to the timing hypothesis are results of subgroup analyses of data from observational studies and large clinical trials. For example, among women who entered the WHI trial with a relatively favorable cholesterol profile, estrogen with or without progestin led to a 40% lower risk of incident CHD. Among women who entered with a worse cholesterol profile, therapy resulted in a 73% higher risk (p for interaction = .02). The presence or absence of the metabolic syndrome **(Chap. 420)** also strongly influenced the relation between HT and incident CHD. Among women with the metabolic syndrome, HT more than doubled CHD risk, whereas no association was observed among women without the syndrome. Moreover, although there was no association between estrogen-only therapy and CHD in the WHI trial cohort as a whole, such therapy was associated with a CHD risk reduction of 40% among participants aged 50–59; in contrast, a risk reduction of only 5% was observed among those aged 60–69, and a risk increase of 9% was found among those aged 70–79 (p for trend by age = .08). For the outcome of total myocardial infarction, estrogen alone was associated with a borderline-significant 45% reduction and a nonsignificant 24% increase in risk among the youngest and oldest women, respectively (p for trend by age = .02). Estrogen was also associated with lower levels of coronary artery calcified plaque in the younger age group. Although age did not have a similar effect in the estrogen-progestin arm of the WHI, CHD risks increased with years since menopause (p for trend = .08), with a significantly elevated risk among women who were ≥20 years past menopause. For the outcome of total myocardial infarction, estrogen-progestin was associated with a 9% risk reduction among women <10 years past menopause as opposed to a 16% increase in risk among women 10–19 years past menopause and a twofold increase in risk among women >20 years past menopause (p for trend = .01). In the large observational Nurses' Health Study, women who chose to start HT within 4 years of menopause experienced a lower risk of CHD than did nonusers, whereas those who began therapy ≥10 years after menopause appeared to receive little coronary benefit. Observational studies include a high proportion of women who begin HT within 3–4 years of menopause, whereas clinical trials include a high proportion of women ≥12 years past menopause; this difference helps to reconcile some of the apparent discrepancies between the two types of studies.

For the outcome of stroke, WHI participants assigned to estrogen-progestin or estrogen alone were ~35% more likely to suffer a stroke than those assigned to placebo. Whether or not age at initiation of HT influences stroke risk is not well understood. In the WHI and the Nurses' Health Study, HT was associated with an excess risk of stroke in all age groups. Further research is needed on age, time since menopause, and other individual characteristics (including biomarkers) that predict increases or decreases in cardiovascular risk associated with exogenous HT. Furthermore, it remains uncertain whether different doses, formulations, or routes of administration of HT will produce different cardiovascular effects.

COLORECTAL CANCER Observational studies have suggested that HT reduces risks of colon and rectal cancer, although the estimated magnitudes of the relative benefits have ranged from 8 to 34% in various meta-analyses. In the WHI (the sole trial to examine the issue), estrogen-progestin was associated with a significant 38% reduction in colorectal cancer over a 5.6-year period, although no benefit was seen with 7 years of estrogen-only therapy. However, a modifying effect of age was observed, with a doubling of risk with HT in women aged 70–79 but no risk elevation in younger women (p for trend by age = .02).

COGNITIVE DECLINE AND DEMENTIA A meta-analysis of 10 case-control and two cohort studies suggested that postmenopausal HT is associated with a 34% decreased risk of dementia. Subsequent randomized trials (including the WHI), however, have failed to demonstrate any benefit of estrogen or estrogen-progestin therapy on the progression of mild to moderate Alzheimer's disease and/or have indicated a potential adverse effect of HT on the incidence of dementia, at least in women ≥65 years of age. Among women randomized to HT (as opposed to placebo) at age 50–55 in the WHI, no effect on cognition was observed during the postintervention phase. Determining whether timing of initiation of HT influences cognitive outcomes will require further study.

OVARIAN CANCER AND OTHER DISORDERS On the basis of limited observational and randomized data, it has been hypothesized that HT increases the risk of ovarian cancer and reduces the risk of type 2 diabetes mellitus. Results from the WHI support these hypotheses. The WHI also found that HT use was associated with an increased risk of urinary incontinence and that estrogen-progestin was associated with increased rates of lung cancer mortality.

ENDOMETRIAL CANCER (WITH ESTROGEN-PROGESTIN) In the WHI, use of estrogen-progestin was associated with a nonsignificant 17% reduction in risk of endometrial cancer. A significant reduction in risk emerged during the postintervention period (see later).

ALL-CAUSE MORTALITY In the overall WHI cohort, estrogen with or without progestin was not associated with all-cause mortality. However, there was a trend toward reduced mortality in younger women, particularly with estrogen alone. For women aged 50–59, 60–69, and 70–79 years, RRs associated with estrogen-only therapy were 0.70, 1.01, and 1.21, respectively (p for trend = .04).

OVERALL BENEFIT-RISK PROFILE Estrogen-progestin was associated with an unfavorable benefit-risk profile (excluding relief from menopausal symptoms) as measured by a "global index"—a composite outcome including CHD, stroke, pulmonary embolism, breast cancer, colorectal cancer, endometrial cancer, hip fracture, and death (Table 407-1)—in the WHI cohort as a whole, and this association did not vary by 10-year age group. Estrogen-only therapy was associated with a neutral benefit-risk profile in the WHI cohort as a whole. However, there was a significant trend toward a more favorable benefit-risk profile among younger women and a less favorable profile among older women, with RRs of 0.84, 0.99, and 1.17 for women aged 50–59, 60–69, and 70–79 years, respectively (p for trend by age = .02). The balance of benefits and risks of estrogen with and without progestin among women aged 50–59 is shown in Fig. 407-3.

CHANGES IN HEALTH STATUS AFTER DISCONTINUATION OF HT In the WHI, many but not all risks and benefits associated with active use of HT dissipated within 5–7 years after discontinuation of therapy. For estrogen-progestin, an elevated risk of breast cancer persisted (RR = 1.28; 95% CI, 1.11–1.48) during a median cumulative 13-year follow-up period (5.6 years of treatment plus 8.2 years of postintervention observation), but most cardiovascular disease risks became neutral. A reduction in hip fracture risk persisted (RR = 0.81; 95% CI, 0.68–0.97), and a significant reduction in endometrial cancer risk emerged (RR = 0.67; 95% CI, 0.49–0.91). For estrogen alone, the reduction in breast cancer risk became statistically significant (RR = 0.79; 95% CI, 0.65–0.97) during a median cumulative 13-year follow-up period (6.8 years of treatment plus 6.6 years of postintervention observation), and significant differences by age group persisted for total myocardial infarction and the global index, with more favorable results for younger women. During a median cumulative 18-year follow-up, estrogen alone was

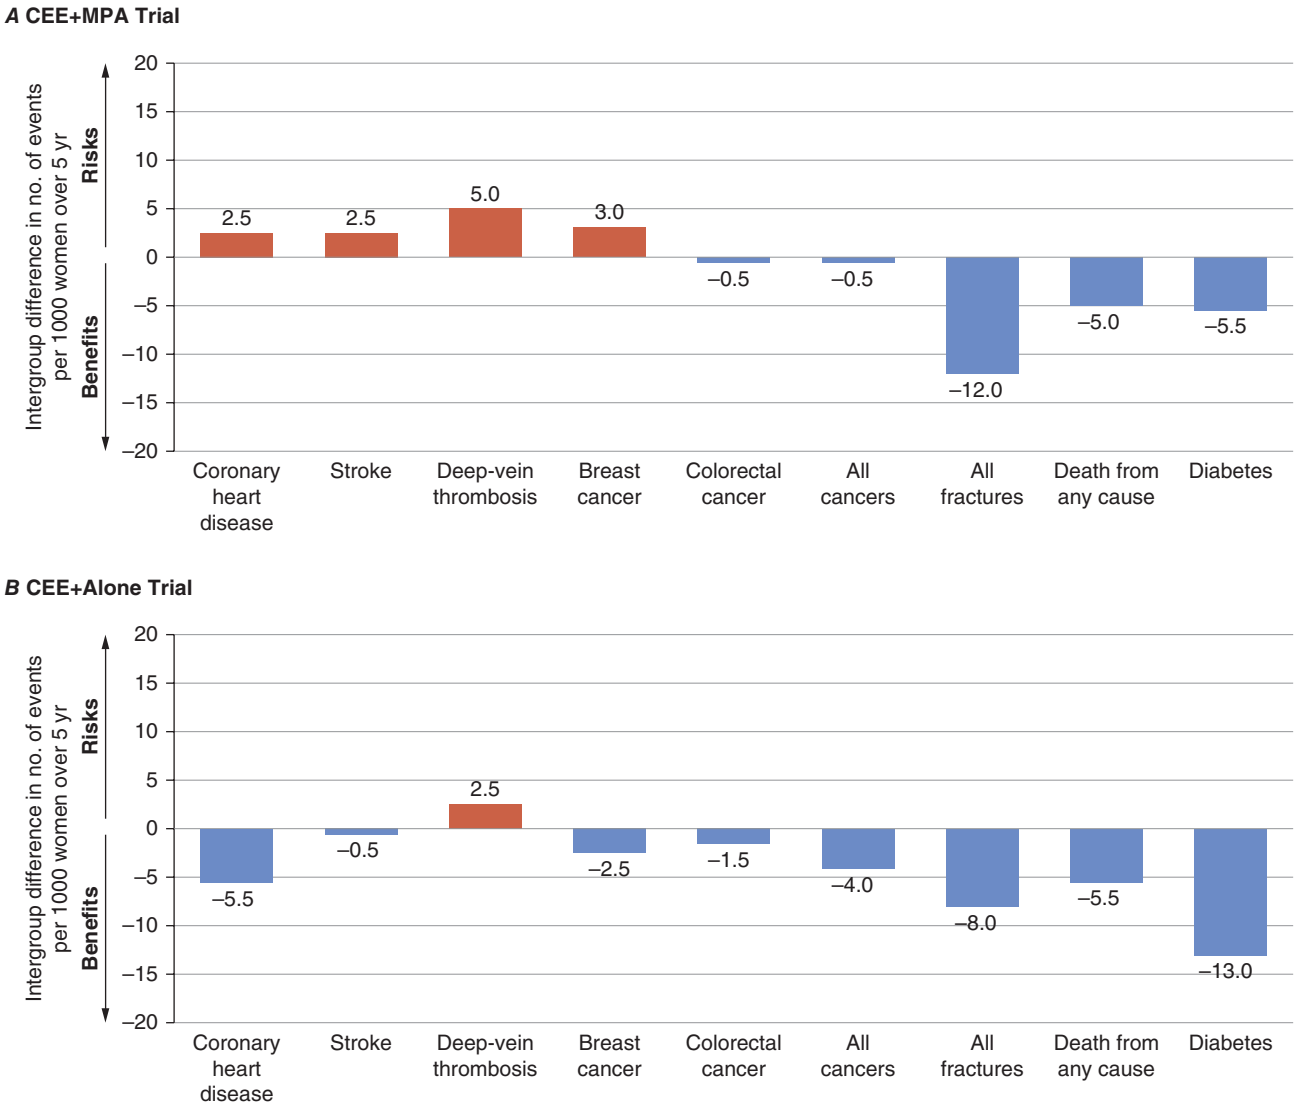

FIGURE 407-3 Benefits and risks of the two hormone therapy (HT) formulations evaluated in the Women's Health Initiative, in women aged 50–59 years. Results are shown for the two formulations, conjugated equine estrogens (CEE) alone or in combination with medroxyprogesterone acetate (MPA). Risks and benefits are expressed as the difference in number of events (number in the HT group minus the number in the placebo group) per 1000 women over 5 years. *(Reproduced with permission from JE Manson, AM Kaunitz: Menopause Management–Getting Clinical Care Back on Track. N Engl J Med 374:803, 2016.)*

associated with a significant reduction in all-cause mortality in women aged 50–59 years (RR = 0.79; 95% CI, 0.64–0.96); the protective effect was seen primarily in those with bilateral oophorectomy (RR = 0.68; 95% CI, 0.48–0.96). During a median cumulative 20-year follow-up, estrogen-progestin was associated with a significant elevation in breast cancer risk (RR = 1.28; 95% CI, 1.13–1.45) and a suggestive elevation in breast cancer mortality (RR =1.35; 95% CI, 0.94–1.95; $p = .11$), whereas estrogen alone was associated with a significant reduction in breast cancer risk (RR = 0.78; 95% CI, 0.65–0.93) and breast cancer mortality (RR = 0.60; 95% CI, 0.37–0.97).

APPROACH TO THE PATIENT

Postmenopausal HT

The rational use of postmenopausal HT requires balancing the potential benefits and risks. Table 407-2 provides one approach to decision-making. This approach applies to women with menopausal symptoms who are age 45 years and older or to women who have had removal of both ovaries, regardless of age. Women below age 45 years or those with uncertain menopausal status may need additional clinical evaluation before determining a management plan. The clinician should first assess whether the patient has moderate to severe hot flashes and/or night sweats—the primary indication for initiation of systemic HT—that do not subside in response to behavioral/lifestyle modifications, such as lowering the thermostat, dressing in layers, avoiding warm beverages, and not smoking. Systemic HT may also be used to prevent osteoporosis in women at high risk of fracture who cannot tolerate alternative osteoporosis therapies. (Vaginal estrogen or other medications may be used to treat genitourinary syndrome of menopause in the absence of vasomotor symptoms [see later].) The benefits and risks of such therapy should be reviewed with the patient, giving more emphasis to absolute than to relative measures of effect and pointing out uncertainties in clinical knowledge where relevant. Because chronic disease rates generally increase with age, absolute risks tend to be greater in older women, even when RRs remain similar. Potential side effects—especially vaginal bleeding that may result from use of the combined estrogen-progestogen formulations recommended for women with an intact uterus—should be noted. The patient's own preference regarding therapy should be elicited and factored into the decision. Contraindications should be assessed routinely and include unexplained vaginal bleeding; liver dysfunction or disease; venous thromboembolism; known blood clotting disorder or thrombophilia (transdermal estrogen may be an option); untreated hypertension; history of endometrial cancer (except stage 1 without deep invasion), breast cancer, or other estrogen-dependent cancer; and history of CHD, stroke, or transient ischemic attack. Relative contraindications to systemic HT include an elevated risk of breast cancer (e.g., women who have one or more first-degree relatives with breast cancer, susceptibility genes such as *BRCA1* or *BRCA2*, or a personal history of cellular atypia detected by breast biopsy); hypertriglyceridemia (>400 mg/dL); an elevated risk of cardiovascular disease; and active gallbladder disease (transdermal estrogen may be an option in the latter three cases because it has a less adverse effect on triglyceride levels, clotting factors, and inflammation factors than oral HT). Primary prevention of heart disease should not be viewed as an expected benefit of HT, and an increase in the risk of stroke as well as a small early increase in the risk of coronary artery disease should be considered. Nevertheless, such therapy may be appropriate if the noncoronary benefits of treatment clearly outweigh the risks. Reassess benefits and risks at least once every 6–12 months, assuming the patient's continued preference for HT, or if the patient's health status changes. A woman who suffers an acute coronary event or stroke while taking HT should discontinue therapy immediately.

Many options for systemic HT are available. Estrogen alone is recommended for women with hysterectomy, whereas estrogen plus progestogen is recommended for women with a uterus. In the United States, the most commonly prescribed oral estrogens for systemic treatment of vasomotor symptoms are 17β-estradiol (1.0 or 0.5 mg/d or other doses) and conjugated equine estrogens (CEE; 0.625, 0.45, or 0.3 mg/d or other doses). The most commonly prescribed transdermal estrogen products are 17β-estradiol skin patches (0.035 or 0.05 mg/d or other doses). The most commonly prescribed progestogens are medroxyprogesterone acetate (MPA; 2.5, 5, or 10 mg/d) and micronized progesterone (100 or 200 mg/d). Also available are oral estrogen-progestin combinations, such as oral CEE and MPA, oral 17β-estradiol or ethinyl estradiol with norethindrone acetate, oral estradiol with progesterone, and other options. CEE/bazedoxifene may be an option for women with a uterus, especially those with concerns about breast tenderness, breast density, or uterine bleeding. Contraindications to CEE/bazedoxifene are similar to those for systemic HT.

Short-term use (<5 years for estrogen-progestogen and <7 years for estrogen alone) is appropriate for relief of menopausal symptoms among women without contraindications to such use. However, such therapy should be avoided by women with an elevated baseline risk of future cardiovascular events. Women who have contraindications for or are opposed to HT may derive benefit from the use of certain antidepressants (including paroxetine, mesylate, venlafaxine, fluoxetine, and others), fezolinetant, gabapentin, or oxybutynin.

Long-term use (≥5 years for estrogen-progestogen and ≥7 years for estrogen alone) is more problematic because a heightened risk of breast cancer must be factored into the decision, especially for estrogen-progestogen. Reasonable candidates for such use include postmenopausal women who have persistent severe vasomotor symptoms along with an increased risk of osteoporosis (e.g., those with osteopenia, a personal or family history of nontraumatic fracture, or a weight <125 lb), who also have no personal or

TABLE 407-2 Approach to Initiating Menopausal Hormone Therapy for Vasomotor Symptom Management

1. Vasomotor symptom assessment
Confirm that hot flashes and/or night sweats are adversely affecting sleep, daytime functioning, or quality of life.
2. Risk factor assessment
Confirm that there are no absolute contraindications to menopausal hormone therapy
Breast, endometrial, or other estrogen-dependent cancer
Cardiovascular disease (heart disease, stroke, transient ischemic attack)
Active liver disease
Undiagnosed vaginal bleeding
3. Menopausal hormone therapy initiation

family history of breast cancer in a first-degree relative or other contraindications, and who have a strong personal preference for therapy. Poor candidates are women with elevated cardiovascular risk, those at increased risk of breast cancer, and those at low risk of osteoporosis. Even for reasonable candidates, strategies to minimize dose and duration of use should be employed. For example, women using HT to relieve intense vasomotor symptoms in early postmenopause should consider discontinuing therapy within 5 years, resuming it only if such symptoms persist. Because of the role of progestogens in increasing breast cancer risk, regimens that employ cyclic rather than continuous progestogen exposure as well as formulations other than MPA should be considered if treatment is extended. For prevention of osteoporosis, alternative therapies such as bisphosphonates or SERMs should be considered. Research on alternative progestogens and androgen-containing preparations has been limited, particularly with respect to long-term safety. Additional research on the effects of these agents on cardiovascular disease, glucose tolerance, and breast cancer will be of particular interest.

For genitourinary symptoms such as vaginal dryness or pain with intercourse/sexual activity, intravaginal estrogen creams, tablets, or rings; prasterone (vaginal dehydroepiandrosterone); and ospemifene are options. Contraindications to low-dose vaginal estrogen include unexplained vaginal bleeding or breast cancer, endometrial cancer, or other estrogen-dependent cancer. Contraindications to ospemifene and prasterone are the same as those for low-dose vaginal estrogen, and contraindications for ospemifene additionally include venous or arterial thromboembolic disease, severe liver disease, and use of estrogens or estrogen agonists-antagonists.

In addition to HT, lifestyle choices such as smoking abstention, adequate physical activity, and a healthy diet can play a role in controlling symptoms and preventing chronic disease. An expanding array of pharmacologic options (e.g., bisphosphonates, SERMs, and other agents for osteoporosis; cholesterol-lowering or antihypertensive agents for cardiovascular disease) should also reduce the widespread reliance on hormone use. However, short-term HT may still benefit some women.

408 Infertility and Contraception

Anuja Dokras, Janet E. Hall

INFERTILITY

The World Health Organization (WHO) categorizes infertility as a disease of the reproductive system. Infertility is the third most common disease worldwide, affecting ~48–72 million couples. It is defined as the inability to achieve a pregnancy over 12 months of unprotected intercourse. The prevalence of infertility, ~17.5% globally, has remained relatively stable over the past few decades. Primary infertility occurs in couples who have never achieved a pregnancy, whereas secondary infertility refers to infertility after achieving at least one pregnancy. During the first year of attempting pregnancy, the fecundability rate, defined as the ability to achieve a pregnancy within one menstrual cycle, is highest in the first 3 months and declines over the next 9 months. Approximately 85% of couples will achieve pregnancy after 12 months, and 95% will achieve pregnancy after 24 months. Increasing trends toward later childbearing can have significant implications due to age-related decrease in the fecundability rate. Compared to women aged 30–31 years of age, fecundability is reduced by 14% in women aged 34–35 years, 19% in women aged 36–37 years, 53% in women aged 40–41 years, and 59% in women aged 42–44 years.

ETIOLOGY

The causes for infertility are generally classified as female factors, male factors, and unexplained infertility **(Fig. 408-1)**. The female causes include tubal factors (pelvic inflammatory disease, endometriosis, prior surgery, salpingitis isthmica nodosum), uterine etiology (fibroids, congenital malformations, uterine scarring), ovulatory dysfunction (polycystic ovary syndrome [PCOS], diminished ovarian reserve, premature ovarian insufficiency), and endocrine dysfunction (hypothyroidism, hyperprolactinemia). Although the probability of achieving a pregnancy decreases after the age of 35 in women, primarily due to chromosomal abnormalities in the oocyte during meiosis, a similar decline has not been observed in men <50 years of age. The male causes of infertility include anatomic factors in the reproductive system (vasectomy, infection, absence of the vas), endocrine factors (hypogonadotropic hypogonadism, hypothyroidism, hyperprolactinemia, morbid obesity, use of certain medications), sexual dysfunction (erectile or ejaculatory dysfunction, decreased libido), and genetic factors contributing to primary testicular dysfunction, including defects in spermatogenesis (Klinefelter's syndrome, Y chromosome microdeletions). The distribution of these causes varies significantly across the world. Overall, female factors are present in 30–40% of couples with infertility, male factors are present in 40–50%, and both male and female factors are identified in 20–30%. Unexplained infertility refers to the absence of any identified abnormality after completing the fertility workup and occurs in up to 30% of couples. As a result, a complete workup of both partners is recommended in all couples presenting with infertility.

FERTILITY EVALUATION

Diagnostic evaluation for infertility is typically initiated after 1 year of unprotected intercourse because 80–85% of couples will achieve a pregnancy over this time period. Evaluation can be initiated even prior to meeting the definition of infertility, especially if one of the partners has risk factors for infertility. If the female partner's age is >35 years, it is recommended to initiate evaluation after 6 months of attempting pregnancy. If the age of the female partner is >40 years, it is recommended to start evaluating the couple immediately. The initial evaluation should include detailed medical history, laboratory testing, radiologic evaluation, and preconception counseling for both partners. As multiple causes for infertility may be identified, it is best to perform the complete diagnostic evaluation prior to initiating treatment.

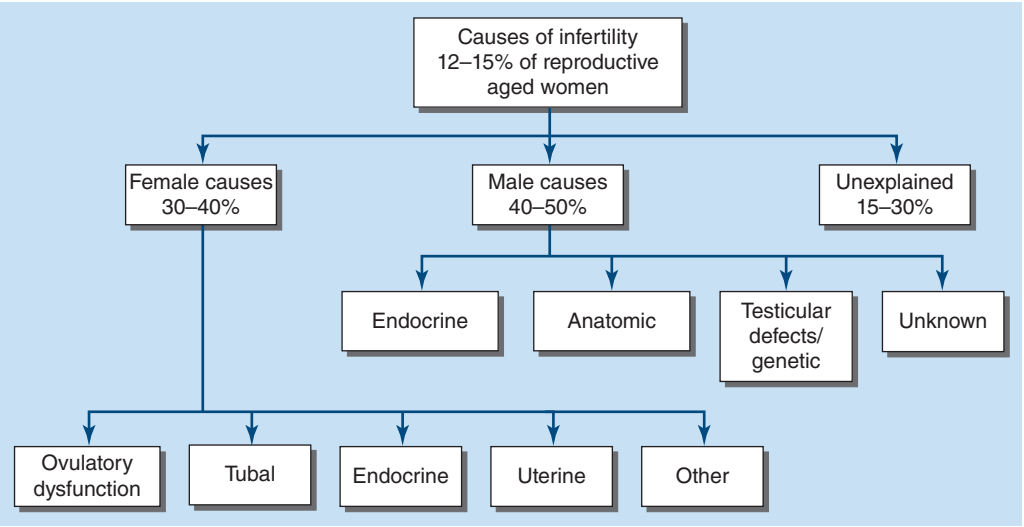

FIGURE 408-1 Causes of infertility.

History and Physical Exam A detailed history obtained from both partners is essential to identify risk factors for infertility. In the female partner, gynecologic history (menstrual frequency, menorrhagia, dysmenorrhea, history of sexually transmitted infections, endometriosis), medical and endocrine history, exposure to pelvic radiation, abdominal or pelvic surgeries, tobacco and alcohol use, medication use including cytotoxic drugs, family history of early menopause, and prior history of pregnancy should be assessed. In addition, frequency of intercourse, timing of intercourse, use of methods to detect ovulation, and concerns regarding sexual dysfunction over the past several months should be ascertained. Physical exam in the female partner should include assessment of weight and blood pressure (BP), thyroid and breast exam, assessment for signs of hyperandrogenism, and pelvic exam to assess uterine size, adnexal masses, and factors that might impact intercourse. Similarly, a detailed history should be obtained in the male partner with specific questions regarding injuries and surgery in the reproductive tract; mumps orchitis; exposure to pelvic radiation; use of androgens, cytotoxic drugs, and other medications; and fertility with any prior partner. The exam in the male partner should include body mass index (BMI), BP, and complete physical exam including testicular exam.

Ultrasound An abdominal and transvaginal pelvic ultrasound can assess uterine (myomas, adenomyosis, müllerian anomalies) and adnexal abnormalities (endometriosis, polycystic-appearing ovaries) and evaluate ovarian reserve (number of antral follicles in both ovaries).

Ovulation Assessment Women who have regular menstrual cycles between 25 and 35 days will typically have ovulatory cycles. Ovulation can be assessed by using ovulation detection strips at home to detect urinary luteinizing hormone (LH) or by measuring a serum progesterone level 7 days after ovulation. Basal body temperatures can also be used to confirm ovulation when a rise in temperature is noted in the luteal phase. However, basal body temperature measurements are less reliable than the above methods.

Hysterosalpingogram An hysterosalpingogram (HSG) is performed during the follicular phase to assess the patency of fallopian tubes by injecting radiopaque contrast through the cervix into the uterus and imaging the flow of contrast through one or both tubes. In addition to identifying tubal pathology, an HSG may identify intrauterine abnormalities such as polyps, submucosal myomas, and adhesions. Although the negative predictive value of HSG for assessing tubal patency is high, the positive predictive value is relatively low. Interestingly, pregnancy rates have been shown to be higher after an HSG test compared to no testing and higher when oil-based contrast was used compared to water-based contrast, likely related to tubal flushing of mucus plugs. Alternate options that are increasingly used include injection of agitated saline contrast through the cervix into the uterus. Tubal patency is assessed by demonstrating passage of agitated saline contrast through the tubes or accumulation in the cul de sac as visualized by ultrasonography. A saline infusion sonogram is more accurate in assessing intrauterine pathology such as polyps and intrauterine scarring compared to HSG and can be combined with ultrasound assessment of the pelvis.

Ovarian Reserve Evaluation Assessment of ovarian reserve includes measurement of serum FSH and estradiol on day 2 or 3 of the menstrual cycle and serum anti-müllerian hormone (AMH). These screening tests combined with age of the female partner and antral follicle counts measured by ultrasound can identify diminished ovarian reserve and provide information on the urgency to initiate treatment. AMH and antral follicle counts are also used to determine starting doses of gonadotropins for fertility treatments. These markers of ovarian reserve, however, do not predict the likelihood of pregnancy and live birth.

Endocrine Tests In women with irregular menses, serum TSH, prolactin, and androgens (total and free testosterone) should be measured to identify other causes for anovulation.

Semen Analysis (see Chap. 403) The semen sample is collected after 2–7 days of abstinence and provides an assessment of sperm count, motility, morphology, volume, and pH. None of the individual sperm parameters are predictive of fertility, but the likelihood of infertility increases with multiple abnormalities. Those with abnormal sperm parameters based on the WHO criteria (*oligoasthenozoospermia* is defined as sperm counts <15 million/mL, motility <40%, and normal morphology <4%) should have a physical exam and endocrine evaluation (serum follicle-stimulating hormone [FSH], LH, prolactin, and thyroid-stimulating hormone [TSH]); those with azoospermia or severe oligospermia (<5 million/mL) should have genetic evaluation (karyotype and Y chromosome microdeletion). Although a DNA sperm fragmentation assay is not part of the initial evaluation, it may be indicated in patients with recurrent pregnancy loss. Sperm antibody testing and scrotal ultrasound should not be routinely performed in infertile men.

Genetic Screening All couples can be offered preconception genetic screening based on ethnicity, family history, or common autosomal recessive conditions.

Of note, diagnostic laparoscopy, postcoital test, endometrial biopsy, thrombophilia, and immunologic testing and karyotype are not indicated as part of the initial workup of infertility.

COUNSELING AND TREATMENT

Preconception Counseling All patients seeking fertility care should be provided with preconception counseling to identify modifiable risks and optimize pregnancy outcomes. This includes counseling

about eating disorders or lifestyle modifications for weight management as obesity in women is associated with an increase in anovulatory cycles, miscarriage rates, and maternal and fetal complications in pregnancy. Obesity in men is associated with abnormal sperm parameters. Preconception counseling regarding smoking cessation is important as evidence suggests that smoking cessation can reverse the detrimental impact of smoking on fecundity. Smoking decreases fertility rates by a direct impact on oocyte DNA and also increases the risk of miscarriage and ectopic pregnancy. In addition, smoking during pregnancy is associated with an increased risk of placental abruption and intrauterine growth restriction (IUGR). Moreover, the impact of smoking on ovarian reserve has been shown to accelerate the time to menopause by 1–4 years. As high levels of caffeine consumption increase the risk of infertility and miscarriage, women should be counseled to restrict caffeine consumption to ≤2 cups while attempting pregnancy and during pregnancy. Use of testosterone products, which are widely used for the treatment of hypoandrogenism and sexual dysfunction in men, should be stopped. Inquiries should be made about possible misuse of androgens for physical appearance or performance enhancement **(Chap. 411)**. As part of the preconception counseling, patients should be informed that the fertile window is typically 5–6 days prior to ovulation, and therefore, intercourse every 1–2 days during this time period will increase the chance of pregnancy. Various methods are used by women to detect ovulation, including basal body temperature measurements, assessment of changes in cervical mucus, and urinary LH kits. A rise in basal body temperatures indicates that ovulation has occurred and therefore cannot be used to time intercourse. LH kits can be used to detect the start of ovulation and subsequently time intercourse on the day of the LH surge and the following day. Physicians should counsel patients that advanced maternal age (>35 years) is associated with a higher risk of aneuploidy and advanced paternal age (>40 years) is associated with adverse health outcomes in the offspring.

Treatment Treatment recommendations depend on the results of the fertility evaluation described above **(Table 408-1)**. The success of different treatments depends on several factors including age of the female partner, assessment of ovarian reserve, history of smoking, BMI, and race.

Tubal Factor Infertility Tubal factor infertility constitutes 30–35% of cases of female infertility, and a large majority are secondary to tubal obstruction resulting from sexually transmitted infections. In vitro fertilization (IVF) was first developed as a treatment for tubal factor infertility as it bypasses the fallopian tubes and allows fertilization of oocytes in the laboratory prior to transcervical transfer into the uterus. IVF offers the highest success rates for couples with tubal factor infertility. Tubal repair or reconstruction is typically not recommended in cases associated with tubal infections or hydrosalpinx, due to both the low success rate in achieving tubal patency and increased risk of ectopic pregnancy. In fact, removal of hydrosalpinges by salpingectomy will improve pregnancy rates in subsequent IVF treatments as it prevents efflux of tubal fluid into the uterine cavity. If a proximal tubal blockage is observed on HSG, radiographically guided cannulation of fallopian tubes can be attempted. In women with bilateral tubal ligation, the decision between microsurgical reanastomosis versus IVF will depend on a number of factors including patient's age, ovarian reserve, number of children desired, partner's semen parameters, experience of the surgeon, and cost of procedure.

TABLE 408-1 Assisted Reproductive Technologies

Ovulation induction Oral agents Injectable hormones	Clomiphene citrate (selective estrogen response modulator) Letrozole (aromatase inhibitor) FSH, LH (gonadotropins)
Intrauterine insemination (IUI)	Office-based procedure by which washed and concentrated ejaculated sperm is deposited in the uterine cavity via a soft catheter passed through the cervix
In vitro fertilization (IVF)	Oocytes are harvested transvaginally under local anesthesia or intravenous sedation and incubated with sperm to facilitate fertilization. The fertilized embryos are cultured for 3 days (cleavage stage) or 5 days (blastocyst stage) prior to transcervical placement of one or more embryos, depending on the age of the female patient, into the uterine cavity under ultrasound guidance.
Intracytoplasmic sperm injection (ICSI)	In cases of severe male factor infertility, a single motile morphologically normal appearing sperm is injected into the oocyte for potential fertilization.

Abbreviations: FSH, follicle-stimulating hormone; LH, luteinizing hormone.

Ovulatory Dysfunction Endocrine conditions such as hypothyroidism and hyperprolactinemia should be treated prior to use of ovulation induction medications. Lifestyle modifications should be recommended in patients with low BMI or obesity. Weight loss in obese women has been shown to increase the likelihood of spontaneous or drug-induced ovulation. First-line treatment for anovulatory infertility (most common etiology is PCOS) includes use of letrozole followed by clomiphene citrate to induce ovulation **(Chap. 406)**. A large majority of women with PCOS (60–80%) respond to these oral medications, and the addition of metformin, combined with the above medications as a second-line agent, may further increase the chance of ovulation, particularly in obese women. In women with hypothalamic amenorrhea, behavioral modifications such as weight gain and decreased exercise may resume ovulation. If there is no response, judicious use of low-dose injectable gonadotropins can induce monofollicular growth. In women with diminished ovarian reserve, treatment can be escalated from ovulation induction with oral medications and intrauterine insemination (IUI) to IVF, as the overall live birth rates are lower. In both women with diminished ovarian reserve and women with premature ovarian insufficiency, the option of using donor oocytes can be offered. In that case, the egg donor will undergo the IVF procedure, the harvested eggs are fertilized with the male partner's sperm, and the fertilized embryos will be transferred to the patient's uterus.

Male Infertility Given the high prevalence of male factor infertility (40–50%), timely evaluation and treatment are recommended. Men with abnormal semen parameters have associated health risks and should have a detailed evaluation by specialists in male reproduction. In men with no sperm (azoospermia) in the ejaculate, further evaluation including a repeat semen analysis followed by physical examination, endocrine tests, and genetics studies should be performed to identify obstructive (40% prevalence) versus nonobstructive etiology. First-line treatment for mild to moderate male factor infertility includes IUI alone or IUI combined with ovulation induction, depending on the female partner's age and other causes of infertility. In men with severe male factor infertility (sperm count <5 million/mL or motility <20%), IVF with intracytoplasmic sperm injection (ICSI) is recommended. In men with obstructive azoospermia, sperm can be procured by direct aspiration from the epididymis or testis. In men with congenital bilateral absence of the vas deferens (CBAVD), testing for *CFTR* mutations and genetic counseling are indicated before to offering IVF with ICSI. In men with nonobstructive azoospermia, microsurgical sperm retrieval from the testes may result in successful pregnancies after IVF-ICSI; however, the use of donor sperm for IUI is an alternate option. Men with hypogonadotropic hypogonadism (e.g., Kallmann's syndrome) can be treated with gonadotropins to initiate spermatogenesis followed by IUI or IVF. Treatment of male sexual dysfunction and avoidance of exogenous androgens are effective strategies for addressing male factor infertility. Repair of a moderate to large varicocele is recommended when associated with abnormal semen parameters or if the patient is symptomatic from the varicocele; however, it may take several months to detect an improvement in semen parameters.

Unexplained Infertility In 15–30% of couples, no clear causes of infertility are identified. In such cases, it is appropriate to initiate ovarian stimulation with oral medications to increase the number of developing oocytes combined with IUI timed to ovulation in order to increase the number of motile sperm in the reproductive tract. Depending on the age of the female partner, this approach offers

modest success rates limiting its use to 3–6 months before recommending IVF. Overall, IVF is associated with a low risk of complications; the risk of ovarian hyperstimulation syndrome is significantly decreased by judiciously monitoring stimulation and using gonadotropin-releasing hormone (GnRH) to trigger ovulation instead of human chorionic gonadotropin (hCG). Multiple pregnancy remains the highest risk associated with IVF despite improvements in cryopreservation of embryos and age-based guidelines for limiting the number of embryos to transfer. In some couples, the IVF treatment may reveal an underlying cause of infertility such as lower fertilization, embryo cleavage, or blastocyst formation rates. Of note, guidelines from different medical societies around the world vary in the rapidity of offering IVF for unexplained infertility.

Uterine Factors Fibroids are the most common benign tumors of the reproductive tract and occur in 50–70% of reproductive-age women. It is not clear whether fibroids decrease the likelihood of pregnancy; submucosal fibroids and intramural fibroids that distort the endometrial cavity may lower pregnancy rates and increase the risk of pregnancy loss. Removal of submucosal fibroids, uterine polyps, and intrauterine adhesions hysteroscopically may improve subsequent pregnancy rates.

Endometriosis Endometriosis is a common gynecologic condition associated with pelvic pain and dysmenorrhea, and in severe cases, it is associated with tubo-ovarian infertility. Approximately 25–50% of infertile women have endometriosis, and 30–50% of women with endometriosis have infertility. Prolonged medical management to suppress endometriotic lesions and surgical treatment of stage 1 and 2 endometriosis have not been shown to improve subsequent fertility rates. Surgical removal of endometriotic lesions or endometriomas in women with stage 3 or 4 endometriosis may improve subsequent pregnancy rates. First-line treatment of infertility associated with endometriosis alone includes use of oral ovulation induction medications and IUI.

PSYCHOLOGICAL ASPECTS OF INFERTILITY

It is well recognized that infertility is associated with psychological stress related not only to the diagnostic and therapeutic procedures themselves but also to repeated cycles of hope and loss associated with each new procedure or cycle of treatment that does not result in the birth of a child. These feelings are often combined with a sense of isolation from friends and family. Counseling and stress-management techniques should be offered early in the evaluation of infertility as many patients do not pursue treatments after the initial consultation. Importantly, infertility and its treatment do not appear to be associated with long-term psychological sequelae.

CONTRACEPTION

The desired ideal number of children per family varies around the globe and is approximately 2.6 in the United States. Couples not using any form of contraception have an 85% chance of achieving a pregnancy over 1 year. Based on these data, couples spend most of their reproductive life preventing a pregnancy and a much smaller proportion attempting to become or being pregnant. It is therefore not surprising that a majority of women who have been sexually active will have used some form of contraception to prevent a pregnancy. Unintended pregnancies primarily occur due to lack of use or inconsistent use of contraceptives rather than failure of the contraceptive method used. Of the different forms of contraception used worldwide in 2022, tubal sterilization was the most common (~219 million) followed by use of male condom (208 million), intrauterine device (IUD) (161 million), and the (birth control) pill (150 million). Contraceptive methods used by married women differ from those used by single women, and the most widely used contraceptive methods differ by world regions. The rates of female sterilization increased steadily in the last century and now show a slight decrease, likely due to the increasing use of long-acting reversible contraceptive (LARC) agents, such as IUDs and implants, which are as effective as sterilization. The convenience of use of contraceptives determines their compliance and efficacy; contraceptives requiring daily and coitus-related use have higher failure rates compared to long-acting reversible and permanent methods. The U.S. Medical Eligibility Criteria (USMEC) for contraceptive use are evidence-based guidelines to help health care providers recommend appropriate contraceptives to women with chronic medical conditions (Table 408-2). This excellent resource is adapted from the WHO guidance and is kept up to date through continual review of published literature.

TABLE 408-2 U.S. Medical Eligibility Criteria (USMEC) for Contraceptive Use

USMEC Category 4 (a condition that represents an unacceptable health risk if the contraceptive method is used)
Smoking: women age ≥35 years who smoke ≥15 cigarettes per day
Known ischemic heart disease or multiple risk factors for cardiovascular disease (older age, smoking, diabetes, low HDL, high LDL, high triglycerides, and hypertension)
Acute DVT
Previous thromboembolic event; high risk of recurrent DVT
Stroke or known thrombogenic mutations
Complicated valvular heart disease
Peripartum cardiomyopathy (<6 months, moderately to severely impaired cardiac function)
Complicated solid organ transplantation
Hypertension (systolic ≥160 mmHg or diastolic ≥100 mmHg, vascular disease)
Systemic lupus erythematous (positive or unknown antiphospholipid antibodies)
Cirrhosis, hepatocellular adenoma or hepatoma (malignant)
Viral hepatitis, acute flare
Pregnancy and early postpartum (<21 days)
Breast-feeding <21days postpartum
Breast cancer
Diabetes: neuropathy/retinopathy/nephropathy
Migraines with aura
USMEC Category 3 (a condition for which the theoretical or proven risks outweigh the advantages for using the method)
Smoking: women ≥35 years who smoke <15 cigarettes/day
Previous thromboembolic event; lower risk of recurrent DVT
Superficial thrombosis (acute or history of)
Past history of breast cancer and no evidence for 5 years
Hypertension (adequately controlled or systolic 140–159 mmHg or diastolic 90–99 mmHg)
Anticonvulsant drug therapy (certain anticonvulsants (phenytoin, carbamazepine, barbiturates, primidone, topiramate, oxcarbazepine)
Antimicrobial therapy: rifampin or rifabutin
Antiretroviral therapy for prevention (preexposure prophylaxis) or treatment of HIV
Bariatric surgery (Roux-en-Y gastric bypass or biliopancreatic diversion)
Breast-feeding 21–42 days postpartum with or without risk factors for VTE

Abbreviation: DVT, deep-vein thrombosis; HDL, high-density lipoprotein; LDL, low-density lipoprotein; VTE, venous thromboembolism.

TYPES OF CONTRACEPTION

These can be classified in a number of ways, such as permanent versus reversible, hormonal versus nonhormonal, or barrier versus nonbarrier (Table 408-3).

Permanent Contraception The permanent forms of contraception include tubal sterilization and vasectomy. Male sterilization has declined globally with a rate of <2% in 2022. Vasectomy is a low-risk procedure typically performed in an outpatient setting with a very low failure rate of 0.1 pregnancies per 100 women per year. It is not immediately effective, and patients should be told to use other forms of contraception for a minimum of 3 months after the procedure. Globally, tubal sterilization rates have also declined steadily and represent 23% of all methods. Tubal sterilization can be performed in the postpartum period or as an interval procedure and has a failure rate of 0.5 pregnancies per 100 women per year. Postpartum sterilization can be

TABLE 408-3 Effectiveness of Different Forms of Contraception

METHOD OF CONTRACEPTION	THEORETICAL EFFECTIVENESS (%)	ACTUAL EFFECTIVENESS (%)	CONTINUED USE AT 1 YEAR (%)	USE OF CONTRACEPTIVE METHOD BY U.S. WOMEN AGE 15–49 (%)
No method	15	15		34.7
Fertility awareness	96	76	47	1.2
Withdrawal	96	78	46	4.4

Current Contraceptive Status Among Women Aged 15–49: United States, 2017–2019 NCHS Data Brief No. 388, October 2020. Available at: *https://www.cdc.gov/nchs/products/databriefs/db388.htm*.

performed during a cesarean section or after a vaginal delivery via mini-laparotomy. Interval procedures can be performed laparoscopically or via mini-laparotomy and include partial or complete salpingectomy or occlusion of the fallopian tubes using electrocoagulation or mechanical devices such as clips. These permanent methods of contraception are highly effective as they avoid the need for user-dependent contraception. All patients should undergo preprocedure counseling regarding risk of failure, permanence of the procedure, regret, and alternatives.

Hormonal Contraceptives • **COMBINED ESTROGEN- AND PROGESTIN-CONTAINING CONTRACEPTIVES** The mechanism of action of the hormonal contraceptives involves negative feedback from continuous estrogen administration, thereby decreasing FSH secretion, follicular development, and formation of a dominant follicle. The continuous progestin suppresses LH secretion and inhibits ovulation, alters endometrial receptivity, thickens the cervical mucus, and impairs tubal motility. These hormones can be delivered via oral pills to be taken daily, as a transdermal patch that is changed weekly, or a vaginal ring that is replaced monthly or annually. There are numerous *pills* available containing different doses of estrogen (<50 μg) and types of estrogen and progestins and varying doses within a pack (monophasic vs multiphasic); the pills can be taken in a cyclic or extended cycle schedule. The contraceptive efficacy is similar with varying doses of estrogen and progestin. Decreasing the duration of hormone-free days may decrease some side effects associated with menses, such as menstrual migraines and dysmenorrhea. The overall failure rate for combined hormonal contraceptives is 8 pregnancies per 100 women per year, although compliance with daily use of pills may be lower, affecting efficacy. The contraceptive patch and vaginal ring have higher compliance compared to daily pills. Use of the *contraceptive patch* is associated with a low risk of skin reactions and a lower efficacy in women weighing >90 kg. The transdermal mode of delivery is associated with a higher steady state comparable to that of a 40-μg ethinyl estradiol oral contraceptive. Hormonal contraceptives offer additional benefits such as regulation of menstrual cycles; suppression of ovarian cysts; and decrease in menorrhagia, dysmenorrhea, and hyperandrogenism symptoms; in addition, they reduce the risk of both endometrial (50% reduction) and ovarian cancer (40% reduction). Common side effects include nausea, breast tenderness, bloating, and intermenstrual bleeding. There may be a mild increase in BP in some patients, and it is recommended to check BP at follow-up visits. In large studies and meta-analyses, hormonal contraceptives are not associated with significant weight gain, mood changes, or effect on libido. Prior to administering hormonal contraceptives, a detailed patient history should be obtained to determine any absolute or relative contraindications to their use. Due to the low but slightly increased risk of deep-vein thrombosis (DVT) associated with estrogen-containing hormonal contraceptives (3–15 per 10,000 women-years), they are contraindicated in the immediate postpartum period, in smokers over the age of 35 years, and in women with a history of hereditary thrombophilias or DVT. The association between risk of DVT and different doses of estrogen (ethinyl estradiol <35 μg) or different routes of administration (transdermal patch) is weak. There is, however, some association between third- and fourth-generation progestins and increased risk of DVT. Routine screening for familial thrombotic disorders is not recommended prior to prescribing hormonal contraceptives. Although obesity is associated with decreased fertility, the vast majority of women with obesity do not experience infertility. The USMEC classifies obesity alone as risk category 2, where the benefits of taking hormonal contraceptives outweigh any theoretical risk.

PROGESTIN-ONLY HORMONAL CONTRACEPTION Different types of progestins are used for contraception in oral pills, injectable forms, subdermal implants, and IUDs and may be an option for women who have contraindications to the use of estrogen-containing contraceptives (e.g., migraine with aura, DVT, stroke, breast-feeding). The failure rate with *progestin-only pills* is 9 pregnancies per 100 women per year, whereas the failure rate of progestin IUDs is 0.1 pregnancies per 100 women per year. In addition to acting as a spermicidal, the *levonorgestrel IUD* also thickens the cervical mucus and thins the endometrium, thereby decreasing its receptivity. The common side effects include irregular bleeding, acne, breast tenderness, and pain,

with higher rates of expulsion when IUDs are inserted in the immediate postpartum period. Breakthrough bleeding or unscheduled bleeding is commonly reported, as estrogen usually serves to stabilize the endometrial lining and prolonged exposure to progestin alone results in a thinner decidualized lining. Depending on the device used, the progestin IUD is effective for 3–7 years. The *injectable form of progesterone* (medroxyprogesterone acetate) is administered intramuscularly or subcutaneously every 3 months with a failure rate of 3 pregnancies per 100 women per year. Its side effects include weight gain, irregular menses, amenorrhea, and mood changes, and there is a slow return to ovulation and fertility after discontinuation (6–9 months). The *subdermal implant* contains etonogestrel and is placed easily over the triceps muscle in the inner arm using local anesthesia. It lasts up to 5 years and has a failure rate of 0.05 pregnancies per 100 women per year. Findings from the Contraceptive Choice research project showed that continuation rates were higher for LARC (IUDs and implants) compared to short-acting methods. LARCs are the most effective reversible form of contraception with high continuation and satisfaction rates; hence, they are a good choice in adolescents and nulliparous women.

Nonhormonal IUD IUDs are a commonly used form of contraception worldwide and are available as hormonal and nonhormonal devices. The nonhormonal copper IUD works as a spermicidal and is effective for up to 12 years with a failure rate of <1 pregnancy per 100 women per year. Patients should be counseled regarding the increased risk of heavy vaginal bleeding and dysmenorrhea resulting in higher discontinuation rates compared to the levonorgestrel-containing IUDs. IUDs can be used in adolescents and adult women and are typically inserted and removed as an office procedure with use of mild analgesics. They can be inserted anytime during a menstrual cycle, referred to as interval insertion, and in the immediate postpartum and postabortion period.

Barrier Contraception The barrier forms of contraception include condoms (male, female) and diaphragm and cervical cap and have lower effectiveness secondary to inconsistent and incorrect use. They offer several advantages including minimal side effects, lower cost, no requirement for a prescription, and protection from sexually transmitted infections. The failure rate for male and female condoms is 17–21 pregnancies per 100 women per year. Spermicidals can be used in conjunction with barrier methods to improve effectiveness.

Lactational Contraception Lactation may serve as an effective form of contraception during the first 6 postpartum months if there is exclusive breast-feeding and menstrual cycles have not resumed. The contraceptive effect occurs due to suppression of GnRH pulsatility associated with suckling. The failure rate under these circumstances can be as low as 0.5–1.5 pregnancies per 100 women per year.

Fertility Awareness The standard days method is typically used by women with regular menstrual cycles whereby they track their cycles to avoid intercourse from cycle days 8–19. The rhythm and withdrawal method are also referred to as traditional methods of contraception.

Emergency Contraception Also known as postcoital contraception, this method is used after an unprotected or inadequately protected act of intercourse. The probability of pregnancy independent of the time of the month is 8%, but the probability varies significantly in relation to proximity to ovulation and may be as high has 30%. Many women are not aware of the availability of emergency contraception and its appropriate use. As the probability of pregnancy is highest if there has been unprotected intercourse during the 3 days prior to ovulation, the timing of administration and type of emergency contraceptive used determine the efficacy. Emergency contraception options include the copper IUD and oral medications such as ulipristal acetate, levonorgestrel, and combined hormonal pills. The copper IUD prevents fertilization and implantation and is the most effective choice if inserted within 5 days of unprotected intercourse. It can be offered to obese women in whom other hormonal forms of emergency contraceptive may be less effective. Ulipristal acetate, a progesterone receptor antagonist, blocks the ability of endogenous progesterone to act on its receptors and inhibits the LH surge, delaying or inhibiting ovulation, and may directly inhibit follicular rupture. It is administered as a 30-mg single dose up to 5 days after unprotected intercourse. Levonorgestrel administered as a single dose will prevent or delay ovulation and is associated with fewer side effects compared to combined hormonal pills. Overall, the failure rate for all hormonal emergency contraception is 1–3%, with ulipristal acetate being the most effective. Side effects are mild and may include nausea, irregular vaginal bleeding, and fatigue. Emergency contraception should be offered to all women who ask for it up to 5 days after unprotected intercourse and not delayed in order to obtain a pregnancy test or perform a clinical examination. Although body weight can affect the efficacy of emergency hormonal contraception, treatment should not be withheld from overweight and obese women.

CONTRACEPTION COUNSELING

Patients should be provided information regarding the different methods of contraception, side effects, noncontraceptive benefits, efficacy, need for strict compliance, and impact on future fertility. In order to facilitate patient-centric care, the provider should discuss plans for future pregnancy and whether childbearing is complete. A detailed patient history should be reviewed to identify potential contraindications such as migraines with aura, smoking, and hypertension. Providers should refer to the most updated USMEC or WHO Medical Eligibility Criteria for Contraceptive Use guidelines when counseling patients with associated comorbidities. As part of the shared decision-making approach, the patient's choice should be the guiding factor, and the discussion should be nonjudgmental. Adolescents should be offered access to the full range of contraceptive options. In a low-risk patient, hormonal contraceptives can be prescribed from menarche to menopause; regular evaluation of side effects and assessment of changes in the patient's medical history, however, are required.

409 Sexual Dysfunction

Kevin T. McVary

Male sexual dysfunction affects up to 31% of middle-aged and elderly men, whereas female sexual dysfunction, although studied less intensely, has a higher prevalence (43%) than male sexual dysfunction. Demographic changes, the popularity of newer treatments, and greater awareness of sexual dysfunction by patients and society have led to increased diagnosis and associated health care expenditures for the management of this common disorder. Sexual health and satisfaction with sex life are important aspects of quality of life for many, including those in poor health. Because many patients are reluctant to initiate discussion of their sex lives, physicians should address this topic directly to elicit a history of sexual dysfunction. Specifically addressing sexual health should be a routine part of the clinical encounter, particularly in those with cardiovascular risk factors.

MALE SEXUAL DYSFUNCTION

PHYSIOLOGY OF MALE SEXUAL RESPONSE

An erection is a neurovascular event, and the cardiovascular system needs to be intact for sexual stimulation to successfully result in an erection. Normal male sexual function includes (1) sufficient libido, (2) the ability to achieve and maintain penile erection, (3) ejaculation, and (4) detumescence. *Libido* refers to sexual desire and is influenced by a variety of visual, olfactory, tactile, auditory, imaginative, and hormonal stimuli. Sex steroids, particularly testosterone, act to increase libido. Libido can be diminished by emotional context, systemic illness, hormonal disturbances, psychiatric disorders, and medications.

Penile tumescence leading to erection depends on an increased flow of blood into the lacunar network accompanied by complete relaxation of the arteries and corporal smooth muscle. The microarchitecture of the corpora is composed of a mass of smooth muscle (trabecula) that contains a network of endothelial-lined vessels (lacunar spaces). Subsequent compression of the trabecular smooth muscle against the fibroelastic tunica albuginea causes a passive closure of the emissary veins and accumulation of blood in the corpora. In the presence of a full erection and a competent valve mechanism, the corpora become noncompressible cylinders from which blood does not escape. This cascade of relaxation and venous occlusion culminates in a rigid erection.

The central nervous system (CNS) exerts an important influence by either stimulating or antagonizing spinal pathways that mediate erectile function and ejaculation. The erectile response is mediated by a combination of central (psychogenic) innervation and peripheral (reflexogenic) innervation. Sensory nerves that originate from receptors in the penile skin and glans converge to form the dorsal nerve of the penis, which travels to the S2-S4 dorsal root ganglia via the pudendal nerve. Parasympathetic nerve fibers to the penis arise from neurons in the intermediolateral columns of the S2-S4 sacral spinal segments. Sympathetic innervation originates from the T-11 to the L-2 spinal segments and descends through the hypogastric plexus.

Neural input to smooth-muscle tone is crucial to the initiation and maintenance of an erection. There is also an intricate interaction between the corporal smooth-muscle cell and its overlying endothelial cell lining **(Fig. 409-1)**. Nitric oxide, which induces vascular relaxation, promotes erection and is opposed by endothelin 1 (ET-1) and Rho kinase, which mediate vascular contraction. Nitric oxide is synthesized from L-arginine by nitric oxide synthase (NOS) and is released from the nonadrenergic, noncholinergic (NANC) autonomic nerve supply to act postjunctionally on smooth-muscle cells. Nitric oxide increases the production of cyclic 3′,5′-guanosine monophosphate (cyclic GMP), which induces relaxation of smooth muscle **(Fig. 409-2)**. Cyclic GMP is metabolized by phosphodiesterase type 5 (PDE-5). Inhibitors of PDE-5 such as the oral medications sildenafil, tadalafil, vardenafil, and avanafil maintain erections by reducing the breakdown of cyclic GMP. However, if nitric oxide is not produced at some level, PDE-5 inhibitors are ineffective, as these drugs facilitate, but do not initiate, the initial enzyme cascade. In addition to nitric oxide, vasoactive prostaglandins (PGE_1, $PGF_{2\alpha}$) are synthesized within the cavernosal tissue and increase cyclic AMP levels, also leading to relaxation of cavernosal smooth-muscle cells.

Ejaculation is stimulated by the sympathetic nervous system; this results in contraction of the epididymis, vas deferens, seminal vesicles, and prostate, causing seminal fluid to enter the urethra. Seminal fluid emission is followed by rhythmic contractions of the bulbocavernosus and ischiocavernosus muscles, leading to ejaculation. This is followed by expulsion, characterized by stereotypic rhythmic contractions of the striated perineal muscles, leading to forceful expulsion of semen with the bladder neck closed. This emission and expulsion are controlled by the autonomic (parasympathetic and sympathetic) and somatic spinal centers, respectively. The synchronization between autonomic and somatic spinal centers is orchestrated by interneurons that form a spinal ejaculation generator that is present in mammals including man.

Premature ejaculation usually is related to anxiety or a learned behavior and is amenable to behavioral therapy or treatment with medications such as selective serotonin reuptake inhibitors (SSRIs). *Retrograde ejaculation* (RE) results when the internal urethral sphincter does not close; it may occur in men with diabetes or after surgery involving the bladder neck. *Anejaculation*, the failure of a portion or the whole of the emission process often confused with RE, is commonly the result of selective alpha blockers used in male voiding dysfunction (e.g., tamsulosin, silodosin).

Detumescence is mediated by norepinephrine from the sympathetic nerves, endothelin from the vascular surface, and smooth-muscle contraction induced by postsynaptic α-adrenergic receptors and activation of Rho kinase. These events increase venous outflow and restore the flaccid state. Venous leak can cause premature detumescence and is caused by insufficient relaxation of the corporal smooth muscle rather than a specific anatomic defect. *Priapism* refers to a persistent and painful erection and may be associated with sickle cell anemia, hypercoagulable states, spinal cord injury, or injection of vasodilator agents into the penis.

ERECTILE DYSFUNCTION

Epidemiology Erectile dysfunction (ED) is not considered a normal part of the aging process. Nonetheless, it is associated with certain physiologic and psychological changes related to age. In the Massachusetts Male Aging Study (MMAS), a community-based survey of men aged 40–70, 52% of responders reported some degree of ED. Complete ED occurred in 10% of respondents, moderate ED in 25%, and minimal ED in 17%. The incidence of moderate or severe ED more than doubled between the ages of 40 and 70. In the National Health and Social Life Survey (NHSLS), which included a sample of men and women aged 18–59, 10% of men also reported being unable to maintain an erection. Incidence was highest among men in the age group 50–59 (21%) and men who were poor (14%), divorced (14%), and less educated (13%).

The incidence of ED is also higher among men with certain medical disorders, such as diabetes mellitus, obesity, lower urinary tract symptoms secondary to benign prostatic hyperplasia (LUTS/BPH), heart disease, hypertension, decreased high-density lipoprotein (HDL) levels, and diseases associated with general systemic inflammation (e.g., rheumatoid arthritis). Cardiovascular disease and ED share etiologies as well as pathophysiology (e.g., endothelial dysfunction), and the degree of ED appears to correlate with the severity of cardiovascular disease. Consequently, ED represents a "sentinel symptom" in patients with occult cardiovascular and peripheral vascular disease.

Smoking is also a significant risk factor in the development of ED. Medications used in treating diabetes or cardiovascular disease are additional risk factors (see below). There is a higher incidence of ED among men who have undergone radiation or surgery for prostate cancer and in those with a lower spinal cord injury. Psychological causes of ED include depression, anger, stress from employment or relationships, anxiety, and other stress-related causes.

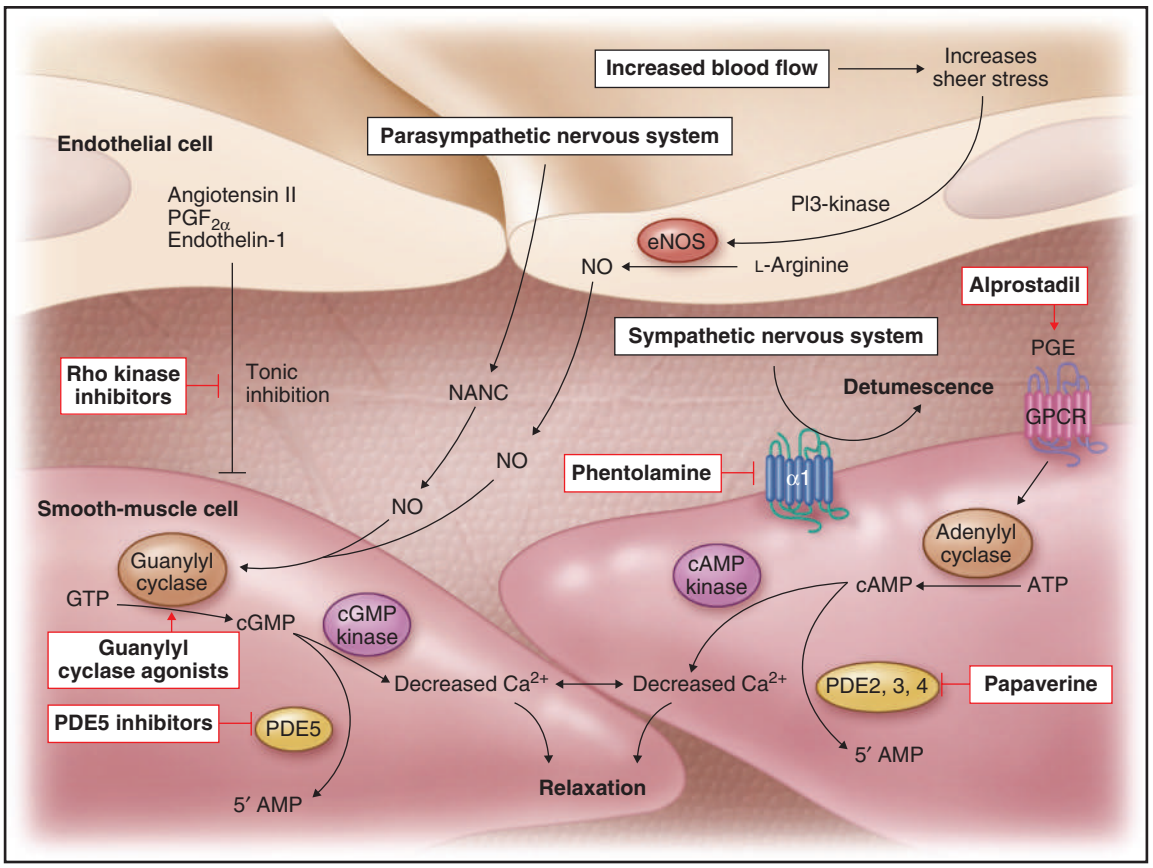

FIGURE 409-1 Pathways that control erection and detumescence. Outflow from the parasympathetic nervous system leads to relaxation of the cavernous sinusoids in two ways, both of which increase the concentration of nitric oxide (NO) in smooth-muscle cells. First, NO is the neurotransmitter in nonadrenergic, noncholinergic (NANC) fibers; second, stimulation of endothelial nitric oxide synthase (eNOS) through cholinergic output causes increased production of NO. The NO produced in the endothelium then diffuses into the smooth-muscle cells and decreases its intracellular calcium concentration through a pathway mediated by cyclic guanosine monophosphate (cGMP), leading to relaxation. A separate mechanism that decreases the intracellular calcium level is mediated by cyclic adenosine monophosphate (cAMP). With increased cavernosal blood flow, as well as increased levels of vascular endothelial growth factor (VEGF), the endothelial release of NO is further sustained through the phosphatidylinositol 3 (PI3) kinase pathway. Active treatments (red boxes) include drugs that affect the cGMP pathway (phosphodiesterase type 5 [PDE-5] inhibitors and guanylyl cyclase agonists), the cAMP pathway (alprostadil), or both pathways (papaverine), along with neural-tone mediators (phentolamine and Rho kinase inhibitors). Agents that are being developed include guanylyl cyclase agonists (to bypass the need for endogenous NO) and Rho kinase inhibitors (to inhibit tonic contraction of smooth-muscle cells mediated through endothelin). α1, α-adrenergic receptor; GPCR, G protein–coupled receptor; GTP, guanosine triphosphate; iCa^{2+}, intracellular calcium; NOS, nitric oxide synthase; PGE, prostaglandin E; PGF, prostaglandin F. *(Reproduced with permission from KT McVary: Clinical practice. Erectile dysfunction. N Engl J Med 357:2472, 2007.)*

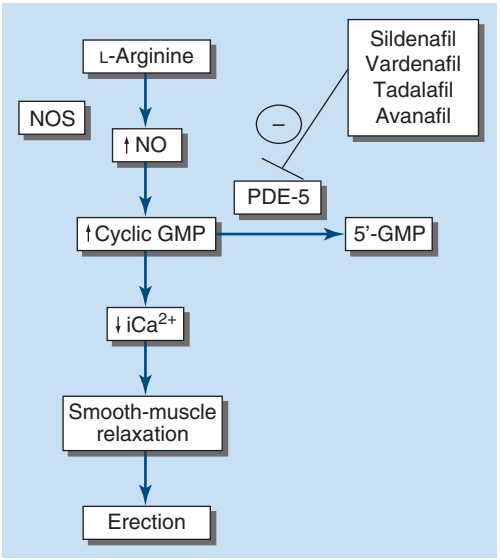

FIGURE 409-2 Biochemical pathways modified by phosphodiesterase type 5 (PDE-5) inhibitors. Sildenafil, vardenafil, tadalafil, and avanafil enhance erectile function by inhibiting PDE-5, thereby maintaining high levels of cyclic 3′,5′-guanosine monophosphate (cyclic GMP). iCa^{2+}, intracellular calcium; NO, nitric oxide; NOS, nitric oxide synthase.

Pathophysiology ED may result from three basic mechanisms: (1) failure to initiate (psychogenic, endocrinologic, or neurogenic), (2) failure to fill (arteriogenic), and (3) failure to store adequate blood volume within the lacunar network (veno-occlusive dysfunction). These categories are not mutually exclusive, and multiple factors contribute to ED. Psychogenic factors frequently coexist with other etiologic factors and should be considered in all cases. Diabetic, atherosclerotic, and drug-related causes account for >80% of cases of ED in older men.

Vasculogenic The most common organic cause of ED is a disturbance of blood flow to and from the penis. Atherosclerotic or traumatic arterial disease can decrease flow to the lacunar spaces, resulting in decreased rigidity and an increased time to full erection. Excessive outflow through the veins despite adequate inflow also may contribute to ED. Structural alterations to the fibroelastic components of the corpora may cause a loss of compliance and inability to compress the tunical veins. This condition may result from aging, increased cross-linking of collagen fibers induced by nonenzymatic glycosylation, hypoxemia, or altered synthesis of collagen associated with hypercholesterolemia.

Neurogenic Disorders that affect the sacral spinal cord or the autonomic fibers to the penis preclude nervous system relaxation of penile smooth muscle, thus leading to ED. In patients with spinal cord injury, the degree of ED depends on the completeness and level of the lesion. Patients with incomplete lesions or injuries to the upper part of the spinal cord are more likely to retain erectile capabilities than

are those with complete lesions or injuries to the lower part. Although 75% of patients with spinal cord injuries have some erectile capability, only 25% have erections sufficient for penetration. Other neurologic disorders commonly associated with ED include multiple sclerosis and peripheral neuropathy. The latter is often due to either diabetes or alcoholism. Pelvic surgery may cause ED through disruption of the autonomic nerve supply.

Endocrinologic Androgens increase libido, but their exact role in erectile function is unclear. Individuals with castrate levels of testosterone can achieve erections from visual or sexual stimuli. Nonetheless, normal levels of testosterone appear to be important for erectile function, in which the upregulation of nitric oxide synthase and the nitric oxide cascade is optimized (Fig. 409-1*A*). Androgen replacement therapy can improve depressed erectile function when it is secondary to hypogonadism; however, *it is not useful for ED when endogenous testosterone levels are normal and should be avoided.* Increased prolactin may decrease libido by suppressing gonadotropin-releasing hormone (GnRH) resulting in decreased testosterone levels. Treatment of hyperprolactinemia with dopamine agonists can restore libido and eugonadism.

Diabetic ED occurs in 35–75% of men with diabetes mellitus. Pathologic mechanisms are related primarily to diabetes-associated vascular and neurologic complications. Diabetic macrovascular complications are related mainly to age, whereas microvascular complications correlate with the duration of diabetes and the degree of glycemic control **(Chap. 415)**. Individuals with diabetes also have reduced amounts of nitric oxide synthase in both endothelial and neural tissues.

Psychogenic Two mechanisms contribute to the inhibition of erections in psychogenic ED. First, psychogenic stimuli to the sacral cord may inhibit reflexogenic responses, thereby blocking activation of vasodilator outflow to the penis. Second, excess sympathetic stimulation in an anxious man may increase penile smooth-muscle tone. The most common causes of psychogenic ED are performance anxiety, depression, relationship conflict, loss of attraction, sexual inhibition, conflicts over sexual preference, sexual abuse in childhood, and fear of pregnancy or sexually transmitted disease. Almost all patients with ED, even when it has a defined organic basis, develop a psychogenic component as a reaction to ED.

Medication-Related Medication-induced ED **(Table 409-1)** is estimated to occur in 25% of men seen in general medical clinics. The adverse effects related to drug therapy are additive, especially in older men. In addition to the drug itself, the underlying disease being treated is likely to contribute to sexual dysfunction (e.g., hypertension). Among the antihypertensive agents, the thiazide diuretics and beta blockers have been implicated most frequently. Calcium channel blockers and angiotensin-converting enzyme inhibitors are cited less frequently. These drugs may act directly at the corporal level (e.g., calcium channel blockers) or indirectly by reducing pelvic blood pressure, which is important in the development of penile rigidity. α-Adrenergic blockers are less likely to cause ED. Estrogens, GnRH agonists, H_2 antagonists, and spironolactone cause ED by suppressing gonadotropin production or by blocking androgen action. Antidepressant and antipsychotic agents—particularly neuroleptics, tricyclics, and SSRIs—are associated with erectile, ejaculatory, orgasmic, and sexual desire difficulties. Among the SSRIs, paroxetine and escitalopram have been associated with the highest risk of sexual dysfunction. Bupropion, nefazodone, and mirtazapine appear less likely to cause sexual dysfunction. A number of molecular pathways have been implicated in antidepressant-induced sexual adverse events. Serotonin has been hypothesized to inhibit normal sexual response by decreasing dopamine-enhanced libido, arousal, and erection and by increasing prolactin release. SSRIs have also been shown to be potent inhibitors of nitric oxide synthase.

If there is a strong association between the institution of a drug and the onset of ED, alternative medications should be considered. Otherwise, it is often practical to treat the ED without attempting multiple changes in medications as it may be difficult to establish a causal role for a drug.

TABLE 409-1 Drugs Associated with Erectile Dysfunction

CLASSIFICATION	DRUGS	POSSIBLE SUBSTITUTES
Diuretics	Thiazides Spironolactone	
Antihypertensives	Calcium channel blockers Methyldopa Clonidine Reserpine Beta blockers Guanethidine	α-Adrenergic blockers Prazosin Terazosin Doxazosin ACE inhibitors
Cardiac/ antihyperlipidemics	Digoxin Gemfibrozil Clofibrate	
Antidepressants	Selective serotonin reuptake inhibitors Tricyclic antidepressants Lithium Monoamine oxidase inhibitors	Bupropion Nefazodone Mirtazapine
Tranquilizers	Butyrophenones Phenothiazines	
H_2 antagonists	Ranitidine Cimetidine	Proton pump inhibitors (PPI) Omeprazole Esomeprazole Pantoprazole Rabeprazole
Hormones	Progesterone Estrogens Corticosteroids GnRH agonists 5α-Reductase inhibitors Cyproterone acetate	
Cytotoxic agents	Cyclophosphamide Methotrexate Roferon-A	
Anticholinergics	Disopyramide Anticonvulsants	
Recreational	Ethanol Cocaine Marijuana	

Abbreviations: ACE, angiotensin-converting enzyme; GnRH, gonadotropin-releasing hormone.

APPROACH TO THE PATIENT

Erectile Dysfunction

A good physician–patient relationship helps unravel the possible causes of ED, many of which require discussion of personal and sensitive topics. For this reason, a primary care provider is often ideally suited to initiate the evaluation. However, a significant percentage of men experience ED and remain undiagnosed unless specifically questioned about this issue. By far the two most common reasons for underreporting of ED are patient embarrassment and perceptions of physicians' inattention to the disorder. Once

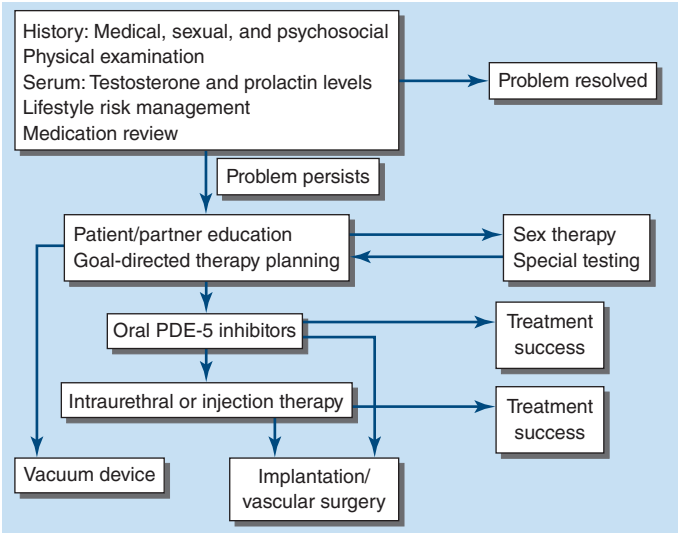

FIGURE 409-3 Algorithm for the evaluation and management of patients with erectile dysfunction. PDE, phosphodiesterase.

the topic is initiated by the physician, patients are more willing to discuss their potency issues. A complete medical and sexual history should be taken in an effort to assess whether the cause of ED is organic, psychogenic, or multifactorial **(Fig. 409-3)**.

Both the patient and his sexual partner should be interviewed regarding sexual history. ED should be distinguished from other sexual problems, such as premature ejaculation. Lifestyle factors such as sexual orientation, the patient's distress from ED, performance anxiety, and details of sexual techniques should be addressed. Validated questionnaires are available to assess ED, including the International Index of Erectile Function (IIEF) and the more easily administered Sexual Health Inventory for Men (SHIM), a validated abridged version of the IIEF. These can assess the severity of ED, measure treatment effectiveness, and guide future management. The initial evaluation of ED begins with a review of the patient's medical, surgical, sexual, and psychosocial histories. The history should note whether the patient has experienced pelvic trauma, surgery, or radiation. In light of the increasing recognition of the relationship between lower urinary tract symptoms (LUTS/BPH) and ED, it is advisable to evaluate for the presence of associated urinary symptoms. Questions should focus on the onset of symptoms, the presence and duration of partial erections, and the progression of ED. A history of nocturnal or early morning erections may be useful for distinguishing physiologic ED from psychogenic ED. Nocturnal erections occur during rapid eye movement (REM) sleep and require intact neurologic and circulatory systems. Organic causes of ED generally are characterized by a gradual and persistent change in rigidity or the inability to sustain nocturnal, coital, or self-stimulated erections. It is also important to address libido, as decreased sexual drive and ED are sometimes the earliest signs of decreased testosterone levels. It is useful to ask whether the problem is confined to coitus with one partner or also involves other partners; ED not uncommonly arises with new or extramarital sexual relationships. Situational ED, as opposed to consistent ED, suggests psychogenic causes. For men with recalcitrant ED, referral to a mental health professional may promote treatment adherence, reduce performance anxiety, and integrate treatments into a sexual relationship. Ejaculation is much less commonly affected than erection, but questions should be asked about whether ejaculation is normal, premature, delayed, or absent. Relevant risk factors should be identified, such as diabetes mellitus, cardiovascular disease, and neurologic disorders. The patient's surgical history should be explored with an emphasis on bowel, bladder, prostate, and vascular procedures. A complete drug history, including tobacco, alcohol, marijuana, and illicit drug inquiries, is also important. Social changes that may precipitate ED are also crucial to the evaluation, including health worries, spousal death, divorce, relationship difficulties, and financial concerns.

Because ED commonly involves a host of endothelial cell risk factors, men with ED report higher rates of overt and silent myocardial infarction. Therefore, ED in an otherwise asymptomatic male warrants consideration of other vascular disorders, including coronary disease. It is now widely recognized that ED often precedes the development of symptomatic coronary disease by several years. In addition, several studies now suggest that ED itself is an independent risk factor for the development of CVD even after correcting for other cardiovascular risk factors.

Men who suffer from ED are at high risk for concomitant LUTS from BPH and vice versa. Given that some treatments of one disorder will impact the other, the clinician should consider an assessment of LUTS in any man with ED.

The physical examination is an essential element in the assessment of ED. Signs of hypertension as well as evidence of thyroid, hepatic, hematologic, cardiovascular, or renal diseases should be sought. An assessment should be made of the endocrine and vascular systems, the external genitalia, and the prostate gland. The penis should be palpated carefully along the corpora to detect fibrotic plaques. Reduced testicular size and loss of secondary sexual characteristics are suggestive of hypogonadism. Neurologic examination should include assessment of anal sphincter tone, investigation of the bulbocavernosus reflex, and testing for peripheral neuropathy.

Although hyperprolactinemia is uncommon, a serum prolactin level should be measured in hypogonadal men, as decreased libido and/or ED may be the presenting symptoms of a prolactinoma or another mass lesion of the sella **(Chap. 392)**. The serum testosterone level should be measured, and if it is low, gonadotropins should be measured to determine whether hypogonadism is primary (testicular) or secondary (hypothalamic-pituitary) in origin **(Chap. 403)**. If not performed recently, serum chemistries, hemoglobin A_{1c}, and lipid profiles may be of value, as they can yield evidence of diabetes, hyperlipidemia, or other systemic diseases associated with ED.

Additional diagnostic testing is rarely necessary in the evaluation of ED. However, in selected patients, specialized testing may provide insight into pathologic mechanisms of ED and aid in the selection of treatment options. Optional specialized testing includes (1) studies of nocturnal penile tumescence and rigidity, (2) vascular testing (in-office injection of vasoactive substances, penile Doppler ultrasound), (3) neurologic testing (biothesiometry-graded vibratory perception, somatosensory-evoked potentials), and (4) psychological diagnostic tests. The information potentially gained from these procedures must be balanced against their invasiveness, cost, and impact on ultimate treatment outcome.

Clinicians should counsel men with ED who have comorbidities known to negatively affect erectile function that lifestyle modifications, including changes in diet and increased physical activity, improve overall health and can improve ED.

TREATMENT

Male Sexual Dysfunction

PATIENT EDUCATION

Patient and partner education is essential in the treatment of ED. In goal-directed therapy, education facilitates understanding of the disease, the results of the tests, and the selection of treatment. Discussion of treatment options helps clarify how treatment is best offered and stratify first- and second-line therapies. Patients with high-risk lifestyle issues such as obesity, smoking, alcohol abuse, and recreational drug use should be counseled on the role those factors play in the development of ED.

Therapies currently employed for the treatment of ED include oral PDE-5 inhibitor (PDE-5i) therapy (most commonly used), injection therapies, testosterone therapy, penile devices, and

TABLE 409-2 PDE-5 Inhibitors[a]

DRUG	ONSET OF ACTION	$T_{1/2}$	DOSE	ADVERSE EFFECTS	CONTRAINDICATIONS
Sildenafil	T_{max} 30–120 min Duration 4 h High-fat meal decreases absorption Alcohol use may affect efficacy	2–5 h	25–100 mg Starting dose 50 mg	Headache, flushing, dyspepsia, nasal congestion, altered vision	Nitrates Hypotension Cardiovascular risk factors Retinitis pigmentosa Change dose with some antiretrovirals Should be on stable dose of alpha blockers
Vardenafil	T_{max} 30–120 min Duration 4–5 h High-fat meal decreases absorption ETOH may affect efficacy	4.5 h	5–10 mg	Headache, flushing, rhinitis, dyspepsia	Same as sildenafil May have minor prolongation of QT interval Concomitant use of class I antiarrhythmic
Tadalafil	T_{max} 30–60 min Duration 12–36 h Plasma concentration not affected by food or ETOH	17.5 h	10 or 20 mg; 2.5 or 5 mg for daily dose	Headache, dyspepsia, backpain, nasal congestion, myalgia	Same as sildenafil
Avanafil	T_{max} 30 min Duration 2 h Plasma concentration not affected by food	3–5 h	50, 100, and 200 mg dose	Headache, flushing, nasal congestion nasopharyngitis back pain	Same as sildenafil

[a]Sildenafil, vardenafil, tadalafil, and the newest option, avanafil, appear to be equally effective, but tadalafil has a longer duration of action and avanafil has a more rapid onset.

Abbreviations: ETOH, ethanol; PDE-5, phosphodiesterase type 5.

psychological therapy. In addition, limited data suggest that treatments for underlying risk factors and comorbidities—for example, weight loss, exercise, stress reduction, and smoking cessation—may improve erectile function.

ORAL AGENTS

Sildenafil, tadalafil, vardenafil, and avanafil are the only approved and effective oral agents for the treatment of ED. These four medications have markedly improved the management of ED because they are effective for the treatment of a broad range of etiologies. They belong to a class of medications that are selective and potent inhibitors of PDE-5, the predominant phosphodiesterase isoform found in the penis. They are administered in graduated doses and enhance erections after sexual stimulation (Fig. 409-2). The onset of action is ~30–120 min, depending on the medication used and other factors, such as recent food intake. Reduced initial doses should be considered for patients who are elderly, are taking concomitant alpha blockers, have renal insufficiency, or are taking medications that inhibit the CYP3A4 metabolic pathway in the liver (e.g., erythromycin, cimetidine, ketoconazole, clarithromycin, diltiazem, itraconazole, ritonavir, verapamil, grapefruit, and possibly itraconazole and mibefradil), as they may increase the serum concentration of the PDE-5i or promote hypotension. Initially, there were concerns about the cardiovascular safety of these drugs. It is known that these agents can act as mild vasodilators. Earlier concerns that the use of PDE-5is would increase cardiovascular events have been reversed as more studies support that a general population of men with ED who take PDE-5is have lower rates of major adverse cardiovascular events and lower overall mortality rates than men not exposed to PDE-5is, even after correcting for baseline cardiovascular risks and concomitant medicines. These studies suggest that PDE-5is may have a significant cardiovascular protective effect and may have potential as preventive cardiology agents.

Several randomized trials have demonstrated the efficacy of this class of medications. There are no compelling data to support the superiority of one PDE-5i over another. Subtle differences between agents have variable clinical relevance **(Table 409-2)**.

Patients may fail to respond to a PDE-5i for several reasons **(Table 409-3)**. Some patients may not tolerate PDE-5i secondary to adverse events from vasodilation in nonpenile tissues expressing PDE-5 or from the inhibition of homologous nonpenile isozymes (i.e., PDE-6 found in the retina). Abnormal vision attributed to the effects of PDE-5i on retinal PDE-6 is of short duration, reported only with sildenafil, and not clinically significant. A more serious concern is the possibility that PDE-5is may cause nonarteritic anterior ischemic optic neuropathy (NAION); although data to support that association are limited, it is prudent to avoid the use of these agents in men with a prior history of NAION.

Testosterone supplementation combined with a PDE-5i may be beneficial in improving erectile function in hypogonadal men with ED who are unresponsive to PDE-5i alone. Side effects associated with PDE-5is include headaches (19%), facial flushing (9%), dyspepsia (6%), and nasal congestion (4%). Approximately 7% of men using sildenafil may experience transient altered color vision (blue halo effect), and 6% of men taking tadalafil may experience loin pain. PDE-5i is contraindicated in men receiving nitrate therapy for cardiovascular disease, including agents delivered by the oral, sublingual, transnasal, and topical routes as they can potentiate its hypotensive effect. Likewise, amyl/butyl nitrate "poppers" may have a fatal synergistic effect on blood pressure. PDE-5is also should be avoided in patients with congestive heart failure and cardiomyopathy because of the risk of vascular collapse. Because sexual activity leads to an increase in physiologic expenditure (5–6 metabolic equivalent tasks [METs]), physicians have been advised to exercise caution in prescribing any drug for sexual activity to those with active coronary disease, heart failure, borderline hypotension, or hypovolemia and to those on complex antihypertensive regimens.

Although the various forms of PDE-5is have a common mechanism of action, there are a few differences among the four agents (Table 409-2). Tadalafil is unique in its longer half-life, and avanafil appears to have the fastest onset of action. Although there are pharmacokinetic and pharmacodynamic differences among these agents, clinically relevant differences are not clear.

TABLE 409-3 Issues to Consider if Patients Report Failure of Phosphodiesterase Type 5 Inhibitor (PDE-5i) to Improve Erectile Dysfunction

1. A trial of medication on at least 6 different days at the maximal dose should be performed before declaring patient nonresponsive to PDE-5i use.
2. Confirm that the patient did not partake in a high-fat meal prior to taking medication; pertains to sildenafil.
3. Failure to include physical and psychic stimulation at the time of foreplay to induce endogenous NO.
4. Took medications at an appropriate time frame *prior* to step 3: half-hour prior for avanafil, 1 h for sildenafil/vardenafil, or 2.5 h for tadalafil.
5. Unrecognized hypogonadism.

Abbreviation: NO, nitric oxide.

ANDROGEN THERAPY

Testosterone replacement is used to treat both primary and secondary causes of hypogonadism **(Chap. 403)**. Men with ED and testosterone deficiency (TD) who are considering ED treatment with a PDE-5i should be informed that PDE-5is may be more effective if combined with testosterone therapy. Androgen supplementation in the setting of normal testosterone is not efficacious in the treatment of ED and is discouraged secondary to additional risk for toxicity without benefit.

The increased scrutiny of testosterone caused the U.S. Food and Drug Administration (FDA) to issue a warning that there is a "weak signal" that testosterone replacement therapy increases the risk of thromboembolic events and may have addictive properties. Although testosterone therapy has known risks, such as water retention in heart failure patients and worsening sleep apnea, increasing evidence suggests that, when monitored appropriately, this therapy decreases the risk for metabolic syndrome, changes body composition by increasing lean muscle mass, and improves insulin sensitivity and average hemoglobin A_{1c}. This evidence, combined with the fact that hypogonadism is a known risk factor for metabolic syndrome and cardiovascular disease, has led to the conclusion that testosterone therapy for age-related hypogonadism in fact improves overall health and decreases the risk of cardiovascular events. It is important to note that men with secondary hypogonadism who desire fertility should not be treated directly with testosterone, but with an alternative such as the selective estrogen receptor modulator (SERM) clomiphene citrate, which increases gonadotropin levels, stimulating testicular testosterone production.

Testosterone circulates in the body in two forms: free and unbound or that bound to proteins such as albumin or sex hormone–binding globulin (SHBG). SHBG has a very high affinity for testosterone, and thus, testosterone bound to SHBG does not bind to the androgen receptor and is not bioavailable. Bioavailable testosterone is any testosterone that is not bound to SHBG. Unfortunately, reliable assays to directly measure bioavailable testosterone or free testosterone are expensive, difficult to perform, and thus not offered by most laboratories. However, direct measurement of SHBG is inexpensive and reliable, allowing free and bioavailable testosterone to be calculated.

Men who receive testosterone should be reevaluated after 3–6 months and at least annually thereafter for testosterone levels, erectile function, and adverse effects, which may include gynecomastia, sleep apnea, development or exacerbation of LUTS or BPH, prostate cancer, lowering of HDL, erythrocytosis, and elevations of liver function tests. Periodic reevaluation should include measurement of hemoglobin, liver function tests, prostate-specific antigen, and digital rectal examination. Therapy should be discontinued in patients who do not respond within 6 months without an alternate explanation (e.g., elevated estradiol).

VACUUM CONSTRICTION DEVICES

Vacuum constriction devices (VCDs) are a well-established noninvasive therapy. They are a reasonable treatment alternative for select patients who cannot take PDE-5is or do not desire other interventions. VCDs draw venous blood into the penis and use a constriction ring to restrict venous return and maintain tumescence. Adverse events with VCD include pain, numbness, bruising, and altered ejaculation. Additionally, many patients complain that the devices are cumbersome and that the induced erections have a nonphysiologic appearance and feel.

INTRAURETHRAL ALPROSTADIL

If a patient fails to respond to oral agents, a reasonable next choice is intraurethral or self-injection of vasoactive substances. Intraurethral prostaglandin E_1 (alprostadil), in the form of a semisolid pellet (doses of 125–1000 μg), is delivered with an applicator. Approximately 65% of men receiving intraurethral alprostadil respond with an erection when tested in the office, but <50% achieve successful coitus at home.

INTRACAVERNOSAL SELF-INJECTION

Injection of synthetic formulations of alprostadil is effective in 70–80% of patients with ED, but discontinuation rates are high because of the invasive nature of administration. Doses range between 1 and 40 μg. Injection therapy is contraindicated in men with a history of hypersensitivity to the drug and men at risk for priapism (hypercoagulable states, sickle cell disease). Side effects include local adverse events, prolonged erections, pain, and fibrosis with chronic use. Various combinations of alprostadil, phentolamine, and/or papaverine sometimes are used.

SURGERY

An important but less frequently used form of therapy for ED involves the surgical implantation of a semirigid or inflatable penile prosthesis. Because of the permanence of prosthetic devices, patients should first consider less invasive options for treatment. These surgical treatments are associated with a low rate of complications and are used for those who do not want the less spontaneous medical treatments, in PDE-5i–refractory ED, or in men who cannot tolerate such medications. Despite the requirement for surgery, penile prostheses are associated with very high rates of patient and partner satisfaction.

SEX THERAPY

A course of sex therapy may be useful for addressing specific interpersonal factors that may affect sexual functioning. These approaches may be useful in patients who have psychogenic or social components to their ED, although data from randomized trials are inconsistent. It is preferable to include both partners in therapy if the patient is involved in an ongoing relationship.

FEMALE SEXUAL DYSFUNCTION

Female sexual dysfunction (FSD) includes chronic sexual conditions in the domains of desire, arousal, pain, and muted orgasm. The associated risk factors for FSD are similar to those in males: cardiovascular disease, endocrine disorders, hypertension, neurologic disorders, and smoking **(Table 409-4)**. Women with hypertension report significantly lower sexual satisfaction (especially younger women).

EPIDEMIOLOGY

Epidemiologic data are limited, but the available estimates suggest that as many as 43% of women complain of at least one sexual problem. Despite their frequency and impact, FSDs are substantially undetected by clinicians and undertreated even when recognized. Despite the recent interest in organic causes of FSD, desire and arousal phase disorders (including lubrication complaints) remain the most common presenting problems when surveyed in a community-based population.

TABLE 409-4 Risk Factors for Female Sexual Dysfunction

Neurologic disease: stroke, spinal cord injury, parkinsonism
Trauma, genital surgery, radiation
Endocrinopathies: diabetes, hyperprolactinemia
Liver and/or renal failure
Cardiovascular disease, especially hypertension
Psychological factors and interpersonal relationship disorders: sexual abuse, life stressors
Medications
Antiandrogens: cimetidine, spironolactone
Antidepressants, alcohol, hypnotics, sedatives
Antiestrogens or GnRH antagonists
Antihistamines, sympathomimetic amines
Antihypertensives: diuretics, calcium channel blockers
Alkylating agents
Anticholinergics

Abbreviation: GnRH, gonadotropin-releasing hormone.

PHYSIOLOGY OF THE FEMALE SEXUAL RESPONSE

The normal female sexual response requires the presence of estrogens. A role for androgens is also likely but less well established. In the CNS, estrogens and androgens work synergistically to enhance sexual arousal and response. A number of studies report enhanced libido in women during preovulatory phases of the menstrual cycle, suggesting that hormones involved in the ovulatory surge (e.g., estrogens) increase desire.

Sexual motivation is heavily influenced by context, including the environment and partner factors. Once sufficient sexual desire is reached, sexual arousal is mediated by the central and autonomic nervous systems. Cerebral sympathetic outflow is thought to increase desire, and peripheral parasympathetic activity results in clitoral vasocongestion and vaginal secretion (lubrication).

The neurotransmitters for clitoral corporal engorgement are similar to those in the male penile tissues, with a prominent role for neural, smooth-muscle, and endothelial released nitric oxide (NO). A fine network of vaginal nerves and arterioles promotes a vaginal transudate. The major transmitters of this complex vaginal response are not certain, but roles for NO and vasoactive intestinal polypeptide (VIP) are supported. There are doubts concerning the construct of a linear relationship between initial desire, arousal, vasocongestion, lubrication, and orgasm. Caregivers should consider a paradigm of a positive emotional and physical outcome with one, many, or no orgasmic peak and release.

Although there are anatomic differences as well as variation in the density of vascular and neural beds in males and females, the primary effectors of sexual response are strikingly similar. Intact sensation is important for arousal. Thus, reduced levels of sexual functioning are more common in women with peripheral neuropathies (e.g., diabetes). Vaginal lubrication is a transudate of serum that results from the increased pelvic blood flow associated with arousal. Vascular insufficiency from a variety of causes may compromise adequate lubrication and result in dyspareunia. Cavernosal and arteriole smooth-muscle relaxation occurs via increased NO synthase (NOS) activity and produces engorgement in the clitoris and the surrounding vestibule. Orgasm requires an intact sympathetic outflow tract; hence, orgasmic disorders are common in female patients with spinal cord injuries.

APPROACH TO THE PATIENT

Female Sexual Dysfunction

Many women do not volunteer information about their sexual response. Open-ended questions in a supportive atmosphere are helpful in initiating a discussion of sexual integrity. Once a complaint has been voiced, a comprehensive evaluation should be performed, including a medical history, a psychosocial history, a physical examination, and limited laboratory testing.

The history should include the usual medical, surgical, obstetric, psychological, gynecologic, sexual, and social information. Past experiences, intimacy, knowledge, and partner availability should also be ascertained. Medical disorders that may affect sexual health should be delineated. They include diabetes, cardiovascular disease, gynecologic conditions, obstetric history, depression, anxiety disorders, and neurologic disease. Medications should be reviewed as they may affect arousal, libido, and orgasm. The need for counseling and recognizing life stresses should be identified. The physical examination should assess the genitalia, including the clitoris. Pelvic floor examination may identify prolapse or other disorders. Laboratory studies are needed, especially if menopausal status is uncertain. Estradiol, follicle-stimulating hormone (FSH), and luteinizing hormone (LH) are usually obtained, and dehydroepiandrosterone (DHEA) should be considered as it reflects adrenal androgen secretion. A complete blood count, liver function assessment, and lipid studies may be useful, if not otherwise obtained. Complicated diagnostic evaluation such as clitoral Doppler ultrasonography and biothesiometry require expensive equipment and are of uncertain utility. It is important for the patient to identify which symptoms are most distressing.

The evaluation of FSD previously occurred exclusively in a psychosocial context. However, inconsistencies between diagnostic categories based only on psychosocial considerations and the emerging recognition of organic etiologies have led to a new classification of FSD. This diagnostic scheme is based on four components that are not mutually exclusive: (1) *hypoactive sexual desire*—the persistent or recurrent lack of sexual thoughts and/or receptivity to sexual activity; hypoactive sexual desire may result from endocrine failure or may be associated with psychological or emotional disorders; (2) *sexual interest arousal disorder*—the persistent or recurrent inability to attain or maintain sexual excitement; (3) *orgasmic disorder*—the persistent or recurrent loss of orgasmic potential after sufficient sexual stimulation and arousal; and (4) *sexual pain disorder*—persistent or recurrent genital pain associated with noncoital sexual stimulation. This newer classification emphasizes "personal distress" as a requirement for dysfunction and provides clinicians with an organized framework for evaluation before or in conjunction with more traditional counseling methods.

TREATMENT

Female Sexual Dysfunction

GENERAL

An open discussion with the patient is important as couples may need to be educated about normal anatomy and physiologic responses, including the role of orgasm, in sexual encounters. Physiologic changes associated with aging and/or disease should be explained. Couples may need to be reminded that clitoral stimulation rather than coital intromission may be more beneficial.

Behavioral modification and nonpharmacologic therapies should be a first step. Patient and partner counseling may improve communication and relationship strains. Lifestyle changes involving known risk factors can be an important part of the treatment process. Emphasis on maximizing physical health and avoiding lifestyles (e.g., smoking, alcohol abuse) and medications likely to produce FSD is important (Table 409-3). The use of topical lubricants may address complaints of dyspareunia and dryness. Contributing medications such as antidepressants may need to be altered, including the use of medications with less impact on sexual function, dose reduction, medication switching, or drug holidays.

HORMONAL THERAPY

In postmenopausal women, estrogen replacement therapy may be helpful in treating vaginal atrophy, decreasing coital pain, and improving clitoral sensitivity **(Chap. 407)**. Menopause and its transition represent significant risk factors for the development of vulvovaginal atrophy–related sexual dysfunction. Available vaginal estrogen preparations include conjugated equine estrogens, estradiol vaginal cream, a sustained-release intravaginal estradiol ring, or a low-dose estradiol tablet. Vaginal estrogen preparations with the lowest systemic absorption rate may be preferred in women with history of breast cancer and severe vaginal atrophy. Vaginal lubricants and moisturizers applied on a regular basis have an efficacy comparable to that of local estrogen therapy and should be offered to women wishing to avoid the use of vaginal estrogens. If a hormonal supplement is chosen, then estrogen replacement in the form of local cream is the preferred method as it avoids systemic side effects. Androgen levels in women decline substantially before menopause. However, low levels of testosterone or DHEA are not effective predictors of a positive therapeutic outcome with androgen therapy. The widespread use of exogenous androgens is not supported by the literature except in select circumstances (premature ovarian failure or menopausal states) and in secondary arousal disorders.

Atrophic vaginitis is very common in postmenopausal women and is most commonly treated with estrogen-based treatments. However, many women are hesitant to use estrogen-based

treatments due to health concerns or are unable to use them due to a history of breast cancer or endometrial cancer. Hyaluronic acid vaginal gel has been found to be efficacious in treating atrophic vaginitis.

ORAL AGENTS

Flibanserin, originally developed as an antidepressant, is approved by the FDA as a treatment for low sexual desire in premenopausal women. Flibanserin, a postsynaptic agonist of serotonin receptor 1A and antagonist of serotonin receptor 2A, increases sexual desire and reduces resultant stress in women with hyposexual desire disorder (HSDD) with few adverse effects. Flibanserin has two principal pharmacologic actions in neural microcircuits: it acts as a full agonist at postsynaptic 5-HT_{1A} receptors and an antagonist at postsynaptic 5-HT_{2A} receptors. Exclusive binding at these receptors differentiates flibanserin from buspirone and bupropion. This action in the prefrontal cortex causes the downstream release of dopamine and norepinephrine and reduction of serotonin. Flibanserin acts selectively on pyramidal neurons that excite brainstem 5-HT neurons yet also selectively on pyramidal neurons that inhibit brainstem norepinephrine and dopamine neurons.

Flibanserin may boost sex drive in women who experience low sexual desire and who find the experience distressing. The drug should be discontinued if there is no improvement in sex drive after 8 weeks. Potentially serious side effects include low blood pressure and dizziness, particularly if it is mixed with alcohol. Other common adverse events include nausea, fatigue, sleepiness, and insomnia. Health care professionals and pharmacies dealing with flibanserin have to undergo a certification (risk evaluation and mitigation strategy [REMS]) process, and patients need to submit a written agreement to abstain from alcohol. The goal of the flibanserin REMS is to inform patients about the increased risk of hypotension and syncope due to an interaction with alcohol.

Bremelanotide, a melanocortin 4 receptor agonist, is also approved for HSDD. It demonstrates significant improvement in desire and a significant decrease in distress related to lack of desire. The most common adverse effects include nausea (40%), facial flushing (20%), and headache (10%). Bremelanotide's place in therapy is unclear, as the trials met statistical significance for change in sexual desire elements and distress related to sexual desire, yet the clinical benefit may only be modest. It is a subcutaneous injection given 45 min prior to sexual activity. Bremelanotide has no clinically significant interactions with ethanol. Prescribing guidelines recommend no more than one dose in 24 h and no more than eight doses per month. Individuals should discontinue use after 8 weeks without benefit.

There is no role for PDE-5is in FDS and should be discouraged.

CLITORAL VACUUM DEVICE

In patients with arousal and orgasmic difficulties, the option of using a clitoral vacuum device may be explored. This handheld battery-operated device has a small soft plastic cup that applies a vacuum over the stimulated clitoris. This causes increased cavernosal blood flow, engorgement, and vaginal lubrication.

410 Women's Health

Emily Nosova, Andrea Dunaif

The clinical discipline of women's health is well established. Indeed, its emphasis on greater attention to patient education and medical decision-making is a paradigm for what has become known as patient-centered health care. Moreover, the recognition of sex differences in gene expression, disease processes, and health outcomes is an important example of precision medicine. Sex difference refers to the biologic differences conferred by sex chromosomes and hormones. In contrast, gender differences are related to psychosocial roles and cultural expectations. The study of sex differences continues to grow as a scientific discipline. In 2016, the National Institutes of Health recognized its importance by implementing the expectation that sex should be considered as a biologic variable in study designs, analyses, and reporting in not only human but also vertebrate animal research. Strong scientific justification must be provided to limit research to only one sex.

DISEASE RISK: REALITY AND PERCEPTION

The leading causes of death are the same in women and men: (1) heart disease and (2) cancer **(Fig. 410-1)**. In 2020, COVID-19 emerged as the third leading cause of death, representing >10% of all deaths that year. Mortality rates due to COVID-19 were slightly lower in women (9.8%) than in men (10.9%). The leading cause of cancer death, lung cancer, is the same in both sexes. Breast cancer is the second leading cause of cancer death in women. Men are more likely than women to die from suicide and accidents. Maternal mortality continues to be higher in the United States than in other industrialized nations and is associated with substantial health disparities in maternal deaths. U.S. maternal mortality rates declined for the majority of the twentieth century given improvements in maternity care and safer surgical techniques; however, the rates began to rise again in 2000. Over the past decade, the mortality rate has remained relatively stable with the exception of a slight rise in 2021–2022, followed by a decline to typical rates again in 2023.

In June 2022, an historic Supreme Court decision overturned *Roe v. Wade* after nearly 50 years, declaring that women no longer had the constitutional right to abortion in the United States. In the year that followed this landmark ruling, more than a dozen states banned abortion, while several enacted abortion protection laws, and at least 70 clinics ceased offering abortion-related services. These changes were projected to affect nearly 30% of women of reproductive age in the United States. A 2022 study found that maternal mortality in states that restricted abortion was 62% higher compared to that of states with more widespread access (28.8 compared to 17.8 per 100,000 live births). Further longitudinal observation is needed to assess the impact of changes in abortion access on maternal and fetal mortality and outcomes.

Women's risk for many diseases increases at menopause. The median age of menopause in Caucasian women from industrialized countries is between 50 and 52 years, where women spend one-third of their lives in the postmenopausal period. Menopause occurs at earlier ages in Hispanic and African-American women as well as in women of lower socioeconomic status. Estrogen levels fall abruptly at menopause,

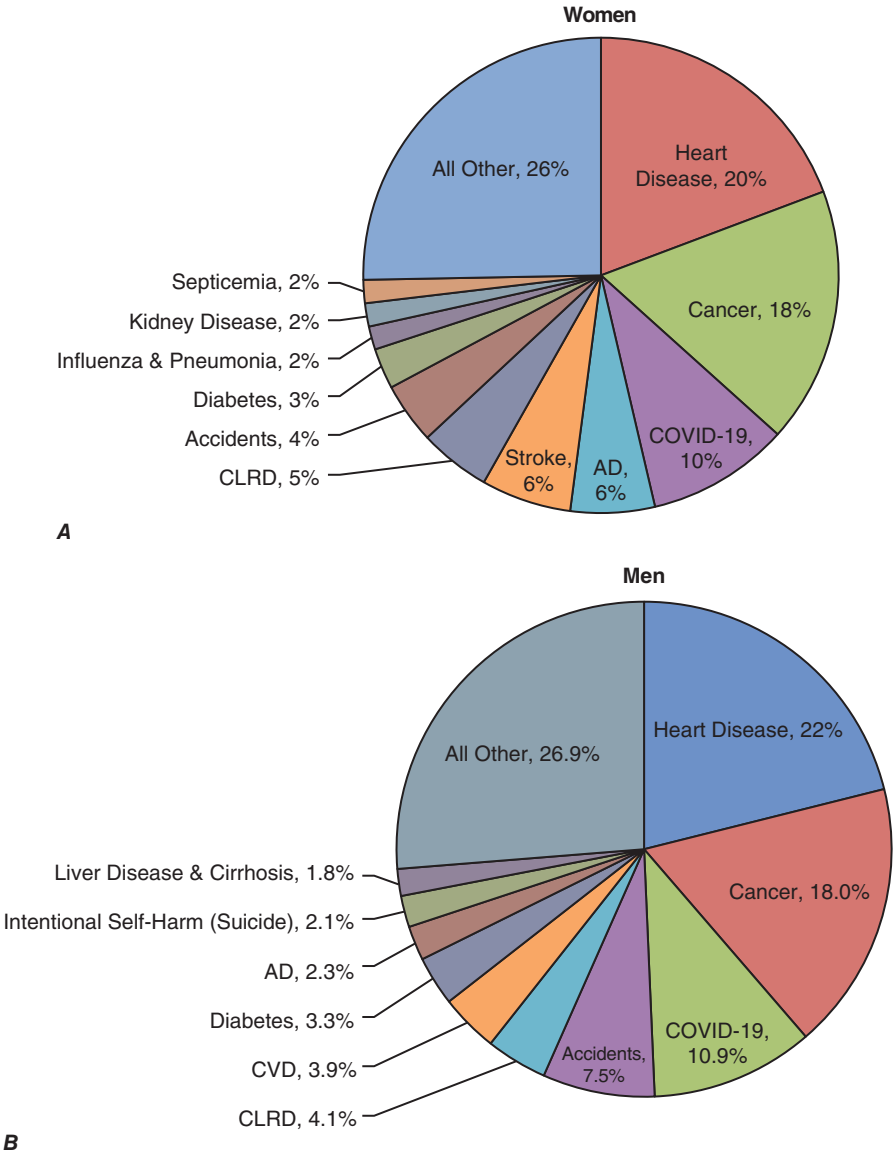

FIGURE 410-1 Percent distribution of 10 leading causes of death in (*A*) women compared to (*B*) men in the United States in 2020. In both women and men, the first, second, and third leading causes of death are the same: heart disease, cancer, and COVID-19, respectively. Causes of death then diverge by sex. Chronic lower respiratory disease (CLRD), stroke, and Alzheimer's disease (AD) cause a larger percentage of deaths in women than in men. Suicide is among the 10 leading causes of death in men but not in women. CVD, cardiovascular disease. *(Data from https://www.cdc.gov/nchs/data/nvsr/nvsr72/nvsr72-14.pdf.)*

inducing a variety of physiologic and metabolic responses. Rates of cardiovascular disease (CVD) increase, and bone density decreases rapidly after menopause.

In the United States, women live on average 5.9 years longer than men, with a life expectancy at birth in 2021 of 79.1 years in women compared with 73.2 years in men of all races. Notably, these estimates represent a decrease in life expectancy from prior years related to the COVID-19 pandemic. Life expectancy is lower in African Americans of both sexes and higher in Hispanics of both sexes than their Caucasian counterparts. Accordingly, elderly women outnumber elderly men, so that age-related conditions, such as hypertension, have a female preponderance.

SEX DIFFERENCES IN HEALTH AND DISEASE

■ ALZHEIMER'S DISEASE

(See also Chap. 442) Alzheimer's disease (AD) affects approximately twice as many women as men. Because the risk for AD increases with age, part of this sex difference is accounted for by the fact that women live longer than men. However, even in relatively younger groups (60–70 years of age), there is still a higher incidence of AD among women. Additional factors may contribute to the increased risk for AD in women, including sex differences in brain size, structure, and functional organization. Multimodal neuroimaging has demonstrated that certain biomarkers of the preclinical phase of AD, including a decline in neuronal mitochondrial function and impaired cerebral glucose metabolism, are evident earlier in women and are even distinguishable during the perimenopausal endocrine transition. There is emerging evidence for sex-specific differences in gene expression, not only for genes on the X and Y chromosomes but also for some autosomal genes. These genetic differences may translate into variable severity of AD, with women experiencing greater deficits in cognition. The ε4 allele of the apolipoprotein E gene (APOε4), a cholesterol carrier integral for lipid transport in the brain, is a major risk factor for AD. Recent studies show that the APOε4 genotype is strongly linked to development of sporadic AD in women. Women who carry either the APOε4 homo- or heterozygous isoform have an increased risk of progressing from healthy aging patterns to cognitive impairment or AD, whereas men who carry either isoform experience marginal impact on their memory or cognition.

Estrogens have pleiotropic genomic and nongenomic effects on the central nervous system, including neurotrophic actions in key areas involved in cognition and memory. Women with AD have lower

endogenous estrogen levels than do women without AD. These observations have led to the hypothesis that estrogen is neuroprotective. The Women's Health Initiative Memory Study (WHIMS), an ancillary study in the Women's Health Initiative (WHI) in women aged ≥65 years, found significantly increased risk for both dementia and mild cognitive impairment in women receiving estrogen alone or estrogen with progestin compared to placebo. However, the Kronos Early Estrogen Prevention Study (KEEPS), a randomized clinical trial of early hormone therapy (HT) initiation after menopause that compared conjugated equine estrogen (CEE), transdermal estradiol (both estrogen arms included cyclic oral micronized progesterone), and placebo, found no adverse effect of HT on cognitive function. In summary, there is no evidence from placebo-controlled trials that HT improves cognitive function.

While studies have shown a link between female sex and AD, other neurodegenerative disorders, including Parkinson's disease (PD) and amyotrophic lateral sclerosis (ALS), exhibit a stronger association with male sex. Men are 1.5 times more likely to develop PD than women across all age groups. A possible explanation for the male predilection may be the effect of Y-chromosome exclusive gene sex-determining region Y (SRY) on nigrostriatal dopaminergic (NSDA) neurons: the SRY upregulates neuronal numbers, synthesis of dopamine, and metabolism of neurons.

CVD AND STROKE

(See also Chap. 284) There are major sex differences in CVD, the leading cause of death in developed countries. However, there are also major gender differences because of perceptions by both women and their health care providers that women are at lower risk for CVD. As a result of these misconceptions, women are less likely to seek medical help when they experience symptoms of CVD. Health care providers are less likely to suspect CVD, so women receive fewer interventions for modifiable risk factors as well as fewer acute interventions than do men. Women and their health care providers are also less aware that prodromal symptoms of cardiac disease differ in women compared to men. Women are less likely than men to present with chest pain and more likely to present with fatigue, shortness of breath, indigestion/nausea, and anxiety.

Sex steroids have major effects on the cardiovascular system and lipid metabolism. Estrogen increases high-density lipoprotein (HDL) and lowers low-density lipoprotein (LDL), whereas androgens have the opposite effect. Estrogen has direct vasodilatory effects on the vascular endothelium, enhances insulin sensitivity, and has antioxidant and anti-inflammatory properties. There is a striking increase in CVD after both natural and surgical menopause, suggesting that endogenous estrogens are cardioprotective. Women also have longer QT intervals on electrocardiograms, and this increases their susceptibility to certain arrhythmias.

CVD presents differently in women, who are usually 10–15 years older than their male counterparts and are more likely to have comorbidities such as hypertension, congestive heart failure, and diabetes mellitus (DM). In the Framingham study, angina was the most common initial symptom of CVD in women, whereas myocardial infarction (MI) was the most common initial presentation in men. Women more often have atypical symptoms such as fatigue, anxiety, nausea, indigestion, and upper back pain. Although awareness that heart disease is the leading cause of death in women has nearly doubled over the past 15 years, women remain less aware that its symptoms are often atypical and are less likely to contact 9-1-1 when they experience such symptoms.

A type of acute coronary syndrome (ACS) termed takotsubo syndrome, initially described in 1990 and characterized as a transient and reversible stress cardiomyopathy, disproportionately affects women. National cohort studies demonstrate that ~2% of all patients presenting to acute care centers with symptoms of ACS are diagnosed with takotsubo, and importantly, 80–90% are postmenopausal women. If stratified by sex, ~10% of patients with suspected ACS are ultimately diagnosed with takotsubo syndrome. Recurrence of this condition is also more common among women. Interestingly, morbidity and mortality rates are higher in men, with cardiogenic shock, cardiac arrest, and mortality occurring more frequently than in women. The pathophysiology that leads to takotsubo is complex: potential inciting mechanisms involve microvascular dysfunction and impaired vascular reactivity, followed by reversible abnormalities in the coronary flow reserve and microvascular resistance. One potential explanation for the striking sex difference is that postmenopausal women have age- and estrogen deficiency–related coronary vasomotor dysfunction. Estrogen improves coronary blood flow through endothelium-dependent and -independent mechanisms; however, its deficiency results in increased sympathetic drive and endothelial dysfunction. An animal study suggested that estrogen supplementation may partially attenuate an excessive cardiovascular response to stress; however, this has not been studied clinically. Furthermore, hypotheses related to estrogen do not explain why takotsubo occurs in men and also appears to be associated with higher mortality rates in men. The specific mechanisms underlying these sex differences in disease prevalence and outcomes remain unknown and require further study.

Deaths from CVD have decreased markedly in men since 1980, whereas CVD deaths only started to decrease substantially in women beginning in 2000. After 2010, death rates from CVD among both sexes stabilized and even began to increase slightly in men. Women with MI are more likely to present with cardiac arrest or cardiogenic shock, whereas men are more likely to present with ventricular tachycardia. Further, younger women with MI are more likely to die than are men of similar age. However, this mortality gap has decreased in recent years because younger women have experienced greater improvements in survival after MI than men. The improvement in survival is due largely to a reduction in comorbidities, suggesting a greater attention to modifiable risk factors in women.

Sex differences account for more variable short-term outcomes observed among women with CVD who receive therapeutic intervention, as compared to men. Women undergoing coronary artery bypass graft surgery have more advanced disease, a higher perioperative mortality rate, less relief of angina, and less graft patency; however, 5- and 10-year survival rates are similar. Women undergoing percutaneous transluminal coronary angioplasty have lower rates of initial angiographic and clinical success than men, but they also have a lower rate of re-stenosis and a better long-term outcome. Women may benefit less and have more frequent serious bleeding complications from thrombolytic therapy compared with men. Factors such as older age, more comorbid conditions, smaller body size, and more severe CVD in women at the time of events or procedures account in part for the observed sex differences.

Important risk factors for CVD in both men and women include elevated cholesterol levels, hypertension, smoking, obesity, low HDL cholesterol levels, DM, and lack of physical activity **(Fig. 410-2)**. Total triglyceride levels are an independent risk factor for CVD in women but not in men. Low HDL cholesterol and DM are more important risk factors for CVD in women than in men. Several disorders conferring increased CVD risk affect women exclusively, such as pregnancy-associated hypertension, preeclampsia, gestational DM, and polycystic ovary syndrome, or predominantly, such as rheumatoid arthritis (RA) and systemic lupus erythematosus (SLE). Cholesterol-lowering drugs are equally effective in men and women for primary and secondary prevention of CVD. In contrast to men, randomized trials showed that aspirin was not effective in the primary prevention of CVD in women; it did significantly reduce the risk of ischemic stroke.

Psychosocial stressors and loneliness may also be important risk factors for the development of CVD in women. A recent cohort study of nearly 60,000 women older than 65 years showed that loneliness and social isolation were associated with a 5% and 8% higher risk of CVD, respectively, even after adjusting for health behaviors and outcomes. Women with greater loneliness and social isolation had a 13–27% higher risk of incident CVD compared with women with relatively less social isolation and less loneliness.

Sex-specific factors related to reproductive and pregnancy history are now recognized as important risk-enhancing factors for CVD in women. Recent studies demonstrate that the greatest risk for CVD

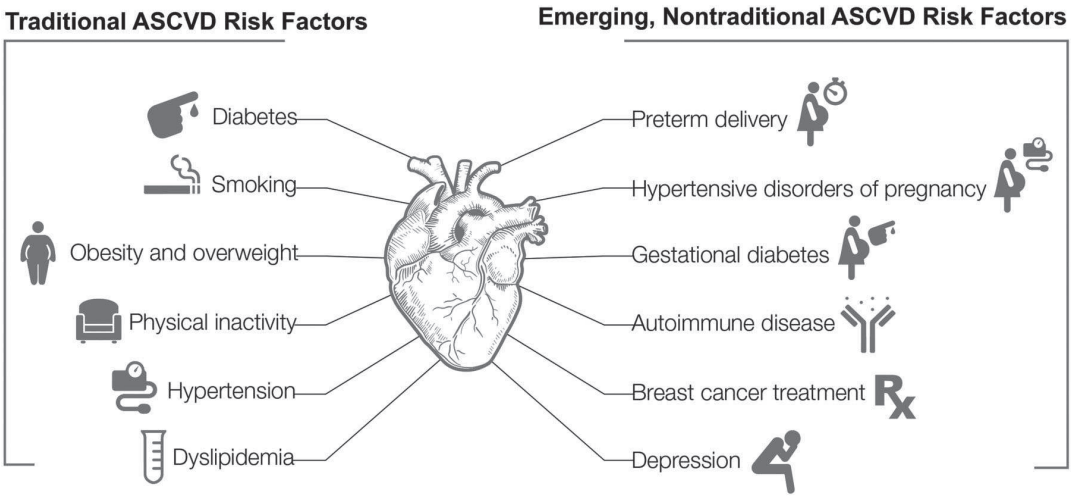

FIGURE 410-2 Traditional and nontraditional risk factors for atherosclerotic cardiovascular disease (ASCVD) in women. *(Reproduced with permission from M Garcia et al: Cardiovascular disease in women: Clinical perspectives. Circ Res 118:1273, 2016.)*

(at least twofold) was conferred by adverse pregnancy outcomes (APO), including a history of stillbirth, preterm birth, or preeclampsia, followed by a 1.5- to 1.9-fold risk with gestational diabetes and hypertension, premature ovarian insufficiency, and placental abruption; the lowest risk (<1.5 fold) was associated with early menarche, early menopause, parity, and polycystic ovary syndrome. Given these strong associations, targeted counseling and increased surveillance of CVD risk factors is warranted for women in high-risk groups. Accordingly, the 2019 American Heart Association (AHA) guidelines included a recommendation to assess for pregnancy complications as a part of routine cardiovascular risk assessment for primary prevention.

The sex differences in CVD prevalence, beneficial biologic effects of estrogen on the cardiovascular system, and reduced risk for CVD in observational studies led to the hypothesis that HT was cardioprotective. However, the WHI, which studied >16,000 women on CEE plus medroxyprogesterone acetate (MPA) or placebo and >10,000 women with hysterectomy on CEE alone or placebo, did not demonstrate a benefit of HT for the primary or secondary prevention of CVD. In addition, CEE plus MPA was associated with an increased risk for CVD, particularly in the first year of therapy, whereas CEE alone neither increased nor decreased CVD risk. Both HT groups were associated with an increased risk for ischemic stroke. In a subgroup analysis of the WHI estrogen-alone trial, a relatively younger age (50–59 years) combined with a history of bilateral salpingo-oophorectomy (BSO) was associated with a >30% CEE treatment–associated reduction in all-cause mortality, whereas CEE-treated older women with prior BSO did not see a significant reduction in any other outcomes, including incidence of coronary artery disease, invasive breast cancer, all-cause mortality, and a composite index of the aforementioned outcomes plus stroke, hip fracture, pulmonary embolism, and colorectal cancer.

These results suggest that postmenopausal women younger than 60 with prior BSO may have mortality benefit from HT, while women older than 60 with BSO may suffer consequences associated with HT. More recent data from KEEPS indicate that even if estrogen therapy is initiated shortly after the menopausal transition, it does not reduce atherosclerotic progression or impact CVD outcomes. Additionally, HT and placebo groups have similar outcomes with respect to venous thromboembolism and breast cancer. Although HT does not slow CVD development as previously thought, findings from KEEPS suggest that treated women experience significant improvements in vasomotor symptoms, mood, sexual function, and bone density, especially when therapy is started sooner after menopause onset. HT is discussed further in **Chap. 407**.

DIABETES MELLITUS

(See also Chap. 415) Women are more sensitive to insulin than men. Despite this, the prevalence of type 2 DM is similar in men and women. There is a sex difference in the relationship between endogenous androgen levels and DM risk. Higher bioavailable testosterone levels are associated with increased risk in women, whereas lower bioavailable testosterone levels are associated with increased risk in men. This observation has been confirmed in a recent Mendelian randomization that found that genetically determined higher testosterone increases risk for DM in women but reduces risk in men. Polycystic ovary syndrome, preeclampsia, pregnancy-associated hypertension, and gestational DM—common conditions in premenopausal women—are associated with a significantly increased risk for type 2 DM. Among individuals with DM, women have a greater risk for MI than do men. Women with DM have a sixfold greater risk of dying of CVD compared to women without DM. Premenopausal women with DM lose the cardioprotective effect of female sex and have rates of CVD identical to those in males. These women have impaired endothelial function and reduced coronary vasodilatory responses, which may predispose to cardiovascular complications. Women with DM are more likely to have left ventricular hypertrophy. Women with DM receive less aggressive treatment for modifiable CVD risk factors than men with DM.

HYPERTENSION

(See also Chap. 288) After age 60, hypertension is more common in U.S. women than in men, largely because of the high prevalence of hypertension in older age groups and the longer survival of women. Isolated systolic hypertension is present in 30% of women >60 years old. Sex hormones affect blood pressure. Both normotensive and hypertensive women have higher blood pressure levels during the follicular phase than during the luteal phase. In the Nurses' Health Study, the relative risk of hypertension was 1.8 in current users of oral contraceptives, but this risk is lower with the newer low-dose contraceptive preparations. Long-term data from this cohort also demonstrate that having gestational hypertension or preeclampsia during a first pregnancy doubled the rate of developing chronic hypertension. HT is not associated with hypertension. Among secondary causes of hypertension, there is a female preponderance of renal artery fibromuscular dysplasia.

The benefits of treatment for hypertension have been dramatic in both women and men. A meta-analysis of the effects of hypertension treatment, the Individual Data Analysis of Antihypertensive Intervention Trial, found a reduction of risk for stroke and major cardiovascular events in women. The effectiveness of various antihypertensive drugs appears to be comparable in women and men; however, women may experience more side effects, such as cough with angiotensin-converting enzyme inhibitors.

AUTOIMMUNE DISORDERS

(See also Chap. 367) Most autoimmune disorders occur more commonly in women than in men; they include autoimmune thyroid and liver diseases, Hashimoto's hypothyroidism, Graves' disease (GD), SLE,

RA, scleroderma, multiple sclerosis (MS), and idiopathic thrombocytopenic purpura. However, there is no sex difference in the incidence of type 1 DM, and ankylosing spondylitis occurs more commonly in men. Sex differences in both immune responses and adverse reactions to vaccines have been reported. For example, there is a female preponderance of postvaccination arthritis.

Adaptive immune responses are more robust in women than in men; this may be explained by the stimulatory actions of estrogens and the inhibitory actions of androgens on the cellular mediators of immunity. Consistent with an important role for sex hormones, there is variation in immune responses during the menstrual cycle, and the activity of certain autoimmune disorders is altered by castration or pregnancy (e.g., RA and MS may remit during pregnancy). Nevertheless, the majority of studies show that exogenous estrogens and progestins in the form of HT or oral contraceptives do not alter autoimmune disease incidence or activity. Exposure to fetal antigens, including circulating fetal cells that persist in certain tissues, has been speculated to increase the risk of autoimmune responses. There is clearly an important genetic component to autoimmunity, as indicated by the familial clustering and HLA association of many such disorders. X chromosome genes also contribute to sex differences in immunity. Indeed, nonrandom X chromosome inactivation may be a risk factor for autoimmune diseases.

HIV INFECTION

(See also Chap. 208) Women (sex assigned at birth) accounted for 18% (6600) of the ~36,100 new HIV diagnoses in the United States in 2021. This represents a similar incidence observed in recent years. Black/African-American women accounted for 54% of new diagnoses among people assigned as female at birth, as compared to white women, who accounted for 23%, and Hispanic/Latino women, who represented about 18% of the newly diagnosed. AIDS remains an important cause of death in younger women, particularly African-American women aged 25–44 years. Heterosexual contact with an at-risk partner is the fastest-growing transmission category, and women are more susceptible to HIV infection during vaginal sex than men. This increased susceptibility is accounted for in part by an increased prevalence of sexually transmitted diseases, i.e., gonorrhea and syphilis, in women.

Some studies have suggested that hormonal contraceptives may increase the risk of HIV transmission. Progesterone has been shown to increase susceptibility to infection in nonhuman primate models of HIV. Women are also more likely to be infected by multiple variants of the virus than men. Women with HIV have more rapid decreases in their CD4 cell counts than do men. Compared with men, HIV-infected women more frequently develop candidiasis, but Kaposi's sarcoma is less common than it is in men. Women have more adverse reactions, such as lipodystrophy, dyslipidemia, and rash, with antiretroviral therapy than do men. This observation is explained in part by sex differences in the pharmacokinetics of certain antiretroviral drugs, resulting in higher plasma concentrations in women.

OBESITY

(See also Chap. 414) The prevalence of both obesity (body mass index ≥30 kg/m^2) and abdominal obesity (waist circumference ≥88 cm in women) are similar in U.S. women and men. According to the most recent National Health and Nutrition Examination Survey data spanning 2017 until prepandemic March 2020, the age-adjusted prevalence of obesity among U.S. adults was 41.8%, and there were no significant differences observed between women and men, even across different age groups. However, some sex-specific differences were observed: the prevalence of obesity was highest among non-Hispanic black women (57.9%) as compared with non-Hispanic white (39.6%), Hispanic (45.7%), and non-Hispanic Asian women (14.5%). Non-Hispanic black women had a higher prevalence of obesity compared to non-Hispanic black men. There were no significant differences in prevalence between men and women among non-Hispanic white, non-Hispanic Asian, or Hispanic adults. More than 80% of patients who undergo bariatric surgery are women. Pregnancy and menopause are risk factors for obesity.

There are major sex differences in body fat distribution. Women characteristically have a gluteal and femoral or gynoid pattern of fat distribution, whereas men typically have a central or android pattern. Women have more subcutaneous fat than men. In women, endogenous androgen levels are positively associated with abdominal obesity, and androgen administration increases visceral fat. In contrast, there is an inverse relationship between endogenous androgen levels and abdominal obesity in men. Further, androgen administration decreases visceral fat in these obese men. The reasons for these sex differences in the relationship between visceral fat and androgens are unknown; however, emerging evidence suggests that there is a contribution of genetic variation. Studies in humans also suggest that sex steroids play a role in modulating food intake and energy expenditure.

In men and women, abdominal obesity characterized by increased visceral fat is associated with an increased risk for CVD and DM. Obesity increases a woman's risk for certain cancers, in particular postmenopausal breast and endometrial cancer, in part because adipose tissue provides an extragonadal source of estrogen through aromatization of circulating adrenal and ovarian androgens, especially the conversion of androstenedione to estrone. Obesity increases the risk of infertility, miscarriage, and complications of pregnancy.

In addition to sex-specific epidemiologic differences in obesity, notable patterns have emerged with the advent and rising popularity of the novel obesity pharmacotherapies, namely the glucagon-like 1 peptide (GLP1) receptor agonists and the combined GLP1/gastric inhibitory polypeptide (GIP) receptor agonists **(Chap. 414)**. In the recent Semaglutide Treatment Effect in People with Obesity (STEP 1–4) studies from 2021, in which weekly semaglutide was compared to placebo for weight management, women comprised 55–80% of the study populations. Subgroup analyses evaluating the efficacy of semaglutide by sex have demonstrated a greater average weight reduction in women participants compared to men. Possible explanations for these findings include a lower average baseline body weight in women, potential differences in eating behavior that may be regulated by differences in sex hormones, and differential rates of gastric emptying. Sex-related differences in gastrointestinal side effects may also play a role. A possible connection may exist at the neurologic level: a recent study in mice demonstrated sex-specific dynamics in GLP1 receptor and GIP receptor expression patterns in metabolically responsive areas of the hypothalamus and the amygdala induced by exposure to a high-fat diet. It remains unclear whether mechanistic differences may explain the differential outcomes in women compared to men who use these medications.

OSTEOPOROSIS

(See also Chap. 423) Osteoporosis is about five times more common in postmenopausal women than in age-matched men, and osteoporotic hip fractures are a major cause of morbidity in elderly women. Men accumulate more bone mass and lose bone more slowly than do women. Sex differences in bone mass are found as early as infancy. Calcium intake, vitamin D, and estrogen all play important roles in bone formation and bone loss. Particularly during adolescence, calcium intake is an important determinant of peak bone mass. Vitamin D deficiency is surprisingly common in elderly women, occurring in >40% of women living in northern latitudes. Receptors for estrogens and androgens have been identified in bone. Estrogen deficiency is associated with increased osteoclast activity and a decreased number of bone-forming units, leading to net bone loss. The aromatase enzyme, which converts androgens to estrogens, is also present in bone. Estrogen is an important determinant of bone mass in men (derived from the aromatization of androgens) as well as in women.

PHARMACOLOGY

On average, women have lower body weights, smaller organs, a higher percentage of body fat, and lower total-body water than men. There are also important sex differences in drug action and metabolism that are not accounted for by these differences in body size and composition. Sex steroids alter the binding and metabolism of a number of drugs. Further, menstrual cycle phase and pregnancy can alter drug action.

Women also take more medications than men, including over-the-counter formulations and supplements. The greater use of medications combined with these biologic differences may account for the reported higher frequency of adverse drug reactions in women than in men.

Two-thirds of cases of drug-induced torsades des pointes, a rare, life-threatening ventricular arrhythmia, occur in women because they have a longer, more vulnerable QT interval. These drugs, which include certain antihistamines, antibiotics, antiarrhythmics, and antipsychotics, can prolong cardiac repolarization by blocking cardiac voltage-gated potassium channels.

PSYCHOLOGICAL DISORDERS

(See also Chap. 463) Depression, anxiety, and affective and eating disorders (bulimia and anorexia nervosa) are more common in women than in men. Epidemiologic studies from both developed and developing nations consistently find major depression to be twice as common in women as in men, with the sex difference becoming evident in early adolescence. Depression occurs in 10% of women during pregnancy and in 10–15% of women during the postpartum period. There is a high likelihood of recurrence of postpartum depression with subsequent pregnancies. The incidence of major depression diminishes after the age of 45 years and does not increase with the onset of menopause. Depression in women appears to have a worse prognosis than does depression in men; episodes last longer, and there is a lower rate of spontaneous remission. Schizophrenia and bipolar disorders occur at equal rates in men and women, although there may be sex differences in symptoms.

Both biologic and social factors account for the greater prevalence of depressive disorders in women. Men have higher levels of the neurotransmitter serotonin. Sex steroids also affect mood, and fluctuations during the menstrual cycle have been linked to symptoms of premenstrual syndrome. Sex hormones differentially affect the hypothalamic-pituitary-adrenal responses to stress. Testosterone appears to blunt cortisol responses to corticotropin-releasing hormone. Both low and high levels of estrogen can activate the hypothalamic-pituitary-adrenal axis.

COVID-19 INFECTION

(See also Chap. 205) Soon after the discovery of COVID-19, which was identified in November 2019 in Wuhan, China, as being caused by the novel coronavirus SARS-CoV-2, it was evident that there were appreciable sex differences in severity and outcomes. Indeed, observational data from the early pandemic, spanning late 2019 to early 2020, demonstrated a higher overall incidence of infectious cases, hospitalizations, intensive care unit admissions, and case-fatality rates among men as compared to women. More pronounced sex differences were observed with advanced age, with a higher overall incidence in older male age groups. These sex differences have persisted among different racial, ethnic, and socioeconomic groups and across all continents, as SARS-CoV-2 became a global pandemic.

There are several potential mechanisms for these sex-specific effects of SARS-CoV-2 infection (Fig. 410-3). The virus's entry point into cells is the membrane-bound angiotensin-converting enzyme 2 (ACE2) receptor, and it also harnesses the primer TMPRSS2, a cellular serine protease. Circulating levels of ACE2, which is expressed in a variety of tissues including the lung, heart, and kidneys, have been reported to be relatively higher in men who have diabetes and/or kidney disease, as well as in healthy men; however, not all studies have reported similar sex differences. One hypothesis is that upregulation of the ACE2 receptor in men may provide greater opportunity for cellular entry, viral replication, and development of symptoms and deleterious sequelae.

ACE2 plays a critical role in bronchial transient secretory cells/type II alveolar cells as well as the renin-angiotensin-aldosterone system (RAAS). In the RAAS, ACE2 opposes angiotensin II's vasoconstrictive actions by converting angiotensin II to the vasodilatory angiotensin 1-7 in critical tissues, including cardiac myocytes, cardiac fibroblasts, and coronary endothelial cells. Importantly, recent evidence has shown the impact of sex and sex hormones on the RAAS and ACE2: estrogen downregulates angiotensin II receptor type 1 and regulates renin activity, as well as modulates local RAAS in the atrial myocardium. Furthermore, it has been shown that ovariectomized females have increased ACE2 activity and expression in their kidney and adipose tissue and that estradiol replacement reduces ACE2 expression. On the contrary, orchiectomized males have decreased ACE2 activity. Estrogen appears to reduce ACE2 expression in the heart and kidney in both rodent and human studies.

TMPRSS2, a vital contributor to SARS-CoV-2 cellular invasion, is a protein that is most abundantly expressed in prostate epithelial tissue, including high-grade prostate cancers and metastases. Accordingly, the protein's involvement in viral priming is thought to be an important reason for the higher case-fatality rate observed in men; however, the association has not yet been proven. TMPRSS2 is also expressed in airway epithelia, where its physiologic function is not entirely clear. Transcription of the cellular protein is regulated by androgenic ligands and androgen receptor binding element; it is unknown whether estrogen plays a role in its regulation. Emerging in vitro studies have demonstrated that a TMPRSS2 inhibitor blocks viral entry into cells. These data may serve as an important foundation for sex-specific and personalized therapeutic approaches in the future.

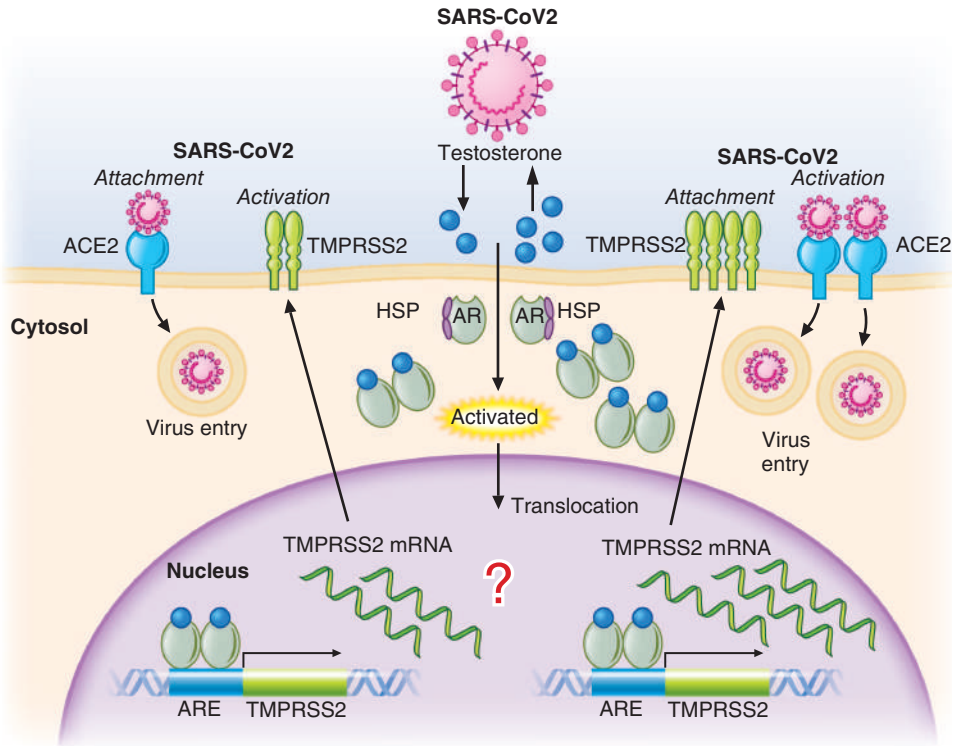

FIGURE 410-3 Proposed sex hormone differences in TMPRSS2-mediated SARS-CoV-2 host cell entry. The virus entry point into cells is the membrane-bound angiotensin-converting enzyme 2 (ACE2) receptor. The cell-membrane protease, TMPRSS2, is also vital for host cell entry. Circulating levels of ACE2, expressed abundantly in the lung, heart, and kidney tissues, have been reported to be relatively higher in men. Upregulation of the ACE2 receptor in men may provide greater opportunity for cellular entry, viral replication, symptom development, and multiorgan involvement. *(Adapted from C Gebhard et al: Impact of sex and gender on COVID-19 outcomes in Europe. Biol Sex Differ 11:29, 2020.)*

SUBSTANCE ABUSE AND TOBACCO

(See also Chaps. 464 and 465) Substance abuse is more common in men than in women. However, nearly one-third of Americans who suffer from alcoholism are women. Women are less likely to be diagnosed with alcoholism than men. A greater proportion of men than women seek help for alcohol and drug abuse. Men are more likely to go to an alcohol or drug treatment facility, whereas women tend to approach a primary care physician or mental health professional for help under the guise of a psychosocial problem. Blood alcohol levels are higher in women than in men after drinking equivalent amounts of alcohol, adjusted for body weight. This greater bioavailability of alcohol in women is due to both the smaller volume of distribution and the slower gastric metabolism of alcohol secondary to lower activity of gastric alcohol dehydrogenase than is the case in men. Women with alcoholism have a higher mortality rate than do women and men without alcoholism. Women also appear to develop alcoholic liver disease and other alcohol-related diseases with shorter drinking histories and lower levels of alcohol consumption. Alcohol abuse also poses special risks to a woman, adversely affecting fertility and the health of the baby (fetal alcohol syndrome). Even moderate alcohol use increases the risk of breast cancer, hypertension, and stroke in women.

More men than women smoke tobacco, but this sex difference continues to decrease. Women have a much larger burden of smoking-related disease. Smoking markedly increases the risk of CVD in premenopausal women and is also associated with a decrease in the age of menopause. Women who smoke are more likely to develop chronic obstructive pulmonary disease and lung cancer than men and at lower levels of tobacco exposure. Postmenopausal women who smoke have lower bone density than women who never smoked. Smoking during pregnancy increases the risk of preterm deliveries and low birth weight infants.

VIOLENCE AGAINST WOMEN

Approximately 15% of women in the United States have experienced rape, physical violence, and/or stalking by an intimate partner, as compared to 4% of men with similar experiences. Adult women are much more likely to be raped by a spouse, ex-spouse, or acquaintance than by a stranger. Intimate partner violence (IPV) is a leading cause of death among young women. Rates of reported IPV in the United States increased dramatically amid stay-at-home orders during the COVID-19 pandemic but have since declined again to prepandemic rates. IPV is an important risk factor for depression, substance abuse, and suicide in women. Screening instruments can identify women experiencing IPV and should be administered in settings that ensure adequate privacy and safety.

SUMMARY

Women's health is now a mature discipline, and the importance of sex differences in biologic processes is well recognized. Nevertheless, ongoing misperceptions about disease risk, not only among women but also among their health care providers, result in insufficient attention to modifiable risk factors. Research into the fundamental mechanisms of sex differences will provide important biologic insights. Further, those insights will have an impact on both women's and men's health.

411 Men's Health

Shalender Bhasin

The emergence of men's health as a distinct discipline within internal medicine is founded on the wide consensus that men and women differ across their life span in their susceptibility to disease, in the clinical manifestations of the disease, and in their response to treatment. Furthermore, men and women weigh the health consequences of illness differently and have different motivation for seeking care. Men and women experience different types of disparities in access to health care services and in the manner in which health care is delivered to them because of a complex array of socioeconomic and cultural factors. Attitudinal and institutional barriers to accessing care, fear and embarrassment due to the perception that it is not manly to seek medical help, and reticence on the part of patients and physicians in discussing issues related to sexuality, substance use, and aging have heightened the need for programs tailored to address the specific health needs of men.

The sex differences in disease prevalence, susceptibility, and clinical manifestations of the disease were discussed in Chap. 410 (Women's Health) and will not be discussed here. It is notable that the two leading causes of death in both men and women—heart disease and cancer—are the same. However, men have higher prevalence of neurodevelopmental and degenerative disorders; substance use disorders, including the use of performance-enhancing drugs and alcohol use disorder; diabetes; cardiovascular disease; liver cirrhosis; and some types of cancer such as prostate, melanoma, and pancreatic cancer; and women have a higher prevalence of autoimmune disorders, depression, rheumatologic disorders, and osteoporosis. Men are substantially more likely to die from accidents, suicides, and homicides than women. Among men 15–34 years of age, unintentional injuries, homicides, and suicides account for over three-fourths of all deaths. Among men 35–64 years of age, heart disease, cancer, and unintentional injuries are the leading causes of death. Among men ≥65 years of age, heart disease, cancer, lower respiratory tract infections, and stroke are the major causes of death.

From 1999 to 2010, the mortality rates in the United States decreased for men and women of all age groups, largely due to reduced death rates from heart attacks, cancer, motor vehicle injuries, and HIV infection. However, since 2010, troubling disparities in sex-specific mortality rates have emerged among middle-aged men in the United States. From 2010 to 2017, the death rates have risen and life expectancy has decreased for young and middle-aged men. The increase in mortality rates among people aged 25–64 was the highest in the Ohio Valley and Appalachia, and in the New England states of New Hampshire, Maine, and Vermont. The rising mortality rates in young and middle-aged men have been attributed to an increase in deaths due to drug overdose, alcohol-related liver disease, and suicide. The rising rates of "deaths of despair" among young and middle-aged men, especially white non-Hispanics, have been associated with deterioration in economic and social well-being, reduced rates of marriage and labor force participation, and poor physical and mental health.

The biologic bases of sex differences in disease susceptibility, progression, and manifestation remain incompletely understood and are likely multifactorial. Undoubtedly, sex-specific differences in the genetic architecture and circulating sex hormones influence disease phenotype; additionally, epigenetic effects of sex hormones during fetal life, infancy, and pubertal development may epigenetically imprint sexual and nonsexual behaviors, body composition, and disease susceptibility. The circulating and tissue concentrations of sex hormones differ substantially in men and women, and these hormonal differences may affect gene expression in cells of males and females in all parts of the body. The presence of only one X chromosome in men renders them more susceptible to X-linked disorders than women. Due to the X inactivation of one randomly chosen X chromosome, women's bodies contain two epigenetically different cell populations. The genes that

do not undergo X inactivation exhibit dosage differences between male and female cells. Expression of the Y chromosome genes in men may affect the function of somatic cells containing the Y chromosome. The loss of Y chromosome with aging in men is associated with increased risk of heart disease, especially heart failure, certain types of cancers, and shortened life span. The differences in the imprinting of maternally and paternally derived genes may also contribute to sex differences in the expression of disease. Reproductive load and physiologic changes during pregnancy, including profound hormonal and metabolic shifts and microchimerism (transfer of cells from the mother to the fetus and from the fetus to the mother), may affect disease susceptibility and disease severity in women. Sociocultural norms of child-rearing practices, societal expectations of gender roles, and the long-term economic impact of these practices and gender roles influence health behaviors and disease risk. Furthermore, the trajectories of age-related changes in sex hormones during the reproductive and postreproductive years vary substantially between men and women and influence the sex-specific patterns of the temporal evolution of age-related conditions such as osteoporosis, breast cancer, and autoimmune disease.

In a reflection of the growing attention on issues related to men's health, men's health clinics have mushroomed all over the country. Although the major threats to men's health have not changed—heart disease, cancer, and unintentional injury continue to dominate the list of major medical causes of morbidity and mortality in men—the men who attend men's health clinics do so largely for sexual, reproductive, and urologic health concerns involving common conditions, such as testosterone deficiency syndromes, age-related decline in testosterone levels, sexual dysfunction, muscle dysmorphia and anabolic-androgenic steroid (AAS) use, lower urinary tract symptoms (LUTS), and medical complications of prostate cancer therapy, which are the subjects of this chapter. Additionally, we are witnessing the emergence of new categories of body image disorders in men that had not been recognized until the 1980s, such as the body dysmorphia syndrome and the use of performance-enhancing drugs to increase muscularity and lean appearance. Although menopause and women's health have been the subject of intense investigation for more than five decades, these issues that are specific to men's health are just beginning to gain the attention that they deserve because of their high prevalence and impact on overall health, well-being, and quality of life.

AGING-RELATED CHANGES IN MALE REPRODUCTIVE FUNCTION

A number of cross-sectional and longitudinal studies (e.g., the Baltimore Longitudinal Study of Aging, the Framingham Heart Study [FHS], the Massachusetts Male Aging Study, and the European Male Aging Study [EMAS]) have established that testosterone concentrations decrease with advancing age. This age-related decline starts in the third decade of life and progresses slowly **(Fig. 411-1)**; the magnitude and trajectory of age-related decline in testosterone levels are affected by adiposity and weight change, comorbid conditions, and genetic factors. Because sex hormone–binding globulin (SHBG) concentrations are higher in older men than in younger men, free or bioavailable testosterone concentrations decline with aging to a greater extent than total testosterone concentrations. In the EMAS, 2.1% of community-dwelling men aged 40–70 years had total testosterone levels <317 ng/dL and a free testosterone level of <64 pg/mL, as well as sexual symptoms. The age-related decline in testosterone is due to defects at all levels of the hypothalamic-pituitary-testicular (HPT) axis. Pulsatile gonadotropin-releasing hormone (GnRH) secretion is attenuated, luteinizing hormone (LH) response to GnRH is reduced, and the frequency, amplitude, and area of LH pulses are reduced in older men. Leydig cell number is reduced and testicular response to LH is impaired. The gradual rise of LH with aging suggests that testis dysfunction is the main cause of declining androgen levels.

In epidemiologic surveys, low total and bioavailable testosterone concentrations in middle-aged and older men are associated with decreased sexual desire, poor erections, and diminished early morning erections; lower appendicular skeletal muscle mass, muscle strength,

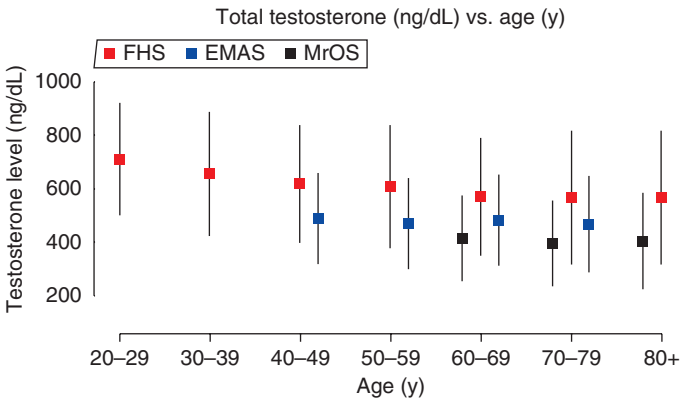

FIGURE 411-1 Age-related decline in total testosterone levels. Total testosterone levels measured using liquid chromatography–tandem mass spectrometry in men of the Framingham Heart Study (FHS), the European Male Aging Study (EMAS), and the Osteoporotic Fractures in Men Study (MrOS). *(Reproduced with permission from S Bhasin et al: Reference ranges for testosterone in men generated using liquid chromatography tandem mass spectrometry in a community-based sample of healthy nonobese young men in the Framingham Heart Study and applied to three geographically distinct cohorts. J Clin Endocrinol Metab 96:2430, 2011.)*

and self-reported physical function; increased risk of mobility limitation and falls; higher visceral fat mass, insulin resistance, and type 2 diabetes; reduced telomere length and increased all-cause and cardiovascular mortality; lower areal and volumetric bone mineral density and bone quality; and higher rates of bone fractures **(Table 411-1)**. Middle-aged and older men with hypogonadism report a high frequency of depressive symptoms. However, testosterone levels have not been consistently associated with major depressive disorder. An analysis of signs and symptoms in older men in the EMAS revealed a syndromic association of sexual symptoms with total testosterone levels <320 ng/dL and free testosterone levels <64 pg/mL in community-dwelling older men. Men with hypogonadism or Klinefelter's syndrome have reduced prostate cancer mortality.

Mendelian randomization studies using data from the United Kingdom Biobank Study found a sexual dimorphic relation between genetically determined testosterone levels and the risk of type 2 diabetes; in men, lower genetically determined testosterone levels were associated with higher risk of type 2 diabetes, but in women, higher genetically determined testosterone levels were associated with higher risk of type 2 diabetes. Higher genetically determined testosterone levels were also associated with increased risk of prostate cancer in men in this study.

TABLE 411-1 Association of Testosterone Levels with Outcomes in Older Men

1. Positively associated with:
   - Muscle mass and muscle strength
   - Self-reported and performance-based measures of physical function
   - Sexual desire
   - Bone mineral density, bone geometry and quality, and volumetric bone mineral density
2. Negatively associated with risk of:
   - Coronary artery disease
   - Type 2 diabetes mellitus
   - Metabolic syndrome
   - All-cause mortality
   - Falls and fracture risk
   - Dementia and Alzheimer's disease
   - Frailty
   - Late-onset low-grade persistent depressive disorder (dysthymia)
3. Not associated with:
   - Lower urinary tract symptoms
   - Erectile dysfunction
   - Major depressive disorder

EFFICACY OF TESTOSTERONE REPLACEMENT THERAPY IN MIDDLE-AGED AND OLDER MEN WITH HYPOGONADISM

Two large, randomized trials—the Testosterone Trials (TTrials) and the Testosterone Replacement Therapy for Assessment of Long-Term Vascular Events and Efficacy Response in Hypogonadal Men (TRAVERSE) trial—have provided the most comprehensive data on the efficacy and safety of testosterone treatment in middle-aged and older men with hypogonadism. The TTrials, a set of seven coordinated placebo-controlled efficacy trials of testosterone replacement therapy, enrolled 788 men, aged 65 years or older, with an average of two morning, fasting total testosterone levels <275 ng/dL and one or more of the following: low sexual desire, mobility limitation, and/or fatigue. The primary aim of the TRAVERSE trial was to compare the effects of testosterone replacement therapy and placebo treatment on major adverse cardiovascular events in middle-aged and older men, 45–80 years, with two fasting, morning testosterone concentrations <300 ng/dL, one or more symptoms of hypogonadism, and preexisting coronary artery disease (CAD) or increased risk of CAD. The eligible participants were randomized with stratification for preexisting CAD to receive either 1.62% transdermal testosterone gel or a placebo gel daily for up to 5 years. Because of its large sample size and long duration, the TRAVERSE trial has provided important data on the efficacy and long-term safety of testosterone replacement therapy. In these and other trials, testosterone treatment was associated with greater improvement in overall sexual activity, sexual desire, and hypogonadal symptoms than placebo (Table 411-2). The effects of testosterone alone on erectile function were small and inconsistent across studies. Nearly 15% of men enrolled in the TRAVERSE trial had anemia; among men with anemia, a greater proportion of testosterone-treated men than placebo-treated men experienced correction of anemia. Testosterone treatment also reduced the incidence of anemia in men who were not anemic at baseline. Fifty percent of men with hypogonadism reported significant depressive symptoms at baseline; however, only 1.5% of men in the TRAVERSE trial met the rigorous definition of late-life-onset, low-grade persistent depressive disorder (previously called dysthymia). Testosterone treatment was more efficacious in improving depressive symptoms and energy level than placebo. Testosterone treatment improved volumetric as well as areal bone mineral density and estimated bone strength; the improvement in volumetric bone density in the spine was greater than in the hip and greater in the trabecular than the peripheral bone. Testosterone treatment also increased lean body mass, muscle strength, and some measures of physical function (Fig. 411-2). In the TTrials, testosterone treatment of older men with mobility limitation improved self-reported walking ability and modestly improved 6-min walking distance but did not affect falls.

In TRAVERSE trial participants who had prediabetes, the incidence of progression from prediabetes to diabetes was similar between testosterone- and placebo-treated groups. Testosterone treatment did not improve glycemic control in men with hypogonadism and prediabetes or diabetes at baseline. Thus, testosterone treatment should not be used alone to improve glycemic control in men with diabetes or prediabetes. These findings of the TRAVERSE trial are in contrast to those of the Testosterone for Diabetes Mellitus (T4DM) trial in men, aged 50–74 years without hypogonadism who had a newly diagnosed type 2 diabetes or were at increased risk for type 2 diabetes. Testosterone treatment in conjunction with a lifestyle program for 2 years reduced the proportion of participants with type 2 diabetes more than

TABLE 411-2 The Potential Benefits of Testosterone Replacement Therapy in Middle-Aged and Older Men with Hypogonadism

Strong Evidence of Efficacy
1. Improves overall sexual activity and sexual desire in men with low libido
2. Relieves hypogonadal symptoms
3. Improves depressive symptoms in men with significant depressive symptoms
4. Improves energy level
5. Corrects unexplained anemia and prevents the development of anemia
6. Increases skeletal muscle mass, reduces whole-body and abdominal fat mass
7. Increases areal and volumetric bone mineral density and estimated bone strength
Suggestive Evidence of Efficacy
1. Modestly improves mobility in older men with mobility limitation
Evidence of Lack of Efficacy
1. Improves cognitive function in older men without cognitive deficit
2. Improves depressive symptoms with major depressive disorder

Note: The Testosterone Trials (TTrials) and the TRAVERSE trial have provided robust evidence of efficacy of testosterone replacement therapy in middle-aged and older men with hypogonadism. The TTrials were a set of seven coordinated placebo-controlled trials whose primary aim was to determine whether testosterone treatment for 1 year of men aged 65 years or older with an average of two fasting morning testosterone levels <275 ng/dL plus one or more of low sexual desire, mobility limitation, and/or low vitality was more efficacious than placebo in improving sexual function, mobility, and/or vitality. The primary aim of the TRAVERSE trial was to compare the effect of testosterone replacement therapy with placebo on major adverse cardiovascular events in middle-aged and older men, 45–80 years of age, with at least two fasting morning testosterone level <300 ng/dL and preexisting coronary artery disease or increased risk of coronary artery disease. Because of its large sample size and longer treatment duration, the TRAVERSE trial has provided some of the most comprehensive evidence of the efficacy and safety of testosterone replacement therapy.

TABLE 411-3 Adverse Events Associated with Testosterone Replacement Therapy in Middle-Aged and Older Men

Adverse Events for Which There Is Strong Evidence
Erythrocytosis
Venous thromboembolic events
Growth of metastatic prostate cancer
Reduced sperm production and fertility
Acne
Increased risk of detection of low-grade prostate cancer
Adverse Events for Which There Is Strong Evidence That Testosterone Treatment Does NOT Increase Risk
Major adverse cardiovascular events
Lower urinary tract symptoms
Adverse Events for Which There Is Weak Evidence
Atrial fibrillation
Bone fractures
Acute kidney injury
Male pattern balding
Adverse Events for Which There Is Insufficient Evidence to Assess Risk
Gynecomastia
Growth of breast cancer

placebo plus lifestyle program. Testosterone therapy has not been shown to improve cognitive function in men who do not have cognitive dysfunction.

SAFETY OF TESTOSTERONE REPLACEMENT THERAPY IN MIDDLE-AGED AND OLDER MEN WITH HYPOGONADISM

Erythrocytosis is the most frequent adverse event associated with testosterone treatment (Table 411-3). In two placebo-controlled trials, the rates of atherosclerosis progression did not differ significantly between the testosterone and placebo groups. In the Cardiovascular Trial of the TTrials, testosterone treatment was associated with a greater increase in the volume of the noncalcified plaque than placebo. In the TRAVERSE trial, which was designed and powered specifically to assess the cardiovascular safety of testosterone, the incidence of major adverse cardiovascular events, which included nonfatal myocardial infarction, cardiovascular death, and nonfatal stroke, was similar between the testosterone- and placebo-treated men. The incidences of high-grade prostate cancer or any prostate cancer, acute urinary retention, invasive surgical procedures for benign prostatic hyperplasia, or initiation of new pharmacologic treatment for benign prostatic hyperplasia were low and did not differ significantly between the testosterone and placebo groups. Testosterone treatment did not worsen lower urinary tract symptoms but was associated with a higher incidence of venous thromboembolic events, atrial fibrillation, and acute kidney injury. The number of clinical bone fractures was greater in the testosterone group than in the placebo group; this finding was surprising because testosterone treatment increases areal and volumetric bone mineral density and estimated bone strength.

APPROACH TO THE PATIENT

Older Men with Age-Related Decline in Testosterone

Population screening of all older men for low testosterone levels is not recommended; testing should be restricted to men who have symptoms or physical features suggestive of hypogonadism. Testosterone treatment of older men with hypogonadism offers some clinical benefits (e.g., improvement of sexual symptoms in men with low libido, improvements in mood and energy, correction of anemia), but also has some potential for adverse effects (e.g., increased risk of venous thromboembolism and atrial fibrillation). An expert panel of the Endocrine Society recommended against testosterone treatment of *all* older men with low testosterone levels. Instead, the expert panel recommended that "testosterone therapy should be offered on an individualized basis … in men >65 years who have symptoms or conditions suggestive of testosterone deficiency (e.g., low libido, significant depressive symptoms, fatigue, or unexplained anemia) and consistently low testosterone." The decision to offer testosterone treatment to older men with hypogonadism should be a shared decision, guided by an individualized assessment of potential benefits and risks and careful weighing of the burden of symptoms/conditions against the potential benefits and risks (Fig. 411-3). Evaluate whether the patient has clear evidence of testosterone deficiency confirmed by two or more early morning, fasting testosterone levels below the lower limit of normal for healthy young men plus the presence of symptoms. Weigh the burden of symptoms/conditions against the known benefits and the uncertainty of long-term harm. Ascertain whether the patient has any conditions that might increase the risk of harm, such as prostate cancer, severe LUTS, erythrocytosis, or a hypercoagulable condition. Older men considering testosterone treatment should undergo baseline evaluation of prostate cancer risk. The initiation of prostate screening and monitoring should be a shared decision because prostate cancer screening has some risks. A shared decision to treat should be accompanied by a standardized monitoring plan to optimize the benefit-to-risk ratio.

AGE-RELATED CHANGES IN FECUNDITY

Although testicular morphology, semen production, and fertility are maintained up to a very old age in men, advanced paternal age is a risk factor for reduced fertility. Compared to men aged 21–25 years, men >50 years have lower sperm motility and sperm morphology, a higher frequency of sperm tail defects, and lower fecundity. The fecundity is reduced when both parents are >40 years old. Increased workforce participation and changing career expectations of women, a higher age at reproductive union, and the availability of contraceptives that enable couples to separate their sexual and procreative lives have underpinned powerful secular trends toward postponement of childbearing to an older age. The median age at first childbirth has been increasing steadily across the world; postponement of childbirth to an older age increases the risk of involuntary childlessness because of the adverse effects of advanced maternal and paternal age on fecundity, increased risk of comorbidities that may indirectly affect fecundity, and the age-related changes in reproductive behaviors. Increased paternal age is associated with increased risk of germline mutations in the *FGFR2*, *FGFR3*, and *RET* genes and the associated autosomal dominant diseases, such as achondroplasia, Pfeiffer's syndrome, thanatophoric dysplasia, Crouzon's syndrome, Apert's syndrome, multiple endocrine neoplasia (MEN) 2A, and MEN 2B. Advanced paternal age also increases the offspring's risk of Klinefelter's syndrome, trisomy 13 and 18, neurodevelopmental disorders such as schizophrenia, autism, bipolar disorders, and cardiac malformations such as ventricular septal defects, atrial septal defects, and patent ductus arteriosus.

Sexual Dysfunction Various forms of sexual dysfunction are a major motivating factor for men seeking care at men's health clinics. The landmark descriptions of the human sexual response cycle by Masters and Johnson demonstrating that men and women display predictable physiologic responses after sexual stimulation provided the basis for rational classification of human sexual disorders. Subsequently, this model was expanded to include sexual desire, resulting in a three-stage model comprising of desire, arousal, and orgasm. Whipple and Brash-McGreer later proposed a circular model of sexual response whereby a positive sexual experience reinforces desire.

The classification of sexual disorders in men has been revised in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-5) and the eleventh revision of the International Classification of Diseases and Related Health Problems (ICD-11). DSM-5 includes three major categories of male sexual disorders: sexual desire disorders, sexual arousal disorders, and orgasmic disorders. The DSM-5 also

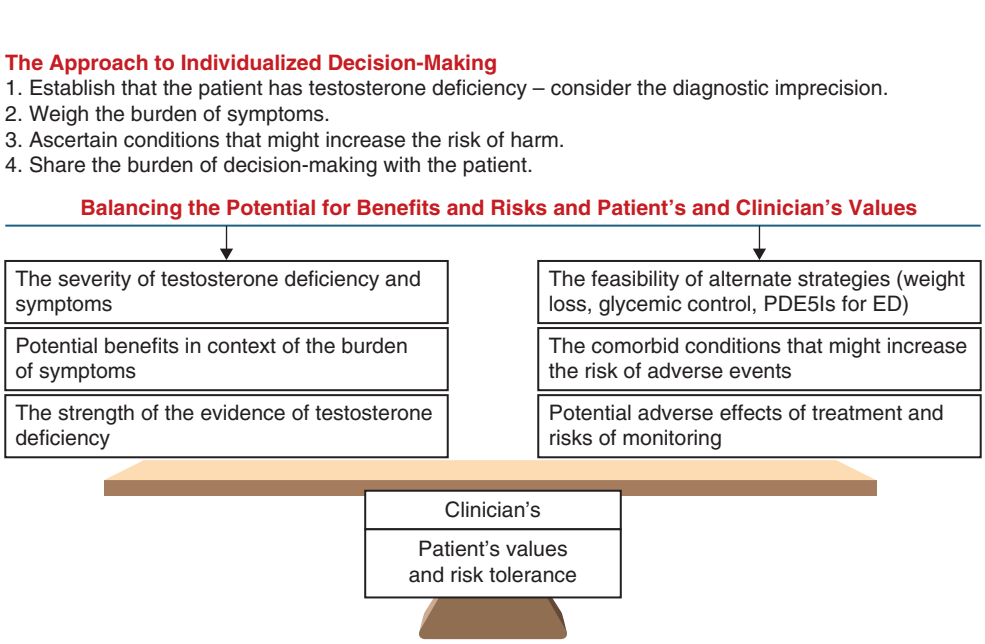

FIGURE 411-3. An approach to individualized, shared treatment decision-making in older men with testosterone deficiency. Testosterone treatment is not indicated in all older men with testosterone deficiency. Consider the diagnostic imprecision in establishing the diagnosis, the burden of symptoms, and the presence of comorbid conditions that might increase the risk of harm. Weigh the potential benefits against the burden of symptoms, the potential of harm from treatment and monitoring in the context of other comorbid conditions, and the feasibility of alternate strategies such as weight loss, improved glycemic control, and the use of selective phosphodiesterase-5 inhibitors (PDE5Is). A shared treatment decision takes into consideration the patient's and clinician's values. ED, erectile dysfunction.

includes an additional category of "other specified sexual dysfunction" due to causes other than those included in the above three categories. Male erectile dysfunction is now referred to as erectile disorder.

Classification of the patient's disorder into these categories is important as the etiologic factors, diagnostic tests, and therapeutic strategies vary for each class of sexual disorder. Historically, the classification and nomenclature for sexual disorders were based on the DSM, based on the erroneous belief that sexual disorders in men are largely psychogenic in origin. However, the recognition of erectile disorder as a manifestation of systemic disease and the availability of easy-to-use oral selective phosphodiesterase-5 (PDE5) inhibitors have placed sexual disorders in men within the purview of the primary care provider. These disorders have been discussed in **Chap. 409** (Sexual Dysfunction).

MUSCLE DYSMORPHIA SYNDROME IN MEN—A FORM OF BODY IMAGE DISORDER

Muscle dysmorphia is a form of body image disorder characterized by a pathologic preoccupation with muscularity and leanness. The men with muscle dysmorphia express a strong desire to be more muscular and lean and report dissatisfaction and embarrassment about their body size and shape, preoccupation with bodybuilding and muscularity, and impairment of social and occupational functioning. Patients with muscle dysmorphia also report higher rates of mood and anxiety disorders and obsessive and compulsive behaviors than individuals without muscle dysmorphia.

Patients with muscle dysmorphia syndrome—nearly all men—are almost always engaged in weightlifting and body building and are more likely to use performance-enhancing drugs, especially AASs, than men in the general population or even weightlifters without body dysmorphia. Muscle dysmorphia disorder exposes men to an increased risk of disease due to the combined interactive effects of the intensity of physical exercise, the use of performance-enhancing drugs, and other lifestyle factors associated with weightlifting and the use of performance-enhancing drugs. No randomized trials of any treatment modalities have been conducted; anecdotally, behavioral and cognitive therapies have been tried with varying degrees of success.

AAS Abuse by Athletes and Recreational Bodybuilders The illicit use of AASs to enhance athletic performance first surfaced in the 1950s among powerlifters and spread rapidly to other sports, professional as well as high school athletes, and recreational bodybuilders. In the early 1980s, the use of AAS spread beyond the athletic community into the general population. Most AAS users are not athletes, but rather recreational weightlifters who use these drugs to look lean and more muscular.

The most commonly used AASs include testosterone esters, nandrolone, stanozolol, methandienone, trenbolone, boldenone, and oxandrolone. AAS users generally use increasing doses of multiple steroids in a practice known as stacking.

The adverse effects of long-term AAS abuse remain poorly understood. Most of the information about the adverse effects of AAS has emerged from case reports, uncontrolled studies, or clinical trials that used replacement doses of testosterone **(Table 411-4)**. The adverse event data from clinical trials using physiologic replacement doses of testosterone have been extrapolated unjustifiably to AAS users who may administer 10–100 times the replacement doses of testosterone over many years and to support the claim that AAS use is safe. A substantial fraction of AAS users also use other drugs that are perceived to be muscle-building or performance-enhancing, such as growth hormone; erythropoiesis-stimulating agents; insulin; stimulants such as amphetamine, clenbuterol, cocaine, ephedrine, and thyroxine; and drugs perceived to reduce adverse effects such as human chorionic gonadotropin (hCG), aromatase inhibitors, or estrogen antagonists. Men who abuse AAS are more likely to engage in other high-risk behaviors than nonusers. The adverse events associated with AAS use may be due to AAS themselves, concomitant use of other drugs, or high-risk behaviors.

The high rates of mortality and morbidities observed in AAS users are alarming. One Finnish study reported 4.6 times the risk of death among elite power lifters than in age-matched men from the general population. The causes of death among power lifters included suicides, myocardial infarction, hepatocellular failure, and non-Hodgkin's lymphoma. A retrospective review of patient records in Sweden also reported higher standardized mortality ratios for AAS users than for nonusers. Studies indicate that 32% of deaths among AAS users were suicidal, 26% homicidal, and 35% accidental. The median age of death among AAS users in this study—24 years—was even lower than that for heroin or amphetamine users.

Numerous reports of cardiac death among young AAS users raise concerns about the adverse cardiovascular effects of AAS. High doses of AAS may induce proatherogenic dyslipidemia, increase thrombosis risk via effects on clotting factors and platelets, induce vasospasm

TABLE 411-4 Potential Adverse Effects Associated with the Use of Anabolic-Androgenic Steroids

A. Four Major Categories of Serious Adverse Effects Associated with the Use of Anabolic-Androgenic Steroids

1. *Cardiovascular*
   - a. Hypertension
   - b. Sudden death
   - c. Cardiomyopathy
   - d. Diastolic dysfunction
   - e. Accelerated atherosclerosis
   - f. Dyslipidemia
2. *Endocrine*
   - a. Suppression of the hypothalamic-pituitary-testicular axis
     - i. Anabolic steroid withdrawal hypogonadism
     - ii. Infertility
     - iii. Testicular atrophy
   - b. Gynecomastia
3. *Neuropsychiatric*
   - a. Major mood disorders
     - i. Hypomania and mania during periods of high-dose anabolic-androgenic steroids use
     - ii. Depression and even suicidality during anabolic steroid withdrawal
   - b. Other behavioral disorders
     - i. Rage reactions
     - ii. Aggressive responding and violence
   - c. Dependence and addiction behaviors
   - d. Cognitive deficits
4. *Musculoskeletal Injuries*
   - a. Tendon injuries
   - b. Other musculoskeletal injuries

B. Other Adverse Events

1. *Hematologic*
   - a. Erythrocytosis
   - b. Venous thromboembolic events
2. *Hepatotoxicity*
   - a. Inflammatory or cholestatic hepatic damage with the use of 17α-alkyl-substituted steroids
   - b. Peliosis hepatis
   - c. Hepatic adenoma
   - d. Hepatocellular carcinoma
3. *Hair and skin*
   - a. Acne
   - b. Scalp hair loss in genetically predisposed men
   - c. Increased body hair
   - d. Striae
4. *Renal*
   - a. Acute kidney injury due to rhabdomyolysis
   - b. Focal glomerulosclerosis

through their effects on vascular nitric oxide, and induce myocardial hypertrophy and fibrosis. The supraphysiologic doses of testosterone and orally administered, 17-α-alkylated, nonaromatizable AAS are associated with marked reductions in high-density lipoprotein (HDL) cholesterol and increases in low-density lipoprotein (LDL) cholesterol.

Studies using tissue Doppler and strain imaging and magnetic resonance imaging (MRI) have reported diastolic and systolic dysfunction, including lower early and late diastolic tissue velocities, reduced E/A ratio, and reduced peak systolic strain in AAS users than in nonusers. Power athletes using AAS often have short QT intervals but increased QT dispersion, which may predispose them to ventricular arrhythmias. Long-term AAS use may be associated with myocardial hypertrophy and fibrosis. Myocardial tissue of power lifters using AAS has been shown to be infiltrated with fibrous tissue and fat droplets. AAS users demonstrate higher coronary artery plaque volume than nonusers, and lifetime AAS dose is associated with coronary atherosclerotic burden.

Long-term AAS use suppresses LH and follicle-stimulating hormone (FSH) secretion and inhibits endogenous testosterone production and spermatogenesis. Men who have used AAS for more than a few months experience marked suppression of the HPT axis after stopping AAS that may be associated with sexual dysfunction, fatigue, infertility, and depressive symptoms. In some long-term AAS users, HPT suppression may last more than a year, and in a few individuals, complete recovery may not occur. The symptoms of androgen deficiency during AAS withdrawal may cause some men to revert back to using AAS, leading to continued use and AAS dependence. As many as 30% of AAS users develop a syndrome of AAS dependence, characterized by long-term AAS use despite adverse medical and psychiatric effects. In some men's health clinics, as many as 25% of young men receiving testosterone replacement therapy have anabolic steroid withdrawal hypogonadism.

Supraphysiologic doses of testosterone may also impair insulin sensitivity. Orally administered androgens have been associated with insulin resistance and diabetes.

Unsafe injection practices, high-risk behaviors, and increased rates of incarceration render AAS users at increased risk of HIV and hepatitis B and C. In one survey, nearly 1 in 10 gay men had injected AAS or other substances, and AAS users were more likely to report high-risk unprotected anal sex than other men. Surveys of male prisoners find high rates of AAS use.

Some AAS users develop hypomanic and manic symptoms during AAS exposure (irritability, aggressiveness, reckless behavior, and psychotic symptoms, sometimes associated with violence) and major depression (sometimes associated with suicidality) during AAS withdrawal. Users may also develop other forms of illicit drug use.

AAS use has been associated with difficulties with spatial as well as working memory, problem solving, and attention, and structural and functional changes in many brain regions involved in inhibitory control and emotional regulation. A structural MRI study of users of high doses of AAS reported smaller cortical, gray matter, putamen, and corpus callosum volumes. Both low and high androgen levels have been associated with increased Aβ and tau-P levels and Aβ toxicity. These data have raised concern that long-term AAS use may increase the risk of Alzheimer's disease and related dementias.

Elevated liver enzymes, cholestatic jaundice, hepatic neoplasms, and peliosis hepatis have been reported with oral, 17-α-alkylated AAS. AAS use may cause muscle hypertrophy without compensatory adaptations in tendons, ligaments, and joints, thus increasing the risk of tendon and joint injuries. AAS use is associated with acne, baldness, and increased body hair.

APPROACH TO THE PATIENT

Detection of AAS Use

AAS users generally mistrust physicians and seek medical help infrequently; when they do seek medical help, it is often for the treatment of AAS withdrawal syndrome, infertility, gynecomastia, or other medical or psychiatric complications of AAS use. The suspicion of AAS use should be raised by the increased hemoglobin and hematocrit levels; suppressed LH, FSH, SHBG and testosterone levels; low HDL cholesterol; and low testicular volume and sperm density in a person who looks highly muscular **(Table 411-5)**. A combination of these findings along with self-report of their use by the patient—which usually can be elicited by a tactful interview—are often sufficient to establish a diagnosis in clinical practice.

Accredited laboratories use gas chromatography and mass spectrometry or liquid chromatography and mass spectrometry to detect AAS abuse. Illicit testosterone use is detected generally by the measurement of the urinary testosterone-to-epitestosterone ratio and confirmed by the use of the ^{13}C:^{12}C ratio in testosterone by the use of isotope ratio combustion mass spectrometry. Exogenous testosterone administration increases urinary testosterone glucuronide excretion and consequently the testosterone-to-epitestosterone

TABLE 411-5 Detection of the Use of Anabolic-Androgenic Steroids

Clinical indicators that should raise suspicion of anabolic-androgenic steroid use
1. "V" muscular phenotype
2. Reduced testicular volume (<15 mL)
3. Excessive concern about leanness and muscularity.

Laboratory indicators
1. Suppressed LH, FSH, and SHBG levels
2. Increased hematocrit

Detection of anabolic-androgenic steroids
1. LC-MS/MS analysis of urine

Detection of exogenous testosterone use
1. Urinary testosterone-to-epitestosterone ratio
2. Isotope ratio mass spectrometry analysis to detect differences in ^{13}C:^{12}C ratio in exogenous and endogenous testosterone

Note: In clinical settings, the use of anabolic-androgenic steroids can often be ascertained simply by direct questioning. Reduced testicular volume, suppressed LH and FSH, and increased hematocrit in an unusually muscular man should raise suspicion of anabolic-androgenic steroid use. Although rarely needed in clinical practice, recent use of anabolic-androgenic steroids can be confirmed by LC-MS/MS analysis of urine. Exogenous testosterone use can be detected using the urinary testosterone-to-epitestosterone ratio and isotope ratio mass spectrometry analysis to detect differences in ^{13}C:^{12}C ratio in exogenous and endogenous testosterone.

Abbreviations: FSH, follicle-stimulating hormone; LC-MS/MS, liquid chromatography–tandem mass spectrometry; LH, luteinizing hormone.

ratio. Ratios >4 suggest exogenous testosterone use but can also reflect genetic variation. Genetic variations in the uridine diphospho-glucuronyl transferase 2B17 (*UGT2B17*), the major enzyme for testosterone glucuronidation, CYP17 (the aromatase gene), SHBG, and 3', 5' cyclic nucleotide phosphodiesterase (PDE7B) affect the testosterone-to-epitestosterone ratio and increase the risk of a false-negative test. Synthetic testosterone has a lower ^{13}C:^{12}C ratio than endogenously produced testosterone, and these differences in the ^{13}C:^{12}C ratio can be detected by isotope ratio combustion mass spectrometry and used to confirm exogenous testosterone use in individuals with a high testosterone-to-epitestosterone ratio.

TREATMENT

Integrated Management of Patients with AAS Use

The nonathlete weightlifters who abuse AAS frequently do not seek medical treatment and often mistrust physicians. They also do not view these drugs and the associated lifestyle as deleterious to their health. Many clinicians erroneously view AAS abuse as largely a problem of cheating in competitive sports, while, in fact, most AAS users are not athletes at all.

In addition to treating the underlying body dysmorphia disorder that motivates the use of these drugs and the addiction behaviors, the treatment should be directed at the symptoms or the condition for which the patient seeks therapy, such as infertility, sexual dysfunction, gynecomastia, or depressive symptoms. Accordingly, therapy may include some combination of cognitive and behavioral therapy for muscle dysmorphia syndrome, antidepressant therapy for depression, selective PDE5 inhibitors for erectile dysfunction, and/or use of selective estrogen receptor modulators, aromatase inhibitors, or hCG to restore testosterone levels.

As discussed above, AASs suppress the male hypothalamic-pituitary-gonadal axis, and men with long-term AAS use may experience symptoms of profound androgen deficiency such as sexual dysfunction, fatigue, and depressive symptoms during AAS withdrawal. Some of these patients may resume AAS use or start using other drugs to combat the distressing withdrawal symptoms. There are no randomized trials of any therapies for AAS withdrawal. Case reports and clinical experience suggest that administration of selective estrogen receptor modulators, CYP19 aromatase inhibitors, or hCG may restore circulating testosterone levels. Clomiphene citrate, a partial estrogen receptor agonist, administered in a dose of 25–50 mg on alternate days, can increase LH and FSH levels and restore testosterone levels in a vast majority of men with AAS withdrawal syndrome. However, the recovery of sexual function during clomiphene administration is variable despite improvements in testosterone levels. Anecdotally, other aromatase inhibitors such as anastrozole have also been used. hCG, administered by intramuscular injections of 1500 to 2000 IU three times each week, can raise testosterone levels into the normal range. Some patients may not respond to either clomiphene or hCG therapy, raising the possibility of irreversible long-term toxic effects of AAS on Leydig cell function.

Cognitive and behavioral therapy to address the body image disorder and addiction behaviors and antidepressants to treat depression may be needed. The opioid antagonist naltrexone blocks AAS dependence in animals. Therefore, treatments for human opioid dependence might also benefit AAS dependence. Many patients who abuse AAS suffer from body image disorder and require psychiatric treatment for this underlying disorder.

LUTS IN MEN

LUTS in men include storage symptoms (urgency, daytime as well as nighttime frequency, and urgency incontinence), voiding disturbances (slow or intermittent stream, difficulty in initiating micturition, straining to void, pain or discomfort during the passage of urine, and terminal dribbling), or postmicturition symptoms (a sense of incomplete voiding after passing urine and postmicturition dribble). The overactive bladder syndrome refers to urgency with or without urgency incontinence, usually with urinary frequency and nocturia, and is often due to detrusor muscle overactivity. A presumptive diagnosis of benign prostatic hyperplasia should be made only in men with LUTS, who have demonstrable evidence of prostate enlargement and obstruction based on the size of the prostate. LUTS have historically been attributed to benign prostatic hyperplasia, although it has become apparent that the pathophysiologic mechanisms of LUTS are complex and multifactorial and may include structural or functional abnormalities of the bladder, bladder neck, prostate, distal sphincter mechanism, and urethra, as well as abnormalities in the neural control of the lower urinary tract and autonomic dysfunction. Diuretics, antihistamines, antidepressants, and other medications that have anticholinergic properties can cause or exacerbate LUTS in older men. The intensity of LUTS tends to fluctuate over time.

LUTS is highly prevalent in older men, affecting nearly 50% of men >65 and 70% of men >80 years old. LUTS adversely affect quality of life because of their impact on sleep, ability to perform activities of daily living, and depressive symptoms. LUTS are often associated with erectile dysfunction.

APPROACH TO THE PATIENT

Lower Urinary Tract Symptoms

Medical evaluation should include assessment of potential causes of symptoms; medications including herbal and over-the-counter products that might contribute to symptoms; the symptom severity and bother using an International Prostate Symptom Score; and in some patients, a frequency-volume chart. The impact of LUTS on sleep, activities of daily living, and quality of life should be evaluated. Evaluation should also include digital prostate examination, neurologic examination focused on perineum and lower extremities, urinalysis, fasting blood glucose, electrolytes, creatinine, and prostate-specific antigen (PSA). Urodynamic studies are not required in most patients but are recommended when invasive surgical therapies are being considered. A urologic referral may be appropriate if the patient has hydronephrosis, renal insufficiency, recurrent urinary tract infections, hematuria, or history of acute urinary retention.

TREATMENT

Patients with LUTS

Considerations of the severity of symptoms; the impact of symptoms on sleep, activities of daily living, and quality of life; the natural history of the disease; and potential adverse effects of the intervention should guide the decision to intervene. In men with mild to moderately severe LUTS, the symptoms typically progress slowly over many years and may remain stable or even improve in some men. The men who have mild symptoms can usually be reassured and followed. Several simple steps such as reducing caffeine and alcohol intake, especially late in the day, taking the diuretic medication early in the day, avoiding excessive water intake close to bedtime, bladder training, pelvic floor exercises including biofeedback to promote pelvic floor relaxation, and timed voiding regimens or double voiding to ensure complete emptying of the bladder may be helpful in reducing the severity of symptoms. Men with mild to moderate bothersome LUTS can be treated effectively using α-adrenergic antagonists, steroid 5α-reductase inhibitors, PDE5 inhibitors, or anticholinergic agents alone or in combination. Selective α-adrenergic antagonists are typically the first line of therapy; their side effects include hypotension, dizziness, nasal congestion, retrograde or delayed ejaculation, and rarely floppy iris syndrome. In men with probable benign prostate obstruction with gland enlargement and LUTS, therapy with steroid 5α-reductase inhibitors, finasteride or dutasteride, improves urinary symptoms and flow rate and reduces prostatic volume. Long-term treatment with 5α-reductase inhibitors can reduce the risk of acute urinary retention and need for prostate surgery. Combined administration of a steroid 5α-reductase inhibitor and an α_1-adrenergic blocker can rapidly improve urinary symptoms and reduce the relative risk of acute urinary retention and surgery. PDE5 inhibitors, when administered chronically alone or in combination with α-adrenergic blockers, are effective in improving LUTS and erectile dysfunction through their effects on nitric oxide–cyclic guanosine monophosphate (cGMP) in the bladder, urethra, and prostate. PDE5 inhibitors do not improve uroflow parameters, and their hypotensive effect may be potentiated by α_1-adrenergic blockers. Anticholinergic drugs are used for the treatment of overactive bladder in men with prominent irritative symptoms, such as frequency, urgency, and incontinence, and no evidence of elevated postvoid residual urine. Containment products, such as pads, can help improve social life in men who have severe storage symptoms, including incontinence. Surgery is indicated when medical therapy fails, symptoms progress despite medical therapy, or the patient develops acute urinary retention, hydronephrosis, renal insufficiency, or recurrent urinary tract infections, or if the patient has postvoid residual urine volume >25% of the urinary bladder volume.

MEDICAL COMPLICATIONS OF PROSTATE CANCER THERAPY

Prostate cancer is the most common malignancy in American men. The majority of these men have low-grade, organ-confined prostate cancer; are treated with radical prostatectomy, radiation, or active surveillance; and have excellent prospects of long-term survival. Substantial improvement in survival in men with prostate cancer has focused attention on the high prevalence of sexual dysfunction, physical dysfunction, and low vitality in the men, which are important contributors to poor quality of life among patients treated for prostate cancer. The pathophysiology of these symptoms after radical prostatectomy or radiation therapy is multifactorial, but denervation and testosterone deficiency are important contributors to these symptoms.

Testosterone deficiency is common in men with prostate cancer. Testosterone levels decline with age, and men with prostate cancer are at risk of having low testosterone levels simply by virtue of their age. However, total and free testosterone levels are even lower in men with prostate cancer who have undergone prostatectomy, when compared to noncancer age-matched controls. Testosterone deficiency in men with prostate cancer is associated with fatigue, sexual dysfunction, mobility limitation, and decreased physical function. A majority of men treated with surgery or radiation therapy will develop sexual dysfunction and incontinence. Although there is some recovery of sexual function with passage of time, 40–50% of men undergoing radical prostatectomy find their sexual performance to be a moderate to large problem 18 months after surgery. Sexual problems are a source of psychosocial distress in men with localized prostate cancer. The men with locally advanced or metastatic prostate cancer who undergo androgen deprivation therapy (ADT) encounter even more distressing symptoms. In addition to fatigue, sexual dysfunction, and hot flushes, these men are at increased risk for diabetes, metabolic syndrome, coronary heart disease, and frailty.

Testosterone Therapy in Men with a History of Prostate Cancer A history of prostate cancer has historically been considered a contraindication for testosterone therapy. This guidance is based on observations that testosterone promotes the growth of metastatic prostate cancer and metastatic prostate cancer generally regresses after orchiectomy and ADT. Androgen receptor signaling plays a central role in maintaining growth of normal prostate and prostate cancer.

The role of testosterone in prostate cancer is complex. Epidemiologic studies and their meta-analyses have not revealed a consistent relationship between serum testosterone or dihydrotestosterone levels and prostate cancer. However, men with hypogonadism or Klinefelter's syndrome have lower prostate cancer mortality than the general population. In a Mendelian randomization analysis of men in the UK Biobank, higher genetically determined bioavailable testosterone levels were associated with increased risk of prostate cancer. Testosterone treatment of older men with low testosterone does not affect intraprostatic androgen levels or the expression of androgen-dependent prostatic genes. The suppression of circulating testosterone levels by a GnRH antagonist also does not affect intraprostatic androgen concentrations. Open-label trials and retrospective analyses of testosterone therapy in men with prostate cancer who have undergone radical prostatectomy and have undetectable PSA levels after radical prostatectomy have found very low rates of PSA recurrence.

A majority of men diagnosed with prostate cancer today have localized disease that can be potentially cured by radical prostatectomy. The men with organ-confined prostate cancer (pT2, N0, M0) and Gleason score 6 or 7 (3+4) are at a very low risk of disease recurrence after radical prostatectomy, with 0.5% biochemical recurrence rate and 0.2% local recurrence rate at >10–15 years. Therefore, men with organ-confined prostate cancer (pT2), Gleason score 6 or 7 (3+4), and a preoperative PSA of <10 ng/mL, who have had undetectable PSA levels (<0.1 ng/mL) for >2 years after radical prostatectomy, have very low risk of disease recurrence (<0.5% at 10 years) and may be considered for testosterone therapy on an individualized basis. If testosterone therapy is instituted, it should be associated with careful monitoring of PSA levels and close consultation with a urologist.

MEDICAL COMPLICATIONS OF ADT

In patients with prostate cancer and distant metastases, ADT improves survival. In patients with locally advanced disease, ADT in combination with external beam radiation or as an adjuvant therapy (post-prostatectomy and pelvic lymphadenectomy) also has been shown to improve survival. However, ADT along with radiation is being increasingly used as primary therapy in men with localized disease and in men encountering biochemical recurrence. The overall use of ADT in men with prostate cancer has increased in the past two decades, and its use in men with localized disease and biochemical recurrence accounts for a substantial fraction of this increase. Since most men with prostate cancer die of conditions other than their primary malignancy, recognition and management of these adverse effects are paramount.

Profound hypogonadism resulting from ADT is associated with sexual dysfunction, vasomotor symptoms, gynecomastia, decreased muscle mass and strength, frailty, increased fat mass, anemia, fatigue, bone loss, loss of body hair, depressive symptoms, and reduced quality of life. Increased risk of diabetes and cardiovascular disease has

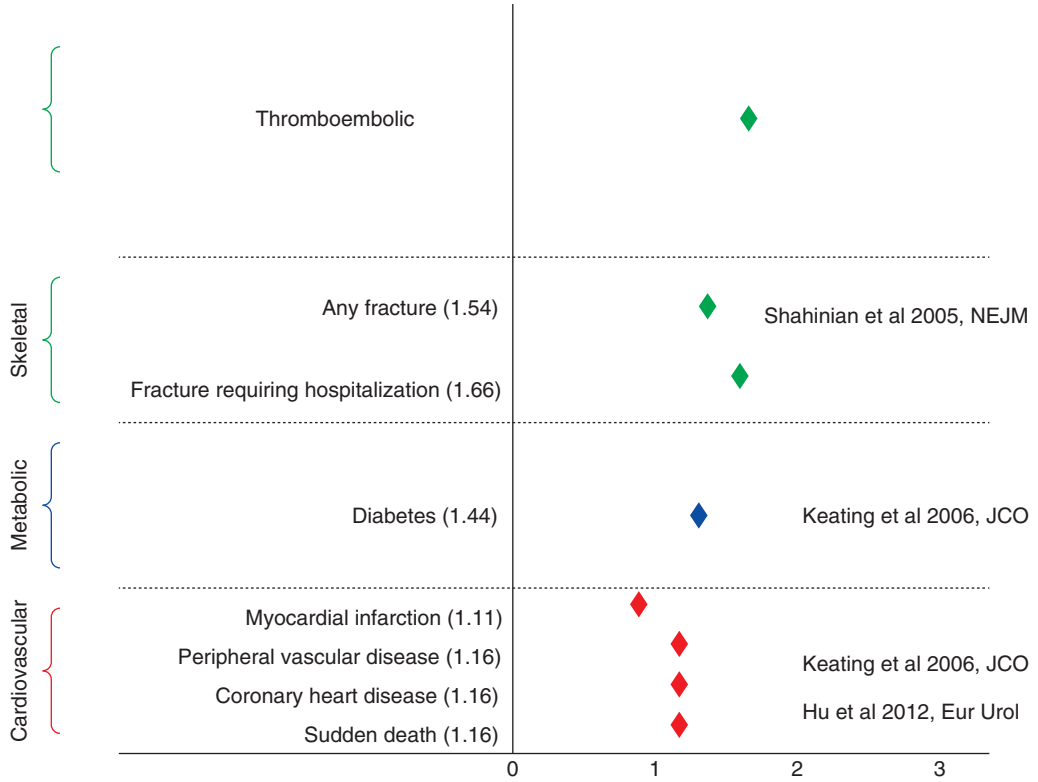

FIGURE 411-4 Adverse cardiometabolic and skeletal effects of androgen deprivation therapy (ADT) in men receiving ADT for prostate cancer. Administration of ADT has been associated with increased risk of thromboembolic events, fractures, and diabetes. Some, but not all, studies have reported increased risk of cardiovascular events in men receiving ADT. *(Data from VB Shahinian et al: N Engl J Med 352:154, 2005; NL Keating et al: J Clin Oncol 24:4448, 2006; JC Hu et al: Eur Urol 61:1119, 2012.)*

recently been added to the list of these complications **(Fig. 411-4)**. Treatment with GnRH agonists in men with prostate cancer is associated with rapid induction of insulin resistance, hyperinsulinemia, and a significant increase in the risk of incident diabetes. Metabolic syndrome is prevalent in >50% of men undergoing long-term ADT when compared to age-matched men with prostate cancer not undergoing ADT and their age-matched eugonadal counterparts. Some but not all studies have reported an increased risk of cardiovascular events, death due to cardiovascular events, and peripheral vascular disease in men undergoing ADT. Some reports suggest that men receiving ADT are at an increased risk of thromboembolic events and cognitive dysfunction. The rates of acute kidney injury are higher in men currently receiving ADT than in men not receiving ADT; the increased risk appears to be particularly associated with the use of combined regimens of a GnRH agonist plus an antiandrogen. ADT also is associated with substantially increased risk of osteoporosis and bone fractures.

APPROACH TO THE PATIENT

Men Receiving ADT

The benefits of ADT in treating nonmetastatic prostate cancer should be carefully weighed against the risks of ADT-induced adverse events **(Table 411-6)**. If ADT is medically indicated, consider whether intermittent ADT is a feasible option. Men being considered for ADT should undergo assessment of cardiovascular, diabetes, and fracture risk; this assessment may include measurement of blood glucose, plasma lipids, and bone mineral density by dual energy x-ray absorptiometry. Institute measures to prevent bone loss, including physical activity, adequate calcium and vitamin D intake, and pharmacologic therapy in men with a previous minimal trauma fracture and those with 10-year risk of a major osteoporotic fracture >20%, unless contraindicated. Bisphosphonates and denosumab have been shown to reduce fracture risk in men undergoing ADT, and zoledronic acid and denosumab have been approved by the U.S. Food and Drug Administration for the prevention of metastasis-related skeletal-related events in this population. Men with prostate cancer who are receiving ADT should be monitored for weight gain and diabetes. Encourage lifestyle interventions, including physical activity and exercise, and attention to weight, blood pressure, lipid profile, blood glucose, and smoking cessation to reduce the risk of cardiometabolic complications. Metformin plus lifestyle intervention can prevent and improve metabolic dysregulation. In randomized trials, gabapentin, medroxyprogesterone, and the serotonin reuptake inhibitor venlafaxine have been shown to be more efficacious than placebo in alleviating hot flushes. The side effects of these medications—increased appetite and weight gain with medroxyprogesterone, gynecomastia with estrogenic compounds, and dry mouth with venlafaxine—should be weighed against their relative efficacy. Acupuncture, soy products, vitamin E, herbal medicines, and transdermal estradiol have been used empirically for the treatment of vasomotor symptoms without clear evidence of efficacy. Gynecomastia can be

TABLE 411-6 Checklist for Men Undergoing Androgen Deprivation Therapy (ADT)

1. Weigh the risks and benefits of ADT and whether intermittent ADT is a feasible and safe option.
2. Perform a baseline assessment including fasting glucose, plasma lipids, blood pressure, bone mineral density, and FRAX score.
3. Optimize calcium and vitamin D intake, encourage structured physical activity and exercise, and consider pharmacologic therapy in men with a previous minimal trauma fracture and those with a 10-year risk of a major osteoporotic fracture >20%, unless contraindicated.
4. Monitor body weight, fasting glucose, plasma lipids, blood pressure, and bone mineral density, and encourage smoking cessation and physical exercise. Consider metformin in those with metabolic disorder.
5. In men who are receiving ADT and who experience bothersome hot flushes, as indicated by sleep disturbance or interference with work or activities of daily living, consider initial therapy with venlafaxine. If ineffective, add medroxyprogesterone acetate or gabapentin.
6. In men who experience painful breast enlargement, consider therapy with an estrogen receptor antagonist, such as tamoxifen.

prevented by the use of an antiestrogen, an aromatase inhibitor, or local radiation therapy; these therapies are effective in alleviating pain and tenderness but are less effective in reducing established gynecomastia. For long-standing gynecomastia that persists after cessation of ADT and is bothersome, mammoplasty is an effective treatment option. Intermittent ADT can reduce the frequency of adverse effects associated with ADT, but its long-term efficacy and safety need further investigation.

PREVENTION OF SEXUALLY TRANSMITTED DISEASES

Adolescent boys and young men aged 15–24 years; men who have sex with men, have multiple sex partners, have unprotected sex without condom, or have sex with sex workers; men who use illicit drugs; men who have a history of previous sexually transmitted infection (STI); and transgender men are at increased risk for STIs. STIs increase the risk of oropharyngeal and anogenital cancers, liver disease, pelvic pain, infertility, inadvertent transmission of infection to others, and emergency department visits and are a preventable cause of excess morbidity and mortality. HIV, hepatitis B and C infections, and syphilis can have additional disease-specific complications. The prevention and treatment of STIs are discussed in **Chap. 141**. Additionally, the Centers for Disease Control and Prevention (CDC) and U.S. Preventive Services Task Force (USPSTF) have published guidelines on the prevention, treatment, and pre- and postexposure prophylaxis of STIs. The approach to the prevention of STIs includes a structured risk assessment; counseling about safe sex practices including condom use; immunization of individuals at risk; diagnosis and treatment of infected individuals whether or not they are symptomatic; detection and treatment of sexual partners; and targeted sex education of adolescents and young men who are at high risk for STIs. The USPSTF recommends screening for HIV in all men aged 15–65 years, regardless of risk, and for hepatitis B virus and syphilis in men at increased risk. Because more than half of STIs occur in persons aged 15–24 years, the USPSTF also recommends behavioral counseling for all sexually active adolescents and adult men at increased risk of STIs to encourage condom use and other protective behaviors, including consideration of abstinence, reducing the number of sex partners, and avoidance of unsafe sex practices. Consistent and correct condom use is the most important method of preventing STIs. Effective immunizations are available against hepatitis B, human papillomavirus (HPV), and *Neisseria meningitides*. The CDC's Advisory Committee on Immunization Practices (ACIP) recommends universal hepatitis B immunization for all unvaccinated adults presenting to an STI clinic, all HIV-infected adults, and health workers. Although ACIP recommends HPV vaccination in males aged 9–21 years and in men aged 9–26 if they have sex with men or have an immunocompromising condition, recent data suggest that the prevalence of HPV and its complications continue to increase until middle age, and some experts recommend extending the age limit for HPV vaccination. Meningococcal vaccination is indicated for men who have sex with men from an area of outbreak and for all HIV-infected men.

Because men seeking care in men's health clinics often do so for sexual and urogenital problems, these visits offer opportunities for counseling, screening, and treatment of STIs and institution of immunization and other preventive measures for STIs.

SEX DIFFERENCES IN COVID-19 DISEASE OUTCOMES

The COVID-19 pandemic has highlighted sex differences in the susceptibility to respiratory viral infections. Men infected with SARS-CoV-2 virus are more likely to have a more severe disease, require mechanical ventilation, have disease complications, and die of the disease than women. Somewhat similar sex differences in morbidity and mortality have been reported for influenza infection. In the United States, the incidence and rates of hospitalization for influenza are higher in men than in women across all age groups. However, the sex-specific mortality rates associated with influenza vary substantially across countries and age groups. The sex differences in susceptibility to SARS-CoV-2 infection and morbidity have been attributed to behavioral factors, such as higher rates of smoking and alcohol use in men; biologic factors, such as higher rates of comorbid conditions in men than in women; sex differences in immune responses, including a poor T lymphocyte response to SARS-CoV-2 infection; and lower expression levels in men of X-linked genes that are involved in the innate detection of RNA viruses and that escape X inactivation in women, resulting in higher expression levels in women. Additionally, the expression of angiotensin-converting enzyme 2 (ACE2) and the cell surface transmembrane protease serine 2 (TMPRSS2), the two host proteins that facilitate the entry of SARS-CoV-2 into the alveolar cells, is regulated by androgens in subsets of lung epithelial cells, and it is possible that higher testosterone levels in men may contribute to increased susceptibility to the infection.

412 Lesbian, Gay, Bisexual, Transgender, Queer or Questioning, Intersex, Asexual, and More (LGBTQIA+) Health

Baligh R. Yehia, Todd P. Levin

UNDERSTANDING LGBTQIA+ HEALTH DISPARITIES

The acceptance of the lesbian, gay, bisexual, transgender, queer or questioning, intersex, asexual, and more (LGBTQIA+) community has greatly increased over the past decade in certain communities and parts of the world. However, numerous studies highlight health disparities involving the care of LGBTQIA+ people. Lesbian and bisexual women are less likely to receive recommended preventive screenings such as breast, cervical, and colorectal cancer screenings. Among men who have sex with men, rates of human papillomavirus–associated anal cancers are 17 times higher than those of heterosexual men. In addition, gay and bisexual men accounted for 68% of all new HIV diagnoses in the United States in 2020 according to the Centers for Disease Control and Prevention, and they disproportionately contract sexually transmitted infections. In 2021, men who have sex with men accounted for 47% of primary and secondary syphilis infections in the United States where the sex of the sexual partner was known. Transgender individuals have a higher prevalence of HIV infection and suicide compared with other groups.

Research has found that LGBTQIA+ individuals are more likely to experience depression, anxiety, and alcohol and drug use than their counterparts. Most concerning are the rates of suicide attempts and ideation among the LGBTQIA+ community, particularly youth. In a 2021 survey of 35,000 LGBTQIA+ youth ages 13–24, 42% seriously considered attempting suicide in the last year, including more than half of transgender and nonbinary youth. Lesbian, gay, and bisexual (LGB) youth are four times more likely to attempt suicide than their heterosexual peers, and 61% of gender variant youth reported suicidal ideation at some point in their life. Additionally, the recent U.S. Transgender Survey found that 40% of transgender young adults and adults reported attempting suicide at some point in their lives.

U.S. studies indicate that substance abuse is twice as common in LGBTQIA+ youth compared with their counterparts. These findings are mirrored among LGBTQIA+ adults: the prevalence of substance abuse disorders is 20–30% compared with ~9% in the general population.

These health issues are compounded by structural barriers to health care, including decreased access to medical care, lack of awareness to the unique health needs of LGBTQIA+ individuals, and stigma and discrimination toward the LGBTQIA+ community. Many LGBTQIA+ individuals perceive the health care setting and providers as threatening, which may lead to avoiding needed medical care or withholding important medical information. A large U.S. survey identified that 8% of LGB and 27% of transgender individuals were refused needed health care, and almost 11% of LGB and 21% of transgender people reported being subjected to harsh or abusive language by health care professionals. Apart from health care settings, more than two-thirds of LGB people report discrimination in their personal lives, and 90% of transgender individuals report harassment, mistreatment, or discrimination at work. Chronic exposure to high levels of stress from real or anticipated discrimination, referred to as "minority stress," may be an important factor contributing to the poor health outcomes experienced by LGBT populations.

While some research on LGBTQIA+ health has been conducted, there remains a great opportunity to better understand the needs and experiences of LGBTQIA+ individuals. Moreover, many LGBTQIA+ individuals experience health disparities across their life cycle (e.g., LGBTQIA+ youth are at greater risk of suicide and homelessness, whereas elderly LGBTQIA+ individuals face barriers to health because of isolation and fewer family supports), necessitating a longitudinal approach to examining LGBTQIA+ health issues. There are more limited data on the health of LGBTQIA+ individuals outside the United States and Europe. However, studies demonstrate that problems are greatest when people cannot be open about their sexual orientation and gender identity. Encouraging greater LGBTQIA+ acceptance and access to health care will be critical to improving outcomes and experiences for LGBTQIA+ communities.

CREATING POSITIVE HEALTH EXPERIENCES FOR LGBTQIA+ PATIENTS

Understanding Gender Identity and Sexual Orientation Addressing health disparities and creating positive health care experiences require an understanding of the diversity of cultural expression and lives of LGBTQIA+ persons. First, providers must be able to distinguish *gender identity* from *sexual orientation*. Gender identity is a person's internal sense of their gender. It should not be confused with sex assigned at birth, which is based on anatomy and biology. Gender identity expands beyond the binary male and female and includes persons who think of their gender as containing elements of both, neither, or another gender. Many individuals who do not identify with the gender that correlates with their sex assigned at birth often use the terms *transgender* or *trans-male* or *trans-female* to identify themselves. Sexual orientation refers to how one thinks of their physical or emotional attraction to others. Sexual orientation has three dimensions: attraction, behavior, and identity. *Attraction* refers to one's desire to be with someone, regardless of one's behavior or stated identity. For example, a woman may be attracted to another woman, but this attraction may never be acted upon and may not form part of her sexual identity. *Behavior* refers to a person's interactions with sexual and romantic partners. Although sexual identity often aligns with behavior, some individuals who identify as heterosexual may have same-gender partners and some individuals who identify as lesbian or gay may have different-gender partners. Lastly, *identity* refers to how a person defines their own sexuality. Common terms for sexual identity include *gay*, *lesbian*, *bisexual*, *straight*, *heterosexual*, *homosexual*, and *asexual* (Tables 412-1 and 412-2). As individuals go through the process of understanding their sexuality and self-identity over time, they may change how they define their sexual identity.

The creation of a welcoming environment requires not making any assumptions about an individual's gender identity or sexual orientation. Both front-line staff and clinicians should be cognizant of patient communication. For example:

- *Instead of saying* "How may I help you, sir?", *say* "How may I help you?"
- *Instead of saying* "She is here for her appointment," *say* "The patient is here in the waiting room."
- *Instead of saying* "Do you have a wife?", *say* "Are you in a relationship?"
- *Instead of saying* "What are your mother's and father's names?", *say* "What are your parents' names?"

Developing Comfort and Competency in Sexual Health Developing comfort discussing sexual health and intimacy is critical to providing appropriate care. After inquiring about healthy relationships and relationship status, a good starting place is to ask if a patient is sexually active and, if so, with whom, how often, and what types of physical interactions and types of sex they have with their partner(s). These discussions can allow clinicians to focus subsequent conversations on issues most relevant to a patient's health. For example, a gay man with multiple sexual partners who engages in receptive anal sex without condoms is at high risk for HIV and sexually transmitted infections (STIs). It will be important to recommend more frequent screenings for STIs and discuss the use of HIV preexposure prophylaxis (PrEP), along with postexposure prophylaxis (PEP), and condoms

TABLE 412-1 Common LGBTQIA+ Terminology and Definitions

TERM	DEFINITION
Agender	Identifying as having no gender, or does not experience gender as a primary identity component.
Asexual	Experiencing little or no sexual attraction to others. Asexual people may still engage in sexual activity.
Assigned female at birth/ assigned male at birth	Refers to the sex that is assigned to an infant, most often based on the infant's anatomic and other biological characteristics. Commonly abbreviated as AFAB (assigned female at birth) or AMAB (assigned male at birth).
Bisexual	A sexual orientation that describes a person who is emotionally and physically attracted to more than one gender.
Cisgender	A person whose gender identity is consistent in a traditional sense with their sex assigned at birth; for example, a person assigned female sex at birth whose gender identity is woman/female. The term cisgender comes from the Latin prefix cis, meaning "on the same side of."
Cisnormativity	Cisnormativity is the assumption that everyone is cisgender, or that being cisgender is the only "normal" gender identity. Cisnormativity puts pressure on people to conform to binary notions of gender expression and gender identity. Cisnormativity can manifest as cissexism, the biased belief that cisgender identity is the superior gender identity. Individuals, communities, policies, and institutions can perpetuate cisnormativity and cissexism, and thus marginalize transgender and gender diverse people and communities.
Gay	A sexual orientation describing people who are primarily emotionally and physically attracted to people of the same gender identity as themselves. Commonly used as an umbrella term for "not straight."
Gender-affirming hormone therapy (GAHT)	Feminizing and masculinizing hormone treatment to align secondary sex characteristics with gender identity.
Gender-affirming surgery (GAS)	Surgeries to modify a person's body to be more aligned with that person's gender identity. Types of GAS include chest and genital surgeries, facial feminization, body sculpting, and hair removal.
Gender-affirming chest surgery	Surgeries to remove and/or construct a person's chest to be more aligned with that person's gender identity. Also referred to as top surgery. Types of chest surgeries include: • Feminizing breast surgery: breast augmentation, chest construction, or breast mammoplasty • Masculinizing chest surgery: mastectomy (removal of breast tissue) and chest contouring
Gender-affirming genital surgeries	Surgeries that help align a person's genitals and/or internal reproductive organs with that person's gender identity, including: • Clitoroplasty (creation of a clitoris) • Hysterectomy (removal of the uterus; may also include removal of the cervix, ovaries, and fallopian tubes) • Labiaplasty (creation of inner and outer labia) • Metoidioplasty (creation of a masculine phallus using testosterone-enlarged clitoral tissue) • Oophorectomy (removal of ovaries) • Orchiectomy (removal of testicles) • Penectomy (removal of the penis) • Phalloplasty (creation of a phallus) • Scrotoplasty (creation of a scrotum and often paired with testicular implants) • Urethral lengthening (to allow voiding while standing) • Vaginectomy (removal of the vagina) • Vaginoplasty (creation of a neo-vagina) • Vulvoplasty (creation of a vulva)
Gender dysphoria	Distress experienced by some people whose gender identity does not align with their sex assigned at birth based on societal expectations; or distress experienced when a person's gender identity and/or gender expression is not affirmed. The degree and severity of gender dysphoria is highly variable among transgender and gender diverse people.
Gender expression	The ways in which people present their gender identity to others, such as through gait, mannerisms, voice, dress, and hairstyle. Cultural and historical contexts influence how people interpret and express gender identity.
Gender identity	A person's inner sense of being a girl/woman/female, boy/man/male, both, neither, or beyond the gender binary.
Gender queer	Describes people whose gender identity goes beyond the gender binary.
Heterosexual	A sexual orientation that describes women who are emotionally and sexually attracted to men, and men who are emotionally and sexually attracted to women. Also referred to as straight.
Heteronormativity	Heteronormativity is the assumption that everyone is heterosexual, or that being heterosexual is the only "normal" sexual orientation. Heteronormative social systems incentivize conforming to the behavior and appearance of heterosexuality. Heteronormativity can manifest as heterosexism, the biased belief that heterosexual identity is the only valid sexual orientation. Individuals, communities, policies, and institutions can perpetuate heteronormativity and heterosexism, and thus marginalize queer people and communities.
Intersex	Describes a group of congenital conditions in which the reproductive organs, genitals, and/or other sexual anatomy do not develop according to traditional expectations for females or males. Intersex can also be used as an identity term for someone with one of these conditions. The medical community sometimes uses the term differences of sex development (DSD) to describe intersex conditions; however, the term intersex is recommended by several intersex community members and groups (Chap. 402).
Lesbian	A sexual orientation describing a woman or non-binary person who is primarily emotionally and physically attracted to women.
Men who have sex with men (MSM)/women who have sex with women (WSW)	Categories used in research and public health to describe those who engage in same-sex sexual behavior, regardless of their sexual orientation. People rarely use the terms MSM or WSW to describe themselves.
Pangender	Describes a person who has multiple gender identities.
Pansexual	A sexual orientation describing a person who can be emotionally and/or physically attracted to people of any gender identity or gender expression.
Pronouns	Pronouns are words used in place of a person's name. Examples of pronouns are she/her/hers, they/them/theirs, he/him/his. Neopronouns are new pronouns that people may use to affirm their gender identity; examples include: xe/xem/xyr and ze/hir/hirs. Some people use their name instead of pronouns.

(*Continued*)

TABLE 412-1 Common LGBTQIA+ Terminology and Definitions (Continued)

TERM	DEFINITION
Queer	An umbrella term used by some to describe people who think of their sexual orientation or gender identity as outside of societal norms. Some people view the term as more fluid and inclusive than traditional categories for sexual orientation and gender identity. Although queer was historically used as a slur, it has been reclaimed by many as a term of empowerment. Nonetheless, some still find the term offensive.
Questioning	Describes an individual who is unsure about or is exploring their own sexual orientation and/or gender identity.
Same-sex attraction (SSA)	Describes the experience of a person who is emotionally and/or physically attracted to people of the same gender. Used most commonly by people who live in religious communities that are not accepting of LGBTQIA+ identities.
Sexual orientation	How a person experiences their physical, emotional, and romantic attachments to other people.
Trans man/transgender man	A transgender person whose gender identity is boy/man/male may use these terms to describe themselves. Some will use the term man.
Trans woman/transgender woman	A transgender person whose gender identity is girl/woman/female may use these terms to describe themselves. Some will use the term woman.
Transgender	An umbrella term for people whose gender identity does not align with the sex they were assigned at birth, based on societal expectations.
Two-spirit	Describes a person who embodies both a masculine and a feminine spirit. This is a culture-specific term used among some Native American, American Indian, and First Nations people. Abbreviated as 2S.

Note: It is important to note that definitions vary across communities, that they change over time, and that not all LGBT people agree with all these definitions.

Source: From *https://www.lgbtqiahealtheducation.org/glossary/en/.*

to prevent HIV and STIs. Additionally, if you are seeing a transgender man, it will be important to know if he still has natal female genitalia to ensure appropriate cancer screening, desire for having biologic children, and contraceptive needs. Notably, many if not most transgender people have not had gender affirmation surgery and retain their natal sex organs.

Creating a Welcoming and Safe Health Care Environment

Hospitals and clinics can take a number of steps to create a welcoming and safe space for LGBTQIA+ patients. This starts by establishing and communicating a nondiscrimination policy that clearly includes gender identity, gender expression, and sexual orientation protections. Additionally, hospitals and clinics can develop and implement an equal visitation policy to ensure equal visitation for LGBTQIA+ patients from same-sex partners, parents, and other family and friends. Staff training in LGBTQIA+ patient-centered care also is a key component of creating inclusive health environments. This includes covering LGBTQIA+ cultural competency, caring for LGBTQIA+ patients, creating an inclusive environment for LGBTQIA+ patients and staff, and other topics important for LGBTQIA+ health.

TABLE 412-2 Outdated and Insensitive Terms to Replace

OUTDATED TERM	RECOMMENDED TERM
Berdache	Two-spirit
Biological female/male	Assigned female/male at birth
Cross-sex hormone therapy; hormone replacement therapy	Gender-affirming hormone therapy
Disorders/differences of sex development	Intersex
Female-to-male (FTM) and male-to-female (MTF)	Transgender man and transgender woman
Gender nonconforming	Gender nonbinary
Hermaphrodite/ambiguous genitalia	Intersex
Homosexual	Gay or lesbian
Legal name	Administrative name or name on legal documents
Preferred name	Chosen name or name used
Preferred pronouns	Pronouns
Sex change/sex reassignment surgery/ gender reconstruction surgery	Gender-affirming surgery
Sexual preference/lifestyle	Sexual orientation
Transgendered	Transgender

Note: Most people consider the listed terms outdated and insensitive. We recommend replacing these words with the suggested terms provided.

Source: Reproduced with permission from LGBTQIA+ Glossary of Terms for Health Care Teams 2020. *https://www.lgbtqiahealtheducation.org/publication/lgbtqia-glossary-of-terms-for-health-care-teams/.*

As hospitals and clinics continue to adopt electronic health records, collecting sexual orientation and gender identity information becomes increasingly important to delivering personalized care to LGBTQIA+ individuals. It allows providers to monitor quality of care, track population-based outcomes, and collect more accurate information for research purposes. Most of this information can be captured by three questions:

- *How do you think of yourself?* As straight or heterosexual; lesbian, gay, or homosexual; bisexual; something else; don't know; choose not to disclose.
- *What is your current gender identity?* Male; female; transgender male/trans man; transgender female/trans woman; genderqueer, neither exclusively male nor female; additional category, please specify; choose not to disclose.
