Frailty, independent of walk distance, has also been recognized increasingly as a marker of poor outcome after lung transplantation and can be assessed using a number of instruments, including the Short Physical Performance Battery (SPPB), Fried Frailty Phenotype (FFP), and others. Most studies utilizing these instruments have been conducted at single centers. While both SPPB and FFP have been shown to correlate with the LAS, FFP has a stronger correlation, and SPPB and FFP may not correlate with each other. The Lung Transplant Frailty Scale (LT-FS) incorporates body composition and serum biomarker measurements and has been demonstrated to be a better predictor of outcomes in the lung transplant population compared to other assessments.

Patients with a history of malignancy are generally required to have experienced a period of remission prior to consideration for transplantation. The necessary length of disease-free survival should be determined in the context of the type of malignancy, stage at diagnosis, and likelihood of recurrence, and often varies by program.

A history of respiratory infection and colonization with resistant organisms is of particular concern in the CF and bronchiectasis populations, although it could affect patients with any advanced lung disease and a history of respiratory infection. Data on outcomes in the presence of resistant *Pseudomonas aeruginosa* infection are conflicting, but, in general, patients who have demonstrated a response to an antimicrobial regimen, even if colonized with resistant organisms, can be considered for transplantation. *Burkholderia cepacia* complex, another group of gram-negative organisms that can infect patients with CF, also presents a unique concern for transplantation. Data show that *B. cenocepacia* (formerly known as Genomovar III) portends the highest risk after transplant, often leading to bacteremia, abscess formation, and early mortality. *B. dolosa* and *B. gladioli* may cause similar posttransplant complications. Patients colonized with other *Burkholderia* species appear to have posttransplant outcomes comparable with the noncolonized population. Published guidelines suggest that those programs offering transplantation to patients colonized with *B. cenocepacia* do so under a research structure and after a specific discussion of the risks of transplantation in this setting with the patients. Other infectious considerations in lung transplant candidates include mycobacterial infections, particularly with rapidly growing organisms such as *M. abscessus*, which can lead to chronic, refractory infections and infections of the chest wall. In the case of fungal infection, assessment of the pathogenicity of the organism, resistance patterns, and, in some cases, responsiveness to pretransplant treatment is beneficial in determining the safety of transplantation.

A history of viral infections such as hepatitis and human immunodeficiency virus (HIV) is generally not considered a contraindication to transplantation. Demonstration of adequate control of infection and responsiveness to therapy are important in preparation for transplantation, and development of a treatment plan that minimizes toxicity and drug interactions, in consultation with transplant pharmacy, should be completed prior to placement on the wait list. Collaborative assessment with transplant infectious disease experts is beneficial whenever the infectious history is a concern for transplant safety.

Nutritional status is another important element to assess in determining candidacy for lung transplantation. Nutritional status has been shown to have a U-shaped relationship with transplant outcomes, with increased mortality risk associated with both underweight (body mass index [BMI] <18) and obesity (specifically BMI >35). Consultation with nutritional experts may allow for modification of this risk prior to transplant. In some underweight patients, placement of an enteral feeding tube and initiation of enteral feedings may be considered.

Psychosocial assessment is also a key component of the evaluation of patients under consideration for lung transplantation, and a multidisciplinary approach with transplant social work, psychiatry, and financial care coordination is often helpful. Assessment for and optimization of psychiatric disorders such as anxiety and depression, which can be exacerbated in the setting of transplantation, substance abuse disorders, and compliance with medical therapy recommendations are all important parts of the pretransplant evaluation. Perioperative pain management planning in the setting of medical therapy for opioid use disorder may require additional multidisciplinary input, but the need for this management plan alone should not preclude transplantation. Transplant candidates require a strong support system given their potential posttransplant care needs. Additionally, confirmation of insurance coverage for all phases of transplant care, expected medication copayments, and financial resources to support other expenses in the setting of transplantation should be completed during the transplant evaluation. Fundraising opportunities and subsidies for medications may need to be pursued in order to proceed safely with listing.

LUNG TRANSPLANT CANDIDATE MANAGEMENT

Lung transplant candidates benefit from meticulous medical care to ensure that they are in optimal condition at the time of transplant. Oxygen is prescribed to maintain adequate systemic oxygenation to allow for moderate physical activity and exertion. Patients should be enrolled in pulmonary rehabilitation programs, if available, and should continue to participate in daily physical exercises.

Patients with pulmonary vascular disease and severe pulmonary hypertension awaiting lung transplantation need special attention to maintain adequate right ventricular function. The use of pulmonary vasodilator therapy is recommended and should not be stopped prior to transplant. Patients who develop secondary pulmonary hypertension should also be assessed for the utility of direct pulmonary vasodilator therapy. Periodic assessment of right ventricular function with echocardiography is recommended, and in patients with clearly worsening ventricular function, right heart catheterization and assessment for responsiveness to short-acting vasodilator therapy should be considered.

In restrictive lung disease patients awaiting transplant, consideration should be given to continuation of immune modulators and/or antifibrotic therapy. Available literature does not indicate that continuation of antifibrotic therapy in lung transplant candidates before transplant portends an increased risk of wound dehiscence or worsened outcomes after transplant. Additionally, increased pulmonary vascular resistance can occur in these patients as the disease progresses, and acute exacerbations have been shown to be associated with severe acute decrease in right ventricular function. Steroids have been utilized in the management of acute exacerbations; however, the negative sequelae of chronic steroid use on wound healing is well established. Therefore, steroid use should be limited as much as possible and, if unavoidable, should be tapered rapidly.

Patients with CF can have pancreatic dysfunction leading to difficulty in maintaining normal blood glucose levels; uncontrolled diabetes mellitus can make the management of posttransplant blood glucose very challenging. Therefore, optimization of diabetes management should be pursued prior to transplantation.

Despite optimal medical therapy, the underlying disease in wait-listed patients will almost always continue to worsen. Prioritization of patients awaiting lung transplant is determined by the CAS system. The LAS system was introduced in 2005 with the goal of minimizing wait-list mortality and maximizing posttransplant survival. This system focused on prioritizing candidates most at risk for death while awaiting transplantation, and its key modeling variables focused on survival metrics. The CAS was introduced in 2023. While incorporating survival as a key component, the CAS also includes variables related to special biological considerations such as blood type and sensitization with human leukocyte antigen (HLA) antibodies, which can impact time to transplantation,

as well as variables related to ethical and practical considerations such as patient access to transplant and efficiency of the planned procedure. In addition, the CAS aims to create an allocation system that addresses prioritization more continuously, rather than placing candidates within firm boundaries or groups that create hard cutoffs for transplant access. While under the LAS patients continued to die at a rate of 10–12 patient deaths per 100 patient-years on the wait list, models of CAS allocation suggest expected improvements in both wait-list mortality and post-transplant survival, as well as improvements in equity in access to transplantation. Further studies of the actual results after implementation will be needed to confirm these expectations.

A major consequence of improved efficiency in matching the sickest patients to the available pool of donors has been an increased use of extracorporeal membrane oxygenation (ECMO) devices to bridge the most critically ill patients to transplant. Mechanical circulatory support with ECMO allows for patients to be potentially weaned from the ventilator, to maintain physical activity and ambulation, and to be in a state of greater robustness as they await transplant. The posttransplant survival rate of patients bridged to transplant with ECMO is equivalent to those transplanted without the need for ECMO in experienced, high-volume centers and better than patients who had previously been transplanted directly from mechanical ventilatory support. Furthermore, with improvements in membrane oxygenator technology, platform miniaturization, and improvements in cannula design, outcomes continue to improve.

DONOR CONSIDERATIONS

The ideal lung donor has remained constant since the inception of lung transplantation in the 1980s **(Table 309-2)**. A donor between 25 and 40 years of age, with a Pao_2/Fio_2 ratio >350, no smoking history, a clear chest x-ray, clean bronchoscopy, and minimal ischemic time is considered the ideal donor; however, it is quite rare that a donor meets all of these criteria for transplantation. In fact, the vast majority of donor lungs used for transplant fall outside these ideal lung donor criteria as established more than three decades ago. Donors must have irreversible brain injury, and the majority of donors are brain dead. Only 20% of all donors with brain death are suitable lung donors due to the development of severe neurogenic pulmonary edema and increased susceptibility of potential lung allografts to infection and injury.

Absolute contraindications to lung donation include radiographic evidence of chronic lung disease such as emphysema and pulmonary fibrosis. Other absolute contraindications include active malignancy, a donor history of severe asthma requiring multiple hospitalizations, and positive HIV status. Relative contraindications include older donor age, severe thoracic trauma with extensive pulmonary contusions, the presence of pulmonary hypertension, and prolonged donor hypotension or acute hypoxemia.

The standard lung donor evaluation includes a donor medical and social history, physical examination, and laboratory examination. Chest imaging is mandatory, as are arterial blood gases, bronchoscopy, and serologic tests for cytomegalovirus (CMV), Epstein-Barr virus (EBV), hepatitis B and C, HIV, *Toxoplasma*, rapid plasma reagin, and herpes simplex virus. The presence of consolidation and atelectasis, while not absolute contraindications to transplant, are often difficult to assess with noncontrast radiographic imaging alone. Ventilation parameters must be evaluated to ensure adequate compliance of the donor lungs, with peak airway pressures <30 cmH_2O being ideal. Direct on-site inspection of the lungs and assessment for nodules, compliance, and full expansion are the final necessary steps before acceptance of donor lungs for transplant.

TABLE 309-2 Characteristics of the Ideal Lung Donor

Donor age	<55 years
ABO compatibility	Identical
Chest radiograph	Clear
$Pao_2:Fio_2$	>300 on PEEP 5 cmH_2O
Tobacco history	<20 pack-years
Chest trauma	Absent
Evidence of aspiration	Absent
Prior thoracic surgery	None
Sputum Gram stain	Negative
Bronchoscopy findings	No purulent secretions

Abbreviation: PEEP, positive end-expiratory pressure.

More recently, there has been an expanded use of allografts from donors after cardiac death (DCD) due to the ability to rehabilitate donor lungs using ex vivo lung perfusion (EVLP). DCD donors are patients who present with irreversible brain injury but without overt brain death. The potential donor allografts are often exposed to a period of prolonged warm ischemia during the donation process; there has been a concern about early graft dysfunction after DCD donation. Steen and colleagues in Lund demonstrated that EVLP could be used to assess these marginal donors prior to transplant. The landmark publication of the Normothermic Ex Vivo Lung Perfusion in Clinical Lung Transplantation trial in 2011 generated renewed interest in DCD lung donors. The group from the University of Toronto was also able to demonstrate that brain-dead donors with unacceptable donor lung parameters could be rehabilitated with the use of EVLP. They were able to salvage up to 50% of selected unsuitable donor lung allografts with the use of acellular normothermic hyperosmotic perfusion with excellent short-term outcomes.

Donor Management Brain death causes severe perturbations in the potential donor lung allograft function. The development of severe pulmonary edema often accompanies brain death. The hemodynamic instability and neurogenic shock that can accompany brain death are also major stressors on the preservation of donor allograft function. The primary goal of donor management is, therefore, the maintenance of hemodynamic stability and preservation of donor lung function. Judicious fluid resuscitation and avoidance of excessive resuscitation should be employed. Volume replenishment should be limited to maintain the central venous pressure between 5 and 8 mmHg. In general, crystalloid fluid boluses are to be avoided. Diabetes insipidus is common in donors and requires the use of intravenous vasopressin to prevent excessive urine loss. In general, blood transfusions should be avoided; however, if necessary, CMV-negative and leukocyte-filtered blood should be used whenever possible. Hypothermia should be avoided as it predisposes to ventricular arrhythmias and metabolic acidosis.

Excessive oxygen delivery should be minimized to prevent free-radical injury to the potential lung allograft. Positive end-expiratory pressures on the ventilator should be maintained to avoid the development of atelectasis. More recently, airway pressure release modes of ventilation have been utilized to preserve lung function and minimize barotrauma from prolonged ventilation.

PROCUREMENT OPERATION

Prior to incision, a thorough bronchoscopic evaluation is completed. The anatomy of the donor airways is defined. Any secretions that may be present are evacuated, and the airways are examined to rule out the presence of any lesions or masses. The epithelial lining is inspected for evidence of excessive friability and hemorrhage, which may indicate significant infection. A median sternotomy incision is employed to access the chest for lung procurement. The pleural spaces are opened and both lungs are inspected, palpated, and gently recruited to evaluate for suspicious nodules, consolidation, and/or pulmonary infarction.

The donor is systemically heparinized, and the main pulmonary artery is cannulated. Fifteen minutes prior to initiation of the explant, prostacyclin is introduced into the main pulmonary artery and allowed to circulate through the lungs. This vasoreactive prostanoid helps to ensure adequate pulmonary flush by dilating the pulmonary vasculature. The heart is arrested first, then the pulmonoplegia solution is instilled into the lungs at a low controlled pressure. Topical iced-saline solution is instilled into both pleural spaces. After the heart has been explanted, the individual pulmonic veins are flushed retrogradely. The lungs are then re-expanded, the trachea is clamped, and the explanted allograft is stored in ice-cold saline solution for transport. If the right and left lungs are being procured for different recipients, the posterior

left atrium, the main pulmonary artery, and the left main-stem bronchus are divided to separate the right and left lungs, and the organs are stored and shipped separately. New preservation technologies and studies of optimal temperature for storage and transport may allow for longer transport times and time to implantation. Investigations of the impacts of these advances are ongoing.

RECIPIENT OPERATION AND EARLY POSTTRANSPLANT CONSIDERATIONS

Recipient Operation The recipient operation can be divided into two parts. The first part involves the explant of the native lung, and the second part involves the implant of the new lung. There are generally three main surgical approaches to the completion of the operation: a right or left thoracotomy, a transverse thoracosternotomy (clamshell), or a median sternotomy. These approaches are all favored by various centers for different benefits. The thoracotomy approach allows for explant and implant of donor lungs without the use of cardiopulmonary bypass (CPB) and is often the preferred approach for single-lung transplant. The clamshell incision offers the advantages of increased exposure compared to either thoracotomy or median sternotomy but comes at the cost of greater morbidity and postoperative wound complications. This incision can be used to perform bilateral lung transplants and allows for the possibility of avoiding CPB. A median sternotomy approach can be used to perform bilateral lung transplant. This approach offers the advantage of fewer wound complications, less postoperative pain, and flexibility with more complex or concomitant cardiac procedures at the time of lung transplant. This approach mandates the use of CPB. The routine use of CPB allows for early pneumonectomies without hemodynamic compromise and can significantly reduce the ischemic time to the second allograft. Additionally, overcirculation to the first allograft can be minimized with the routine use of CPB. Others prefer to avoid CPB as avoidance may be associated with decreased need for blood product administration and lower incidence of primary graft dysfunction.

Over the past 5 years, there has been a movement away from CPB for mechanical circulatory support toward ECMO. ECMO is an alternative strategy for providing hemodynamic and pulmonary support of the patient undergoing lung transplantation. The key difference between CPB and ECMO is the ability to salvage shed blood with CPB, the use of a blood reservoir with CPB, and the ability to filter air from the venous system before it is delivered to the arterial circuit with CPB. This flexibility is provided by exposing the blood in the system to a much larger foreign surface and has been associated with significantly increased inflammation and tendency for thrombosis. Therefore, ECMO requires much lower levels of anticoagulation than CPB. The advantages of ECMO-supported lung transplantation are a tendency toward less blood product administration and, in situations in which CPB support periods are longer (>180 min), a tendency to decreased rates of primary graft dysfunction. Data suggest that the use of ECMO for mechanical support during lung transplant is safer than lung transplant with no mechanical support, and the recommendation is to use ECMO for all cases. Its use may especially be helpful for cases that are expected to require longer support times. Careful attention to avoid the entrainment of air into the circuit is mandatory throughout the ECMO support period.

Anesthetic monitoring for lung transplant should include arterial pressure monitoring, pulse oximetry, continuous electrocardiographic monitoring, temperature monitoring, and urine output monitoring. Large-bore IV access and central venous access are vital to manage the patient safely. On a selective basis, pulmonary artery pressure monitoring and transesophageal echocardiographic monitoring may be useful. For patients without the planned use of CPB, double-lumen endotracheal tubes are mandatory, whereas they can be avoided for patients transplanted on CPB.

Once access to the thorax has been completed, the hilar structures are isolated and divided. The bronchial anastomosis is completed first, and the anastomosis is checked to ensure that it is secure by insufflating the lung gently while keeping the anastomosis under saline solution to observe for bubbles. The donor left atrial cuff incorporating the pulmonary vein is connected to the native left atrium, and the donor right or left pulmonary artery is connected to the native pulmonary artery. After completion of the vascular anastomoses, the lungs are gently reperfused. During this early reperfusion period, lung-protective ventilation strategies are employed and oxygen tension is reduced. The patient is transitioned to normal ventilation, drains are placed in the thoracic cavity, and the wounds are closed.

Induction of Immunosuppression Initiation of immunosuppression starts with induction of the patient under general anesthesia. Many programs utilize an induction agent (most commonly an interleukin 2 [IL-2] receptor/CD25 antagonist, but antithymocyte globulin, anti-CD52 monoclonal antibodies, or other induction agents may also be used), and systemic corticosteroids and purine modulators are administered after induction is complete. If an IL-2 receptor antagonist is utilized for induction, a second dose is administered 4 days after the original dose. An additional dose of methylprednisolone is administered after allograft reperfusion in the operating room. Three-drug immune suppression is initiated with a calcineurin inhibitor, purine modulator, and continued systemic corticosteroids. In patients with severe acute renal dysfunction, calcineurin inhibitor initiation may be delayed.

Perioperative Considerations and Complications Early morbidity and mortality after lung transplant most commonly are sequelae of primary graft dysfunction or infection. Very rarely, hyperacute rejection has been observed; however, with the implementation of robust systems to ensure ABO and HLA compatibility at the time of transplant, the occurrence of hyperacute rejection is extremely uncommon. Primary graft dysfunction (PGD) encompasses a constellation of findings that result in poor early graft function after transplant. This phenomenon is often the consequence of ischemia-reperfusion injury in the allograft and is not related to infection or rejection. It is characterized by a diffuse pattern of infiltrates on the chest x-ray and poor pulmonary gas exchange with Pao_2:Fio_2 ratios <300, with severe PGD characterized by diffuse severe infiltrates and a Pao_2:Fio_2 ratio of <100 at 72 h posttransplant. Most cases of PGD are mild and self-limiting, resolving with supportive care. However, if the PGD is severe and worsening despite maximal medical therapy, diuresis, inotropic therapy, maximal ventilation support, and paralysis of the patient, mechanical circulatory support with ECMO can become necessary. The incidence of severe PGD has been steady over the past two decades at approximately 10–15% in most programs. Severe PGD at 72 h posttransplant portends an increased mortality risk and is a risk factor for chronic lung allograft dysfunction (CLAD).

Bacterial, viral, and fungal infections are leading causes of morbidity and mortality in lung transplantation. The lung is one of the few solid organs that is in continuous contact with the environment. Each breath has the potential to introduce new organisms, and the reduced lymphatic function and mucociliary clearance in the transplanted lung increase the risk of serious infection. The highest incidence of infection is early after lung transplant and coincides with the intensity of immune suppression. Early infections, occurring within the first month after transplantation, are commonly bacterial (especially gram-negative bacilli) and manifest as pneumonia, mediastinitis, urinary tract infections, catheter sepsis, and skin infections. Patients can develop pathogenic infections with organisms associated with pretransplant colonization, and perioperative antibiotic regimens are often deployed to address this. Viral infections, and CMV infections in particular, can lead to severe recipient disease and early loss of graft and life. The majority of transplant programs employ antiviral prophylaxis in the early transplant period to avoid such complications. Invasive fungal infections peak in frequency between 10 days and 2 months after transplantation. Fungal prophylaxis regimens in the early posttransplant period vary widely. Treatment consists of inhaled amphotericin B in the setting of airway infection and/or azole therapy with more advanced or invasive disease. The institution of prophylaxis with oral trimethoprim-sulfamethoxazole (or atovaquone or inhalational pentamidine for sulfa-allergic patients) has effectively prevented *Pneumocystis* pneumonia. The risk of *Pneumocystis* infection is highest

during the first year after transplant. However, as infections can also occur late after transplant, most centers recommend prophylactic therapy be continued for life.

LONG-TERM MANAGEMENT OF LUNG TRANSPLANT RECIPIENTS

While survival after lung transplantation continues to improve by era, the survival rates in this group are lower than in other solid-organ cohorts. Approximately 50% of lung transplant recipients will experience at least one episode of acute rejection in the first posttransplant year, and by 5 years posttransplant, approximately half will have developed chronic rejection. As a result, posttransplant immune suppression regimens may be more aggressive than in other solid-organ recipients, as described above. The immunosuppressive regimen must be balanced against the potential toxicities that accrue with these medications over time.

Acute cellular rejection in lung transplant recipients is most common in the first posttransplant year, with a decreased but not absent frequency thereafter. Infections can stimulate cellular rejection, most clearly demonstrated in the setting of CMV infection, but also noted after other infections. Most programs incorporate a schedule of routine surveillance bronchoscopy to assess for acute cellular rejection posttransplant. Donor-derived cell-free DNA, which is produced in the setting of cell turnover and parenchymal injury, is increasingly being explored as a noninvasive method of detection of allograft dysfunction, most importantly in the setting of acute and chronic rejection. Acute cellular rejection manifests as a lymphocytic infiltrate involving the distal small vessels and capillaries and/or a lymphocytic bronchiolitis involving the distal airways of the lung. Acute cellular rejection, a risk factor for the development of CLAD, is treated with augmented immune suppression. Antibody-mediated rejection in its classic form is a neutrophilic vasculitis associated with the small vessels and capillaries of the lung, with associated deposition of by-products of the complement cascade, in the setting of allograft dysfunction and circulating donor-specific HLA antibodies in the blood. The manifestations of antibody-mediated rejection in the lung allograft are less specific than in other organs. Further research is ongoing into the diagnostic and treatment considerations of this entity in lung transplantation.

CLAD is an overarching description of the syndrome of long-term allograft rejection. The classic manifestation of CLAD is obliterative bronchiolitis, the development of fibrinous material within the distal airways that leads to small-airways obstruction. As transbronchial biopsies are insensitive for diagnosing obliterative bronchiolitis, a clinical diagnostic designation of bronchiolitis obliterans syndrome can be made when specific PFT criteria are met and other causes of PFT decline are excluded. CLAD can also present as a restrictive phenotype, with imaging demonstrating upper lobe–predominant pleural thickening, small lung volumes, and interstitial changes on high-resolution computed tomography (CT). Numerous therapies for CLAD have been utilized, including azithromycin, montelukast, extracorporeal photopheresis, alemtuzumab, and others, with varying degrees of success.

Infection is a significant complication of lung transplantation, with persistent risk over the lifetime of the transplant recipient. As time progresses, the chance of opportunistic infection increases. The risk of bacterial infection and fungal infection remains, and can affect the lung parenchyma, airways and anastomotic sites, and other organs. Viral infections, such as CMV reactivation and infection, EBV-associated posttransplant lymphoproliferative disease, and other rarer infections, can also develop in the later posttransplant setting as well.

Numerous longer-term medical complications can be seen in lung transplant recipients. Essential hypertension, diabetes mellitus, chronic renal insufficiency, and bone loss are some examples of chronic medical conditions observed following transplantation. A multidisciplinary approach to care that involves the patient's primary care physician, local pulmonologist, and appropriate subspecialists, along with transplant pharmacy, as well as social work and care coordination, is beneficial in addressing the complex needs of lung transplant recipients over time. Predictors of short- and long-term outcomes after lung transplantation are outlined in Table 309-3.

TABLE 309-3 Predictors of Survival After Lung Transplantation

	1-YEAR SURVIVAL	≥10-YEAR SURVIVAL
Donor factors	HCV donor	
Recipient factors	Age <70 years Diagnosis other than pulmonary fibrosis, pulmonary hypertension, sarcoidosis, A1AT O_2 requirement <5 L CI >2 Outpatient at time of transplant Preserved recipient eGFR Total bilirubin <2	Age 18–35 years
Donor/recipient factors	Non–female-to-male transplant Donor/recipient weight ratio >0.7	Higher levels of HLA matching
Operative factors	Avoidance of unplanned conversion to cardiopulmonary bypass Decreased ischemic time	Bilateral lung transplant
Posttransplant factors	PaO_2/FIO_2 >260 at 72 h Absent need for postoperative ECMO support	Fewer hospitalizations for rejection
Other factors	Higher center volume	Higher center volume

Abbreviations: A1AT, α_1 antitrypsin deficiency; ECMO, extracorporeal membrane oxygenation; eGFR, estimated glomerular filtration rate; Fio_2, fraction of inspired oxygen; HCV, hepatitis C virus; HLA, human leukocyte antigen; Pao_2, partial pressure of oxygen.

310 Interventional Pulmonary Medicine

Lonny Yarmus, David Feller-Kopman

Interventional pulmonary medicine is a subspecialty of pulmonary and critical care medicine focusing on the evaluation and management of patients with thoracic malignancy, central airway obstruction, pleural disease, and advanced obstructive lung disease such as chronic obstructive pulmonary disease (COPD)/emphysema and asthma. Novel minimally invasive interventions have drastically changed the way we care for patients. In this chapter, we will summarize recent developments and evolving technologies in interventional pulmonology (IP).

DIAGNOSTIC BRONCHOSCOPY

With the introduction of the rigid bronchoscope by Gustav Killian in 1897, the mortality associated with foreign-body aspiration dropped from over 90% to less than 5%, as patients no longer had to suffer from airway obstruction and postobstructive pneumonia. Shigeto Ikeda developed the flexible bronchoscope in 1967, allowing access to the peripheral airways and lung parenchyma. In 2018, the first robotic-assisted bronchoscopy platforms were introduced, providing a novel approach with the ability to reach further into the peripheral lung reliably with precise control. Bronchoscopy has remained an important diagnostic and therapeutic procedure, and recent technology has significantly increased its utility.

ENDOBRONCHIAL ULTRASOUND

The diagnosis and staging of lung cancer remain one of the most important roles of advanced diagnostic bronchoscopy and IP. Convex endobronchial ultrasound (cEBUS) is a flexible bronchoscope combined with ultrasound technology that allows for real-time visualization during transbronchial needle aspiration (TBNA) of mediastinal and hilar lymph nodes and masses adjacent to the airways **(Fig. 310-1)**.

With a sensitivity of 90% and a specificity of 100%, cEBUS is the gold standard for lung cancer staging and can also provide sufficient tissue to perform molecular profiling to guide targeted therapies in lung cancer with adequacy rates for testing that exceed 95%. cEBUS is also extremely helpful in diagnosing mediastinal and hilar adenopathy due to sarcoidosis. The use of endobronchial ultrasound to diagnose lymphomas has historically been of limited utility owing to lack of tissue architecture in needle aspirates. However, advances in cEBUS using a cryobiopsy technique in lieu of needle aspirate have shown promise in providing adequate tissue and histopathologic architecture from intranodal cryobiopsy.

PERIPHERAL BRONCHOSCOPY

Evaluations of pulmonary nodules and lung masses are frequent indications for bronchoscopy as a way to achieve a minimally invasive diagnosis. Historically, the diagnostic yield of bronchoscopy to target peripheral pulmonary lesions was <60%. Multiple guidance platforms now allow for improved access in the periphery of the lung.

Smaller or ultrathin bronchoscopes <4 mm in diameter can be combined with available imaging tools to improve target localization. Radial-probe endobronchial ultrasound utilizes a radial scanning ultrasound probe that is inserted through the bronchoscope and into the lung, producing a real-time image of the target lesion. Electromagnetic navigation bronchoscopy (ENB) involves image-guidance systems that manipulate thin-slice computed tomography (CT) images to create virtual airway reconstructions used as guided maps during bronchoscopy. Robotic-assisted bronchoscopic platforms offer the enhanced articulation and stability of a robotic arm, replacing the traditional flexible bronchoscope. Recent innovation has allowed for advances in intraprocedural imaging. Mobile cone beam CT scanners in combination with advanced peripheral bronchoscopy allow for image confirmation of a biopsy within the lesion of interest. Studies are currently underway to explore further the utility of these systems for peripheral lesion biopsy and the impact of advanced imaging techniques.

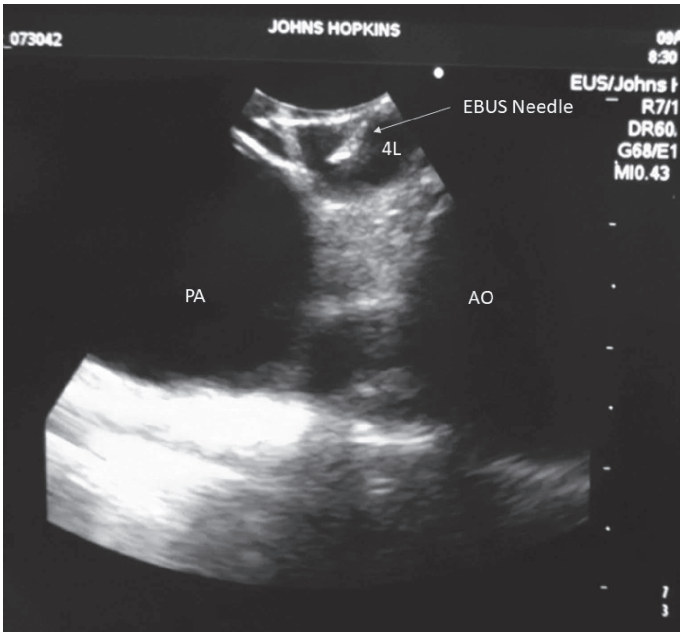

FIGURE 310-1 Endobronchial ultrasound transbronchial needle aspiration image of needle under ultrasound guidance sampling station 4L lymph node. AO, aorta; PA, pulmonary artery.

THERAPEUTIC BRONCHOSCOPY

Therapeutic bronchoscopy is indicated for the relief of malignant and nonmalignant central airway obstruction, asthma, and emphysema. Active research is also focusing on the utility of bronchoscopy for the ablation of early-stage lung cancer, as well as the treatment of chronic bronchitis.

CENTRAL AIRWAY OBSTRUCTION

Central airway obstruction (CAO) describes obstruction of the trachea, main stem bronchi, bronchus intermedius, and/or lobar bronchi, and can present as intrinsic (endoluminal), extrinsic (extraluminal), or mixed (extraluminal tumor resulting in mass effect and endoluminal involvement) **(Fig. 310-2)**. The differential diagnosis of CAO is shown in **Table 310-1**.

Patients often initially present with cough and exertional dyspnea, but then progress with increasing severity of obstruction to dyspnea at rest, stridor, and respiratory failure. Patients may also have wheezing, hemoptysis, or symptoms of postobstructive infection. Rigid bronchoscopy is the preferred tool to manage CAO in conjunction with ablative therapies, balloon bronchoplasty, and airway stenting to offer rapid symptomatic relief with immediate reductions in the level of required care. Therapeutic bronchoscopy for CAO has been shown to significantly improve both quality of life and survival.

ABLATIVE THERAPIES FOR CAO

Ablative therapy in the airway consists of both heat (laser, electrocautery, and argon plasma coagulation) and cold (cryotherapy) modalities. These techniques are most commonly used to destroy tumor and provide hemostasis. The cryoprobe can also be used for foreign-body removal. Other modalities, such as brachytherapy (BRT) and photodynamic therapy (PDT), have a delayed therapeutic effect and are often not suitable for situations where immediate relief of airway obstruction is desired.

BRONCHOPLASTY

Bronchoplasty (or bronchial dilation) can be achieved with the barrel of the rigid bronchoscope or with balloons that can be passed via the rigid or flexible bronchoscope. Bronchoplasty is most commonly used for dilation of stenotic airways or disruption of webs related to nonmalignant causes of airway diseases. Although dilation generally leads to immediate relief of the stenosis, results can be short-lived, and hence, this technique is often combined with airway stenting. Complications are rare but can include airway tears if proper techniques are not followed.

AIRWAY STENTING

After airway patency is achieved, airway stents can be utilized to prevent recurrence of CAO. Reports of endoscopically implantable stents for the airways date back to 1914. Airway stents are commonly used to treat patients with CAO due to extrinsic compression from a variety of malignant and nonmalignant disorders. Stents are effective and lead to symptomatic relief in >90% of patients. A variety of airway stents are available, each with its own benefits and detriments; it is important to choose the right stent for the specific indication. Stent complications are not uncommon and include migration, mucostasis, infection, and the development of granulation tissue. First-generation biodegradable stents, custom three-dimensional printed stents, and drug-coated

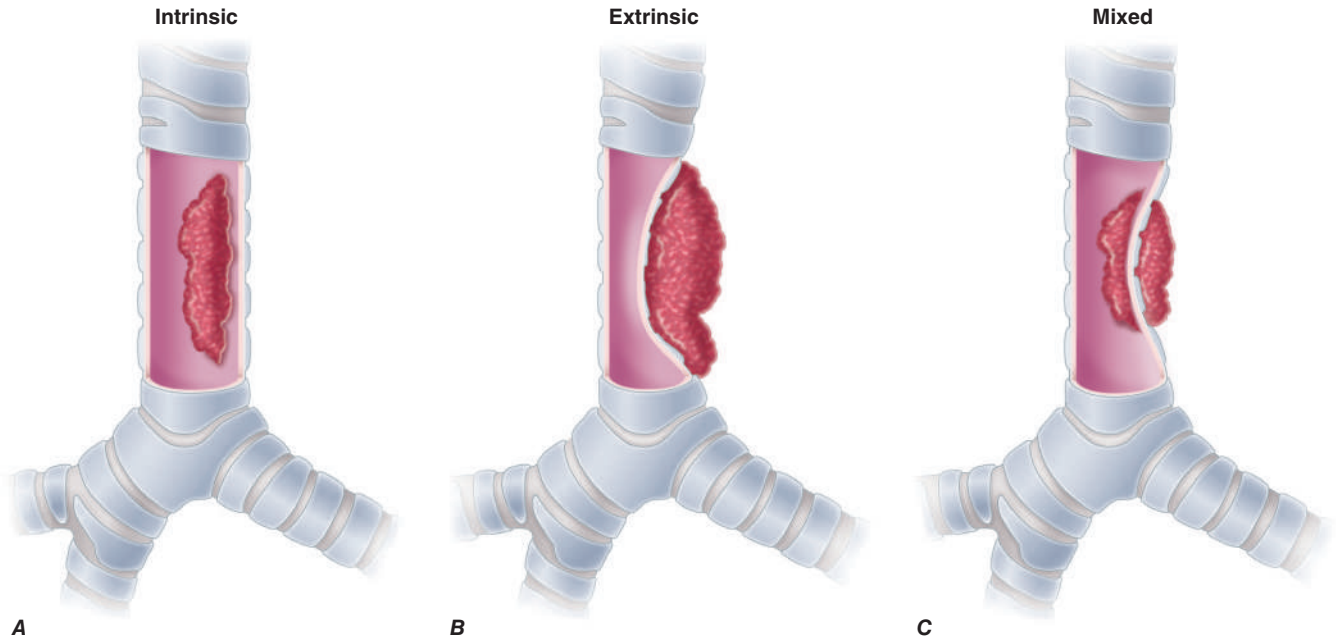

FIGURE 310-2 Types of central airway obstruction.

stents are currently being evaluated, working toward a personalized medicine approach wherein stents are tailored to an individual's airway anatomy and underlying disease.

ENDOBRONCHIAL INTRATUMORAL CHEMOTHERAPY

Endobronchial intratumoral chemotherapy (EITC) is an intervention aimed at improving and/or maintaining airway patency in patients with malignant CAO, with the potential to eliminate the need for airway stenting and its associated complications. Under bronchoscopic guidance, high-dose therapeutics can be safely injected directly into tumor to enhance response and limit systemic side effects. Multiple studies are ongoing to assess the efficacy of EITC.

TABLE 310-1 Differential Diagnosis of Central Airway Obstruction

MALIGNANT	NONMALIGNANT
Primary airway carcinoma	Lymphadenopathy
Bronchogenic	Sarcoidosis
Carcinoid adenoid cystic	Infectious (i.e., tuberculosis, histoplasmosis)
Mucoepidermoid	Cartilage
Metastatic carcinoma to the airway	Relapsing polychondritis
Bronchogenic	Granulation tissue from endotracheal tubes
Renal cell	Tracheostomy tubes
Breast	Airway stents
Thyroid	Foreign bodies

	Foreign-body goiter
	Mucus plug
	Blood clot

ABLATIVE THERAPIES FOR EARLY-STAGE LUNG CANCER

Bronchoscopic ablation of early-stage lung cancer has long been described as the "holy grail" of bronchoscopy due to the appeal of staging, diagnosing, and treating biopsy-proven early-stage lung cancer in one procedural setting. There is limited experience with bronchoscopic radiofrequency ablation (B-RFA) and microwave ablation (MWA) as a potential means to treat early-stage lung cancer. Ultimately, the efficacy of bronchoscopic ablation of early-stage nonoperable lung cancer must be proven in longitudinal studies demonstrating noninferiority in survival as compared to the current gold standard of stereotactic body radiation therapy (SBRT). To date, there are extremely limited safety and efficacy data for bronchoscopic ablation with multiple studies currently ongoing. Until there are adequate data to support the safe and effective use of this approach, bronchoscopic ablation is not recommended for clinical use.

BRONCHOSCOPIC THERAPIES FOR ASTHMA

Bronchial thermoplasty (BT) is a treatment for patients with severe persistent asthma who remain symptomatic despite maximal medical treatment that delivers radiofrequency energy to the airways to reduce their smooth muscle mass. A pivotal randomized clinical trial did not show a change in forced expiratory volume in 1 s (FEV_1) or airway hyperresponsiveness but was able to demonstrate an improvement in quality of life and reduction in exacerbation rates, visits to the emergency department, and days lost from school or work. At this time, the ideal asthma phenotypes and ideal candidates for this treatment modality remain to be determined, and thus, the utility of this approach remains limited.

BRONCHOSCOPIC THERAPIES FOR CHRONIC OBSTRUCTIVE PULMONARY DISEASE

The National Emphysema Treatment Trial (NETT), published in 2003, demonstrated that lung volume reduction (LVR) surgery for severe emphysema confers improved survival and exercise capacity in patients with upper lobe–predominant disease and poor exercise capacity. At the same time, it showed high perioperative morbidity and mortality. During the last decade, several bronchoscopic therapeutic modalities have been tested, including valves, coils, steam, stents, and foam, in

patients with severe emphysema to mimic the physiologic effects of surgical lung volume reduction (SLVR) in a less invasive fashion.

BRONCHOSCOPIC LUNG VOLUME REDUCTION

Bronchoscopic lung volume reduction (BLVR) via valve placement involves placement of one-way valves in airways leading to areas of the lung with significant emphysema, allowing air and mucus to exit but blocking air entry to achieve lobar collapse. Several clinical trials on BLVR with valves have demonstrated improvements in lung function and overall improvement in quality of life and exercise tolerance. The overall safety profile of these valve systems compares favorably with SLVR with a lower rate of perioperative morbidity and mortality.

PLEURAL INTERVENTIONS

Thoracic ultrasound has become invaluable in the evaluation of patients with pleural effusion and pneumothorax. Medical thoracoscopy (also called *pleuroscopy*) is a minimally invasive technique most commonly used to evaluate recurrent exudative pleural effusions and is associated with a diagnostic yield of >95%.

Indwelling pleural catheters (IPCs) have gained tremendous popularity and have been declared by evidence-based guidelines to be as acceptable as chemical pleurodesis for the management of symptomatic malignant pleural effusions. When comparing IPC and pleurodesis via talc slurry, two multicentered, open-label, randomized controlled trials demonstrated IPC effectively relieved dyspnea, decreased the duration of hospital stay, and lessened the need for future procedures. A recent study in patients without significant lung entrapment has shown that the outpatient administration of talc through an indwelling pleural catheter for the treatment of malignant pleural effusion resulted in a significantly higher chance of pleurodesis at 35 days than an indwelling catheter alone, with no deleterious effects.

Pleural infection (empyema or complex parapneumonic effusion) is commonly encountered in clinical practice. The mainstay of therapy typically consisted of antibiotics, drainage of the infected pleural space with tube thoracostomy, and possible need for surgical decortication. The landmark Multicenter Intrapleural Sepsis Trial (MIST2) demonstrated that intrapleural sequential administration of recombinant tissue plasminogen activator (rtPA) and DNase resulted in significant radiographic and clinical improvements and allowed >90% of patients to avoid surgery. Randomized controlled trials are currently underway comparing intrapleural administration of rtPA and DNase to surgical decortication.

PNEUMOTHORAX AND PERSISTENT AIR LEAK

Persistent air leak is defined as a nonresolving pneumothorax with an air leak lasting more than 5–7 days. For over a decade, the U.S. Food and Drug Administration has maintained a humanitarian device exemption for compassionate use of the Spiration Valve System for management of persistent air leak following lobectomy, segmentectomy, or LVR surgery, although the device has also been used "off label" for the treatment of persistent air leak due to primary and secondary spontaneous pneumothoraces.

SUMMARY

IP provides diagnostic and therapeutic options that span the spectrum of benign and malignant airway and pleural disorders. The constant innovations in diagnostic and treatment modalities have continued to help push the boundaries of pulmonary medicine.

Section 1 Respiratory Critical Care

311 Approach to the Patient with Critical Illness

Rebecca M. Baron, Anthony F. Massaro

The care of critically ill patients requires a thorough understanding of pathophysiology and centers initially on the resuscitation of patients at the extremes of physiologic deterioration. This resuscitation is often fast-paced and occurs early when a detailed awareness of the patient's chronic medical problems may not yet be possible. While physiologic stabilization is taking place, intensivists attempt to gather important background medical information to supplement the real-time assessment of the patient's current physiologic condition. Numerous tools are available to assist intensivists in the assessment of pathophysiology and management of incipient organ failure, offering a window of opportunity for diagnosing and treating underlying disease(s) in a stabilized patient. However, despite these tools, ongoing clinical bedside assessment is imperative for care of the critically ill patient. Indeed, the use of interventions to support the patient, such as mechanical ventilation and renal replacement therapy, is commonplace in the intensive care unit (ICU). An appreciation of the risks and benefits of such aggressive and often invasive interventions is vital to ensure an optimal outcome. Nonetheless, intensivists must recognize when a patient's chances for recovery are remote or nonexistent and must counsel and comfort dying patients and their significant others if an initial trial of invasive supportive care is either not effective or is not appropriate for the patient's current condition. Critical care physicians often must redirect the goals of care from resuscitation and cure to comfort when the resolution of an underlying illness is not possible. The COVID-19 pandemic has heightened the need and priority for effective critical care practices (Chap. 205), as well as the need for additional support for post-ICU care and recovery for ICU survivors

ASSESSMENT OF ILLNESS SEVERITY

In the ICU, illnesses are frequently categorized by degree of severity. Numerous severity-of-illness (SOI) scoring systems have been developed and validated over the past three decades. Although these scoring systems have been validated as tools to assess populations of critically ill patients, their utility in predicting individual patient outcomes at the bedside is not clear. Their utility may be more applicable toward defining patient populations for clinical trial outcomes and broader epidemiologic studies. SOI scores are also useful in guiding hospital administrative policies, directing the allocation of resources such as nursing and ancillary care, and assisting in assessments of quality of ICU care over time. Scoring system validations are based on the premise that age, chronic medical illnesses, and derangements from normal physiology are associated with increased mortality rates. All existing SOI scoring systems are derived from patients who have already been admitted to the ICU. Nevertheless, there has been increased recent clinical use of scoring systems due to revised consensus guidelines for definitions of sepsis, as will be detailed below.

The most commonly utilized scoring systems are the SOFA (Sequential Organ Failure Assessment) and the APACHE (Acute Physiology and Chronic Health Evaluation). There has been more recent interest in the use of a "quick" SOFA, or qSOFA, scoring system for prognostication of sepsis outcomes.

THE SOFA SCORING SYSTEM

The SOFA scoring system is composed of scores from six organ systems, graded from 0 to 4 according to the degree of dysfunction (Table 311-1). The score accounts for clinical interventions; it can be measured repeatedly (i.e., each day), and rising scores correlate with increasing mortality. The most recent sepsis consensus conference guidelines incorporated an increase of at least two points in the SOFA score from baseline as diagnostic of sepsis in the setting of suspected or documented infection. Patients with suspected infection can be predicted to have poor outcomes typical of sepsis if they have at least two of the following clinical criteria: respiratory rate ≥22 breaths/min, altered mental status, or systolic blood pressure ≤100 mmHg. Recently, a new bedside clinical score using two or more of the above clinical criteria has emerged and is termed quick SOFA (qSOFA). qSOFA is intended to screen patients for risk of poor outcomes from sepsis from

TABLE 311-1 Calculation of SOFA Score[a]

	SCORE				
SYSTEM	0	1	2	3	4
Respiration Pao_2/Flo_2, mmHg (kPa)	≥400 (53.3)	<400 (53.3)	<300 (40)	<200 (26.7) with respiratory support	<100 (13.3) with respiratory support
Coagulation Platelets, × 10^3/μL	≥150	<150	<100	<50	<20
Liver Bilirubin, mg/dL (μmol/L)	<1.2 (20)	1.2–1.9 (20–32)	2.0–5.9 (33–101)	6.0–11.9 (102–204)	>12.0 (204)
Cardiovascular	MAP ≥70 mmHg	MAP <70 mmHg	Dopamine <5 or dobutamine (any dose)[b]	Dopamine 5.1–15 or epinephrine ≤0.1 or norepinephrine ≤0.1[b]	Dopamine >15 or epinephrine >0.1 or norepinephrine >0.1[b]
Central nervous system Glasgow Coma Scale[c]	15	13–14	10–12	6–9	<6
Renal Creatinine, mg/dL (μmol/L) or urine output, mL/d	<1.2 (110)	1.2–1.9 (110–170)	2.0–3.4 (171–299)	3.5–4.9 (300–440) or <500	>5.0 (440) or <200

out-of-hospital, emergency department, and hospital ward settings. qSOFA was not developed, nor is it currently recommended, as a sepsis diagnostic screening tool, but studies are investigating its utility as such, especially in resource-poor settings that may not have the ability to measure all the components of the SOFA score.

THE APACHE II SCORING SYSTEM

The APACHE II system is the most commonly used SOI scoring system in North America. Age, type of ICU admission (after elective surgery vs nonsurgical or after emergency surgery), chronic health problems, and 12 physiologic variables (the worst values for each in the first 24 h after ICU admission) are used to derive a score. The predicted hospital mortality rate is derived from a formula that takes into account the APACHE II score, the need for emergency surgery, and a weighted, disease-specific diagnostic category (Table 311-2). The relationship between APACHE II score and mortality risk is illustrated in Fig. 311-1. Updated versions of the APACHE scoring system (APACHE III and APACHE IV) have been published.

OTHER SCORING SYSTEMS

There are numerous other scoring systems that have been developed, and there are ongoing studies evaluating their utility. In particular, there is increasing interest in utilizing electronic health medical record scoring systems that might better incorporate larger and real-time data sets from patients, and that can alert providers to patients at risk for sepsis and/or poor outcomes from clinical illness.

SHOCK (SEE ALSO CHAP. 314)

INITIAL EVALUATION

Shock, a common condition necessitating ICU admission or occurring in the course of critical care, is defined by the presence of multisystem end-organ hypoperfusion. Clinical indicators include reduced mean arterial pressure (MAP), tachycardia, tachypnea, cool skin and extremities, acute altered mental status, and oliguria. The end result of multiorgan hypoperfusion is tissue hypoxia, often with accompanying lactic acidosis. Because the MAP is the product of cardiac output and systemic vascular resistance (SVR), reductions in blood pressure can be caused by decreases in cardiac output and/or SVR. Accordingly, once shock is contemplated, the initial evaluation of a hypotensive patient should include an early bedside assessment of the adequacy of cardiac output (Fig. 311-2). Clinical evidence of *diminished* cardiac output includes a narrow pulse pressure (systolic blood pressure minus diastolic blood pressure)—a marker that correlates with stroke

[a]The APACHE II score is the sum of the acute physiology score (vital signs, oxygenation, laboratory values), the Glasgow coma score, age, and chronic health points. The worst values during the first 24 h in the ICU should be used. For serum creatinine, double the point score for acute renal failure. [b]Glasgow coma score (GCS) = eye-opening score + verbal (intubated or nonintubated) score + motor score. [c]For GCS component of acute physiology score, subtract GCS from 15 to obtain points assigned. [d]Hepatic: cirrhosis with portal hypertension or encephalopathy; cardiovascular: class IV angina (at rest or with minimal self-care activities); pulmonary: chronic hypoxemia or hypercapnia, polycythemia, ventilator dependence; renal: chronic peritoneal or hemodialysis; immune: immunocompromised host.

Abbreviations: (A – a) DO_2, alveolar-arterial oxygen difference; FIO_2, fraction of inspired oxygen; PaO_2, partial pressure of oxygen; WBC, white blood cell count.

volume—and cool extremities with delayed capillary refill, colloquially termed "cold shock." It is important to palpate proximal extremities (e.g., thigh region) rather than distal extremities to determine relative "coolness," because patients with peripheral vascular disease may always have cool distal extremities. Signs of *increased* cardiac output include a widened pulse pressure (particularly with a reduced diastolic pressure), warm extremities with bounding pulses, and rapid capillary refill, colloquially termed "warm shock." If a hypotensive patient has clinical signs of increased cardiac output, it can be inferred that the reduced blood pressure is from decreased SVR.

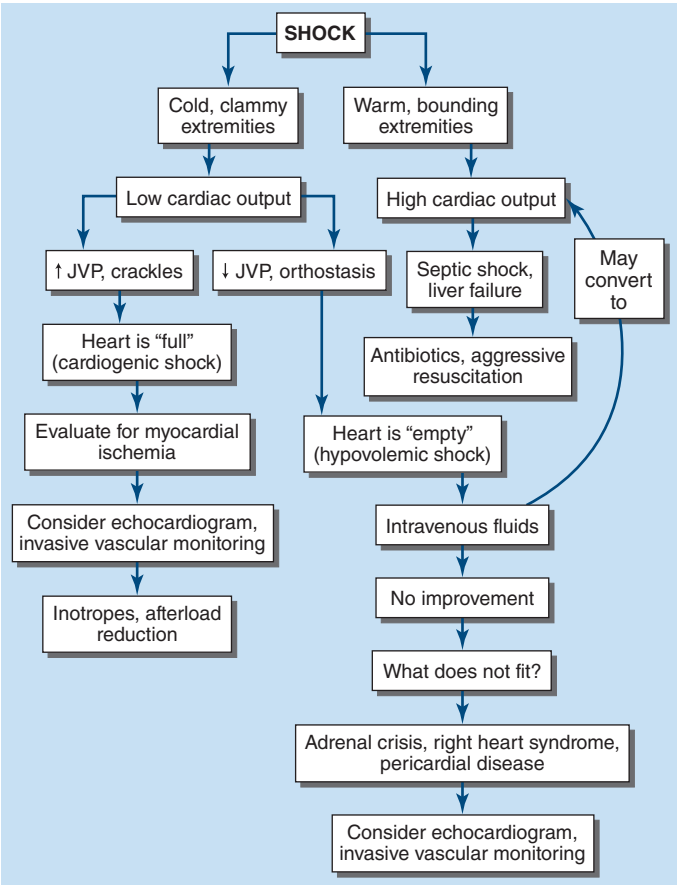

FIGURE 311-2 Approach to the patient in shock. JVP, jugular venous pressure.

In hypotensive patients with signs of reduced cardiac output, an assessment of intravascular volume status is appropriate. A hypotensive patient with decreased intravascular volume status may have a history suggesting hemorrhage or other volume losses (e.g., vomiting, diarrhea, polyuria). Although evidence of a reduced jugular venous pressure (JVP) is often sought, static measures of right atrial pressure do not predict fluid responsiveness reliably; the *change* in right atrial pressure as a function of spontaneous respiration is a better predictor of fluid responsiveness **(Fig. 311-3)**. Patients with fluid-responsive (i.e., hypovolemic) shock also may manifest large changes in pulse pressure as a function of respiration *during* mechanical ventilation **(Fig. 311-4)**. Other bedside metrics can help with judging whether a patient remains fluid-responsive, including responses to volume challenge or a straight leg raise (that increases venous return) that correlate with improved perfusion. Such tools include judging changes in JVP or central venous oxygen saturation, assessing changes in pulse pressure variation, determining changes in inferior vena cava collapse by ultrasound, and examining changes in left ventricular stroke volume using echocardiography. None of these measurements has been shown to be independently correlative, but a combination of these assessments with clinical judgment can help determine whether a patient remains volume-responsive. A hypotensive patient with increased intravascular volume and cardiac dysfunction may have S_3 and/or S_4 gallops on examination, increased JVP, extremity edema, and crackles on lung auscultation. The chest x-ray may show cardiomegaly, widening of the vascular pedicle, Kerley B lines, and pulmonary edema. There is increasing use of ultrasonography in place of chest radiography in resource-limited settings. Chest pain and electrocardiographic changes consistent with ischemia may be noted **(Chap. 316)**.

In hypotensive patients with clinical evidence of increased cardiac output, a search for causes of decreased SVR is appropriate. These patients usually require targeted initial volume resuscitation (as described above), after an initial fluid bolus, to achieve euvolemia, and often require vasopressors to maintain vascular tone. The most common cause of high-cardiac-output hypotension is sepsis **(Chap. 315)**. Patients with suspected sepsis should receive early broad-spectrum, appropriately dosed antibiotics and source control when feasible. Other causes of high-cardiac output hypotension include liver failure, severe pancreatitis, adrenal insufficiency, burns, trauma, anaphylaxis, thyrotoxicosis, and peripheral arteriovenous shunts.

Insertion of lines for monitoring and caring for critically ill patients may be necessary. Over the last two decades, management of shock has improved to the point where not all patients will require central venous and arterial lines, and recent sepsis guidelines support use of peripheral lines for pressors administration, if needed, while central access is being obtained. However, if a patient demonstrates that shock is not quickly resolving, as indicated by a persistent need for vasopressors and/or repeated measurement of the JVP and/or central venous O_2 saturation, then insertion of an arterial line for monitoring blood pressures and arterial blood gases, as well as a central venous line for administration of vasoactive agents and monitoring of the JVP and/or central venous O_2 saturation, may be required. Ideally, lines should be inserted under sterile conditions using a protocolized checklist approach, and lines should be removed as soon as they are no longer necessary to avoid risk of line-associated infection.

In summary, the most common categories of shock are hypovolemic, cardiogenic, and high-cardiac-output with decreased SVR (high-output hypotension). Certainly, more than one category can occur simultaneously (e.g., hypovolemic and septic shock). It may often be the case that an initial presentation with septic shock can present a cardiac strain, especially in patients with underlying heart dysfunction, such that later cardiac insufficiency may arise.

The initial assessment of a patient in shock should take only a few minutes. It is important that aggressive targeted resuscitation is instituted on the basis of the initial assessment, particularly since early resuscitation from septic and cardiogenic shock may improve survival (see below). If the initial bedside assessment yields equivocal or confounding data, more objective assessments such as ultrasound/echocardiography may be useful as described above. In spontaneously

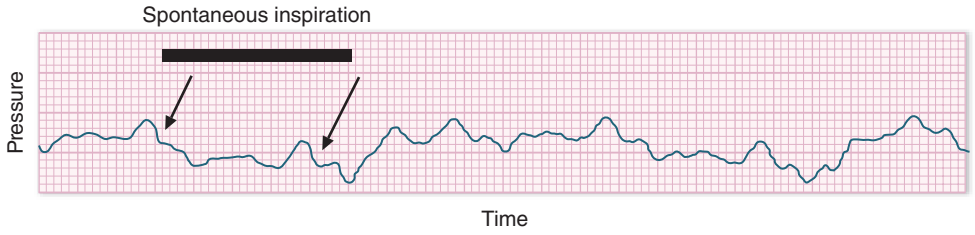

FIGURE 311-3 Right atrial pressure change during spontaneous respiration in a patient with shock whose cardiac output will increase in response to intravenous fluid administration. The right atrial pressure decreases from 7 mmHg to 4 mmHg. The horizontal bar marks the time of spontaneous inspiration.

breathing patients, inferior vena cava collapse seen on ultrasound may predict a fluid-responsive state. Increasingly, ultrasound of the thorax and abdomen is used by intensivists as an extension of the physical examination to assess rapidly imputed filling volumes, adequacy of cardiac performance, and for indices of other specific conditions (e.g., pericardial tamponade, pulmonary embolus, pulmonary edema, pneumothorax). The goal of aggressive resuscitation is to reestablish adequate tissue perfusion and thus to prevent or minimize end-organ injury. It is equally important not to over-resuscitate patients, as it is increasingly appreciated that excess fluid resuscitation is likely not beneficial. Thus, targeted fluid resuscitation is the goal.

MECHANICAL VENTILATORY SUPPORT (SEE ALSO CHAP. 313)

During the initial resuscitation of patients in shock, principles of advanced cardiac life support should be followed. An early assessment of the ability of a patient to protect their airway and to maintain adequate gas exchange is mandatory. Early intubation and mechanical ventilation often are required. Reasons for the institution of endotracheal intubation and mechanical ventilation include acute hypoxemic respiratory failure and ventilatory failure, which frequently accompany shock. Acute hypoxemic respiratory failure may occur in patients with cardiogenic shock and pulmonary edema **(Chap. 316)** as well as in those who are in septic shock with pneumonia or acute respiratory distress syndrome (ARDS) **(Chaps. 204, 312, and 315)**. Ventilatory failure often occurs as a consequence of an increased load on the respiratory system in the form of acute metabolic (often lactic) or respiratory acidosis, or decreased lung compliance (e.g., from pulmonary edema or pneumonia). Inadequate perfusion to respiratory muscles in the setting of shock may be another reason for early intubation and mechanical ventilation. Normally, the respiratory muscles receive a very small percentage of the cardiac output. However, in patients who are in shock with respiratory distress, the percentage of cardiac output dedicated to respiratory muscles may increase by 10-fold or more. Lactic acid production from inefficient respiratory muscle activity can present an additional ventilatory load.

Mechanical ventilation may relieve the work of breathing and allow redistribution of a limited cardiac output to other vital organs. Patients demonstrate respiratory distress by an inability to speak full sentences, accessory use of respiratory muscles, paradoxical abdominal muscle activity, extreme tachypnea (>40 breaths/min), and decreasing respiratory rate despite an increasing drive to breathe. When patients with shock are supported with mechanical ventilation, a major goal is for the ventilator to initially assume all or the majority of the work of breathing, facilitating a state of minimal respiratory muscle work. With the institution of mechanical ventilation for shock, further declines in MAP are frequently seen. The reasons include impeded venous return from positive-pressure ventilation, reduced endogenous catecholamine secretion once the stress associated with respiratory failure abates, and the actions of drugs used to facilitate endotracheal intubation (e.g., propofol, opiates). Patients with right heart dysfunction or preexisting pulmonary hypertension may also have diminished cardiac output related to the increases in right ventricular afterload resulting from positive-pressure ventilation. Accordingly, hypotension should be anticipated during and following endotracheal intubation. Because many of these patients may be fluid-responsive, IV volume administration should be considered, and vasopressor support peri-intubation may also be necessary. Figure 311-2 summarizes the diagnosis and treatment of different types of shock. **For further discussion of individual forms of shock, see Chaps. 314, 315, and 316.**

RESPIRATORY FAILURE

Respiratory failure is one of the most common reasons for ICU admission. In some ICUs, ≥75% of patients require mechanical ventilation during their stay. Respiratory failure can be categorized mechanistically on the basis of pathophysiologic derangements in respiratory function.

TYPE I: ACUTE HYPOXEMIC RESPIRATORY FAILURE

This type of respiratory failure occurs with alveolar flooding and subsequent ventilation-perfusion mismatch and intrapulmonary shunt physiology. Alveolar flooding may be a consequence of pulmonary edema, lung injury, pneumonia, or alveolar hemorrhage. Pulmonary edema can be further categorized as occurring due to elevated pulmonary microvascular pressures, as seen in heart failure and intravascular volume overload or ARDS ("low-pressure pulmonary edema," **Chap. 312**). This syndrome is defined by acute onset (≤1 week) of bilateral opacities on chest imaging that are not fully explained by cardiac failure or fluid overload and often includes ventilation-perfusion mismatch and shunt physiology requiring positive end-expiratory pressure (PEEP). A new global definition for ARDS has been proposed that does not rely upon chest radiography, arterial blood gases, or use of ventilatory support with PEEP. Type I respiratory failure occurs in clinical settings such as sepsis, gastric aspiration, pneumonia, COVID-19 **(Chap. 205)**, near-drowning, multiple blood transfusions, and pancreatitis. The mortality rate among patients with ARDS was traditionally very high (50–70%), although changes in patient care have led to mortality rates closer to 30% (see below). The COVID-19 pandemic resulted in a substantially increased incidence of viral-mediated ARDS.

It is well established that mechanical ventilation of patients with ARDS may propagate lung injury. As seen in **Fig. 311-5**, the pressure-volume relationship of the lung in ARDS is not linear. Alveoli may collapse at very low lung volumes. Animal studies have suggested that repeated stretching and overdistention of injured alveoli during mechanical ventilation can further injure the lung. Concern over this alveolar overdistention, termed *ventilator-induced "volutrauma,"* led to a multicenter, randomized, prospective trial comparing traditional ventilator strategies for ARDS (large tidal volume: 12 mL/kg of ideal body weight) with a low tidal volume (6 mL/kg of ideal body weight). This study showed a dramatic reduction in mortality rate in the low-tidal-volume group from that in the high-tidal-volume group (31 vs 39.8%). Other studies have suggested that large tidal volumes may lead to ARDS in patients who initially do

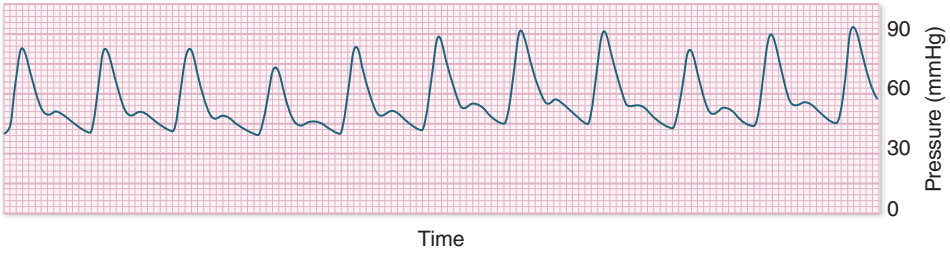

FIGURE 311-4 Pulse pressure change during mechanical ventilation in a patient with shock whose cardiac output will increase in response to intravenous fluid administration. The pulse pressure (systolic minus diastolic blood pressure) changes during mechanical ventilation in a patient with septic shock.

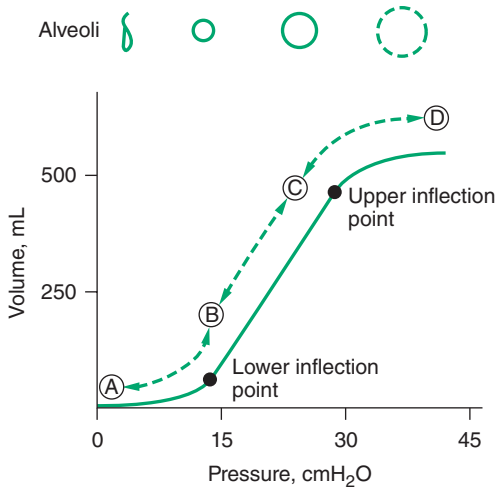

FIGURE 311-5 Pressure-volume relationship in the lungs of a patient with acute respiratory distress syndrome (ARDS). At the lower inflection point, collapsed alveoli begin to open and lung compliance changes. At the upper deflection point, alveoli become overdistended. The shape and size of alveoli are illustrated at the top of the figure.

not have this problem. Prone positioning has been shown to improve survival in those with severe ARDS and has been more broadly applied in many centers in COVID-19 ARDS. Select patients may benefit from neuromuscular blockade in ARDS. In addition, a "fluid-conservative" management strategy (maintaining a low central venous pressure [CVP] or pulmonary capillary wedge pressure [PCWP]) is associated with fewer days of mechanical ventilation than a "fluid-liberal" strategy (maintaining a relatively high CVP or PCWP) in ARDS in those patients who have been resuscitated from shock. There is growing interest in avoiding intubation in patients with ARDS by the use of a variety of devices, such as masks, high-flow oxygen delivery systems, and helmets for respiratory support that were more broadly applied during the COVID pandemic and likely more so in resource-limited settings when feasible; however, this must be balanced by concern that higher tidal volumes during spontaneous breathing with these devices could result in progression of preexisting lung injury.

TYPE II RESPIRATORY FAILURE: HYPERCAPNEIC RESPIRATORY FAILURE

This type of respiratory failure is a consequence of alveolar hypoventilation and results from the inability to eliminate carbon dioxide effectively. Mechanisms are categorized by impaired central nervous system (CNS) drive to breathe (colloquially termed, "won't breathe"), impaired strength with failure of neuromuscular function in the respiratory system, and increased load(s) on the respiratory system (with the latter two colloquially termed, "can't breathe"). Reasons for diminished CNS drive to breathe include drug overdose, brainstem injury, sleep-disordered breathing, and severe hypothyroidism. Reduced strength can be due to impaired neuromuscular transmission (e.g., myasthenia gravis, Guillain-Barré syndrome, amyotrophic lateral sclerosis) or respiratory muscle weakness (e.g., myopathy, electrolyte derangements, fatigue).

The overall load on the respiratory system can be subclassified into resistive loads (e.g., bronchospasm), loads due to reduced lung compliance (e.g., alveolar edema, atelectasis, intrinsic positive end-expiratory pressure [auto-PEEP]—see below), loads due to reduced chest wall compliance (e.g., pneumothorax, pleural effusion, abdominal distention), and loads due to increased minute ventilation requirements (e.g., pulmonary embolus with increased dead-space fraction, sepsis).

The mainstays of therapy for hypercapnic respiratory failure are directed at reversing the underlying cause(s) of ventilatory failure. Noninvasive positive-pressure ventilation with a tight-fitting facial or nasal mask, with avoidance of endotracheal intubation, may stabilize these patients in certain circumstances. This approach has been shown to be beneficial in treating patients with exacerbations of chronic obstructive pulmonary disease; it has been tested less extensively in other kinds of respiratory failure but may be attempted nonetheless with close monitoring in the absence of contraindications (e.g., hemodynamic instability, inability to protect the airway, respiratory arrest, significant airway secretions, significant aspiration risk).

TYPE III RESPIRATORY FAILURE: LUNG ATELECTASIS

This form of respiratory failure results from lung atelectasis. Because atelectasis occurs so commonly in the perioperative period, this form is also called *perioperative respiratory failure*. After general anesthesia, decreases in functional residual capacity lead to collapse of dependent lung units. Such atelectasis can be treated by frequent changes in position, chest physiotherapy, upright positioning, and control of incisional and/or abdominal pain. Noninvasive positive-pressure ventilation may also be used to reverse regional atelectasis.

TYPE IV RESPIRATORY FAILURE: METABOLIC DEMANDS

This form most often results from hypoperfusion of respiratory muscles in patients in shock. Normally, respiratory muscles consume <5% of total cardiac output and oxygen delivery. Patients in shock often experience respiratory distress due to pulmonary edema (e.g., in cardiogenic shock), lactic acidosis, and anemia. In this setting, up to 40% of cardiac output may be distributed to the respiratory muscles. Intubation and mechanical ventilation can allow redistribution of the cardiac output away from the respiratory muscles and back to vital organs while the shock is treated. In addition, other causes of significant metabolic acidosis might require ventilatory support while reversal of the underlying cause of the acidosis is addressed.

CARE OF THE MECHANICALLY VENTILATED PATIENT

Mechanically ventilated patients frequently require sedatives and analgesics. Opiates are the mainstay of therapy for analgesia in mechanically ventilated patients. After adequate pain control has been ensured, additional indications for sedation include anxiolysis; treatment of subjective dyspnea; reduction of autonomic hyperactivity, which may precipitate myocardial ischemia; and reduction of total O_2 consumption (Vo_2). Nonbenzodiazepine sedatives are preferred because benzodiazepines are associated with increased delirium and worse patient outcomes.

The neuromuscular blocking agent cisatracurium is occasionally used to facilitate mechanical ventilation in patients with profound ventilator dyssynchrony despite optimal sedation, particularly in the setting of severe ARDS. Use of these agents may result in prolonged weakness—a myopathy known as the *postparalytic syndrome*. For this reason, neuromuscular blocking agents typically are used as a last resort when aggressive sedation fails to achieve patient–ventilator synchrony. Because neuromuscular blocking agents result in pharmacologic paralysis without altering mental status, sedative-induced amnesia is mandatory when these agents are administered.

Amnesia can be achieved reliably with propofol and benzodiazepines such as lorazepam and midazolam. Outside the setting of pharmacologic paralysis, few data support the idea that amnesia is mandatory in all patients who require intubation and mechanical ventilation. Because many of these critically ill patients have impaired hepatic and renal function, sedatives and opiates may accumulate when given for prolonged periods. A nursing protocol–driven approach to sedation of mechanically ventilated patients or daily interruption of sedative infusions paired with daily spontaneous breathing trials has been shown to prevent excessive drug accumulation and shorten the duration of both mechanical ventilation and ICU stay (see below).

(See also Chap. 313.) Whereas a thorough understanding of the pathophysiology of respiratory failure is essential for optimal patient care, recognition of a patient's readiness to be liberated from mechanical ventilation is likewise important. Several studies have shown that daily spontaneous breathing trials can identify patients who are ready for extubation. Accordingly, all intubated, mechanically ventilated patients should undergo daily screening of respiratory function.

If oxygenation is stable (i.e., Pao_2/FIo_2 [partial pressure of oxygen/fraction of inspired oxygen] >200 and PEEP ≤5 cmH_2O), cough and airway reflexes are intact, and no vasopressor agents or sedatives are being administered, the patient has passed the screening test and should undergo a spontaneous breathing trial (SBT). If sedatives are being administered, the patient can undergo a spontaneous awakening trial (SAT), as well, to determine if they are able to maintain adequate alertness and respiratory status without sedatives. The SAT/SBT trial consists of a period of breathing through the endotracheal tube without significant ventilator support (continuous positive airway pressure [CPAP] of 5 cmH_2O with or without low-level pressure support [e.g., 5 cmH_2O] and an open T-piece breathing system have all been validated) for 30–120 min. The spontaneous breathing trial is declared a failure and stopped if *any* of the following occur: (1) respiratory rate >35/min for >5 min, (2) O_2 saturation <90%, (3) heart rate >140/min or a 20% increase or decrease from baseline, (4) systolic blood pressure <90 mmHg or >180 mmHg, or (5) increased anxiety or diaphoresis. If, at the end of the spontaneous breathing trial, none of the above events has occurred, the patient can be considered for an extubation trial. Such protocol-driven approaches to patient care can have an important impact on the duration of mechanical ventilation and ICU stay. Despite such a careful approach to liberation from mechanical ventilation, up to 10% of patients develop respiratory distress after extubation and may require resumption of mechanical ventilation. Many of these patients will require reintubation. The use of noninvasive ventilation as a rescue strategy in patients in whom extubation fails may be associated in some patients with worse outcomes than are obtained with immediate reintubation. Some studies suggest that there are subgroups of patients who might benefit from administration of noninvasive ventilation or high-flow nasal oxygen therapy upon extubation, as it is believed that low levels of PEEP and/or inspiratory flow delivered by these devices after extubation may be helpful.

MULTIORGAN SYSTEM FAILURE

Multiorgan system failure, which is commonly associated with critical illness, is defined by the simultaneous presence of physiologic dysfunction and/or failure of two or more organs. Typically, this syndrome occurs in the setting of severe sepsis, shock of any kind, severe inflammatory conditions such as pancreatitis, and trauma. The fact that multiorgan system failure occurs commonly in the ICU is a testament to our current ability to stabilize and support single-organ failure. The ability to support single-organ failure aggressively (e.g., by mechanical ventilation or by renal replacement therapy) has reduced rates of early mortality in critical illness. As a result, it is less common for critically ill patients to die in the initial stages of resuscitation. Instead, many patients succumb to critical illness later in the ICU stay, after the initial presenting problem may have been stabilized.

Although there is debate regarding specific definitions of organ failure, several general principles governing the syndrome of multiorgan system failure apply. First, organ failure, no matter how it is defined, must persist beyond 24 h. Second, mortality risk increases with the accrual of failing organs. Third, the prognosis worsens with increased duration of organ failure. These observations remain true across various critical care settings (e.g., medical vs surgical).

MONITORING IN THE ICU

Because respiratory failure and circulatory failure are common in critically ill patients, monitoring of the respiratory and cardiovascular systems is undertaken frequently. Evaluation of respiratory gas exchange is routine in critical illness. The "gold standard" remains arterial blood-gas analysis, in which pH, Pao_2, partial pressure of carbon dioxide (Pco_2), and O_2 saturation are measured directly. With arterial blood-gas analysis, the two main functions of the lung—oxygenation of arterial blood and elimination of CO_2—can be assessed directly. In fact, the arterial blood pH, which has a profound effect on the drive to breathe, can be assessed only by such sampling. Venous pH obtained through an indwelling central venous line can approximate arterial pH. Although sampling of arterial blood is generally safe and may be undertaken more frequently through insertion of a temporary indwelling arterial line, it may be painful and cannot provide continuous information. In light of these limitations, noninvasive monitoring of respiratory function is often employed.

PULSE OXIMETRY

The most commonly utilized noninvasive technique for monitoring respiratory function, pulse oximetry takes advantage of differences in the absorptive properties of oxygenated and deoxygenated hemoglobin. At wavelengths of 660 nm, oxyhemoglobin reflects light more effectively than does deoxyhemoglobin, whereas the reverse is true in the infrared spectrum (940 nm). A pulse oximeter passes both wavelengths of light through a perfused digit such as a finger, and the relative intensity of light transmission at these two wavelengths is recorded. From this information, the relative percentage of oxyhemoglobin is derived. Since arterial pulsations produce phasic changes in the intensity of transmitted light, the pulse oximeter is designed to detect only light of alternating intensity. This feature allows distinction of arterial and venous blood O_2 saturations. Studies during the COVID pandemic noted that pulse oximetry overestimates oxygen saturation in patients with darker skin, thus making correlation with arterial Pao_2 more imperative.

RESPIRATORY SYSTEM MECHANICS

Respiratory system mechanics can be measured in patients during mechanical ventilation **(Chap. 313)**. When volume-controlled modes of mechanical ventilation are used, accompanying airway pressures can easily be measured as long as the patient is breathing passively. The peak airway pressure is determined by two variables: airway resistance and respiratory system compliance. At the end of inspiration, inspiratory flow can be stopped transiently. This end-inspiratory pause (*plateau pressure*) is a static measurement, affected only by respiratory system compliance and not by airway resistance. Therefore, during volume-controlled ventilation, the difference between the peak (airway resistance + respiratory system compliance) and plateau (respiratory system compliance only) airway pressures provides a quantitative assessment of airway resistance. Accordingly, during volume-controlled ventilation, patients with increases in airway resistance typically have increased peak airway pressures as well as abnormally high gradients between peak and plateau airway pressures (typically >10–15 cmH_2O) at a constant inspiratory flow rate of 1 L/s. The compliance of the respiratory system is defined by the change in volume of the respiratory system per unit change in pressure; thus, a quantitative assessment of compliance is provided by the tidal volume divided by the plateau pressure minus PEEP.

The respiratory system can be divided into two components: the lungs and the chest wall. Normally, respiratory system compliance is ~100 mL/cmH_2O. Pathophysiologic processes such as pleural effusions, pneumothorax, and increased abdominal girth all reduce chest wall compliance. Lung compliance may be reduced by pneumonia, pulmonary edema, alveolar hemorrhage, interstitial lung disease, or auto-PEEP. Accordingly, patients with abnormalities in compliance of the respiratory system (lungs and/or chest wall) typically have elevated peak *and* plateau airway pressures but a normal gradient between these two pressures. Auto-PEEP occurs when there is insufficient time for emptying of alveoli before the next inspiratory cycle. Because the alveoli have not decompressed completely, alveolar pressure remains positive at the end of exhalation (*functional residual capacity*). This phenomenon results most commonly from obstruction of distal airways in disease processes such as asthma and COPD. Auto-PEEP with resulting alveolar overdistention may result in diminished lung compliance, reflected by abnormally increased plateau airway pressures. Modern mechanical ventilators allow breath-to-breath display of pressure and flow, permitting detection of potential problems such as patient–ventilator dyssynchrony, airflow obstruction, and auto-PEEP **(Fig. 311-6)**.

CIRCULATORY STATUS

Oxygen delivery (Qo_2) is a function of cardiac output and the content of O_2 in the arterial blood (Cao_2). The Cao_2 is determined by the

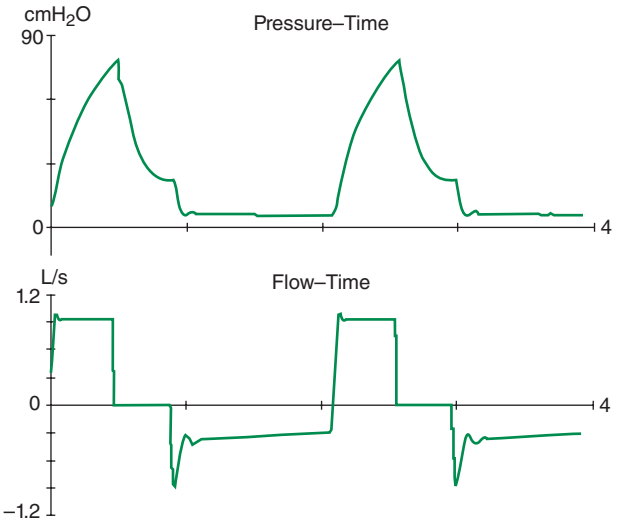

FIGURE 311-6 Increased airway resistance with auto–positive end-expiratory pressure (PEEP). The top waveform (airway pressure vs time) shows a large difference between the peak airway pressure (80 cmH_2O) and the plateau airway pressure (20 cmH_2O). The bottom waveform (flow vs time) demonstrates airflow throughout expiration (reflected by the flow tracing on the negative portion of the abscissa) that persists up to the next inspiratory effort.

hemoglobin concentration, the arterial hemoglobin saturation, and dissolved O_2 not bound to hemoglobin. For normal adults:

$$\begin{aligned} Qo_2 &= 50 \text{ dL/min} \times (1.39 \times 15 \text{ g/dL [hemoglobin concentration]} \\ &\quad \times 1.0 \text{ [hemoglobin \% saturation]} + 0.0031 \times 10 \text{ [Pao}_2\text{]}) \\ &= 50 \text{ dL/min (cardiac output)} \times 21.6 \text{ mL } O_2 \text{ per dL blood (Cao}_2\text{)} \\ &= 1058 \text{ mL } O_2 \text{ per min} \end{aligned}$$

It is apparent that nearly all the O_2 delivered to tissues is bound to hemoglobin and that the dissolved O_2 (Pao_2) contributes very little to O_2 content in arterial blood or to O_2 delivery. Normally, the content of O_2 in mixed venous blood (C^-vo_2) is 15.76 mL/dL since the mixed venous blood is 75% saturated. Therefore, the normal tissue extraction ratio for O_2 is $Cao_2 - C^-vo_2/Cao_2$ ([21.16 – 15.76]/21.16) or ~25%. A pulmonary artery catheter (see discussion below) allows measurements of O_2 delivery and the O_2 extraction ratio.

Information on the venous O_2 saturation allows assessment of global tissue perfusion. A reduced venous O_2 saturation may be caused by inadequate cardiac output, reduced hemoglobin concentration, and/or reduced arterial O_2 saturation. An abnormally high oxygen consumption (Vo_2) may also lead to a reduced venous O_2 saturation if O_2 delivery is not concomitantly increased. Abnormally increased Vo_2 in peripheral tissues may be caused by problems such as fever, agitation, shivering, and thyrotoxicosis.

The pulmonary artery catheter originally was designed as a tool to guide therapy for acute myocardial infarction but has been used in the ICU for evaluation and treatment of a variety of other conditions, such as ARDS, septic shock, congestive heart failure, and acute renal failure. This device has never been validated as a tool associated with reduction in morbidity and mortality rates. Indeed, despite numerous prospective studies, mortality or morbidity rate benefits associated with use of the pulmonary artery catheter have never been reported in any setting. Accordingly, it appears that routine pulmonary artery catheterization is not indicated as a means of monitoring and characterizing circulatory status in most critically ill patients, especially as monitoring of the venous O_2 saturation via an indwelling central venous line has proven helpful in many critical illness settings. However, there are still select circumstances where pulmonary artery catheterization may prove helpful when used by those with appropriate experience in its insertion and data interpretation.

PREVENTION OF COMPLICATIONS OF CRITICAL ILLNESS

SEPSIS IN THE CRITICAL CARE UNIT

(See also Chap. 315) Sepsis is defined as life-threatening organ dysfunction (i.e., an increase in SOFA of 2 points or more) caused by a dysregulated response to infection. Poor outcomes can be anticipated in patients with two or more of the following: respiratory rate ≥22 breaths/min, altered mentation, and systolic blood pressure ≤100 mmHg. Sepsis is a leading cause of death in noncoronary ICUs in the United States, with case rates expected to increase as the population ages and a higher percentage of people are vulnerable to infection.

NOSOCOMIAL INFECTIONS IN THE ICU

Many therapeutic interventions in the ICU are invasive and predispose patients to infectious complications. These interventions include endotracheal intubation, indwelling vascular catheters, transurethral bladder catheters, and other catheters placed into sterile body cavities (e.g., tube thoracostomy, percutaneous intraabdominal drainage catheterization). The longer such devices remain in place, the more prone to infections patients become from these devices. For example, ventilator-associated events such as ventilator-associated pneumonia correlate strongly with the duration of intubation and mechanical ventilation. Therefore, an important aspect of preventive care is the timely removal of invasive devices as soon as they are no longer needed. Moreover, multidrug-resistant organisms are commonplace in the ICU.

Infection control is critical in the ICU. Care bundles, which include measures such as frequent hand washing, are effective but underutilized strategies. Other components of care bundles, such as protective isolation of patients colonized or infected by drug-resistant organisms, are also commonly used. Studies evaluating multifaceted, evidence-based strategies to decrease catheter-related bloodstream infections have shown improved outcomes with strict adherence to measures such as hand washing, full-barrier precautions during catheter insertion, chlorhexidine skin preparation, avoidance of the femoral site, and timely catheter removal.

DEEP-VENOUS THROMBOSIS (DVT) (SEE ALSO CHAP. 290)

All ICU patients are at high risk for this complication because of their predilection for immobility. Therefore, all should receive some form of prophylaxis against DVT if feasible. The most commonly employed forms of prophylaxis are subcutaneous chemoprophylaxis (e.g., low-dose heparin) injections and sequential compression devices for the lower extremities. Observational studies report an alarming incidence of DVTs despite the use of these standard prophylactic regimens. Furthermore, heparin prophylaxis may result in heparin-induced thrombocytopenia, another nosocomial complication in critically ill patients.

Low-molecular-weight heparins such as enoxaparin are more effective than unfractionated heparin for DVT prophylaxis in high-risk patients (e.g., those undergoing orthopedic surgery) and are associated with a lower incidence of heparin-induced thrombocytopenia, although their use may be limited in patients with renal dysfunction given their renal clearance.

STRESS ULCERS

Prophylaxis against stress ulcers is not necessary for all ICU patients. It should only be administered to high-risk patients, such as those with coagulopathy or respiratory failure requiring mechanical ventilation. While there has been debate about the optimal agent for stress ulcer prophylaxis, a number of recent studies have supported improved efficacy of proton pump inhibitors (PPIs) in reducing bleeding risk compared with other agents (e.g., histamine-2 receptor antagonist [H2 blocker] or sucralfate). There exist concerns for increased risk of pneumonia and *Clostridium difficile* colitis with PPIs compared with other agents, although the data are not definitive, and the improved efficacy of PPIs in patients at high risk for stress ulcers may outweigh these potential infectious risks.

NUTRITION AND GLYCEMIC CONTROL

Nutrition and glycemic control are important issues that may be associated with respiratory failure, impaired wound healing, and dysfunctional immune response in critically ill patients. Early enteral feeding is reasonable, with some data suggesting that permissive underfeeding of nonprotein calories is not inferior to full-goal feeding. Certainly, enteral feeding, if possible, is preferred over parenteral nutrition, which

is associated with numerous complications, including hyperglycemia, fatty liver, cholestasis, and sepsis. When parenteral feeding is necessary to supplement enteral nutrition, delaying this intervention until day 8 in the ICU results in better recovery and fewer ICU-related complications. Tight glucose control has been an area of controversy in critical care. Although one study showed a significant mortality benefit when glucose levels were aggressively normalized in a large group of surgical ICU patients, other studies of both medical and surgical ICU patients suggested that tight glucose control resulted in increased rates of mortality likely attributable, in part, to hypoglycemic episodes. Thus, current guidelines suggest targeting glucose levels of ≤180 mg/dL in critically ill patients, rather than targeting tighter control.

ICU-ACQUIRED WEAKNESS

ICU-acquired weakness occurs frequently in patients who survive critical illness. Both neuropathies and myopathies have been described, most commonly after ~1 week in the ICU. The mechanisms behind ICU-acquired weakness syndromes are poorly understood, and they are known to present with heterogeneous muscle pathophysiology. Very early physical and occupational therapy in mechanically ventilated patients reportedly results in significant improvements in functional independence at hospital discharge as well as in reduced durations of mechanical ventilation and delirium.

ANEMIA

Studies have shown that most ICU patients are anemic as a result of chronic inflammation. Phlebotomy also contributes to ICU anemia. A large multicenter study involving patients in many different ICU settings challenged the conventional notion that a hemoglobin level of 100 g/L (10 g/dL) is needed in critically ill patients, with similar outcomes noted in those whose transfusion trigger was 7 g/dL. Red blood cell transfusion is associated with impairment of immune function and increased risk of infections as well as of ARDS and volume overload, all of which may explain the findings in this study. A conservative transfusion strategy has shown similar outcomes in septic shock, postcardiac surgery, and post–hip surgery patients.

ACUTE KIDNEY FAILURE

(See also Chap. 321) Acute kidney failure occurs in a significant percentage of critically ill patients. The most common underlying etiology is acute tubular necrosis, usually precipitated by hypoperfusion and/or nephrotoxic agents. Currently, no pharmacologic agents are available for prevention of kidney injury in critical illness. Studies have shown convincingly that low-dose dopamine, fenoldopam, and vasopressin are *not* effective in protecting the kidneys from acute injury.

NEUROLOGIC DYSFUNCTION IN CRITICALLY ILL PATIENTS

DELIRIUM

(See also Chap. 29) Delirium is defined by (1) an acute onset of changes or fluctuations in mental status, (2) inattention, (3) disorganized thinking, and (4) an altered level of consciousness (i.e., a state other than alertness). Delirium is reported to occur in a wide range of mechanically ventilated ICU patients and can be detected by the Confusion Assessment Method for the ICU (CAM-ICU) or the Intensive Care Delirium Screening Checklist (ICDSC). These tools are used to ask patients to answer simple questions and perform simple tasks and can be used readily at the bedside. The differential diagnosis of delirium in ICU patients is broad and includes infectious etiologies (including sepsis), medications (particularly sedatives and analgesics), drug withdrawal, metabolic/electrolyte derangements, intracranial pathology (e.g., stroke, intracranial hemorrhage), seizures, hypoxia, hypertensive crisis, shock, and vitamin deficiencies (particularly thiamine). The etiology of a patient's ICU delirium impacts the prognosis. Those with persistent ICU delirium not related to sedatives have increases in length of hospital stay, time on mechanical ventilation, cognitive impairment at hospital discharge, and 6-month mortality rate. Interventions to reduce ICU delirium are limited. The sedative dexmedetomidine has been less strongly associated with ICU delirium than midazolam in some studies. In addition, very early physical and occupational therapy in mechanically ventilated patients has been demonstrated to reduce delirium.

ANOXIC CEREBRAL INJURY

(See also Chap. 318) This condition is common after cardiac arrest and often results in severe and permanent brain injury in survivors. Active cooling of patients to 33°C after cardiac arrest is controversial, with some studies showing improved neurologic outcomes and others showing no such improvement when compared to maintaining normothermia. Certainly, patients post cardiac arrest should have a temperature targeted to no higher than normothermia.

STROKE

(See also Chap. 437) Stroke is a common cause of neurologic critical illness. Hypertension must be managed carefully, because abrupt reductions in blood pressure may be associated with further brain ischemia and injury. Acute ischemic stroke treated with tissue plasminogen activator (tPA) has an improved neurologic outcome when treatment is given within 4.5 h of onset of symptoms, with likely increased benefit associated with earlier administration. The mortality rate is not reduced when tPA is compared with placebo, despite the improved neurologic outcome. The risk of cerebral hemorrhage is significantly higher in patients given tPA. No consistent overall benefit is seen when tPA therapy is given beyond 4.5 h after symptom onset. Heparin has not been convincingly shown to improve outcomes in patients with acute ischemic stroke. Decompressive craniectomy is a surgical procedure that relieves increased intracranial pressure in the setting of space-occupying brain lesions or brain swelling from stroke; available evidence suggests that this procedure may improve survival among select patients (e.g., ≤55 years of age), albeit at a cost of increased disability for some.

SUBARACHNOID HEMORRHAGE

(See also Chap. 437) Subarachnoid hemorrhage may occur secondary to aneurysm rupture and is often complicated by cerebral vasospasm, re-bleeding, and hydrocephalus. Vasospasm can be detected by either transcranial Doppler assessment or cerebral angiography; it is typically treated with the calcium channel blocker nimodipine, aggressive IV fluid administration to avoid hypovolemia, and therapy aimed at maintaining adequate central perfusion pressure, typically with vasoactive drugs such as phenylephrine. IV fluids and vasoactive drugs (hypertensive hypervolemic therapy) are used to overcome the cerebral vasospasm. Early surgical clipping or endovascular coiling of aneurysms is advocated to prevent complications related to re-bleeding. Hydrocephalus, typically heralded by a decreased level of consciousness, may require ventriculostomy drainage.

STATUS EPILEPTICUS (SEE ALSO CHAP. 436)

Recurrent or relentless seizure activity is a medical emergency. Cessation of seizure activity is required to prevent irreversible neurologic injury. Lorazepam is the most effective benzodiazepine for treating status epilepticus and is the treatment of choice for controlling seizures acutely. Maintenance of seizure control should be effected with a loading dose of fosphenytoin, valproate, or levetiracetam, as these agents have been shown to have similar efficacy and side effects.

BRAIN DEATH

(See also Chap. 318) Although deaths of critically ill patients usually are attributable to irreversible cessation of circulatory and respiratory function, a diagnosis of death also may be established by irreversible cessation of all functions of the entire brain, including the brainstem, even if circulatory and respiratory functions remain intact on artificial life support. Such a diagnosis requires demonstration of the absence of cerebral function (no response to any external stimulus) and brainstem functions (e.g., unreactive pupils, lack of ocular movement in response to head turning or ice-water irrigation of ear canals, positive apnea test [no drive to breathe]). Many U.S. institutions have a protocol based upon their state's requirements for declaration of brain death. Absence of brain function must have an established cause and be permanent without possibility of recovery; a sedative effect, hypothermia,

hypoxemia, neuromuscular paralysis, and severe hypotension must be ruled out. If there is uncertainty about the cause of coma, studies of cerebral blood flow and electroencephalography should be performed.

WITHHOLDING OR WITHDRAWING CARE

(See also Chap. 13) Withholding or withdrawal of care occurs commonly in the ICU setting. The Task Force on Ethics of the Society of Critical Care Medicine reported that it is ethically sound to withhold or withdraw care if a patient or the patient's surrogate makes such a request or if the physician judges that the goals of therapy are not achievable. Because all medical treatments are justified by their expected benefits, the loss of such an expectation justifies the act of withdrawing or withholding such treatment; these two actions are judged to be fundamentally similar. An underlying stipulation derived from this report is that an informed patient should have their wishes respected with regard to life-sustaining therapy. Implicit in this stipulation is the need to ensure that patients are thoroughly and accurately informed regarding the plausibility and expected results of various therapies.

The act of informing patients and/or surrogate decision-makers is the responsibility of the physician and other health care providers. If a patient or surrogate desires therapy deemed futile by the treating physician, the physician is not obligated ethically to provide such treatment. Rather, arrangements may be made to transfer the patient's care to another care provider. Whether the decision to withdraw life support should be initiated by the physician or left to surrogate decision-makers alone is not clear. One study reported that slightly more than half of surrogate decision-makers preferred to receive such a recommendation, whereas the rest did not. Critical care providers should meet regularly with patients and/or surrogates to discuss prognosis when the withholding or withdrawal of care is being considered. After a consensus among caregivers has been reached, this information should be relayed to the patient and/or surrogate decision-maker. If a decision to withhold or withdraw life-sustaining care for a patient has been made, aggressive attention to analgesia and anxiolysis is needed. Often, an independent hospital ethics service can be of benefit in navigating complex decision-making.

312 Acute Respiratory Distress Syndrome

Rebecca M. Baron, Bruce D. Levy

Acute respiratory distress syndrome (ARDS) is a clinical syndrome of severe dyspnea of rapid onset, hypoxemia, and diffuse pulmonary infiltrates leading to respiratory failure. ARDS can be caused by diffuse lung injury from many underlying medical and surgical disorders. The lung injury may be direct (e.g., toxic inhalation) or indirect (e.g., sepsis) (Table 312-1). The clinical features of ARDS are listed in Table 312-2. By expert consensus, ARDS was defined in 2012 by three categories based on the degrees of hypoxemia (Table 312-2). These stages of mild, moderate, and severe ARDS are associated with mortality risk and with the duration of mechanical ventilation in survivors. A more recent global definition of ARDS has been proposed that does not rely upon arterial blood gases, chest radiography, or use of positive end-expiratory pressure on invasive or noninvasive mechanical ventilation, recognizing the challenge of resource-poor settings and increasing use of high-flow nasal oxygen and noninvasive means of respiratory support.

The annual incidence of ARDS prior to the COVID-19 pandemic was estimated to be as high as 60 cases per 100,000 population. Approximately 10% of all intensive care unit (ICU) admissions involve patients with ARDS. This chapter will focus on non–COVID-19 ARDS. Please see Chap. 205 for more information on COVID.

ETIOLOGY

While many medical and surgical illnesses have been associated with the development of ARDS, most cases (>80%) are caused by a relatively small number of clinical disorders: pneumonia and sepsis (~40–60%), followed in incidence by aspiration of gastric contents, trauma, multiple transfusions, and drug overdose. Among patients with trauma, the most frequently reported surgical conditions in ARDS are pulmonary contusion, multiple bone fractures, and chest wall trauma/flail chest, whereas head trauma, near-drowning, toxic inhalation, and burns are more rare causes. The risks of developing ARDS are increased in patients with more than one predisposing medical or surgical condition.

Several other clinical variables have been associated with the development of ARDS. These include older age, chronic alcohol abuse, pancreatitis, pneumonia and sepsis (40–60%, including pandemic COVID pneumonia and other respiratory viruses), and severity of critical illness. Trauma patients with an Acute Physiology and Chronic Health Evaluation (APACHE) II score ≥16 (Chap. 311) have a 2.5-fold increased risk of developing ARDS.

CLINICAL COURSE AND PATHOPHYSIOLOGY

The natural history of ARDS is marked by three phases—exudative, proliferative, and fibrotic—that each have characteristic clinical and pathologic features (Fig. 312-1).

TABLE 312-1 Clinical Disorders Commonly Associated with ARDS

DIRECT LUNG INJURY	INDIRECT LUNG INJURY
Pneumonia	Sepsis
Aspiration of gastric contents	Severe trauma
Pulmonary contusion	Multiple bone fractures
Near-drowning	Flail chest
Toxic inhalation injury	Head trauma
	Burns
	Multiple transfusions
	Drug overdose
	Pancreatitis
	Postcardiopulmonary bypass

TABLE 312-2 Diagnostic Criteria for ARDS Based on 2012 Berlin Criteria

SEVERITY: OXYGENATION[a]	ONSET	CHEST RADIOGRAPH[b]	ABSENCE OF LEFT ATRIAL HYPERTENSION
Mild: 200 mmHg < Pao_2/Fio_2 ≤300 mmHg *Moderate:* 100 mmHg < Pao_2/Fio_2 ≤200 mmHg *Severe:* Pao_2/Fio_2 ≤100 mmHg	Acute: Within 1 week of a clinical insult or new or worsening respiratory symptoms	Bilateral opacities consistent with pulmonary edema not fully explained by effusions, lobar/lung collapse, or nodules	Hydrostatic edema is not the primary cause of respiratory failure. If no ARDS risk factor is present, then some objective evaluation is required (e.g., echocardiography) to rule out hydrostatic edema

[a]As assessed on at least 5 cmH_2O of positive end-expiratory pressure (PEEP). 2023 proposed updates to the Berlin criteria include: (1) consideration of ARDS in nonintubated patients using Pao_2/Fio_2 ≤300 mmHg or Spo_2/Fio_2 (S/F) ≤315 mmHg (if Spo_2 ≤97% as measured by pulse oximetry) on high-flow nasal oxygen with flow of ≥30 L/min or noninvasive ventilation/continuous positive airway pressure with at least 5 cmH_2O of PEEP; (2) addition of S/F ratios to consideration of ARDS in intubated patients (mild: 235 < Spo_2/Fio_2 ≤ 315 mmHg; moderate: 148 < Spo_2/Fio_2 ≤ 235 mmHg; severe: Spo_2/Fio_2 ≤148 mmHg [if Spo_2 ≤97%]); and (3) consideration of ARDS in resource-limited settings if Spo_2/Fio_2 ≤ 315 mmHg (if Spo_2 ≤97%) without requirement for PEEP, minimum oxygen flow rate, or specific respiratory support devices. It should be noted that pulse oximetry may overestimate the oxygen saturation in patients with darker skin tones, such that correlation with Pao_2 should be considered when feasible. [b]The 2023 proposed update to the Berlin criteria permits ultrasound as an alternative imaging modality, especially in resource-limited settings.

Abbreviations: ARDS, acute respiratory distress syndrome; Fio_2, inspired O_2 percentage; Pao_2, arterial partial pressure of O_2; Spo_2, peripheral saturation of O_2.

Exudative Phase In this phase, alveolar capillary endothelial cells and type I pneumocytes (alveolar epithelial cells) are injured, with consequent loss of the normally tight alveolar barrier to fluid and macromolecules. Edema fluid that is rich in protein accumulates in the interstitial and alveolar spaces (Fig. 312-2). Proinflammatory cytokines (e.g., interleukin 1, interleukin 6, interleukin 8, and tumor necrosis factor α [TNF-α]) and lipid mediators (e.g., leukotriene B_4) are increased in this acute phase, leading to the recruitment of leukocytes (especially neutrophils) into the pulmonary interstitium and alveoli. In addition, condensed plasma proteins aggregate in the air spaces with cellular debris and dysfunctional pulmonary surfactant to form hyaline membrane whorls. Pulmonary vascular injury also occurs early in ARDS, with vascular obliteration by microthrombi and fibrocellular proliferation (Fig. 312-3).

Alveolar edema often predominantly involves *dependent* portions of the lung with diminished aeration. Collapse of large sections of dependent lung can contribute to decreased lung compliance. Consequently, intrapulmonary shunting and hypoxemia develop and the work of breathing increases, leading to dyspnea. The pathophysiologic alterations in alveolar spaces are exacerbated by microvascular occlusion that results in reductions in pulmonary arterial blood flow to ventilated portions of the lung (and thus in increased dead space and pulmonary vascular resistance) and in pulmonary hypertension. Thus, in addition to severe hypoxemia, hypercapnia secondary to an increase in pulmonary dead space can be prominent in ARDS.

The exudative phase usually encompasses the first 7 days of illness after exposure to a precipitating ARDS risk factor, with the patient experiencing the onset of respiratory symptoms. Although usually presenting within 12–36 h after the initial insult, symptoms can be delayed by 5–7 days. Dyspnea develops, with a sensation of rapid shallow breathing and an inability to get enough air. Tachypnea and increased work of breathing result frequently in respiratory fatigue and ultimately in respiratory failure. Laboratory values are generally nonspecific and are primarily indicative of underlying clinical disorders. The chest radiograph usually reveals opacities consistent with pulmonary edema and often involves at least three-quarters of the lung fields (Fig. 312-2). While characteristic for ARDS, these radiographic findings are not specific and can be indistinguishable from cardiogenic pulmonary edema (Chap. 316). Unlike the latter, however, the chest x-ray in ARDS may not demonstrate cardiomegaly, pleural effusions, or pulmonary vascular redistribution as is often present in pure cardiogenic pulmonary edema. If no ARDS risk factor is present, then some objective evaluation is required (e.g., echocardiography) to exclude a cardiac etiology for hydrostatic edema. Chest computed tomography (CT) in ARDS also reveals the presence of bilateral pulmonary infiltrates and demonstrates extensive heterogeneity of lung involvement (Fig. 312-4).

Because the early features of ARDS are nonspecific, alternative diagnoses must be considered, although it is possible that there can be coexisting conditions with ARDS. In the differential diagnosis of ARDS, the most common disorders are cardiogenic pulmonary edema, bilateral pneumonia, and alveolar hemorrhage. Less common diagnoses to consider include acute interstitial lung diseases (e.g., acute interstitial pneumonitis; Chap. 304), acute immunologic injury (e.g., hypersensitivity pneumonitis; Chap. 299), toxin injury (e.g., radiation pneumonitis; Chap. 80), and neurogenic pulmonary edema (Chap. 39).

Proliferative Phase This phase of ARDS usually lasts from approximately day 7 to day 21. Many patients recover rapidly during this phase. Despite this improvement, many patients still experience dyspnea, tachypnea, and hypoxemia. Some patients develop progressive lung injury and early changes of pulmonary fibrosis during the proliferative phase. Histologically, the first signs of resolution are often

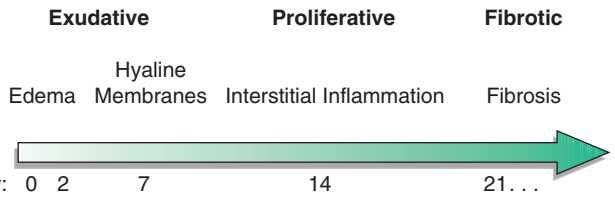

FIGURE 312-1 Diagram illustrating the time course for the development and resolution of acute respiratory distress syndrome (ARDS). The exudative phase is notable for early alveolar edema and neutrophil-rich leukocytic infiltration of the lungs, with subsequent formation of hyaline membranes from diffuse alveolar damage. Within 7 days, a proliferative phase ensues with prominent interstitial inflammation and early fibrotic changes. Approximately 3 weeks after the initial pulmonary injury, most patients recover. However, some patients enter the fibrotic phase, with substantial fibrosis and bullae formation.

FIGURE 312-2 A representative anteroposterior chest x-ray in the exudative phase of acute respiratory distress syndrome (ARDS) shows bilateral opacities consistent with pulmonary edema that can be difficult to distinguish from left ventricular failure.

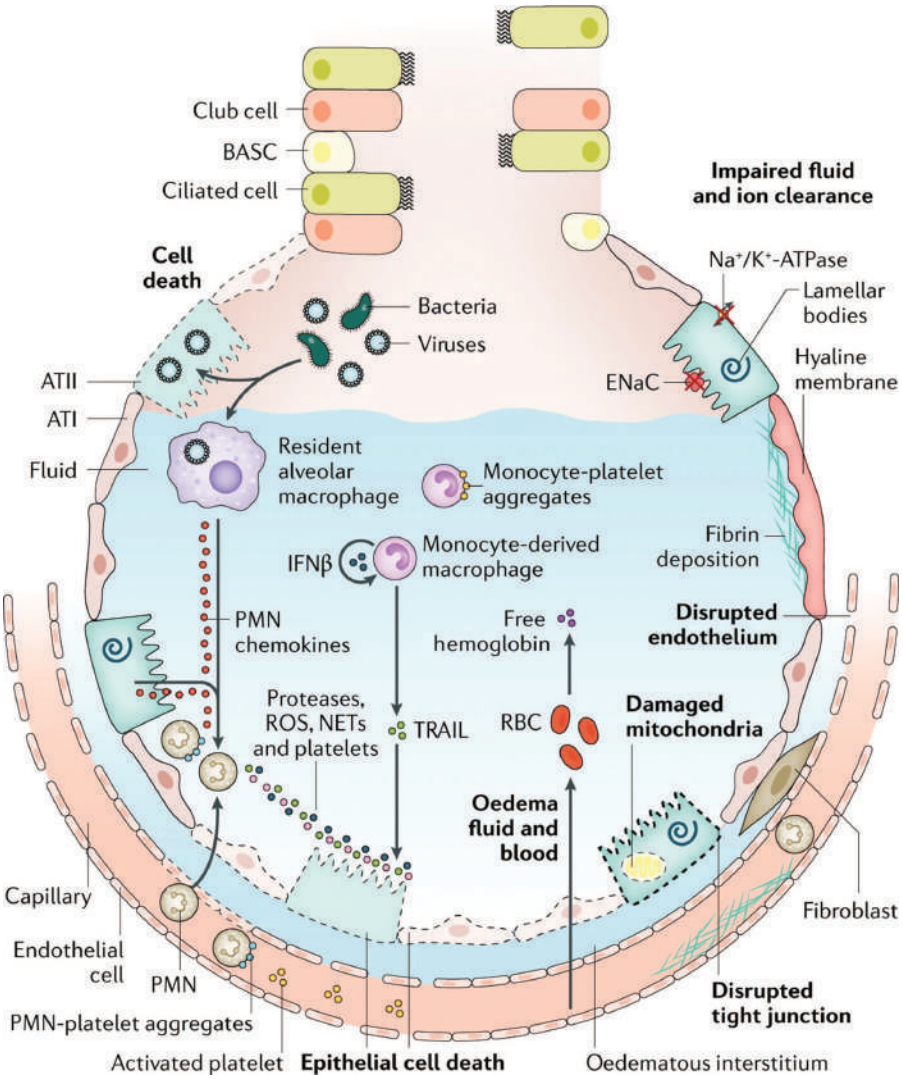

FIGURE 312-3 The injured alveolus in the acute phase of acute lung injury and the acute respiratory distress syndrome. A variety of insults (e.g., bacteria, viruses) can injure the epithelium, and this direct injury is propagated by subsequent activation of downstream pathways. Activation of Toll-like receptors (not shown) on alveolar type II (ATII) epithelial cells and resident macrophages induces the secretion of chemokines, which recruit circulating immune cells into the airspaces. As neutrophils migrate across the epithelium, they release toxic mediators, including proteases, reactive oxygen species (ROS) and neutrophil extracellular traps (NETs), which have an important role in host defense but also can exacerbate endothelial and epithelial injury. Monocytes also migrate into the lung and can cause injury, including epithelial cell apoptosis via interferon (IFN)-β-dependent release of tumor necrosis factor (TNF)-related apoptosis-inducing ligand (TRAIL), which activates death receptors. Activated platelets form aggregates with polymorphonuclear (PMN) leukocytes (which are involved in NET formation) and monocytes. Red blood cells (RBCs) release cell-free hemoglobin, which exacerbates injury via oxidant-dependent mechanisms. Epithelial injury also includes injury to the plasma membrane, which can be induced by bacterial pore-forming toxins or mechanical stretch (often related to mechanical ventilation), and mitochondrial dysfunction. Together, these and other effects result in endothelial and epithelial permeability, which further facilitate the transmigration of leukocytes and lead to the influx of edematous fluid and RBCs. Airspace filling with edematous fluid causes hypoxemia, often resulting in the need for mechanical ventilation. Vascular injury and alveolar edema can contribute to decreased ability to excrete CO_2 (hypercapnia), accounting for increased pulmonary dead space in acute respiratory distress syndrome. In turn, hypoxemia and hypercapnia impair sodium transport, reducing alveolar edema clearance. ATI, alveolar type I cell; BASC, bronchioalveolar stem cell; ENaC, epithelial sodium channel. *(Reproduced with permission from MA Matthay et al: Acute respiratory distress syndrome. FIGURE 312-4 A representative CT scan of the chest during the exudative phase of acute respiratory distress syndrome (ARDS), in which *dependent* alveolar edema and atelectasis predominate.

evident in this phase, with the initiation of lung repair, the organization of alveolar exudates, and a shift from neutrophil- to lymphocyte-predominant pulmonary infiltrates. As part of the reparative process, type II pneumocytes proliferate along alveolar basement membranes. These specialized epithelial cells synthesize new pulmonary surfactant and differentiate into type I pneumocytes.

Fibrotic Phase While many patients with ARDS recover lung function 3–4 weeks after the initial pulmonary injury, some enter a fibrotic phase that may require long-term support on mechanical ventilators and/or supplemental oxygen. Histologically, the alveolar edema and inflammatory exudates of earlier phases convert to extensive alveolar-duct and interstitial fibrosis. Marked disruption of acinar architecture leads to emphysema-like changes, with large bullae. Intimal fibroproliferation in the pulmonary microcirculation causes progressive vascular occlusion and pulmonary hypertension. The physiologic consequences include an increased risk of pneumothorax, reductions in lung compliance, and increased pulmonary dead space. Patients in this late phase experience a substantial burden of excess

morbidity. Lung biopsy evidence for pulmonary fibrosis in any phase of ARDS is associated with increased mortality risk.

TREATMENT

Acute Respiratory Distress Syndrome

GENERAL PRINCIPLES

Recent reductions in ARDS mortality rates are largely the result of general advances in the care of critically ill patients **(Chap. 311)**. Thus, caring for these patients requires close attention to (1) the recognition and treatment of underlying medical and surgical disorders (e.g., pneumonia, sepsis, aspiration, trauma); (2) the minimization of unnecessary procedures and their complications; (3) standardized "bundled care" approaches for ICU patients, including prophylaxis against venous thromboembolism, gastrointestinal bleeding, aspiration, excessive sedation, prolonged mechanical ventilation, and central venous catheter infections; (4) prompt recognition of nosocomial infections; and (5) provision of adequate nutrition via the enteral route when feasible.

MANAGEMENT OF MECHANICAL VENTILATION

(See also Chap. 313) Patients meeting clinical criteria for ARDS frequently become fatigued from increased work of breathing and progressive hypoxemia, requiring mechanical ventilation for support, although increasing use of high-flow nasal oxygen and noninvasive ventilation has enabled some patients to avoid mechanical ventilation.

Minimizing Ventilator-Induced Lung Injury Despite its life-saving potential, mechanical ventilation can aggravate lung injury from high tidal volumes. Experimental models have demonstrated that ventilator-induced lung injury can arise from at least two principal mechanisms: "volutrauma" from repeated alveolar overdistention from excess tidal volume (that might also coincide with increased alveolar pressures, or "barotrauma") and "atelectrauma" from recurrent alveolar collapse. As is evident from chest CT (Fig. 312-4), ARDS is a heterogeneous disorder, often principally involving dependent portions of the lung with relative sparing of other regions. Because compliance differs in affected versus more "normal" areas of the lung, attempts to fully inflate the consolidated lung may lead to overdistention of and injury to the more normal areas. Ventilator-induced injury can be demonstrated in experimental models of acute lung injury, in particular with high-tidal-volume (V_T) ventilation.

A large-scale, randomized controlled trial sponsored by the National Institutes of Health and conducted by the ARDS Network compared low V_T ventilation (6 mL/kg of predicted body weight) to conventional V_T ventilation (12 mL/kg predicted body weight). Lower airway pressures were also targeted in the low-tidal-volume group (i.e., plateau pressure measured on the ventilator after a 0.5-s pause after inspiration), with pressures targeted at ≤30 cmH_2O in the low-tidal-volume group versus ≤50 cmH_2O in the high-tidal-volume group. The mortality rate was significantly lower in the low V_T patients (31%) than in the conventional V_T patients (40%). This improvement in survival represents a substantial ARDS mortality benefit.

Minimizing Atelectrauma by Prevention of Alveolar Collapse In ARDS, the presence of alveolar and interstitial fluid and the loss of surfactant can lead to a marked reduction of lung compliance. Without an increase in end-expiratory pressure, significant alveolar collapse can occur at end-expiration, with consequent impairment of oxygenation. In most clinical settings, positive end-expiratory pressure (PEEP) is adjusted to minimize F_{IO_2} (inspired O_2 percentage) and provide adequate P_{AO_2} (arterial partial pressure of O_2) without causing alveolar overdistention. It should be noted that high-flow nasal cannula may provide low levels of PEEP. Currently, there is no consensus on the optimal method to set PEEP on the ventilator because numerous trials have proved inconclusive. Possible approaches include using the table of PEEP-F_{IO_2} combinations from the ARDS Network trial group, generating a static pressure-volume curve for the respiratory system and setting PEEP just above the lower inflection point on this curve to maximize respiratory system compliance, and measuring esophageal pressures to estimate transpulmonary pressure (which may be particularly helpful in patients with a stiff chest wall). Of note, a recent phase 2 trial in patients with moderate-to-severe ARDS demonstrated no benefit of routine use of esophageal pressure-guided PEEP titration over empirical high PEEP-F_{IO_2} titration. Until more data become available on how best to optimize PEEP settings in ARDS, clinicians can use these options or a practical approach to empirically measure "best PEEP" at the bedside to determine the optimal settings that best promote alveolar recruitment, minimize alveolar overdistention and hemodynamic instability, and provide adequate P_{AO_2} while minimizing F_{IO_2} **(Chap. 313)**.

Prone Positioning While several prior trials demonstrated that mechanical ventilation in the prone position improved arterial oxygenation without a mortality benefit, a 2013 trial demonstrated a significant reduction in 28-day mortality with prone positioning (32.8 to 16.0%) for patients with severe ARDS (P_{AO_2}/F_{IO_2} <150 mmHg) early in their course of illness. Thus, many centers increased the use of prone positioning in severe ARDS, especially during the COVID pandemic, with the understanding that this maneuver requires a critical care team that is experienced in "proning," as repositioning critically ill patients can be hazardous, leading to accidental endotracheal extubation, loss of central venous catheters, and orthopedic injury.

OTHER STRATEGIES IN MECHANICAL VENTILATION

Recruitment maneuvers that transiently increase PEEP to high levels to "recruit" atelectatic lung can increase oxygenation, but a mortality benefit has not been established, and in fact, recruitment maneuvers were shown to increase mortality when combined with higher baseline PEEP settings. *Alternate modes of mechanical ventilation*, such as airway pressure release ventilation and high-frequency oscillatory ventilation, have not been proven beneficial over standard modes of ventilation in ARDS management. *In one study, lung-replacement therapy with extracorporeal membrane oxygenation* (ECMO) was shown to improve mortality for patients with ARDS in the United Kingdom who were referred to an ECMO center (though only 75% of referred patients received ECMO) and thus may have utility in select adult patients with severe ARDS as a rescue therapy. A subsequent study demonstrated that initial use of ECMO in patients with severe ARDS was not superior to use of ECMO as a rescue strategy for patients who failed standard ARDS management.

FLUID MANAGEMENT

(See also Chap. 311) Increased pulmonary vascular permeability leading to interstitial and alveolar edema fluid rich in protein is a central feature of ARDS. In addition, impaired vascular integrity augments the normal increase in extravascular lung water that occurs with increasing left atrial pressure. Maintaining a low left atrial filling pressure minimizes pulmonary edema and prevents further decrements in arterial oxygenation and lung compliance; improves pulmonary mechanics; and shortens ICU stay and the duration of mechanical ventilation. Thus, aggressive attempts to reduce left atrial filling pressures with fluid restriction and diuretics should be an important aspect of ARDS management, limited only by hypotension and hypoperfusion of critical organs such as the kidneys.

NEUROMUSCULAR BLOCKADE

In severe ARDS, sedation alone can be inadequate for the patient-ventilator synchrony required for lung-protective ventilation. In a multicenter, randomized, placebo-controlled trial of early neuromuscular blockade (with cisatracurium besylate) for 48 h, patients with severe ARDS had increased survival and ventilator-free days without increasing ICU-acquired paresis. A subsequent trial demonstrated no mortality benefit for early neuromuscular blockade for

48 h in patients with moderate-to-severe ARDS. This more recent study supports the notion that selective use of neuromuscular blockade might be beneficial in those ARDS patients with ventilatory dyssynchrony despite sedation.

GLUCOCORTICOIDS

Many attempts have been made to treat both early and late ARDS with glucocorticoids, with the goal of reducing potentially deleterious pulmonary inflammation. Few studies have shown any significant mortality benefit. Current evidence does *not* support the routine use of glucocorticoids in the care of ARDS patients. More recent guidelines have supported the use of low-dose hydrocortisone (200 mg over 24 h) in sepsis patients with refractory hypotension and in patients with severe community-acquired pneumonia, which are conditions that often coexist with ARDS.

OTHER THERAPIES

Clinical trials of surfactant replacement and multiple other medical therapies have proved disappointing. Pulmonary vasodilators such as inhaled nitric oxide and inhaled epoprostenol sodium can transiently improve oxygenation in some patients but have not been shown to improve survival or decrease time on mechanical ventilation.

RECOMMENDATIONS

Many clinical trials have been undertaken to improve the outcome of patients with ARDS; most have been unsuccessful in modifying the natural history. While results of large clinical trials must be judiciously applied to *individual* patients, evidence-based recommendations are summarized in **Table 312-3**, and an algorithm for the initial therapeutic goals and limits in ARDS management is provided in **Fig. 312-5**. Please note that these recommendations apply to non–COVID-19 ARDS. Please see recommendations for COVID-19 ARDS in **Chap. 205**.

TABLE 312-3 Evidence-Based Recommendations for ARDS Therapies

TREATMENT	RECOMMENDATION[a]
Mechanical ventilation	
Low tidal volume	A
Minimized left atrial filling pressures	B
High-PEEP or "open lung"	B[b]
Prone position	B[b]
Recruitment maneuvers	C[b]
High-frequency ventilation	D
ECMO	B[b]
Early neuromuscular blockade (routine use)	C[b]
Glucocorticoid treatment	D[c]
Inhaled vasodilators (e.g., inhaled NO, inhaled epoprostenol)	C
Surfactant replacement, and other anti-inflammatory therapy (e.g., ketoconazole, PGE_1, NSAIDs)	D

[a]Key: A, recommended therapy based on strong clinical evidence from randomized clinical trials; B, recommended therapy based on supportive but limited clinical data; C, recommended only as alternative therapy on the basis of indeterminate evidence; D, not recommended on the basis of clinical evidence against efficacy of therapy. [b]As described in the text, there is no consensus on optimal PEEP setting in ARDS, but general consensus supports an open lung strategy that minimizes alveolar distention with some studies favoring the high PEEP-F_{IO_2} ARDS table; prone positioning was shown to improve mortality in severe ARDS in one randomized controlled clinical trial; recruitment maneuvers combined with high PEEP were shown to increase mortality in one study; ECMO may be beneficial in select patients with severe ARDS; early neuromuscular blockade demonstrated a mortality benefit in one randomized controlled trial in patients with severe ARDS but was not replicated in a subsequent study, suggesting routine use of early neuromuscular blockade in all subjects with moderate-severe ARDS may not be beneficial. [c]While there are no direct supportive data for use of glucocorticoids in ARDS, there are recent data supporting the consideration of low-dose hydrocortisone in two conditions frequently encountered in patients with ARDS: (1) the 2021 Surviving Sepsis guidelines recommend consideration of low-dose hydrocortisone in patients with refractory hypotension due to septic shock, and (2) a recent study demonstrated a mortality benefit of low-dose hydrocortisone in patients with severe community-acquired pneumonia.

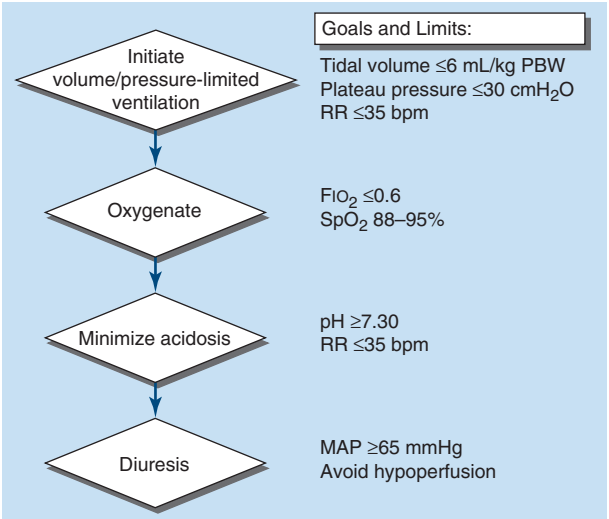

FIGURE 312-5 Algorithm for the initial management of acute respiratory distress syndrome (ARDS). Clinical trials have provided evidence-based therapeutic goals for a stepwise approach to the early mechanical ventilation, oxygenation, and correction of acidosis and diuresis of critically ill patients with ARDS. F_{IO_2}, inspired O_2 percentage; MAP, mean arterial pressure; PBW, predicted body weight; RR, respiratory rate; Spo_2, arterial oxyhemoglobin saturation measured by pulse oximetry.

PROGNOSIS

Mortality In the Large Observational Study to Understand the Global Impact of Severe Acute Respiratory Failure (LUNG SAFE) trial, hospital mortality estimates for ARDS were 34.9% for mild ARDS, 40.3% for moderate ARDS, and 46.1% for severe ARDS. There is substantial variability, but a trend toward improved ARDS outcomes over time appears evident. Of interest, mortality in ARDS is largely attributable to nonpulmonary causes, with sepsis and nonpulmonary organ failure accounting for >80% of deaths. Thus, improvement in survival is likely secondary to advances in the care of septic/infected patients and those with multiple organ failure **(Chap. 311)**.

The major risk factors for ARDS mortality are nonpulmonary. Advanced age is an important risk factor. Patients aged >75 years have a substantially higher mortality risk (~60%) than those <45 (~20%). Moreover, patients >60 years of age with ARDS and sepsis have a threefold higher mortality risk than those <60 years of age. Other risk factors include preexisting organ dysfunction from chronic medical illness—in particular, chronic liver disease, chronic alcohol abuse, and chronic immunosuppression **(Chap. 311)**. Patients with ARDS arising from direct lung injury (including pneumonia, pulmonary contusion, and aspiration; Table 312-1) are nearly twice as likely to die as those with indirect causes of lung injury, while surgical and trauma patients with ARDS—especially those without direct lung injury—generally have a higher survival rate than other ARDS patients.

Increasing severity of ARDS, as defined by the consensus Berlin definition, predicts increased mortality. Surprisingly, there is little additional value in predicting ARDS mortality from other parameters of lung injury, including the level of PEEP (≥10 cmH_2O), respiratory system compliance (≤40 mL/cmH_2O), the extent of alveolar infiltrates on chest radiography, and the corrected expired volume per minute (≥10 L/min) (as a surrogate measure of dead space).

Functional Recovery in ARDS Survivors While it is common for patients with ARDS to experience prolonged respiratory failure and remain dependent on mechanical ventilation for survival, it is a testament to the resolving powers of the lung that the majority of

patients who survive regain nearly normal lung function. Patients usually recover maximal lung function within 6 months. One year after endotracheal extubation, more than one-third of ARDS survivors have normal spirometry values and diffusion capacity. Most of the remaining patients have only mild abnormalities in pulmonary function. Unlike mortality risk, recovery of lung function is strongly associated with the extent of lung injury in early ARDS. Low static respiratory compliance, high levels of required PEEP, longer durations of mechanical ventilation, and high lung injury scores are all associated with less recovery of pulmonary function. Of note, when physical function is assessed 5 years after ARDS, exercise limitation and decreased physical quality of life are often documented despite normal or nearly normal pulmonary function. When caring for ARDS survivors, it is important to be aware of the potential for a substantial burden of psychological problems in patients and family caregivers, including significant rates of depression and posttraumatic stress disorder. Investigations into sequelae of COVID ARDS have provided additional insight into long-term ICU outcomes. Please see **Chap. 205** for information regarding COVID prognosis and recovery.

313 Mechanical Ventilatory Support

Scott Schissel

Mechanical ventilation refers to devices that deliver positive pressure gas, of varying oxygen content, to patients with acute or chronic respiratory failure. Hypoxemic respiratory failure refractory to supplemental oxygen and requiring mechanical ventilation is most often due to ventilation-perfusion mismatch or shunt caused by processes such as pneumonia, pulmonary edema, alveolar hemorrhage, acute respiratory distress syndrome (ARDS), and sequelae of trauma or surgery. Hypercapnic respiratory failure is most frequently caused by severe exacerbations of obstructive lung disease, including asthma and chronic obstructive pulmonary disease (COPD); loss of central respiratory drive from acute neurologic events, such as stroke, intracranial hemorrhage, or drug overdose; and respiratory muscle weakness from diseases such as Guillain-Barré syndrome. Mechanical ventilation may also be necessary if patients have an artificial airway placed (an endotracheal tube) due to poor airway protection, such as in coma or in the context of a large upper gastrointestinal hemorrhage and vomiting, or due to processes leading to large airway obstruction, such as laryngeal edema. Finally, since mechanical ventilation can lower the work of breathing compared to spontaneous ventilation, it is a useful adjunct therapy for shock and multiorgan system failure.

PRINCIPLES OF MECHANICAL VENTILATION

Although contemporary mechanical ventilators use positive pressure to inflate the lungs, a patient's response to pressure applied across the lung (transpulmonary pressure) depends on the elastic properties of their lungs and chest wall; the amount of pressure needed to inflate a lung is the same, therefore, whether applied positively via mechanical ventilation or negatively using the diaphragm and chest wall muscles. In ARDS, for example, lungs are "stiff" or poorly compliant and often require much more pressure to achieve a physiologic tidal volume **(Fig. 313-1)**, which, over time, may lead to respiratory muscle fatigue. If a patient with ARDS is on mechanical ventilation and makes no spontaneous respiratory effort, using sedation and neuromuscular blockade, the amount of positive pressure needed to inflate the lung is equal to the negative inflation pressure required if the patient were spontaneously breathing; however, the work of breathing is removed on a ventilator, allowing for sustainable ventilation.

Mechanical ventilation can be lifesaving by restoring adequate oxygenation and correcting hypercapnia. Optimal application of positive-pressure ventilation, however, requires avoiding underinflation, which can cause cycles of alveolar recruitment then collapse and, at the other extreme, alveolar overinflation **(Fig. 313-2)**; collectively, these processes can cause ventilator-induced lung injury by barotrauma and volume trauma. Optimal tidal volume ventilation occurs along the lung pressure–volume curve where respiratory system compliance is greatest, or where the smallest change in applied pressure leads to the greatest increase in lung volume (Fig. 313-2, *shaded box*). To prevent too low lung volumes at end-exhalation, where alveolar collapse occurs, the ventilator can be set to maintain a specified positive pressure at end-exhalation, or positive end-expiratory pressure (PEEP) (Fig. 313-2*B*). Lower tidal volume ventilation (goal 6 mL/kg of ideal body weight)

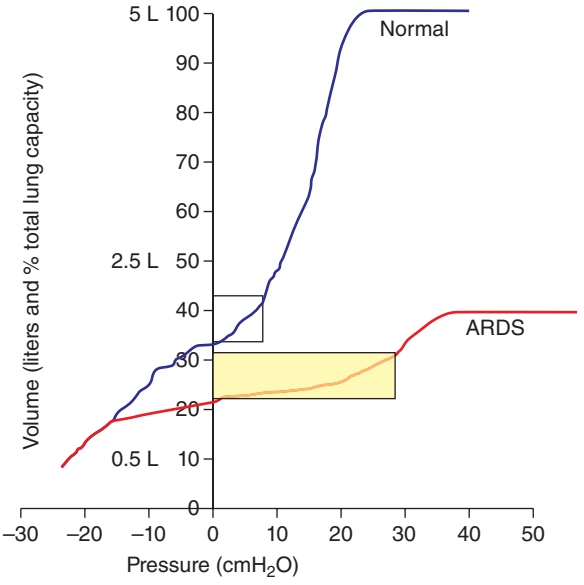

FIGURE 313-1 Hypothetical pressure-volume curves of patients with normal lung function (normal) and acute respiratory distress syndrome (ARDS). A tidal volume breath of 0.5 L in the normal lung requires 8 cmH_2O of pressure (*open box*), but in ARDS requires 28 cmH_2O (*shaded box*).

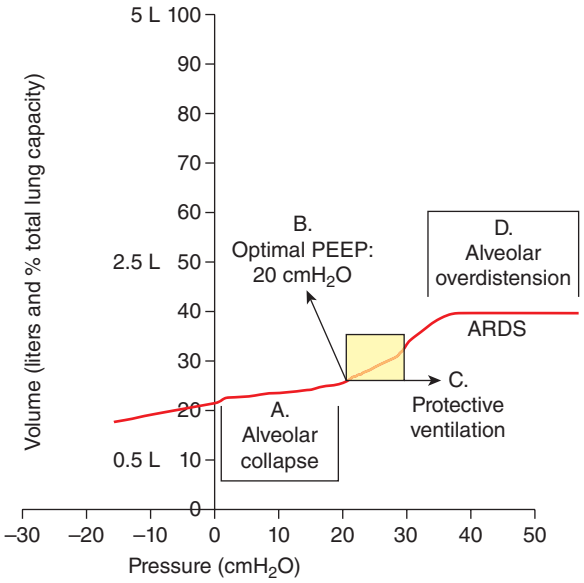

FIGURE 313-2 Hypothetical pressure-volume curve of a patient with acute respiratory distress syndrome (ARDS), demonstrating optimal positive end-expiratory pressure (PEEP) and protective ventilation. A tidal volume breath of 0.5 L initiated at a PEEP of 20 cmH_2O (*B*), after the area of greatest alveolar collapse (*A*). End inhalation occurs within the most compliant portion of the pressure-volume curve (*C*) and at a pressure <30 cmH_2O, before the area where lung overdistention occurs (*D*), minimizing lung injury.

can help prevent the end-inhalation, or "plateau," pressure (measured just after flow stops at end-inhalation) from exceeding 30 cmH_2O; this approach minimizes barotrauma and volume trauma–induced lung injury, especially in ARDS patients (Fig. 313-2*C*).

MECHANICAL VENTILATION MODES

Mechanical ventilation entails controlling or monitoring the same basic variables involved in spontaneous, negative-pressure breathing, including respiratory rate, tidal volume (V_T), inspiratory flow rate and time, and the fraction of inspired oxygen (FIO_2). In addition, the PEEP is a variable specific to positive-pressure ventilation and set by the clinician. The mechanical ventilation mode determines how much control the clinician and ventilator have over these variables versus the patient; for example, assist control (AC) mode allows for essentially complete operator control of all variables, whereas pressure support (PS) permits the patient to control important variables, such as respiratory rate, V_T, and flow rates (Table 313-1).

ASSIST CONTROL VENTILATION

AC allows the clinician to control nearly all ventilator variables and is widely used when patients cannot safely participate in their own ventilatory efforts, such as when deeply sedated or unstable from acute respiratory failure or other critical illness. Most AC ventilation is in *volume control* mode where the operator sets a specific V_T and respiratory rate, thereby assuring a minimum minute ventilation (V_E). In addition to the set rate, patients can get additional, fully supported breaths at the set V_T by making an inspiratory effort, which is sensed by the ventilator and triggers the breath. The inspiratory flow rate is set by the operator; thus, a dyspneic patient may meet resistance on inhalation if their desired flow rate is higher than the set rate, possibly leading to patient distress and increased work of breathing. In AC volume mode, the operator also sets the PEEP and FIO_2. Importantly, since V_T is an independent variable in volume control (i.e., set by the clinician), the end-inhalation (or plateau) pressure is a dependent variable not controlled by the clinician but rather determined by the compliance of the lung. Inspiratory pressures must be monitored, therefore, to minimize barotrauma.

Although AC is often volume controlled, it can be used in a *pressure control* mode, also referred to as pressure control ventilation (PCV). The key difference between volume control and PCV is that an inspiratory (or "driving") pressure is set instead of a tidal volume in PCV; thus, every time the ventilator delivers a breath, it raises the airway pressure to the set amount above PEEP until inspiratory flow decreases below a set threshold, therefore ending inhalation. The resulting tidal volume will, therefore, vary depending on the compliance of the lung. In a sedated and paralyzed patient (making no respiratory effort), the pressure required to generate a specific tidal volume (*x*) using PCV should, in the same patient, be equal to the plateau pressure in volume control mode where tidal volume is set at *x*. Importantly, since lung compliance can change dynamically, tidal volume may also change with PCV; tidal volume and minute ventilation, therefore, must be monitored since there is no assurance of delivered ventilation volumes as with volume control. PCV is often used to limit peak airway and lung distending (plateau) pressures in situations where high pressure can cause harm, such as in ARDS or after thoracic surgery with fresh suture lines in the airways or lung parenchyma. Importantly, however, inspiratory flow rate and volume are dependent variables in PCV, unlike in volume control ventilation, and not set by the clinician. Spontaneously breathing patients on PCV can generate a relative negative pressure in the

TABLE 313-1 Key Features of Commonly Used Mechanical Ventilation Modes

MODE	VARIABLES SET BY CLINICIAN (INDEPENDENT)	MONITORED VARIABLES (DEPENDENT)	ADVANTAGES	DISADVANTAGES
Assist control–volume control	V_T Respiratory rate PEEP FIO_2 Inspiratory flow rate	Peak inspiratory airway pressure End-inhalation (plateau) pressure V_E	Guarantee minimum V_T and V_E Control V_T, limiting volume trauma	Barotrauma from high plateau pressure Patient-ventilator dyssynchrony, increased work of breathing
Assist control–pressure control	Inspiratory driving pressure Respiratory rate PEEP FIO_2	Tidal volume V_E	Limit barotrauma (if patient respiratory efforts minimal) Inspiratory flow can vary with patient effort (improved comfort/synchrony)	V_T and V_E not mandated; must monitor closely Patient's respiratory effort can lead to large V_T and volume trauma
Pressure-regulated volume control	V_T Respiratory rate PEEP FIO_2	Peak inspiratory airway pressure End-inhalation (plateau) pressure V_E	Patient effort can vary inspiratory flow, increasing comfort, and ventilator synchrony Guarantee minimum V_T and V_E	Variable patient effort can lead to V_T larger than set V_T; monitor to prevent volume trauma
Pressure support	Inspiratory pressure PEEP FIO_2	V_T Respiratory rate V_E	Patient effort preserved and controls V_T, inspiratory flow, and respiratory rate, allowing for ventilator synchrony	Apnea and hypoventilation possible; must monitor respiratory rate, V_T, and V_E closely

Abbreviations: FIO_2, fraction of inspired oxygen; PEEP, positive end-expiratory pressure; V_E, minute ventilation; V_T, tidal volume.

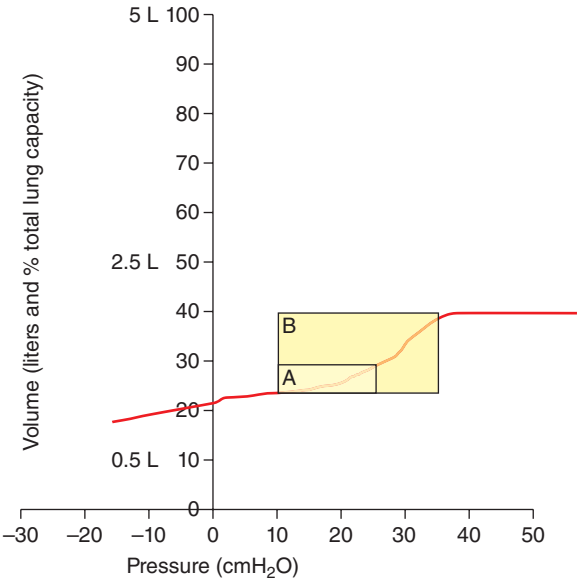

FIGURE 313-3 Hypothetical pressure-volume curve of a patient on pressure control ventilation, paralyzed (*A*) and breathing spontaneously (*B*). (*A*) Paralyzed patient (*light shaded box*): positive end-expiratory pressure (PEEP), 10 cmH_2O; inspiratory (driving) pressure, 15 cmH_2O; end-inhalation (plateau) pressure, 25 cmH_2O; tidal volume (V_T), 300 mL. (*B*) Breathing patient (*dark shaded box*): PEEP, 10 cmH_2O; inspiratory (driving) pressure, 15 cmH_2O; patient effort (negative "pulling" pressure), 10 cmH_2O; end-inhalation (plateau) pressure displayed on ventilator, 25 cmH_2O; net end-inhalation (transalveolar) pressure, 35 cmH_2O; V_T, 700 mL.

ventilator circuit, transiently decreasing the positive pressure below the set point; the ventilator responds by increasing gas flow until it restores the set pressure, resulting in higher inspiratory flow rates, a higher tidal volume for that breath, and importantly, increased pressure across the alveoli, equal to the absolute (negative) pressure generated by the patient plus the positive pressure set by the clinician **(Fig. 313-3)**. Since mechanical ventilators do not routinely measure or graphically display the negative pressure generated by the patient, clinicians can be unaware of this additional transalveolar pressure and potential harm by volume and barotrauma; importantly, therefore, clinicians should monitor for increases in tidal volume on PCV.

PRESSURE-REGULATED VOLUME CONTROL VENTILATION

Advances in ventilator technology, such as flow and pressure sensors and microprocessors, allow for additional modes of mechanical ventilation that meld the benefits of volume and pressure control ventilation. Pressure-regulated volume control (PRVC) ventilation is a fully supported mode of ventilation where the clinician sets a target tidal volume, as in volume control ventilation, but it allows a patient to make spontaneous respiratory efforts and vary inspiratory flow rates, as in PCV, enhancing patient comfort and ventilator synchrony. PRVC senses patient inspiratory efforts and delivers the least amount of positive pressure to achieve the targeted tidal volume; since patient efforts can vary and ventilator adaptation is not instantaneous, tidal volumes can vary from breath to breath on PRVC. In disease states where tidal volume needs tight control to prevent volume trauma, such as in ARDS, PRVC must be used cautiously if the patient can make significant respiratory effort.

PRESSURE SUPPORT VENTILATION

Pressure support ventilation (PSV) and PCV are very similar except there is no mandated ventilation or set mechanical respiratory rate on PSV, and ventilator support is entirely patient triggered and controlled. The clinician sets the F_{IO_2}, PEEP, and maximum inspiratory pressure. When patients make a negative-pressure inspiratory effort on PSV, the ventilator senses this pressure change and increases positive pressure to the set inspiratory pressure level, maintaining it until flow decreases below a set threshold (often ~20% of peak inspiratory flow); at this point, inhalation ends and pressure drops back to the set PEEP. The tidal volume on PSV is monitored but not assured, is determined by lung compliance, and depends on the patient's sustaining an inspiratory effort. Tidal volume, minute ventilation, and respiratory rate, therefore, must be closely monitored on PSV to detect hypopnea/apnea and hypoventilation. PSV is often used when patients are less sedated and able to participate in respiratory work, such as when transitioning off mechanical ventilation or on a ventilator only for airway support.

NONINVASIVE POSITIVE PRESSURE VENTILATION

Noninvasive ventilation (NIV) is historically referred to positive-pressure ventilation and is delivered via a nasal or full-face mask at a continuous pressure (continuous positive airway pressure [CPAP]) or at different inspiratory and expiratory pressures (bi-level positive airway pressure [BiPAP]). Most current noninvasive ventilators, however, can function in full support modes, including volume control ventilation. NIV is particularly beneficial for acute respiratory failure where the underlying cause responds quickly to treatment, minimizing the need for prolonged mechanical ventilatory support. For moderate acute hypercarbia, blood pH between 7.25 and 7.35, due to exacerbations of chronic obstructive pulmonary disease (COPD), NIV, for example, reduces the need for endotracheal intubation and shortens hospital length of stay; more severe acute respiratory acidosis from COPD exacerbations (blood pH <7.2) generally requires mechanical ventilation with an endotracheal tube. NIV can also be an important adjunct treatment for respiratory failure from acute cardiogenic pulmonary edema, where interventions, such as diuresis and vasodilator therapy, can rapidly improve gas exchange and respiratory mechanics. NIV, particularly with volume support modes, is effective in managing chronic respiratory failure from restrictive lung diseases, such as severe scoliosis and respiratory muscle weakness, and in COPD complicated by chronic hypercapnia, where nocturnal NIV reduces COPD-related hospital admissions. Despite the technical innovations in NIV and expanding clinical applications, several important contraindications to using mechanical ventilation without a secure airway, such as an endotracheal tube or tracheostomy tube, include delirium, difficulty managing respiratory secretions, and hemodynamic instability **(Table 313-2)**.

STRATEGIES TO OPTIMIZE GAS EXCHANGE ON MECHANICAL VENTILATION

ARTERIAL OXYGENATION

The optimal partial pressure of arterial oxygen (Pa_{O_2}) and oxygen saturation measured by pulse oximetry (Sp_{O_2}) during mechanical ventilation remain uncertain. Although tissue hyperoxia can cause oxidative injury with some clinical studies of mechanically ventilated patients suggesting worse clinical outcomes with higher F_{IO_2} and when Pa_{O_2} frequently reaches supraphysiologic levels, randomized studies comparing conservative oxygen delivery to a more liberal oxygen strategy have not demonstrated a clear advantage to conservative oxygen delivery. In ARDS, targeting a lower Pa_{O_2} of 55–70 mmHg (or Sp_{O_2} of 88–92%) versus a higher, but more physiologic, Pa_{O_2} of 90–105 mmHg (or Sp_{O_2} >96%) did not lower mortality, with adverse events being more frequent in the lower Pa_{O_2} group, including mesenteric ischemia. Pa_{O_2} and Sp_{O_2} targets, therefore, should be individualized to patients considering circumstances where even mild hyperoxia may be harmful, such as in recovery from ischemic brain injury, and, conversely, where lower Pa_{O_2} levels (<55–70 mmHg) may be less optimal, such as in patients with ARDS and evidence of bowel dysfunction. Regardless

TABLE 313-2 Common Contraindications to Noninvasive Ventilation

Inability to protect the airway, such as severe encephalopathy
High risk for aspiration, such as vomiting or severe upper gastrointestinal bleeding
Difficulty clearing respiratory secretions
Facial trauma or surgery
Upper airway obstruction or compromise
Significant hemodynamic instability

of the approach, there is no evidence that a supraphysiologic Pao_2 (>100 mmHg) has clinical benefit; thus, sustained hyperoxia should be avoided.

Arterial hypoxemia refractory to standard mechanical ventilation techniques is common in severe acute lung disease, especially ARDS. In general, if the FIO_2 requirement is >0.6 or the Pao_2:FIO_2 ratio is <150 mmHg, additional interventions should be considered to improve arterial oxygenation. The application of adequate PEEP to prevent alveolar collapse during exhalation improves oxygenation by decreasing ventilation/perfusion ($\dot{V}/\dot{Q}$) mismatch and shunt in areas of atelectatic lung. PEEP should ideally be set at the lower inflection point of the most compliant region of the lung pressure-volume curve (Fig. 313-2*B*). Although optimal PEEP may improve arterial oxygenation, achieving best PEEP has not been shown to improve clinical outcomes definitively and may have deleterious effects, including barotrauma with pneumothorax and hypotension from decreasing venous return to the right ventricle. Patients with refractory hypoxemia are often dyspneic on mechanical ventilation and make significant respiratory efforts dyssynchronous with the ventilator despite deep sedation, leading to poor ventilation and preventing optimal $\dot{V}/\dot{Q}$ matching. In this context, neuromuscular blockade can be very effective at restoring effective mechanical ventilation and optimizing gas exchange. Although a necessary intervention at times, neuromuscular blockade does not improve overall outcomes in ARDS, can contribute to critical illness myopathy, and requires adequately deep sedation to prevent conscious paralysis; thus, it should be used only when necessary to treat refractory hypoxemia. In ARDS, diseased lung is predominantly dependent, and placing the patient in a prone position for extended periods can significantly improve arterial oxygenation. The role of prone positioning in other disease states is unknown and can be associated with adverse events unless performed by a trained team, such as dislodging endotracheal tubes and central venous catheters. Delivery of pulmonary vasodilator medications through the airway can improve perfusion to ventilated alveolar units, therefore improving $\dot{V}/\dot{Q}$ matching and arterial oxygenation. Inhaled prostacyclins, such as epoprostenol, and nitric oxide are commonly used to treat refractory hypoxemia and can increase, on average, the Pao_2:FIO_2 ratio by 20–30 mmHg. Hypoxemia refractory to these multiple interventions may require consideration of transitioning to extracorporeal membrane oxygenation (ECMO; see below).

HYPERCAPNIA

Except for rare circumstances of excess CO_2 production (VCO_2), which can occur in the setting of fever, sepsis, overfeeding, and thyrotoxicosis, most hypercapnia is due to inadequate alveolar ventilation (V_A) from an increase in the fraction of dead space (V_D) [the volume of each breath not participating in CO_2 exchange] relative to the total minute ventilation (V_E), expressed as $V_A = V_E (1 - V_D/V_T)$. Normal physiologic dead space is approximately 150 mL (~2 mL/kg), making the V_D/V_T for a 500-mL tidal volume breath 0.3. In acute respiratory failure due to ARDS, for example, V_D may increase due to poorly perfused but ventilated portions of lung while ventilation strategies lead to low V_T; thus, a modest increase in V_D to 200 mL and a low V_T of 300 mL will result in a V_D/V_T of 0.66, a situation where hypercapnia may easily develop. Hypercapnia in the context of low tidal volume (6 mL/kg) ventilation for ARDS often causes acute respiratory acidosis that can be managed with higher respiratory rates, up to 30 breaths/min. Respiratory acidosis is often tolerated down to a pH of 7.2, so-called "permissive hypercapnia," but progressive acidosis may require intravenous alkalinizing therapy (e.g., sodium bicarbonate or tromethamine) or accepting an increase in V_T. In severe exacerbations of obstructive lung disease, COPD, and status asthmaticus, hypercapnia and acute respiratory acidosis are common despite mechanical ventilation, with average $Paco_2$ values of 65 mmHg and blood pH of 7.20 after initial endotracheal intubation. Poor alveolar ventilation is primarily due to dead space created by alveolar capillary compression in areas of alveolar overdistension and lung hyperinflation. Increasing minute ventilation by increasing the respiratory rate or tidal volume will, therefore, often paradoxically worsen hypercapnia by increasing gas trapping and V_D/V_T. The optimal ventilator strategy for severe obstructive lung disease physiology entails using lower respiratory rates, usually 9–12 breaths/min, and moderate tidal volumes (7–9 mL/kg) to maintain a minute ventilation of ~10 L/min; higher minute ventilation usually worsens hyperinflation and can cause barotrauma. To prevent dyspneic patients from driving hyperventilation, deeper sedation and occasionally neuromuscular blockade are necessary until severe bronchial obstruction responds to medical therapy. Although permissive hypercapnia can minimize barotrauma and volume trauma during mechanical ventilation, hypercapnia has adverse effects including increased intracranial pressure, pulmonary artery vasoconstriction, and even depressed cardiac contractility **(Table 313-3)**. The benefits and risks of a hypercapnia ventilatory strategy must, therefore, account for the individual patient's comorbid medical conditions, for example, acute neurologic injury and risk of critical increases in intracranial pressure.

TABLE 313-3 Adverse Effects of Hypercapnia[a]

Rightward shift of the oxyhemoglobin curve
Cerebral vasodilation
Increased intracranial pressure
Sympathetic-adrenal stimulation
Reduced cardiac contractility (especially in the presence of β-adrenergic blocking therapy)

[a]Some effects decrease if cellular pH is corrected.

COMPLICATIONS OF MECHANICAL VENTILATION

AIRWAY

Endotracheal intubation and mechanical ventilation can lead to several pulmonary and extrathoracic complications, especially when patients remain on mechanical ventilation for >7 days. Upper airway complications from endotracheal tube placement include vocal cord trauma (edema, avulsion, paralysis), tracheal stricture due to granulation tissue, and tracheomalacia. Vocal cord injury can lead to postextubation stridor (PES) and need for replacement of an endotracheal tube. PES risk factors include prolonged (>7 days) or traumatic intubation, large endotracheal tube size, previous episode of PES, and head/neck surgery or trauma. Patients with PES risk factors should have the balloon cuff deflated on their endotracheal tube and assessed for air passing across the balloon (so-called "cuff leak test"). Patients with no cuff leak have an approximate 30% risk of PES and may need further assessment for causes of PES, with endotracheal tube removal delayed until the underlying process is treated.

ADVERSE CARDIOPULMONARY EFFECTS OF POSITIVE-PRESSURE VENTILATION

High positive intrathoracic pressure, such as sustained inspiratory plateau pressures >30 cmH_2O or high PEEP, can cause several manifestations of lung barotrauma, including worsening of acute lung injury, pneumomediastinum, pneumothorax, and even pneumoperitoneum. Although positive-pressure ventilation can improve left-sided heart failure by decreasing left ventricular preload and afterload, right ventricular failure and pulmonary arterial hypertension can worsen due to inadequate right ventricular preload and an increase in right ventricular afterload and pulmonary vascular resistance; these effects on the right ventricular and pulmonary circulation should be considered when choosing a ventilatory strategy in patients with severe right-sided heart disease. In addition, blunted central venous return can cause upper and lower extremity edema, especially in the setting of aggressive IV fluid resuscitation and vascular leak related to the underlying critical illness.

VENTILATOR-ASSOCIATED PNEUMONIA

Several factors during mechanical ventilation, such as violation of natural airway defenses, sedation with depressed cough, and micro-aspiration, all increase the risk of bacterial entry into the lower respiratory tract and development of pneumonia. Ventilator-associated pneumonia (VAP)

occurs in up to 15% of mechanically ventilated patients and causes death in nearly 50% of patients. VAP is a lower respiratory tract infection that occurs ≥48 h after initiating mechanical ventilation and requires the following: (1) new pulmonary opacities on chest x-ray, (2) a clinical change consistent with pneumonia (fever, increased sputum, leukocytosis, or increase in ventilator support, such as increased FIO_2 or PEEP), and (3) positive microbial culture obtained from the lower respiratory tract via deep endotracheal suctioning or bronchoscopy specimen (bronchoalveolar lavage or protected endobronchial brushing). Most VAP pathogens are typical hospital-acquired bacteria including *Staphylococcus aureus*, *Pseudomonas aeruginosa*, and several other enteric gram-negative rods. In cases of suspected VAP, early empiric antibiotic therapy generally requires an intravenous β-lactam with broad gram-negative rod activity, such as piperacillin-tazobactam, cefepime, or ceftazidime. Empiric therapy for methicillin-resistant *S. aureus* (MRSA) with vancomycin or linezolid or for multidrug-resistant enteric gram-negative rods with a carbapenem should depend on local intensive care unit (ICU) infection control data or individual patient risk for these resistant bacteria. If possible, based on respiratory cultures, empiric antibiotic regimens should be narrowed and total treatment duration should be 7 days. Given the significant morbidity and mortality for VAP, prevention strategies are paramount and should be part of standardized care or "bundles." VAP prevention interventions supported by clinical trial evidence include head-of-bed elevation to at least 30–45° (70% VAP reduction compared to supine position), specialized endotracheal tube use with a suction port above the cuff to minimize aspirated secretions (50% VAP reduction), minimization of ventilator circuit tubing changes (prevents bacterial entry), and hand hygiene before handling the ventilatory circuit. Practices with uncertain value in reducing VAP but still reasonable include limiting deep tracheal suctioning, daily sedation interruption, and routine mouth and dental care.

OTHER

The systemic physiologic stress associated with mechanical ventilation and necessary adjunctive therapies, such as sedation and neuromuscular blockade, can cause significant extrathoracic complications. The more common disorders include gastrointestinal stress ulcers and bleeding, deep venous thrombosis and pulmonary embolism, sleep disruption and delirium, and critical illness–associated myopathy that sometimes leads to prolonged mechanical ventilation. To minimize the risk of these adverse events, ICUs should institute care bundles including daily interruption of sedatives and assessment for extubation and prophylaxis for deep venous thrombosis.

LIBERATION FROM MECHANICAL VENTILATION

Discontinuing mechanical ventilation and transitioning a patient back to spontaneous breathing is often referred to as ventilator "weaning," implying dependency on positive-pressure ventilation once started. Although patients on prolonged mechanical ventilation can develop respiratory muscle weakness, this occurs in a minority of patients. Approaching removal of ventilator support as a "wean" extends unnecessary mechanical ventilation time up to 40%. Liberating a patient from mechanical ventilation, therefore, should be more active by frequently assessing a patient's readiness for spontaneous breathing, determined largely by resolution of the underlying process causing respiratory failure **(Fig. 313-4)**. Important criteria indicating a patient may be ready for extubation include the following: underlying disease process has improved, patient is awake and largely off sedative medications, FIO_2 ≤0.5, PEEP <8 cmH_2O, and SaO_2 >88%, stable hemodynamics, and manageable respiratory secretions with adequate cough. These criteria should be assessed daily, and if achieved, patients should have a spontaneous breathing trial (SBT), which is a maneuver wherein positive pressure is set to a minimum to compensate for endotracheal tube resistance (usually 5–7 cmH_2O) and the patient breathes spontaneously from 30 to 120 min. A patient "passes" the SBT if they appear comfortable overall (no marked anxiety or diaphoresis) and have a respiratory rate <35, SaO_2 >90%, systolic blood pressure between 90 and 180 mmHg, and heart rate change of <20%. Patients passing an SBT have a >70% chance of successful extubation. Incorporating extubation "readiness" screening followed by SBT into a care protocol leads to 25% fewer ventilator days and a 10% decrease in ICU length of stay compared to traditional ventilator weaning. Although many physiologic variables correlate with successful liberation from mechanical ventilation, such as minute ventilation, negative inspiratory force generation, and the respiratory rate–to–tidal volume ratio (Tobin index), overrelying on these measures versus the outcome of an SBT leads to unnecessary delays in extubation. Risk factors for failing extubation even after a successful SBT include age >65, congestive heart failure, COPD, Acute Physiology and Chronic Health Enquiry (APACHE-II) score >12, body mass index (BMI) >30, significant secretions, more than two medical comorbidities, and >7 days on mechanical ventilation. Patients with these risk factors transitioned immediately after extubation to noninvasive respiratory support using either high-flow oxygen or positive-pressure NIV have significantly lower rates of reintubation and need to resume mechanical ventilation. Although NIV

TABLE 313-4 Main Types and Key Features of Extracorporeal Gas Exchange

TERM	DESCRIPTION	KEY FEATURES	IMPORTANT TECHNICAL NOTES
VA-ECMO (venoarterial extracorporeal membrane oxygenation)	Deoxygenated blood drains via venous catheter to a pump and membrane oxygenator; blood is then returned to the arterial system	Circulatory and respiratory support	Requires large vascular catheters (16–30 Fr) Higher blood flow rates (2–6 L/min)
VV-ECMO (venovenous-ECMO)	Deoxygenated blood drains via venous catheter to a pump and membrane oxygenator; blood is then returned to the venous system	Respiratory support	Requires large vascular catheters (20–30 Fr) Higher blood flow rates (2–5 L/min)
$ECCO_2R$ (extracorporeal CO_2 removal)	Venous catheter drains blood to a CO_2 removal device; blood then returns via a venous catheter	Partial respiratory support, CO_2 removal only	Requires smaller vascular catheters (14–18 Fr) Lower blood flow rates (0.25–2 L/min)

is indicated for patients with hypercapnia after extubation, high-flow oxygen support for all other patients may be preferable given similar efficacy to NIV in preventing reintubation and generally better patient comfort. Although many factors can cause a patient to fail an SBT or require reintubation and continued mechanical ventilation, common processes perpetuating mechanical ventilation include critical illness myopathy and polyneuropathy, myocardial ischemia, congestive heart failure, vascular and extravascular volume overload, delirium, malnutrition, and electrolyte abnormalities (hypophosphatemia, hypokalemia, and hypomagnesemia). These processes should be evaluated and treated, as necessary, in patients failing attempts to discontinue mechanical ventilation.

EXTRACORPOREAL GAS EXCHANGE

Despite interventions to optimize oxygenation and alveolar ventilation on mechanical ventilation, some patients suffer life-threatening hypoxemia, refractory respiratory acidosis, and barotrauma, and may be candidates for salvage therapy with extracorporeal gas exchange, a procedure whereby blood continuously circulates outside the body through a device that oxygenates it, removes CO_2, and then returns blood to the patient's circulation. Although often referred to as ECMO, modern gas exchange membranes both deliver oxygen and remove CO_2, replacing the gas exchange function of the lung. The main components of an ECMO "circuit" include vascular cannulas to remove and return blood to the patient, a pump to circulate blood, and a gas exchange membrane. ECMO can provide varying levels of both respiratory and circulatory support depending on the clinical situation **(Table 313-4)**. In a patient both in shock and requiring full respiratory support, the ECMO circuit would include a central venous cannula (V) to remove blood and a central arterial cannula (A) to return oxygenated blood at relatively high flow rates (up to 6 L/min) providing mechanical circulatory support, so-called VA-ECMO. In the absence of shock, both the draining and return vascular cannulas can be central venous, or VV-ECMO, but blood flow is still relatively high (2–5 L/min) to provide adequate oxygen delivery to tissues. In situations where a patient's lungs can provide adequate oxygenation but insufficient CO_2 removal, such as severe obstructive lung disease exacerbations, a venovenous circuit with low blood flows (0.25–2 L/min) is often adequate to remove CO_2 and treat refractory respiratory acidosis, a process called extracorporeal CO_2 removal ($ECCO_2R$). ECMO continues to evolve, including the use of hybrid circuits. For example, if patients on traditional VA-ECMO have asymmetric hypoxia in the upper body, an additional venous return catheter can be placed in an internal jugular vein to deliver additional oxygenated blood; this hybrid circuit would be V (removal)-VA (dual arterial and venous return)-ECMO. Moreover, several ECMO centers now have mobile ECMO equipment and teams, allowing patients who are too unstable for transfer to an ECMO center to start on ECMO and facilitate transfer to an ECMO center for further care.

Although technologic advances in the ECMO pumps, gas exchange membranes, and even vascular catheters have reduced ECMO-related complications, the procedure is resource-intensive and still associated with several adverse events, including cannula site hemorrhage and vascular injury, catheter-related infection, pneumothorax, pulmonary and gastrointestinal hemorrhage, limb ischemia, intracranial hemorrhage, and disseminated intravascular coagulation (DIC). Clinical outcomes for ECMO patients remain promising, including for patients with severe respiratory failure from SARS-CoV-2 infection treated with ECMO. However, the overall mortality benefit from ECMO, especially in ARDS, remains unclear. Selecting patients most likely to benefit from ECMO, therefore, is very important, and in addition to exhausting traditional mechanical ventilatory support, patients being considered for ECMO should have a reversible underlying illness or be eligible for organ transplant (heart and/or lung), no chronic severe end-organ disease (e.g., severe kidney disease), no contraindication to systemic anticoagulation, a good functional status before the acute illness requiring ECMO, and a good neurologic prognosis.

Section 2 Shock and Cardiac Arrest

314 Approach to the Patient with Shock

Rebecca M. Baron, Anthony F. Massaro

Shock is the clinical condition of organ dysfunction resulting from an imbalance between cellular oxygen supply and demand resulting in cellular and tissue hypoxia. This life-threatening condition is common reason for requiring care in the intensive care unit (ICU).

A multitude of heterogeneous disease processes can lead to shock. The organ dysfunction seen in early shock is often reversible with restoration of adequate oxygen supply. Left untreated, shock transitions from this potentially reversible phase to an irreversible phase and death from irreversible multisystem organ dysfunction. The clinician is required to identify the patient with shock promptly, make a preliminary assessment of the type of shock present, and initiate therapy to prevent irreversible organ dysfunction and death. In this chapter, we review a commonly used classification system that organizes shock into four major types based on the underlying physiologic derangement. We discuss the initial assessment utilizing the history, physical examination, and initial diagnostic testing to confirm the presence of shock and determine the type of shock causing the organ dysfunction. Finally, we will discuss key principles of initial therapy with the aim of reducing the high morbidity and mortality associated with shock.

PATHOPHYSIOLOGY OF SHOCK

The cellular oxygen imbalance of shock is most commonly related to impaired oxygen delivery in the setting of circulatory failure. Shock can also develop during states of increased oxygen consumption or impaired oxygen utilization. An example of impaired oxygen utilization is cyanide poisoning, which causes uncoupling of oxidative phosphorylation. This chapter will focus on the approach to the patient with shock related to inadequate oxygen delivery.

In the setting of insufficient oxygen supply, the cell is no longer able to support aerobic metabolism. With adequate oxygen, the cell metabolizes glucose to pyruvate, which then enters the mitochondria where ATP is generated via oxidative phosphorylation. Without sufficient oxygen supply, the cell is forced into anaerobic metabolism, in which pyruvate is metabolized to lactate with much less ATP generation (per mole of glucose). Maintenance of the homeostatic environment of the cell is dependent on an adequate supply of ATP. ATP-dependent ion pumping systems, such as the Na^+/K^+ ATPase, consume 20–80% of the cell's energy. Inadequate oxygen delivery and subsequent decreased ATP disrupt the cell's ability to maintain osmotic, ionic, and intracellular pH homeostasis. Influx of calcium can lead to activation of calcium-dependent phospholipases and proteases, causing cellular swelling and death. In addition to direct cell death, cellular hypoxia can cause damage at the organ system level via leakage of the intracellular contents into the extracellular space activating inflammatory cascades and altering the microvascular circulation.

DETERMINANTS OF OXYGEN DELIVERY

Because shock is the clinical manifestation of inadequate oxygen delivery relative to cellular needs, we will review determinants of oxygen delivery (DO_2). Disease processes affecting any of the components of oxygen delivery have the potential to lead to the development of shock. Disturbances to key determinants of oxygen delivery form the basis of the four major shock types described below.

The two major components of DO_2 are cardiac output (CO) and arterial oxygen content (CaO_2):

$$DO_2 = CO \times CaO_2$$

The two components of CO are heart rate (HR) and stroke volume (SV), which can be substituted in the above equation as

$$DO_2 = (HR \times SV) \times CaO_2$$

The major determinants of SV are preload, afterload (systemic vascular resistance [SVR]), and cardiac contractility. The relationship can be represented as

$$SV \propto (\text{Preload} \times \text{Contractility})/SVR$$

In this equation, preload refers to the myocardial fiber length before contraction (the ventricular end-diastolic volume). Contractility refers to the ability of the ventricle to contract independent of preload and afterload. The SVR represents the afterload, or the force against which the ventricle must contract.

The CaO_2 is composed of oxygen carried by convection with hemoglobin (arterial oxygen saturation, or SaO_2) and oxygen dissolved in arterial blood (partial pressure of oxygen, or PaO_2), given as

$$CaO_2 \text{ (in mL/dL)} = (Hb \times 1.34 \times SaO_2) + (PaO_2 \times 0.003)$$

A disease process that affects these variables (HR, preload, contractility, SVR, SaO_2, or hemoglobin (Hb)) has the potential to reduce oxygen delivery and cause cellular hypoxia. Each of the shock types described below has a distinctive physiologic hemodynamic profile corresponding with alterations in one of the variables affecting oxygen delivery described above.

CLASSIFICATION OF SHOCK

While there is a heterogeneous list of specific conditions that can cause shock, it is helpful to categorize these processes into four major shock types based on the primary physiologic derangement leading to reduced oxygen delivery and cellular hypoxia. The four major shock types are distributive, cardiogenic, hypovolemic, and obstructive. Table 314-1 outlines these major shock types, as well as specific disease processes that can result in that physiologic derangement. Each shock type has a distinct hemodynamic profile (Table 314-2). Familiarity with the major shock types and their unique hemodynamic profile is essential so that when evaluating a patient presenting with shock, the clinician can use the history, physical examination, and diagnostic testing to determine the type of shock present and promptly begin appropriate initial therapy to restore oxygen delivery.

Distributive Shock Distributive shock is the condition of reduced oxygen delivery where the primary physiologic disturbance is a reduction in SVR. It is unique among the types of shock in that there is a compensatory increase in CO (Table 314-2). The central venous

TYPE OF SHOCK	CVP	PCWP	CARDIAC OUTPUT	SYSTEMIC VASCULAR RESISTANCE
Distributive	↓	↓	↑	↓
Cardiogenic	↑	↑	↓	↑
Obstructive	↑	↓↑	↓	↑
Hypovolemic	↓	↓	↓	↑

Abbreviations: CVP, central venous pressure; PCWP, pulmonary capillary wedge pressure.

pressure (CVP) and pulmonary capillary wedge pressure (PCWP) are usually reduced. The most common cause of distributive shock is sepsis. Sepsis has been redefined as the dysregulated host response to infection resulting in life-threatening organ dysfunction. When this process is accompanied by persistent hypotension requiring vasopressor support (despite adequate volume resuscitation) with end-organ hypoperfusion as measured by an elevated lactate level, it is classified as septic shock. Other processes that are manifest as cellular hypoxia related to a primary reduction of SVR include pancreatitis, severe burns, and liver failure. Anaphylaxis is predominantly an IgE-mediated allergic reaction that can rapidly develop after exposure to an allergen (e.g., food, medication, or insect bite), in which there is a profound distributive type of shock possibly mediated through histamine release. In this setting, there is evidence of both venous and arterial vasodilation. Studies have demonstrated extravasation of up to 35% of the circulating blood volume within 10 min. Patients with severe brain or spinal cord injury may have a reduction of SVR related to disruption of the autonomic pathways that regulate vascular tone. In these patients, there is pooling of blood in the venous system with a resulting decrease in venous return and decreased CO. A final category of patients who present with distributive shock consists of those with adrenal insufficiency. Adrenal insufficiency may be related to chronic steroid use, medications (immune checkpoint inhibitor–associated primary adrenal insufficiency), or other processes that might affect the adrenal glands, including metastatic malignancy, adrenal hemorrhage, infection (e.g., tuberculosis, HIV), autoimmune adrenalitis, or amyloidosis. In conditions of stress (such as infection or surgery), the deficit in adrenal function may become apparent with an inability to increase cortisol leading to vasodilation as well as aldosterone deficiency–mediated hypovolemia.

Cardiogenic Shock Cardiogenic shock is characterized by reduced oxygen delivery related to a reduction in CO owing to a primary cardiac problem. There is usually a compensatory increase in SVR in cardiogenic shock. When the cardiac process (e.g., myocardial infarction) affects the left ventricle (LV), there will be elevation of the PCWP and when it affects the right ventricle (RV), the CVP will be elevated. As detailed above, the CO (and accordingly the DO_2) can be reduced by alterations in the SV or HR. In cardiogenic shock, the SV may be reduced by processes that affect myocardial contractility (e.g., myocardial infarction, ischemic cardiomyopathies, and primary myocarditis) or mechanical valvular disease (acute mitral insufficiency or aortic insufficiency). Both bradyarrhythmias and tachyarrhythmias (from either an atrial or ventricular source) may have associated hemodynamic consequences with a reduction in CO.

Hypovolemic Shock Hypovolemic shock encompasses disease processes that reduce CO (and oxygen delivery) via a reduction in preload. In addition to the reduced CO, this shock type is characterized by an elevated SVR and low CVP and PCWP related to decreased intravascular volume. Any process causing a reduction in intravascular volume can cause shock of this type. Hypovolemic shock is most commonly related to hemorrhage, which may be external (secondary to trauma) or internal (most commonly upper or lower gastrointestinal [GI]) bleeding). Hypovolemic shock can also be seen with nonhemorrhagic processes. Examples include GI illnesses causing profound emesis or diarrhea, renal losses (e.g., osmotic diuresis associated with diabetic ketoacidosis or diabetes insipidus), or skin loss (e.g., severe burns, inflammatory conditions such as Stevens-Johnson syndrome).

Obstructive Shock Obstructive shock is also characterized by a reduction in oxygen delivery related to reduced CO, but in this case, the etiology of the reduced CO is an extracardiac pulmonary vascular or mechanical process impairing blood flow. Specific processes that can impede venous return to the heart and reduce CO include tension pneumothorax (PTX), cardiac tamponade, and restrictive pericarditis. Similarly processes that obstruct cardiac outflow, such as pulmonary embolism, venous air embolism, fat embolism (right heart), or aortic dissection (left heart), are included in this shock type category.

Mixed Shock The types of shock outlined in this classification scheme are not mutually exclusive; not uncommonly, a patient will present with more than one type of shock. For example, the initial physiologic disturbance leading to reduced perfusion and cellular hypoxia in sepsis might be distributive shock. In this setting, a sepsis-induced cardiomyopathy can develop, which reduces myocardial contractility, thus producing a cardiogenic component to what now would be described as a mixed type of shock.

Undifferentiated Shock Upon initial presentation, many patients have undifferentiated shock in which the shock type and specific disease process are not apparent. Using the history, physical examination, and initial diagnostic testing (including hemodynamic monitoring), the clinician attempts to classify a patient with one of the types of shock outlined above so that proper therapy can be initiated to restore tissue perfusion and oxygen delivery.

The epidemiology of shock is dependent on the clinical setting. A 2019 study of the etiology of shock in the emergency department (ED) of a university hospital in Denmark revealed that among 1553 patients with shock, 30.8% had hypovolemic shock, 27.2% had septic shock, 23.4% had distributive nonseptic shock, 14% had cardiogenic shock, and only 0.9% had obstructive shock. In the ICU setting, septic shock predominates. A 2010 study (from eight hospitals) demonstrated that 62% of ICU shock patients had septic shock, 16% hypovolemic shock, 15% cardiogenic shock, and only 2% obstructive shock. Among specialty ICUs, the distribution of shock type differentiates further. In the medical ICU, the largest number of patients have distributive shock related to sepsis. In contrast, a 2019 study of shock in 16 cardiac ICUs found that 66% of shock patients were assessed as having cardiogenic shock. Mortality associated with shock is high, but differences are seen between the types of shock. Septic shock and cardiogenic shock have the highest mortality rates. In the ED study from Denmark, the 90-day mortality of the septic and cardiogenic patients was 56.2% and 52.3%, respectively. These numbers coincide with other studies. Hypovolemic shock is associated with a lower mortality rate.

STAGES OF SHOCK

Regardless of type, shock progresses through a continuum of three stages. These stages are compensated shock (preshock), shock (decompensated shock), and irreversible shock. During compensated shock, the body utilizes a variety of physiologic responses to counteract the initial insult and attempts to reestablish the adequate perfusion and oxygen delivery. At this point, there are no overt signs of significant organ dysfunction. Laboratory evaluation may demonstrate mild organ dysfunction (i.e., elevated creatinine or troponin) or a mild elevation of lactate. The specific compensatory response is determined by the initial pathophysiologic defect. In early sepsis with reduction in SVR, there is a compensatory rise in HR (and CO). With early hemorrhagic volume loss, there will be a compensatory increase in SVR and HR. As the host compensatory responses are overwhelmed, the patient transitions into true shock with evidence of organ dysfunction. Appropriate interventions to restore perfusion and oxygen delivery during these initial two phases of shock can reverse the organ dysfunction. If untreated the patient will progress to the third phase of irreversible shock. At this point, the organ dysfunction is permanent and often the patient progresses to multisystem organ dysfunction.

TABLE 314-3 Key Principles in the Treatment of Shock

1. Recognize shock early
2. Assess for type of shock present
3. Initiate therapy simultaneous with the evaluation into the etiology of shock
4. Involve all members of the multidisciplinary team
5. Aim of therapy is to restore oxygen delivery
6. Identify etiologies of shock that require additional lifesaving interventions

EVALUATION OF THE PATIENT WITH SHOCK

The initial evaluation of the patient with shock utilizes the history, physical examination, and diagnostic testing toward two specific aims. The first aim is confirmation of the presence of shock. Given the reversible nature of the organ dysfunction in early shock, it is important that the clinician has a high clinical suspicion for this condition. The possibility of shock should be considered in all patients presenting with new organ dysfunction or hypotension. This early recognition of the presence of shock is an essential tenet of shock care **(Table 314-3)**. The second aim of the initial assessment (history, physical examination, and diagnostic testing) is to identify either a specific shock etiology or to determine the type of shock present. In some patients, the type of shock and etiology will be readily apparent (e.g., the patient with hypovolemic shock from a gunshot wound), but in many cases, the cause is determined only after further evaluation. We will discuss the role of the history, physical examination, and diagnostic testing toward these specific aims. While the assessment of shock etiology is ongoing, the initiation of therapy should not be delayed while the final diagnosis is being determined. Evaluation of shock etiology and initiation of therapy should be simultaneous and as expedient as possible.

History Obtaining a concise, focused history is essential. If the patient is unable to provide a history, ancillary information from family or friends accompanying the patient, emergency medical services (EMS) personnel, or nursing facility (if applicable) should be obtained, and a brief chart review should be performed. Often, a patient with shock will present with nonspecific symptoms such as weakness, malaise, or lethargy. When focal symptoms are reported, it is important to determine whether the symptom is related to the primary process causing shock or a result of inadequate oxygen delivery for cellular metabolic needs. For example, a patient with distributive shock from urosepsis could report chest discomfort in the setting of tissue hypoxia. As the history is being obtained, the clinician must be attentive to any details indicating new organ dysfunction. The most easily identified new organ dysfunction from the history is the presence of a newly altered mental status or decrease in urine output (oliguria). In some cases, the type of shock (and the specific disease process) is apparent from the initial history. Patients with distributive shock from sepsis may present with fever and a history suggesting a focal site of infection (e.g., cough, sputum production, abdominal discomfort, diarrhea, flank discomfort, or dysuria). Anaphylactic distributive shock may be suggested by the onset of pruritis, hives, dyspnea, and new facial edema after exposure to common allergens. Cardiogenic shock may be identified by the onset of exertional chest discomfort. The patient with significant arrhythmia may have an initial complaint of palpitations with syncope or presyncope. Hypovolemic shock may be identified in patients who present with a history of trauma (blunt or penetrating) or GI bleed (hematemesis, melena, or bright red blood per rectum). A patient with hypertension and tearing chest or back pain may be presenting with acute aortic dissection and obstructive-type shock. Asymmetric leg swelling, acute-onset chest pain with dyspnea in the setting of immobility, and/or underlying malignancy raises concern for obstructive shock due to pulmonary embolism.

For most patients, the specific etiology will be less clear, but the history can be helpful in raising the likelihood of a particular type of shock. As an example, a patient with a preexisting immune dysfunction or medication-induced neutropenia may present with hypoperfusion and new organ dysfunction, in which the clinician must have a high suspicion for septic shock. Similarly, a patient with extensive cardiac disease requires a higher suspicion for cardiogenic shock.

Physical Examination The physical examination can assist in the identification of shock (in both the compensated stage prior to overt evidence of organ dysfunction and decompensated stage). The examination also can add insight into what type of shock is present (distributive, cardiogenic, hypovolemic, or obstructive).

Shock is most commonly seen in the setting of circulatory failure. Vital signs are frequently abnormal. In most cases, this is manifest as hypotension (a systolic blood pressure [SBP] <90 mmHg or mean arterial pressure [MAP] <65 mmHg), but isolated blood pressure measurements below these values do not define shock on their own. Many patients may have underlying conditions such as peripheral vascular disease or autonomic dysfunction or are on medications that cause longstanding low blood pressure without any evidence of organ dysfunction. Alternatively, patients with underlying hypertension may develop shock and organ dysfunction at higher blood pressures. Evaluating the patient's current blood pressure in relation to the patient's baseline blood pressure and observing hemodynamic trends and correlation with end-organ perfusion over short time intervals are more useful than an absolute SBP or MAP value. Tachycardia is a common compensatory mechanism in shock. The absence of an elevated heart rate does not exclude shock as patients with underlying cardiac conduction system disease or on home nodal blocking medications may have a diminished or absent tachycardic response. Alternatively, one cannot be reassured by an elevated heart rate without hypotension, as many younger patients can compensate for an extended period of time before developing hypotension. Tachypnea is another vital sign abnormality seen early in shock as the body compensates for a developing metabolic acidosis. While these early compensatory responses are nonspecific, the clinician should recognize these findings early as they may herald the development of end-organ dysfunction if perfusion and oxygen delivery are not restored.

The physical examination can confirm the presence of shock prior to the return of laboratory testing. The central nervous system (CNS), kidney, and skin are the organ systems most easily assessed for evidence of organ dysfunction. These organ systems are considered the "windows" through which we can identify organ dysfunction. Decreased oxygen delivery to the brain is manifest as confusion and encephalopathy. In the early stage of shock, the body will redirect blood flow to the CNS to maintain adequate perfusion. In the patient with shock and altered mental status, all the usual compensatory mechanisms have been outstripped by the magnitude of shock pathophysiology. New encephalopathy represents a manifestation of decompensated shock. To assess renal function during the physical examination, one should evaluate the patient's urine output since the time of presentation. If not already present, a urinary catheter should be placed for accurate hourly assessment of urine output. In patients with normal baseline renal function, oliguria (<0.5 mL/kg per h) may indicate shock. Finally, cold and clammy skin is a sign of hypoperfusion with compensatory vasoconstriction to redirect blood flow centrally (brain, heart). Progressive vasoconstriction can lead to mottling of the skin. Capillary refill time (CRT) is the time it takes for color to return to an external capillary bed after pressure is applied. In the setting of shock, the CRT is delayed.

Many components of the examination provide insight into hemodynamics and assist in elucidating the type of shock present. The physical examination may be used to differentiate shock with high CO (distributive) from that with low CO (cardiogenic shock, hypovolemic shock, and obstructive shock). Examination findings suggestive of high-output shock (distributive) include warm peripheral extremities and large pulse pressure (with low diastolic pressure). Alternatively, cool extremities with narrow pulse pressure would indicate low CO forms of shock. Among types of shock with low CO, the examination can be used to distinguish between conditions with increased intravascular filling pressure (cardiogenic shock, obstructive shock) and intravascular volume depletion (hypovolemic shock). Elevation of jugular venous pressure (JVP) and presence of peripheral edema are seen with high right-sided cardiac pressures. The JVP may be elevated in cardiogenic shock (with right-sided failure) and obstructive shock (pulmonary embolism) but reduced (JVP <8 cm) in hypovolemic shock. Similarly,

patients with cardiogenic shock and right-sided cardiac dysfunction may have peripheral edema, but this is not an examination finding typically present in acute hypovolemic shock. Distinguishing cardiogenic from obstructive shock can also be aided by physical examination. Rales on pulmonary auscultation may be related to left-sided cardiac dysfunction. The presence of cardiogenic shock would be further supported by an S3 gallop. One must remember, however, that it is well established that patients with chronic heart failure do not present with the classical findings of acute heart failure.

At times, the physical examination may identify the specific etiology of shock. This is particularly helpful in the patient who cannot provide a detailed history. The examination may demonstrate the site of an untreated infection (e.g., cellulitis, abscess). The examination may reveal a brady- or tachyarrhythmia leading to development of shock. Similarly, large ecchymosis may indicate a significant bleed related to trauma or spontaneous retroperitoneal bleeding. The rectal examination may reveal GI hemorrhage. Pulsus paradox and elevated JVP may suggest the presence of cardiac tamponade. Patients with a tension PTX may have a paucity of breath sounds over the affected side, deviation of the trachea away from the affected side, or subcutaneous emphysema.

Combinations of easily assessed examination components have been organized into a scoring system to identify high-risk patient populations. The shock index (SI) is defined as the HR/SBP, with a normal SI being 0.5–0.7. An elevated SI (>0.9) has been proposed to be a more sensitive indicator of transfusion requirement and of patients with critical bleeding among those with hypovolemic (hemorrhagic) shock than either HR or BP alone. The SI may also identify patients at risk for postintubation hypotension. This concept of use of a clinical score to identify at-risk patients has been extended to patients with distributive shock from sepsis. The quick Sequential Organ Failure Assessment (qSOFA) score is a rapid assessment scale that assigns a point for SBP <100, respiratory rate >22, or altered mental status (Glasgow Coma Scale <15). A qSOFA ≥2 (with a concern for infection) is associated with a significantly greater risk of death or prolonged ICU stay. The Third International Consensus Definition of Sepsis has recommended the use of the qSOFA to identify the most acutely ill subset of patients with sepsis (longer length of stay, increased need for ICU admission, and higher in-hospital mortality).

Diagnostic Testing Laboratory evaluation should be initiated promptly in all patients with suspected shock. The laboratory evaluation is directed toward the dual aim of assessing the extent of end-organ dysfunction and of gaining insight into the possible etiology of shock. Table 314-4 outlines the recommended initial laboratory evaluation of the patient with undifferentiated shock.

BLOOD TESTS Evaluation of lactate, blood urea nitrogen (BUN), creatinine, and transaminases provides an assessment of the extent of end-organ dysfunction related to shock. (See discussion of lactate below.) Urine electrolytes with subsequent calculation of the fractional excretion of sodium (FE_{Na}) or fractional excretion of urea (FE_{Urea}) may indicate states of hypovolemia or decreased effective circulating volume. Elevation of alkaline phosphatase may suggest biliary obstruction and may thereby identify a source of infection in patients with distributive shock. Elevation of cardiac enzymes can indicate a primary cardiac problem with myocyte damage related to ischemia, myocarditis, or a pulmonary embolism. An elevation of the white blood cell count may raise suspicion for an infective process, but this is certainly not diagnostic; an accompanying left shift may improve the sensitivity of this measure. Reductions in hemoglobin and hematocrit are seen in patients with hemorrhagic hypovolemic shock (although an actively bleeding patient may have normal values on initial presentation). While the extent of acidosis may be determined with a venous blood gas (VBG), if there is accompanying hypoxemia, an arterial blood gas should be obtained. For patients with undifferentiated shock, there should always be a high index of suspicion for possible infection. Urinalysis and urine sediment should be sent to evaluate for pyuria. Blood cultures, urine cultures, and sputum cultures should be obtained. Radiographic evaluation should be directed to seek sources of infection suggested by the history and physical examination.

TABLE 314-4 Initial Laboratory Evaluation of Undifferentiated Shock

11. CXR

Abbreviations: CXR, chest x-ray; ECG, electrocardiogram; INR, international normalized ratio; PT, prothrombin time; PTT, partial thromboplastin time.

Lactate measurement has a role in the diagnosis, risk stratification, and, potentially, the treatment of shock. Increased lactate (hyperlactemia) and lactic acidosis (hyperlactemia and pH <7.35) are common in shock. Lactate is a product of anaerobic glucose metabolism. In glycolysis, the enzyme phosphofructokinase metabolizes glucose to pyruvate. Under aerobic conditions, the pyruvate is then converted (in the mitochondria) to acetyl CoA and enters the Krebs cycle with resulting ATP generation through oxidative phosphorylation. In the setting of cellular hypoxia, the Krebs (tricarboxylic acid) cycle cannot oxidize the pyruvate, and thus the pyruvate is converted to lactate by the enzyme lactate dehydrogenase. Under normal conditions, lactate is produced from skeletal muscle, brain, skin, and intestine. In the setting of reduced oxygen delivery and cellular hypoxia, the amount of lactate produced from these tissues increases (and other tissue can begin to produce lactate). While most of the studies have been performed in patients with septic shock, there is evidence that elevated lactate correlates with a worse outcome. A recent systematic literature review evaluating the role of lactate measurement in a variety of critically ill populations supported the value of serial lactate measurements in the evaluation of critically ill patients and their response to therapy.

Electrocardiogram The electrocardiogram (ECG) is an essential part of the evaluation of the patient with shock. There may be a bradycardic or tachycardic arrhythmia causing a reduction in CO. ST-segment elevation myocardial infarction may be identified. The presence of the S1 Q3 T3 pattern would raise concerns for pulmonary embolism. Reduced voltage in the presence of electrical alternans raises the possibility of pericardial tamponade.

Chest X-Ray The chest x-ray (CXR) can demonstrate a new focal alveolar or interstitial infiltrate suggesting an infectious process (and possible distributive septic shock). Bilateral cephalization of the pulmonary vasculature, peribronchial cuffing, septal thickening, and intralobular thickening are typical of pulmonary edema and a cardiogenic process. The CXR can be used to confirm or exclude the presence of a pneumothorax. CXR findings are neither sensitive nor specific for pulmonary embolism. In select cases, there may be the finding of a peripheral wedge-shaped opacity indicating pulmonary infarction, an enlarged pulmonary artery, or regional vascular oliguria. A chest computed tomography (CT) angiogram may be needed to exclude the diagnosis of pulmonary embolism and further evaluate the thorax.

Point-of-Care Ultrasound Point-of-care ultrasound (POCUS) has an increasing role in the evaluation and treatment of shock. Benefits of POCUS include its low cost, rapidity with which it can be obtained, and noninvasive nature. It has diagnostic value in patients who present with undifferentiated shock. In patients with mixed shock, it can give insight into the relative contribution of the individual shock types. Several structured protocols exist for evaluation of undifferentiated shock including the Rapid Ultrasound for Shock and Hypotension (RUSH), the Abdominal and Cardiothoracic Evaluation with Sonography in Shock (ACES), and Sequential Echographic Scanning Assessing

Mechanism or Origin of Shock of Indistinct Cause (SESAME). These protocols share common components to assess cardiac function, evaluate intravascular volume status, and identify fluid collections. In a rapid and protocolized manner, views are obtained of the heart, lungs, pleural space, inferior vena cava, abdominal aorta, abdomen, and pelvis. Some of the protocols extend to view the deep veins of the lower extremity.

POCUS transthoracic echocardiography (TTE) is central to the POCUS evaluation of shock. TTE utilizes both the two-dimensional (2D) and M mode. It focuses the examination on LV function, RV function, and the pericardium. The 2D mode can evaluate LV size, wall thickness, and ventricular function. Ventricular size and thickness can suggest longer standing cardiac processes. Evaluation of LV function through estimation of left ventricular ejection fraction (LVEF) can identify shock with globally reduced LV function or regional wall motion abnormalities. Similarly, the assessment of RV function also examines RV size and wall thickness (to identify conditions such as elevated pulmonary pressures or suggest pulmonary embolism). An additional important assessment includes evaluation for pericardial tamponade. Two-dimensional echocardiography can also be used to assess valve function, including acute processes, such as mitral valve rupture. Assessment of valvular function is often an evaluation that requires a higher skilled practitioner. The performance of the bedside echocardiogram by the critical care practitioner does not replace formal examination by the echocardiography service or assessment by a cardiologist.

Another component of POCUS includes inferior vena cava (IVC) evaluation to assess intravascular filling. A collapsible IVC in spontaneously breathing patients at the end of expiration suggests reduced intravascular volume. Evaluation of the pleural space for effusion has been a longstanding role of ultrasound, and POCUS pleural space evaluation can be more sensitive than CXR for identifying a PTX. Defined views of the abdomen can identify significant intrabdominal fluid collections indicating hemorrhage or possible infection. Examinations that extend to the proximal deep veins of the lower extremity can identify deep-venous thrombosis, raising the possibility of pulmonary embolism as an etiology of shock. While POCUS can aid in determining the etiology of shock, a 2018 international randomized controlled study utilizing POCUS to evaluate undifferentiated shock in 273 ED patients did not demonstrate a benefit in survival at 30 days or hospital discharge. In addition, there was no difference in amount of IV fluids administered, inotrope use, CTs ordered, or need for ICU care or length of stay.

One significant limitation of POCUS is that performance and interpretation of testing are operator dependent. Familiarity with basic ultrasound techniques and interpretation is now expected in the ED and critical care setting. Accordingly, competency standards have been proposed for emergency medicine and critical care providers in both basic and advanced POCUS techniques.

INITIAL TREATMENT OF SHOCK

Because shock can progress rapidly to an irreversible stage, a key principle in shock management is to initiate treatment for circulatory shock simultaneously with efforts to elucidate shock etiology (Table 314-3). If the initial history, physical examination, and laboratory evaluation have identified the shock type or the specific etiology, then therapy is directed to reverse the underlying physiologic abnormality causing the hypoperfusion and reduced oxygen delivery. To expedite care, all members of the multidisciplinary team (physicians, nurses, pharmacists, and respiratory therapists) must be involved in the development and delivery of care. Details of the optimal care for the specific disease processes leading to shock may be found in other chapters of this text. As many patients will present with undifferentiated shock, in this section, we will discuss treatment directed at the patient with undifferentiated shock. At the conclusion of this section, we will highlight etiologies of shock that require initiation of lifesaving specific therapy.

A key early consideration is to ensure adequate intravenous access. Placement of two peripheral venous catheters (16 or 18 gauge) will provide initial access for the aggressive volume resuscitation that is often required for patients with distributive or hypovolemic shock. If there is concern for distributive shock with sepsis, this IV access will also permit prompt antibiotic administration. For patients with ongoing hypotension despite adequate volume resuscitation, placement of a central venous catheter (CVC) is indicated to provide therapy with vasopressors and inotropes. The CVC will provide a mechanism for hemodynamic monitoring (CVP), as well as a means to obtain central venous oxygen saturations ($ScvO_2$). The $ScvO_2$ is a surrogate of mixed venous oxygen saturation and thus can provide insight into the adequacy of oxygen delivery. Central venous access using a sheath will provide an access point for placement of a Swan-Ganz catheter if more detailed assessment of hemodynamic measurements is required (PCWP, CO, and SVR) and/or if larger bore central access is required for more aggressive volume or blood administration as in hemorrhagic shock. If the patient presents critically ill or in the midst of cardiopulmonary arrest, the quickest method of obtaining central access will be through the use of an intraosseous device. Placement of an arterial line allows for intravascular measurement of blood pressure and continuous determination of MAP. In addition, it can provide insight into the adequacy of volume resuscitation through the measurement of systolic or pulse pressure variation. The arterial line will provide access for determination of arterial oxygen tension, which is helpful since peripheral oximetry measurements (SpO_2) can be unreliable in states of tissue hypoperfusion. The arterial line facilitates repeated measures of acid-base status and lactate to assess the impact of treatment. All patients with shock should have a urinary catheter placed to permit hourly assessment of renal function as another potential indication of the adequacy of resuscitation.

Volume Resuscitation Initial volume resuscitation has the aim of restoring tissue perfusion and is crucial to optimal shock therapy. Assessment of current intravascular volume status and determination of the optimal amount of necessary volume resuscitation are challenging. The physiologic goal of volume resuscitation is to move the patient to the non–preload-dependent portion of the Starling curve. Most patients with any of the four shock types will benefit from an increase in intravascular volume. For patients with distributive shock, the need for early aggressive volume replacement is well established. In the past, the use of early goal-directed therapy (EGDT) in septic shock targeted specific measures of CVP, MAP, and SvO_2 to guide volume resuscitation (and initiation of vasopressors and inotropes). More recent studies have demonstrated that targeted resuscitation using invasive monitoring is not universally required, but in all of these studies, patients in the "usual care" arms of the study received early initial volume resuscitation. For patients with suspected septic shock, a minimum of 30 mL/kg as an initial volume of resuscitation is recommended by the Surviving Sepsis Campaign. While the need for volume resuscitation is most apparent for patients with distributive or hypovolemic shock, even some patients with cardiogenic shock may benefit from cautious volume replacement. In these patients, there should be a careful assessment of volume status prior to volume administration.

In general, volume replacement therapy should be given as a bolus with a predefined endpoint to assess the effect of the volume resuscitation. Most commonly, the volume resuscitation will begin with crystalloid. In patients with hypovolemic shock due to ongoing hemorrhage, volume replacement with packed red blood cells is warranted. In cases of massive transfusion, platelets and fresh frozen plasma should be provided to offset the dilution of these components during volume replacement. Because hemoglobin is a key determinant of CaO_2, red cell administration may be a part of volume replacement even without hemorrhage in order to optimize oxygen delivery if hemoglobin content is <7 g/dL.

Assessment of intravascular volume status (and the adequacy of volume resuscitation) begins with the physical examination (described above). The passive leg raise (PLR) test can predict responsiveness to additional IV fluid by providing the patient with an endogenous volume bolus. While the patient is resting in a semirecumbent position at a 45° angle, the bed is placed in Trendelenburg position such that the patient's head becomes horizontal and the legs are extended at a

45° angle. There is then an immediate (within 1 min) assessment of changes in CO (or pulse pressure variation as a surrogate). It is important to emphasize that one does not merely look for changes in blood pressure; if the shock patient is mechanically ventilated, there is the option of looking at changes in SV variation (or pulse pressure variation) during the respiratory cycle to assess volume responsiveness. A >12% SV variation suggests a volume-responsive state. This measurement requires that the patient be in a volume cycle mode of ventilation, without breath-to-breath variations in intrathoracic pressure and without arrhythmias. A final caveat to the use of these parameters to assess volume status is that these studies were performed on patients being ventilated with tidal volumes larger than currently used to minimize ventilator-induced lung injury.

There is also increased use of echocardiography to assist in determination of intravascular fluid status, with a variety of static and dynamic variables that the trained operator can assess. The most commonly used parameters to assess adequacy of volume resuscitation are IVC diameter and IVC collapse. Alternatively, serial assessments of LV function can be performed while volume is being administered. Placement of a pulmonary artery catheter (PAC) is another tool for assessment of volume status. This more invasive measure involves placement of the PAC into the central venous circulation and through the right heart. Ports in the PAC (Swan-Ganz catheter) allow for direct measurement of CVP, pulmonary artery (PA), and PCWPs. The PCWP is used as a surrogate for LA pressure. While studies have not identified a mortality or length-of-stay benefit with routine use of PA catheterization, there are cases where it may be beneficial. Patients with mixed shock (distributive and cardiogenic) or those with ongoing shock of unclear etiology are examples of situations in which it should be considered.

The need for continued volume replacement must be frequently reassessed. As the patient continues to receive treatment for shock, the initial proper strategy regarding volume management may change in light of development of processes that independently require a different volume-management strategy. For patients who initially present with shock but then develop respiratory failure related to acute respiratory distress syndrome (ARDS) or renal failure, it may be reasonable to begin volume removal.

Vasopressor and Inotropic Support If intravascular volume status has been optimized with volume resuscitation but hypotension and inadequate tissue perfusion persist, then vasopressor and/or inotropic support should be initiated. The use of vasopressors and inotropes must be tailored to the primary physiologic disturbance. The clinician must understand the receptor selectivity of various agents and that for some agents the selectivity may be dose dependent. In patients with distributive shock, the primary aim is to increase the SVR. Norepinephrine is the first-choice vasopressor in septic shock, with potent α_1 and β_1 adrenergic effects. The α_1 causes vasoconstriction, while β_1 has positive inotropic and chronotropic effects. At higher doses, epinephrine has a similar profile (at lower doses, the β effects predominate) but is associated with tachyarrhythmia, myocardial ischemia, decreased splanchnic blood flow, pulmonary hypertension, and acidosis. In distributive shock, vasopressin deficiency may be present. Vasopressin acts on the vasopressin receptors to reverse vasodilation and redistribute flow to the splanchnic circulation. In a randomized trial in patients with septic shock, the addition of low-dose vasopressin to norepinephrine did not reduce all-cause 28-day mortality compared to norepinephrine alone but suggested a potential benefit in the less "sick" population. Vasopressin is safe and has a role as a second agent for hypotension in septic shock. Dopamine does not have a role as a first-line agent in distributive shock. A randomized controlled study in patients with all-cause circulatory shock did not show a survival benefit from dopamine but did reveal an increase in adverse events (arrhythmia). In this study, the subgroup of patients with cardiogenic shock had increased mortality. For patients with cardiogenic shock, dobutamine is a first-line agent; it is a synthetic catecholamine with primarily β-mediated effects and minimal α adrenergic effects. The β_1 effect is manifest in increased inotropy, and the β_2 effect leads to vasodilation with decreased afterload; it can be used with norepinephrine in patients with mixed distributive and cardiogenic shock.

OXYGENATION AND VENTILATION SUPPORT

In addition to the cellular hypoxia caused by circulatory failure, patients with shock may present with hypoxemia. For patients with distributive shock, this may be related to a primary pulmonary process (e.g., pneumonia in a patient with septic shock). For patients with cardiogenic or obstructive shock, hypoxemia may be related to pulmonary edema as a result of LV dysfunction and elevations of PCWP. For patients with all types of shock, there can be development of ARDS and subsequent $\dot{V}/\dot{Q}$ (ventilation/perfusion) mismatch and shunt. Supplemental oxygen should be initiated and titrated to maintain SpO_2 of 92–95%. This may require intubation and initiation of mechanical ventilation. If the patient requires intubation and initiation of mechanical ventilation, this should be provided promptly so as to minimize the duration of tissue hypoxia. Patients with shock may have high minute ventilatory needs to compensate for metabolic acidosis. As shock progresses, they may not be able to maintain adequate respiratory compensation, which may be a second indication to initiate mechanical ventilator support. If mechanical ventilation support is initiated, it is important to provide ventilation with lung-protective strategies focused on low tidal volume ventilation and optimization of positive end-expiratory pressure to minimize ventilator-induced lung injury. In addition, there should be daily sedation cessation to assess underlying neurologic function and minimize time on mechanical ventilation. There are currently few data to support the use of noninvasive ventilation in the setting of shock.

Antibiotic Administration Sepsis is the most common cause of shock. For patients presenting with undifferentiated shock, if the diagnosis of septic shock is being entertained, then broad-spectrum antibiotics should be administered after obtaining appropriate cultures. For patients with sepsis, every hour of delay in appropriate antibiotic administration is associated with an increase in mortality. While it is ideal to initiate antibiotics after appropriate cultures, the inability to obtain cultures should not delay the start of treatment. When sepsis is excluded as a cause of shock, an important aspect of antibiotic stewardship is to stop all antibiotics.

Specific Causes of Shock Requiring Tailored Intervention The initial evaluation (history, physical examination, and diagnostic testing) may have identified an etiology of shock that requires urgent lifesaving intervention in addition to the initial treatment steps outlined above. Patients with distributive shock secondary to anaphylaxis require removal of the inciting allergen, administration of epinephrine, and vascular support with IV fluid resuscitation and vasopressors. Adrenal insufficiency requires replacement with IV stress-dose steroids. Cardiogenic shock patients with arrhythmia may require treatment as outlined in advanced cardiac life support algorithms or placement of an artificial pacemaker. In cases of acute ischemic events, consideration must be given to revascularization and temporary mechanical supportive measures. In the case of valve dysfunction, emergency surgery may be considered. Patients with hypovolemic shock due to hemorrhage may require surgical intervention in the case of trauma or endoscopic or interventional radiology procedures in the case of a GI source of blood loss. Sources of occult bleeding can include soft tissue injury sites including bleeding after long-bone fractures, retroperitoneal bleeding, and the GI tract. Among patients with obstructive shock, a tension PTX would necessitate immediate decompression. Proximal pulmonary embolism requires evaluation for thrombolytic therapy or surgical removal of the clot. Dissection of the ascending aorta may require surgical intervention.

315 Sepsis and Septic Shock

Jeffrey R. Strich, Daniel S. Chertow

Sepsis is an infectious syndrome that results in considerable morbidity, mortality, and long-term sequelae among survivors. Sepsis, derived from the Greek word *sipsi*, "to make rotten," was first described by Hippocrates in the 400s B.C. In the 1800s, Sir William Osler opined on sepsis by saying, "except on few occasions, the patient appears to die from the body's response to infection rather than from it." The first consensus definition of sepsis, published in 1992, recognized sepsis as the body's systemic response to infection. To operationalize this definition, systemic inflammatory response syndrome (SIRS) clinical criteria were established, which included temperature <36°C or >38°C, heart rate >90 beats/min, respiratory rate >20 breaths/min or partial pressure of CO_2 <32 mmHg, and leukocyte count <4000/μL or >12,000/μL or >10% bands. Suspected infection with two or more SIRS criteria was classified as sepsis, while the term *severe sepsis* required evidence of hypoperfusion or end-organ dysfunction including oliguria, acute alteration in mental status, or lactic acidosis. Septic shock was defined as sepsis-induced hypotension, determined by systolic blood pressure <90 mmHg or reduced ≥40 mmHg from baseline, absent other causes, despite adequate volume resuscitation. Sepsis-2, the second consensus definition established in 2003, acknowledged clinical complexity beyond existing SIRS criteria and expanded the list of clinical and laboratory criteria to diagnose sepsis. Sepsis-3, established in 2016 as the current consensus definition, abandoned SIRS criteria, given poor specificity for distinguishing sepsis from other noninfectious inflammatory processes, and eliminated the term *severe sepsis*. Sepsis was redefined as life-threatening organ dysfunction caused by a dysregulated host response to infection, and septic shock was defined as a subset of sepsis in which profound circulatory, cellular, and metabolic abnormalities increase mortality risk beyond sepsis alone.

EPIDEMIOLOGY

Each year, an estimated 48.9 million sepsis cases occur globally, and 1.7 million cases occur in the United States. Data from >400 U.S. academic, community, and federal hospitals indicate that sepsis occurs in ~6% of hospitalized adults, with stable incidence over time **(Fig. 315-1)**. Approximately 11 million sepsis deaths occur globally each year, accounting for one in five total global deaths, with 85% occurring in low- and middle-income countries. An estimated 350,000 sepsis deaths or discharges to hospice occur annually in the United States, with an estimated 15% overall mortality among U.S. hospitalized adults with sepsis (Fig. 315-1) and up to 40% mortality in patients with septic shock. Data from the U.S. Centers for Medicare and Medicaid Services indicate the aggregate cost for inpatient hospital and skilled nursing facility sepsis admissions was an estimated $13.4 billion dollars in 2018. A retrospective evaluation of sepsis costs in U.S. hospitals during 2010–2016 suggests a cost of $16,324 and $38,298 per sepsis and septic shock admission, respectively.

PATHOGENS AND SITES OF INFECTION

Approximately 88% of sepsis cases are community onset, defined as being detected within 48 h of hospitalization, whereas an estimated 12% are hospital onset, detected after 48 h of hospitalization. While viruses, fungi, and other pathogens may induce sepsis, the role of bacterial infection is best described. An estimated 53% of sepsis cases in the United States are bacterial culture positive, with a relatively even split between gram-positive and gram-negative organisms.

A retrospective cohort study of 17,430 adult community-onset culture-positive sepsis cases from 104 U.S. hospitals during 2009 to 2015 identified *Staphylococcus aureus*, *Streptococcus* spp., and *Enterococcus* spp. as the most prevalent gram-positive organisms isolated, of which 13.6% were antibiotic-resistant, including methicillin-resistant *S. aureus* (MRSA) and vancomycin-resistant enterococci (VRE). *Escherichia coli*, *Klebsiella* spp., and *Pseudomonas aeruginosa* were the most frequently isolated gram-negative organisms, of which 13.2% were resistant to ceftriaxone, extended-spectrum β-lactams, or carbapenems. The most frequently reported anatomic site of primary infection was the urinary tract (48.9%), followed by the respiratory tract (32.9%), an intraabdominal site (13.6%), and skin or soft tissue (10.3%). Bacteria were most frequently isolated from urine (52.1%), blood (40.0%), and the respiratory tract (16.7%).

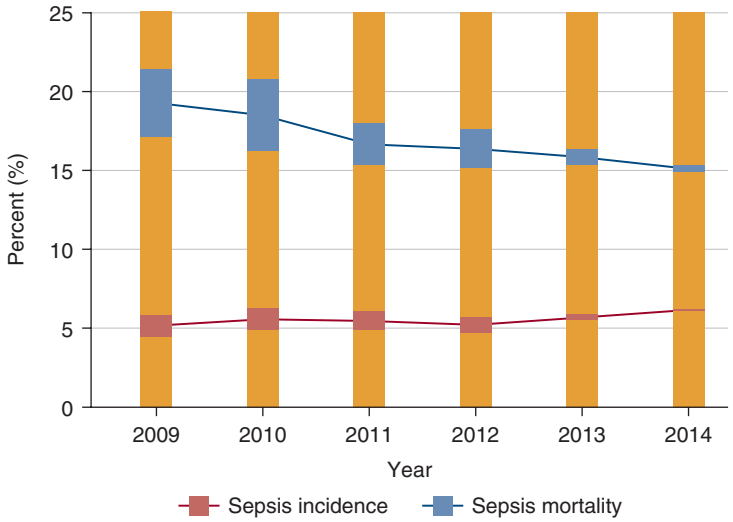

FIGURE 315-1 Sepsis incidence and mortality. Sepsis incidence and mortality. Sepsis incidence is expressed as a proportion of sepsis cases among 7,801,624 adult hospitalizations across 409 U.S. hospitals from 2009–2014. Mortality is the proportion of sepsis deaths among sepsis cases.

Patients with hospital-onset sepsis differ from community-onset sepsis patients in that they more often have comorbidities and experience intraabdominal infections and bacteremia with *Enterococcus*, *Candida*, and *Pseudomonas*. Patients with hospital-onset sepsis also experience higher intensive care unit (ICU) admission rates, longer hospital length of stay, and increased mortality.

RISK AND PROGNOSTIC FACTORS

U.S. Centers for Disease Control and Prevention (CDC) data from 2021 show that sepsis mortality increases with age and is higher among men than women in all age groups: 232.7 versus 173.0 (65–74 years), 477.3 versus 349.8 (75–84 years), and 1037.8 versus 755.5 (≥85 years) deaths per 100,000 population, respectively. Preexisting medical conditions including diabetes and obesity; neurologic, respiratory, or cardiac conditions; renal or hepatic insufficiency; and cancer or other immunosuppressing conditions increase sepsis mortality risk. Recent hospital admission for any reason has also been associated with threefold increased risk of developing sepsis in the following 90 days.

Multiple composite illness severity scoring systems have been applied to hospitalized septic patients to predict outcome or guide stratification or post-hoc analyses in clinical trials or observational studies of sepsis. For example, the Sequential Organ Failure Assessment (SOFA) score quantifies dysfunction in six organ systems including neurologic, using the Glasgow Coma Scale score; cardiovascular, using mean arterial blood pressure or use of vasoactive agents; respiratory, using the ratio of arterial blood partial pressure of oxygen (Pao_2) to fraction of inspired oxygen (Fio_2) or use of mechanical ventilation; hepatic, using serum bilirubin levels; renal, using serum creatinine levels; and coagulation, using blood platelet levels. Elevated SOFA scores are associated with increased sepsis mortality at the population level but cannot accurately predict outcomes of individual patients.

Improved stratification of sepsis patients based on clinical "phenotype," determined by clustering of clinical variables using machine learning tools to better predict outcome, has been proposed. In a retrospective analysis of >45,000 patients who met Sepsis-3 criteria, statistical, machine learning, and simulation tools were applied to clinical data obtained within 6 h of emergency room presentation to identify α, β, γ, and δ phenotypes, with associated 2%, 5%, 15%, and 32% mortality rates, respectively. Beyond using immediately available clinical data to identify sepsis phenotypes, integration of transcriptional and proteomic data to define sepsis "endotypes" has also been attempted. While these approaches hold promise to guide improved clinical trial design and patient care, additional research is needed to contextualize and operationalize them across patients and pathogens.

PATHOGENESIS

The host-pathogen interaction during sepsis is heterogeneous, based on patient demographic and clinical factors and pathogen type and virulence. Consequently, the pathophysiology and molecular pathogenesis of sepsis vary across hosts and pathogens. However, a working framework for sepsis pathogenesis, with commonalities across hosts and pathogens, provides a basis for understanding which factors contribute to organ injury and dysfunction during severe infections. During local infection, a prototypical physiologic response is characterized by pathogen recognition followed by balanced inflammatory, anti-inflammatory, and repair responses resulting in pathogen clearance with minimal disruption to systemic homeostasis. During sepsis, however, pathogen components and exuberant cellular and soluble immune responses contribute to systemic illness, resulting in end-organ injury and dysfunction **(Fig. 315-2)**. Pathogen components and host responses to infection may also impair or delay adaptive immunity and tissue repair.

Pathologic responses in sepsis are mediated by myeloid lineage cells (i.e., neutrophils, monocytes, macrophages, and dendritic cells), lymphoid lineage cells (i.e., natural killer [NK] cells and lymphocytes), parenchymal cells (e.g., endothelial and epithelial cells), and soluble mediators (e.g., cytokines, chemokines, nitric oxide, histamine, prostaglandin, and bradykinin). Activated leukocytes adhere to endothelium, migrate into tissue, and perform end-effector functions, including reactive oxygen species (ROS) generation, that contribute to tissue injury. Activation of endothelial cells, platelets, the clotting cascade, and the complement system contribute to a prothrombotic state. When platelets and clotting factors are consumed, hemorrhage risk increases. Pathophysiologic manifestations of sepsis include systemic vasodilation, capillary leakage with interstitial fluid accumulation, and microvascular thrombosis resulting in impaired oxygen delivery, uptake, and utilization. Taken together, these factors drive cellular injury and end-organ dysfunction.

TRIGGERS OF HOST IMMUNE RESPONSES

Host immune responses in sepsis are initiated by pathogen components termed pathogen-associated molecular patterns (PAMPs) and propagated by host factors termed damage-associated molecular patterns (DAMPs). PAMPs and DAMPs interact with innate and adaptive immune cells and parenchymal cells early during sepsis, amplifying immune responses. PAMPs include bacterial lipopolysaccharide (LPS) or other bacterial cell wall or membrane components, pathogen nucleic acids, including single- or double-stranded RNA, and other pathogen-related molecules. DAMPs include proteins, lipids, nucleic acids, and other components released from injured cells. Examples include histones, high mobility group box 1 proteins, S100 proteins, oxidized phospholipids, double-stranded DNA, and adenosine triphosphate. PAMPs and DAMPs are recognized by extra- or intracellular receptors, termed pattern recognition receptors (PRRs). Multiple PRRs, including toll-like receptors (TLR), of which 10 have been described in humans, C-type lectin receptors (CLR), receptors for advanced glycation end products (RAGE), retinoic acid–inducible gene-I-like receptors (RIG-I), and nucleotide-binding oligomerization domain-like (NOD) receptors, have been implicated in sepsis signaling. Recognition of PAMPs and DAMPs by PRRs on innate immune cells such as neutrophils, monocytes, and macrophages activates inflammatory pathways, triggers release of proinflammatory cytokines and chemokines, and increases surface expression of vascular adhesion molecules.

MYELOID RESPONSES

Neutrophils, monocytes, and macrophages provide early innate immune defenses against invading pathogens but also contribute to sepsis pathogenesis by promoting inflammation and cellular injury and, in some cases, limiting adaptive immunity. Differentiated mature neutrophils are the most abundant circulating leukocytes in healthy individuals. Upon activation during sepsis, neutrophils upregulate surface adhesion molecule expression (e.g., CD11b) to bind endothelium. Within the microvasculature, neutrophils release neutrophil extracellular traps (NETs), web-like structures of DNA decorated with antimicrobial proteins such as cathepsin-G, myeloperoxidase, and neutrophil elastase to limit dissemination of invading pathogens. NETs interact with activated platelets, endothelial cells, and fibrin to form microvascular thromboses. Activated neutrophils also migrate into tissues to combat microbes through phagocytosis, degranulation, ROS generation, NET formation, and proinflammatory cytokine and chemokine release. Neutrophil granule components degrade extracellular matrix, while ROS oxidize proteins and lipids contributing to cellular injury and dysfunction. Soluble inflammatory mediators further recruit immune cells to sites of infection, exacerbating inflammation and cellular injury. Mediators such as interleukin (IL) 6, granulocyte-macrophage colony-stimulating factor, and granulocyte colony-stimulating factor trigger release of immature neutrophils from the bone marrow, a process termed emergency granulopoiesis that is associated with poor outcomes in septic patients.

Monocytes are innate myeloid cells that circulate in healthy individuals for up to 7 days following release from the bone marrow. Three main monocyte populations are defined by CD14 and CD16 surface expression, including classical (CD14+, CD16–), intermediate (CD14+, CD16+), and nonclassical ($CD14^{low}CD16+$) monocytes. Classical monocytes account for 85% of circulating monocytes in healthy individuals but rapidly migrate to infected tissues during sepsis, resulting in transient monocytopenia and an increased proportion of circulating nonclassical and intermediate monocytes. Nonclassical monocytes are more terminally differentiated blood-resident monocytes thought to patrol the endothelium during sepsis. Monocytes

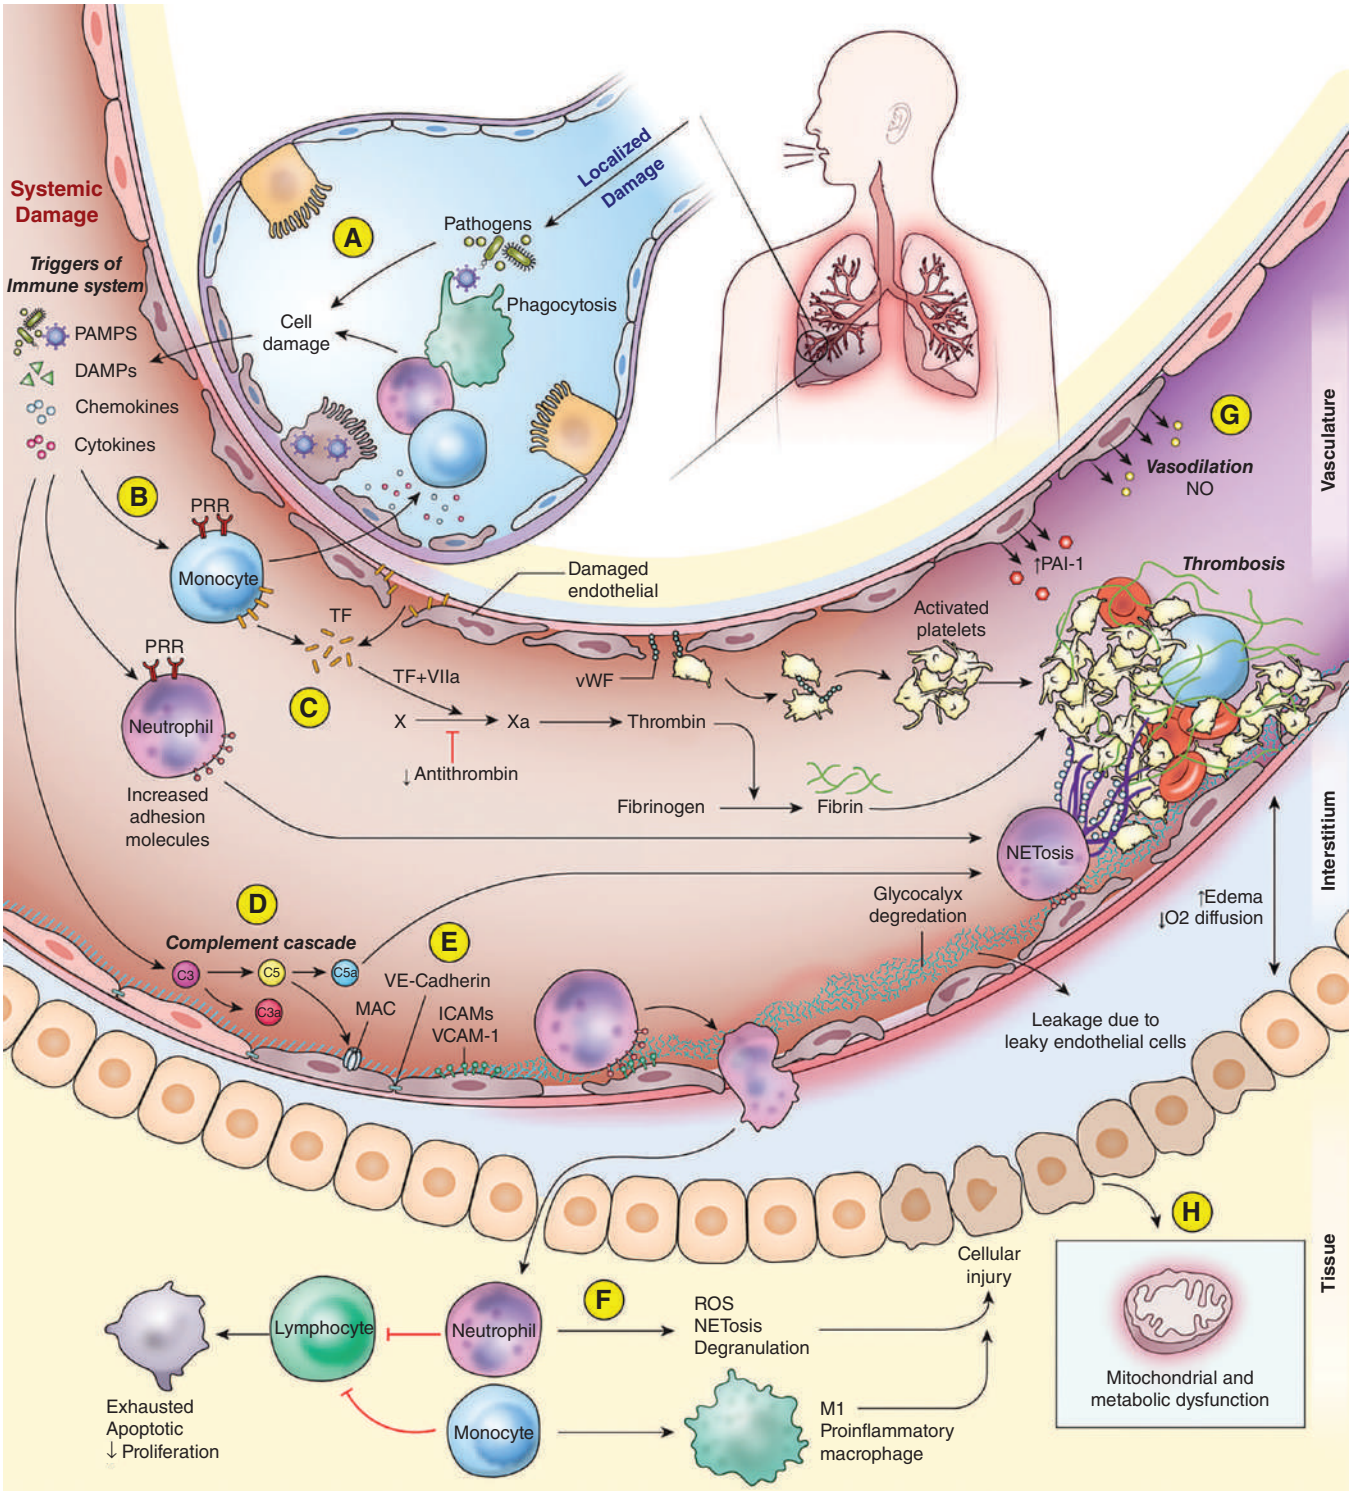

FIGURE 315-2 Sepsis pathogenesis. (A) Invading pathogens and tissue-resident and recruited leukocyte responses induce localized cell damage. **(B)** Systemic damage is mediated by pathogen-associated molecular patterns (PAMPs), damage-associated molecular patterns (DAMPs), cytokines, and chemokines that activate pattern recognition receptors (PRRs) on circulating monocytes and neutrophils. **(C)** Increasing tissue factor (TF) on endothelium and leukocytes triggers the clotting cascade and fibrin generation. Adherent neutrophils release extracellular traps (NETs) and microthrombi form, composed of leukocytes, fibrin, and platelet aggregates, bound together by von Willebrand factor (vWF). Antithrombin levels are decreased, promoting clot formation, and plasminogen activator inhibitor-1 (PAI-1) levels are increased, impairing clot breakdown. **(D)** Complement activation generates C3a and C5a, which activate platelets and myeloid cells. The C5b-9 membrane attack complex (MAC) promotes endothelial injury. **(E)** Activated and injured endothelium increase intercellular adhesion molecules (ICAMs) and vascular cell adhesion molecule (VCAM)-1 expression, glycocalyx breakdown, apoptosis, and loss of intercellular vascular endothelial (VE)-cadherin and tight junctions contributing to interstitial edema, decreased oxygen diffusion, and leukocyte migration. **(F)** Activated neutrophils degranulate and release reactive oxygen species (ROS) and NETs, and monocytes differentiate into proinflammatory (M1) macrophages, contributing to cellular injury and dysfunction. Activated myeloid cells also suppress lymphocyte function, through exhaustion, apoptosis, and decreased proliferation. **(G)** Arterial vasodilation, partially mediated by excess nitric oxide, contributes to tissue hypoperfusion and ischemia. **(H)** With or without adequate oxygen delivery, cellular mitochondrial and metabolic functions are disrupted during sepsis.

that migrate into tissues are exposed to PAMPs, DAMPS, cytokines, and other mediators, stimulating them to differentiate into dendritic cells or macrophages. Dendritic cells are phenotypically and transcriptionally diverse professional antigen-presenting cells with a broad PRR and cytokine secretion repertoire. These cells contribute to pathogen clearance and inflammation and bridge innate and adaptive immune responses through antigen presentation and lymphocyte activation. Macrophages that originate from bone marrow–derived monocytes are distinct from tissue-resident macrophages, which derive from embryonic progenitors. Depending on environmental conditions within tissues, bone marrow–derived monocytes polarize to become proinflammatory (M1) or anti-inflammatory, reparative (M2) macrophages. M1 macrophages contribute to pathogen clearance through phagocytosis, extracellular trap formation, ROS generation, and inflammatory cytokine release (e.g., IL-1β, IL-6, and tumor necrosis factor [TNF]-α). However, these same effector functions contribute to tissue injury. Macrophages also process and present antigens on surface major histocompatibility complex (MHC) II molecules, which are required for development of antigen-specific effector and memory B- and T-cell responses. This essential link between myeloid and lymphoid cells can be disrupted by diverse pathogen-induced mechanisms including downregulation of MHC surface expression or interruption of antigen processing or presentation by pathogen proteins and other components.

While myeloid cells typically contribute to inflammation in sepsis, a subset of pathologically activated myeloid cells in tissues, termed myeloid-derived suppressor cells, functionally suppress NK-cell, T-cell, and B-cell function, contributing to immunosuppression in sepsis.

LYMPHOID RESPONSES

NK cells are a heterogenous group of innate lymphocytes that migrate to sites of infection, contribute to pathogen clearance, and mediate inflammatory responses during sepsis. NK cells have activating and inhibitory cell surface receptors that modulate their activity. NK-cell PRRs recognize PAMPs including LPS, peptidoglycan, and double-stranded RNA. NK-cell cytokine receptors recognize inflammatory cytokines including type 1 interferons (IFN) and IL-12. Activated NK cells release proinflammatory cytokines including IFN-γ and IL-32, which activate myeloid cells in a positive feedback loop. Activated NK cells also directly kill infected cells that have downregulated MHC class I surface molecule expression, through release of cytotoxic granules including perforin and granzyme. In studies of human sepsis, circulating NK cells with increased CD69 expression, indicative of activation, and increased plasma concentrations of IFN-γ and granzyme A and B support a proinflammatory role of NK cells. However, NK cells also release IL-10, known to suppress myeloid cell–mediated inflammatory responses, highlighting an anti-inflammatory role of NK cells in sepsis as well.

B- and T-cell responses in sepsis are essential for recognizing and clearing pathogens. B cells produce antibodies against foreign antigens and form antigen-specific memory cells. CD8+ T cells lyse infected cells that present foreign antigens in association with MHC surface molecules and form memory cells. CD4+ (T_H1) cells activate CD8+ T cells and support memory T-cell formation, CD4+ (T_H2) cells contribute to B-cell class switching, and CD4+ (T_H17) cells protect against extracellular fungal and bacterial infections. B- and T-cell dysfunction in sepsis impairs adaptive immunity and predisposes to subsequent infections among survivors. Contributing factors to adaptive immune dysfunction in sepsis include death of lymphocytes in the circulation and tissue, cellular exhaustion, decreased proliferation, and apoptosis-refractory regulatory T cells, all of which can inhibit inflammatory responses. Functional manifestations of T-cell exhaustion include impaired cytokine production and diminished cytotoxic activity, while diminished antibody production is observed in exhausted B cells.

ENDOTHELIAL ACTIVATION

During homeostasis, endothelial cells line blood vessels and regulate vascular tone and the exchange of cells, fluid, and molecules between the bloodstream and surrounding tissues. The endothelial glycocalyx, a network of proteoglycans, glycoproteins, glycolipids, glycosaminoglycans, and bound plasma proteins, lines luminal endothelium and maintains homeostatic functions. During sepsis, PAMPs and DAMPs activate endothelial cells, altering their structure and function. Glycocalyx breakdown disrupts blood flow and mediates proadhesive, procoagulant, and proinflammatory endothelial properties. Activated endothelial cells increase surface adhesion molecule expression, including intercellular adhesion molecules (ICAMs) and vascular cell adhesion molecule (VCAM)-1, that coordinates leukocyte adhesion, rolling, and diapedesis. Activated endothelium promotes clotting through increased tissue factor (TF) expression and platelet adhesion and impairs fibrinolysis through increased plasminogen activator inhibitor (PAI)-1 release, among other factors. Activated endothelial cells also produce proinflammatory cytokines, including IL-1β, IL-6, and IFN-α, contributing to local and systemic inflammation. Beyond glycocalyx breakdown, barrier function is impaired through endothelial cell apoptosis and loss of intercellular adherence (e.g., vascular endothelial [VE]-cadherin) and tight junctions. Loss of endothelial barrier function contributes to interstitial fluid accumulation, increased interstitial pressure, and tissue hypoperfusion. Alterations in endothelial cell nitric oxide (NO) metabolism in sepsis contribute to systemic vasodilation and cellular injury.

COAGULOPATHY

The coagulation system, composed of plasma proteins, platelets, and the endothelium, maintains vascular integrity. During sepsis, PAMPs and DAMPs interact with these components, innate immune cells, and the complement system to promote thrombus formation and impair clot breakdown. Increased TF expression on activated leukocytes and endothelium triggers the extrinsic clotting cascade, thereby driving thrombin-mediated conversion of fibrinogen to fibrin. Endothelial injury exposes von Willebrand factor (vWF) on subendothelial surfaces, which binds platelets via glycoprotein Ib receptors, and platelets bind fibrinogen via glycoprotein IIb/IIIa receptors. Activated platelets and endothelium release additional vWF from intracellular stores (i.e., Weibel-Palade bodies in endothelial cells), forming multimers that aggregate platelets at the endothelial surface. Activated monocytes and neutrophils bind to these platelet aggregates, and neutrophils release NETs, contributing to a meshwork of fibrin-rich microthrombi. The complement system, which is composed of >50 soluble or membrane bound proteins, also contributes to microthrombi formation. During sepsis all three complement pathways (classical, alternative, and lectin) become activated. Release of C3a and C5a anaphylatoxins further activates platelets and myeloid cells, and assembly of the membrane attack complex (MAC), composed of C5b-9, promotes endothelial injury. Counterregulatory anticoagulant molecules, including antithrombin, tissue factor pathway inhibitor, and activated protein C, are impaired in sepsis, and increased activity of antifibrinolytic molecules, including PAI and thrombin-activatable fibrinolysis inhibitor, limit clot breakdown. When clotting factors and platelets are consumed, spontaneous and provoked hemorrhage can occur.

CELLULAR INJURY AND DYSFUNCTION

A hallmark of sepsis is multiorgan cellular injury and dysfunction. Arterial hypotension due to systemic vasodilation, myocardial depression, and hypovolemia; increased interstitial edema due to vascular leakage resulting in increased oxygen diffusion distance; and microcirculatory dysfunction in part due to endothelial activation, injury, and microvascular thrombosis all contribute to inadequate oxygen delivery and cellular injury and dysfunction during sepsis. Cell death or dysfunction can also result from direct interactions with PAMPs, DAMPs, activated leukocytes, and their associated mediators including cytokines, chemokines, toxic granules, ROS, and reactive nitrogen species (RNS), including peroxynitrite, nitrogen dioxide, and dinitrogen trioxide. ROS and RNS contribute to protein and lipid oxidation and DNA damage of proximate cells. Even in the setting of adequate oxygen delivery, cellular mitochondrial and metabolic functions are disrupted during sepsis, including ATP generation through glycolysis and oxidative phosphorylation, ion (i.e., Na^+, K^+, and Ca^{2+}) homeostasis, and regulation of cell death pathways.

CLINICAL MANIFESTATIONS AND MANAGEMENT

Sepsis may present with nonspecific signs and symptoms including fever, tachycardia, lethargy, and myalgias with or without localizing end-organ findings such as cough, pyuria, or abdominal pain or evidence of end-organ dysfunction such as oliguria or altered mental status. There is no gold standard diagnostic test for sepsis, so epidemiologic, demographic, clinical, laboratory, radiologic, and microbiologic parameters must be considered in diagnosing sepsis. In addition to a focused history and physical examination to elicit signs, symptoms, and physical manifestations of sepsis, an initial laboratory evaluation should include complete blood count with differential, basic metabolic panel, liver function test, serum lactate, coagulation panel, urinalysis, and point-of-care pathogen testing when available. Microbiologic testing with culture of blood and other potentially infected sites (e.g., urine, sputum, wound), ideally prior to antimicrobial administration, should be performed to identify a specific infection and guide antimicrobial therapy. Focused imaging examination by x-ray, computed tomography, or ultrasound of potentially infected sites (e.g., lung, abdomen) to support a diagnosis of sepsis and guide efforts to control the source of infection should also be pursued. Sepsis mimics include but are not limited to noninfectious inflammatory febrile syndromes such as connective tissue diseases and vasculitides; heart failure and other noninfectious causes of pneumonitis or lung injury; noninfectious abdominal syndromes including mesenteric ischemia and inflammatory bowel disease; and hypotension due to noninfectious causes including hypovolemia, autonomic dysfunction, and adrenal insufficiency. In a recent study of septic patients admitted to the ICU, 25% were retrospectively deemed to have sepsis mimics. The most common mimics were cardiovascular (e.g., heart failure, cardiac arrest) and respiratory (e.g., noninfectious chronic obstructive pulmonary disease). In patients with suspected sepsis or septic shock in whom infection is not confirmed, continuous reevaluation for alternative diagnoses is imperative.

RECOGNIZING SEPSIS

Early recognition and treatment of bacterial septic shock with appropriate antibiotics has been associated with reduced mortality. Therefore, the 2023 CDC Hospital Sepsis Program Core Elements guidance document and the 2021 Surviving Sepsis Campaign guidelines recommend hospitals have dedicated sepsis improvement programs that include standard operating procedures for sepsis screening and early treatment. To operationalize updated Sepsis-3 definitions, consensus criteria for sepsis include an increase of ≥2 in SOFA score from baseline in patients with suspected or confirmed infection, and criteria for septic shock include septic patients requiring vasopressor therapy to maintain a mean arterial pressure >65 mmHg and lactate >2 mmol/L despite fluid resuscitation. To more rapidly screen patients for sepsis, the quick (q)SOFA score has been proposed, which includes respiratory rate ≥22 breaths/min, Glasgow Come Scale score <15, and systolic blood pressure ≤100 mmHg. A qSOFA score ≥2 is associated with poor outcome and is more specific, although less sensitive, than SIRS criteria for identifying patients with end-organ dysfunction due to infection. Multiple other sepsis screening tools have been proposed including the National Early Warning Score, the Modified Early Warning Score, and the artificial intelligence–based Targeted Real-Time Early Warning System. Given that each screening tool has advantages and limitations, none is preferentially endorsed for sepsis screening by the 2021 Surviving Sepsis Campaign guidelines.

INITIAL SEPSIS MANAGEMENT

Initial treatment of patients with sepsis or septic shock includes timely blood pressure and end-organ support, antimicrobial therapy, and identification and elimination of the source of infection. The 2021 Surviving Sepsis Campaign treatment guidelines provide the most up-to-date and evidenced-based approach for initial and subsequent treatment of patients with sepsis and septic shock. Initial management recommendations include obtaining intravenous access with peripheral or central venous catheters, administering appropriate and timely antibiotics, treating life-threating hypotension with intravenous crystalloid and vasopressor therapy, and managing respiratory insufficiency or failure with supplemental oxygen, airway support, and mechanical ventilation, when indicated. Following initial stabilization in patients who are critically ill or in shock, admission to the ICU within 6 h should be targeted.

Of these interventions, early appropriate antibiotic administration in patients with bacterial septic shock has been most clearly associated with improved survival. In patients with bacterial septic shock, there is an estimated 7–8% increase in mortality for every 1-h delay in appropriate antibiotic administration following shock recognition. Consequently, in patients with suspected or confirmed septic shock, immediate empiric antimicrobial therapy within 1 h of shock recognition is recommended. The association between time to antibiotics and mortality in patients with suspected or confirmed sepsis without shock has not been established. In patients in whom a diagnosis of sepsis is less certain and shock is absent, further time-limited clinical evaluation is recommended prior to empiric antibiotic administration. If an alternative diagnosis is not identified within 3 h of clinical presentation, empiric antibiotic administration is recommended.

Selection of initial empiric antibiotics should consider site of infection and potential etiologic organisms; community versus health care exposure; known prior infections, antibiotic usage, and local antimicrobial resistance profiles; and the patient's immune status, comorbidities, and illness severity. Recommendations for initial empiric antibiotic use based on site of infection and other pertinent factors are summarized in **Table 315-1**. In patients with undifferentiated sepsis, in whom the primary site of infection is unclear, use of broad-spectrum antibiotics with a high likelihood of in vitro susceptibility to all organisms likely causing infection is recommended. In patients in whom *Pseudomonas* is not considered a likely pathogen, then a third-generation cephalosporin such as ceftriaxone or cefotaxime is recommended for gram-negative bacteria coverage. If *Pseudomonas* is likely, then cefepime, piperacillin-tazobactam, or a carbapenem such as imipenem or meropenem is recommended for gram-negative bacteria coverage. In patients at risk for highly resistant gram-negative infections (e.g., patients with prior known highly resistant infections or colonization), use of two empiric gram-negative antibiotics is recommended. Finally, in patients with undifferentiated sepsis with risk factors for MRSA (e.g., frequent health care exposure or hospital-onset sepsis), vancomycin or linezolid administration is recommended.

Optimization of antibiotic delivery, such as administering β-lactam antibiotics prior to vancomycin, prolonged infusion of β-lactam antibiotics after the initial infusion, and optimization of pharmacokinetics/pharmacodynamics, should be considered in consultation with trained pharmacy and infectious diseases experts. Routine empiric antifungal therapy use in patients with undifferentiated sepsis is not recommended. However, in patients at increased risk of fungal infection (e.g., recent abdominal surgery, parenteral nutrition, liver failure, diabetes, colonization of multiple anatomic sites with *Candida* spp.), empiric echinocandin administration is recommended. While the Surviving Sepsis Campaign does not provide recommendations on antiviral use, remdesivir or neuraminidase inhibitor (e.g., oseltamivir) administration in septic patients with severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2) and influenza infection, respectively, should be considered.

In addition to providing appropriate and timely antibiotics, identifying sources of infection amendable to control is imperative. Examples include, but are not limited to, intraabdominal abscess, bowel perforation, pyelonephritis, cholangitis, and necrotizing skin and soft tissue infections that are amendable to surgical or procedural source control. Source control should occur as rapidly as possible. Furthermore, removal of indwelling catheters should occur if the catheter appears infected (e.g., erythema or purulence at the catheter insertion site), if endovascular infection (e.g., endocarditis) is suspected or documented, and in critically ill patients without a clear alternate source of infection. Finally, antibiotic stewardship to limit development of resistant organisms and other antibiotic-associated complications (e.g., *Clostridioides difficile* infection, hypersensitivity/allergic reaction, and acute kidney

TABLE 315-1 Site-Specific Empiric Antibiotic Recommendations

SITE OF INFECTION	INITIAL EMPIRIC THERAPY	OTHER CONSIDERATIONS
Pulmonary		
CAP	Multidrug therapy with a β-lactam (ampicillin + sulbactam, ceftriaxone, or ceftaroline) and a macrolide (azithromycin or clarithromycin) Monotherapy with a respiratory fluoroquinolone (levofloxacin or moxifloxacin)	Risk factors for MRSA and/or *Pseudomonas aeruginosa*: add vancomycin or linezolid for MRSA coverage; replace standard CAP therapy with antipseudomonal coverage such as piperacillin-tazobactam, cefepime, meropenem, or imipenem. Recommendation based on "local validation" of risk factors for community-onset MRSA or *P. aeruginosa* or prior isolation of these organisms in the previous year, particularly from respiratory specimens.
HAP/VAP	Multidrug therapy with vancomycin or linezolid and piperacillin-tazobactam, cefepime, ceftazidime, imipenem, meropenem, or aztreonam	Two antipseudomonal antibiotics from different classes (addition of fluoroquinolones, aminoglycosides, or polymyxins) if prior intravenous antibiotic use within 90 days for HAP/VAP and septic shock at time of VAP, ARDS preceding VAP, 5 or more days of hospitalization prior to VAP, or acute renal replacement therapy prior to VAP. If prior colonization with carbapenem-resistant Enterobacterales or KPC-producing organism, ceftazidime-avibactam and meropenem-vaborbactam should be considered, but further efficacy data are needed. Empiric regimens should be informed by local distribution of pathogens and their antimicrobial susceptibilities.
Central Nervous System		
Health care–associated ventriculitis and meningitis	Vancomycin and cefepime, ceftazidime, or meropenem	β-Lactam choice based on local in vitro susceptibility patterns. If carbapenem-resistant *Acinetobacter* is suspected, addition of meropenem and colistin or polymyxin B.
Meningitis	Vancomycin and ceftriaxone	Age >50, alcohol abuse, or immunocompromised: add ampicillin. Penetrating head trauma, CSF shunt, or postneurosurgery, vancomycin and cefepime, ceftazidime, or meropenem. Clinical presentation suggestive of *Rickettsia* or *Ehrlichia*, add doxycycline.
Skin and Soft Tissue		
Necrotizing fasciitis including Fournier gangrene	Multidrug therapy with vancomycin or linezolid and piperacillin-tazobactam, a carbapenem, or ceftriaxone and metronidazole	Prompt surgical consultation is recommended for patients with aggressive infections associated with signs of systemic toxicity or suspicion of necrotizing fasciitis or gas gangrene.
Nonpurulent cellulitis/ erysipelas (severe)	Vancomycin and piperacillin-tazobactam	Emergent surgical inspection to rule out necrotizing process.
Purulent furuncle/ carbuncle/abscess (severe)	Vancomycin, daptomycin, linezolid, telavancin, or ceftaroline	Incision and drainage as indicated.
Intraabdominal		
Community-onset extrabiliary (mild)	Cefoxitin, ertapenem, moxifloxacin, or tigecycline	Health care setting with high prevalence of ESBL-producing Enterobacterales or >20% of *Pseudomonas* resistant to ceftazidime, consider carbapenem or piperacillin-tazobactam.
Community-onset extrabiliary (severe)	Imipenem-cilastatin, meropenem, doripenem, or piperacillin-tazobactam	Health care associated: imipenem-cilastatin, meropenem, or piperacillin-tazobactam, levofloxacin, or cefepime each along with metronidazole, vancomycin added to each regimen.
Community-onset biliary (mild to moderate)	Cefazolin, cefuroxime, or ceftriaxone	Empiric therapy should be driven by local microbiologic data and source control performed as indicated.
Community-onset biliary (severe) or cholangitis	Imipenem-cilastatin, meropenem, or piperacillin-tazobactam, levofloxacin, or cefepime each in combination with metronidazole	
Genitourinary		
Acute pyelonephritis (IDSA archived)	Ceftriaxone, trimethoprim-sulfamethoxazole, or ciprofloxacin	Requiring hospitalization: intravenous fluoroquinolone, aminoglycoside, extended-spectrum cephalosporin, extended-spectrum penicillin, or carbapenem with choice of agents based on local resistance data. Do not use fluoroquinolone if >10% resistance prevalence or trimethoprim-sulfamethoxazole in areas of high resistance.

Abbreviations: ARDS acute respiratory distress syndrome; CAP, community acquired pneumonia; CSF, cerebrospinal fluid; HAP, hospital-acquired pneumonia; IDSA, Infectious Diseases Society of America; KPC, *Klebsiella pneumoniae* carbapenemase; ESBL, extended spectrum beta-lactamase; MRSA, methicillin-resistant *Staphylococcus aureus*; VAP, ventilator-associated pneumonia.

injury) requires regular reassessment of the patient's clinical course and available microbiologic data to guide narrowing the spectrum of antibiotic therapy and using shorter rather than longer courses of therapy.

NEUROLOGIC COMPLICATIONS

Encephalopathy, manifested by altered consciousness, cognition, or attention, ranging from mild delirium to coma, that is not attributable to an alternative etiology, is the most common neurologic complication of sepsis (Table 315–2). Sepsis-associated encephalopathy occurs in over half of septic patients and is associated with increased mortality and long-term functional and neuropsychiatric sequalae among survivors. Septic patients may also experience hyper- or hypoactive delirium, seizure, stoke, central nervous system infection, or coma, not directly attributable to sepsis. Thus, further diagnostic evaluation is needed in septic patients with clinical findings indicative of seizures (i.e., electroencephalogram), stroke (i.e., brain imaging), or meningoencephalitis (i.e., lumbar puncture) to identify and treat these complications. Underlying factors contributing to sepsis-associated encephalopathy include decreased cerebral perfusion, microcirculatory and blood-brain barrier disruption, and exposure of brain parenchyma to circulating inflammatory mediators and oxidative stress resulting in neuronal injury, dysfunction, and death. Neuronal and glial apoptosis

TABLE 315-2 Organ-Specific Clinical Findings and Management

	EPIDEMIOLOGY	CLINICAL FINDINGS	DIAGNOSIS	TREATMENT
Neurologic	54% of septic patients develop encephalopathy	Altered consciousness, cognition, or attention; seizure, stroke, or meningism	EEG, brain imaging (MRI or CT), lumbar puncture	Early recognition and supportive care; treat underlying cause; correct metabolic and electrolyte abnormalities; limit neurotoxic agents and sedatives
Cardiovascular	25% of septic patients develop shock and half have myocardial dysfunction	Tachycardia, hypotension, skin mottling, prolonged capillary refill, oliguria, altered mental status	Invasive blood pressure monitoring, dynamic assessment of volume status, echocardiogram	Intravenous fluid resuscitation with balanced crystalloid, ~30 mL/kg; vasopressors for persistent hypotension, norepinephrine (first agent), vasopressin (second agent), epinephrine (third agent); hydrocortisone 200 mg/d if ongoing vasopressor requirement; consider adding dobutamine to norepinephrine or switch to epinephrine in septic shock patients with decreased LVEF; consider use of pulmonary artery catheter in patients with mixed septic and cardiogenic shock
Respiratory	7% of septic patients develop ARDS	Tachypnea, hypoxia, increased work of breathing	Chest x-ray or ultrasound with noncardiogenic bilateral infiltrates and Pa_{O_2}/F_{IO_2} <300 mmHg or Sp_{O_2}/F_{IO_2} ≤315	Maintain Sp_{O_2} 90–96%; use high-flow nasal canula in patients with adequate neurologic status; target plateau pressure <30 cmH_2O and tidal volume of 6–8 mL; consider rescue therapies in patients with refractory hypoxia
Genitourinary	67% of septic patients have acute kidney injury	Oligura or anuria	Elevated serum creatinine and blood urea nitrogen, acidemia, hyperkalemia	Treat underlying infection, maintain renal perfusion, avoid nephrotoxic agents; start renal replacement therapy for progressive acidemia, hyperkalemia, uremia, or volume overload; infuse sodium bicarbonate if renal failure and pH ≤7.2.
Gastrointestinal	50% of septic shock patients have liver dysfunction	Right upper quadrant pain, asterixis, jaundice	Elevated bilirubin, alkaline phosphatase, and transaminases; right upper quadrant ultrasound	Treat underlying infection, avoid hypotension and hepatoxic agents; stress ulcer prophylaxis for high-risk patients; enteral feeding if shock controlled within 48 h; parenteral feeding if nutrition goal not met within 7 days; insulin if blood glucose ≥180 g/dL
Hematologic	35% of septic shock patients have disseminated intravascular coagulation	Clinical or subclinical thrombosis or hemorrhage	Thrombocytopenia, increased fibrin split products, decreased fibrinogen, prolonged PT/INR	Administer cryoprecipitate for fibrinogen <150 mg/dL, platelets for platelet count ≤50×10^9/L and evidence of bleeding, and fresh frozen plasma for prolongated PT/INR and evidence of bleeding; transfuse packed red blood cells for hemoglobin <7.0 g/dL

Abbreviations: ARDS, acute respiratory distress syndrome; CT, computed tomography; EEG, electroencephalogram; INR, international normalized ratio; LVEF, left ventricular ejection fraction; MRI, magnetic resonance imaging; PT, prothrombin time.

are correlative findings at autopsy among fatal cases. The management of sepsis-associated encephalopathy includes early recognition, treatment of the underlying infection, supportive care including correction of metabolic or electrolyte abnormalities, and limiting exposure to pharmacologic agents that are neurotoxic (e.g., cefepime) or have central nervous system effects including opiates and benzodiazepines that might exacerbate the condition or predispose to long-term disability or neurocognitive dysfunction.

CARDIOVASCULAR DYSFUNCTION

Cardiovascular comprise, manifested as hypotension or shock, occurs in ~25% of septic patients. Hypotension results from peripheral arteriolar vasodilation and decreased cardiac venous return due to venous vasodilation and intra- to extravascular fluid shifts. Clinical signs of diminished tissue perfusion include skin mottling, prolonged capillary refill time, oliguria, and altered mental status. During early compensated shock, heart rate and cardiac output increase. As septic shock progresses, loss of vascular smooth muscle contractility, despite endogenous neurohormonal stimuli and exogenous catecholamine administration, results in progressive or refractory shock.

Up to half of patients with septic shock also have myocardial dysfunction, which is associated with increased mortality. Sepsis-induced cardiomyopathy manifests as decreased left ventricular ejection fraction, increased end-diastolic volume index, and right ventricular impairment. Contributing factors to sepsis-induced cardiomyopathy include global ischemia, hypoxia, and impaired myocardial metabolism; endothelial damage, increased adhesion molecule expression, and coronary microcirculatory dysfunction; and direct cardiomyocyte suppression, mitochondrial dysfunction, or cardiomyocyte death from exposure to inflammatory mediators including cytokines (e.g., IL-1β, IL-6, and TNF-α), complement proteins, and NO.

Intravenously administered fluids and vasopressors are used to restore and maintain blood pressure and tissue perfusion in the setting of septic shock. An indwelling arterial catheter should be placed as soon as feasible to continuously monitor blood pressure invasively. Crystalloid solutions are preferred over colloid for initial volume resuscitation, although colloid such as albumin can be considered in patients who have already received large volumes of crystalloid. Balanced crystalloid solution, such as lactated Ringer's, may be preferrable to 0.9% normal saline, which is more likely to induce hyperchloremic metabolic acidosis associated with renal vasoconstriction and kidney injury. Use of pentastarch or hydroxyethyl starch is associated with severe kidney injury and death and should be avoided.

Crystalloid should be administered as a bolus over 5–10 min at a volume of ~30 mL/kg. However, 30 mL/kg may not be appropriate for all patients, including those with end-stage renal disease and systolic heart failure. Protocolized fluid resuscitation targets including central venous pressure (CVP) of 8–12 mmHg, central venous oxygen saturation >70%, and urine output ≥0.5 mL/kg per h have not been associated with improved mortality and so are not recommended to guide total fluid replacement. Instead, dynamic assessment of volume responsiveness using capillary refill time, passive leg raise maneuver, and point-of-care ultrasound, with iterative reevaluation, should guide total volume administered and is preferred over static measurements of volume responsiveness such as CVP. Notably, a 2017–2018 clinical trial conducted in 28 ICUs in five countries found that resuscitation guided by capillary refill time compared with lactate level–targeted resuscitation did not reduce all-cause 28-day mortality, an important finding for sepsis care in resource-limited settings.

In patients who have received adequate fluid resuscitation yet remain hypotensive, a continuous norepinephrine drip should be initiated as

the first-line vasopressor to maintain a mean arterial pressure target of ≥65 mmHg. Vasopressin should be added as a second agent, and epinephrine as a third agent, if needed, to achieve the blood pressure target. A contemporary randomized clinical trial tested the efficacy of early restrictive (i.e., prioritizing vasopressors and lower intravenous fluid volumes) versus liberal (i.e., prioritizing higher volumes of intravenous fluids before vasopressors use) fluid management in the first 4 h of presentation in patients with septic shock. Across 1563 patients at 60 U.S. medical centers, there was no difference in 90-day mortality. In septic patients with evidence of myocardial dysfunction (e.g., low cardiac output, elevated filling pressures) and evidence of persistent hypoperfusion following adequate volume resuscitation, consideration should be given to adding dobutamine to norepinephrine or using epinephrine alone to increase inotropy. While routine use of pulmonary artery catheters to guide fluid management in sepsis has not been associated with improved outcomes, use may be considered in patients with mixed septic and cardiogenic shock.

In patients with septic shock and ongoing requirement for vasopressor therapy, it is recommended to start intravenous corticosteroids with hydrocortisone at a dose of 200 mg/d often provided as 50 mg every 6 h.

ACUTE LUNG INJURY

Lung injury, manifesting as acute hypoxic respiratory insufficiency or failure, and termed acute respiratory distress syndrome (ARDS), complicates ~7% of sepsis cases. ARDS is a syndrome that is classified by noncardiogenic diffuse pulmonary infiltrates and hypoxemia, in which infiltrates can be determined by x-ray or ultrasound imaging, and hypoxemia can be determined by Pao_2/Fio_2 <300 mmHg or percent oxygen saturation (Spo_2)/Fio_2 ≤315. The pathogenesis of ARDS overlaps with that of sepsis, in which activated myeloid cells and soluble inflammatory mediators disrupt pneumocytes' and endothelial cells' structure and function, resulting in leakage of plasma components and further recruitment of immune cells into lung alveolar and interstitial spaces. The histopathologic correlate of ARDS is diffuse alveolar damage, which progresses through early exudative, then proliferative, and finally fibrotic stages.

Initial management of acute lung injury in sepsis requires administration of oxygen to meet cellular metabolic demand while limiting cellular injury from oxidative stress, with a reasonable Spo_2 target being 90–96%. In patients with adequate neurologic status, and absent other specific contraindications, high-flow nasal canula is preferred over noninvasive ventilation to improve hypoxia in patients without hypercapnia. For patients with ARDS who require invasive mechanical ventilation, targeting a plateau pressure of <30 cmH_2O and a tidal volume of 6–8 mL/kg, based on ideal body weight, has been associated with reduced mortality and is recommended. In patients with refractory hypoxia despite low tidal volume ventilation, rescue measures including prone positioning, neuromuscular blockade, and venovenous extracorporeal membrane oxygenation should be considered.

ACUTE KIDNEY INJURY

Acute kidney injury (AKI) occurs in up to two-thirds of patients with sepsis or septic shock and is associated with increased mortality and risk of chronic kidney disease and disability among survivors. Sepsis-associated AKI presents with oliguria or anuria and elevated serum creatinine and blood urea nitrogen and accounts for all AKI cases occurring within 7 days of sepsis onset. Sepsis-associated AKI may be attributed to sepsis, associated complications (e.g., abdominal compartment syndrome), and clinical management including administration of nephrotoxic substances such as antibiotics and intravenous contrast dye. Factors that contribute to pathogenesis of AKI due to sepsis alone, termed sepsis-induced AKI, include renal hypoperfusion, microvascular injury and dysfunction, inflammatory cellular and soluble mediators, and altered renal tubular metabolic and mitochondrial function. Many serum and urine biomarkers have been evaluated to improve early recognition and treatment of sepsis-associated AKI. However, to date, none have been shown to improve outcomes.

Management of sepsis-associated AKI includes treating underlying infection, maintaining renal perfusion with fluid resuscitation and vasopressors to achieve blood pressure goals, avoiding nephrotoxic agents when possible, and identifying and treating reversible causes. Initiating early renal replacement therapy (RRT), including intermittent hemodialysis or continuous renal replacement therapy (CRRT), during sepsis-associated AKI is not associated with improved outcomes, and so RRT should be started for standard definitive indications including progressive acidemia, hyperkalemia, uremia, or volume overload. CRRT is better tolerated than intermittent hemodialysis in patients with septic shock, allowing for less dynamic intravascular volume shifts and so is preferred in these patients when available. Sodium bicarbonate infusion should be considered only in patients with AKI and severe metabolic acidemia (pH ≤7.2) to maintain vasopressor effectiveness and mitigate fatal ventricular arrythmia risk.

GASTROINTESTINAL COMPLICATIONS

Approximately 50% of patients with septic shock develop liver dysfunction, which is associated with increased mortality. Clinical findings may include right upper quadrant pain, jaundice, and asterixis depending on severity. Common laboratory findings include elevated serum bilirubin and alkaline phosphatase levels and elevated transaminases if marked hypotension occurs. Sepsis-induced cholestasis is attributed to impaired bile formation and decreased flow in a nonobstructive pattern. The liver plays an essential role in microbial clearance, in which the Kupffer cells phagocytose bacteria, release proinflammatory cytokines and chemokines, and bind platelets. Neutrophils are recruited to liver sinusoids, release NETs to trap pathogens, and contribute to a proinflammatory and prothrombotic environment. In autopsy studies of fatal sepsis, hepatitis and steatosis are detected in most patients, while portal inflammation, centrilobular necrosis, hepatocellular apoptosis, and cholangitis may also be detected. Management of liver injury and dysfunction during sepsis includes treating the underlying infection and avoiding hypotension and hepatoxic medications. In septic patients with elevated serum bilirubin, abdominal ultrasound should be performed to evaluate for biliary obstruction, cholecystitis, and cholangitis.

Sepsis has also been associated with alteration of the intestinal mucosa including increased epithelial permeability, changes in gut microbiota, and translocation of enteric microbes into circulation. In patients with sepsis and septic shock and risk factors for gastrointestinal bleeding (e.g., mechanical ventilation, coagulopathy, preexisting liver disease, high organ failure score, and need for RRT), stress ulcer prophylaxis is recommended. Decreased splanchnic perfusion and increased interstitial edema contribute to impaired intestinal absorption, which in combination with the catabolism of sepsis contributes to nutritional deficiencies. The route and timing of supplemental nutrition administration in patients with sepsis and septic shock are debated. Current recommendations are to initiate enteral nutrition early, within 48 h of diagnosis, in patients in whom shock is controlled with fluids and vasopressors and absent contraindications like bowel ischemia. The rationale for early enteral feeding is to maintain enteric epithelial integrity while limiting negative nitrogen and caloric balance. Supplemental use of parenteral nutrition is suggested if nutritional goals are unmet within 7 days by enteric feeding and supplemental glucose infusion. Insulin therapy is recommended for patients with blood glucose levels >180 mg/dL.

HEMATOLOGIC COMPLICATIONS

Coagulation abnormalities in sepsis are common, ranging from isolated thrombocytopenia to disseminated intravascular coagulation (DIC), and can manifest with clinical or subclinical thrombosis and hemorrhage. Up to 35% of septic shock patients meet DIC criteria, including thrombocytopenia, increased fibrin split products, decreased fibrinogen, and prolonged prothrombin time (PT)/international normalized ratio (INR), which is associated with increased mortality. Given that DIC is a late manifestation of coagulation abnormalities in sepsis, a scoring system for earlier detection of sepsis-induced coagulopathy (SIC) has been proposed. SIC scoring, which considers platelet counts, PT, and SOFA score, is more sensitive than DIC criteria for recognizing coagulation abnormalities in sepsis. However, the clinical utility of SIC

for guiding interventions or improving outcomes in sepsis is unproven. The pathogenesis of coagulation abnormalities in sepsis, as discussed above, is attributed to activation of innate immune cellular and soluble responses including cytokines, chemokines, and complement; endothelial activation and injury; platelet activation and aggregation; and clotting cascade induction, suppression of antithrombotic molecules, and activation of antifibrinolytic molecules. This procoagulant milieu results in platelet and clotting factor consumption, which paradoxically increases bleeding risk. Current recommendations for DIC management focus on mitigating bleeding risk. Recommendations include administration of cryoprecipitate to patients with fibrinogen <150 mg/dL; administration of fresh frozen plasma to patients with prolongated PT/INR and evidence of bleeding; and administration of platelets to patients with platelet counts $\leq 50 \times 10^9$/L and evidence of bleeding. Platelet transfusion thresholds are lower in patients at increased bleeding risk including patients undergoing chemotherapy, post–hemopoietic stem cell transplantation patients, and postsurgical patients. Venous thromboembolism prophylaxis, with low-molecular-weight heparin preferred over unfractionated heparin, is recommended in patients with sepsis or septic shock. Full-dose anticoagulation is not recommended for prophylactic use in septic patients, but instead is reserved for standard treatment indications including deep-venous thrombosis and pulmonary embolism.

Anemia is common in septic patients, and transfusion of packed red blood cells to maintain hemoglobin >7.0 g/dL is recommended. However, a more conservative, higher hemoglobin target may be appropriate in some patients based on individual factors including degree of hypoxemia, myocardial ischemia, and active hemorrhage.

HOST-TARGETED THERAPIES

Despite years of effort and many promising preclinical studies, there are currently no U.S. Food and Drug Administration–approved therapies targeting pathologic immune responses during bacterial sepsis. Failed therapeutic targets include proinflammatory mediators (e.g., anti-TNF, anti-IL-1, anti-TLR-4, anti-C5a), components of the coagulation cascade (e.g., antithrombin III, activated protein C, thrombomodulin), and many others. Other adjunctive therapies that have been evaluated include polymyxin-B hemoperfusion, intravenous immunoglobulin, and vitamin C, all determined to be not beneficial. Future work aimed at developing host-targeted sepsis therapies will require a deeper understanding of cellular and soluble mediators contributing to its pathogenesis in blood and tissues and how these mediators vary across host, pathogen, and timing of infection. Emerging technologies including single-cell transcriptomics, proteomics, metabolomics, and spatial-transcriptomics should aid in identifying novel therapeutic targets, and innovative, adaptive clinical trial designs will help stratify heterogeneous septic patients into likely responders to specific therapies.

DEESCALATING CARE AND LIMITING LONG-TERM SEQUALAE

In sepsis survivors who remain hospitalized, care should focus on limiting complications and optimizing long-term outcomes. Indwelling central venous and urinary catheters should be removed when no longer needed. Early mobilization, deep-venous thrombosis prevention, discontinuing unnecessary intravenous fluids, and judicious use of diuretics in patients with significant fluid overload are all important interventions. Many sepsis survivors experience long-term complications including physical, cognitive, and psychological sequelae. Physical sequelae include prolonged fatigue, muscle loss, weakness, and diminished functional capacity. Cognitive and psychological sequelae include cognitive decline, dementia, depression, and decreased quality of life. Sepsis survivors have increased risk of cardiovascular events, including myocardial infarction and stroke, recurrent infection, readmission, and death. Fifty percent of initial sepsis survivors are rehospitalized within 1 year, and one in six die within the first year. Most deaths following sepsis occur in the first 6 months, but the risk of death remains elevated for up to 2 years. Common causes of readmission include heart failure, myocardial infarction, pneumonia, chronic obstructive pulmonary disease, and urinary tract infections. Given the high prevalence of long-term sequelae and complications among sepsis survivors, the 2021 Surviving Sepsis Campaign Guidelines recommend that hospital discharge plans include screening for economic and social support and establishing follow-up with providers who can assess and support physical, cognitive, and psychological issues.

316 Cardiogenic Shock and Pulmonary Edema

David H. Ingbar, Holger Thiele

Cardiogenic shock and pulmonary edema are each life-threatening high-acuity conditions that require treatment as medical emergencies, usually in an intensive care unit (ICU) or cardiac intensive care unit (CICU). The most common joint etiology is severe left ventricular (LV) dysfunction from myocardial infarction (MI) that leads to pulmonary congestion and/or systemic hypoperfusion **(Fig. 316-1)**. The pathophysiologies of pulmonary edema and shock are discussed in **Chaps. 39 and 314**, respectively.

CARDIOGENIC SHOCK

Cardiogenic shock (CS) is a low cardiac output state resulting in life-threatening end-organ hypoperfusion and hypoxia. The clinical presentation is typically characterized by persistent hypotension (<90 mmHg systolic blood pressure [BP]) or <60–65 mmHg mean arterial pressure that is unresponsive to volume replacement and/or requires use of vasopressors to maintain adequate BP) and is accompanied by clinical features of peripheral hypoperfusion, such as elevated arterial lactate (>2 mmol/L). Objective hemodynamic parameters such as cardiac index or pulmonary capillary wedge pressure can help confirm a cardiogenic cause of shock but are not mandatory. The in-hospital mortality rates range from 40 to 60%, depending on shock severity and the associated underlying cause. The Society for Cardiovascular Angiography and Interventions (SCAI) classification of CS

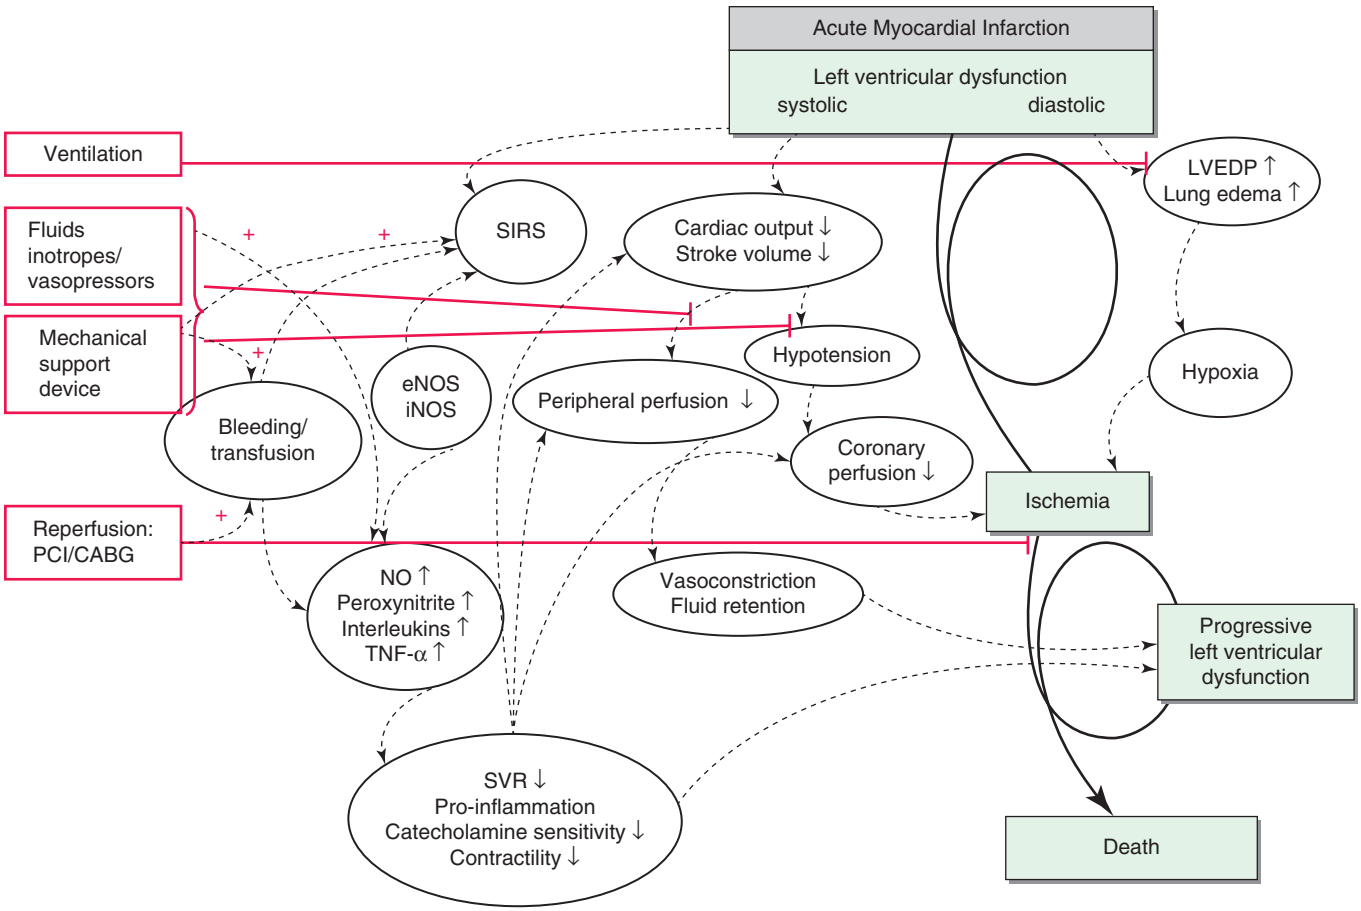

FIGURE 316-1 Pathophysiology of cardiogenic shock and potential treatment targets. The pathophysiologic concept of the expanded cardiogenic shock spiral and treatment targets. CABG, coronary artery bypass grafting; eNOS, endothelial nitric oxide synthase; iNOS, inducible nitric oxide synthase; LVEDP, left ventricular end-diastolic pressure; NO, nitric oxide; PCI, percutaneous coronary intervention; SIRS, systemic inflammatory response syndrome; SVR, systemic vascular resistance; TNF, tumor necrosis factor. *(Reproduced with permission from H Thiele et al: Shock in acute myocardial infarction: The Cape Horn for trials? Eur Heat J 31:1828, 2010.)*

that was introduced in 2019 includes five categories: (A) at risk, (B) beginning or preshock, (C) classical, (D) deteriorating, and (E) extremis CS **(Fig. 316-2)**. Preshock is defined as clinical evidence of relative hypotension or tachycardia without hypoperfusion. These patients should be monitored closely and treated early to avoid development of classical CS. Extremis CS includes cases in which considerations about futility of treatment should be done and possibly palliative care initiated. The SCAI definition recently was updated based on several validation studies; it still includes the stages A–E but also includes a three-axis model based on (1) shock severity, (2) phenotype and etiology, and (3) risk modifiers such as cardiac arrest.

Although declining in incidence, acute MI with LV dysfunction remains the most frequent cause of CS, with other causes listed in **Table 316-1**. Circulatory failure based on cardiac dysfunction may be caused by primary myocardial failure, most commonly secondary to acute MI **(Chap. 286)**, and less frequently by acute or chronic heart failure as a cause of cardiomyopathy or myocarditis **(Chaps. 266–270)**, cardiac tamponade **(Chap. 281)**, arrhythmias **(Chap. 261)**, or critical valvular heart disease **(Chap. 262)**.

Incidence The incidence of CS complicating acute MI has decreased to 5–10%, largely due to increasing use of early mechanical reperfusion therapy for acute MI. Shock is more common with ST-segment elevation MI (STEMI) than with non-STEMI **(Chap. 286)**.

LV failure accounts for ~80% of cases of CS complicating acute MI. Acute severe mitral regurgitation (MR), ventricular septal rupture (VSR), predominant right ventricular (RV) failure, and free wall rupture or tamponade account for the remainder. A recently recognized uncommon cause of transient CS is the Takotsubo syndrome.

Pathophysiology The understanding of the complex pathophysiology of CS has evolved over the past decades. In general, a profound depression of myocardial contractility results in a deleterious spiral of reduced cardiac output, low BP, and ongoing myocardial ischemia, followed by further contractility reduction (Fig. 316-1). This vicious cycle usually leads to death if not interrupted. CS can result in both acute and subacute derangements to the entire circulatory system. Hypoperfusion of vital organs and extremities remains a clinical hallmark. Although ineffective stroke volume is the inciting event, inadequate circulatory compensation also may contribute to shock. Initial peripheral vasoconstriction may improve coronary and peripheral perfusion at the cost of increased afterload, potentially worsening ischemia. However, over the course of CS, the systemic inflammation response triggered by acute cardiac injury often induces pathologic vasodilatation. Inflammatory cytokines and inducible (as well as endothelial) nitric oxide (NO) synthase may augment production of NO and its by-product, peroxynitrite, which has a negative inotropic effect and is cardiotoxic. Lactic acidosis and hypoxemia contribute to the vicious circle, as severe acidosis reduces the efficacy of endogenous and exogenous catecholamines. During ICU or CICU support, bleeding and/or transfusions may trigger inflammation and are usually associated with higher mortality (Fig. 316-1).

Patient Profile In patients with MI, older age, prior MI, diabetes mellitus, anterior MI location, and multivessel coronary artery disease with extensive coronary artery stenoses are associated with an increased risk of CS. Shock associated with a first inferior MI should prompt a search for a mechanical cause or RV involvement. CS may rarely occur in the absence of significant coronary stenosis, as seen in Takotsubo syndrome or fulminant myocarditis.

Timing Shock is present on admission in approximately one-quarter of MI patients who develop CS; of the remaining patients, one-quarter develop it rapidly thereafter, within 6 h of MI onset, and

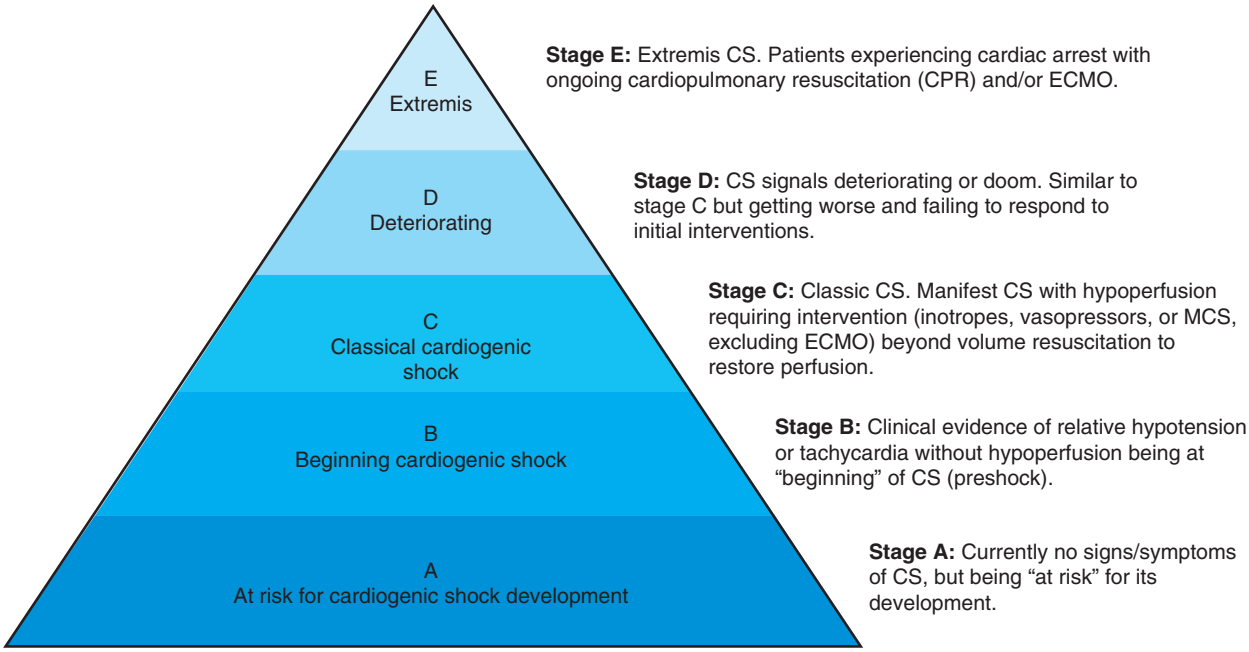

FIGURE 316-2 Shock severity definition. Five categories of cardiogenic shock (CS). **Stage A:** At risk: Patients "at risk" for cardiogenic shock development but not currently experiencing signs/symptoms of cardiogenic shock. **Stage B:** Patients with clinical evidence of relative hypotension or tachycardia without hypoperfusion being at "beginning" of cardiogenic shock. **Stage C:** Patients in the state of "classic" cardiogenic shock. **Stage D:** Cardiogenic shock signals deteriorating or "doom." **Stage E:** Patients in "extremis," such as those experiencing cardiac arrest with ongoing cardiopulmonary resuscitation and/or extracorporeal membrane oxygenation (ECMO) cardiopulmonary resuscitation. MCS, mechanical circulatory support. *(Reproduced with permission from H Thiele et al: Management of cardiogenic shock complicating myocardial infarction: An update 2019. Eur Heart J 40:2671, 2019.)*

another quarter develop shock later on the first day. Later onset of CS may be due to reinfarction, marked infarct expansion, or mechanical complications.

Diagnosis For these unstable patients, supportive therapy must be initiated simultaneously with diagnostic evaluation **(Fig. 316-3)**. A focused history and physical examination should be performed along with an electrocardiogram (ECG), chest x-ray, arterial blood gas (ABG) analysis, lactate measurement, and blood specimens for laboratory analysis. Initial echocardiography is an invaluable tool to elucidate the underlying cause of CS and also assess if it is predominantly left, right, or biventricular in origin.

CLINICAL FINDINGS Most patients initially are dyspneic, pale, apprehensive, and diaphoretic, and mental status may be altered. The pulse is typically weak and rapid, or occasionally, severe bradycardia due to high-grade heart block may be present. Systolic BP is typically reduced (<90 mmHg, or catecholamines are required to maintain BP >90 mmHg), but occasionally, BP may be maintained by very high systemic vascular resistance. Tachypnea and jugular venous distention may be present. Typically, there is a weak apical pulse and a soft S_1, and an S_3 gallop may be audible. Acute, severe MR and VSR usually are associated with characteristic systolic murmurs **(Chap. 286)**. Crackles are audible in most patients with LV failure. Oliguria/anuria is common. CS patients often require early mechanical ventilation (~80%) for management of acute hypoxemia, increased work of breathing, and hemodynamic instability; vasopressors often are required to maintain adequate BP.

LABORATORY FINDINGS The white blood cell count and C-reactive protein typically are elevated. Renal function often is progressively impaired. Newer renal function markers such as cystatin C or neutrophil gelatinase–associated lipocalin (NGAL) do not add prognostic information over creatinine. Hepatic transaminases are elevated due to liver hypoperfusion in ~20% of patients, which is a marker of high mortality. By definition, in SCAI shock criteria, the arterial lactate level is elevated to >2 mmol/L; if higher, prognosis is worse, and those with lactate >8 mmol/L are in SCAI stage E. ABGs usually demonstrate hypoxemia and an anion gap metabolic acidosis. Glucose levels at admission are often elevated, a strong independent predictor for mortality. Cardiac markers, creatine kinase and its MB fraction, and troponins I and T are typically markedly elevated in acute MI.

ELECTROCARDIOGRAM In acute MI with CS, Q waves and/or ST elevation in multiple leads or left bundle branch block are usually present. Approximately one-half of MIs with CS are anterior infarctions. Global ischemia due to severe left main stenosis usually is accompanied by ST-segment elevation in lead aVR and ST depressions in multiple leads.

CHEST ROENTGENOGRAM The chest x-ray typically shows pulmonary vascular congestion and often pulmonary edema but may be normal in up to a third of patients. The heart size is usually normal when CS results from a first MI but may be enlarged when it occurs in a patient with a previous MI.

ECHOCARDIOGRAM An echocardiogram **(Chap. 248)** should be obtained promptly in patients with suspected/confirmed CS to help define its etiology. Echocardiography is able to delineate the extent of infarction/myocardium in jeopardy and the presence of mechanical complications such as VSR, MR, or cardiac tamponade. Furthermore, RV impairment, valvular obstruction or insufficiency, dynamic LV outflow tract obstruction, and proximal aortic dissection with aortic regurgitation or tamponade may be seen, or indirect evidence for pulmonary embolism may be obtained **(Chap. 290)** **(Table 316-2)**.

PULMONARY ARTERY CATHETERIZATION The use of pulmonary artery catheter (PAC) hemodynamic monitoring had declined until recently because clinical trials have shown no mortality benefit. The recent increase in PAC use arose because hemodynamic data and waveforms can be helpful in both diagnosis and management. Recent observational data suggest better outcome with PAC use applied in this way. PAC hemodynamic data can confirm the presence and severity of CS, involvement of the right ventricle, left-to-right shunting, pulmonary artery pressures and transpulmonary gradient, and pulmonary and systemic vascular resistance. It can help in recognition of acute MR, decreased left atrial filling pressure, right or left dominance, and secondary septic causes and also can exclude left-to-right shunts. Equalization of diastolic pressures suggests cardiac tamponade, but echocardiogram is more definitive. The detailed hemodynamic profile can be used to individualize and monitor therapy and to provide prognostic information, such as cardiac index and cardiac power. The use of a PAC is currently recommended by the American Heart Association for potential utilization in cases of diagnostic or CS management uncertainty or in patients with severe CS who are unresponsive

TABLE 316-1 Etiologies of Cardiogenic Shock[a] and Cardiogenic Pulmonary Edema

Etiologies of Cardiogenic Shock or Pulmonary Edema
Acute myocardial infarction/ischemia
Left ventricular failure
Ventricular septal rupture
Papillary muscle/chordal rupture–severe mitral regurgitation
Ventricular free wall rupture
Other conditions complicating large myocardial infarctions
Excess negative inotropic or vasodilator medications
Post–cardiac arrest
Postcardiotomy
Refractory sustained supraventricular or ventricular tachyarrhythmias
Refractory sustained bradyarrhythmias
Acute fulminant myocarditis
End-stage cardiomyopathy
Takotsubo syndrome/apical ballooning syndrome
Hypertrophic cardiomyopathy with severe outflow obstruction
Aortic dissection with aortic insufficiency or tamponade
Severe valvular heart disease
Critical aortic or mitral stenosis
Acute severe aortic regurgitation or mitral regurgitation
Toxic/metabolic
β Blocker or calcium channel antagonist overdose
Pheochromocytoma
Scorpion venom
Hypertensive crisis
Post–cardiac arrest stunning
Myocardial depression in setting of septic shock or systemic inflammatory response syndrome
Myocardial contusion
Other Etiologies of Cardiogenic Shock[b]
Right ventricular failure due to:
Acute myocardial infarction
Acute or decompensated chronic cor pulmonale
Pericardial tamponade
Toxic/metabolic
Severe acidosis, severe hypoxemia

[a]The etiologies of cardiogenic shock are listed. Most of these can cause pulmonary edema instead of shock or pulmonary edema with cardiogenic shock. [b]These cause cardiogenic shock but not pulmonary edema.

to initial therapy. PAC use also can help differentiate noncardiogenic pulmonary edema.

ADVANCED HEMODYNAMIC MONITORING Recently, new central venous catheter systems linked to computer-based algorithms provide continuous monitoring of a variety of derived hemodynamic parameters, including cardiac output, stroke volume, stroke volume variation, and systemic vascular resistance **(Table 316-3)**. When combined with a femoral arterial catheter, calculated extravascular lung water and pulmonary permeability index can be monitored. The information allows for more rational therapy and assessment but has not yet shown improved clinical outcomes in patients with shock or pulmonary edema.

CARDIAC CATHETERIZATION AND CORONARY ANGIOGRAPHY The definition of the coronary anatomy provides useful information and is immediately indicated in all patients with CS complicating MI for further reperfusion treatment. Furthermore, cardiac catheterization should also be considered for resuscitated cardiac arrest survivors without ST-segment elevation in CS because ~70% of these patients have relevant coronary artery disease. However, routine early invasive coronary angiography did not show a survival benefit in hemodynamically stable patients after resuscitation from cardiac arrest without ST-segment elevation in two recent large, randomized trials. Consequently, guidelines were revised to avoid routine immediate cardiac catheterization in these patients.

TREATMENT

Acute Myocardial Infarction

GENERAL MEASURES

In addition to the usual treatment of acute MI **(Chap. 286)**, initial therapy is aimed at maintaining adequate systemic and coronary perfusion by raising the BP with vasopressors and adjusting volume status to a level that ensures optimum LV filling pressure (Fig. 316-3). There is some interpatient variability, but generally, adequate perfusion occurs with a mean arterial BP of 60–65 mmHg or a systolic BP of ~90 mmHg. Hypoxemia and acidosis need to be corrected, particularly since acidemia attenuates vasoconstriction by catecholamines. Up to 90% of patients require ventilatory support, decreasing the stress from increased work of breathing (see "Pulmonary Edema," below) (Fig. 316-3). Moderate glucose control (≤180 mg/dL or 10.0 mmol/L) should be a goal, and hypoglycemia must be avoided. Negative ionotropic agents should be discontinued. Bradyarrhythmias may require transvenous pacing. Recurrent ventricular tachycardia or rapid atrial fibrillation may require immediate treatment **(Chap. 253)**.

REPERFUSION-REVASCULARIZATION

Rapid revascularization of the infarct-related artery is the only evidence-based treatment strategy for mortality reduction in CS and forms the mainstay therapeutic intervention for CS due to MI (Fig. 316-2). In the SHOCK trial, 132 lives were saved per 1000 patients treated with early revascularization with percutaneous coronary intervention (PCI) or coronary artery bypass graft (CABG) compared with initial medical therapy. Outcome benefit correlates strongly with the time between symptom onset, first medical contact, and reperfusion. In general, PCI with drug-eluting stents of the infarct-related artery is the preferred reperfusion strategy. Approximately 80% of CS patients present with multivessel coronary artery disease. In these patients, culprit-only PCI with possible staged revascularization is the method of choice because it reduces mortality and requirement for renal replacement therapy at 30 days and 1 year in comparison to immediate multivessel PCI, as shown in the CULPRIT-SHOCK trial. The major driver for the reduction in the composite endpoint was a reduction in 30-day mortality. Updated recent clinical practice guidelines recommend avoiding immediate nonculprit PCI. Currently, vascular access for diagnostic angiography and PCI via the radial artery are preferred when feasible over femoral arterial access due to the greater safety of radial artery access. CABG is currently performed in only 5% of cases, mainly if coronary anatomy is not amenable to PCI.

VASOPRESSORS AND INOTROPES

Inotropic agents are theoretically appealing in CS treatment. However, current evidence is scarce. Vasoactive medications often are used in the management of patients with CS, and all have important disadvantages, including increases in myocardial oxygen consumption, afterload, lethal arrhythmias, and possible myocardial cell death. As a consequence, catecholamines should be used in the lowest possible doses for the shortest possible time. Despite their frequent use, little clinical outcome data prove their benefit or are available to guide the initial selection of vasoactive therapies in patients with CS. No vasopressor has been demonstrated to change outcome in large clinical trials. Norepinephrine is reasonable as the first-line vasopressor based on randomized trials compared to dopamine and also epinephrine. Norepinephrine was associated with fewer adverse events, including arrhythmias, compared to dopamine in a randomized trial of patients with several etiologies of circulatory shock and with improved survival in a prespecified subgroup of CS patients. Norepinephrine dosing is usually begun at

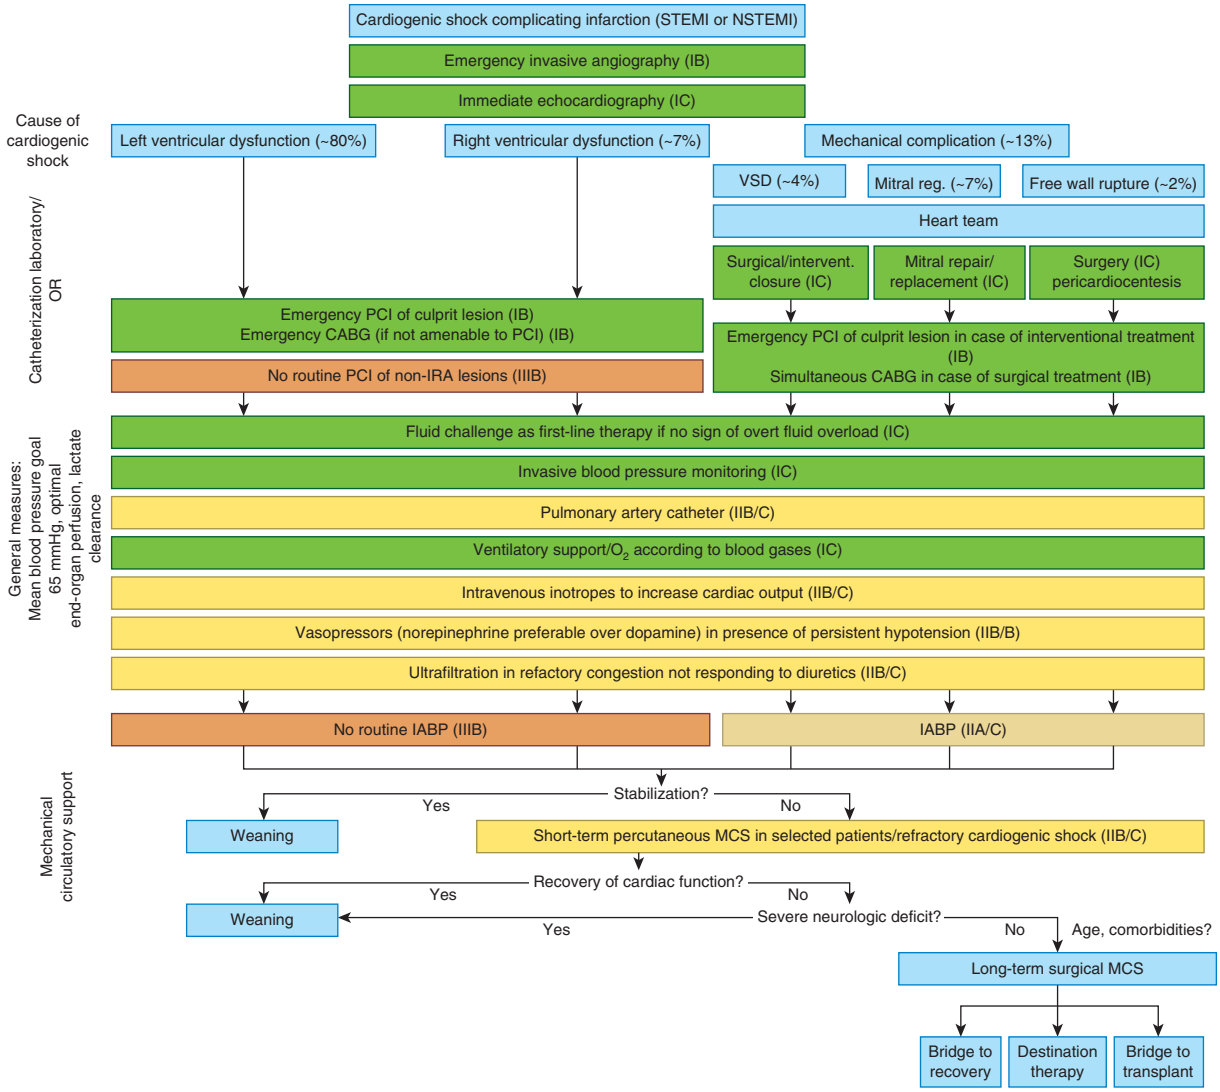

FIGURE 316-3 Emergency management of patients with cardiogenic shock (CS) complicating acute myocardial infarction (AMI). Treatment algorithm for patients with CS. The class of recommendation and level of evidence according to European Society of Cardiology guidelines are provided (see "Further Reading"). CABG, coronary artery bypass grafting; ECG, electrocardiogram; IABP, intraaortic balloon pump; IRA, infarct-related artery; MCS, mechanical circulatory support; NSTEMI, non–ST-segment elevation myocardial infarction; PCI, percutaneous coronary intervention; STEMI, ST-segment elevation myocardial infarction; VSD, ventricular septal defect. *(Reproduced with permission from H Thiele et al: Management of cardiogenic shock complicating myocardial infarction: An update 2019. Eur Heart J 40:2671, 2019.)*

2–4 μg/min and titrated upward based on BP. Norepinephrine was associated with lower lactate levels and less refractory CS compared to epinephrine. Dopamine's hemodynamic effects vary depending on dose, and there is interpatient variability in responses. Low doses stimulate renal dopaminergic receptors, and with increasing doses, there is stimulation of first β-adrenergic receptors and then α-adrenergic receptors. Dopamine should be avoided as first-line therapy for MI with CS based on hemodynamic and proarrhythmogenic effects.

Dobutamine is a synthetic sympathomimetic amine with positive inotropic action and minimal positive chronotropic activity at low doses (2.5 μg/kg per min) but moderate chronotropic activity at higher doses. Its vasodilating activity often precludes its use when a vasoconstrictor effect is required. Levosimendan may also be appealing despite a lack of randomized data but was not beneficial for organ dysfunction in sepsis and also in high-risk patients undergoing cardiovascular surgery. Milrinone—a phosphodiesterase-3 inhibitor and inodilator—was recently shown to have no benefit in comparison with dobutamine.

MECHANICAL CIRCULATORY SUPPORT

The most commonly used mechanical circulatory support (MCS) device has been the intraaortic balloon pump (IABP), which is inserted into the aorta via the femoral artery and provides passive hemodynamic support. However, routine IABP use in conjunction with early revascularization (predominantly with PCI) did not reduce 30-day, 12-month, or 6-year mortality in the IABP-SHOCK II trial. IABP also had no benefit on secondary endpoints (arterial lactate, catecholamine doses, renal function, or intensive care severity of illness unit scores). IABP is no longer recommended for CS with LV failure.

Active MCS devices to support the left, right, or both ventricles can be placed percutaneously or surgically. Temporary percutaneous MCS can be used as bridge to recovery, to surgically implanted durable devices, to heart transplantation, or as a temporizing measure when the neurologic status is uncertain. Percutaneous MCS, including the TandemHeart and Impella devices, and also venoarterial extracorporeal membrane oxygenation (VA-ECMO) have been used in patients not responding to standard treatment (catecholamines, fluids, and IABP) and also as a first-line treatment. Active percutaneous MCS results in better hemodynamic support compared to IABP. However, the appropriate role of MCS, in particular Impella, is uncertain because a positive impact on clinical outcomes or mortality has not yet been demonstrated in trials or meta-analyses. More recent observational data with matched comparisons comprising several ten thousands of patients even showed higher mortality and more complications with active devices such as Impella. Recently the results of the Danish-Germany (DanGer) shock trial

TABLE 316-2 Utility of the Echocardiogram in Cardiogenic Shock or Pulmonary Edema

CLINICAL QUESTION	INFORMATION

were published: in 360 selected patients with anterior ST-elevation myocardial infarction without high risk of hypoxic brain injury comparing a microaxial flow pump with 3.5 L/min versus standard of care, the active MCS was associated with better 180-day outcome. Despite the long recruitment period, the narrow inclusion criteria, and several open questions such as a high increase in mortality from 30 days to 6-months in the control arm, a very short ICU time in the control group, and the highest ever reported renal replacement therapy frequency in the active MCS arm, this randomized trial is an important study supporting the use of MCS in selected patients.

Recent randomized data of VA-ECMO versus control in CS did not show a survival benefit in the ECLS-SHOCK trial. VA-ECMO was accompanied by significantly higher complications, such as moderate/severe bleeding or peripheral ischemic complications. The lack of mortality benefit and higher complication rates with VA-ECMO use were confirmed in an individual patient data meta-analysis.

Surgically implanted devices can support the circulation as bridging therapy for cardiac transplant candidates or as destination therapy (Chap. 271). Assist devices should be used selectively in suitable patients based on decisions by a multidisciplinary team with expertise in the selection, implantation, and management of MCS devices (Fig. 316-3).

Prognosis The expected death rates for patients with MI complicated by CS range widely based on age, severity of hemodynamic abnormalities, severity of clinical hypoperfusion (arterial lactate, renal function), and performance of early revascularization. The recently introduced IABP-SHOCK II score predicts prognosis based on six readily available variables: age >73 years; prior stroke; glucose at admission >10.6 mmol/L (191 mg/dL); creatinine at admission >132.6 μmol/L (1.5 mg/dL); Thrombolysis in Myocardial Infarction (TIMI) flow grade after PCI <3; and arterial blood lactate at admission >5 mmol/L. It also may help guide treatment strategies. The SCAI CS severity definition with stages A to E is also helpful in prognosis estimation.

SHOCK SECONDARY TO RIGHT VENTRICULAR INFARCTION

Persistent CS due to predominant RV failure accounts for only 5% of CS complicating MI. It often results from proximal right coronary artery occlusion. The salient features are relatively high right atrial pressures, RV dilation and dysfunction, and only mildly or moderately depressed LV function. High right-sided pressures may be absent

[a]There is significant patient-to-patient variation. Pressure may be normalized if cardiac output is low. [b]Forrester et al classified non-reperfused MI patients into four hemodynamic subsets. (From JS Forrester et al: N Engl J Med 295:1356, 1976.) PCW pressure and CI in clinically stable subset 1 patients are shown. Values in parentheses represent range. [c]"Isolated" or predominant RV failure. [d]PCW and pulmonary artery pressures may rise in RV failure after volume loading due to RV dilation and right-to-left shift of the interventricular septum, resulting in impaired LV filling. When biventricular failure is present, the patterns are similar to those shown for LV failure.

Abbreviations: CI, cardiac index; LV, left ventricular; MI, myocardial infarction; P/SBF, pulmonary/systemic blood flow; PAS/D, pulmonary artery systolic/diastolic; PCW, pulmonary capillary wedge; RA, right atrium; RV, right ventricular; RVS/D, right ventricular systolic/diastolic; SVR, systemic vascular resistance.

Source: Table prepared with the assistance of Krishnan Ramanathan, MD.

without volume loading. However, CS often has overlap combinations of both RV and LV ischemia, given a shared septum and the effect of ventricular interdependence on RV function. Management of isolated RV CS includes fluid administration to optimize right atrial pressure (10–15 mmHg); avoidance of excess fluids, which shifts the interventricular septum into the LV; catecholamines; early reestablishment of infarct-artery flow; and possibly right-sided MCS.

MITRAL REGURGITATION

(See also Chap. 286) Acute severe MR due to papillary muscle dysfunction and/or rupture may complicate MI and result in CS and/or pulmonary edema. This complication most often occurs on the first day, with a second peak several days later. The diagnosis is confirmed by echocardiography (Table 316-2). Afterload reduction with IABP and, if tolerated, vasodilators to reduce pulmonary edema is recommended as a bridge to surgery or interventional treatment. Mitral valve repair or reconstruction is the definitive therapy and should be performed early in the course in suitable candidates. Other options include percutaneous edge-to-edge repair, which has been successful in case series and registries (Fig. 316-3).

VENTRICULAR SEPTAL RUPTURE

(See also Chap. 286) VSR complicating MI is a relatively rare event associated with very high mortality if CS is present (>80%). The incidence of infarct-related VSR without reperfusion was 1–2% but has decreased to 0.2% in the era of reperfusion. VSR occurs a median of 24 h after infarction but may occur up to 2 weeks later. Echocardiography demonstrates shunting of blood from the left to the right ventricle and may visualize the opening in the interventricular septum. Current American guidelines recommend immediate surgical VSR closure, irrespective of the patient's hemodynamic status, to avoid further hemodynamic deterioration. European guidelines differ with a more selective approach based on heart team evaluation. IABP support as a bridge to surgery is recommended based on expert opinion. Active MCS may, however, be more appropriate for stabilization of the patient. Given high mortality, suboptimal surgical results, and the ineligibility for surgery of many patients, interventional percutaneous VSR umbrella device closure has been developed. Results of interventional VSR closure suggest a similar outcome as surgery. The heart team should decide how to close the VSR (Fig. 316-3).

FREE WALL RUPTURE

Myocardial rupture is a dramatic complication of MI that is most likely to occur during the first week after the onset of symptoms. The clinical presentation typically is a sudden loss of pulse, BP, and consciousness with ongoing sinus rhythm on ECG (pulseless electrical activity) due to cardiac tamponade **(Chap. 281)**. Free wall rupture may also result in CS due to subacute tamponade when the pericardium temporarily seals the rupture sites. Definitive surgical repair is required (Fig. 316-3).

ACUTE FULMINANT MYOCARDITIS

(See also Chaps. 266–270) Myocarditis can mimic acute MI with ST abnormalities or bundle branch block on the ECG and marked elevation of cardiac markers. Acute myocarditis causes CS in a small proportion of cases. These patients are typically younger than those with CS due to acute MI and often do not have typical ischemic chest pain. Echocardiography usually shows global LV dysfunction. Initial management is the same as for CS complicating acute MI but does not involve revascularization. Endomyocardial biopsy is recommended to determine the diagnosis and need for immunosuppressives for entities such as giant cell myocarditis. Refractory CS can be managed with MCS.

PULMONARY EDEMA

The etiologies and pathophysiology of pulmonary edema are discussed in Chap. 39.

Diagnosis Acute pulmonary edema usually presents with the rapid onset of dyspnea at rest, tachypnea, tachycardia, and severe hypoxemia. Crackles and wheezing due to alveolar flooding, increased airway fluid, and airway compression from peribronchial cuffing may be audible. Release of endogenous catecholamines often causes hypertension.

It is often difficult to distinguish between cardiogenic and noncardiogenic causes of acute pulmonary edema. *Echocardiography* may identify systolic and diastolic ventricular dysfunction and valvular lesions. ECG ST elevation and evolving Q waves are usually diagnostic of acute MI and should prompt immediate institution of MI protocols and coronary artery revascularization therapy **(Chap. 286)**. Brain natriuretic peptide levels, when substantially elevated, support heart failure as the etiology of acute dyspnea with pulmonary edema **(Chap. 264)**.

The use of a PAC permits measurement of pulmonary capillary wedge pressures (PCWP) and helps differentiate high-pressure (cardiogenic) from normal-pressure (noncardiogenic) causes of pulmonary edema. Pulmonary artery catheterization is indicated when the etiology of the pulmonary edema is uncertain, when edema is refractory to therapy, or when it is accompanied by refractory hypotension. Data derived from use of a PAC often alter the treatment plan, but no impact on mortality rates has been demonstrated.

TREATMENT

Pulmonary Edema

The treatment of pulmonary edema depends on the specific etiology. As an acute, life-threatening condition, a number of measures must be applied immediately to support the circulation, gas exchange, and lung mechanics. Simultaneously, conditions that frequently complicate pulmonary edema, such as infection, acidemia, anemia, and acute kidney dysfunction, must be corrected.

SUPPORT OF OXYGENATION AND VENTILATION

Patients with acute cardiogenic pulmonary edema generally have an identifiable cause of acute LV failure—such as arrhythmia, ischemia/infarction, or myocardial decompensation **(Chap. 264)**—that may be rapidly treated, with improvement in gas exchange. In contrast, noncardiogenic edema usually resolves much less quickly, and most patients require mechanical ventilation.

Oxygen Therapy Support of oxygenation is essential to ensure adequate O_2 delivery to peripheral tissues, including the heart. Generally, the goal is O_2 saturation of 92% or more, but very high saturation (>98%) may be detrimental. For non-CS acute hypoxemic respiratory failure patients with normal $Paco_2$, O_2 administration by high-flow nasal cannula for acute hypoxemic respiratory failure has better outcomes than use of bilevel positive airway pressure (BiPAP).

Positive-Pressure Ventilation Pulmonary edema increases the work of breathing and the O_2 requirements of this work, imposing a significant physiologic stress on the heart. When oxygenation or ventilation is not adequate despite supplemental O_2, positive-pressure ventilation by face or nasal mask or by endotracheal intubation should be initiated. Noninvasive ventilation (NIV) **(Chap. 313)** can rest the respiratory muscles, improve oxygenation and cardiac function, and reduce the need for intubation. While NIV is believed effective for cardiogenic pulmonary edema, Cochrane analyses have not yet substantiated this benefit. In refractory cases, mechanical ventilation can relieve the work of breathing more completely than can NIV. Helmet ventilation is a new technique for ventilation with positive pressure without intubation. Mechanical ventilation with positive end-expiratory pressure can have multiple beneficial effects on pulmonary edema, as it: (1) decreases both preload and afterload, thereby improving cardiac function; (2) redistributes lung water from the intraalveolar to the extraalveolar space, where the fluid interferes less with gas exchange; and (3) increases lung volume to avoid atelectasis.

Renal Replacement Therapy For pulmonary edema patients with refractory volume overload, metabolic acidosis (pH <7.15–7.25), hypoxemia, and/or persistent hyperkalemia, renal replacement therapy should be considered. For patients who are hypotensive or require ionotropic support, continuous renal replacement therapy usually is better tolerated than intermittent hemodialysis.

REDUCTION OF PRELOAD

In most forms of pulmonary edema, the quantity of extravascular lung water is determined by a combination of the PCWP, the pulmonary vascular permeability, and the intravascular volume status.

Diuretics The loop diuretics furosemide, bumetanide, and torsemide are effective in most forms of pulmonary edema, even in the presence of hypoalbuminemia, hyponatremia, or hypochloremia. Furosemide is also a venodilator that rapidly reduces preload before any diuresis occurs and is the diuretic of choice. The initial dose of furosemide should be ≤0.5 mg/kg, but a higher dose (1 mg/kg) is required in patients with renal insufficiency, chronic diuretic use, or hypervolemia or after failure of a lower dose. Combinations of diuretics and/or continuous infusion are helpful to achieve the desired degree of diuresis in selected patients.

Nitrates Nitroglycerin and isosorbide dinitrate act predominantly as venodilators but have coronary vasodilating properties as well. Their onset is rapid, and they are effectively administered by a variety of routes. Sublingual nitroglycerin (0.4 mg × 3 every 5 min) is first-line therapy for acute cardiogenic pulmonary edema. If pulmonary edema persists in the absence of hypotension, sublingual may be followed by IV nitroglycerin, commencing at 5–10 μg/min. IV nitroprusside (0.1–5 μg/kg per min) is a potent venous and arterial vasodilator. It is useful for patients with pulmonary edema and hypertension but is not recommended in states of reduced coronary artery perfusion. It requires close monitoring and titration using an arterial catheter for continuous BP measurement.

Morphine Given in 2- to 4-mg IV boluses, morphine is a transient venodilator that reduces preload while relieving dyspnea and anxiety. These effects can diminish stress, catecholamine levels, tachycardia, and ventricular afterload in patients with pulmonary edema and systemic hypertension. However, some registry trials showed increased mortality with use of morphine.

Angiotensin-Converting Enzyme (ACE) Inhibitors ACE inhibitors reduce both afterload and preload and are recommended for hypertensive patients. A low dose of a short-acting agent may be initiated and followed by increasing oral doses. In acute MI with heart failure, ACE inhibitors reduce short- and long-term mortality rates. The optimal starting point of ACE inhibitors has not been tested so far.

Other Preload-Reducing Agents IV recombinant brain natriuretic peptide (nesiritide) is a potent arterial and venous vasodilator with diuretic properties and is effective in the treatment of cardiogenic pulmonary edema. It should be reserved for refractory patients and is not recommended in the setting of ischemia or MI. Endothelin antagonists are being studied as they inhibit vasoconstriction and can improve cardiac output and decrease PCWP.

Physical Methods In nonhypotensive patients, venous return can be reduced by use of the sitting position with the legs dangling along the side of the bed.

Inotropic and Inodilator Drugs The sympathomimetic amines dopamine and dobutamine (see above) are potent inotropic agents. The bipyridine phosphodiesterase-3 inhibitors (inodilators), such as milrinone (50 μg/kg followed by 0.25–0.75 μg/kg per min), stimulate myocardial contractility while promoting peripheral and pulmonary vasodilation. Inodilators may be helpful in selected patients with cardiogenic pulmonary edema and severe LV dysfunction, but there is little published clinical data. Angiotensin II is a vasoconstrictor and possible positive inotrope that can raise BP in many types of shock. It is expensive and has not been shown to have additive or superior benefit to other vasopressors in CS.

Digitalis Glycosides Once a mainstay of treatment because of their positive inotropic action **(Chap. 264)**, digitalis glycosides are rarely used at present. However, they may be useful for control of ventricular rate in patients with rapid ventricular response to atrial fibrillation or flutter and LV dysfunction with pulmonary edema, because they do not have the negative inotropic effects of other drugs that inhibit atrioventricular nodal conduction.

Intraaortic Balloon Counterpulsation IABP **(Chap. 271)** may be helpful in rare instances of acute MR but is not typically used for pulmonary edema with CS.

***Treatment of Tachyarrhythmias and Atrioventricular Resynchronization* (See also Chap. 259)** Sinus tachycardia or atrial fibrillation can result from elevated left atrial pressure and sympathetic stimulation. Tachycardia itself can limit LV filling time and raise left atrial pressure further. Although relief of pulmonary congestion will slow the sinus rate or ventricular response in atrial fibrillation, a primary tachyarrhythmia may require cardioversion. In patients with reduced LV function and without atrial contraction or with lack of synchronized atrioventricular contraction, placement of an atrioventricular sequential pacemaker should be considered **(Chap. 251)**.

Reduction in Pulmonary Vascular Permeability At present, no clinical therapies have been demonstrated as clinically effective to reduce the "leakiness" of the pulmonary capillaries.

Stimulation of Alveolar Fluid Clearance A variety of drugs and cellular therapies can stimulate alveolar epithelial ion transport and upregulate the clearance of alveolar solute and water, but this strategy has not been proven beneficial in clinical trials thus far.

SPECIAL CONSIDERATIONS

Risk of Iatrogenic Cardiogenic Shock In the treatment of pulmonary edema, vasodilators lower BP, and their use, particularly in combination, may lead to hypotension, coronary artery hypoperfusion, and shock (Fig. 316-1). In general, patients with a *hypertensive* response to pulmonary edema tolerate and benefit from these medications. In normotensive patients, low doses of single agents should be instituted sequentially, as needed, and with close monitoring.

***Acute Coronary Syndromes* (See also Chap. 286)** Acute STEMI complicated by pulmonary edema is associated with in-hospital mortality rates of 20–40%. After immediate stabilization, coronary artery blood flow must be reestablished rapidly. Early primary PCI is the method of choice; alternatively, a fibrinolytic agent should be administered. Early coronary angiography and revascularization by PCI or CABG also are indicated for patients with non–ST-segment elevation acute coronary syndrome.

Takotsubo Syndrome Takotsubo syndrome is an acute reversible heart failure syndrome characterized by acute onset of left-sided heart failure with reversible ST-segment elevation and some increase in troponin levels, usually triggered by a major physical or emotional, stressful event. At end systole, there often is the appearance of LV apical "ballooning." Most patients recover and return to normal ventricular function. However, prognosis is similar or even worse in comparison to patients with acute MI.

Extracorporeal Membrane Oxygenation (ECMO) For patients with acute, severe, noncardiogenic edema with a potential rapidly reversible cause, ECMO may be considered in highly selected patients as a temporizing supportive measure to achieve adequate gas exchange, with current survival to discharge rates of 50–60%. Usually, venovenous ECMO is used in this setting. ECMO can function as a bridge to transplantation or other interventions.

Unusual Types of Edema Specific etiologies of pulmonary edema may require particular therapy. Reexpansion pulmonary edema can develop after removal of longstanding pleural space air or fluid. These patients may develop hypotension or oliguria with pulmonary edema resulting from rapid fluid shifts into the lung. Diuretics and preload reduction are contraindicated, and intravascular volume repletion often is needed while supporting oxygenation and gas exchange.

High-altitude pulmonary edema often can be prevented by use of dexamethasone, calcium channel–blocking drugs, or long-acting inhaled β_2-adrenergic agonists. Treatment includes descent from altitude, bed rest, oxygen, and, if feasible, inhaled NO; nifedipine may also be effective.

For pulmonary edema resulting from upper airway obstruction, recognition of the obstructing cause is key because treatment then is to relieve or bypass the obstruction.

317 Cardiovascular Collapse, Cardiac Arrest, and Sudden Cardiac Death

Christine M. Albert, William H. Sauer

OVERVIEW AND DEFINITIONS (SEE TABLE 317-1)

Cardiovascular collapse is severe hypotension from acute cardiac dysfunction or loss of peripheral vasculature resistance resulting in cerebral hypoperfusion and loss of consciousness. This condition can be the result of a cardiac arrhythmia, severe myocardial or valvular dysfunction, loss of vascular tone, and/or acute disruption of venous return. When effective circulation is restored spontaneously, patients present with syncope **(see Chap. 23)**. In the absence of spontaneous resolution, cardiac arrest occurs, ultimately resulting in death if resuscitation attempts are unsuccessful or not initiated. Underlying etiologies for cardiovascular collapse include benign conditions, such as neurocardiogenic syncope, but also life-threatening conditions including ventricular tachyarrhythmias, severe bradycardia, severely depressed myocardial contractility, as with massive acute myocardial infarction (MI) or pulmonary embolus, and other catastrophic events interfering with cardiac function such as myocardial rupture with cardiac tamponade or papillary muscle rupture with torrential mitral regurgitation.

Sudden cardiac arrest (SCA) refers to an *abrupt* loss of cardiac function resulting in complete cardiovascular collapse due either to an acute life-threatening cardiac arrhythmia or abrupt loss of myocardial pump function that requires emergency medical intervention for restoration of effective circulation. Most SCAs occur outside the hospital, and fewer than 10% of these victims survive to be discharged from the hospital despite undergoing attempted resuscitation by emergency medical services (EMS). For those who die prior to hospital admission, a cardiovascular cause for the arrest is often presumed based upon the absence of evidence for a traumatic or other noncardiac cause at the time of the arrest. If the patient does not survive a SCA, the death is classified as a sudden cardiac death (SCD). Deaths that occur during hospitalization or within 30 days after resuscitated cardiac arrest are usually counted as SCDs in epidemiologic studies.

SCD also includes a broader category of unexplained rapid deaths thought to be due to cardiac causes where resuscitation was not attempted. In epidemiologic studies, SCD is usually defined as an unexpected death without obvious extracardiac cause that occurs in association with a witnessed rapid collapse or within 1 hour of symptom onset. This definition is based on the presumption that rapid deaths are often due to an arrhythmia, an assumption that cannot always be validated. Approximately half of all SCDs are not witnessed. In the United States, few deaths undergo autopsies, and noncardiac conditions that evolve rapidly such as acute cerebral hemorrhage, aortic rupture, and pulmonary embolism cannot be excluded without an autopsy. Therefore, definitive information necessary to establish the cause of death is usually not available. In unwitnessed cases, the definition is often further expanded to include unexpected deaths where the subject was documented to be well when last observed within the preceding 24 hours. This expanded definition further decreases the certainty that the death was due to an arrhythmia or other cardiac causes, and recent data suggest that noncardiac causes may comprise a larger than expected percentage of these unwitnessed sudden deaths. Most countries, including the United States, do not have national surveillance systems or reporting requirements for SCD; thus, the true incidence and frequency of SCD and its different mechanisms can only be estimated.

EPIDEMIOLOGY

DEMOGRAPHICS

SCA and SCD are major public health problems that account for 15% of all deaths and comprise 50% of all cardiac deaths. In the United States alone, there are an estimated 350,000 EMS-attended out-of-hospital cardiac arrests and 210,000 SCDs in the adult population annually. The estimated societal burden of premature death due to SCD is 2 million years of potential life lost for men and 1.3 million years of potential life lost for women, which is greater than most other leading causes of death. Although cardiac pathology, particularly coronary heart disease (CHD), underlies the majority of SCDs, up to two-thirds of all SCDs occur as the first clinical expression of previously undiagnosed heart disease. SCD rates have declined but not as steeply as rates for CHD in general. Age, gender, race, and geographic region all influence the incidence of SCD. Rates of out-of-hospital cardiac arrest are lower in Asia (52.5 per 100,000 person-years) than Europe (86.4 per 100,000 person-years), North America (98.1 per 100,000 person-years), and Australia (111.9 per 100,000 person-years), and also vary within geographic regions of the United States. SCD is rare in individuals younger than 35 years of age (1–3 per 100,000 per year) and increases markedly with age as the incidence of coronary artery disease (CAD), heart failure (HF),

TABLE 317-1 Distinction Between Cardiovascular Collapse, Cardiac Arrest, and Death

TERM	DEFINITION	QUALIFIERS	MECHANISMS
Cardiovascular collapse	Sudden loss of effective circulation due to cardiac and/or peripheral vascular factors that may reverse spontaneously (e.g., neurocardiogenic syncope transient hypotension) or require interventions (e.g., hypovolemia, tamponade, ventricular fibrillation).	Broad term that includes cardiac arrest as well as transient events that characteristically revert spontaneously presenting as syncope.	Same as cardiac arrest, plus neurocardiogenic syncope or other causes of transient loss of blood flow.
Cardiac arrest	Abrupt cessation of cardiac function resulting in loss of effective circulation that may be reversible by prompt emergency medical intervention.	Rare spontaneous reversions; likelihood of successful intervention relates to mechanism of arrest, clinical setting, availability of emergency medical services, and prompt return of circulation.	Ventricular fibrillation, ventricular tachycardia, asystole, bradycardia, pulseless electrical activity, noncardiac mechanical factors (e.g., pulmonary embolism).
Sudden cardiac death	Sudden unexpected death attributed to cardiac arrest, which occurs within 1 hour of symptom onset.	In unwitnessed cases, the definition is often expanded to include unexpected deaths where the subject was documented to be well within the preceding 24 hours.	Same as cardiac arrest.

and other predisposing conditions also increases. Although absolute SCD rates increase with age, the proportion of deaths that are due to SCD decreases as other causes of death increase.

Women have a lower incidence of SCD and SCA than men, and women are more likely to present with pulseless electrical activity (PEA) and to have their SCD occur at home as compared with men. Possibly related to these factors, the SCD rate has not declined as much for younger women compared to men in recent years. Black as opposed to white Americans have higher rates of SCD, are more likely to have unwitnessed arrests and to be found with PEA, and have lower rates of survival. Socioeconomic disparities, with resuscitation being less likely in low-income neighborhoods, are contributing factors but do not appear to account for the entirety of the elevated SCD rate in blacks. Alternatively, individuals of Hispanic ethnicity appear to have lower rates of SCD, despite having a higher prevalence of cardiac risk factors. It appears that the incidence of SCD may be relatively low among Asian populations as well, both within the United States and globally. These gender and racial differences in SCD/SCA incidence and survival are poorly understood and warrant further research.

RISK FACTORS (SEE FIG. 317-1)

The presence of overt structural heart disease and/or certain types of inherited arrhythmia syndromes markedly elevates SCD risk (see Chaps. 261 and 262). Preexisting CHD and HF are the most prevalent predisposing cardiac conditions and are associated with a four- to tenfold increase in SCD risk. Correspondingly, SCD shares many of the same risk factors with CHD and heart failure (HF), including hypertension, diabetes, hypercholesterolemia, obesity, and smoking. Diabetes is a particularly strong risk factor for SCD even in patients with established CHD. Hypertension and resultant left ventricular hypertrophy (LVH) appear to be particularly important markers of SCD risk in blacks, in whom the prevalence of these conditions is greater. Smoking markedly elevates risk, and smoking cessation lowers risk particularly among individuals who have not yet developed overt CHD. Serum cholesterol appears to be more strongly related to SCD at younger ages, and the benefits of cholesterol lowering on SCD incidence have not been firmly established. There also appears to be a genetic component to SCD risk that is distinct from that associated with other manifestations of atherosclerosis. A history of SCD in a first-degree relative is associated with an increased risk for SCD, and with the occurrence of ventricular fibrillation (VF) during acute MI, but is not associated with an increased risk for acute MI. These data suggest that genetic factors may predispose to fatal ventricular arrhythmia in the setting of ischemia, rather than to CHD in general.

Obstructive sleep apnea and seizure disorders are also associated with increased SCD risk; the underlying mechanism is not clear but may be due to hypoxia-induced cardiac arrest. Atrial fibrillation also appears to be associated with an increased risk of SCD, which is partly, but not entirely, accounted for by its association with underlying heart disease. Patients with chronic kidney disease are also at higher SCD risk with annualized SCD rates approaching 5.5% in patients undergoing dialysis. Electrolyte shifts and LVH, which are common in this population, have been suggested to play a role. There are also potential dietary influences on SCD risk. Individuals with higher intakes of polyunsaturated fatty acids, particularly n-3 fatty acids, and other components of a Mediterranean-style diet have lower SCD risks in observational studies, possibly due to antiarrhythmic effects of dietary components. Low levels of alcohol intake may be beneficial, but heavy intake (>3 drinks/day) appears to elevate risk.

PRECIPITATING FACTORS

SCD/SCA occurs with higher frequency at certain times, locations, and in association with certain activities and exposures. Although not consistently observed across all studies, there do appear to be circadian variations in the incidence of SCD and cardiac arrest, with peaks in incidence in the morning hours and again in the later afternoon. There is also seasonal variability in SCD rates, which may be related to temperature and light exposure. Rates are highest during winter in the northern hemisphere and summer in the southern hemisphere. SCD rates also acutely peak during disasters such as earthquakes and terrorist attacks. SCA arrests are more likely to occur in certain locations as well, with notable clustering around train stations, airports, and other public places where there is significant population transit. SCD rates tend to be higher in urban areas, and individuals who live near major roadways are at elevated SCD risk. There is also a well-recognized acute elevation in SCD risk that occurs during or shortly after bouts of vigorous exertion, and men appear to be more susceptible. Habitual exercise and training lower this acute risk but do not eliminate it entirely. Exertion-associated SCDs are particularly tragic and highly publicized when they occur in highly trained athletes; however, the majority of such deaths actually occur in the general population. The common thread among these precipitating factors is likely heightened autonomic tone, which can promote ischemia and has direct proarrhythmia and electrophysiologic actions that lower the threshold for sustained VF.

CAUSES OF SUDDEN CARDIAC DEATH

UNDERLYING HEART DISEASE (FIG. 317-1)

Our understanding regarding the diseases that contribute to SCD is derived primarily from autopsy series and cardiac evaluations in cardiac arrest survivors, which are highly variable in level of detail. Despite the limitations of these data, it is generally accepted that sudden death due to cardiac causes is most commonly due to CAD, although the proportion with CAD varies markedly by age, race, and sex. It is estimated that ~70% of SCDs in white men are due to CAD, as compared with only 40–50% in women and blacks. The proportion of SCDs with underlying CAD may be even lower in Asian ethnicities. Recent data suggest that the proportion of SCDs with CAD on autopsy may be declining in some parts of Europe and the United States, and,

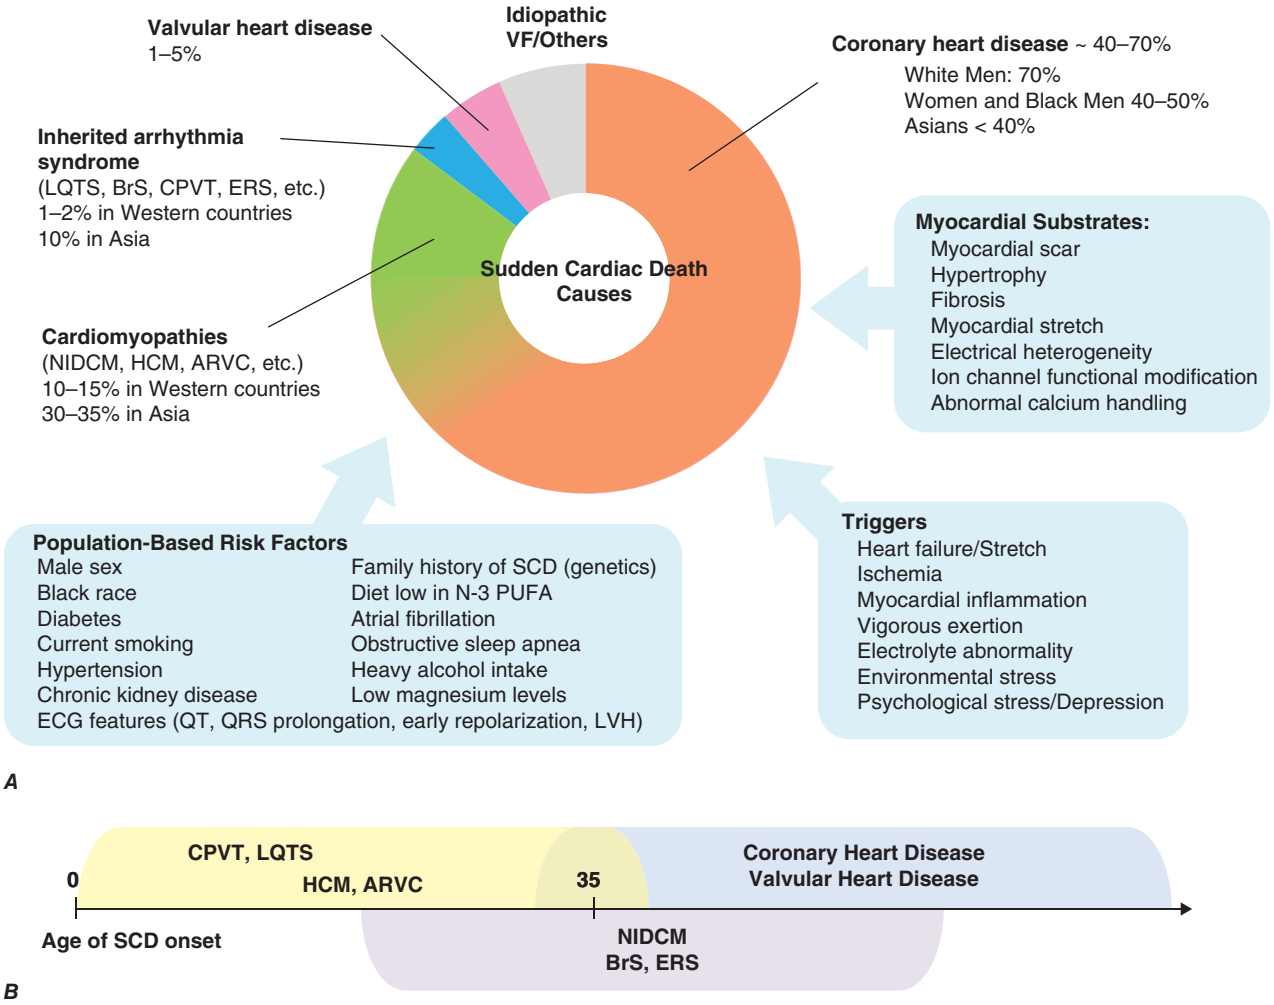

FIGURE 317-1 ***A.*** Proportionate causes, substrates, risk factors, and triggers of sudden cardiac death (SCD). ***B.*** Variation of causes by age of onset. ARVC, arrhythmogenic right ventricular cardiomyopathy; BrS, Brugada syndrome; CPVT, catecholaminergic ventricular tachycardia; ECG, electrocardiogram; ERS, early repolarization syndrome; HCM, hypertrophic cardiomyopathy; LQTS, long QT syndrome; LVH, left ventricular hypertrophy; NICDM, nonischemic cardiomyopathy; PUFA, polyunsaturated fatty acid; SCD, sudden cardiac death; VF, ventricular fibrillation. *(Reproduced with permission from M Hayashi et al: The spectrum of epidemiology underlying sudden cardiac death. Circ Res 116:1887, 2015.)*

at the same time, increasing in parts of Japan and other parts of Asia. Beyond CAD, nonischemic cardiomyopathies (hypertrophic, dilated, and infiltrative) are the second most frequent cause of SCD in the United States and European countries. Other less common causes include valvular heart disease, myocarditis, myocardial hypertrophy (often from hypertension), and rare primary electrical heart diseases such as long QT and Brugada syndromes. On average, 5–10% of SCA victims do not have a significant cardiac abnormality at the time of autopsy or after extensive premortem cardiac evaluation, and this also varies by gender and race. Before 35 years of age, atherosclerotic CAD accounts for a much smaller proportion of deaths, with hypertrophic cardiomyopathy (HCM), coronary artery anomalies, myocarditis, arrhythmogenic right ventricular cardiomyopathy, and primary ion channelopathies accounting for a significant number of these deaths.

CARDIAC RHYTHMS AND SUDDEN DEATH

The initial rhythm found when EMS arrive at the scene of an out-of-hospital cardiac arrest is an important indication of the potential cause of the arrest and of the prognosis. In the early days of EMS systems, over half of victims were found in VF, giving rise to the hypothesis that ischemic VF or ventricular tachycardia (VT) degenerating to VF was the most common event. The proportion of cardiac arrests found in VF has decreased markedly since the 1970s, to only 20–25% in more recent studies, and PEA and asystole are now the most common scenarios. However, the vast majority of cardiac arrests are not monitored at the time of collapse, and since arrhythmias are inherently unstable once hemodynamic collapse occurs, the rhythm at the time of EMS arrival may not reflect the rhythm that initially precipitated the SCA because VF and primary bradycardias can degenerate into asystole. Nonetheless, VF as an initial rhythm still predominates in public locations or in other situations when there is a short time frame between witnessed arrest and arrival of EMS, suggesting that VF remains a common initial precipitating rhythm. However, there are also data to support an absolute decrease in VF incidence. Proposed explanations include decreases in underlying CHD incidence, increased use of beta blockers in CHD, and implantable cardioverter defibrillators (ICD) in high-risk patients. There also appears to be an increase in PEA incidence over the past several years, suggesting that the proportion of SCD due to abrupt hemodynamic collapse in the absence of preceding fatal arrhythmia may be increasing. Proposed explanations for these proportional changes in PEA versus VF include the aging of the population and the increased prevalence of end-stage cardiovascular disease and other severe comorbidities. These older, sicker patients may be more likely to have arrests in the home and to have acute precipitants leading to PEA (i.e., respiratory, metabolic, vascular) and/or be less likely to sustain VF up to the point of EMS arrival.

DISEASE-SPECIFIC MECHANISMS

CAD can cause SCD through several mechanisms **(Table 317-2)**. The most common cause is acute MI or transient myocardial ischemia that leads to polymorphic VT and VF **(see Chap. 262)**. Other primary mechanisms include severe bradyarrhythmias such as heart block with a slow escape rhythm, or PEA due to a massive MI or associated myocardial rupture. Areas of ventricular scar from prior infarcts increase

TABLE 317-2 Causes of Cardiovascular Collapse and Sudden Cardiac Arrest

CAUSE	PATHOPHYSIOLOGIC SUBSTRATE	RHYTHM PRESENTATION
Cardiac Causes		
Coronary artery disease Atherosclerotic, coronary spasm, congenital anomalies	Acute myocardial ischemia/infarction, ventricular rupture, tamponade Ventricular scar from healed infarction	Polymorphic VT/VF Bradyarrhythmia Pulseless electrical activity VT VF
Cardiomyopathies Dilated, hypertrophic, ARVC, infiltrative disease, valvular disease with LV failure	Ventricular scar Ventricular hypertrophy Pump failure	VT Polymorphic VT/VF Pulseless electrical activity Bradyarrhythmia
Congenital heart disease (Tetralogy of Fallot, VSD, others)	Ventricular scar from surgical repair Hypertrophy	VT Bradyarrhythmias Polymorphic VT/VF
Aortic stenosis	Obstruction to aortic outflow Ventricular hypertrophy	Bradyarrhythmia Pulseless electrical activity Bradyarrhythmia Polymorphic VT/VF
Mitral valve prolapse/mitral regurgitation	Pump failure Ventricular scar	Polymorphic VT/VF
Arrhythmia syndromes without structural heart disease: Genetic: Long QT Brugada CPVT Idiopathic VF, early repolarization Drug toxicities (acquired long QT, others) Electrolyte abnormalities (severe hypokalemia)	Abnormal cellular electrophysiology	Polymorphic VT/VF
Wolff-Parkinson-White syndrome	Accessory atrioventricular connection	Pre-excited AF/VF
Commotio cordis	Blunt precordial impact	Polymorphic VT/VF
Noncardiac Causes of Cardiovascular Collapse		
Pulmonary embolism		PEA
Stroke		PEA, bradyarrhythmia
Aortic dissection		PEA, VF
Exsanguination/hypovolemia		PEA
Tension pneumothorax		PEA
Sepsis		PEA
Neurogenic		PEA, bradyarrhythmia
Drug overdose		PEA, bradyarrhythmia

Abbreviations: AF, atrial fibrillation; ARVC, arrhythmogenic right ventricular cardiomyopathy; CPVT, catecholaminergic polymorphic ventricular tachycardia; LV, left ventricle; PEA, pulseless electrical activity; VF, ventricular fibrillation; VSD, ventricular septal defect; VT, ventricular tachycardia.

the predisposition to reentrant VT, which often degenerates to VF. Once patients have suffered an MI, their risk of SCD elevates up to 10-fold, with the highest absolute rates in the first 30 days after MI. The mechanisms underlying SCD vary at different time points after MI, with nonarrhythmic causes such as myocardial rupture and/or extensive reinfarction predominating early, within the first 1–2 months, and ischemic polymorphic VT and/or scar-related ventricular arrhythmias prevailing later. VT and sudden death can, and often do, occur years after an initial MI.

Cardiomyopathies and Other Forms of Structural Heart Disease Scar-mediated reentrant VT can also occur in a host of nonischemic cardiomyopathies in which replacement fibrosis and/or inflammatory ventricular infiltrates occur (Chap. 261). In congenital heart disease, surgical scars created during corrective surgery, such as those performed to correct ventricular septal defects in tetralogy of Fallot, can also serve as the substrate for ventricular reentry. Other common predisposing processes such as LVH, ventricular stretch due to fluid overload, and cardiomyocyte dysfunction can result in electrical heterogeneity and other electrophysiologic changes that predispose to ventricular arrhythmias, including ion channel alterations that prolong action potential duration, impair cellular calcium handling, and diminish cellular coupling. These processes occur in a wide variety of diseases associated with depressed ventricular function and/or hypertrophy, including CAD, valvular heart disease, myocarditis, and nonischemic cardiomyopathies.

Absence of Structural Heart Disease In the absence of structural heart disease, VF can be due to an inherited ion channel abnormality, as in long QT and Brugada syndromes (Chap. 262), rapid atrial fibrillation associated with Wolff-Parkinson-White syndrome (Chap. 256), or drug toxicities, such as polymorphic VT due to drugs that prolong the QT interval (Chap. 263). Blunt, nonpenetrating precordial impact over the (left) chest wall can lead to commotio cordis and is a rare cause of SCD in otherwise healthy individuals. PEA can result from pulmonary emboli, exsanguination, or the terminal phase of respiratory arrest.

MANAGEMENT OF CARDIAC ARREST

As the ability to predict SCA in the population is very limited, community approaches to reduce death focus on the rapid identification of victims and implementation of resuscitation measures by those

who first encounter the victim, most likely the lay public, who ideally summon EMS and initiate basic life-support measures with chest compressions. The approach is codified in the "out-of-hospital chain of survival," which includes: (1) initial evaluation and recognition of the SCA and activation of the emergency response system; (2) rapid initiation of cardiopulmonary resuscitation (CPR) with an emphasis on chest compressions; (3) defibrillation as quickly as possible usually with an automatic external defibrillation applied by the lay rescuer or emergency medical technician (EMT); (4) advanced life support; (5) postcardiac arrest care; and (6) recovery from cardiac arrest. There have been major advances in each of these areas, and survival rates to hospital discharge for out-of-hospital cardiac arrest have increased, particularly for patients found in VT or VF, where survival rates can approach 30% in some regions. Overall survival rates for out-of-hospital cardiac arrest are also higher for patients receiving CPR, with recent studies in Europe reporting survival rates of 16%. Multiple studies have pointed to socioeconomic disparities in the administration of CPR and application of automatic external defibrillators (AEDs) contributing to reduced survival rates from out-of-hospital cardiac arrest in black and Hispanic populations in the United States.

The initial goal of resuscitation is to achieve the return of spontaneous circulation (ROSC). Success is strongly related to the time between collapse and initiation of resuscitation, decreasing markedly after 5 min, and the rhythm at the time of EMT arrival, being best for VT, worse for VF, and poor for PEA and asystole. Outcomes are also determined by the age, clinical state, and comorbidities of the victim prior to the arrest.

INITIAL EVALUATION AND INITIATION OF CPR

The rescuer should check for a response from the victim, shout for help, and call or ask someone else to call their local emergency number (e.g., 911), ideally on a cell phone that can be placed on speaker mode at the patient's side such that the responding dispatcher can provide instructions and queries to the rescuer. Consideration of aspiration or airway obstruction is important, and if suspected, a Heimlich maneuver may dislodge the obstructing body. A trained health care provider would also check for a pulse (taking no longer than 10 seconds so as not to delay initiation of chest compressions) and assess breathing. Gasping respirations and brief seizure activity are common during SCA and may be misinterpreted as breathing and responsiveness. Chest compressions should be initiated without delay and administered at a rate of 100–120/min depressing the sternum by 5 cm (2 in.) and allowing full chest recoil between compressions. Chest compressions generate forward cardiac output with sequential filling and emptying of the cardiac chambers, with competent valves maintaining forward direction of flow. Interruption of chest compressions should be minimized to reduce end-organ ischemia. Ventilation may be administered with two breaths for every 30 compressions if a trained rescuer is present, but for lay rescuers without training, chest compressions alone ("hands-only CPR") are more likely to be effectively applied and of similar benefit. If a second rescuer is present, they should be sent to seek out an AED, which are now widely available in many public areas.

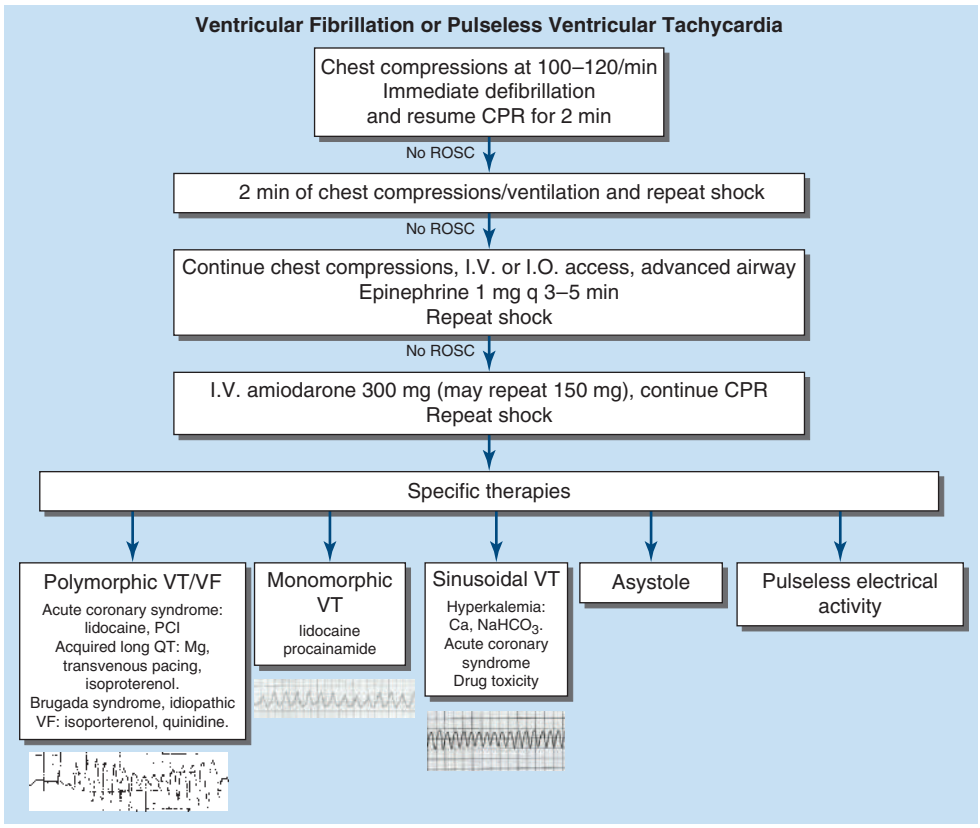
RHYTHM-BASED MANAGEMENT (SEE FIG. 317-2)

The rapidity with which defibrillation/cardioversion is achieved is an important predictor of outcome. A defibrillator, most often an AED, should be applied as soon as available. AEDs are easily used by lay rescuers and trained first responders, such as police officers and trained security guards. When the arrest is witnessed, the use of AEDs by lay responders can improve cardiac arrest survival rates. Once patches are applied to the chest, a brief pause in chest compressions is required to allow the AED to record the rhythm. An AED will advise delivery of a shock if the recorded rhythm meets criteria for VF or VT. Chest compressions are continued while the defibrillator is being charged. As soon as a diagnosis of VF or VT is established, a 200-J biphasic waveform shock should be delivered. Chest compressions are resumed immediately and continue for 2 min until the next rhythm check. If VT/VF is still present, a second maximal energy shock is delivered. This sequence is continued until personnel to administer advanced life support are available or ROSC is achieved. Electrocardiogram (ECG) rhythm strips produced by the AED should be retrieved, as the initial rhythm can be an important consideration in determining the cause of the arrest and to guide further therapy and evaluation if resuscitation is successful.

When advanced cardiac life support is available, an intravenous line is established for administration of medication and consideration given to placement of an advanced airway (endotracheal tube or supraglottic airway device). Intraosseous access may be considered if attempts at intravenous access are not successful or are not feasible. Epinephrine 1 mg every 3–5 min may be administered intravenously or intraosseously. If circulation is not restored or the patient is less than fully conscious despite return of circulation, confirmation that acidosis and hypoxia are adequately addressed should be assessed with arterial blood gas analysis. If metabolic acidosis persists after successful defibrillation and with adequate ventilation, 1 mEq/kg $NaHCO_3$ may be administered.

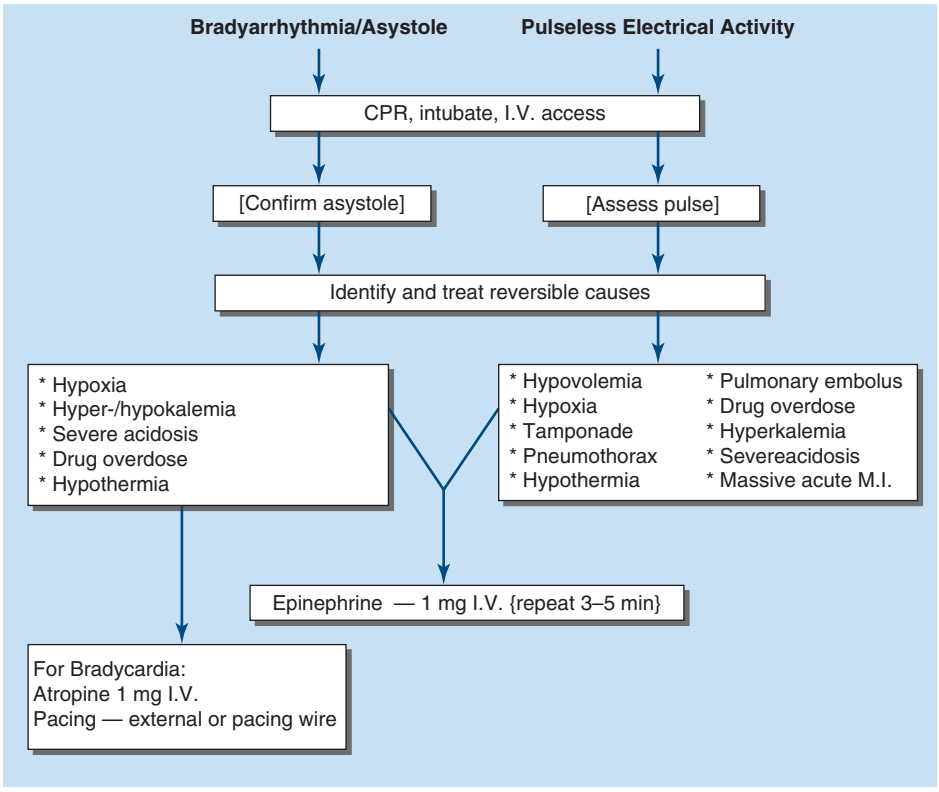
The cardiac rhythm guides resuscitation when monitoring is available. VT is treated with external shocks synchronized to the QRS when VT is monomorphic, and asynchronous shocks for polymorphic VT or VF. If VT/VF recurs after one or more shocks, amiodarone 300 mg can be administered as a bolus via intravenous or intraosseous route in the hope that arrhythmia recurrence will be prevented after the next shock, followed by a 150-mg bolus if the arrhythmia recurs. If amiodarone fails, lidocaine can be administered.

Consideration of etiology should also guide therapy (Chaps. 261 and 262). Commonly encountered causes of recurrent VT/VF may be due to ongoing myocardial ischemia or infarction that would benefit from emergent coronary angiography and revascularization, or QT prolongation causing the polymorphic VT torsades des pointes that may respond to administration of magnesium. Hyperkalemia should respond to administration of calcium, while other measures are implemented to reduce serum potassium.



PEA/asystole should be managed with CPR, ventilation, and administration of epinephrine. Causes of PEA/asystole that require specific therapy should be considered including airway obstruction, hypoxia, hypovolemia, acidosis, hyperkalemia, hypothermia, toxins, cardiac tamponade, tension pneumothorax, pulmonary embolism, and MI. Naloxone should be administered if opiate overdose is suspected.

POSTCARDIAC ARREST ACUTE MANAGEMENT



Following restoration of effective circulation, the possibility of acute MI should be immediately assessed. The majority of patients who have ST elevation consistent with acute MI will be found to have a culprit coronary stenosis/occlusion and emergent coronary angiography with percutaneous angioplasty, and stenting is recommended. Emergent angiography may also be considered if cardiogenic shock, electrical instability, signs of significant myocardial damage, or ongoing ischemia is present. Emergent or early angiography has not been found to result in better outcomes compared to delayed angiography in patients presenting with out-of-hospital cardiac arrest due to a VT/VF with no ECG evidence of ST-segment elevation. Thus, decisions regarding which patients without ST-segment elevation should undergo urgent angiography are complex, and factors such as hemodynamic or electrical instability and evidence of ongoing ischemia are taken into consideration.

Hemodynamic instability is often present following resuscitation, and further ischemic end-organ damage is a major consideration. Optimizing ventilation with consideration of acidosis, hypoxemia, and electrolyte abnormalities is important. Maintaining systolic blood pressure at >90 mmHg and mean blood pressure >65 mmHg is desirable and may require administration of vasopressors and adjustment of volume status. Potentially treatable reversible causes, including hyperkalemia, severe hypokalemia, and drug toxicity with QT prolongation causing torsades des pointes, should be identified and treated (Chap. 262).

After stable spontaneous circulation is achieved, brain injury due to ischemia and reperfusion is a major determinant of survival and accounts for over two-thirds of deaths. The probability of successful

FIGURE 317-2 Algorithm for approach to cardiac arrest due to ventricular tachycardia (VT) or ventricular fibrillation (VF; shockable rhythm). ***A.*** Chest compressions with ventilation and defibrillation or cardioversion should be initiated as soon as possible. Defibrillation should be repeated with minimal interruption of chest compressions. Once an intravenous or intraosseous access is established, administration of epinephrine defibrillation and amiodarone and defibrillation are performed. Further therapy can be guided by possible causes as suggested by the initial or recurrent cardiac rhythm as shown. CPR, cardiopulmonary resuscitation; I.O., intraosseous; I.V., intravenous; PCI, percutaneous coronary intervention; ROSC, return of spontaneous circulation. ***B.*** Algorithm for approach to cardiac arrest due to bradyarrhythmias/asystole and pulseless electrical activity. Chest compressions with ventilation (and intubation) should be initiated as soon as possible, and intravenous access should be obtained. Once an intravenous or intraosseous access is established, administration of epinephrine is performed. At the same time, an investigation for potential reversible causes should be made and any such causes should be treated if present. For bradycardic rhythms, atropine 1 mg administered intravenously and external subcutaneous or transvenous pacing are also performed. Defibrillation should be repeated with minimal interruption of chest compressions. Further therapy can be guided by possible causes. CPR, cardiopulmonary resuscitation; I.O., intraosseous; I.V., intravenous; M.I., myocardial infarction.

neurologic recovery decreases rapidly with time from collapse to ROSC and is <30% at 5 min in the absence of bystander CPR. The time between collapse and restoration of circulation is generally imprecise, and some patients have a period of hypotensive VT prior to complete collapse, such that a reported long period before the arrival of rescuers does not always preclude good neurologic recovery. Therapeutic hypothermia (targeted temperature management) has been shown to improve the likelihood of survival and neurologic recovery in patients who present with shockable (VT or VF) rhythms and is recommended for all cardiac arrest patients who remain comatose, regardless of presenting rhythm, who have lack of purposeful response to verbal commands following ROSC. A constant target temperature of 32–37.5°C for at least 24 h is recommended, although a recent trial failed to demonstrate benefit compared with a strategy of targeted normothermia with early and aggressive treatment of fever. Shivering suppression with analgesics and sedatives may be needed. Induction of hypothermia should be started in the hospital, as no benefit was shown for implementation before hospital arrival, and administration of large volumes of cold saline for this purpose increased the risk of pulmonary edema. Brain injury is often accompanied by seizures and status epilepticus that may have further deleterious effects, warranting periodic or continuous electroencephalography (EEG) monitoring. Treatment of clinically apparent seizures is indicated and may also be reasonable in those with EEG patterns on the ictal-interictal continuum on monitoring. Several other therapies hoped to improve postarrest outcomes have been assessed but have not been shown to be beneficial, including administration of corticosteroids, hemofiltration, and efforts to tightly control blood glucose.

Hypothermia and sedation preclude reliable prognostication for neurologic recovery. Functional neurologic assessment for neurologic recovery is generally deferred for at least 72 hours after return to normothermia, typically 4–5 days after the cardiac arrest. Features that predict poor outcome include the absence of pupillary reflex to light, status myoclonus, absence of EEG reactivity to external stimuli, and persistent burst suppression on EEG.

LONG-TERM MANAGEMENT AFTER SURVIVAL OF OUT-OF-HOSPITAL CARDIAC ARREST

For patients who survive cardiac arrest and have neurologic recovery, the likely underlying cause of the arrest guides further treatment. For arrests not due to an obvious noncardiac cause, a full evaluation for the forms of structural heart disease outlined in Fig. 317-1 and Table 317-2 should be performed including an assessment for underlying CAD and ischemia as well as echocardiography and/or cardiac magnetic resonance imaging (MRI) to look for evidence of prior MI, valvular disease, and nonischemic cardiomyopathies, and to provide an assessment of left ventricular ejection fraction (LVEF). If the initial evaluation is not definitive or is suggestive of an inflammatory cardiomyopathy (i.e., sarcoidosis, myocarditis), a cardiac positron emission tomography (PET) scan and/or endomyocardial biopsy may also be performed. Patients without obvious structural abnormalities should undergo an evaluation for primary electrical disease (long QT syndrome [LQTS], Brugada syndrome, early repolarization syndrome, or Wolff-Parkinson-White syndrome). In cases where a heritable syndrome is suspected, further genetic evaluation should be considered. Diagnostic electrophysiology studies are warranted in selected patients to assess inducible arrhythmias, or provocative testing, such as with epinephrine challenge for LQTS, or sodium channel blocker (e.g., procainamide) challenge for Brugada syndrome.

Patients with shockable rhythms at arrest (VF and VT) that are not deemed to have been due to a transient reversible cause and have reasonable life expectancy should undergo insertion of an ICD for secondary prevention of SCA/SCD. Most of these patients will be found to have CAD. Patients with a VF arrest that occurs within the first 48 h of a documented acute MI generally do not require an ICD because they have a similar risk of sudden death over the next 5 years as infarct survivors who did not have a cardiac arrest. However, patients who have a large infarction with acutely depressed LVEF (e.g., <35%) have an increased risk for future development of life-threatening ventricular arrhythmias related to reentry in the infarct scar **(Chap. 259)**. The percentage of patients with such large infarcts has been declining due to improved revascularization strategies for acute MI. Implantation of an ICD early after MI in these patients does not, however, improve overall survival, in part because a significant number of sudden deaths in the first 3 months are due to recurrent myocardial ischemia or myocardial rupture, rather than cardiac arrhythmias. For patients with large infarcts, a wearable defibrillator that will treat VT/VF if it occurs may be used while left ventricular remodeling is taking place, followed by reevaluation of arrhythmia risk after the infarct is healed to determine if an ICD is warranted. Patients who experience VF in the hospital >48 h after MI or in the setting of myocardial ischemia without infarction may be at risk for recurrent VT/VF. These patients should be evaluated and optimally treated for ischemia. If there is evidence that clearly implicates ischemia immediately preceding the onset of VF without evidence of a prior MI, coronary revascularization may be adequate therapy. Others may warrant ICD implantation. When the cardiac arrest is due to sustained monomorphic VT, a prior infarct scar is often present, and the recurrence rate is significant regardless of whether the arrest occurred in association with elevated serum troponin. In this circumstance, even when revascularization is performed for ischemia, an ICD is usually warranted owing to the risk of recurrence of scar-related VT.

Patients who have cardiac arrest due to a treatable reversible cause, such as hyperkalemia or drug toxicity with QT prolongation causing torsades des pointes **(Chap. 262)**, which can be adequately addressed and prevented by other means, do not usually need an ICD. An ICD is usually recommended for cardiac arrest due to VT or VF without a clearly reversible cause, particularly when structural heart disease, such as hypertrophic or dilated cardiomyopathy, arrhythmogenic cardiomyopathy, cardiac sarcoidosis, or a cardiac syndrome associated with sudden death, including Brugada syndrome, or LQTS is present **(Chaps. 261 and 262)**. In patients with structural heart disease, it is important to recognize that life-threatening arrhythmias can be an indication of terminal, end-stage heart disease with minimal prospect for meaningful survival despite successful resuscitation, and ICDs will not alter the course of these patients and should not be implanted in this situation unless there is a prospect for cardiac replacement therapy with future cardiac transplantation or a ventricular assist device.

Finally, the psychological needs of both the SCA survivor and family members need to be assessed and addressed. Comprehensive rehabilitation and treatment plans for physical, neurologic, cardiopulmonary, and cognitive impairments of the SCA survivor should be formulated before hospital discharge.

PREVENTION OF SCD

Although advances in CPR and postresuscitation care have improved survival rates after cardiac arrest, 90% of patients will not survive to be discharged from the hospital. Of those who do survive, a proportion (~20%) are left with severe neurologic and/or physical disability. The majority of cardiac arrests do not occur in public places where AEDs and rapid defibrillation have the greatest impact. Patients who suffer an arrest at home also have longer EMS response times and are much less likely to be found in VF. Finally, 50% of cardiac arrests are not witnessed, precluding effective resuscitation efforts. Thus, preventive efforts are critical to reducing mortality from cardiac arrest.

SCD RISK STRATIFICATION

The presence of overt structural heart disease and/or primary electrical heart disease is associated with an increased risk of SCD that varies with the severity and type of disease. For patients with structural heart disease, depressed left ventricular function is the best validated marker for risk, and clinical HF elevates risk further. After MI, SCD risk increases gradually as the LVEF decreases to 40% and then exponentially thereafter. In addition to LVEF and congestive heart failure, other potential markers of increased SCD risk in the setting of structural heart disease include unexplained syncope, sustained VT induced at electrophysiologic study (EP study), left ventricular scar size and heterogeneity on cardiac magnetic resonance, markers of altered

autonomic function and altered repolarization, and QRS prolongation. The majority of these tests, with the exception of the EP study in post-MI patients, broadly predict death from cardiovascular causes and are not able to discriminate between patients who will die suddenly from an arrhythmia and those who will die of other cardiac causes. For example, patients with the greatest degree of systolic HF and/or lowest LVEF, although at elevated risk for SCD, are more likely to die from pump failure. Although sustained VT at EP study does identify individuals at a higher risk of SCA versus non-SCA in certain subsets of patients, the sensitivity of the test is generally inadequate when LV function is significantly reduced.

PREVENTIVE THERAPIES FOR SCD IN HIGH-RISK POPULATIONS

Therapy with beta-adrenergic blockers has been demonstrated to reduce SCD risk in a multitude of settings, including after MI, among patients with ischemic and nonischemic cardiomyopathy, and in LQTS. Angiotensin-converting enzyme inhibitors, aldosterone antagonists, and more recently angiotensin receptor/neprilysin inhibitors and sodium-glucose cotransporter 2 inhibitors (SGLT2i) have been associated with reductions in SCD in subsets of patients with structural heart disease, primarily ischemic and nonischemic cardiomyopathy accompanied by HF. Coronary artery bypass grafting has also been associated with reductions in SCD risk, and revascularization may lower SCD risk through reduction in ischemic events and resultant improvements in left ventricular systolic function by reducing areas of hibernating myocardium.

For patients whose disease continues to confer a substantial risk of sustained VT or VF on optimal medical therapy, an ICD is recommended **(Table 317-3)**. The ICD indication in these patients is referred to as "primary prevention of sudden death." The indications for primary prevention ICDs vary depending on the type of underlying structural heart disease and its severity, and the strength of evidence varies by indication. In some cases, there are slight differences in the

TABLE 317-3 Implantable Cardioverter Defibrillator (ICD) Indications

	ESC GUIDELINES	AHA/ACC/HRS GUIDELINES	LEVEL OF EVIDENCE
Secondary Prevention			
All Disease States with VT or VF			
Cardiac arrest due to VF or hemodynamically unstable sustained VT after evaluation to define the cause of the event and to exclude any completely reversible causes	Class I	Class I	A
Structural heart disease and spontaneous hemodynamically stable sustained VT	Class IIa	Class I	B
Structural heart disease and spontaneous hemodynamically not-tolerated sustained VT	Class I	Class I	B
Sustained VT and normal or near-normal ventricular function	–	Class IIa	C
Syncope			
Patients with syncope and inducible VT or VF at EP study	–	Class I	B
Patients with syncope and structural heart disease in whom invasive and noninvasive studies have failed to determine a cause	–	Class IIb	C
Primary Prevention			
Coronary Artery Disease			
LVEF ≤35% + NYHA functional class II–III	Class I	Class I	A
LVEF ≤35% (ESC) + NYHA functional class I	Class IIa	–	B
LVEF ≤30% (AHA) + NYHA functional class I	–	Class I	A
LVEF ≤40% + NSVT + inducible monomorphic VT	Class IIa	Class I	B
LVEF ≤40% + unexplained syncope + inducible monomorphic VT	Class IIa	Class I	B
Nonischemic Cardiomyopathy			
LVEF ≤35% + NYHA functional class II–II	Class IIa	Class I	A
LVEF ≤35% + NYHA functional class I	–	Class IIb	B
Pathogenic mutation in *LMNA* gene + 2 or more risk factors (NSVT, LVEF <45%, nonmissense mutation, male sex)	–	Class IIa	C
LMNA mutation with estimated 5-year risk of VA ≥10% + NSVT or LVEF <50% or AV conduction delay	Class IIa	–	C
LVEF >35% and ≥ 2 risk factors (syncope, LGE on CMR, inducible VT at PES, pathogenic mutations in *PLN*, *FLNC*, and *RBM20* genes)	Class IIa	–	C
NYHA Functional Class IV Candidates for Advanced Heart Failure Therapy			
Awaiting cardiac transplant	Class IIa	Class IIa	C
With destination LVAD and sustained VT	Class IIa	–	B
With destination LVAD	–	Class IIa	B
Arrhythmogenic Right Ventricular Cardiomyopathy			
Arrhythmic syncope	Class IIa	Class IIa	B
Moderate right (<40%) or left (<45%) ventricular dysfunction and NSVT or inducible monomorphic VT	Class IIa	–	C
Significant right ventricular dysfunction with LVEF ≤35%	–	Class I	B
Significant right ventricular dysfunction with RVEF ≤35%	Class IIa	Class I	C
Hypertrophic Cardiomyopathy			
Maximum left ventricular wall thickness >30 mm	–	Class IIa	B
SCD in first-degree relative presumably due to HCM	–	Class IIa	B
Unexplained syncope	–	Class IIa	B
NSVT or abnormal blood pressure response during exercise + additional SCD risk modifiers or high-risk features	–	Class IIa	C

(*Continued*)

TABLE 317-3 Implantable Cardioverter Defibrillator (ICD) Indications (Continued)

	ESC GUIDELINES	AHA/ACC/HRS GUIDELINES	LEVEL OF EVIDENCE
NSVT or abnormal blood pressure response during exercise without additional SCD risk modifiers or high-risk features	–	Class IIb	C
Estimated 5-year risk of sudden death based on the HCM Risk–SCD Calculator ≥6%	Class IIa	–	B
Estimated 5-year risk of sudden death based on HCM Risk–SCD Calculator (≥4 to <6%) AND	Class IIa	–	B
Significant LGE on CMR or			
LVEF <50% or			
Abnormal blood pressure during exercise test or

strength of recommendation among professional societies in Europe and America for implantation of an ICD, but overall, there is agreement on ICD implantation for the highest-risk patients. In patients with a history of MI >40 days ago, primary prevention ICDs are indicated for those with class II–III New York Heart Association (NYHA) HF and LVEF <35% and those who are NYHA functional class I with LVEF <30%. Although ICDs have not been found to be beneficial when implanted within 40 days of an MI, those with recent or old MI, nonsustained VT, LVEF <40%, and inducible sustained VT at EP study also warrant an ICD. In general, these criteria are not applied to patients who are within 90 days of myocardial revascularization, since some will experience improvement in ventricular function and older trial data suggested there was no benefit with ICDs in these patients. High-risk patients with low LVEFs may be considered for a wearable defibrillator with later reassessment of ventricular function and ICD placement.

ICDs for primary prevention of sudden death are also recommended for patients with diseases other than CAD that put them at risk for SCD. Primary prevention ICDs are currently indicated in select high-risk patients with HCM, arrhythmogenic right ventricular dysplasia, cardiac sarcoidosis, Brugada syndrome, and congenital LQTS. ICDs are currently also recommended for those with nonischemic dilated cardiomyopathy (DCM) who have an LVEF ≤35% and who have NYHA functional class II or III symptoms on guideline-directed medical therapy. In addition to invasive electrophysiologic testing, new risk stratification methods for certain conditions have emerged, including genetic findings and the presence of late gadolinium enhancement (LGE) on MRI. For example, the European guidelines account for pathogenic mutations associated with a high risk of ventricular arrhythmias in patients with nonischemic cardiomyopathy, hypertrophic cardiomyopathy, and long QT syndrome. The presence of LGE has been shown to be a risk factor for sudden death in patients with cardiac sarcoidosis and hypertrophic cardiomyopathy, and thus, this imaging finding has been incorporated into ICD implantation guidelines.

TABLE 317-4 Implantable Cardioverter Defibrillator (ICD) Not Indicated

Patients who do not have a reasonable expectation of survival with an acceptable functional status for at least 1 year, even if they meet ICD implantation criteria.
Patients with incessant VT or VF.
Patients with significant psychiatric illnesses that may be aggravated by device implantation or that may preclude systematic follow-up.
Patients with drug-refractory New York Heart Association class IV congestive heart failure who are not candidates for cardiac transplantation or cardiac resynchronization therapy.
Syncope of undetermined cause in a patient without inducible ventricular tachyarrhythmias and without structural heart disease.
VF or VT is amenable to surgical or catheter ablation in patients without other disease predisposing to sudden cardiac arrest (e.g., atrial arrhythmias associated with Wolff-Parkinson-White syndrome, RV or LV outflow tract VT, idiopathic VT, or fascicular VT in the absence of structural heart disease).
Patients with ventricular tachyarrhythmias due to a completely reversible disorder in the absence of structural heart disease (e.g., electrolyte imbalance, drugs, or trauma).

Abbreviations: LV, left ventricular; RV, right ventricular; VF, ventricular fibrillation; VT, ventricular tachycardia.

Although the ICD is very effective for treatment of arrhythmic sudden death, competing causes of mortality must be considered in patients with severe cardiomyopathy. Data from a recent randomized trial, the Danish Study to Assess the Efficacy of ICDs in Patients with Non-ischemic Systolic Heart Failure on Mortality (DANISH), performed in patients with nonischemic DCM and LVEF ≤35%, who also had elevated N-terminal pro-B-type natriuretic peptide levels and NYHA class II–IV HF, have resulted in some debate regarding the utility of ICDs in this population. This trial did not demonstrate an overall mortality benefit of the ICD despite a reduction in the incidence of SCD. In subgroup analyses, mortality benefits were observed in younger patients in whom the competing risk of dying from other causes of death was lower. These data underscore the importance of considering competing risks for other causes of mortality when deciding to implant a primary prevention ICD. Patients who are likely to die from other causes are unlikely to benefit from an ICD. Patients who do not have a reasonable expectation of survival with an acceptable functional status for at least 1 year should not undergo ICD placement. There are also other circumstances where an ICD is not indicated even if there is a significant sudden death risk (Table 317-4).

THE CHALLENGE OF SCD PREVENTION (FIG. 317-3)

The Greatest Number of Sudden Deaths Occur in "Low-Risk" Patients While patients with reduced left ventricular

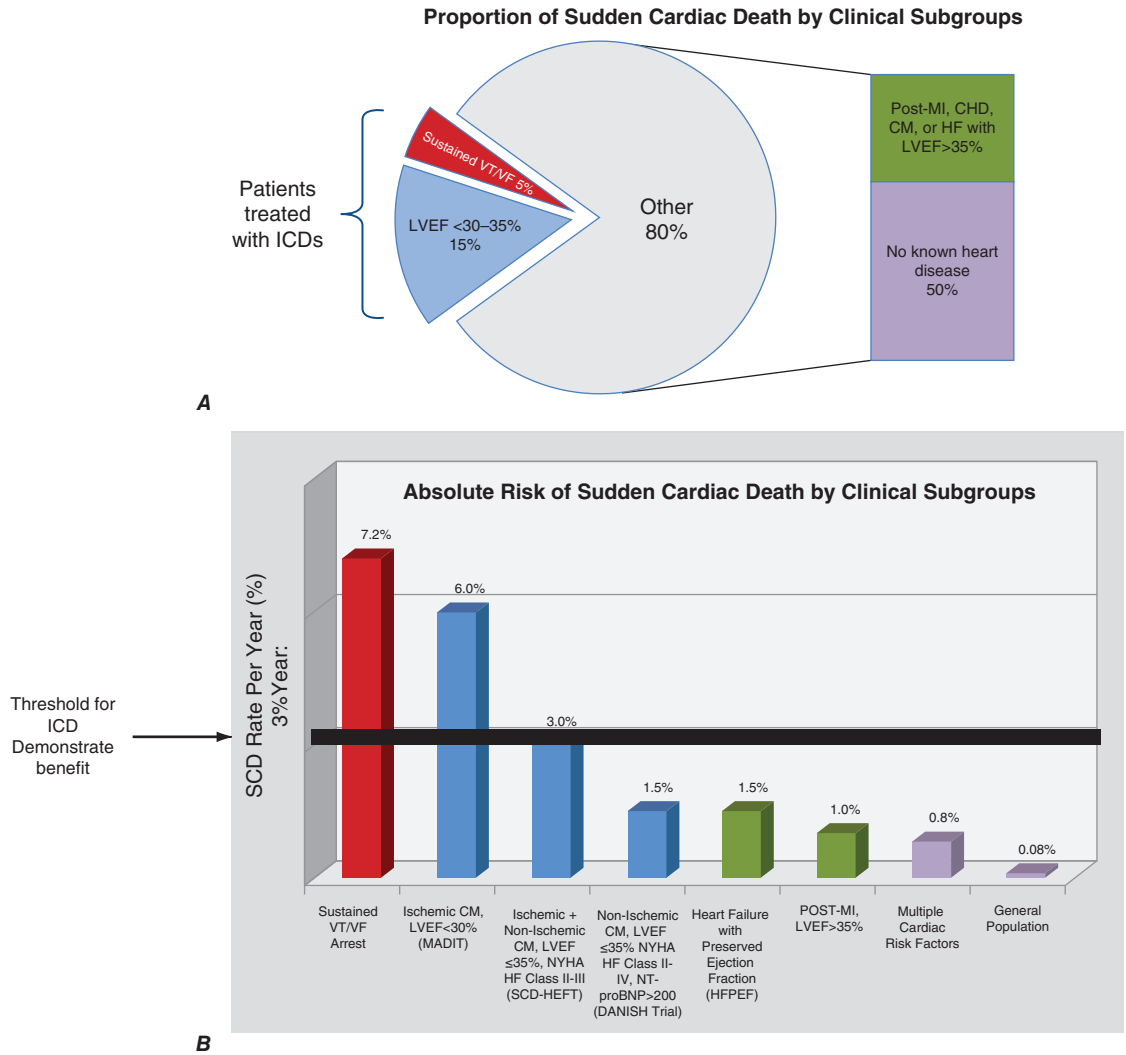

FIGURE 317-3 ***A.*** Proportion of sudden cardiac deaths that occur in clinical subgroups of the population treated and not treated with implantable cardioverter defibrillators (ICDs). ***B.*** Absolute risk of sudden cardiac death within clinical subgroups in comparison to the threshold of risk where ICDs demonstrated benefit.

function and HF are at substantially elevated SCD risk, only ~20% of all SCDs occur in patients with poor left ventricular function. Most SCDs occur in individuals with preserved ventricular function who would not qualify for a primary prevention ICD. Although SCD rates are elevated compared to the general population, the absolute SCD risk in patients with CHD or HF who have an LVEF >35% is not high enough to warrant consideration of ICD therapy. While the incidence of SCD is lower in patients with preserved LVEF, SCD accounts for a greater proportion of cardiac deaths, and active efforts are being made to advance SCD risk stratification in this segment of the population. However, at present, SCD prevention primarily involves cardiac risk factor modification and standard medical therapy for the underlying condition.

Preventing Sudden Death in the General Population Only about one-half of men and one-third of women who suffer SCA are recognized to have heart disease prior to the event, and only half have warning symptoms prior to the event. SCD often occurs without warning as the first manifestation of cardiac disease. In order to prevent these SCDs, preventive interventions would need to be employed broadly to the general population. Although several risk scores have recently been developed with the intent to stratify SCD risk in low-risk populations, the clinical utility to date is limited by the low absolute incidence of SCD, which is estimated to be only 50–90 per 100,000 in the general adult population. Therefore, current efforts aimed at preventing SCD in general populations primarily focus on modification of the SCD risk factors outlined previously. Individuals who adhere to a low-risk, healthy lifestyle that includes avoidance of smoking, maintaining a healthy body weight, participating in moderate exercise, and a Mediterranean-type dietary pattern have markedly lower rates of SCD. A substantial number of SCDs are likely to be preventable through lifestyle modifications and treatment of risk factors.

Section 3 Neurologic Critical Care

318 Nervous System Disorders in Critical Care

J. Claude Hemphill, III, Wade S. Smith, S. Andrew Josephson, Daryl R. Gress

Life-threatening neurologic illness may be caused by a primary disorder affecting any region of the neuraxis or may occur as a consequence of a systemic disorder such as hepatic failure, multisystem organ failure, or cardiac arrest **(Table 318-1)**. Neurologic critical care focuses on preservation of neurologic tissue and prevention of secondary brain injury caused by ischemia, hemorrhage, edema, herniation, and elevated intracranial pressure (ICP). Encephalopathy is a general term describing brain dysfunction that is diffuse, global, or multifocal. Severe acute encephalopathies represent a group of various disorders due to different neurologic or systemic etiologies but that share the common themes of primary and secondary brain injury.

PATHOPHYSIOLOGY

Brain Edema Swelling, or edema, of brain tissue occurs with many types of brain injury. The two principal types of edema are vasogenic and cytotoxic. *Vasogenic edema* refers to the influx of fluid and solutes into the brain through an incompetent blood-brain barrier (BBB). In the normal cerebral vasculature, endothelial tight junctions associated with astrocytes create an impermeable barrier (the BBB), through which access into the brain interstitium is dependent upon specific transport mechanisms. The BBB may be compromised in ischemia, trauma, infection, and metabolic derangements, and typically develops rapidly following injury. *Cytotoxic edema* results from cellular swelling, membrane breakdown, and ultimately cell death. Clinically significant brain edema usually represents a combination of vasogenic and cytotoxic components. Edema can lead to increased ICP as well as tissue shifts and brain displacement or herniation from focal processes **(Chap. 30)**. These tissue shifts can cause injury by mechanical distention and compression in addition to the ischemia of impaired perfusion consequent to the elevated ICP.

Ischemic Cascade and Cellular Injury When delivery of substrates, principally oxygen and glucose, is inadequate to sustain cellular function, a series of interrelated biochemical reactions known as the *ischemic cascade* is initiated **(see Fig. 437-2)**. The release of excitatory amino acids, especially glutamate, leads to influx of calcium and sodium ions, which disrupt cellular homeostasis. An increased intracellular calcium concentration may activate proteases and lipases, which then lead to lipid peroxidation and free radical–mediated cell membrane injury. Cytotoxic edema ensues, and ultimately necrotic cell death and tissue infarction occur. This pathway to irreversible cell death is common to ischemic stroke, global cerebral ischemia, and traumatic brain injury.

Penumbra refers to areas of ischemic brain tissue that have not yet undergone irreversible infarction, implying that these regions are potentially salvageable if ischemia can be reversed. Factors that may exacerbate ischemic brain injury include systemic hypotension and hypoxia, which further reduce substrate delivery to vulnerable brain tissue, and fever, seizures, and hyperglycemia, which can increase cellular metabolism, outstripping compensatory processes. Clinically, these events are known as *secondary brain insults* because they lead to exacerbation of the primary brain injury. Prevention, identification, and treatment of secondary brain insults are fundamental goals of management.

An alternative pathway of cellular injury is *apoptosis*. This process implies programmed cell death, which may occur in the setting of ischemic stroke, global cerebral ischemia, traumatic brain injury, and

possibly intracerebral hemorrhage. Apoptotic cell death can be distinguished histologically from the necrotic cell death of ischemia and is mediated through a different set of biochemical pathways; apoptotic cell death occurs without cerebral edema and therefore is often not seen on brain imaging. At present, interventions for prevention and treatment of apoptotic cell death remain less well defined than those for ischemia.

Cerebral Perfusion and Autoregulation Brain tissue requires constant perfusion in order to ensure adequate delivery of substrate. The hemodynamic response of the brain has the capacity to preserve perfusion across a wide range of systemic blood pressures. Cerebral perfusion pressure (CPP), defined as the mean systemic arterial pressure (MAP) minus the ICP, provides the driving force for circulation across the capillary beds of the brain. *Autoregulation* refers to the physiologic response whereby cerebral blood flow (CBF) is regulated via alterations in cerebrovascular resistance in order to maintain perfusion over wide physiologic changes such as neuronal activation or changes in hemodynamic function. If systemic blood pressure drops, cerebral perfusion is preserved through vasodilation of arterioles in the brain; likewise, arteriolar vasoconstriction occurs at high systemic pressures to prevent hyperperfusion, resulting in fairly constant perfusion across a wide range of systemic blood pressures (Fig. 318-1). At the extreme limits of MAP or CPP (high or low), flow becomes directly related to perfusion pressure. These autoregulatory changes occur in the microcirculation and are mediated by vessels below the resolution of those seen on angiography. CBF is also strongly influenced by pH and $Paco_2$. CBF increases with hypercapnia and acidosis and decreases with hypocapnia and alkalosis because of pH-related changes in cerebral vascular resistance. This forms the basis for the use of hyperventilation to lower ICP, and this effect on ICP is mediated through a decrease in both CBF and intracranial blood volume. Cerebral autoregulation is a complex process critical to the normal homeostatic functioning of the brain, and this process may be disordered focally and unpredictably in disease states such as traumatic brain injury and severe focal cerebral ischemia.

Cerebrospinal Fluid (CSF) and ICP The cranial contents consist essentially of brain, CSF, and blood. CSF is produced principally in the choroid plexus of each lateral ventricle, exits the brain via the foramens of Luschka and Magendie, and flows over the cortex to be absorbed into the venous system along the superior sagittal sinus. In adults, ~150 mL of CSF are contained within the ventricles and surrounding the brain and spinal cord; the cerebral blood volume is also ~150 mL. The bony skull offers excellent protection for the brain but allows little tolerance for additional volume. Significant increases in volume eventually result in increased ICP. Obstruction of CSF outflow, edema of cerebral tissue, or increases in volume from tumor or hematoma may increase ICP. Elevated ICP diminishes cerebral perfusion and can lead to tissue ischemia. Ischemia in turn may lead to vasodilation via autoregulatory mechanisms designed to restore cerebral perfusion. However, vasodilation also increases cerebral blood volume, which in turn then increases ICP, lowers CPP, and provokes further ischemia. This vicious cycle is commonly seen in traumatic brain injury, massive intracerebral hemorrhage, and large hemispheric infarcts with significant tissue shifts.

APPROACH TO THE PATIENT

Severe Brain Dysfunction

Critically ill patients with severe central nervous system (CNS) dysfunction require rapid evaluation and intervention in order to limit primary and secondary brain injury. Initial neurologic evaluation should be performed concurrent with stabilization of basic respiratory, cardiac, and hemodynamic parameters. Significant barriers may exist to neurologic assessment in the critical care unit, including endotracheal intubation and the use of sedative or paralytic agents to facilitate procedures.

An impaired level of consciousness is common in critically ill patients. The essential first task in assessment is to determine

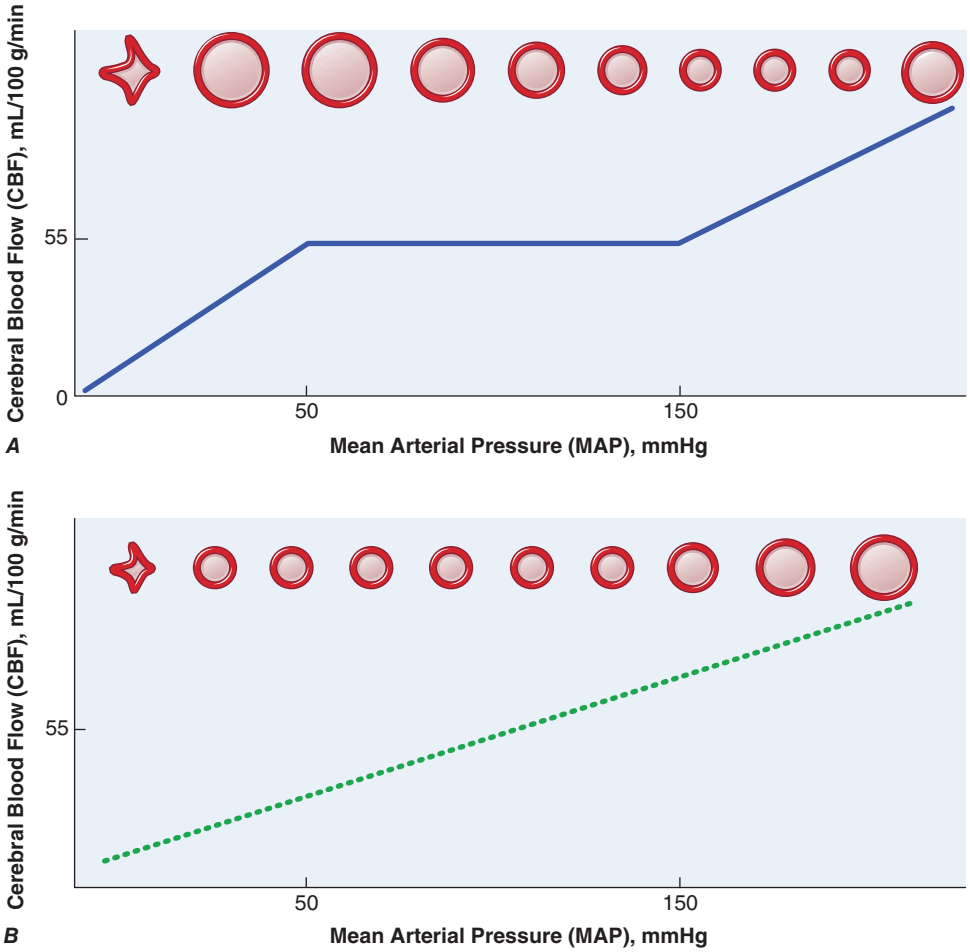

FIGURE 318-1 Pressure autoregulation of cerebral blood flow. In the normal state where autoregulation is intact ***A***, cerebral perfusion is constant over a wide range of systemic blood pressures (BP). This is mediated by dilation and constriction of small cerebral arterioles (*round circles*). Below the BP threshold for maximal dilation, cerebral blood flow becomes pressure-dependent and decreases, whereas above the threshold for maximum constriction, cerebral blood flow increases with increasing systemic BP. In severe brain injury, autoregulatory mechanisms may be impaired and cerebral blood flow becomes pressure-dependent throughout (***B***). At the extremes of BP, there may be vascular collapse (very low BP) or forced vasodilation (very high BP).

whether the cause of dysfunction is related to a diffuse, usually metabolic, process or whether a focal, usually structural, process is implicated. Examples of diffuse processes include metabolic encephalopathies related to organ failure, drug overdose, or hypoxia-ischemia. Focal processes include ischemic and hemorrhagic stroke and traumatic brain injury, especially with intracranial hematomas. Because these two categories of disorders have fundamentally different causes, treatments, and prognoses, the initial focus is on making this distinction rapidly and accurately. **The approach to the comatose patient is discussed in Chap. 30; etiologies are listed in Table 30-1.**

Minor focal deficits may be present on the neurologic examination in patients with metabolic encephalopathies. However, the finding of prominent focal signs such as pupillary asymmetry, hemiparesis, gaze palsy, or visual field deficit should suggest the possibility of a structural lesion. All patients with a decreased level of consciousness associated with focal findings should undergo an urgent neuroimaging procedure, as should all patients with coma of unknown etiology. Computed tomography (CT) scanning is usually the most appropriate initial study because it can be performed quickly in critically ill patients and demonstrates hemorrhage, hydrocephalus, and intracranial tissue shifts well. Magnetic resonance imaging (MRI) may provide more specific information in some situations, such as acute ischemic stroke (diffusion-weighted imaging [DWI]). Any suggestion of trauma from the history or examination should alert the examiner to the possibility of cervical spine injury and prompt an imaging evaluation using CT or MRI. Neurovascular imaging using CT or MRI angiography or venography is increasingly available and may suggest arterial occlusion or cerebral venous thrombosis.

Acute brainstem ischemia due to basilar artery thrombosis may cause brief episodes of spontaneous extensor posturing superficially resembling generalized seizures. Coma of sudden onset, accompanied by these movements and cranial nerve abnormalities, necessitates emergency imaging. A noncontrast CT scan of the brain may reveal a hyperdense basilar artery indicating thrombus in the vessel, and subsequent CT or MR angiography can assess basilar artery patency.

Other diagnostic studies are best used in specific circumstances, usually when neuroimaging studies fail to reveal a structural lesion and the etiology of the altered mental state remains uncertain. Electroencephalography (EEG) can be important in the evaluation of critically ill patients with severe brain dysfunction. The EEG of metabolic encephalopathy typically reveals generalized slowing. One of the most important uses of EEG is to help exclude inapparent seizures, especially nonconvulsive status epilepticus. Untreated continuous or frequently recurrent seizures may cause neuronal injury, making the diagnosis and treatment of seizures crucial in this patient group. Lumbar puncture (LP) may be necessary to exclude infectious or inflammatory processes, and an elevated opening pressure may be an important clue to cerebral venous sinus thrombosis. In patients with coma or profound encephalopathy, it is preferable to perform a neuroimaging study prior to LP. If bacterial meningitis is suspected, an LP may be performed urgently, but most often, it is prudent to administer antibiotics empirically before the diagnostic studies are completed. Standard laboratory evaluation of

critically ill patients should include assessment of serum electrolytes (especially sodium and calcium), glucose, renal and hepatic function, complete blood count, and coagulation. Serum or urine toxicology screens should be performed in patients with encephalopathy of unknown cause. EEG and LP are most useful when the mechanism of the altered level of consciousness is uncertain; they are not routinely performed for diagnosis in clear-cut cases of stroke or traumatic brain injury.

Monitoring of ICP can be an important tool in selected patients. In general, patients who should be considered for ICP monitoring are those with primary neurologic disorders, such as stroke or traumatic brain injury, who are at significant risk for secondary brain injury due to elevated ICP and decreased CPP. Included are patients with the following: severe traumatic brain injury (Glasgow Coma Scale [GCS] score ≤8 [see **Table 454-1**]); large tissue shifts from supratentorial ischemic or hemorrhagic stroke; or hydrocephalus from subarachnoid hemorrhage (SAH), intraventricular hemorrhage, or posterior fossa stroke. An additional disorder in which ICP monitoring can add important information is fulminant hepatic failure, in which elevated ICP may be treated with barbiturates or, eventually, liver transplantation. In general, ventriculostomy is preferable to ICP monitoring devices that are placed in the brain parenchyma, because ventriculostomy allows CSF drainage as a method of treating elevated ICP. However, parenchymal ICP monitoring is most appropriate for patients with diffuse edema and small ventricles (which may make ventriculostomy placement more difficult) or any degree of coagulopathy (in which ventriculostomy carries a higher risk of hemorrhagic complications) **(Fig. 318-2)**.

TREATMENT OF ELEVATED ICP

Elevated ICP may occur in a wide range of disorders, including head trauma, intracerebral hemorrhage, SAH with hydrocephalus, and fulminant hepatic failure. Because CSF and blood volume can be redistributed initially, by the time elevated ICP occurs, intracranial compliance is severely impaired. At this point, any small increase in the volume of CSF, intravascular blood, edema, or a mass lesion may result in a significant increase in ICP and a decrease in cerebral perfusion. This is a fundamental mechanism of secondary ischemic brain injury and constitutes an emergency that requires immediate attention. In general, ICP should be maintained at <20 mmHg and CPP should be maintained at ≥60 mmHg.

Interventions to lower ICP are ideally based on the underlying mechanism responsible for the elevated ICP **(Table 318-2)**. For example, in hydrocephalus from SAH, the principal cause of elevated ICP is impairment of CSF drainage. In this setting, ventricular drainage of CSF is likely to be sufficient and most appropriate. In head trauma and stroke, cytotoxic edema may be most responsible, and the use of osmotic agents such as mannitol or hypertonic saline becomes an appropriate early step. As described above, elevated ICP may cause tissue ischemia, and, if cerebral autoregulation is intact, the resulting vasodilation can lead to a cycle of worsening ischemia. Paradoxically, administration of vasopressor agents to increase MAP may actually lower ICP by improving perfusion, thereby allowing autoregulatory vasoconstriction as ischemia is relieved and ultimately decreasing intracranial blood volume.

Early signs of elevated ICP include drowsiness and a diminished level of consciousness. Neuroimaging studies may reveal evidence of edema and mass effect. Hypotonic IV fluids should be avoided, and elevation of the head of the bed is recommended. Patients must be carefully observed for risk of aspiration and compromise of the airway as the level of alertness declines. Coma and unilateral pupillary changes are late signs and require immediate intervention. Emergent treatment of elevated ICP is most quickly achieved by intubation and hyperventilation, which causes vasoconstriction and reduces cerebral blood volume. To avoid provoking or worsening cerebral ischemia, hyperventilation, if used at all, is best administered only for short periods of time until a more definitive treatment can be instituted. Furthermore, the effects of hyperventilation on ICP are short-lived, often lasting only for several hours because of the buffering capacity of the cerebral interstitium, and rebound elevations of ICP may accompany abrupt discontinuation of hyperventilation. As the level of consciousness declines to coma, the ability to follow the neurologic status of the patient by examination lessens and measurement of ICP assumes greater importance. If a ventriculostomy device is in place, direct drainage of CSF to reduce ICP is possible. Finally, high-dose barbiturates, decompressive hemicraniectomy, and hypothermia are sometimes used for refractory elevations of ICP, although these have significant side effects and only decompressive hemicraniectomy has been shown to improve outcome in select patients.

SECONDARY BRAIN INSULTS

Patients with primary brain injuries, whether due to trauma or stroke, are at risk for ongoing secondary ischemic brain injury.

TABLE 318-2 Stepwise Approach to Treatment of Elevated Intracranial Pressure (ICP)[a]

Insert ICP monitor—ventriculostomy versus parenchymal device

General goals: maintain ICP <20 mmHg and CPP ≥60 mmHg. For ICP >20–25 mmHg for >5 min:

1. Elevate head of the bed; midline head position
2. Drain CSF via ventriculostomy (if in place)
3. Osmotherapy—mannitol 25–100 g q4h as needed (maintain serum osmolality <320 mosmol) or hypertonic saline (30 mL, 23.4% NaCl bolus)
4. Glucocorticoids—dexamethasone 4 mg q6h for vasogenic edema from tumor, abscess (avoid glucocorticoids in head trauma, ischemic and hemorrhagic stroke)
5. Sedation (e.g., morphine, propofol, or midazolam); add neuromuscular paralysis if necessary (patient will require endotracheal intubation and mechanical ventilation at this point, if not before)
6. Hyperventilation—to $Paco_2$ 30–35 mmHg (short-term use or skip this step)
7. Pressor therapy—phenylephrine, dopamine, or norepinephrine to maintain adequate MAP to ensure CPP ≥60 mmHg (maintain euvolemia to minimize deleterious systemic effects of pressors). May adjust target CPP in individual patients based on autoregulation status.
8. Consider second-tier therapies for refractory elevated ICP
   a. Decompressive craniectomy
   b. High-dose barbiturate therapy ("pentobarb coma")
   c. Hypothermia to 33°C

[a]Throughout ICP treatment algorithm, consider repeat head computed tomography to identify mass lesions amenable to surgical evacuation. May alter order of steps based on directed treatment to specific cause of elevated ICP.

Abbreviations: CPP, cerebral perfusion pressure; CSF, cerebrospinal fluid; MAP, mean arterial pressure; $Paco_2$, arterial partial pressure of carbon dioxide.

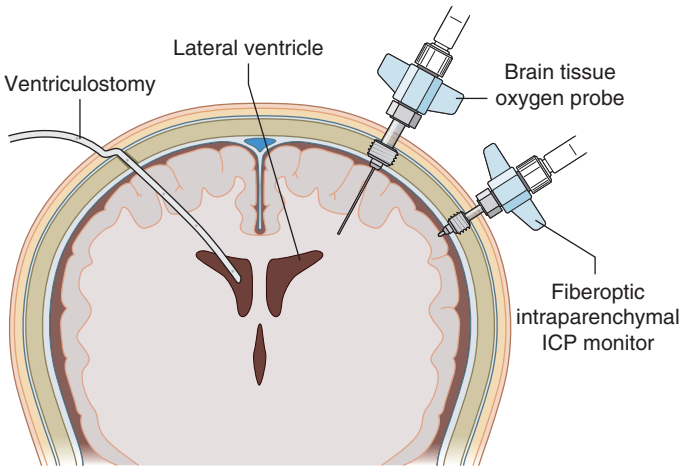

FIGURE 318-2 Intracranial pressure (ICP) and brain tissue oxygen monitoring. A ventriculostomy allows for drainage of cerebrospinal fluid to treat elevated ICP. Fiberoptic ICP and brain tissue oxygen monitors are usually secured using a screw-like skull bolt. Cerebral blood flow and microdialysis probes (not shown) may be placed in a manner similar to the brain tissue oxygen probe.

Because secondary brain injury can be a major determinant of a poor outcome, strategies for minimizing secondary brain insults are an integral part of the critical care of all patients. Although elevated ICP may lead to secondary ischemia, most secondary brain injury is mediated through other clinical events that exacerbate the ischemic cascade already initiated by the primary brain injury. Episodes of secondary brain insults are usually not associated with apparent neurologic worsening. Rather, they lead to cumulative injury limiting eventual recovery, which manifests as a higher mortality rate or worsened long-term functional outcome. Thus, close monitoring of vital signs is important, as is early intervention to prevent secondary ischemia. Avoiding hypotension and hypoxia is critical, as significant hypotensive events (systolic blood pressure <90 mmHg) as short as 10 min in duration have been shown to adversely influence outcome after traumatic brain injury. Even in patients with stroke or head trauma who do not require ICP monitoring, close attention to adequate cerebral perfusion is warranted. Hypoxia (pulse oximetry saturation <90%), particularly in combination with hypotension, also leads to secondary brain injury. Likewise, fever and hyperglycemia both worsen experimental ischemia and have been associated with worsened clinical outcome after stroke and head trauma. Aggressive control of fever with a goal of normothermia is warranted but may be difficult to achieve with antipyretic medications and cooling blankets. The value of newer surface or intravascular temperature control devices for the management of refractory fever is under investigation. The use of IV insulin infusion is encouraged for control of hyperglycemia because this allows better regulation of serum glucose levels than SC insulin. A reasonable goal is to maintain the serum glucose level at <10.0 mmol/L (<180 mg/dL), although episodes of hypoglycemia appear equally detrimental and the optimal targets remain uncertain. New cerebral monitoring tools that allow continuous evaluation of brain tissue oxygen tension, CBF, cortical spreading depolarizations, and cerebral metabolism (via microdialysis) may further improve the management of secondary brain injury.

CRITICAL CARE DISORDERS OF THE CNS

HYPOXIC-ISCHEMIC BRAIN INJURY

This occurs from lack of delivery of oxygen to the brain because of extreme hypotension (hypoxia-ischemia) or hypoxia due to respiratory failure. Causes include myocardial infarction, cardiac arrest, shock, asphyxiation, paralysis of respiration, and carbon monoxide or cyanide poisoning. In some circumstances, hypoxia may predominate. Carbon monoxide and cyanide poisoning are sometimes termed *histotoxic hypoxia* because they cause a direct impairment of the respiratory chain.

Clinical Manifestations Mild degrees of pure hypoxia, such as occur at high altitudes, cause impaired judgment, inattentiveness, motor incoordination, and, at times, euphoria. However, with hypoxia-ischemia, such as occurs with circulatory arrest, consciousness is lost within seconds. If circulation is restored within 3–5 min, full recovery may occur, but if hypoxia-ischemia lasts beyond 3–5 min, some degree of permanent cerebral damage often results. Except in extreme cases, it may be difficult to judge the precise degree of hypoxia-ischemia, and some patients make a relatively full recovery after even 10 min or more of global cerebral ischemia. The brain is more tolerant to pure hypoxia than it is to hypoxia-ischemia. For example, a Pao_2 as low as 20 mmHg (2.7 kPa) can be well tolerated if it develops gradually and normal blood pressure is maintained, whereas short durations of very low or absent cerebral circulation may result in permanent impairment.

Clinical examination at different time points after a hypoxic-ischemic insult (especially cardiac arrest) is useful in assessing prognosis for long-term neurologic outcome. The prognosis is better for patients with intact brainstem function, as indicated by normal pupillary light responses and intact oculocephalic (doll's eyes), oculovestibular (caloric), and corneal reflexes. Absence of these reflexes and the presence of persistently dilated pupils that do not react to light are concerning prognostic signs. A lower likelihood of a favorable outcome from hypoxic-ischemic brain injury is suggested by an absent pupillary light reflex or extensor or absent motor response to pain 5–7 days following the injury, excluding patients with metabolic disturbances and those treated with high-dose sedative medications or hypothermia, which confound interpretation of these signs. Electrophysiologically, the bilateral absence of the N20 component of the somatosensory evoked potential (SSEP) after several days also conveys a poor prognosis. Also, the presence of a burst-suppression pattern of myoclonic status epilepticus on EEG **(Fig. 318-3)** or a nonreactive EEG is associated with a lower likelihood of good functional outcome. A very elevated serum level (>60 μg/L) of the biochemical marker neuron-specific enolase (NSE) obtained during first 1–3 days following injury is indicative of brain damage after resuscitation from cardiac arrest and is associated with worse outcome. Current approaches to prognostication after cardiac arrest encourage the use of a multimodal approach that includes these diagnostic tests, along with CT or MRI neuroimaging, in conjunction with clinical neurologic assessment. The administration of mild hypothermia after cardiac arrest (see "Treatment") may affect the time points when these clinical and electrophysiologic predictors become reliable in identifying patients with a very low likelihood of clinically meaningful recovery. For example, the false-positive rate for incorrect prediction of poor neurologic outcome may be as high as 21% (95% confidence interval [CI] 8–43%) for patients treated with mild hypothermia who exhibit 3-day motor function no better than extensor posturing. Thus, sufficient time from injury is important to ensure accuracy of prognostic assessment and to avoid the self-fulfilling prophecy of poor outcome when withdrawal of life-sustaining therapy is undertaken in a patient who has the potential for recovery. The minimum observation period to ensure accuracy of prognostication remains unclarified, but some patients may awaken after a week or longer. Long-term consequences of hypoxic-ischemic encephalopathy include persistent coma or an unresponsive wakeful state **(Chap. 30)**, dementia **(Chap. 31)**, visual agnosia **(Chap. 32)**, parkinsonism, choreoathetosis, cerebellar ataxia, myoclonus, seizures, and an amnestic state, which may be a consequence of selective damage to the hippocampus.

Pathology Principal histologic findings are extensive multifocal or diffuse laminar cortical injury **(Fig. 318-4)**, with frequent involvement of the deep gray nuclei and hippocampus. The hippocampal CA1 neurons are vulnerable to even brief episodes of hypoxia-ischemia, perhaps explaining why selective persistent memory deficits may occur after brief cardiac arrest. Scattered small areas of infarction or neuronal loss may be present in the basal ganglia, hypothalamus, or brainstem. In some cases, extensive bilateral thalamic scarring may affect pathways that mediate arousal, and this pathology may be responsible for the unresponsive wakeful state (previously known as the vegetative state). A specific form of hypoxic-ischemic brain injury, so-called watershed infarcts, occurs at the distal territories between the major cerebral arteries and can cause cognitive deficits, including visual agnosia, and weakness that is greater in proximal than in distal muscle groups.

Diagnosis Diagnosis is based on the history of a hypoxic-ischemic event such as cardiac arrest. Blood pressure <70 mmHg systolic or Pao_2 <40 mmHg is usually necessary, although both absolute levels and duration of exposure are important determinants of cellular injury. Carbon monoxide intoxication can be confirmed by measurement of carboxyhemoglobin and is suggested by a cherry red color of the venous blood and skin, although the latter is an inconsistent clinical finding.

TREATMENT

Hypoxic-Ischemic Brain Injury

Treatment should be directed at restoration of normal cardiorespiratory function. This includes securing a clear airway, ensuring adequate oxygenation and ventilation, and restoring cerebral

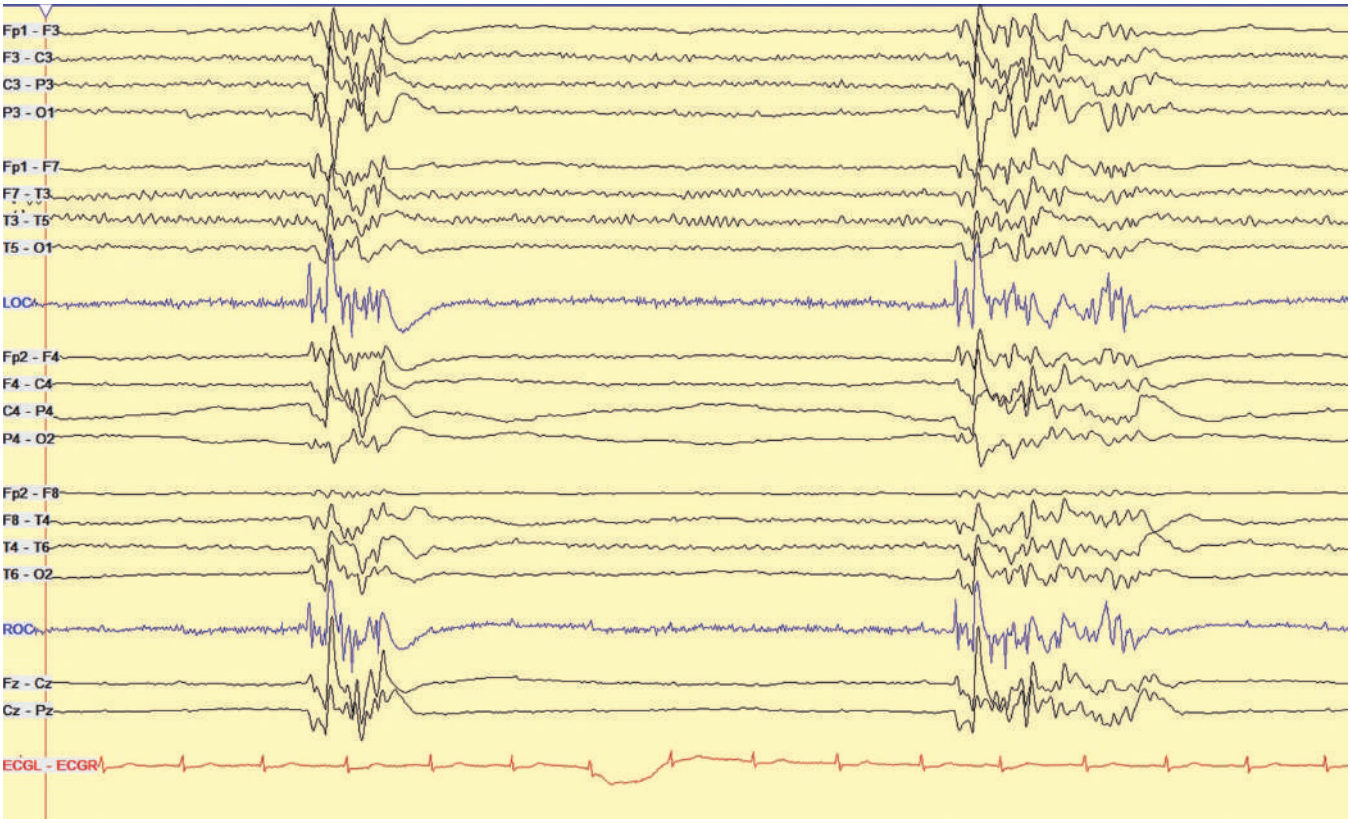

FIGURE 318-3 Electroencephalography (EEG) after cardiac arrest. A burst-suppression pattern is seen in a comatose patient with severe hypoxic-ischemic encephalopathy after cardiac arrest. In this patient, each burst on EEG was associated with a whole-body jerking movement leading to the clinical and electrophysiologic diagnosis of myoclonic status epilepticus.

perfusion, whether by cardiopulmonary resuscitation, fluid, pressors, or cardiac pacing. Hypothermia may target the neuronal cell injury cascade and has substantial neuroprotective properties in experimental models of brain injury. Several clinical trials found that mild hypothermia (33°C) administered for 12–24 h improved functional outcome in patients who remained comatose after resuscitation from cardiac arrest. These trials varied in the patients included, with some involving out-of-hospital arrest with a shockable cardiac rhythm and others including in-hospital arrest and focusing on those with nonshockable rhythms. Two larger subsequent clinical trials that included patients with high rates of bystander cardiopulmonary resuscitation and primary cardiac causes of arrest did not find hypothermia to 33°C as beneficial. In one, targeted temperature management (TTM) to 33 or 36°C resulted in similar outcomes, while in another, early treatment of fever (temperature ≥37.8°C) resulted in similar outcomes to those of patients treated with hypothermia to 33°C. Given these heterogeneous findings from clinical trials, there exists variability in how clinicians treat patients with hypoxic-ischemic brain injury from cardiac arrest. Current guidelines recommend selecting and maintaining a constant temperature between 32 and 37.5°C during postarrest temperature control for patients who have no meaningful response to verbal commands after return of spontaneous circulation (ROSC). It is our current practice to target either 33 or 36°C. Fever should be avoided in all cases. Potential complications of hypothermia include systemic coagulopathy and an increased risk of infection.

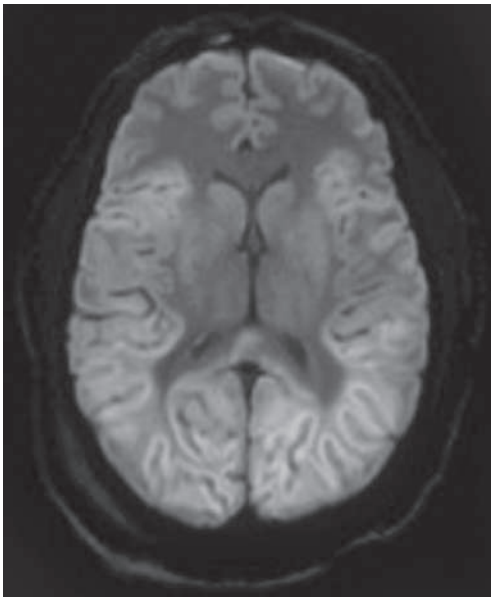

FIGURE 318-4 Hypoxic-ischemic brain injury after cardiac arrest. Diffusion-weighted magnetic resonance imaging shows reduced diffusion (bright signal) throughout the cerebral cortex as well as in the caudate, globus pallidus, and thalamus bilaterally.

Additional clinical trials have been conducted to assess whether targeting specific physiologic parameters that may impact cerebral blood flow and oxygen delivery after ROSC can improve outcome. A factorial design clinical trial tested both a higher mean arterial blood pressure target (77 vs 63 mmHg) and a higher partial pressure of oxygen target (98–105 vs 68–75 mmHg) and found no differences in clinical outcome. Likewise, targeting early mild hypercapnia ($Paco_2$ 50–55 vs 35–45 mmHg) did not improve outcome in a separate clinical trial.

Anticonvulsants may be needed to control seizures, although these are not usually given prophylactically. Myoclonic status epilepticus within 24 h after a primary circulatory arrest generally portends a poor prognosis, even if seizures are controlled. A clinical trial of complete suppression of rhythmic and periodic EEG activity for 48 h did not result in improved patient outcomes compared with standard care that included TTM, and therefore, this strategy should likely not be practiced. Posthypoxic myoclonus may respond

to oral administration of clonazepam at doses of 1.5–10 mg daily or valproate at doses of 300–1200 mg daily in divided doses.

Severe acute carbon monoxide intoxication may be treated with hyperbaric oxygen. Carbon monoxide and cyanide intoxication can also cause a delayed encephalopathy. Little clinical impairment is evident when the patient first regains consciousness, but a parkinsonian syndrome characterized by akinesia and rigidity without tremor may develop. Symptoms can worsen over months, accompanied by increasing evidence of damage in the basal ganglia as seen on both CT and MRI.

POSTCARDIAC BYPASS BRAIN INJURY

CNS injuries following open heart or coronary artery bypass grafting (CABG) surgery are common and include acute encephalopathy, stroke, and a chronic syndrome of cognitive impairment. Hypoperfusion and embolic disease are frequently involved in the pathogenesis of these syndromes, although multiple mechanisms may be involved in these critically ill patients who are at risk for various metabolic and polypharmaceutical complications.

The frequency of hypoxic injury secondary to inadequate blood flow intraoperatively has been markedly decreased by modern surgical and anesthetic techniques. Despite these advances, some patients still experience neurologic complications from cerebral hypoperfusion or suffer focal ischemia from carotid or focal intracranial stenoses in the setting of regional hypoperfusion. Postoperative infarcts in the border zones between vascular territories are often attributed to systemic hypotension, although these infarcts can also result from embolic disease.

Embolic disease is likely the predominant mechanism of cerebral injury during cardiac surgery as evidenced by diffusion-weighted MRI and intraoperative transcranial Doppler ultrasound studies. Thrombus in the heart itself as well as atheromas in the aortic arch can become dislodged during cardiac surgeries, releasing a shower of particulate matter into the cerebral circulation. Cross-clamping of the aorta, manipulation of the heart, extracorporeal circulation techniques ("bypass"), arrhythmias such as atrial fibrillation, and introduction of air through suctioning have all been implicated as potential sources of emboli.

This shower of microemboli results in a number of clinical syndromes. Occasionally, a single large embolus leads to an isolated large-vessel stroke that presents with obvious clinical focal deficits. When there is a high burden of very small emboli, an acute encephalopathy can occur postoperatively, presenting as either a hyperactive or hypoactive confusional state, the latter of which is frequently and incorrectly ascribed to depression or a sedative-induced delirium. When the burden of microemboli is lower, no acute syndrome is recognized, but the patient may suffer a chronic cognitive deficit.

METABOLIC ENCEPHALOPATHIES

Altered mental states, variously described as confusion, delirium, disorientation, and encephalopathy, are present in many patients with severe illness in an intensive care unit (ICU). Older patients are particularly vulnerable to delirium **(Chap. 29)**, a confusional state characterized by disordered perception, frequent hallucinations, delusions, and sleep disturbance. This is often attributed to medication effects, sleep deprivation, pain, and anxiety. The presence of delirium is associated with a worse outcome in critically ill patients, even in those without an identifiable CNS pathology such as stroke or brain trauma. In these patients, the cause of delirium is often multifactorial, resulting from organ dysfunction, sepsis, and especially the use of medications given to treat pain, agitation, or anxiety. Critically ill patients are often treated with a variety of sedative and analgesic medications, including opiates, benzodiazepines, neuroleptics, and sedative-anesthetic medications, such as propofol. In critically ill patients requiring sedation, use of the centrally acting α_2 agonist dexmedetomidine may reduce delirium and shorten the duration of mechanical ventilation compared to the use of benzodiazepines such as lorazepam or midazolam. The presence of family members in the ICU may also help to calm and orient agitated patients, and in severe cases, low doses of neuroleptics (e.g., haloperidol 0.5–1 mg) can be useful. Current strategies focus on limiting the use of sedative medications when this can be done safely.

In the ICU setting, several metabolic causes of an altered level of consciousness predominate. Hypercarbic encephalopathy can present with headache, confusion, stupor, or coma. Hypoventilation syndrome occurs most frequently in patients with a history of chronic CO_2 retention who are receiving oxygen therapy for emphysema or chronic pulmonary disease **(Chap. 307)**. The elevated $Paco_2$ leading to CO_2 narcosis may have a direct anesthetic effect, and cerebral vasodilation from increased $Paco_2$ can lead to increased ICP. Hepatic encephalopathy is suggested by asterixis and can occur in chronic liver failure or acute fulminant hepatic failure. Both hyperglycemia and hypoglycemia can cause encephalopathy, as can hypernatremia and hyponatremia. Confusion, impairment of eye movements, and gait ataxia are the hallmarks of acute Wernicke's disease (see below).

SEPSIS-ASSOCIATED ENCEPHALOPATHY

Pathogenesis In patients with sepsis, the systemic response to infectious agents leads to the release of circulating inflammatory mediators that appear to contribute to encephalopathy. Critical illness, in association with the systemic inflammatory response syndrome (SIRS), can lead to multisystem organ failure. This syndrome can occur in the setting of apparent sepsis, severe burns, or trauma, even without clear identification of an infectious agent. Many patients with critical illness, sepsis, or SIRS develop encephalopathy without obvious explanation. This condition is broadly termed *sepsis-associated encephalopathy*. Although the specific mediators leading to neurologic dysfunction remain uncertain, it is clear that the encephalopathy is not simply the result of metabolic derangements of multiorgan failure. The cytokines tumor necrosis factor, interleukin (IL) 1, IL-2, and IL-6 are thought to play a role in this syndrome.

Diagnosis Sepsis-associated encephalopathy presents clinically as a diffuse dysfunction of the brain without prominent focal findings. Confusion, disorientation, agitation, and fluctuations in level of alertness are typical. In more profound cases, especially with hemodynamic compromise, the decrease in level of alertness can be more prominent, at times resulting in coma. Hyperreflexia and frontal release signs such as a grasp or snout reflex **(Chap. 32)** can be seen. Abnormal movements such as myoclonus, tremor, or asterixis can occur. Sepsis-associated encephalopathy is quite common, occurring in the majority of patients with sepsis and multisystem organ failure. Diagnosis is often difficult because of the multiple potential causes of neurologic dysfunction in critically ill patients and requires exclusion of structural, metabolic, toxic, and infectious (e.g., meningitis or encephalitis) causes. The mortality rate of patients with sepsis-associated encephalopathy severe enough to produce coma approaches 50%, although this principally reflects the severity of the underlying critical illness and is generally not a direct result of the encephalopathy. Patients dying from severe sepsis or septic shock may have elevated levels of the serum brain injury biomarker S-100β and neuropathologic findings of neuronal apoptosis and cerebral ischemic injury. Successful treatment of the underlying critical illness almost always results in substantial improvement of the encephalopathy. However, although severe disability to the level of chronic unresponsive wakeful or minimally conscious states is uncommon, long-term cognitive dysfunction clinically similar to dementia is being increasingly recognized in some survivors, especially in older patients.

OSMOTIC DEMYELINATION SYNDROME (CENTRAL PONTINE MYELINOLYSIS)

This disorder often presents in a devastating fashion as quadriplegia and pseudobulbar palsy, although less severe presentations may occur. Predisposing factors include severe underlying medical illness or nutritional deficiency; most cases are associated with rapid correction of hyponatremia or with hyperosmolar states, and clinical symptoms are usually identified a few days after sodium correction. Previously termed *central pontine myelinolysis*, the more accurate term *osmotic demyelination syndrome* is now preferred. The pathology consists of

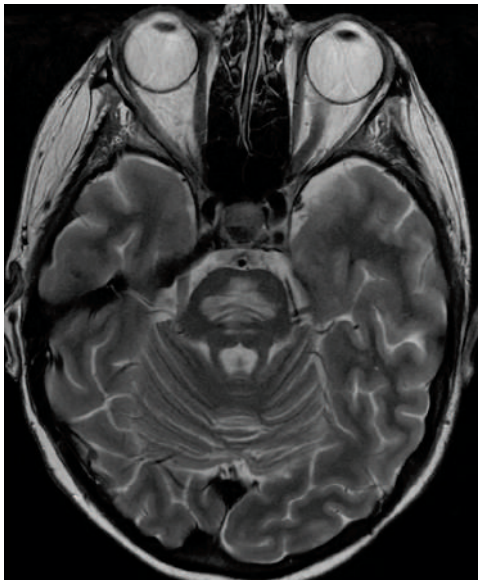

FIGURE 318-5 Osmotic demyelination syndrome. Axial T2-weighted magnetic resonance scan through the pons reveals a symmetric area of abnormal pontine high signal intensity that characteristically involves transverse pontine fibers and spares the descending corticospinal tracts. *(Image courtesy of Dr. Jared Narvid, Department of Radiology & Biomedical Imaging, University of California, San Francisco.)*

demyelination without inflammation in the base of the pons, with relative sparing of axons and nerve cells. MRI is useful in establishing the diagnosis **(Fig. 318-5)** and may also identify partial forms that present as confusion, dysarthria, and/or disturbances of conjugate gaze without quadriplegia. Occasional cases present with lesions outside of the brainstem. Therapy for the restoration of severe hyponatremia should aim for gradual correction, i.e., by ≤8 mmol/L (8 meq/L) within 24 h and 15 mmol/L (15 meq/L) within 48 h.

WERNICKE'S DISEASE

Wernicke's disease is a common and preventable disorder due to a deficiency of thiamine **(Chap. 344)**. In the United States, alcoholics account for most cases, but patients with malnutrition due to hyperemesis, starvation, renal dialysis, cancer, HIV/AIDS, or rarely gastric surgery are also at risk. The characteristic clinical triad is ophthalmoplegia, ataxia, and global confusion. However, only one-third of patients with acute Wernicke's disease present with the classic clinical triad. Most patients are profoundly disoriented, indifferent, and inattentive, although rarely they have an agitated delirium related to ethanol withdrawal. If the disease is not treated, stupor, coma, and death may ensue. Ocular motor abnormalities include horizontal nystagmus on lateral gaze, lateral rectus palsy (usually bilateral), conjugate gaze palsies, and rarely ptosis. Gait ataxia probably results from a combination of polyneuropathy, cerebellar involvement, and vestibular paresis. The pupils are usually spared, but they may become miotic with advanced disease.

Wernicke's disease is usually associated with other manifestations of nutritional disease, such as polyneuropathy. Rarely, amblyopia or myelopathy occurs. Tachycardia and postural hypotension may be related to impaired function of the autonomic nervous system or to the coexistence of cardiovascular beriberi. Patients who recover show improvement in ocular palsies within hours after the administration of thiamine, but horizontal nystagmus may persist. Ataxia improves more slowly than the ocular motor abnormalities. Approximately half recover incompletely and are left with a slow, shuffling, wide-based gait and an inability to tandem walk. Apathy, drowsiness, and confusion improve more gradually. As these symptoms recede, an amnestic state with impairment in recent memory and learning may become more apparent (*Korsakoff's psychosis*). Korsakoff's psychosis is frequently persistent; the residual mental state is characterized by gaps in memory, confabulation, and disordered temporal sequencing.

Pathology Periventricular lesions surround the third ventricle, aqueduct, and fourth ventricle, with petechial hemorrhages in occasional acute cases and atrophy of the mammillary bodies in most chronic cases. There is frequently endothelial proliferation, demyelination, and some neuronal loss. These changes may be detected by MRI **(Fig. 318-6)**. The amnestic defect is related to lesions in the dorsal medial nuclei of the thalamus.

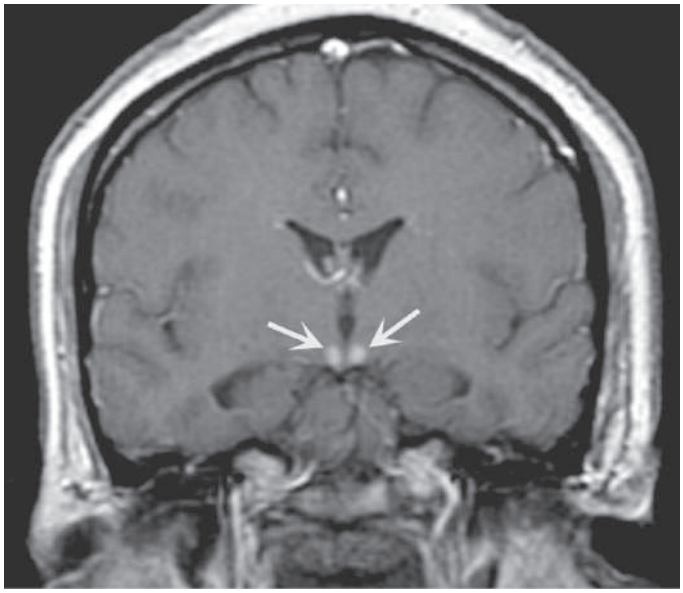

FIGURE 318-6 Wernicke's disease. Coronal T1-weighted postcontrast magnetic resonance imaging reveals abnormal enhancement of the mammillary bodies (*arrows*), typical of acute Wernicke's encephalopathy.

Pathogenesis Thiamine is a cofactor of several enzymes, including transketolase, pyruvate dehydrogenase, and α-ketoglutarate dehydrogenase. Thiamine deficiency produces a diffuse decrease in cerebral glucose utilization and results in mitochondrial damage. Glutamate accumulates due to impairment of α-ketoglutarate dehydrogenase activity and, in combination with the energy deficiency, may result in excitotoxic cell damage.

TREATMENT

Wernicke's Disease

Wernicke's disease is a medical emergency and requires immediate administration of high-dose thiamine, in a dose of 500 mg IV. The dose should be begun prior to treatment with IV glucose solutions and continued three times daily for 2–3 days. Thiamine may then be given in a dose of 250 mg IV or IM daily for 5 more days (in conjunction with other B vitamins), with oral thiamine then continued at 100 mg daily until the patient is no longer considered at risk. Glucose infusions may precipitate Wernicke's disease in a previously unaffected patient or cause a rapid worsening of an early form of the disease. For this reason, thiamine should be administered to all alcoholic patients requiring parenteral glucose.

HYPERPERFUSION DISORDERS (POSTERIOR REVERSIBLE ENCEPHALOPATHY SYNDROME)

Several seemingly diverse syndromes including hypertensive encephalopathy, eclampsia, postcarotid endarterectomy syndrome, and toxicity from calcineurin inhibitor and other medications share the common pathogenesis of hyperperfusion likely due to endothelial dysfunction. Vasogenic edema is typically the primary process leading to neurologic dysfunction, and this is thought to result from one of two mechanisms: exceeding the cerebral autoregulatory threshold leading to increased CBF and capillary leakage into the interstitium, or direct impairment of the BBB itself. The predilection of all of the hyperperfusion disorders to affect the posterior rather than anterior portions of the brain may be due to a lower threshold for autoregulatory breakthrough in the posterior circulation or a vasculopathy that is more common in these blood vessels.

TABLE 318-3 Common Etiologies of Posterior Reversible Encephalopathy Syndrome

Disorders in which increased capillary pressure dominates the pathophysiology
Hypertensive encephalopathy, including secondary causes such as renovascular hypertension, pheochromocytoma, cocaine use, etc.
Postcarotid endarterectomy syndrome
Preeclampsia/eclampsia
Disorders in which endothelial dysfunction dominates the pathophysiology
Calcineurin inhibitor toxicity (e.g., cyclosporine, tacrolimus)
Chemotherapeutic agent toxicity (e.g., cytarabine, azathioprine, 5-fluorouracil, cisplatin, methotrexate, tumor necrosis factor α antagonists)
HELLP syndrome (hemolysis, elevated liver enzyme levels, low platelet count)
Hemolytic-uremic syndrome (HUS)

These disorders of hyperperfusion can be divided into those caused primarily by increased pressure and those due to endothelial dysfunction from a toxic or autoimmune etiology **(Table 318-3)**. In reality, both of these processes likely play some role in each of these disorders. The clinical presentation of all of the hyperperfusion syndromes is similar with prominent headaches, seizures, or focal neurologic deficits. Headaches have no specific characteristics, range from mild to severe, and may be accompanied by alterations in consciousness ranging from confusion to coma. Seizures may be present, and these can be of multiple types depending on the severity and location of the edema. Nonconvulsive seizures have been described; therefore, a low threshold for obtaining an electroencephalogram (EEG) should be maintained. The typical focal deficit in hyperperfusion states is cortical visual loss, given the tendency of the process to involve the occipital lobes. However, any focal deficit can occur depending on the area affected, as evidenced by patients who, after carotid endarterectomy, exhibit neurologic dysfunction referable to the ipsilateral newly reperfused hemisphere. It appears as if the rapidity of rise, rather than the absolute value of pressure, is the most important risk factor.

MRI classically exhibits the high T2 signal of edema primarily in the posterior occipital lobes, not respecting any single vascular territory **(Fig. 318-7)**. CT is less sensitive but may show a pattern of patchy hypodensity in the involved territory. The term *posterior reversible encephalopathy syndrome* (PRES) is often used to describe these conditions; however, the clinical syndrome is not always reversible or limited just to the posterior brain regions. Vessel imaging may demonstrate narrowing of the cerebral vasculature, especially in the posterior circulation; whether this noninflammatory vasculopathy is a primary cause of the edema or occurs as a secondary phenomenon remains unclear.

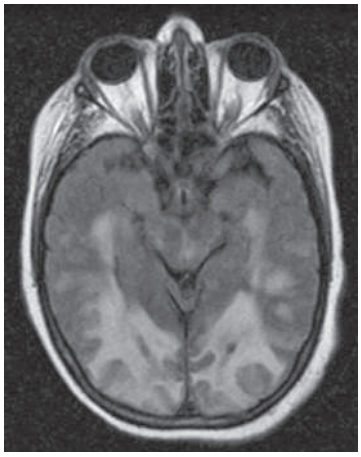

FIGURE 318-7 Axial fluid-attenuated inversion recovery (FLAIR) magnetic resonance imaging (MRI) of the brain in a patient taking cyclosporine after liver transplantation, who presented with seizures, headache, and cortical blindness. Increased signal is seen bilaterally in the occipital lobes predominantly involving the white matter, consistent with a hyperperfusion state secondary to calcineurin inhibitor exposure.

Other ancillary studies such as CSF analysis often yield nonspecific results. Many of the substances that have been implicated, such as cyclosporine, can cause this syndrome even at low doses or after years of treatment. Therefore, normal serum levels of these medications do not exclude them as inciting agents.

Treatment involves judicious lowering of the blood pressure with IV agents such as labetalol or nicardipine, removal of the offending medication, and treatment of an underlying medical condition such as eclampsia. If the blood pressure is very elevated, it is reasonable to lower the MAP by ~20% initially, as further lowering of the pressure may cause secondary ischemia and possibly infarction as pressure drops below the lower range of the patient's autoregulatory capability. Seizures must be identified and controlled, often necessitating continuous EEG monitoring. Anticonvulsants are effective when seizure activity is identified, but in the special case of eclampsia, there is evidence to support the use of magnesium sulfate for seizure control.

POST–SOLID ORGAN TRANSPLANT BRAIN INJURY

Immunosuppressive medications are administered in high doses to patients after solid organ transplant, and many of these compounds have well-described neurologic complications. In patients with headache, seizures, or focal neurologic deficits taking calcineurin inhibitors, the diagnosis of hyperperfusion syndrome should be considered, as discussed above. This neurotoxicity occurs mainly with cyclosporine and tacrolimus and can present even in the setting of normal serum drug levels. Treatment primarily involves lowering the drug dosage or discontinuing the drug. Sirolimus has very few recorded cases of neurotoxicity and may be a reasonable alternative for some patients. Another example of an immunosuppressive medication with neurologic complications is the leukoencephalopathy seen with methotrexate, especially when it is administered intrathecally or with concurrent radiotherapy. In any solid organ transplant patient with neurologic complaints, a careful examination of the medication list is required to search for these possible drug effects.

Cerebrovascular complications of solid organ transplant are often first recognized in the immediate postoperative period. Border zone territory infarctions can occur, especially in the setting of systemic hypotension during cardiac transplant surgery. Embolic infarctions classically complicate cardiac transplantation, but all solid organ transplant procedures place patients at risk for systemic emboli. When cerebral embolization accompanies renal or liver transplantation surgery, a careful search for right-to-left shunting should include evaluation of the heart with agitated saline echocardiography (i.e., "bubble study"), as well as looking for intrapulmonary shunting. Renal and some cardiac transplant patients often have advanced atherosclerosis, providing a risk for stroke. Imaging with CT or MRI should be done when cerebrovascular complications are suspected to confirm the diagnosis and to exclude intracerebral hemorrhage, which most often occurs in the setting of coagulopathy secondary to liver failure or after cardiac bypass procedures.

Given that patients with solid organ transplants are chronically immunosuppressed, infections are a common concern **(Chap. 148)**. In any transplant patient with new CNS signs or symptoms such as seizure, confusion, or focal deficit, the diagnosis of a CNS infection should be considered and evaluated through imaging (usually MRI) and possibly LP. The most common pathogens responsible for CNS infections in these patients vary based on time since transplant. In the first month posttransplant, common pathogens include the usual bacterial organisms associated with surgical procedures and indwelling catheters. Starting in the second month posttransplant, opportunistic infections of the CNS become more common, including *Nocardia* and *Toxoplasma* species as well as fungal infections such as aspergillosis. Viral infections that can affect the brain of the immunosuppressed patient, such as herpes simplex virus, cytomegalovirus, human herpesvirus type 6 (HHV-6), and varicella, also become more common after the first month posttransplant. Beyond 6 months, immunosuppressed posttransplant patients still remain at risk for these opportunistic bacterial, fungal, and viral infections but can also suffer late CNS infectious complications such as progressive multifocal leukoencephalopathy

(PML) associated with JC virus **(Chap. 142)** and Epstein-Barr virus–driven clonal expansions of B cells resulting in posttransplant lymphoproliferative disorder or CNS lymphoma **(Chap. 95)**.

CNS COMPLICATIONS OF CHECKPOINT INHIBITOR AND CHIMERIC ANTIGEN RECEPTOR T-CELL THERAPY

Cancer immunotherapy is now a widely used treatment for both solid tumors and hematologic malignances. Two types of this immunotherapy, checkpoint inhibitors and chimeric antigen receptor (CAR) T-cell (CAR-T) therapy, can carry significant neurologic toxicity that may manifest as encephalopathy, cerebral edema, or white matter demyelination. These complications may be severe and require neurocritical care evaluation and intervention.

Immune checkpoint inhibitors are monoclonal antibodies that bind to normally occurring checkpoint proteins such as PD-1, PD-L1, and CTLA-4, thereby freeing T cells to attack cancerous cells. Currently available checkpoint inhibitors include pembrolizumab, nivolumab, cemiplimab, atezolizumab, avelumab, durvalumab, and ipilimumab. Common side effects are diarrhea, rash, and pneumonitis. Neurologic side effects occur in ~5% of patients treated with monotherapy and ~10% undergoing combination therapy, presumably as a result of shared antigens between tumor cells and self, leading to an autoimmune process **(Chap. 99)**. CNS adverse events include limbic encephalitis, cerebellitis, and myelitis. A clinical syndrome of encephalopathy, memory disturbances, and seizures may occur. Peripheral nervous system complications such as myasthenia gravis, myositis, and neuropathy have also been described and may be even more common than CNS manifestations.

Patients who develop CNS neurologic symptoms while on checkpoint inhibitor treatment should undergo MRI studies of the brain or spinal cord, based on clinical symptoms. Mesial temporal lobe hyperintensities and a lymphocytic CSF pleocytosis may be present. EEG may be appropriate to evaluate for subclinical seizures. Various autoantibodies such as anti-Ma2, anti-GFAP, anti-Hu, and anti-CASPR2 have been described but are not required for diagnosis. Treatment consists of discontinuing the checkpoint inhibitor and administering high-dose glucocorticoids. Intravenous immunoglobulins and plasmapheresis have been used in severe cases. For mild cases, restarting the checkpoint inhibitor may be considered; however, relapse with fatal necrotizing encephalitis has been described. Given that checkpoint inhibitor–treated patients are immunocompromised, before checkpoint inhibitor–related neurotoxicity is diagnosed, it is imperative to rule out an alternative diagnosis such as cerebral metastases, infection, or stroke.

CAR-T therapy for leukemia or lymphoma involves removing a patient's T cells and genetically engineering them using a disarmed virus to produce surface chimeric antigen receptors that, when given back to the patient, recognize antigens on tumor cells. CAR-T therapy is frequently associated with significant side effects, which usually occur as either cytokine release syndrome (CRS) or neurotoxicity. These two types of CAR-T side effects are distinct but often occur in the same patient, and both occur within days of initiation of CAR-T treatment. CRS is a clinical syndrome of hypotension, fever, and hypoxia, which may have associated multiorgan dysfunction. CRS occurs in 80–100% of CAR-T–treated patients and is due to widespread release of proinflammatory cytokines. Treatment is with the IL-6 receptor pathway blocker tocilizumab, which can alleviate CRS symptoms without impairing the antitumor efficacy of the CAR-T cells; glucocorticoids may also be administered.

CAR-T neurotoxicity is less common but still occurs in more than half of treated patients. Clinical manifestations may include headache, encephalopathy, aphasia, seizures, tremors, and life-threatening cerebral edema. Predictors of occurrence of neurotoxicity include earlier and more severe CRS, fever, elevated C-reactive protein and serum ferritin, and older patient age. Treatment of CAR-T neurotoxicity also involves administration of tocilizumab (as most of these patients also have CRS) and glucocorticoids. In addition to these treatments, patients with CAR-T neurotoxicity should also undergo brain imaging and EEG if indicated based on symptoms, with concurrent treatment of cerebral edema and seizures if present.

CRITICAL CARE DISORDERS OF THE PERIPHERAL NERVOUS SYSTEM

Critical illness with disorders of the peripheral nervous system (PNS) arises in two contexts: (1) primary neurologic diseases that require critical care interventions such as intubation and mechanical ventilation, and (2) secondary PNS manifestations of systemic critical illness, often involving multisystem organ failure. The former include acute polyneuropathies such as Guillain-Barré syndrome **(Chap. 458)**, neuromuscular junction disorders including myasthenia gravis **(Chap. 459)** and botulism **(Chap. 158)**, and primary muscle disorders such as polymyositis **(Chap. 377)**. The latter result either from the systemic disease itself or as a consequence of interventions and as a group are often referred to as ICU-acquired weakness (ICUAW).

General principles of respiratory evaluation in patients with PNS involvement, regardless of cause, include assessment of pulmonary mechanics, such as maximal inspiratory force (MIF) and vital capacity (VC), and evaluation of strength of bulbar muscles. Regardless of the cause of weakness, endotracheal intubation should be considered when the MIF falls to below –25 cmH_2O or the VC is <1 L. Also, patients with severe palatal weakness may require endotracheal intubation in order to prevent acute upper airway obstruction or recurrent aspiration. Arterial blood gases and oxygen saturation from pulse oximetry are used to follow patients with potential respiratory compromise from PNS dysfunction. However, intubation and mechanical ventilation should be undertaken based on clinical assessment rather than waiting until oxygen saturation drops or CO_2 retention develops from hypoventilation. Noninvasive mechanical ventilation may be considered initially in lieu of endotracheal intubation in myasthenia gravis but is generally insufficient in patients with severe bulbar weakness or ventilatory failure with hypercarbia. **Principles of mechanical ventilation are discussed in Chap. 313.**

NEUROPATHY

Although encephalopathy may be the most obvious neurologic dysfunction in critically ill patients, dysfunction of the PNS is also quite common. It is typically present in patients with prolonged critical illnesses lasting several weeks and involving sepsis; clinical suspicion is aroused when there is failure to wean from mechanical ventilation despite improvement of the underlying sepsis and critical illness. *Critical illness polyneuropathy* refers to the most common PNS complication related to critical illness; it is seen in the setting of prolonged critical illness, sepsis, and multisystem organ failure. Neurologic findings include diffuse weakness, decreased reflexes, and distal sensory loss. Electrophysiologic studies demonstrate a diffuse, symmetric, distal axonal sensorimotor neuropathy, and pathologic studies have confirmed axonal degeneration. The precise mechanism of critical illness polyneuropathy remains unclear, but circulating factors such as cytokines, which are associated with sepsis and SIRS, are thought to play a role. It has been reported that up to 70% of patients with the sepsis syndrome have some degree of neuropathy, although far fewer have a clinical syndrome profound enough to cause severe respiratory muscle weakness requiring prolonged mechanical ventilation or resulting in failure to wean. Aggressive glycemic control with insulin infusions appears to decrease the risk of critical illness polyneuropathy. Treatment is otherwise supportive, with specific intervention directed at treating the underlying illness. Although spontaneous recovery is usually seen, the time course may extend over weeks to months and necessitate long-term ventilatory support and care even after the underlying critical illness has resolved.

DISORDERS OF NEUROMUSCULAR TRANSMISSION

A defect in neuromuscular transmission may be a source of weakness in critically ill patients. Botulism **(Chap. 158)** may be acquired by ingesting botulinum toxin from improperly stored food or may arise from an anaerobic abscess from *Clostridium botulinum* (wound botulism). Infants

can present with generalized weakness from gut-derived *Clostridium* infection, especially if they are fed honey. Diplopia and dysphagia are early signs of food-borne botulism. Treatment is mostly supportive, although use of antitoxin early in the course may limit the duration of the neuromuscular blockade. General ICU care is similar to patients with Guillain-Barré syndrome or myasthenia gravis with focused care to avoid ulcer formation at pressure points, deep venous thromboprophylaxis, and infection prevention. Public health officers should be rapidly informed when the diagnosis is made to prevent further exposure to others from the tainted food or source of wound botulism (such as injection drug use).

Undiagnosed myasthenia gravis **(Chap. 459)** may be a consideration in weak ICU patients; however, persistent weakness secondary to impaired neuromuscular junction transmission is almost always due to administration of drugs. A number of medications impair neuromuscular transmission; these include antibiotics, especially aminoglycosides, and beta-blocking agents. In the ICU, the nondepolarizing neuromuscular blocking agents (nd-NMBAs), also known as muscle relaxants, are most commonly responsible. Included in this group of drugs are such agents as pancuronium, vecuronium, rocuronium, and cisatracurium. They are often used to facilitate mechanical ventilation or other critical care procedures, but with prolonged use, persistent neuromuscular blockade may result in weakness even after discontinuation of these agents hours or days earlier. Risk factors for this prolonged action of neuromuscular blocking agents include female sex, metabolic acidosis, and renal failure.

Prolonged neuromuscular blockade does not appear to produce permanent damage to the PNS. Once the offending medications are discontinued, full strength is restored, although this may take days. In general, the lowest dose of neuromuscular blocking agent should be used to achieve the desired result, and when these agents are used in the ICU, a peripheral nerve stimulator should be used to monitor neuromuscular junction function.

MYOPATHY

Critically ill patients, especially those with sepsis, frequently develop muscle weakness and wasting, often in the face of seemingly adequate nutritional support. *Critical illness myopathy* is an overall term that describes several different discrete muscle disorders that may occur in critically ill patients. The assumption has been that a catabolic myopathy may develop as a result of multiple factors, including elevated cortisol and catecholamine release and other circulating factors induced by the SIRS. In this syndrome, known as *cachectic myopathy*, serum creatine kinase levels and electromyography (EMG) are normal. Muscle biopsy shows type II fiber atrophy. Panfascicular muscle fiber necrosis may also occur in the setting of profound sepsis. This less common *acute necrotizing intensive care myopathy* is characterized clinically by weakness progressing to a profound level over just a few days. There may be associated elevations in serum creatine kinase and urine myoglobin. Both EMG and muscle biopsy may be normal initially but eventually show abnormal spontaneous activity and panfascicular necrosis with an accompanying inflammatory reaction. Acute rhabdomyolysis can occur from alcohol ingestion or from compartment syndromes.

A *thick-filament myopathy* may occur in the setting of glucocorticoid and nd-NMBA use. The most frequent scenario in which this is encountered is the asthmatic patient who requires high-dose glucocorticoids and nd-NMBA to facilitate mechanical ventilation. This muscle disorder is not due to prolonged action of nd-NMBAs at the neuromuscular junction but, rather, is an actual myopathy with muscle damage; it has occasionally been described with high-dose glucocorticoid use or sepsis alone. Clinically this syndrome is most often recognized when a patient fails to wean from mechanical ventilation despite resolution of the primary pulmonary process. Pathologically, there may be loss of thick (myosin) filaments. Thick-filament critical illness myopathy has a good prognosis. If patients survive their underlying critical illness, the myopathy invariably improves and most patients return to normal. However, because this syndrome is a result of true muscle damage, not just prolonged blockade at the neuromuscular junction, this process may take weeks or months, and tracheotomy with prolonged ventilatory support may be necessary. Some patients do have residual long-term weakness, with atrophy and fatigue limiting ambulation. At present, it is unclear how to prevent this myopathic complication, except by avoiding use of nd-NMBAs, a strategy not always possible. Monitoring with a peripheral nerve stimulator can help to avoid the overuse of these agents. However, this is more likely to prevent the complication of prolonged neuromuscular junction blockade than it is to prevent this myopathy.

319 Approach to the Patient with Renal Disease or Urinary Tract Disease

Julian L. Seifter

The upper urinary tract consists of the kidneys, their vasculature, the renal parenchyma, and its collecting system. The lower urinary tract is composed of the peristaltic ureters from each kidney; the bladder, which receives and stores urine from each ureter; and the urethra, which, upon bladder contraction, excretes the final urine. The excretory system begins with a plasma ultrafiltrate from renal cortical glomeruli, modified by the renal tubules of the nephron, and ends with the excretion of urinary water and solutes.

Disease at any level of these functional structures may be asymptomatic at patient presentation or may cause nonspecific complaints such as fatigue. There may be signs that are highly specific for a site of dysfunction (such as proteinuria or polyuria), or referable to a structure (but not diagnostic of a particular disease), or highly characteristic of a specific diagnosis (such as polycystic kidney disease). Patients with a disorder of the kidney may present without symptoms but with signs of urinary tract disease (such as painless microhematuria or an incidental mass noted on an abdominal imaging study).

It is especially important to perform renal testing in patients with systemic disease; for example, routine screening for microalbuminuria and an estimated glomerular filtration rate (eGFR) in diabetes mellitus (DM). One should look at renal function when a patient's history includes known risk for renal or urinary tract complications, for example, lithium for psychiatric treatment, occupational use of lead, or, in the case of bladder cancer, exposure to aniline dyes. This chapter will address an approach to patients with and without known history of kidney disease, as well as those who have one of a wide variety of systemic illnesses that involve the kidney or the lower urinary tract.

To begin with the evaluation of renal disorders, note that it is time-consuming and wasteful to do random testing prematurely, which would generate a very long list of potential diagnoses. A better approach is to review the evidence from the history, physical examination, and basic laboratory studies to arrive at a logical basis for targeted tests that would identify a particular disease process (Table 319-1). The findings are influenced by the regions of the kidney that are involved and by factors such as family history, toxic exposures, the patient's birth weight for gestational age, and time course of any findings. As a rule, kidney diseases that begin primarily with glomerular dysfunction have albuminuria as the hallmark, whereas kidney diseases that begin in the tubular structures may present primarily with electrolyte disorders or disorders of dilution and concentration of the urine. In both glomerular and tubular disorders, upon progressing to chronic disease, the distinction is more difficult because glomerular diseases eventually affect the tubular interstitium and tubular diseases progress to glomerular dysfunction and scarring.

The complement cascade (a name suggestive of the torrents of a waterfall) has been implicated in a number of diseases via successive steps of activation and amplification of proinflammatory complement proteins. The complement cascade has three pathways, the classical, the alternative, and the lectin-binding, each of which can cause disease if the pathway is dysregulated. In the alternative pathway, the activating signal for producing complement to augment (i.e., complement) the inflammatory response is the presence of circulating antigen-antibody immune complexes. The sites of inflammation are tissue deposits of these complexes. Though immune complex deposition is not specific to the kidney, as a pathologic finding, its presence has great diagnostic and mechanistic value for many forms of systemic and nonsystemic renal disease, encompassing glomerular, tubular, and vascular structures. In the process of stepwise activation of complement, components are released into the circulation primarily from hepatocytes.

Complement component C3 is an important protein in the classical, alternative, and lectin pathways. In the presence of C3 convertase, C3 yields C3a and C3b, the latter of which has further proinflammatory effects: an amplification loop for C3, production of C4 and C5, activation of antibody production, formation of the membrane attack complex (C5b-9), and augmentation of immune complex clearance. In the alternative complement cascade, the heightened proinflammatory response, as seen in a positive feedback loop, circumvents proinflammatory excess by several inhibitory effects of hereditary factors D, H and I. An unsuppressed proinflammatory cycle could lead to life-threatening endothelial damage, which underlies the damage caused by interaction with the coagulation cascade causing thrombotic microangiopathies (TMAs), including thrombotic thrombocytopenic purpura (TTP). The latter is deficient in AdamTS13, an enzyme that inhibits shortening of Von Willebrand factor (VWF), polymer that in its normal length attracts platelets and thus prevents clotting. Failure to find a low level of AdamTS13 in the blood introduces the possibility of atypical HUS. These disease

TABLE 319-1 Acute Kidney Injury

FEATURES	PRERENAL	RENAL	POSTRENAL
Context	Heart failure, hepatic failure, burns, shock, post-op, dehydration, renovascular disease, vascular, drugs	ATN, bilateral cortical necrosis, AIN, crush injuries, myoglobulinuria, hemoglobinuria, ischemia, sepsis, recent contrast drugs	Bladder outlet obstruction, obstruction of solitary kidney, abdominal mass, bilateral stones, drugs
Urine output	Oliguria (usually <500 mL/d) Anuria	Oliguria Normal Polyuria	Anuria Polyuria Both
Clinical history and exam	Trauma, shock, hypotension, burns, GI, sweat, or renal losses	Rhabdomyolysis, hemolysis, thrombotic microangiopathy, AIN, atheroemboli	Extrinsic ureteral obstruction retroperitoneal disease, bladder outlet or urethral obstruction by prostate or cervical cancer
Urinalysis	Concentrated acid urine, hyaline casts, crystalluria	"Muddy brown" granular casts, hematuria, dysmorphic RBCs, RBC casts in GN, WBC casts in AIN, eosinophils in atheroemboli	Intrarenal obstruction by uric acid or CaPhos in tumor lysis syndrome, blood clots in lower urinary tract bleeding, CaOx after ethylene glycol ingestion
Urine chemistry	Low FENa ≤1%, U/P Cr ≥40, UNa ≤10, U/P Osm ≥1	FENa 1–3%, U/P Cr ≤40, UOsm ~isosmotic	Early looks like prerenal, late looks like renal
Laboratory studies	High BUN/Cr ratio, usually hypercatabolic with increased uric acid; may have hyper- or hyponatremia	May have eosinophilia in allergic AIN, high phosphate, low Ca, high PTH, metabolic acidosis	Hydronephrosis on ultrasound, extrinsic or intrinsic diseases on CT scan, tumors on MRI

Abbreviations: AIN, acute interstitial nephritis; ATN, acute tubular necrosis; BUN, blood urea nitrogen; Ca, calcium; CaPhos, calcium phosphate; Cr, creatinine; CT, computed tomography; FENa, fractional excretion of sodium, GI, gastrointestinal; GN, glomerulonephritis; MRI, magnetic resonance imaging; PTH, parathyroid hormone; RBC, red blood cell; U/P, urine/plasma; WBC, white blood cell.

syndromes consist of the triad of microangiopathic hemolytic anemia (with schistocytes, high serum lactate dehydrogenase, and low haptoglobin), thrombocytopenia, and end-organ dysfunction (skin, gastrointestinal, renal, and central nervous systems). Some hereditary diseases have now been recognized as dysregulation of the complement cascade, with a failure to modulate a complement-mediated inflammatory response. Investigations of immune complex disease such as lupus (systemic lupus erythematosus [SLE]), syphilis, and cryoglobulinemia have shed light on the role of complement in the activity of these disorders. Many inhibitors including C3 and C5 convertase have been investigated because of potential drug therapies to correct dysregulation. Serum complement is usually low in these immune complex diseases.

In the following discussion, the focus is on symptoms and signs that constitute the major syndromes observed in the patient with kidney or lower urinary tract disease. These syndromes are the foundation for the diagnosis of particular diseases. Emphasis will be on new classifications of disease, a better understanding of the role of complement and its dysregulation in nephrologic disorders, use of biomarkers, and the impact of genomic knowledge on the expression, identification, and treatment of disorders.

NEPHRITIC SYNDROMES

Nephritis literally means an inflammatory condition of the kidney. Nephritic inflammation may occur in association with infection, allergic response to medications, systemic autoimmune disorders, or toxic exposures. The kidneys may be one of many organs, or the only organ, involved in the inflammatory disorder. Inflammation with enlargement of the kidneys is often associated with point tenderness over the flank and sometimes exquisite costovertebral angle tenderness, requiring gentle palpation for diagnosis.

Nephritic syndromes can be further subdivided depending on the inflamed structures within the kidney, including glomerular, tubulointerstitial, and vascular; and on the time course of progression of the inflammatory process, which may be acute, subacute, or chronic.

GLOMERULONEPHRITIS

Classification of glomerulonephritis (GN) has been challenging because of overlapping features of infection-related and immunologic-mediated pathology. GN is associated with hypertension, volume expansion, and an abnormal urinalysis. In most cases, the volume expansion manifests as edema and hypertension; in the child, ascites may develop; and in the elderly, restlessness and anxiety may be the first signs of incipient acute pulmonary edema. There may be orthopnea at night or dyspnea on exertion, with or without significant peripheral edema. Acute GN is usually associated with low urine output (oliguria) or, at times, complete anuria, low urine sodium content, and concentrated urine, resulting in the retention of salt and water. It is vital to observe a spun urinary sediment to diagnose active GN.

The disease presentation may be acute or subacute, occurring over days or weeks, as in postinfectious GN, or as a chronic, smoldering process with inexorable progression to chronic kidney failure over several months to years. The pathologic correlate of these presentations—the relative amount of acute inflammatory, proliferative, or necrotizing lesions in renal tissue versus chronic sclerotic and atrophic findings on renal biopsy—reflects the acuity versus chronicity of disease. Therefore, in these progressive destructive conditions, early diagnosis is critical, and treatment for acute reversible disease should be instituted as quickly as possible.

The evaluation of the findings on history, physical examination, and urinalysis in narrowing diagnostic possibilities for a specific etiology of the glomerular syndromes is demonstrated in **Fig. 319-1**. The nephritic urinalysis shows hematuria, proteinuria, cells or clumps of cells, and cellular casts in the spun urinary sediment. The cells in the urine are usually a mixture of red blood cells (hematuria) and inflammatory cells (pyuria), including polymorphonuclear (PMN) leukocytes. Microscopic hematuria is invisible to the naked eye, as opposed to macroscopic hematuria, which is often described as cola or "tea-colored" urine, caused by hemoglobin entering an acid urine, forming hematin. The process of urinary erythrocytes crossing the glomerular membrane barrier causes the red blood cells to become misshapen or dysmorphic. It is unusual in these nephritic syndromes to see blood clots or gross hematuria, a term used for overtly blood-red urine that is often accompanied by dysuria and characterizes trauma and other syndromes of lower urinary tract bleeding. However, in episodes of immunoglobulin A (IgA) nephropathy, glomerular hematuria is often gross as red blood cells traverse diseased glomerular basement membrane (GBM).

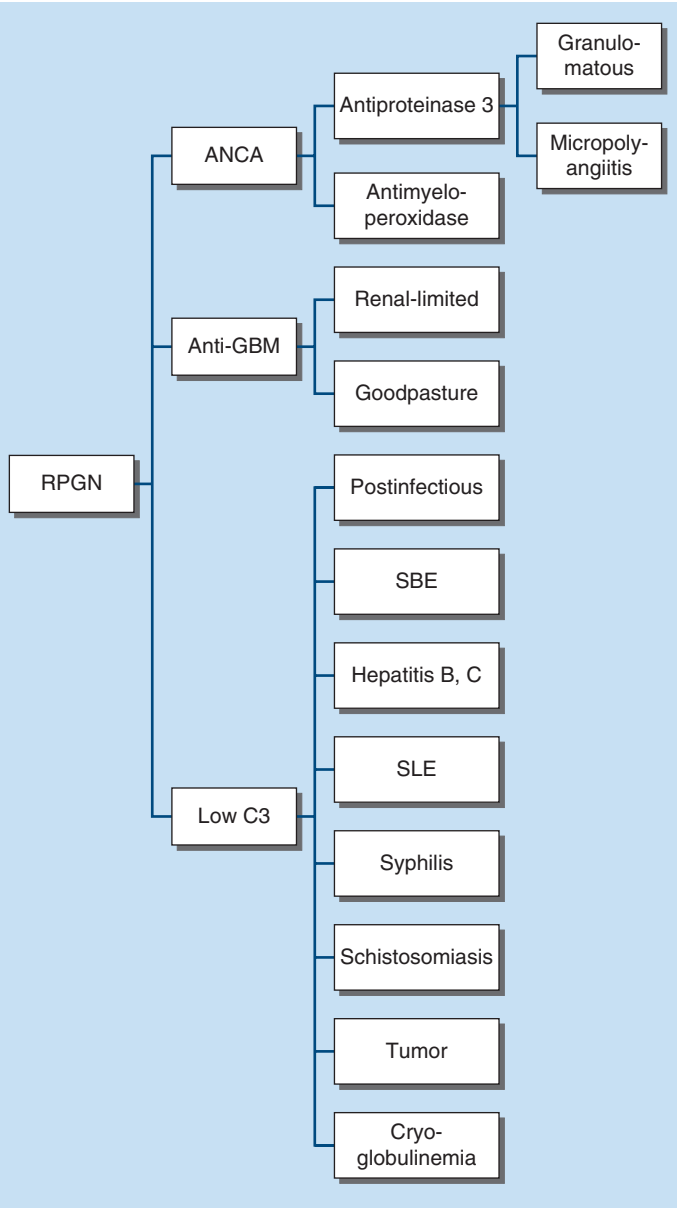

FIGURE 319-1 Rapidly progressive glomerulonephritis (RPGN). The syndrome of RPGN is diagnosed clinically. The three major categories are the antineutrophilic cytoplasmic antibodies (ANCAs; ANCA-positive vasculitides), anti–glomerular basement membrane antibody-positive (anti-GBM), and immune complex disorders with low C3 complement. C3 is synthesized in the liver, bound to circulating infectious or neoplastic antigens with their antibody complexes, deposited in the glomerular subendothelium, and associated with nonrenal manifestations. Syphilis is usually accompanied by vasculitis, and cryoglobulins may be seen in the setting of hepatitis C or myeloma and often lower C4 as well. SBE, subacute bacterial endocarditis; SLE, systemic lupus erythematosus.

Postinfectious Glomerulonephritis In postinfectious glomerulonephritis (PIGN), the classic example of acute GN, the immune response involves formation of antibody-bacterial antigen complexes within the circulation, usually 10 days to 3 weeks after infection of the pharynx or skin (as in impetigo) by specific nephritogenic strains of β-hemolytic group A streptococci. The deposition of these immune complexes amplifies and activates the complement cascade, causing an intense inflammatory response that accounts for the active (nephritic) sediment in the urine and decreased circulating C3 levels in the blood. The cellular proliferation is intense enough to minimize filtering

surface area, causing a prerenal retention of Na^+ and water, oliguria, and sometimes anuria. Pathologically, the proliferation disrupts capillary blood flow, hence the description of "bloodless capillaries" for this condition.

In the general population, the incidence of PIGN has decreased given the widespread availability of antibiotics, specifically the penicillins and sulfa drugs. At the time of presentation with renal findings, there may be no ongoing infection, but rather a continued immune response to specific bacterial antigens. Antibiotics may not be necessary if the infection has resolved. Evidence indicating the initial infection may still be present in the form of titers of streptozyme, anti–streptolysin O, and anti–deoxyribonuclease B. Upon deposition, the circulating immune complexes bind and activate C3 complement, which, with other cytokines, causes a proliferative pattern of injury with subendothelial glomerular deposits. Taken together, there is increased clearance of total hemolytic complement and C3, causing hypocomplementemia. Over time, subepithelial deposits known as humps develop and proteinuria increases. As subendothelial deposits clear, nephritic signs disappear. Infective endocarditis, both acute and subacute, may also result in circulating immune complexes even while the patient remains on antibiotic treatment. These glomerulonephritic conditions are also recognized clinically by low C3 complement levels in the blood.

In PIGN, the postinfectious cases should be distinguished from cases of *infection-associated* GN that occur during an ongoing infection, such as a staphylococcal (often methicillin-resistant *Staphylococcus aureus*) abscess, osteomyelitis, or empyema, which are treated with antibiotics and purulent drainage and are characteristically associated with IgA deposition in the glomeruli. PIGN is also to be distinguished from synpharyngitic hematuria, another glomerular syndrome that frequently produces a heavier excretion of red blood (gross hematuria), which may appear to the patient as a frightening hemorrhage. The patient may present with this concern, so it is important for the clinician to recognize that as little as 10–20 mL of blood will turn a liter of urine red. Synpharyngitic hematuria, usually occurring simultaneously with, or 1–3 days into, a viral pharyngitis, is most often related to IgA nephropathy (IgAN) rather than PIGN. Though C3 complement is deposited in both PIGN and IgAN, only PIGN is associated with low complement levels in the blood.

IgAN is one of the leading causes of renal failure worldwide and is a common type of GN that is caused by the mesangial deposition of C3 binding to excess galactose-deficient IgA-1 immunoglobulin. This results in damage to the basement membrane, manifesting as hematuria and renal insufficiency. Although IgAN is a common disease, particularly in Asia, data on prevalence are often based on clinical assumptions rather than kidney biopsy and, therefore, are inaccurate. Treatment is based on each patient's personal presentation, but all patients need management of hypertension and proteinuria, often with anti–angiotensin II inhibitors. Because of its association with viral infections, IgAN has historically been treated with removal of lymphoid tissue with strategies such as tonsillectomy. Other treatments have included fish oils and corticosteroids. However, recent advances in understanding the lectin and alternative pathways of complement have led to investigation of targeted therapies based on kidney biopsies showing IgA-1 and glomerular deposition of mannan-binding lectin, which occurs in 50% of patients with IgAN. Complement blockers, B-cell therapies, and plasma cell therapies are currently either in use or being further investigated to treat patients with a genetic predisposition for high levels of galactose-deficient IgA-1 in order to antagonize development of autoantibodies to the abnormal IgA1 or to interfere with the proinflammatory complement binding to the largely mesangial deposits of the immune complexes. Avacopan, a selective C5a receptor inhibitor effective in treating antineutrophil cytoplasmic antibody-associated (ANCA)-vasculitis, lowers proteinuria in IgAN nephropathy.

The U.S. Food and Drug Administration has recently approved an oral dual endothelin 1 and angiotensin II receptor antagonist for the reduction of proteinuria in adults with primary IgAN at high risk for rapid disease progression. These individuals typically have a urine protein-to-creatinine ratio of >1.5 g/g and decreased GFR. Patients with chronic kidney disease and either micro- or macrohematuria as a sign of disease have been less likely to receive a renal biopsy than patients with azotemia or proteinuria. Increasing appreciation that patients with IgAN have a more rapid GFR decline to end-stage kidney disease has encouraged greater use of renal pathology to guide a more aggressive management strategy. Attention to risk factors and advances in development of novel pharmacologic approaches based on a better understanding of the pathogenesis of IgAN have led to greater judgement to perform a renal biopsy for diagnosis and treatment. Increasing appreciation that patients with IgAN, particularly those of African ancestry with high-risk APOL1 alleles have a more rapid GFR decline, and clinicians are encouraged to make use of renal pathology to guide a more aggressive management strategy.

Rapidly Progressive Glomerulonephritis (RPGN) Rapidly progressive glomerulonephritis (RPGN) is a syndrome arising from a variety of causes (Fig. 319-1). Pathologically, it is associated with a proliferation of glomerular parietal epithelial cells and inflammatory cells, known as cellular crescents, that surround and compress the capillaries, reducing the filtration surface area. Over time, the crescents become fibrotic and atrophic with global loss of the glomerular tuft. When >50% of glomeruli are affected (diffuse), this highly destructive process usually leads to global glomerulosclerosis. When <50% of glomeruli are acutely affected (focal) and only part of each glomerulus (segment) is involved, a condition known as focal and segmental necrotizing GN develops, with or without crescents. When such lesions heal, focal segmental glomerulosclerosis (FSGS) results. This pathological finding on biopsy must be distinguished from the primary podocytopathy (FSGS that causes nephrotic syndrome) and from adaptive changes seen in most progressive chronic kidney diseases. Recognition of RPGN and choice of appropriate therapy are extremely important because, if left unchecked, the capillaritis can lead to complete and irreversible loss of kidney function, as well as fatal pulmonary hemorrhage when associated with lung vasculitis.

In the case of RPGN, one may see the typical signs of the nephritic syndrome, usually with subnephrotic proteinuria, although other clues to diagnosis may be present in pulmonary-renal syndromes, where the patient may present with hemoptysis, interstitial lung disease, epistaxis, or upper airway symptoms of sinusitis or nasal congestion. Blood testing, including at least three necessary immunologic studies, help narrow the differential diagnosis. The antineutrophil cytoplasmic antibody (ANCA) test, particularly anti-proteinase-3 antibodies (cANCA) or anti-myeloperoxidase (pANCA), is diagnostic for the pauci-immune disorders of systemic vasculitis, such as granulomatous vasculitis (formerly known as Wegener's granulomatosis), giant cell arteritis, and microscopic polyangiitis, which are particularly associated with pulmonary and upper respiratory disease. In ANCA-positive diseases, the kidney and peripheral vessels are the target of autoantibodies, which attract complement and result in inflammatory vasculitis. Churg-Strauss syndrome, which is both granulomatous and eosinophilic, is a vasculitis associated with asthma.

By contrast, a positive test for anti-GBM antibodies, with or without a positive ANCA, would be consistent with renal-limited anti-GBM disease. One key distinction between ANCA-positive vasculitis and anti-GBM disease is that the vasculitides may recur, even subclinically historically at different times, whereas onset of anti-GBM is usually a single acute fulminant presentation that must be diagnosed rapidly with the ANCA and anti-GBM studies and renal pathology and treated promptly with plasma exchange followed by anti-inflammatory medication and cyclophosphamide or rituximab as immunotherapy to preserve kidney function. A positive anti-GBM test, when associated with pulmonary hemorrhage, is consistent with Good pasture disease, which is a disorder most often seen in an elderly population or in young males who smoke or have a history of inhaling hydrocarbon solvents. Not infrequently, both anti-GBM and ANCA are present with pathology showing pauci-immune disease, where the proposed role of ANCA is to expose the GBM epitope. This disorder should be treated in the same way as ANCA itself. The goal of plasmapheresis is to

remove all of the GBM autoantibody, which may take weeks to months. The circulating IgG anti-GBM, complexed in situ with C3 complement, is directed at an epitope in the α3 chain of the non-collagenous domain of Type 4 collagen in the basement membrane. This occurs at the site absent in hereditary nephritis. People with hereditary nephritis do not develop anti-GBM disease; however, if they receive a kidney in which the donor kidney contains the missing antigen, they may present with fulminant anti-GBM disease.

The immune complex diseases that may also manifest as RPGN may have low circulating levels of the third component of complement (C3) secondary to focal or diffuse immune complex deposits in the glomerular capillary subendothelial space. Certain of these disorders, such as SLE and cryoglobulinemia, can present with pulmonary hemorrhage. Patients with cryoglobulinemia often have low C4 complement and a high rheumatoid factor, and the syndrome may be caused by paraproteinemias or hepatitis C. Another cause of crescentic RPGN but with normal levels of C3 complement is a form of IgA vasculitis (Henoch-Schönlein purpura), a syndrome of skin vasculitis characterized by palpable purpura, gastrointestinal bleeding, arthralgias, and pulmonary hemorrhage. The C3 complement (also an acute-phase reactant) is detected on the kidney biopsy, particularly with galactose-deficient IgA1, in the mesangium rather than the capillary loops, and is associated with mesangial cell proliferation but not with low serum levels of C3 or IgA. The diagnostic tests and distinct diseases associated with these immune complex disorders are shown in Fig. 319-1.

ACUTE TUBULOINTERSTITIAL NEPHRITIS

Tubulointerstitial nephritis (TIN) comprises inflammatory disorders of the renal tubules and interstitium that may be caused by infection, autoimmune disease, or allergic immunologic responses to certain drugs **(Fig. 319-2)** and that have a time course ranging from days to weeks or months.

Acute allergic immune tubulointerstitial nephritis (ATIN) usually develops 1 day to 2 weeks following an exposure, change in dose, or re-exposure to an offending drug (anamnestic response) and may be associated with rapid and potentially reversible loss of kidney function, making early diagnosis imperative. Associated heavy glomerular proteinuria sometimes occurs with the use of nonsteroidal anti-inflammatory drugs (NSAIDs) or ampicillin, whereas protein secreted by the proximal tubule (β_2-microglobulinuria) indicates tubular disease. Clinically, there may be fever, rash, and eosinophilia, any of which is typical with certain types of penicillins, cephalosporins, fluoroquinolones, and some biologic cancer drugs that act as checkpoint inhibitors (CPIs), but are atypical for NSAIDs. Patients who recover from CPI-induced acute kidney injury (AKI) may resume treatment with the inhibitor. The urinalysis usually shows pyuria and at times eosinophiluria, but the most characteristic cell types are activated T lymphocytes, eosinophils, and plasma cells, along with white blood cell casts. A cyto-centrifuged urine sample in a small test tube, when exposed to centrifugal forces, sprays sediment onto a slide mounted perpendicular to the tube's aperture. The slide, then stained with Giemsa, best demonstrates these cell types.

The patient may experience symptoms of polyuria, tender kidneys, and signs of tubular dysfunction, including nephrogenic diabetes insipidus, hypo- or hyperkalemia, and hyperchloremic metabolic acidosis. Common drugs that cause ATIN include proton pump inhibitors (PPIs) and sulfa drugs, especially sulfamethoxazole, as well as sulfa-containing diuretics such as acetazolamide, thiazides, furosemide, and, less frequently, bumetanide. PPIs may increase risk for ATIN in patients on CPIs. Frequently, rifampin and several other drugs cause noncaseating granulomatous interstitial nephritis. In caseating granulomas resulting from hematogenous spread of *Mycobacterium tuberculosis*, the first granulomas appear connected to the glomeruli in the cortex, where oxygen tension is at its highest. Granulomatous tubulointerstitial nephritis may occur in sarcoidosis and histoplasmosis.

Systemic infections including bacterial, viral, fungal, and parasitic may induce tubulointerstitial nephritis and were first described pathologically in the preantibiotic era as Councilman's nephritis in the course of scarlet fever. Autoimmune interstitial nephritis is seen in diseases such as lupus nephritis, ANCA-positive vasculitis, and other rheumatic disorders including Sjögren's syndrome, which may present with dry eyes as part of sicca syndrome. In a patient with photophobia and red painful eyes, the clinician should look at renal function and the urinalysis for evidence of tubulointerstitial nephritis uveitis syndrome.

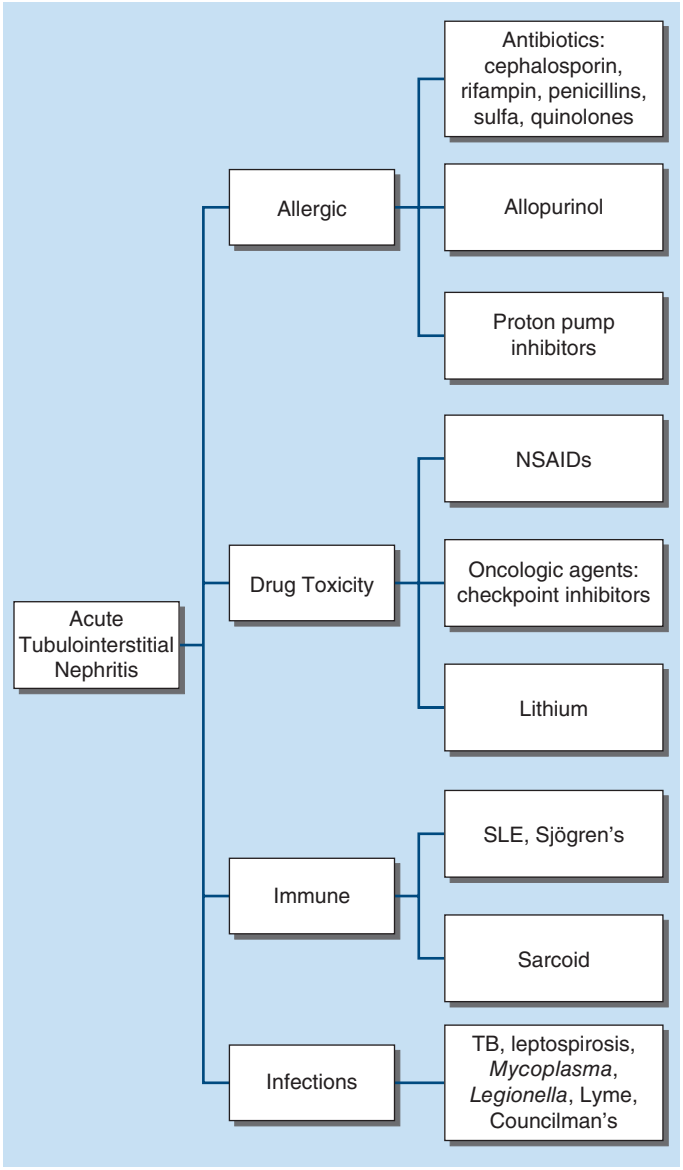

FIGURE 319-2 Acute tubulointerstitial nephritis. Diseases resulting from injury to the tubular and interstitial components of the renal cortex and medulla are shown. NSAID, nonsteroidal anti-inflammatory drug; SLE, systemic lupus erythematosus; TB, tuberculosis.

CHRONIC TUBULOINTERSTITIAL NEPHRITIS

Noninflammatory interstitial diseases are often caused by toxic exposures that damage the tubular interstitial structures. For example, a cancer patient on ifosfamide may develop Fanconi's syndrome, indicating proximal tubule damage. Heavy-metal exposures such as cadmium, lead, and mercury from old dental fillings may lead to proximal tubule injury and, once again, Fanconi's syndrome. A patient with hypomagnesemia and AKI may have had past exposure to platinum-containing chemotherapeutic agents, and a patient with nephrogenic diabetes insipidus, unresponsive to antidiuretic hormone, may have had treatment with lithium, analgesics, or chemotherapy. Hypokalemia and interstitial disease are consistent with a past history of exposure to aminoglycosides or amphotericin B. The patient with the former may complain of hearing loss, and the patient with the latter may present with hypokalemia and renal tubular acidosis (RTA).

Chronic interstitial diseases should be suspected in cases of paraproteinemia (light-chain nephropathy or amyloidosis) and in patients who ingest herbal remedies containing aristolochic acid, as occurs commonly in China and has been determined to be the cause of Balkan nephropathy. Perhaps the most common cause of chronic interstitial nephritis is prolonged analgesic use to treat chronic pain (not only NSAIDs but also acetaminophen or combinations of phenacetin, aspirin, and caffeine) as part of the analgesic syndrome. Clinicians should inquire about a prior history of pain and also gastrointestinal symptoms that may precede the kidney disease; the analgesic drugs often go unreported by the patient. It is important to recognize this syndrome because, if the drugs are not discontinued, a later development may be uroepithelial cancers of the distal ureter and urinary bladder. Lithium after prolonged use can also cause chronic interstitial nephritis along with nephrogenic diabetes insipidus and slowly progressive kidney failure.

Patients who have hypercalcemia or hyperoxaluria may develop nephrocalcinosis (a form of interstitial nephritis) that is characterized by calcifications within the renal parenchyma, often at the cortical medullary boundary. When nephrocalcinosis and nephrolithiasis are concurrent, the most common etiologies include hypercalcemic disorders, particularly primary hyperparathyroidism, and congenital medullary sponge disease (tubular ectasia), as well as hereditary distal RTA. In patients with DM, chronic analgesic use, or sickle cell diseases, the phenomenon of papillary necrosis is associated with chronic interstitial damage characterized by nephrogenic diabetes insipidus. For example, phenacetin toxicity is a result of the drug concentrating in the medulla due to the normal urinary concentrating mechanism; ironically, the first function lost because of medullary toxicity is the ability to concentrate the urine. In the ensuing papillary necrosis, the patient may observe solids in the urine, which are sloughed tissue from the ischemic medulla. When a patient with inflammatory bowel disease or one who has had gastric bypass procedures such as the Roux-en-Y develops kidney injury, with or without calcium oxalate kidney stones, a 24-h urine oxalate measurement must be determined to diagnose intestinal hyperoxaluria, which otherwise may lead to nephrocalcinosis. Chronic bacterial pyelonephritis is not a common cause of chronic renal failure, as it rarely affects both kidneys. Acute pyelonephritis in a solitary kidney or transplanted kidney may cause AKI.

PROTEINURIC STATES AND NEPHROTIC SYNDROME

Proteinuric States Some patients notice generalized edema and foamy urine, manifestations of albuminuria. Proteinuria is not synonymous with nephrotic syndrome (NS). In DM, the urinary loss of 30–300 mg/d of microalbuminuria (MALB) defines excessive albuminuria. Glomerular proteinuria, which typically occurs after years of small-vessel disease (explaining the likelihood of coincident small-vessel retinopathy), predicts future development of progressive renal failure and NS. The rate of renal progression is greater with hypertension, obesity, and poor glucose control. Further risks are partial nephrectomy, hepatitis C, and FSGS in patients of African ancestry, possibly related to predisposition by and prevalence of *APOL1* gene mutations. APOL1-mediated kidney disease is caused by two risk variants of the *APOL1* gene. Gene expression occurs only when a second hit of infection or inflammation triggers damage to podocytes and glomerular endothelial cells, creating channels in those cells that result in dysfunction and proteinuria.

Because treatment of patients with MALB is indicated, the clinician caring for diabetic patients should screen regularly for the presence of small amounts of albumin in the urine, which can be detected as microalbuminuria by radioimmunoassay. Subnephrotic albuminuria is characteristic of focal diseases of the kidney with <50% of glomeruli involved, whereas NS is likely when disease is diffuse, involving most glomeruli. Lower levels of albuminuria are characteristic of GN, as discussed above.

Microalbuminuria is beneath detection by urinary dipstick protein analysis. Any detectable albuminuria on dipstick is called overt proteinuria and, when detected at the highest level on the strip, is consistent with nephrotic proteinuria. The dipstick measurement picks up only the most acidic proteins like albumin but not proteins with a higher isoelectric point, most notably kappa and lambda light chains found in multiple myeloma. A patient being evaluated for renal disease should have either a timed direct measure of albumin or protein or, at least, a urinary microalbumin-to-creatinine ratio. The filtration of light chains may cause glomerular damage and albuminuria (kappa light-chain nephropathy or lambda AL amyloid) but does not reliably indicate glomerular damage because their charge and molecular weight allow them to freely cross the glomerular barrier. Such filtration is considered overflow proteinuria.

A laboratory measurement of albumin or total protein concentration should be normalized to urine creatinine concentration as a ratio in order to discount the effects of urinary dilution or concentration. It is also important to note that the ratio of total protein concentration to creatinine concentration is not specific for albumin excretion and may indicate the presence of light chains. The detection of light chains requires serum or urine protein immunoelectrophoresis.

Nephrotic Syndrome NS has three defining features: edema, hypoalbuminemia (<3.5 g/dL), and proteinuria >3.5 g/d. This syndrome is often associated with lipid abnormalities such as high low-density lipoprotein, low high-density lipoprotein, and lipiduria. The urine may contain large tubular epithelial cells that are engulfed with lipids in a recognizable shape under polarized light. These oval fat bodies may also contain cholesterol monohydrate crystals, which appear as Maltese crosses. Under low light, the refractile lipid may be seen as fatty casts.

Clinically, patients present with generalized edema, and in contrast to heart failure with orthopnea, facial, eyelid, and periorbital swelling is observed in NS. Penile and scrotal edema can be severe enough to obstruct urethral urine flow in men. In some cases, edema may form large bullae that may rupture, predisposing to ulceration and cellulitis. The skin becomes smooth and may appear to "weep." Additionally, patients may present with hoarseness caused by vocal cord edema. Occasionally, nephrotic range proteinuria is not associated with edema (i.e., in the case of HIV-associated nephropathy [HIVAN], which is more common in African Americans with HIV infection). In these cases, rapid loss of renal function may occur due to implosion of the glomerular capillary by proliferation of visceral epithelial cells that crush the glomerular loops, decreasing capillary flow and filtering surface area (collapsing glomerulopathy). This glomerulopathy is a severe, treatment-resistant form of FSGS. Very heavy proteinuria is often noted in this syndrome.

Other secondary forms of FSGS, more often not associated with NS, include remnant kidney after partial surgical removal, adaptive injury, chronic hypoxemia from chronic lung or congenital heart disease, sickle cell diseases, recurrent vasculitis with healing of some glomeruli, obesity, and congenital urogenital anomalies. Secondary forms of FSGS are shown in **Fig. 319-3**.

NS is a hypercatabolic state with negative nitrogen balance due to proximal tubule absorption and lysosomal catabolism exceeding hepatic albumin synthesis. A characteristic finding of rapid-onset hypoalbuminemia in NS is horizontal linear white lines in the nail bed, known as Muehrcke's lines. When NS in the adult occurs abruptly, with severe elevation of cholesterol, one must consider glomerular epithelial injury (podocytopathy), which may be idiopathic minimal change disease (MCD), a name historically based on the appearance of renal tissue on light microscopy and which is often preceded by an upper respiratory infection, allergies, or immunization. Secondary causes of MCD are Hodgkin's lymphoma or other lymphoproliferative disorders. MCD can occur at any age and in the adult may present with AKI as well, primarily because of the underlying vascular disease and hypoalbuminemia.

Age is an important aspect in the onset of NS, in that young children <6 years of age frequently have MCD. Several gene mutations encoding for proteins of the podocyte, such as nephrin (*NPHS1*) and podocin (*NPHS2*) in the slit diaphragm, have been shown to be responsible for most cases of hereditary NS **(Table 319-2)**.

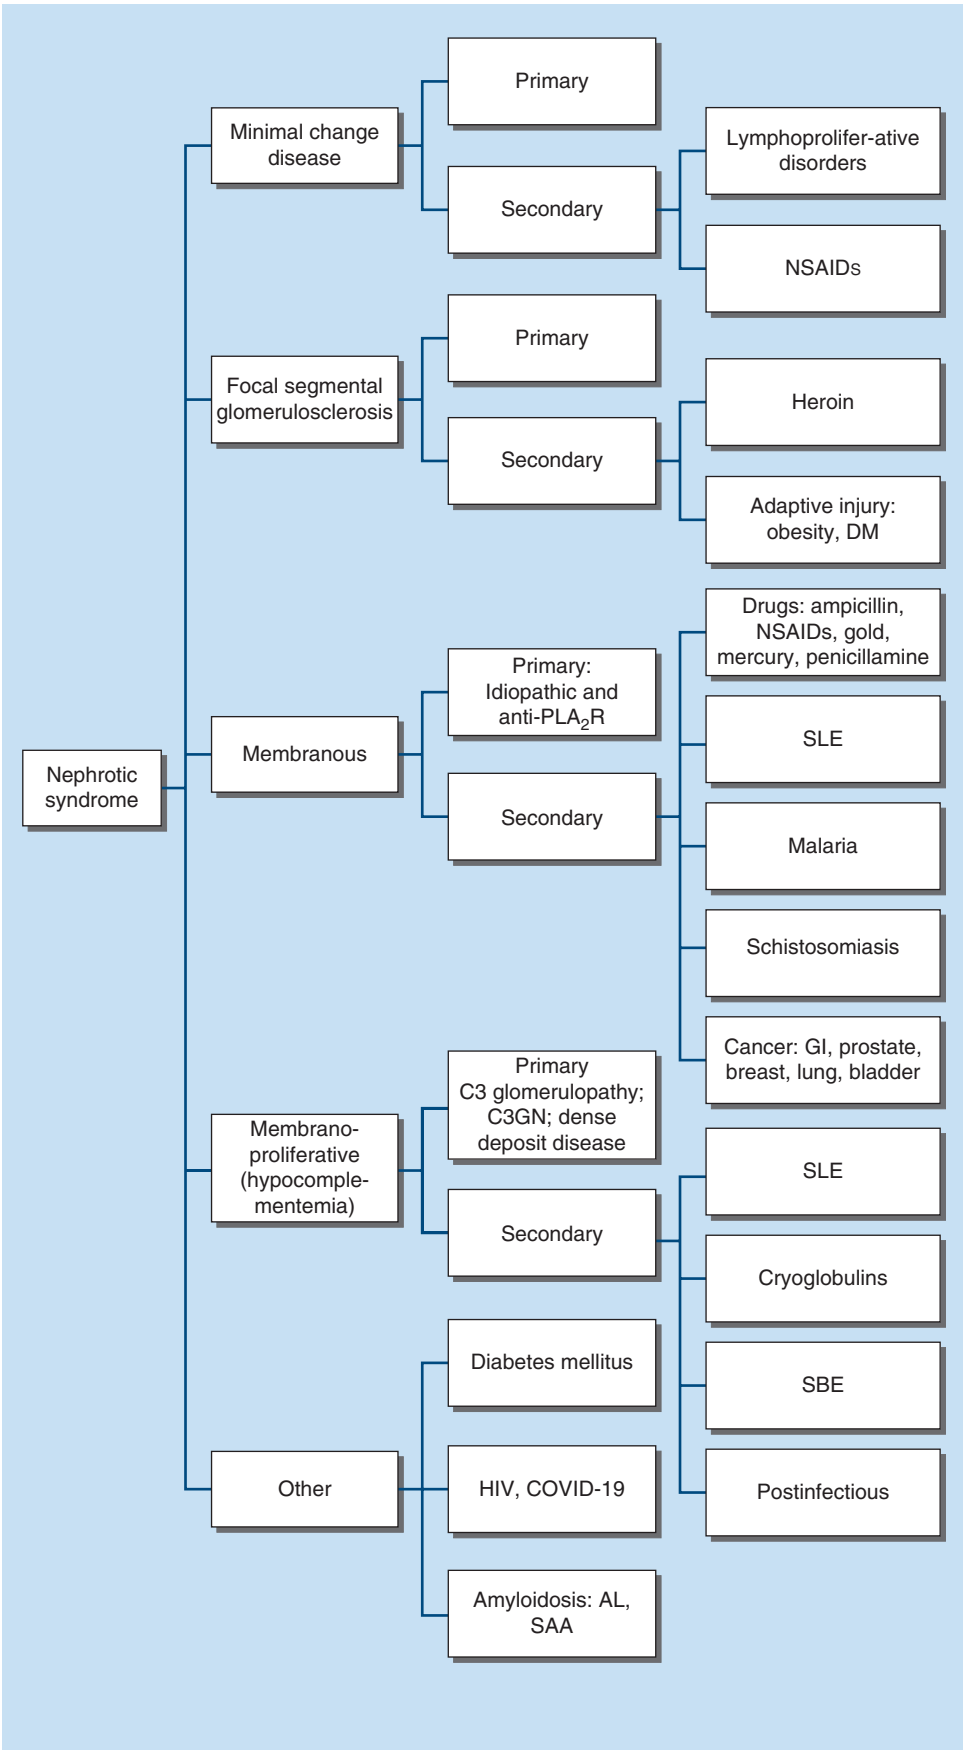

FIGURE 319-3 Nephrotic syndrome. Different pathologic syndromes are broken down into idiopathic and secondary causes. Seventy percent of primary membranous nephropathy (MN) is associated with antibodies to the integral subepithelial basement membrane antigen phospholipase A_2 receptor (PLA_2R). The former term for primary membranoproliferative glomerulonephritis has been replaced by pathologic syndromes involving complement deposition (C3 glomerulopathy and dense-deposit disease in children). AL amyloid is the form of amyloidosis secondary to λ light-chain deposition, and serum amyloid A (SAA) is the protein associated with chronic inflammatory diseases such as rheumatoid arthritis, familial Mediterranean fever, and tuberculosis. DM, diabetes mellitus; GI, gastrointestinal; NSAID, nonsteroidal anti-inflammatory drug; SBE, subacute bacterial endocarditis; SLE, systemic lupus erythematosus.

TABLE 319-2 Hereditary and Congenital Diseases

HEREDITARY GLOMERULAR DISEASES: NEPHROTIC SYNDROME OR RENAL FAILURE	HEREDITARY TUBULAR DISEASES	APOL1	CILIOPATHIES	CHANNELOPATHIES	CONGENITAL ANOMALIES
Podocyte mutations; basement membrane mutations; hereditary nephritis; X-linked and somatic mutations; *COL4A5*; Alport's syndrome with hematuria, neurosensory hearing loss, conus lentus; Fabry's disease (X-linked alpha-galactosidase deficiency)	Fanconi's syndrome with renal glycosuria, proximal tubule renal tubular acidosis (RTA), hypophosphatemia, hypouricemia; distal RTA with hearing loss, renal calcification; nephrogenic diabetes insipidus; hyper- or hypotensive disorders with hypo- or hyperkalemia; metabolic alkalosis or acidosis	Mutant allele in African-American population, leading to susceptibility to further injury in many other disorders including diabetes mellitus, IgAN	Autosomal dominant and recessive polycystic kidney disease; medullary cystic kidneys (metabolic acidosis and salt-wasting); other phenotypes	Gitelman's and Bartter's syndromes; disorders of epithelial sodium channel and proton pumps	Unilateral agenesis; dysgenetic disease; medullary sponge kidney (hematuria, stones, or infection); horseshoe kidneys (proteinuria); malposition; ureteropelvic obstruction; cystoureteral reflux (proteinuria)

In children who have a serum albumin concentration <2 g/dL, tissue ischemia may develop, causing a "nephrotic crisis," in which severe abdominal pain may be mistaken for a surgical abdomen. A 20-year-old presenting with NS may have MCD, FSGS, or membranous nephropathy (MN).

Similar to MCD, MN may be of primary or secondary etiology. Whereas NS is a cause of a hypercoagulable state, particularly when it is accompanied by severe hypoalbuminemia (<2 g/dL), MN in NS is most often associated with renal vein thrombosis (RVT) for a number of reasons, among them being urinary loss of antithrombin-3 and plasminogen, as well as hyperfibrinogenemia. RVT may present with back pain, renal failure or hematuria, increased edema in the lower extremities, or pulmonary emboli.

NS with heavy proteinuria or large kidneys on ultrasound in advanced stages of chronic kidney disease (CKD) is often noted in diabetic nephropathy, amyloid, HIVAN, and MN with RVT. MN may be the presenting finding in cases of SLE, whereas diffuse proliferative GN with low C3, when associated with SLE, occurs in patients who also have signs and symptoms of joint, skin, or systemic organ involvement. A cause of very early MN is an idiosyncratic reaction to NSAIDs, even when taken in small amounts. Many other drugs including penicillamine, mercury, and gold can cause MN. Proteinuria from any cause may present earlier, or increase, when DM, obesity, partial nephrectomy, or increased renal venous pressure exists.

Solid tumors, particularly lung, gastric, intestinal, bladder, breast, and prostate, may underlie a paraneoplastic syndrome of MN. While it is important to take a history and examine the patient carefully for signs of cancer, it is not the rule to work up every patient with MN exhaustively for the disease. Neoplastic nephropathy may be a sign of recurrent disease and may even be recognized by tumor antigens. MN also occurs in the context of many infectious diseases, including syphilis, malaria, schistosomiasis, and hepatitis B. Recently, 70% of patients with primary MN have been found to have circulating levels of an autoantibody to the phospholipase A_2 receptor (anti-PLA_2R) in the subepithelial region of the GBM. Compared to non-PLA_2R patients, fewer patients in this group have drug-induced MN and are more likely to experience spontaneous remission; one of four subclasses of immunoglobulins has been implicated in TIN and sometimes MN as part of a multiorgan disease. IgG4 increases in response to chronic exposure to an antigen; it has been associated with autoimmune diseases such as acute pancreatitis-1 (AP1) and severe and often allergic asthma and is often detected by high levels in the blood. Patients who are thought to have diabetic nephropathy on clinical grounds are often found to have an additional diagnosis, particularly MN, on renal biopsy. The increased frequency of MN in DM may indicate that glomerular hyperfiltration accentuates the proteinuria of MN or is associated with a genetic variant, *COL45A5*. Diabetic nephropathy is perhaps the most common reason for the renal patient to begin dialysis; therefore, much attention has been paid to the progressive nature of chronic failure in these patients. Risk factors include those that affect hemodynamics and blood sugar. In the poorly controlled diabetic patient, increased blood pressure, renal plasma flow, and GFR develop in single nephrons that are spared until glomerular sclerosis in other nephrons has already occurred. This finding is clinically evident by the presence of proteinuria or low GFR. The proteinuria is responsive to angiotensin II–inhibiting drugs such as angiotensin-converting enzyme inhibitors, angiotensin II receptor blockers, and renin inhibitors. Sodium-glucose cotransporter 2 (SGLT2) inhibitors in the proximal tubule of the kidney create glycosuria, improve glucose control, and have been shown to reduce the rate of progression. The more glucose filtered during periods of hyperglycemia, the greater are the renal interstitial glucose and advanced glycation end products that cause fibrosis.

Patients who have nephrotic and nephritic sediments in childhood may have membranoproliferative glomerular nephritis with low C3 as a primary disease (C3 glomerulopathy or dense-deposit disease). The adult presenting with a nephrotic and nephritic profile should be considered to have an immune complex disorder unless proven otherwise. In amyloidosis, there may be a simultaneous and severe tubular syndrome in addition to the albuminuria, consisting of nephrogenic diabetes insipidus and a hyperkalemic RTA. When NS is associated with Fanconi's syndrome (glycosuria, phosphaturia, uricosuria, and aminoaciduria), one must consider multiple myeloma in the adult.

HEMATURIA AND LOWER URINARY TRACT SYNDROMES

Since blood could enter the urinary tract from any structure, identifying the source is the necessary first step. As a rule, hematuria associated with flank pain or ureteral colic is more characteristic of a lower urinary tract source, such as a stone or an obstructing lesion. However, when flank pain without colic is noted, one has to consider swelling of the kidney and stretching of the renal capsule, as might be seen in acute urinary obstruction, kidney infection, interstitial nephritis, and, on occasion, acute glomerular nephritis. Heavy bleeding with clots is more characteristic of lower tract bleeding but could result from trauma to the kidney. In patients who have acute flank pain and hypertension, assuming the pain is due to a kidney stone may miss an occlusive vascular event from an embolus or in situ clot within the arterial blood supply. Patients who engage in strenuous exercise may develop hematuria that can be ruled out by retesting the urine after a week or two of rest. True hematuria can be distinguished from hemoglobinuria and myoglobinuria by urinalysis.

Symptoms of lower urinary tract disorders are dysuria, urinary frequency, urgency, incomplete emptying, hematuria that is most pronounced at the beginning of flow, and a poor urinary stream. Among these disorders are urinary tract infections and prostatic hypertrophy. Hematuria of recent onset noted in the fourth decade of life or beyond should undergo a urologic evaluation and most likely cystoscopic examination of the bladder. However, chronic hematuric conditions may be associated with chronic glomerular disease such as thin basement membrane, hereditary nephritis, or IgAN. This is why it is so important to search for previous examinations such as insurance, military, or employment examinations done in the past to determine if hematuria was present in order to establish chronicity.

ACUTE KIDNEY INJURY

AKI is defined by the retention of nitrogenous solutes such as urea, uric acid, and creatinine. The creatinine concentration goes up primarily related to the amount of water absorbed along the nephron. Because urea but not creatinine has a reabsorptive component, clearance of urea is less than the clearance of creatinine. With a constant catabolic rate, a decrease in glomerular filtration alone will affect the blood urea nitrogen (BUN) and creatinine proportionately. By contrast, in a disorder associated with enhanced urinary concentration (high antidiuretic hormone [ADH]), where urea and water have increased reabsorption in the process of concentrating the urine, the retention of urea nitrogen exceeds that of creatinine, accounting for an elevated BUN-to-creatinine ratio. Oliguria or oligoanuric states are often characterized as prerenal, defined as preglomerular vascular disease or low perfusion states; renal, indicating intrinsic renal disease; or postrenal, indicating obstructive nephropathy or uropathy (see Table 319-1).

Prerenal states are often related to a decreased perfusion pressure to the glomerular capillaries or some other interference with filtration. The differential diagnosis includes proliferative GN (the bloodless capillary); a preglomerular vascular disease such as scleroderma or TMA; the use of pressors for the maintenance of blood pressure; vasoconstrictive substances including cocaine, iodinated IV contrast media, hemoglobin or myoglobin, and certain antibiotics such as vancomycin, cyclosporine, and tacrolimus (calcineurin inhibitors); and other vasoconstrictive drugs, such as NSAIDs and renal nerve stimulators. Hypercalcemia and hypoxia are also vasoconstrictive. Correcting hypoxemia has a diuretic effect.

Intrinsic Renal Disease All of these disorders will decrease perfusion pressure and decrease GFR while stimulating sodium and water reabsorption. Therefore, the characteristic urinary findings are low urinary sodium excretion and concentrated urine. The urine sodium concentration is usually low and the urine to plasma creatinine concentration is usually >40. The same result could occur in bilateral renal artery stenosis, heart failure, and other circulatory collapse. If there is damage done to the renal tubules (so-called intrinsic renal disease), there may or may not be oliguria, and in fact, there could be polyuria (unresponsiveness to ADH) and sodium-wasting, potassium-wasting, and acid-base disorders, each of which may predominate. One of the most frequent causes of oliguric acute renal failure is acute tubular necrosis, caused by gram-negative sepsis, hemodynamic collapse, hemoglobinuria or myoglobinuria, and medication or toxin ingestion. Examples are crush injury, heroin and alcohol stupor, and compartment syndrome. Drug causes include NSAIDs, aminoglycosides, and chemotherapeutic drugs such as cisplatin and methotrexate.

Postrenal States Postrenal states accompanied by anuria suggest complete obstruction to the flow of urine, while polyuria and bland urinary sediment suggest incomplete obstruction combined with ADH unresponsiveness. The fractional excretion of sodium is usually >1–2%, whereas in oliguric prerenal syndromes, the fractional excretion of sodium is usually <1%. Exception to the low sodium excretion would be in the case of hyperchloremic metabolic alkalosis, where chloride is being conserved and sodium excreted with bicarbonate.

Urinary tract obstruction (UTO) is usually characterized by hydronephrosis visualized with ultrasound imaging or large volumes of urine removed by bladder catheterization, indicating bladder outlet obstruction. Exceptions to finding hydronephrosis on an imaging study include the extrinsic obstructive compression of the kidney or ureter in retroperitoneal disease; cases in which imaging was done too early, for example <4 days after obstruction; or when the patient was simultaneously obstructed and volume depleted.

As previously mentioned, acute tubular diseases that are not primarily due to inflammation can be caused by intratubular obstruction, hyperoxaluric states, or uric acid or phosphates in tumor lysis syndrome following chemotherapy for lymphoproliferative disorders. Other drug therapies that cause tubular injury include cisplatin, ifosfamide, methotrexate, aminoglycosides, and amphotericin B, and toxicity through exposure to heavy metals.

Kidney injury in the setting of systemic disease with dysfunction in other organs includes cardiorenal, pulmonary-renal, and hepatorenal syndromes. Other syndromes that typically involve the kidney include febrile illness, systemic infection with septic shock, hemodynamic collapse due to cytokines, or capillary leak syndrome. These syndromes and the endothelial origins of TMAs and hemolytic-uremic syndrome are shown in **Fig. 319-4**. Obstetric patients with abruptio placenta may develop bilateral cortical necrosis and, as a consequence, anuria and, often, irreversible renal failure. In addition, patients with atheroembolic syndrome can present with AKI or chronic progressive damage following an aortic catheterization. If the blood vessels catheterized involve the aortic arch, an encephalopathic syndrome that can mimic uremic encephalopathy may follow. As many as 70% of patients with COVID-19 who required ventilators during the early phase of the pandemic developed multiorgan failure, including AKI. AKI may also be a risk for CKD following a COVID-19 infection, but most patients return to baseline function.

CHRONIC KIDNEY DISEASE AND THE UREMIC SYNDROME

CKD, progressing over months to years, can be the long-term result of any of the aforementioned diseases. If the time course is unknown, other ways to diagnose CKD versus a more recent kidney disorder are useful (i.e., the finding of bilaterally small kidneys on a renal ultrasound). Kidneys imaged by this method are normally 10–12 cm in length. Small kidneys, <8 cm, are likely atrophic with irreversibly low function; but in some cases of CKD, such as in DM, the kidneys may be large despite kidney failure. Remarkably, even atrophic kidneys may still produce renin to sustain blood pressure and erythropoietin to minimize anemia; however, due to low calcitriol in CKD, patients develop secondary hyperparathyroidism. The normal parathyroid gland weighing 25 mg would be limited in raising parathyroid hormone (PTH) levels, such that very elevated PTH likely favors a diagnosis of CKD. Thinning of the renal cortex is also a sign of chronicity.

DM accounts for ~50% of CKD patients who progress to end-stage renal disease (ESRD). Other important causes leading to ESRD are IgAN; ischemic nephropathy without proteinuria manifesting after age 50 with hypertension and signs of other large-vessel disease, such as intermittent claudication from peripheral vascular disease; stroke; and coronary artery disease. By contrast, renal arterial disease due to fibromuscular dysplasia seen predominantly in white women in the fourth decade of life does not progress to renal failure and is a treatable form of hypertension. Other arterial diseases include polyarteritis nodosum and, in medium-sized vessels, a Kawasaki-like illness affecting children, which has had a 30-fold increase since the onset of COVID-19 as part of the multisystem inflammatory syndrome.

Hereditary and congenital diseases of the kidney are shown in Table 319-2. Autosomal dominant polycystic kidney disease (PCKD) occurs in all ethnic populations. The patient may first show signs of cysts in late teen years with hypertension, urinary or cyst infection, or pain and bleeding. Kidney stones may be seen. By the age of 30, individuals with the disorder will have ultrasound-detectable cysts. The clinician should be aware that a diagnosis of PCKD requires multiple cysts in both kidneys. Cysts are also found in the liver. The first manifestation of PCKD may be a cerebral hemorrhage, since brain aneurysms are present in a small subset of patients with this disease, most commonly in the circle of Willis. In PCKD, rapid progression of kidney failure has been observed and previously explained by the crowding out of normal nephrons by the cysts. Cyst enlargement is due to fluid secretion as well as increased growth of the cyst wall. It is helpful to measure the size of cysts and to antagonize growth with tolvaptan, an inhibitor of vasopressin type 2 receptors in the collecting duct. Vasopressin, however, is a growth factor for cysts. Risk factors for more rapid progression include African-American heritage, obesity, liver abnormalities, and hypertension.

Hereditary nephritis with many variations includes Alport syndrome, involving a gene mutation (*COL4A5*) affecting the α3 region of the noncollagenous domain of the alpha 3 chain type IV collagen in GBM. There is an X-linked pattern of genetic transmission, where

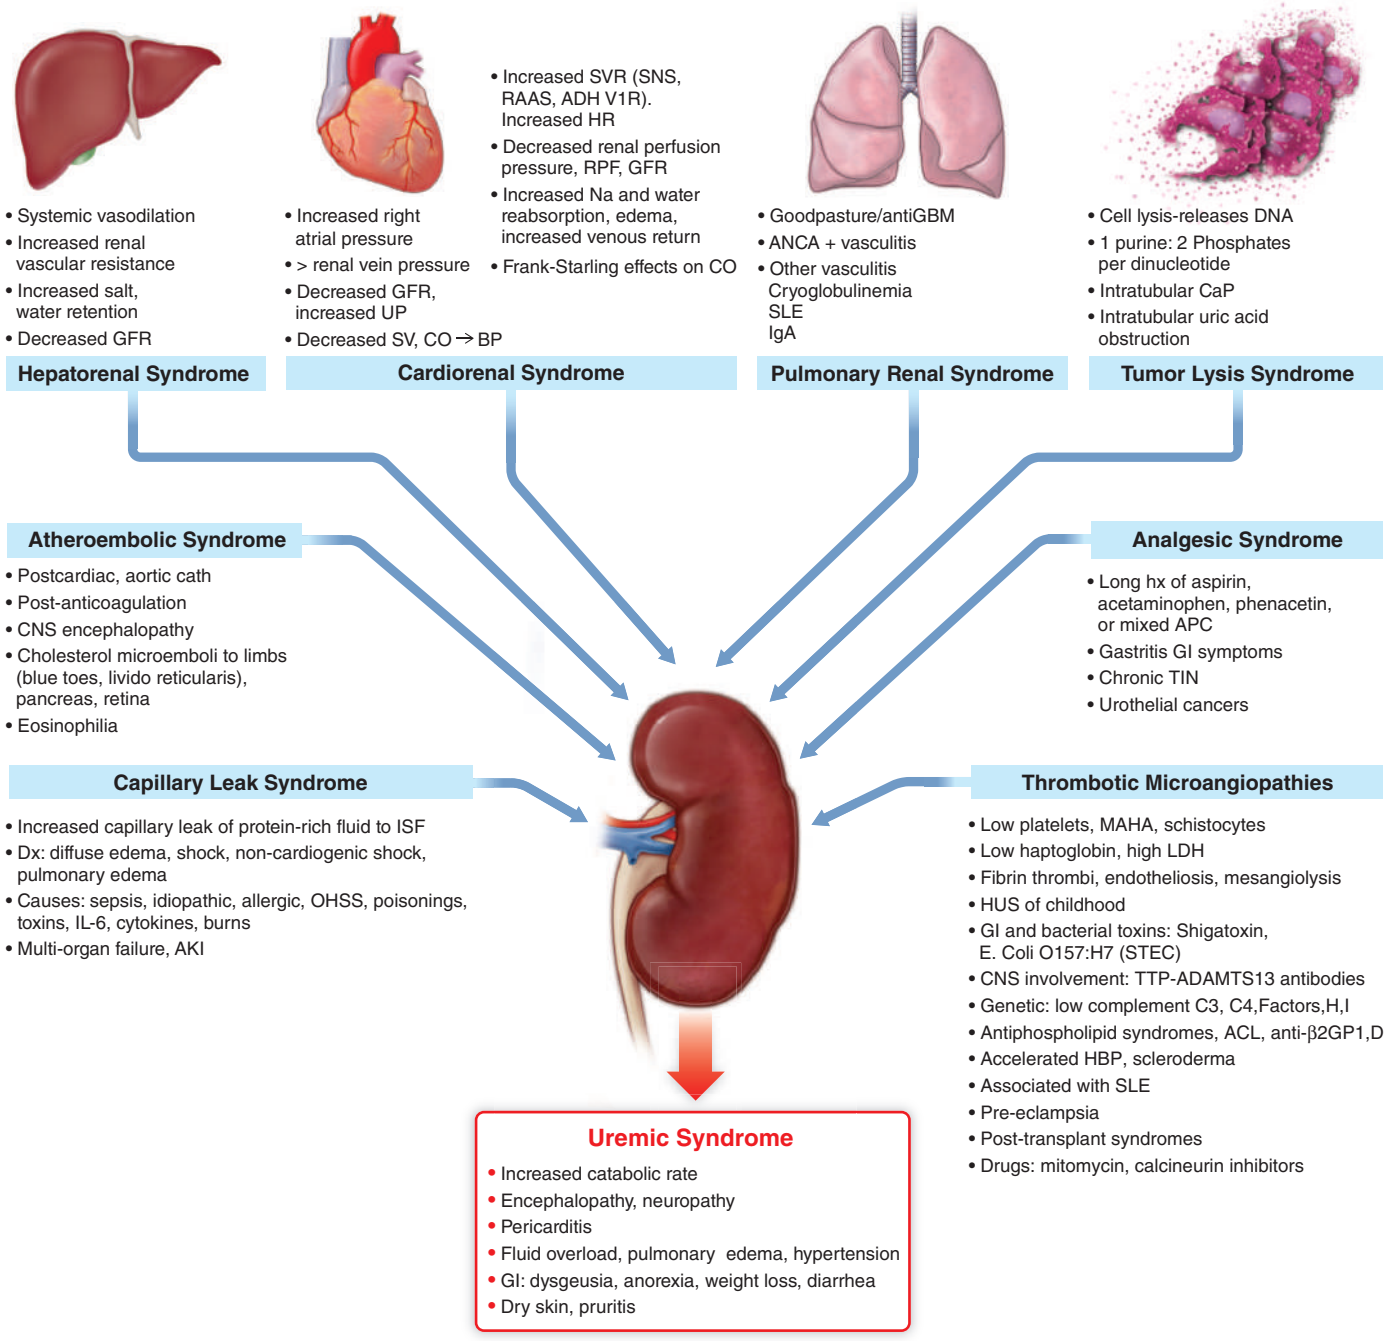

FIGURE 319-4 Categories of systemic or non-renal-based syndromes that involve the kidney and in advanced cases can cause the uremic syndrome requiring renal replacement therapy. ACL, anticardiolipin antibodies; ADH V1R, antidiuretic hormone V1 receptor; AKI, acute kidney injury; ANCA, antineutrophil cytoplasmic antibody; anti-2GP1, anti-β-2-glycoprotein-1; APC, aspirin, phenacetin, caffeine; BP, blood pressure; CaP, calcium phosphate crystals; CNS, central nervous system; CO, cardiac output; GBM, glomerular basement membrane; GFR, glomerular filtration rate; GI, gastrointestinal; HBP, high blood pressure; HR, heart rate; HUS, hemolytic-uremic syndrome; hx, history; IgA, immunoglobulin A; IL, interleukin; ISF, interstitial fluid; LDH, lactate dehydrogenase; MAHA, microangiopathic hemolytic anemia; OHSS, ovarian hyperstimulation syndrome; RAAS, renin-angiotensin-aldosterone system; RPF, renal plasma flow; SLE, systemic lupus erythematosus; SV, stroke volume; SNS, sympathetic nervous system; STEC, Shiga toxin–producing *Escherichia coli*; SVR systemic vascular resistance; TIN, tubulointerstitial nephritis; TTP, thrombotic thrombocytopenic purpura; UP, urine protein.

males may be most severely affected by renal failure in middle age. The syndrome involves hematuria, neurosensory hearing loss, and ocular deformities of the lens. A predominant symptom in hereditary nephritis is microscopic hematuria, and the pathological correlate to this is thin basement membranes. It must be distinguished from the less severe and more commonly related condition known as thin basement membrane disease as a cause of hematuria.

Certain congenital abnormalities of the kidney, such as horseshoe and ectopic kidneys, also shown in Table 319-2, consist of low nephron numbers that may result in secondary FSGS. The condition known as ureteral reflux is an abnormality involving the functional insertion of the ureter into the muscular bladder, which normally closes off the ureter upon bladder contraction. In reflux disease, the ureter cannot prevent retrograde flux of urine during micturition. In children, this may cause hypertension and, in some cases, secondary FSGS. Surgical correction of the abnormality may be curative, but the child may outgrow it in adulthood.

The stages of CKD are listed in Table 319-3 and are central in terms of planning for renal replacement therapy (dialysis and transplantation) and for assessing and slowing the rate of progression, defined as the decline in GFR over time. In CKD, the eGFR is determined by the current stable serum creatinine, which is entered into one of several equations derived from clinical trial data that compare the subject's value to actual measurements of GFR. For example, the Modification of Diet in Renal Disease (MDRD) study used radioisotope (I^{125}-iothalamate) clearance to measure true GFR. The equation

TABLE 319-3 Stages of Chronic Kidney Disease (CKD)

STAGES OF CKD, ABNORMALITY >3 MONTHS	RANGE OF eGFR	CLINICAL FEATURES	IMPORTANCE
1	>60 mL/min/1.73 m^2	Abnormal urinalysis, abnormal renal imaging	Risk of progression to later stages increases with increased proteinuria and dependent on cause of disease
2	>60 mL/min/1.73 m^2	Abnormal urinalysis, abnormal renal imaging	Mild risk of progression to later stages increases with increased proteinuria and dependent on cause of disease
3a	45–60 mL/min/1.73 m^2	Cardiovascular disease or other organ damage	Moderate risk of progression of disease. Pay attention to other vascular risk factors, high BP, lipids, smoking, weight
3b	30–45 mL/min/1.73 m^2	Proteinuria	High risk of progression
4	15–30 mL/min/1.73 m^2		High likelihood of progression to ESRD, need preparation and education regarding choices for RRT including transplant and dialysis
5	<15 mL/min/1.73 m^2		Highest risk of requiring RRT

Abbreviations: BP, blood pressure; eGFR, estimated glomerular filtration rate; ESRD, end-stage renal disease; RRT, renal replacement therapy.

contains additional factors such as age and sex to derive the current eGFR, corrected for 1.73 m^2 body surface area. This value of eGFR is not a creatinine clearance or a measurement of GFR.

There has been debate about the inclusion of corrective factors that would alter the result from that equation based on the patient's ethnicity and race. For example, it has been recommended in some centers to multiply the eGFR value by a factor of 1.2 in African-American patients in order to correct for the perceived underestimate of GFR using the MDRD equation. There is considerable objection to making this correction, which may have the effect of introducing bias based on race. Because the corrected eGFR will give a higher value to the GFR, there could be delays in discussion of renal replacement therapy and in initiation of treatment. Consequently, the correction has fallen out of favor. Recently, an alternative, the Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI), has been used that excludes race as a parameter. Another method of estimating GFR uses cystatin-C, a known filtration marker for GFR. Levels of the patient's current cystatin-C are compared to historical values of cystatin-C from populations where the true GFR was the comparator. Both creatinine and cystatin-C methods are susceptible to error because they do not take into account renal and extrarenal clearance or, in the case of creatinine, muscle mass.

During the course of CKD, the clinician must evaluate the patient for symptoms and signs of worsening renal function. When the eGFR is <15–20 mL/min, the patient should already have had conversations about choices of eventual treatment and, if indicated, surgical preparation for peritoneal dialysis or hemodialysis. Attention should be given to the sensitive topic of transition to a lifesaving but mechanical procedure. It is also important to discuss transplantation and issues of timing. The ethical standard is for separate clinicians to evaluate the recipient and donor of a kidney transplant. Confidentiality and privacy are essential. Importantly, access to transplantation has not been offered equally to minority populations, and it is incumbent on clinicians to avoid bias by discussing the option with every patient.

Symptoms of CKD are often nonspecific and include fatigue, weakness, loss of appetite and taste, weight loss, mood changes, and metabolic encephalopathy that may involve cognitive changes such as decline in executive function and the ability to calculate and remember. Other symptoms are peripheral and autonomic neuropathies and sleep and movement disorders such as restless legs and asterixis or myoclonus. Patients with CKD lose their ability to concentrate urine and, therefore, have an obligate urine output of ~2 L. This results in nocturia since the bladder fills during the night. Ironically, the loss of nocturia may be sensed by the patient as an improvement of symptoms but actually indicates worsening oliguria. Pruritus commonly occurs. Clinical issues include changes in medications and doses. The full uremic syndrome is characterized by severe hypertension, the above-mentioned encephalopathic manifestations, gastrointestinal bleeding, pericarditis, severe electrolyte disturbances, particularly hyperkalemia, and secondary hyperparathyroidism. Anemia is frequently present, and although it may be due to iron deficiency or decreased erythropoietin, other causes of anemia should be investigated. Patients respond well to erythropoietic stimulating agents, with the goal of therapy >10 g/dL but <12 g/dL. Notably, not all patients are anemic. For example, some patients with UTO, PCKD, renal vascular disease, and renal cell carcinoma may in fact have erythrocytosis.

In NS, heavy proteinuria may persist throughout the course of CKD and carries a worse prognosis. In all kidney diseases, including the nephritic processes, renal disease may progress to late stages even when the acute inflammation has subsided; however, the underlying mechanisms of progressive renal failure involve inflammatory pathways (reflected in elevated levels of C-reactive protein and erythrocyte sedimentation rate in CKD), emphasizing the importance of managing risk factors for cardiovascular disease, such as hypertension, smoking, hyperlipidemias, diabetes mellitus, and obesity, early in the course of CKD.

Some chronic renal syndromes may present with predominant tubular dysfunction, including genetic diseases known as channelopathies. Examples are the depletion of electrolytes such as phosphorus and potassium and proximal RTA due to Fanconi's syndrome, mentioned above; hypokalemic alkalosis and volume depletion in Bartter's syndrome (mutations resulting in abnormal loop of Henle function); and electrolyte losses in Gitelman's syndrome, a defect in the thiazide-sensitive sodium-chloride transporter. Gitelman's syndrome also causes hypochloremic hypokalemic metabolic alkalosis. Bartter's and Gitelman's syndromes can be distinguished by examining the urine for the usual solutes regulated by these transporters. Thus, Bartter's syndrome is associated with hypercalciuria and the inability to put out a concentrated urine, whereas Gitelman's syndrome is associated with hypocalciuria and preserved ability to concentrate the urine. Fanconi's syndrome results in hypokalemic acidosis and can be distinguished from distal RTA, which is not associated with the loss of glucose, amino acids, and phosphate in the urine.

Disorders involving the collecting duct and its transporters of sodium, potassium, and acid base can result in syndromes that also suggest particular diagnoses. For example, polyuria due to inappropriate free water losses and insensitive to ADH is characteristic of nephrogenic diabetes insipidus, and it is common to see simultaneous defects in potassium secretion and hydrogen ion secretion with hypertension suggesting blockade of one of the sodium regulators of the epithelial sodium channel. These disorders are usually associated with hyporenin and/or hypoaldosterone states, which include UTO, type 4 RTAs in DM, amyloidosis, or Addison's disease. In contrast to this, hypokalemic metabolic alkalosis with volume expansion may suggest an adrenal adenoma, unilateral renal artery stenosis, adrenocorticotropic hormone–secreting tumors, licorice abuse, or potassium-sparing diuretics. Although genomic testing may reveal gene mutations characteristic of a disorder, such testing should not be automatic since many mutations require the presence of other high-risk conditions (a "second hit") or are only indirectly associated with the development of disease.

RENAL MASSES

Patients with renal cell carcinoma may have been diagnosed via an incidental finding in an abdominal imaging study or sometimes by a

palpable mass best felt with the patient supine, usually in a thin patient but occasionally due to a very large protruding mass. Very large masses or multiple masses that are easily palpable may represent cystic diseases of the kidney, including PCKD or even a single cyst, versus a congenital ureteral pelvic obstruction. Other times, a renal cell carcinoma can present as anemia, possibly caused by hematuria, or as back pain associated with metastatic lytic vertebral lesions. Metastases may involve the lungs and bone marrow as well.

IMAGING AND RENAL BIOPSY INDICATIONS

For hematuric syndromes, imaging may provide valuable information, particularly in a patient who has heavy bleeding or blood clots in the urine. Renal pathology may be detected as an abdominal mass, as in the setting of renal cell carcinoma, chronic UTO, or cystic diseases of the kidney including PCKD and simple cyst. If the patient has a known history of tubular sclerosis or the finding of skin fibroadenoma, one might identify a renal mass found on CT imaging as an angiomyolipoma.

The renal ultrasound is efficacious in determining the size and symmetry of the kidneys and in excluding urinary obstruction. It is useful in detecting renal cysts or masses but less effective in kidney stone disease. Ultrasound is not as accurate a tool as a computed tomography (CT) scan for angiomyolipomas. The renal-limited noncontrast CT scan is the standard test for nephrolithiasis but carries the risk of accumulative radiation. Magnetic resonance imaging (MRI) is often useful in evaluating and following renal masses, including renal cell carcinoma. The patient with renal disease may develop a toxic complication of systemic sclerosis after receiving multiple gadolinium studies for MRI enhancement; new contrast agents to replace it are emerging. CT scans with high-osmolality iodinated contrast media, administered in large volumes, remain an important cause of AKI (contrast nephropathy) in elderly male patients with vascular disease of the kidney, multiple myeloma, hepatic disease, extracellular fluid depletion, DM, or concurrent use of NSAIDs. The accompanied radiation is a concern for radiation exposure.

Radioisotope scanning is useful in demonstrating the percentage of renal function coming from each kidney. Finally, in many of the diseases discussed above, diagnosis ultimately depends on renal biopsy and pathologic evaluation.

320 Cell Biology and Physiology of the Kidney

Alfred L. George, Jr., Eric G. Neilson

The kidney is one of the most highly differentiated organs in the body. At the conclusion of embryologic development, nearly 30 different cell types form a multitude of filtering capillaries and segmented nephrons enveloped by a dynamic interstitium. This cellular diversity modulates a variety of complex physiologic processes. Endocrine functions, the regulation of blood pressure and intraglomerular hemodynamics, solute and water transport, acid-base balance, and removal of drug metabolites are all accomplished by intricate mechanisms of renal response. This breadth of physiology hinges on the clever ingenuity of nephron architecture that evolved as complex organisms came out of water to live on land.

EMBRYOLOGIC DEVELOPMENT

Kidneys develop from intermediate mesoderm under the timed or sequential control of a growing number of genes, described in **Fig. 320-1**. The transcription of these genes are determined or guided by morphogenic cues, the orientation of cilia-derived planar cell polarity, and the generational legacy of epigenetic marks that invite two ureteric buds to each penetrate bilateral metanephric blastema, where they induce primary mesenchymal cells to form early nephrons. The two ureteric buds emerge from posterior nephric ducts and mature into separate collecting systems that eventually form a renal pelvis and ureter. Induced mesenchyme undergoes mesenchymal epithelial transitions to form comma-shaped bodies at the proximal end of each ureteric bud leading to the formation of S-shaped nephrons that cleft and enjoin with penetrating endothelial cells derived from sprouting angioblasts. Under the influence of vascular endothelial growth factor A (VEGF-A), these penetrating cells form capillaries with surrounding mesangial cells that differentiate into a glomerular filter for plasma water and solute. The ureteric buds branch, and each branch produces a new set of nephrons. The number of branching events ultimately determines the total number of nephrons in each kidney. There are ~900,000 glomeruli in each kidney in normal-birth-weight adults and as few as 225,000 in low-birth-weight adults, with the latter producing numerous comorbid risks.

Glomeruli evolve as complex capillary filters with fenestrated endothelia under the guiding influence of VEGF-A and angiopoietin-1 secreted by adjacently developing podocytes. Epithelial podocytes facing the urinary space envelop the exterior basement membrane supporting these emerging endothelial capillaries. Podocytes are partially polarized and periodically slough into the urinary space by epithelial-mesenchymal transition and, to a lesser extent, apoptosis, only to be replenished by migrating parietal epithelia from Bowman capsule. Impaired replenishment results in heavy proteinuria. Podocytes attach to the basement membrane by special foot processes and share a slit-pore membrane with their neighbor. The slit-pore membrane forms a filter for plasma water and solute by the synthetic interaction of nephrin, annexin-4, CD2AP, FAT, ZO-1, P-cadherin, podocin, TRPC6, PLCE1, and Neph 1-3 proteins. Mutations in many of these proteins also result in heavy proteinuria. The glomerular capillaries are embedded in a mesangial matrix shrouded by parietal and proximal tubular epithelia forming Bowman capsule. Mesangial cells have an embryonic lineage consistent with arteriolar or juxtaglomerular cells and contain contractile actin-myosin fibers. These mesangial cells make contact with glomerular capillary loops, and their local matrix holds them in condensed arrangement.

Between nephrons lies the renal interstitium. This region forms a functional space surrounding glomeruli and their downstream tubules, which are home to resident and trafficking cells such as fibroblasts, dendritic cells, occasional lymphocytes, and lipid-laden macrophages. The cortical and medullary peritubular capillaries, which siphon off

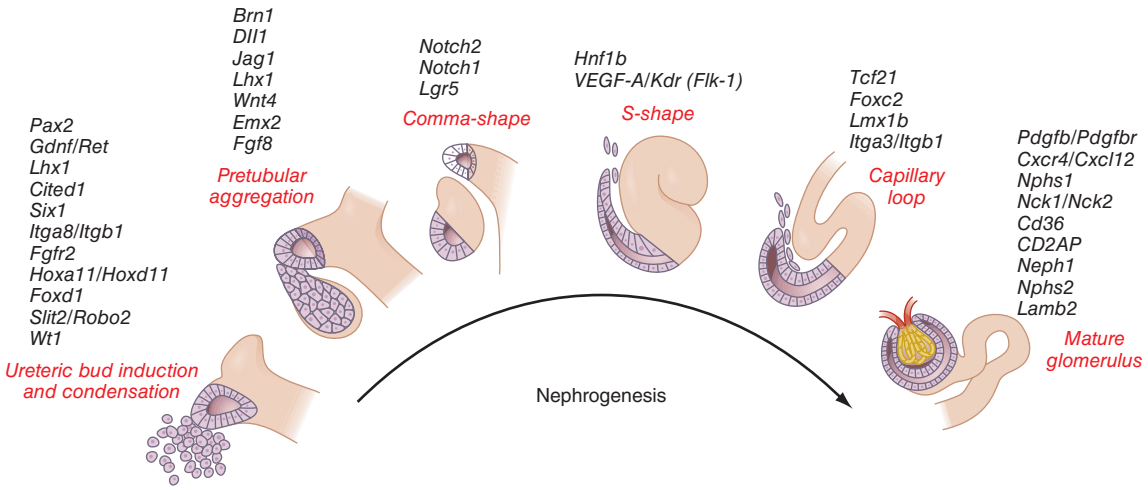

FIGURE 320-1 Genes controlling renal nephrogenesis. A growing number of genes have been identified at various stages of glomerulotubular development in the mammalian kidney. The genes listed have been tested in various genetically modified mice, and their location corresponds to the classical stages of kidney development postulated by Saxen in 1987.

solute and water following tubular reclamation of glomerular filtrate, are also part of the interstitial fabric as well as a web of connective tissue that supports the kidney's emblematic architecture of folding tubules. The relational precision of these structures determines the unique physiology of the kidney.

Each nephron is partitioned during embryologic development into a proximal tubule, descending and ascending limbs of the loop of Henle, distal tubule, and the collecting duct. These classic tubular segments build from subsegments lined by highly unique epithelia serving regional physiology. All nephrons have the same structural components, but there are two types whose structures depend on their location within the kidney. The majority of nephrons are cortical, with glomeruli located in the mid-to-outer cortex. Fewer nephrons are juxtamedullary, with glomeruli at the boundary of the cortex and outer medulla. Cortical nephrons have short loops of Henle, whereas juxtamedullary nephrons have long loops of Henle. There are critical differences in blood supply as well. The peritubular capillaries surrounding cortical nephrons are shared among adjacent nephrons. By contrast, juxtamedullary nephrons depend on individual capillaries called *vasa recta* that run alongside the long loops of Henle. Cortical nephrons perform most of the glomerular filtration because there are more of them and because their afferent arterioles are larger than their respective efferent arterioles. The juxtamedullary nephrons, with longer loops of Henle, create an osmotic gradient for concentrating urine. How developmental instructions specify the differentiation of all these unique epithelia among various tubular segments is still unknown.

DETERMINANTS AND REGULATION OF GLOMERULAR FILTRATION

Renal blood flow normally drains ~20% of the cardiac output, or 1000 mL/min. Blood reaches each nephron through the afferent arteriole leading into a glomerular capillary where ultrafiltration forms the tubular fluid. The distal ends of the glomerular capillaries coalesce to form an efferent arteriole leading to the first segment of a second capillary network (cortical peritubular capillaries or medullary vasa recta) surrounding the tubules **(Fig. 320-2*A*)**. Thus, nephrons have two capillary beds arranged in a series separated by the efferent arteriole that regulates the hydrostatic pressure in both capillary beds. The distal capillaries empty into small venous branches that coalesce into larger veins to eventually form the renal vein.

The hydrostatic pressure gradient across the glomerular capillary wall is the primary driving force for glomerular filtration. Oncotic pressure within the capillary lumen, determined by the concentration of unfiltered plasma proteins, partially offsets the hydrostatic pressure gradient and opposes filtration. As the oncotic pressure rises along the length of the glomerular capillary, the driving force for filtration falls to zero en route to the efferent arteriole. Approximately 20% of the renal plasma flow is filtered into Bowman space, and the ratio of glomerular filtration rate (GFR) to renal plasma flow determines the filtration fraction. Several factors, mostly hemodynamic, contribute to the regulation of filtration under physiologic conditions.

Although glomerular filtration is affected by renal artery pressure, this relationship is not linear across the range of physiologic blood pressures due to autoregulation of GFR. Autoregulation of glomerular filtration is the result of three major factors that modulate either afferent or efferent arteriolar tone; these include an autonomous vasoreactive (myogenic) reflex in the afferent arteriole, *tubuloglomerular feedback* (TGF), and angiotensin II–mediated vasoconstriction of the efferent arteriole. The myogenic reflex is a first line of defense against fluctuations in renal blood flow. Acute changes in renal perfusion pressure evoke reflex constriction or dilatation of the afferent arteriole in response to rising or falling pressure, respectively. This phenomenon helps protect the glomerular capillary from sudden changes in systolic pressure.

TGF changes the rate of filtration and tubular flow by reflex vasoconstriction or dilatation of the afferent arteriole. TGF is mediated by specialized cells in the thick ascending limb of the loop of Henle called the *macula densa* that act as sensors of solute concentration and tubular fluid flow rate. With high tubular flow rates, a proxy for an inappropriately high filtration rate, greater solute delivery to the macula densa **(Fig. 320-2*B*)** evokes vasoconstriction of the afferent arteriole, causing GFR to return toward normal. One component of the soluble signal from the macula densa is adenosine triphosphate (ATP) released by the cells during increased NaCl reabsorption. ATP is metabolized in the extracellular space to generate adenosine, a potent vasoconstrictor of the afferent arteriole. During conditions associated with a fall in filtration rate, a lower rate of solute delivery to the macula densa attenuates TGF, allowing afferent arteriolar dilatation and restoring GFR to normal levels. Angiotensin II and reactive oxygen species enhance TGF, whereas nitric oxide (NO) blunts TGF. A distinct feedback mechanism may exist between the connecting tubule and GFR in which high Na^+ delivery evokes afferent arteriolar dilation possibly mediated by prostaglandins.

The third component underlying autoregulation of GFR involves angiotensin II. During states of reduced renal blood flow, renin is released from granular cells within the wall of the afferent arteriole near the macula densa in a region called the juxtaglomerular apparatus (Fig. 320-2*B*). Renin, a proteolytic enzyme, catalyzes the conversion of angiotensinogen to angiotensin I, which is subsequently converted to angiotensin II by angiotensin-converting enzyme (ACE) **(Fig. 320-2*C*)**. Angiotensin II evokes vasoconstriction of the efferent arteriole, and the resulting increased glomerular hydrostatic pressure elevates GFR to normal levels.

MECHANISMS OF RENAL TUBULAR TRANSPORT

The renal tubules are composed of highly differentiated epithelia that vary in morphology and function along the nephron (Fig. 320-3). The cells lining the various tubular segments form monolayers connected to one another by a specialized region of the adjacent lateral membranes called the *tight junction*. Tight junctions form an occlusive barrier that separates the lumen of the tubule from the interstitial spaces surrounding the tubule and also apportions the cell membrane into discrete domains: the apical membrane facing the tubular lumen and the basolateral membrane facing the interstitium. This regionalization allows cells to allocate membrane proteins and lipids asymmetrically. Owing to this feature, renal epithelial cells are said to be *polarized*. The asymmetric assignment of membrane proteins, especially proteins mediating transport processes, provides the machinery for directional movement of fluid and solutes by the nephron.

EPITHELIAL SOLUTE TRANSPORT

There are two types of epithelial transport. Movement of fluid and solutes sequentially across the apical and basolateral cell membranes (or vice versa) mediated by transporters, channels, or pumps is called *cellular transport*. By contrast, movement of fluid and solutes through the narrow passageway between adjacent cells is called *paracellular transport*. Paracellular transport occurs through tight junctions, indicating that they are not completely "tight" or occlusive. Indeed, some epithelial cell layers allow rather robust paracellular transport to occur (*leaky epithelia*), whereas other epithelia have more restrictive tight junctions (*tight epithelia*). In addition, because the ability of ions to flow through the paracellular pathway determines the electrical resistance across the epithelial monolayer, leaky and tight epithelia are also referred to as low- or high-resistance epithelia, respectively. The proximal tubule contains leaky epithelia, whereas distal nephron segments, such as the collecting duct, contain tight epithelia. Leaky epithelia are most well suited for bulk fluid reabsorption, whereas tight epithelia allow for more refined control and regulation of transport.

MEMBRANE TRANSPORT

Cell membranes are composed of hydrophobic lipids that repel water and aqueous solutes. The movement of solutes and water across cell membranes is made possible by discrete classes of integral membrane

proteins, including channels, pumps, and transporters. These different mechanisms mediate specific types of transport activities, including *active transport* (pumps), *passive transport* (channels), *facilitated diffusion* (transporters), and *secondary active transport* (cotransporters). Active transport requires metabolic energy generated by the hydrolysis of ATP. Active transport pumps are ion-translocating ATPases, including the ubiquitous Na^+/K^+-ATPase, the H^+-ATPases, and Ca^{2+}-ATPases. Active transport creates asymmetric ion concentrations across a cell membrane and can move ions against a chemical gradient. The potential energy stored in a concentration gradient of an ion such as Na^+ can be used to drive transport through other mechanisms (secondary active transport). The movement of solutes through a membrane protein by simple diffusion is called passive transport. This activity is mediated by channels created by selectively permeable membrane proteins, and it allows solute or water to move across a membrane driven by favorable *concentration gradients* or *electrochemical potential*. Facilitated diffusion is a specialized type of passive transport mediated by simple transporters called *carriers* or *uniporters*. For example, hexose transporters such as GLUT2 mediate glucose transport by tubular cells. These transporters are driven by the concentration gradient for glucose that is highest in extracellular fluids and lowest in the cytoplasm due to rapid metabolism. Many other transporters operate by translocating two or more ions/solutes in concert either in the same direction (*symporters* or *cotransporters*) or in opposite directions (*antiporters* or *exchangers*) across the cell membrane. The movement of two or more ions/solutes may produce no net change in the balance of electrostatic charges across the membrane (*electroneutral*), or a transport event may alter the balance of charges (*electrogenic*). Several inherited disorders of renal tubular solute and water transport occur as a consequence of mutations in genes encoding a variety of channels, transporter proteins, and their regulators **(Table 320-1)**.

The rate of tubular fluid flow through the nephron is highly variable, for which reason ion transport needs to be adjusted accordingly. Renal epithelial cells have the ability to monitor tubular fluid flow by mechanisms involving cellular structures (apical microvilli, primary cilium) or mechanosensing ion channels. Tubular transport is regulated in response to changes in fluid flow through changes in intracellular Ca^{2+} or by purinergic receptor-mediated signal transduction.

SEGMENTAL NEPHRON FUNCTIONS

Each anatomic segment of the nephron has unique characteristics and specialized functions enabling selective transport of solutes and water **(Fig. 320-3*A*)**. Through sequential events of reabsorption and secretion along the nephron, tubular fluid is progressively conditioned into urine. Knowledge of the major tubular mechanisms responsible for solute and water transport is critical for understanding hormonal regulation of kidney function and the pharmacologic manipulation of renal excretion.

PROXIMAL TUBULE

The proximal tubule is responsible for reabsorbing ~60% of filtered NaCl and water, as well as ~90% of filtered bicarbonate and most critical nutrients such as glucose and amino acids. The proximal tubule uses both cellular and paracellular transport mechanisms. The apical membrane of proximal tubular cells has an expanded surface area available for reabsorption created by a dense array of microvilli called the *brush border*, and leaky tight junctions enable high-capacity fluid reabsorption.

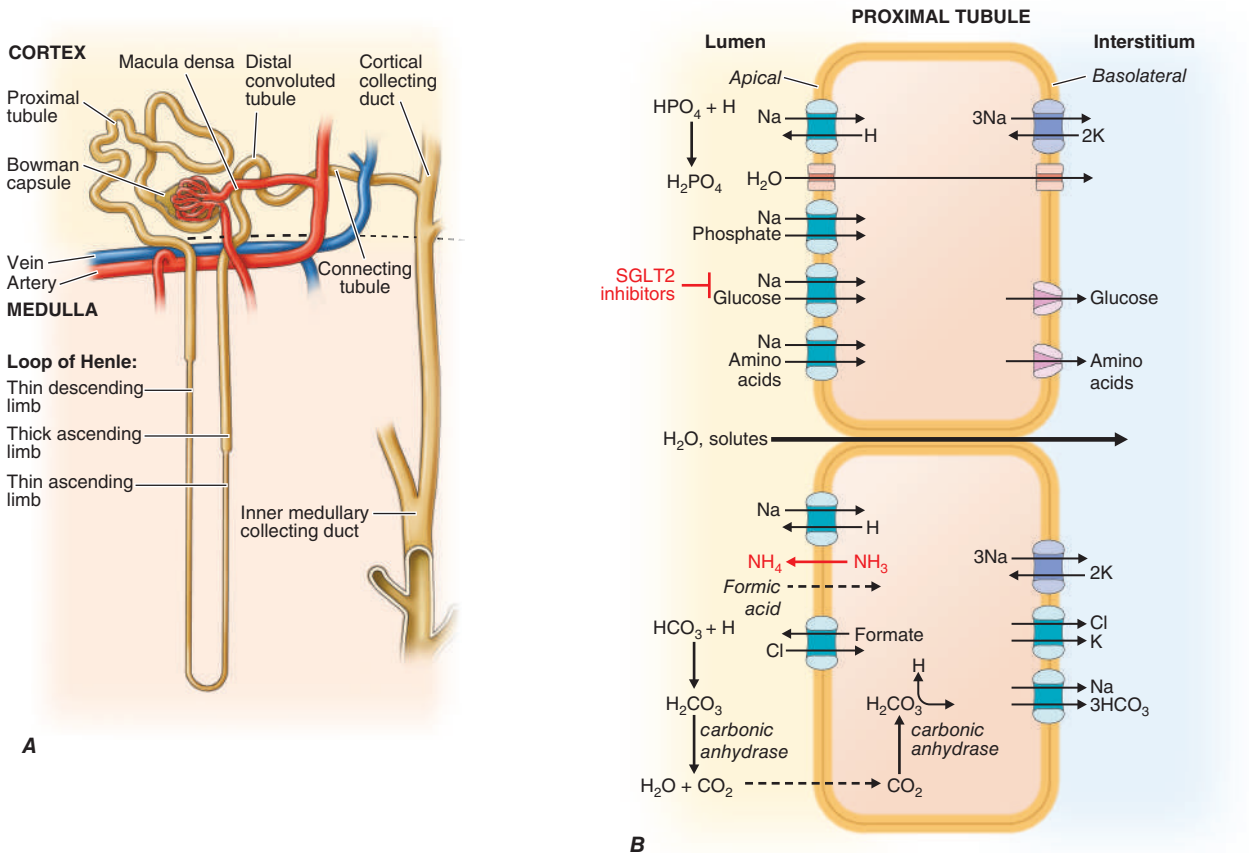

FIGURE 320-3 Transport activities of the major nephron segments. Representative cells from five major tubular segments are illustrated with the lumen side (apical membrane) facing left and interstitial side (basolateral membrane) facing right. ***A.*** Overview of entire nephron. ***B.*** Proximal tubular cells. ***C.*** Typical cell in the thick ascending limb of the loop of Henle. ***D.*** Distal convoluted tubular cell. ***E.*** Cortical collecting duct principal cell. ***F.*** Cortical collecting duct type A and type B intercalated cells. ***G.*** Typical cell in the inner medullary collecting duct. The major membrane transporters, channels, and pumps are drawn with *arrows* indicating the direction of solute or water movement. For some events, the stoichiometry of transport is indicated by numerals preceding the solute. Targets for major diuretic agents are labeled. The actions of hormones are illustrated by *arrows with plus signs* for stimulatory effects and *lines with perpendicular ends* for inhibitory events. The *dashed line* indicates water impermeability of cell membranes in the thick ascending limb and distal convoluted tubule.

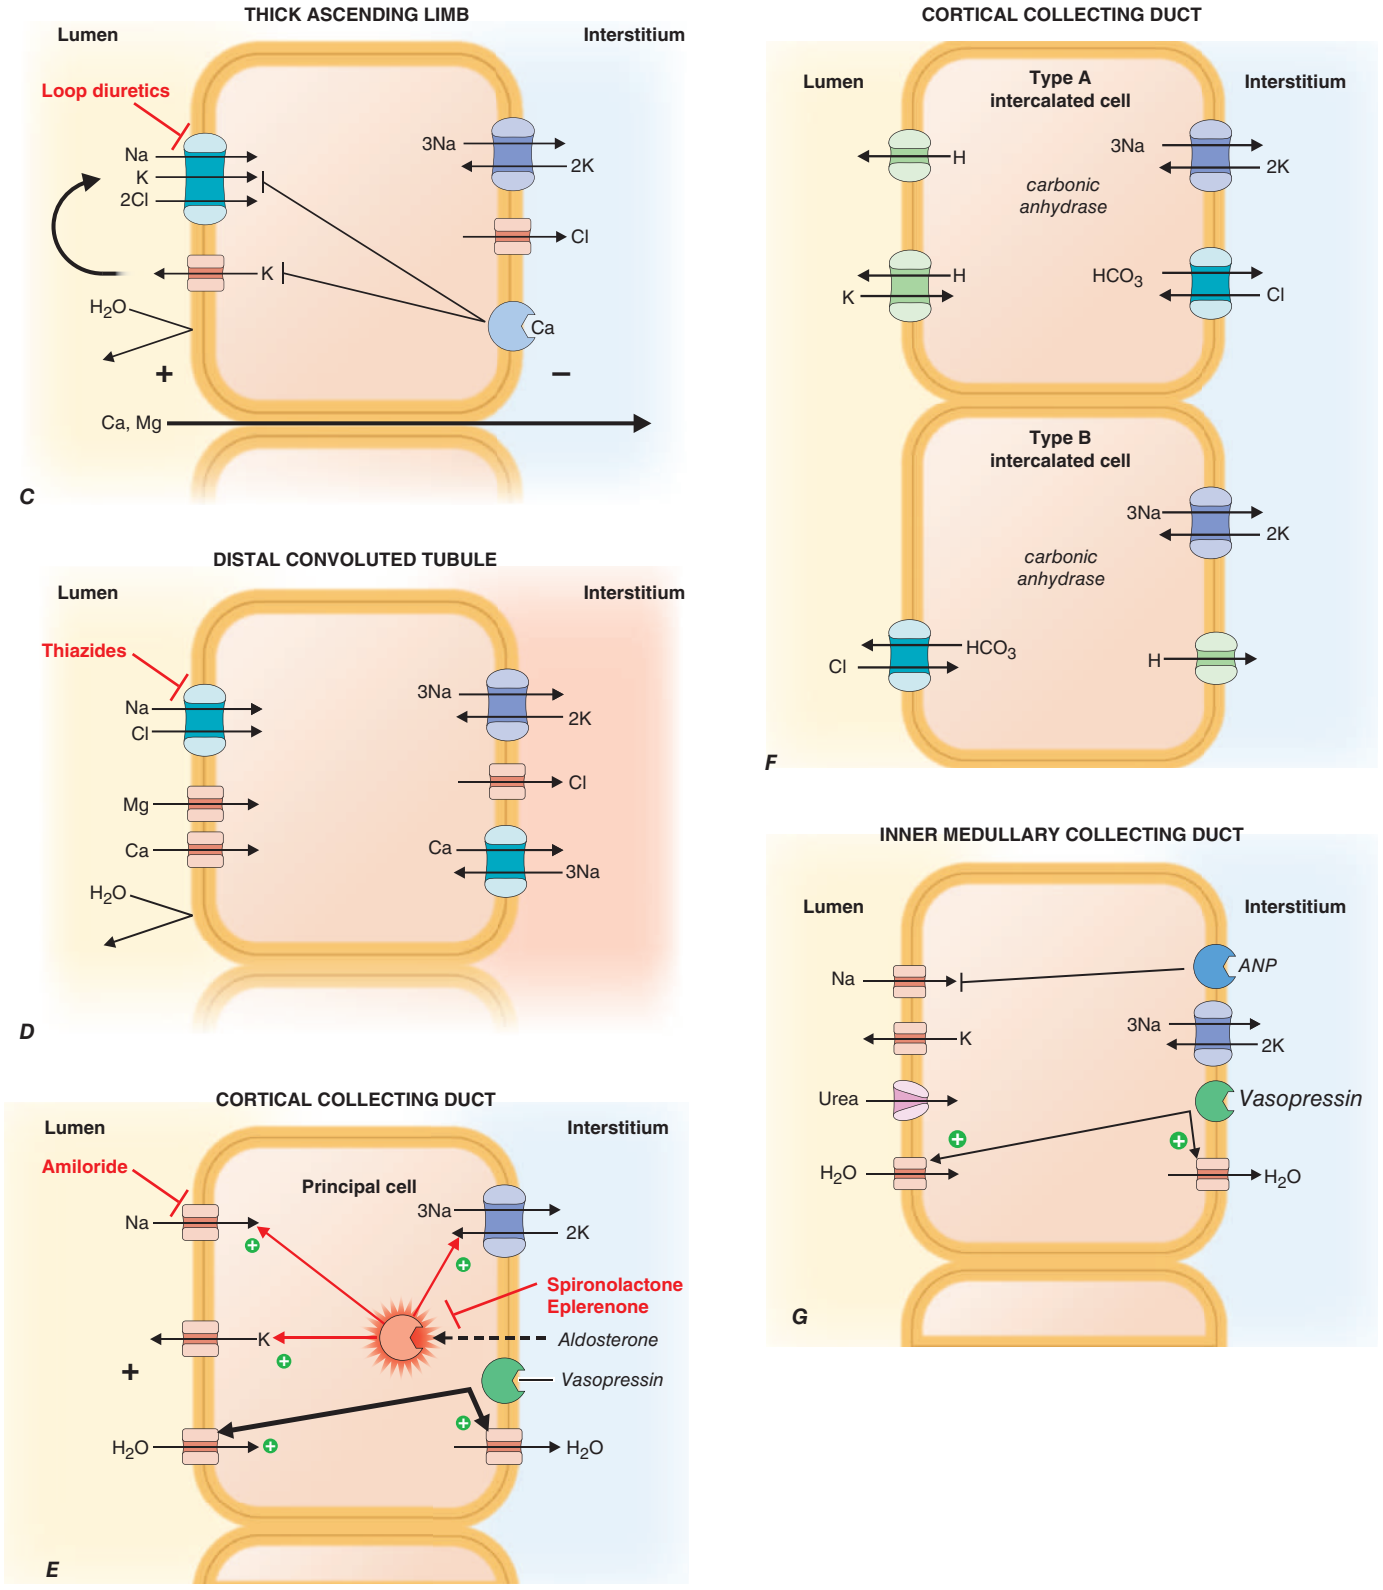

FIGURE 320-3 (Continued)

Solute and water pass through these tight junctions to enter the lateral intercellular space where absorption by the peritubular capillaries occurs. Bulk fluid reabsorption by the proximal tubule is driven by high oncotic pressure and low hydrostatic pressure within the peritubular capillaries. Cellular transport of most solutes by the proximal tubule is coupled to the Na^+ concentration gradient established by the activity of a basolateral Na^+/K^+-ATPase (Fig. 320-3*B*). This active transport mechanism maintains a steep Na^+ gradient by keeping intracellular Na^+ concentrations low. Solute reabsorption from the tubular lumen is coupled to the Na^+ gradient by Na^+-dependent transporters such as Na^+-glucose and Na^+-phosphate cotransporters present in apical membranes. In addition to the paracellular route, water reabsorption also occurs through the cellular pathway enabled by constitutively active water channels (aquaporin-1) present on both apical and basolateral membranes.

Proximal tubular cells reclaim nearly all filtered bicarbonate by a mechanism dependent on carbonic anhydrases. Filtered bicarbonate is first titrated by protons delivered to the lumen mainly by apical

TABLE 320-1 Inherited Disorders Affecting Renal Tubular Ion and Solute Transport

DISEASE OR SYNDROME	PROTEIN (*GENE*)	OMIM[a]
Disorders Involving the Proximal Tubule		
Proximal renal tubular acidosis	Sodium bicarbonate cotransporter (*SLC4A4*, 4q21)	604278
Fanconi-Bickel syndrome	Glucose transporter, GLUT2 (*SLC2A2*, 3q26.2)	227810
Isolated renal glycosuria	Sodium glucose cotransporter (*SLC5A2*, 16p11.2)	233100
Cystinuria		
Type I	Cystine, dibasic and neutral amino acid transporter (*SLC3A1*, 2p16.3)	220100
Non-type I	Amino acid transporter, light subunit (*SLC7A9*, 19q13.1)	600918
Lysinuric protein intolerance	Amino acid transporter (*SLC7A7*, 4q11.2)	222700
Dicarboxylic aminoaciduria	Glutamate transporter (*SLC1A1*, 9q24.2)	222730
Hartnup disorder	Neutral amino acid transporter (*SLC6A19*, 5p15.33)	34500
Hypophosphatemic nephrolithiasis/osteoporosis 1	Sodium phosphate cotransporter (*SLC34A1, 5q35.3)*	612286
Hereditary hypophosphatemic rickets with hypercalcemia	Sodium phosphate cotransporter (*SLC34A3*, 9q34)	241530
Renal hypouricemia		
Type 1	Urate-anion exchanger (*SLC22A12*, 11q13)	220150
Type 2	Urate transporter, GLUT9 (*SLC2A9*, 4p16.1)	612076
Dent's disease	Chloride channel, ClC-5 (*CLCN5*, Xp11.22)	300009
X-linked recessive nephrolithiasis with renal failure	Chloride channel, ClC-5 (*CLCN5*, Xp11.22)	310468

Familial hypocalciuric hypercalcemia	Calcium-sensing receptor (*CASR*, 3q13.33)	145980
Familial hypomagnesemia type 3	Claudin-16 (*CLDN16*, 3q27)	248250
Familial hypomagnesemia type 5	Claudin-19 (*CLDN19*, 1p34.2)	603959
Isolated renal magnesium loss	Sodium potassium ATPase, γ_1-subunit (*ATP1G1*, 11q23)	154020
Disorders Involving the Distal Tubule and Collecting Duct		
Gitelman syndrome	Sodium chloride cotransporter (*SLC12A3*, 16q13)	263800
Primary hypomagnesemia with secondary hypocalcemia	Melastatin-related transient receptor potential cation channel 6 (*TRPM6*, 9q22)	602014
Pseudoaldosteronism (Liddle's syndrome)	Epithelial sodium channel β and γ subunits (*SCNN1B*, *SCNN1G*, 16p12.1)	177200
Recessive pseudohypoaldosteronism type 1	Epithelial sodium channel, α, β, and γ subunits (*SCNN1A*, 12p13; *SCNN1B*, *SCNN1G*, 16pp12.1)	264350
Pseudohypoaldosteronism type 2 (Gordon's hyperkalemia-hypertension syndrome)	Kinases WNK-1, WNK-4 (*WNK1*, 12p13; *WNK4*, 17q21.31)	145260
X-linked nephrogenic diabetes insipidus	Vasopressin V2 receptor (AVPR2, Xq28)	304800
EAST/SeSAME syndrome	Potassium channel Kir4.1 (*KCNJ10*, 1q23.2)	612780
Nephrogenic diabetes insipidus (autosomal)	Water channel, aquaporin-2 (*AQP2*, 12q13)	125800
Distal renal tubular acidosis		
autosomal dominant	Anion exchanger-1 (*SLC4A1*, 17q21.31)	179800
autosomal recessive	Anion exchanger-1 (*SLC4A1*, 17q21.31)	602722
with neural deafness	Proton ATPase, β1 subunit (*ATP6V1B1*, 2p13.3)	192132
with normal hearing	Proton ATPase, 116-kD subunit (*ATP6V0A4*, 7q34)	602722

[a]Online Mendelian Inheritance in Man database (*https://www.ncbi.nlm.nih.gov/omim*).

membrane Na^+/H^+ exchange. The resulting carbonic acid (H_2CO_3) is metabolized by brush border carbonic anhydrase to water and carbon dioxide. Dissolved carbon dioxide then diffuses into the cell, where it is enzymatically hydrated by cytoplasmic carbonic anhydrase to re-form carbonic acid. Finally, intracellular carbonic acid dissociates into free protons and bicarbonate anions, and bicarbonate exits the cell through a basolateral Na^+/HCO_3^- cotransporter. This process is saturable, which can result in renal bicarbonate excretion when plasma levels exceed the physiologically normal range (24–26 meq/L). Carbonic anhydrase inhibitors such as acetazolamide block proximal tubule bicarbonate reabsorption and are useful for alkalinizing the urine.

The proximal tubule contributes to acid secretion by two mechanisms involving the titration of the urinary buffers ammonia (NH_3) and phosphate. Renal NH_3 is produced by glutamine metabolism in the proximal tubule. Subsequent diffusion of NH_3 out of the proximal tubular cell enables trapping of H^+, which is secreted by apical Na^+/H^+ exchange, in the lumen as ammonium ion (NH_4^+). Cellular K^+ levels inversely modulate proximal tubular ammoniagenesis, and in the setting of high serum

K^+ from hypoaldosteronism, reduced ammoniagenesis promotes type IV renal tubular acidosis. Filtered hydrogen phosphate ion (HPO_4^{2-}) is also titrated in the proximal tubule by secreted H^+ to form $H_2PO_4^-$, and this reaction constitutes a major component of the urinary buffer referred to as titratable acid. Most filtered phosphate ion is reabsorbed by the proximal tubule through a sodium-coupled cotransport process that is regulated by parathyroid hormone (PTH).

Chloride is poorly reabsorbed throughout the first segment of the proximal tubule, and a rise in Cl^- concentration counterbalances the removal of bicarbonate anion from tubular fluid. In later proximal tubular segments, cellular Cl^- reabsorption is initiated by apical exchange of cellular formate for higher luminal concentrations of Cl^-. Once in the lumen, formate anions are titrated by H^+ (provided by Na^+/H^+ exchange) to generate neutral formic acid, which can diffuse passively across the apical membrane back into the cell where it dissociates a proton and is recycled. Basolateral Cl^- exit is mediated by a K^+/Cl^- cotransporter.

Reabsorption of glucose is nearly complete by the end of the proximal tubule. Cellular transport of glucose is mediated by apical Na^+-glucose cotransport coupled with basolateral, facilitated diffusion by a glucose transporter. This process is also saturable, leading to glycosuria when plasma levels exceed 180–200 mg/dL, as seen in untreated diabetes mellitus. Inhibitors of the Na^+-glucose cotransporter SLGT2 in proximal tubules block glucose reabsorption and lower blood glucose, which has therapeutic benefits in diabetes mellitus and chronic diabetic kidney disease.

The proximal tubule possesses specific transporters capable of secreting a variety of organic acids (carboxylate anions) and bases (mostly primary amine cations). Organic anions transported by these systems include several protein-bound drugs not filtered at the glomerulus (penicillins, cephalosporins, salicylates, and others). Organic cations secreted by the proximal tubule include various biogenic amine neurotransmitters (dopamine, acetylcholine, epinephrine, norepinephrine, and histamine) and creatinine. The ATP-dependent transporter P-glycoprotein encoded by *ABCB1* is expressed in brush border membranes and secretes several medically important drugs, including cyclosporine, digoxin, tacrolimus, and various cancer chemotherapeutic agents. Certain drugs such as cimetidine and trimethoprim compete with endogenous compounds for transport by the organic cation pathways. Although these drugs elevate serum creatinine levels, there is no actual change in GFR in this setting.

Calcium and phosphorus homeostasis depends on normal functioning of the proximal tubule. Approximately 60–70% of filtered calcium and ~85% of filtered phosphorus (in the form of inorganic phosphate) are reabsorbed by the proximal tubule. Whereas calcium reabsorption is mostly by passive diffusion through the paracellular route, phosphate reabsorption is mediated by sodium-coupled cotransport. In addition to direct reabsorption, the proximal tubule contributes to systemic mineral balance by participating in specific endocrine pathways. Circulating 25-hydroxy vitamin D (calcidiol) is bioactivated by proximal tubular 1α-hydroxylase to produce 1,25-di-hydroxy vitamin D (calcitriol), the most active form of the hormone, which acts on the small intestine to promote calcium absorption. Phosphate balance is affected by circulating fibroblast growth hormone 23 (FGF23), a bone-derived hormone that interacts with its receptor (FGFR1) and co-receptor (Klotho) on proximal tubular cells to suppress sodium-phosphate cotransport and promote renal phosphate excretion. PTH stimulates proximal tubular 1α-hydroxylation of vitamin D, whereas it suppresses sodium-phosphate cotransport. Derangements in PTH and FGF23 account for abnormal calcium and phosphate balance in chronic kidney disease.

The proximal tubule, through distinct classes of Na^+-dependent and Na^+-independent transport systems, reabsorbs amino acids efficiently. These transporters are specific for different groups of amino acids. For example, cystine, lysine, arginine, and ornithine are transported by a system comprising two proteins encoded by the *SLC3A1* and *SLC7A9* genes. Mutations in either *SLC3A1* or *SLC7A9* impair reabsorption of these amino acids and cause the disease cystinuria. Peptide hormones, such as insulin and growth hormone, β_2-microglobulin, and other small proteins, are taken up by the proximal tubule through a process of absorptive endocytosis and are degraded in acidified endocytic lysosomes. Acidification of these vesicles depends on a multi-subunit vacuolar H^+-ATPase and a separate Cl^-/H^+ exchanger encoded by *CLCN5*. Impaired acidification of endocytic vesicles because of *CLCN5* pathogenic variants causes low-molecular-weight proteinuria in Dent's disease.

LOOP OF HENLE

The loop of Henle consists of three major segments: descending thin limb, ascending thin limb, and ascending thick limb. Approximately 15–25% of filtered NaCl is reabsorbed in the loop of Henle, mainly by the thick ascending limb. The loop of Henle has an important role in urinary concentration by contributing to the generation of a hypertonic medullary interstitium in a process called *countercurrent multiplication*. The loop of Henle is the site of action for the most potent class of diuretic agents (loop diuretics) and also contributes to reabsorption of calcium and magnesium ions.

The descending thin limb is highly water permeable owing to dense expression of constitutively active aquaporin-1 water channels. By contrast, water permeability is negligible in the ascending thin and thick limbs. In the thick ascending limb, there is a high level of secondary active NaCl transport enabled by the $Na^+/K^+/2Cl^-$ cotransporter on the apical membrane in series with basolateral Cl^- channels and Na^+/K^+-ATPase **(Fig. 320-3*C*)**. The $Na^+/K^+/2Cl^-$ cotransporter is the molecular target for loop diuretics. Tubular fluid K^+ is the limiting substrate for this cotransporter (tubular concentration of K^+ is similar to plasma, ~4 meq/L), but transporter activity is maintained by K^+ recycling through an apical potassium channel. The cotransporter also enables reabsorption of NH_4^+ in lieu of K^+, and this leads to accumulation of both NH_4^+ and NH_3 in the medullary interstitium. An inherited disorder of the thick ascending limb, Bartter's syndrome, is a salt-wasting renal disease associated with hypokalemia and metabolic alkalosis. Loss-of-function mutations in one of five distinct genes encoding components of the $Na^+/K^+/2Cl^-$ cotransporter (*NKCC2*), apical K^+ channel (*KCNJ1*), basolateral Cl^- channel (*CLCNKB*, *BSND*), or calcium-sensing receptor (*CASR*) can cause Bartter's syndrome.

Potassium recycling also contributes to a positive electrostatic charge in the lumen relative to the interstitium that promotes divalent cation (Mg^{2+} and Ca^{2+}) reabsorption through a paracellular pathway. A Ca^{2+}-sensing, G protein–coupled receptor (CaSR) on basolateral membranes regulates NaCl reabsorption in the thick ascending limb through dual signaling mechanisms using either cyclic AMP or eicosanoids. This receptor enables a steep relationship between plasma Ca^{2+} levels and renal Ca^{2+} excretion. Loss-of-function mutations in CaSR cause familial hypercalcemic hypocalciuria because of a blunted response of the thick ascending limb to extracellular Ca^{2+}. Mutations in *CLDN16* encoding paracellin-1, a transmembrane protein located within the tight junction complex, leads to familial hypomagnesemia with hypercalciuria and nephrocalcinosis, suggesting that the ion conductance of the paracellular pathway in the thick limb is regulated.

The loop of Henle contributes to urine-concentrating ability by establishing a *hypertonic medullary interstitium* that promotes water reabsorption by the inner medullary collecting duct located downstream in the nephron. *Countercurrent multiplication* produces a hypertonic medullary interstitium using two countercurrent systems: the loop of Henle (opposing descending and ascending limbs) and the vasa recta (medullary peritubular capillaries enveloping the loop). The countercurrent flow in these two systems helps maintain the hypertonic environment of the inner medulla, but NaCl reabsorption by the thick ascending limb is the primary initiating event. Reabsorption of NaCl without water dilutes the tubular fluid and adds new osmoles to medullary interstitial fluid. Because the descending thin limb is highly water permeable, osmotic equilibrium occurs between the descending limb tubular fluid and the interstitial space, leading to progressive solute trapping in the inner medulla. Maximum medullary interstitial osmolality also requires partial recycling of urea mediated by urea transporters in the inner medullary collecting duct.

DISTAL CONVOLUTED TUBULE

The distal convoluted tubule reabsorbs ~5% of filtered NaCl. This segment is composed of a tight epithelium with little water permeability. The major NaCl-transporting pathway uses an apical membrane, electroneutral thiazide-sensitive Na^+/Cl^- cotransporter in tandem with basolateral Na^+/K^+-ATPase and Cl^- channels **(Fig. 320-3*D*)**. Apical Ca^{2+}-selective channels (TRPV5) and basolateral Na^+/Ca^{2+} exchange mediate calcium reabsorption in the distal convoluted tubule. Ca^{2+} reabsorption is inversely related to Na^+ reabsorption and is stimulated by PTH. Blocking apical Na^+/Cl^- cotransport will reduce intracellular Na^+, favoring increased basolateral Na^+/Ca^{2+} exchange and passive apical Ca^{2+} entry. Loss-of-function mutations of *SLC12A3* encoding the apical Na^+/Cl^- cotransporter cause Gitelman syndrome, a salt-wasting disorder associated with hypokalemic alkalosis and hypocalciuria. Mutations in *TRPM6* encoding Mg^{2+} permeable ion channels also cause familial hypomagnesemia with hypocalcemia. A molecular complex of TRPM6 and TRPM7 proteins is critical for Mg^{2+} reabsorption in the distal convoluted tubule. Basolateral Mg^{2+} exit from these cells is postulated to involve Na^+/Mg^{2+} exchange.

COLLECTING DUCT

The collecting duct modulates the final composition of urine. The two major divisions, the cortical collecting duct and inner medullary collecting duct, contribute to reabsorbing ~4–5% of filtered Na^+ and are important for hormonal regulation of salt and water balance. Cells in both segments of the collecting duct express vasopressin-regulated water channels (aquaporin-2 on the apical membrane, aquaporin-3 and -4 on the basolateral membrane). The antidiuretic hormone vasopressin binds to the V2 receptor on the basolateral membrane and triggers an intracellular signaling cascade through G protein–mediated activation of adenylyl cyclase, which raises intracellular levels of cyclic AMP. This signaling cascade stimulates the insertion of water channels into the apical membrane of collecting duct cells to promote water permeability, water reabsorption, and production of concentrated urine. In the absence of vasopressin, collecting duct cells are water impermeable, and urine remains dilute. Nonpeptide V2 receptor blockers (vaptans) antagonize the antidiuretic effect of vasopressin and produce a water diuresis to treat symptomatic hyponatremia and can slow the progression of polycystic kidney disease.

The cortical collecting duct contains *high-resistance epithelia* with two cell types. Principal cells are the main water-reabsorbing, Na^+-reabsorbing, and K^+-secreting cells, and the site of action of aldosterone, K^+-sparing diuretics, and mineralocorticoid receptor antagonists such as spironolactone and eplerenone. The other cells are type A and B intercalated cells. Type A intercalated cells mediate acid secretion and bicarbonate reabsorption also under the influence of aldosterone. Type B intercalated cells mediate bicarbonate secretion and acid reabsorption.

Virtually all transport is mediated through the cellular pathway for both principal cells and intercalated cells. In principal cells, passive apical Na^+ entry occurs through an amiloride-sensitive, epithelial Na^+ channel (ENaC) with basolateral exit mediated by the Na^+/K^+-ATPase **(Fig. 320-3*E*)**. This Na^+ reabsorptive process is tightly regulated by aldosterone and is physiologically activated by a variety of proteolytic enzymes that cleave extracellular domains of ENaC; plasmin in the tubular fluid of individuals affected by nephrotic syndrome, for example, activates ENaC, leading to Na^+ retention. Aldosterone enters the cell across the basolateral membrane, binds to a cytoplasmic mineralocorticoid receptor, and then translocates into the nucleus, where it modulates gene transcription, which potentiates Na^+ reabsorption and K^+ secretion. Activating mutations in ENaC increase Na^+ reclamation and produce hypokalemia, hypertension, and metabolic alkalosis (Liddle's syndrome). The potassium-sparing diuretics amiloride and triamterene block ENaC, resulting in lower Na^+ reabsorption.

Principal cells secrete K^+ through an apical membrane potassium channel. Several forces govern the secretion of K^+. Most importantly, the high intracellular K^+ concentration generated by Na^+/K^+-ATPase creates a favorable concentration gradient for K^+ secretion into tubular fluid. With reabsorption of Na^+ without an accompanying anion, the tubular lumen becomes negative relative to the cell interior, creating a favorable electrical gradient for secretion of potassium. When Na^+ reabsorption is blocked, the electrical component of the driving force for K^+ secretion is blunted, and this explains lack of excess urinary K^+ loss during treatment with potassium-sparing diuretics or mineralocorticoid receptor antagonists. K^+ secretion is also promoted by aldosterone actions that potentiate regional Na^+ transport, which favor more lumen electronegativity, and by increasing the number and activity of potassium channels. Fast tubular fluid flow rates that occur during volume expansion or diuretics acting "upstream" of the cortical collecting duct also promote K^+ secretion, as does the presence of relatively nonreabsorbable anions (including bicarbonate and semisynthetic penicillins) that contribute to the lumen-negative potential. Off-target effects of certain antibiotics, such as trimethoprim and pentamidine, block ENaCs and predispose to hyperkalemia, especially when renal K^+ handling is impaired for other reasons. Principal cells, as described below, also participate in water reabsorption in response to vasopressin.

Intercalated cells do not participate in Na^+ reabsorption but instead mediate acid-base balance. These cells perform two types of transport: active H^+ transport mediated by H^+-ATPase (proton pump) and Cl^-/HCO_3^- exchange. Intercalated cells arrange the two transport mechanisms on opposite membranes to enable either acid or base secretion. Type A intercalated cells have an apical proton pump that mediates acid secretion and a basolateral Cl^-/HCO_3^- anion exchanger for bicarbonate reabsorption (Fig. 320-3*E*). Aldosterone increases the number of H^+-ATPase pumps, sometimes contributing to the development of metabolic alkalosis. Secreted H^+ is buffered by NH_3 that has diffused into the collecting duct lumen from the surrounding interstitium. By contrast, type B intercalated cells have the Cl^-/HCO_3^- exchanger on the apical membrane to mediate bicarbonate secretion while the proton pump resides on the basolateral membrane to enable H^+ reabsorption. Under conditions of acidemia, the kidney preferentially uses type A intercalated cells to secrete the excess H^+ and generate more HCO_3^-. The opposite is true in states of bicarbonate excess with alkalemia where the type B intercalated cells predominate. An extracellular protein called *hensin* mediates this adaptation.

Inner medullary collecting duct cells share many similarities with principal cells of the cortical collecting duct. They have apical Na^+ and K^+ channels that mediate Na^+ reabsorption and K^+ secretion, respectively **(Fig. 320-3*F*)**. Sodium reabsorption by inner medullary collecting duct cells is also inhibited by the natriuretic peptides *atrial natriuretic peptide* or *renal natriuretic peptide* (urodilatin); the same gene encodes both peptides but uses different posttranslational processing of a common preprohormone to generate different proteins. Atrial natriuretic peptides are secreted by atrial myocytes in response to volume expansion, whereas urodilatin is secreted by renal tubular epithelia. Natriuretic peptides interact with either apical (urodilatin) or basolateral (atrial natriuretic peptides) receptors on inner medullary collecting duct cells to stimulate guanylyl cyclase and raise levels of cytoplasmic cGMP. This effect in turn reduces the activity of the apical Na^+ channel in these cells and attenuates net Na^+ reabsorption, producing natriuresis.

The inner medullary collecting duct transports urea out of the lumen, returning urea to the interstitium, where it contributes to the hypertonicity of the medullary interstitium. Urea is recycled by diffusing from the interstitium into the descending and ascending limbs of the loop of Henle.

HORMONAL REGULATION OF SODIUM AND WATER BALANCE

The balance of solute and water in the body is determined by the amounts ingested, distributed to various fluid compartments, and excreted by skin, bowel, and kidneys. *Tonicity*, the osmolar state determining the volume behavior of cells in a solution, is regulated by water balance **(Fig. 320-4*A*)**, and *extracellular blood volume* is regulated by Na^+ balance **(Fig. 320-4*B*)**. The kidney is a critical modulator of both physiologic processes.

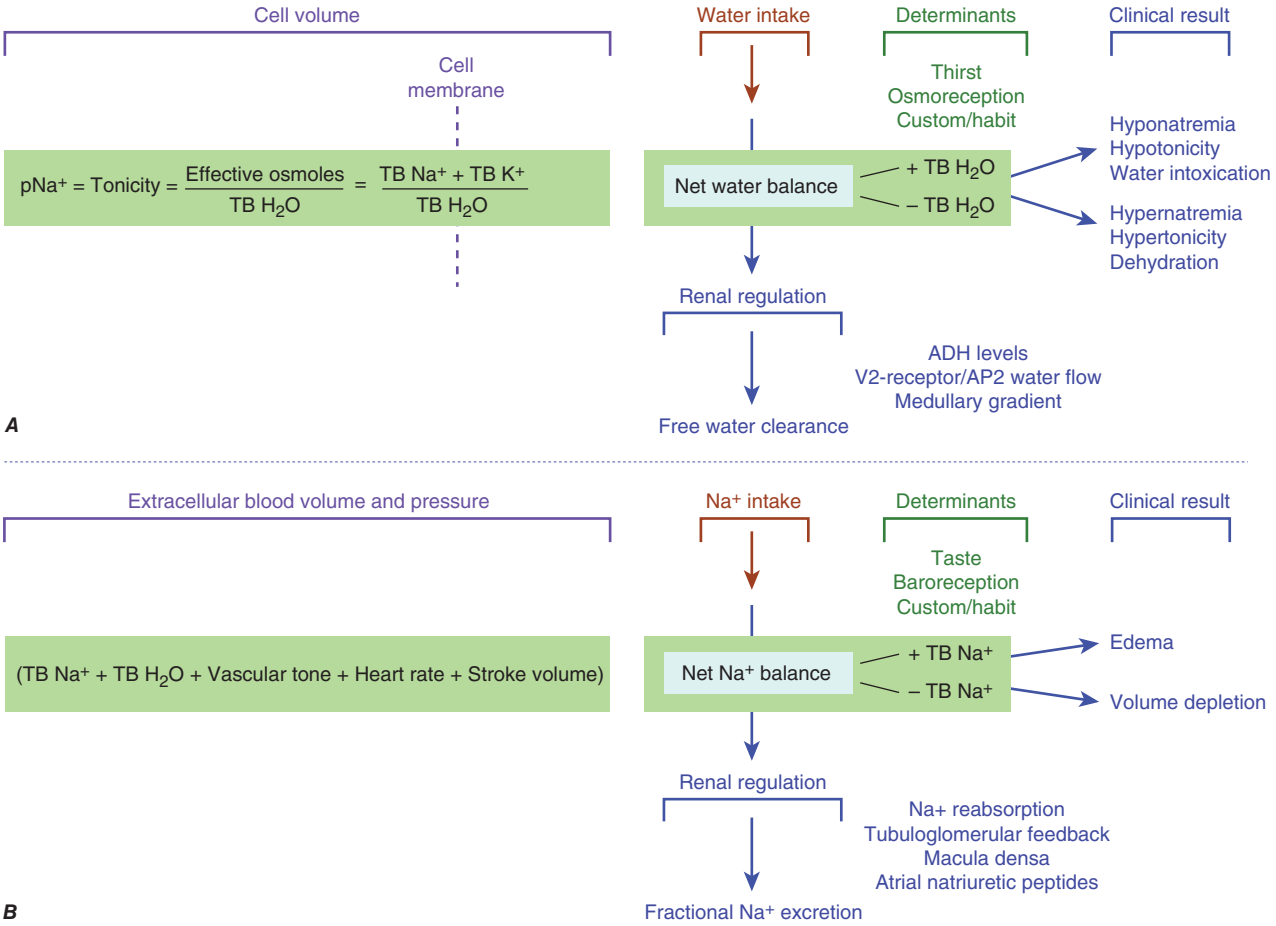

FIGURE 320-4 Determinants of sodium and water balance. ***A.*** Plasma Na^+ concentration is a surrogate marker for plasma tonicity. Tonicity is determined by the number of effective osmoles in the body divided by the total body H_2O (TB H_2O), which translates simply into the total body Na (TB Na^+) and anions outside the cell separated from the total body K (TB K^+) inside the cell by the cell membrane. Net water balance is determined by the integrated functions of thirst, osmoreception, Na reabsorption, vasopressin release, and the strength of the medullary gradient in the kidney, keeping tonicity within a narrow range of osmolality (~280 mosmol/L). When water metabolism is disturbed and total body water increases, hyponatremia, hypotonicity, and water intoxication occur; when total body water decreases, hypernatremia, hypertonicity, and dehydration occur. ***B.*** Extracellular blood volume and pressure are an integrated function of total body Na^+ (TB Na^+), total body H_2O (TB H_2O), vascular tone, heart rate, and stroke volume that modulates volume and pressure in the vascular tree of the body. This extracellular blood volume is determined by net Na balance under the control of taste, baroreception, habit, Na^+ reabsorption, macula densa/tubuloglomerular feedback, and natriuretic peptides. When Na^+ metabolism is disturbed and total body Na^+ increases, edema occurs; when total body Na^+ is decreased, volume depletion occurs. ADH, antidiuretic hormone; AQP2, aquaporin-2.

WATER BALANCE

Tonicity depends on the variable concentration of *effective osmoles* inside and outside the cell causing water to move in either direction across its membrane. Classic effective osmoles, like Na^+, K^+, and their anions, are solutes trapped on either side of a cell membrane, where they collectively partition and obligate water to move and find equilibrium in proportion to retained solute. Normal tonicity (~280 mosmol/L) is rigorously defended by osmoregulatory mechanisms that control water balance to protect tissues from inadvertent *dehydration* (cell shrinkage) or *water intoxication* (cell swelling), both of which impair cell function (Fig. 320-4*A*).

The mechanisms that control osmoregulation are distinct from those governing extracellular volume, although there is some shared physiology in both processes. While cellular concentrations of K^+ have a determinant role in any level of tonicity, the routine surrogate marker for assessing clinical tonicity is the concentration of serum Na^+. Any reduction in total body water, which raises the Na^+ concentration, triggers a brisk sense of thirst and conservation of water by decreasing renal water excretion mediated by release of vasopressin from the posterior pituitary. Conversely, a lower plasma Na^+ concentration triggers more renal water excretion by suppressing the secretion of vasopressin. Whereas all cells expressing mechanosensitive TRPV1, 2, or 4 channels, among potentially other sensors, respond to changes in tonicity by altering their volume and Ca^{2+} concentration, only $TRPV^+$ neuronal cells connected to the organum vasculosum of the lamina terminalis are *osmoreceptive*. Only these cells, because of their neural connectivity and adjacency to a minimal blood-brain barrier, modulate the downstream release of vasopressin by the posterior lobe of the pituitary gland. Secretion is stimulated primarily by changing tonicity and secondarily by other nonosmotic signals such as variable blood volume, stress, pain, nausea, and some drugs. The release of vasopressin by the posterior pituitary increases linearly as plasma tonicity rises above normal, although this varies, depending on the perception of extracellular volume (one form of cross-talk between mechanisms that regulate blood volume and osmolality). Changing the intake or excretion of water provides a means for adjusting plasma tonicity; thus, osmoregulation governs water balance.

The kidneys contribute to maintaining water balance through the regulation of renal water excretion. The ability to concentrate urine to an osmolality exceeding that of plasma enables water conservation, whereas the ability to produce urine more dilute than plasma promotes excretion of excess water. For water to enter or exit a cell, the cell membrane must express aquaporins. In the kidney, aquaporin-1 is constitutively active in all water-permeable segments (e.g., proximal tubule, descending thin limb of the loop of Henle), whereas aquaporin-2, -3, and -4 in the collecting duct promote vasopressin-regulated water permeability. Net water reabsorption is ultimately driven by the osmotic gradient between dilute tubular fluid and a hypertonic medullary interstitium.

SODIUM BALANCE

The perception of *extracellular blood volume* is determined, in part, by the integration of arterial tone, cardiac stroke volume, heart rate, and the water and solute content of extracellular fluid. Na^+ and accompanying anions are the most abundant extracellular effective osmoles and together support a blood volume around which pressure is generated. Under normal conditions, this volume is regulated by sodium balance (Fig. 320-4*B*), and the balance between daily Na^+ intake and excretion is under the influence of *baroreceptors* in regional blood vessels and vascular hormone sensors modulated by atrial natriuretic peptides, the renin-angiotensin-aldosterone system, Ca^{2+} signaling, adenosine, vasopressin, and the neural adrenergic axis. If Na^+ intake exceeds Na^+ excretion (positive Na^+ balance), then a rising blood volume will trigger a proportional increase in urinary Na^+ excretion. Conversely, when Na^+ intake is less than urinary excretion (negative Na^+ balance), blood volume will fall and trigger enhanced renal Na^+ reabsorption, leading to decreased urinary Na^+ excretion.

The renin-angiotensin-aldosterone system is the best-understood hormonal system modulating renal Na^+ excretion. Renin is synthesized and secreted by granular cells in the wall of the afferent arteriole. Its secretion is controlled by several factors, including β_1-adrenergic stimulation to the afferent arteriole, input from the macula densa, and prostaglandins. Renin and ACE activity eventually produce angiotensin II that directly and indirectly promotes renal Na^+ and water reabsorption. Stimulation of proximal tubular Na^+/H^+ exchange by angiotensin II directly increases Na^+ reabsorption. Angiotensin II also promotes Na^+ reabsorption along the collecting duct by stimulating aldosterone secretion by the adrenal cortex. Constriction of the efferent glomerular arteriole by angiotensin II indirectly boosts the filtration fraction and raises peritubular capillary oncotic pressure to promote tubular Na^+ reabsorption. Finally, angiotensin II inhibits renin secretion through a negative feedback loop. Alternative metabolism of angiotensin by ACE2 generates the vasodilatory peptide angiotensin 1-7 that acts through Mas receptors to counterbalance several actions of angiotensin II on blood pressure and renal function (Fig. 320-2*C*).

Aldosterone is synthesized and secreted by granulosa cells in the adrenal cortex. It binds to cytoplasmic mineralocorticoid receptors in the collecting duct principal cells and boosts the activity of ENaC, apical membrane K^+ channel, and basolateral Na^+/K^+-ATPase. These effects are mediated in part by aldosterone-stimulated transcription of the gene encoding serum/glucocorticoid-induced kinase 1 (SGK1). The activity of ENaC is increased by SGK1-mediated phosphorylation of the ubiquitin-protein ligase Nedd4-2 that promotes ubiquitination and recycling of the Na^+ channel from the plasma membrane. Phosphorylated Nedd4-2 has impaired interactions with ENaC, leading to higher channel density at the plasma membrane and greater capacity for Na^+ reabsorption by the collecting duct.

Chronic exposure to aldosterone is associated with lower urinary Na^+ excretion lasting only a few days, after which Na^+ excretion returns to previous levels. This phenomenon, called *aldosterone escape*, is explained by lower proximal tubular Na^+ reabsorption following blood volume expansion. Excess Na^+ that is not reabsorbed by the proximal tubule overwhelms the reabsorptive capacity of more distal nephron segments. This escape may be facilitated by atrial natriuretic peptides that lose their effectiveness in the clinical settings of heart failure, nephrotic syndrome, and cirrhosis, leading to severe Na^+ retention and volume overload.

321 Acute Kidney Injury

Sushrut S. Waikar, Joseph V. Bonventre

Acute kidney injury (AKI) is defined by the impairment of kidney filtration and excretory function over days to weeks (generally known or expected to have occurred within 7 days), resulting in the retention of nitrogenous and other waste products normally cleared by the kidneys. The generally accepted Kidney Disease: Improving Global Outcomes (KDIGO) definition of AKI is an increase in serum creatinine (SCr) of ≥0.3 mg/dL within 48 h or an increase in SCr ≥1.5 times from baseline over 7 days or urine output <0.5 mL/kg per h for >6 h. AKI is not a single disease but rather a designation for a heterogeneous group of conditions that share common diagnostic features: specifically, an increase in filtration markers (SCr or cystatin C) often associated with a reduction in urine volume. It is important to recognize that AKI is a clinical diagnosis and not a structural one. A patient may have AKI with or without injury to the kidney parenchyma making the term a misnomer. AKI can range in severity from asymptomatic and transient changes in laboratory parameters of glomerular filtration rate (GFR), to overwhelming and rapidly fatal derangements in the ability of the kidney to maintain effective circulating volume regulation, excrete nitrogenous wastes and metabolic toxins, and maintain electrolyte and acid-base composition of the plasma.

EPIDEMIOLOGY

AKI complicates 5–7% of acute-care hospital admissions and up to 30% of admissions to the intensive care unit (ICU). AKI severity is staged based on the magnitude of the rise in SCr and severity and duration of oliguria (Table 321-1). The incidence of AKI has grown by more than fourfold in the United States since 1988 and is estimated to have a yearly incidence of 500 per 100,000 population, higher than the yearly incidence of stroke. Morbidity of AKI in those admitted to the ICU exceeds 50% in many studies. AKI also has longer term implications even if the patient survives the hospitalization. AKI increases the risk

TABLE 321-1 Staging of Acute Kidney Injury Severity

STAGE	SERUM CREATININE	URINE OUTPUT
1	1.5–1.9 times baseline OR ≥0.3 mg/dL (≥26.5 μmol/L) increase	<0.5 mL/kg per h for 6–12 h
2	2.0–2.9 times baseline	<0.5 mL/kg per h for ≥12 h
3	3.0 times baseline OR increase in serum creatinine to ≥4.0 mg/dL (≥353.6 μmol/L) OR initiation of renal replacement therapy OR, in patients <18 years of age, decrease in eGFR to <35 mL/min per 1.73 m^2	<0.3 mL/kg per h for ≥24 h OR Anuria for ≥12 h

Abbreviation: eGFR, estimated glomerular filtration rate.

for the development or worsening of chronic kidney disease (CKD) and also increases the risk of future cardiovascular disease. AKI may also occur in the community. Common causes of community-acquired AKI include volume depletion, heart failure, adverse effects of medications, obstruction of the urinary tract, or malignancy. The most common clinical settings for hospital-acquired AKI are sepsis, major surgical procedures, critical illness involving heart or liver failure, and nephrotoxic medication administration. Clinically, AKI more commonly develops when ischemia or other insults occur in the context of limited renal functional reserve. The healthy kidney has the ability to increase its regional or overall function in response to damage to a subset of nephrons or in response to a perceived need to enhance excretion, such as in response to a protein load. With normal aging, there is reduction in this capacity, which is also reduced in individuals with CKD or coexisting insults such as sepsis, vasoactive or nephrotoxic drugs, rhabdomyolysis, or the systemic inflammatory states associated with burns and pancreatitis. When there is reduced renal reserve, any additional impairment in GFR is likely to be reflected by a change in SCr or cystatin C and hence a more likely diagnosis of AKI.

AKI IN THE DEVELOPING WORLD

AKI is also a major medical complication in the developing world, where the epidemiology differs from that in developed countries due to differences in demographics, economics, environmental factors, and comorbid disease burden. While certain features of AKI are common in developed and developing countries—particularly because urban centers of some developing countries increasingly resemble those in the developed world—many etiologies for AKI are region-specific, such as envenomations from snakes, spiders, caterpillars, and bees; infectious causes such as malaria and leptospirosis; and crush injuries and resultant rhabdomyolysis from earthquakes. In developing countries, resources to diagnose and manage AKI are often limited.

ETIOLOGY AND PATHOPHYSIOLOGY

The causes of AKI have traditionally been divided into three broad categories: prerenal azotemia, intrinsic renal parenchymal disease, and postrenal obstruction **(Fig. 321-1)**.

PRERENAL AZOTEMIA

Prerenal azotemia (from "azo," meaning nitrogen, and "-emia," meaning in the blood), the most common form of AKI, results from inadequate renal plasma flow and intraglomerular hydrostatic pressure to support normal glomerular filtration. The most common clinical conditions associated with prerenal azotemia are hypovolemia, decreased cardiac output, and medications that interfere with renal autoregulatory vascular responses such as nonsteroidal anti-inflammatory drugs (NSAIDs) and inhibitors of the renin-angiotensin system **(Fig. 321-2)**. Sodium-glucose cotransporter 2 (SGLT-2) inhibitors used for the treatment of diabetes mellitus and related complications do not appear to increase the risk of AKI despite their effects on lowering intraglomerular pressure and inducing natriuresis; in fact, recent studies have suggested a protective effect of these agents in preventing AKI.

By definition, prerenal azotemia involves no parenchymal damage to the kidney and is rapidly reversible once parenchymal blood flow and intraglomerular hemodynamics are restored. In many cases, however, prerenal azotemia may coexist with other forms of intrinsic AKI associated with processes acting directly on the renal parenchyma. Prolonged periods of prerenal azotemia may lead to ischemic injury to the tubular cells with necrosis, hence termed acute tubular necrosis (ATN).

Normal GFR is maintained in part by renal blood flow and the relative resistances of the afferent and efferent renal arterioles, which determine the glomerular plasma flow rate and the transcapillary hydraulic pressure gradient that drive glomerular ultrafiltration. Mild degrees of hypovolemia and reductions in cardiac output elicit compensatory renal vasoconstriction and enhanced reabsorption of salt and water to maintain blood pressure and increase intravascular volume to sustain perfusion to the cerebral and coronary vessels. Mediators of this response include angiotensin II, norepinephrine, and vasopressin (also termed antidiuretic hormone). Glomerular filtration can be maintained despite reduced renal blood flow by angiotensin II–mediated renal efferent arteriolar vasoconstriction. In addition, a myogenic reflex within the afferent arteriole leads to dilation in the setting of low perfusion pressure, thereby maintaining glomerular perfusion. Intrarenal biosynthesis of vasodilator prostaglandins (prostacyclin, prostaglandin E_2), kallikrein and kinins, and possibly nitric oxide (NO) also increases in response to low renal perfusion pressure. Autoregulation is also accomplished by tubuloglomerular feedback, in which decreases in solute delivery to the macula densa (specialized cells within the distal tubule) elicit dilation of the juxtaposed afferent arteriole in order to maintain glomerular perfusion, a mechanism mediated, in part, by NO. There is a limit, however, to the ability of

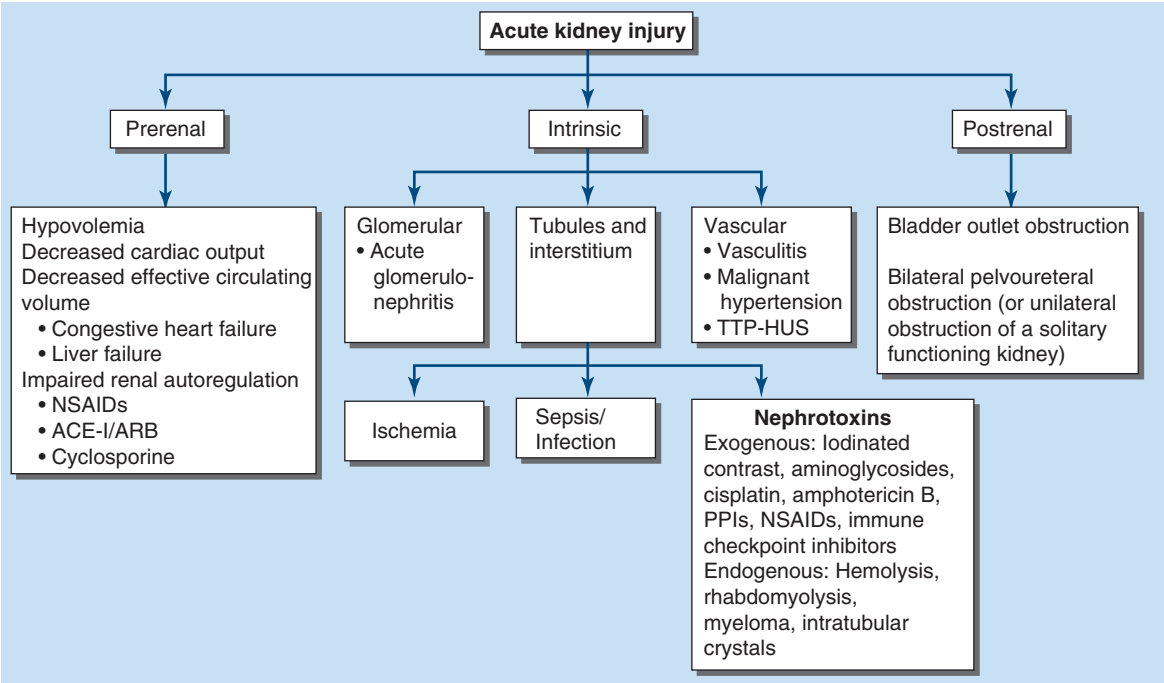

FIGURE 321-1 Classification of the major causes of acute kidney injury. ACE-I, angiotensin-converting enzyme inhibitor-I; ARB, angiotensin receptor blocker; NSAIDs, nonsteroidal anti-inflammatory drugs; PPI, proton pump inhibitors; TTP-HUS, thrombotic thrombocytopenic purpura–hemolytic-uremic syndrome.

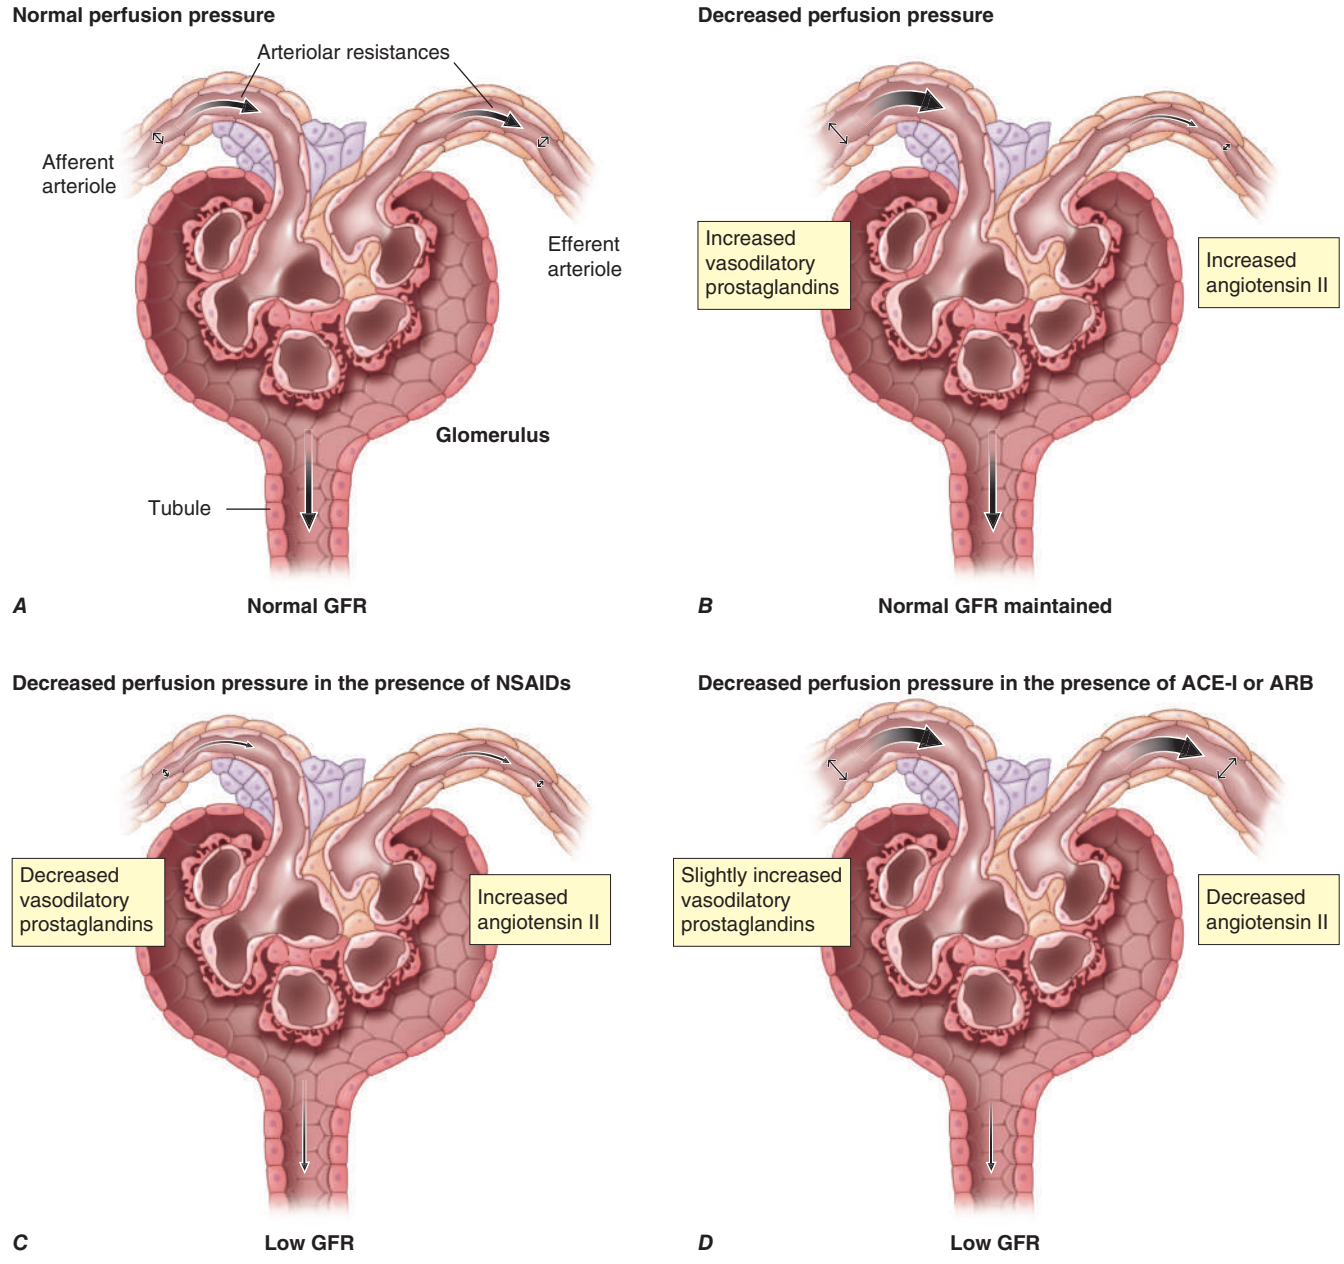

FIGURE 321-2 Intrarenal mechanisms for autoregulation of the glomerular filtration rate (GFR) under decreased perfusion pressure and reduction of the GFR by drugs. ***A.*** Normal conditions and a normal GFR. ***B.*** Reduced perfusion pressure within the autoregulatory range. Normal glomerular capillary pressure is maintained by afferent vasodilatation and efferent vasoconstriction. Angiotensin constricts afferent (preglomerular) and efferent (postglomerular) arterioles but preferentially increases efferent arteriolar resistance. ***C.*** Reduced perfusion pressure with a nonsteroidal anti-inflammatory drug (NSAID). Loss of vasodilatory prostaglandins increases afferent resistance; this causes the glomerular capillary pressure to drop below normal values and the GFR to decrease. ***D.*** Reduced perfusion pressure with an angiotensin-converting enzyme inhibitor (ACE-I) or an angiotensin receptor blocker (ARB). Loss of angiotensin II action reduces efferent resistance; this causes the glomerular capillary pressure to drop below normal values and the GFR to decrease. *(From JG Abuelo: Normotensive ischemic acute renal failure. N Engl J Med 357:797, 2007. Copyright © 2007, Massachusetts Medical Society. Reprinted with permission from Massachusetts Medical Society.)*

these counterregulatory mechanisms to maintain GFR in the face of systemic hypotension. Even in healthy adults, renal autoregulation usually fails once the systolic blood pressure falls below 80 mmHg.

A number of factors determine the robustness of the autoregulatory response and the risk of prerenal azotemia. Atherosclerosis, long-standing hypertension, and older age can lead to hyalinosis and myointimal hyperplasia, causing structural narrowing of the intrarenal arterioles and impaired capacity for renal afferent vasodilation. In CKD, renal afferent vasodilation may be operating at maximal capacity in order to maximize GFR in response to reduced functional renal mass. Drugs can affect the compensatory changes evoked to maintain GFR. NSAIDs inhibit renal prostaglandin production, limiting renal afferent vasodilation. Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) limit renal efferent vasoconstriction; this effect is particularly pronounced in patients with bilateral renal artery stenosis or unilateral renal artery stenosis (in the case of a solitary functioning kidney) because, as indicated above, efferent arteriolar vasoconstriction is needed to maintain GFR due to low renal perfusion. The combined use of NSAIDs with ACE inhibitors or ARBs poses a particularly high risk for developing prerenal azotemia.

Hepatorenal syndrome is a cause of AKI in individuals with multiorgan pathobiology affecting kidney and liver. Many individuals with advanced liver disease exhibit a hemodynamic profile that resembles prerenal azotemia in the setting of total-body volume overload. Systemic vascular resistance is markedly reduced due to primary arterial vasodilation in the splanchnic circulation, resulting ultimately in activation of vasoconstrictor responses similar to those seen in hypovolemia. AKI is a common complication in this setting, and it can be triggered by volume depletion and spontaneous bacterial peritonitis.

The hepatorenal syndrome, which represents the advanced stage of impaired perfusion to the kidneys secondary to advanced liver disease, is difficult to distinguish from prerenal azotemia and is a diagnosis of exclusion. A particularly poor prognosis is seen in the case of type 1 hepatorenal syndrome, in which AKI persists despite volume administration and withholding of diuretics. Type 2 hepatorenal syndrome is a less severe form characterized mainly by refractory ascites.

INTRINSIC AKI

The most common causes of intrinsic AKI are sepsis, ischemia, and nephrotoxins, both endogenous and exogenous **(Fig. 321-3)**. As mentioned previously, in many cases, prerenal azotemia advances to tubular injury. Although often the AKI is attributed to "acute tubular necrosis," human biopsy confirmation of tubular necrosis is, in general, often lacking in cases of sepsis and ischemia; indeed, processes such as inflammation, apoptosis, and altered regional perfusion may be important contributors pathophysiologically without frank necrosis. There are other potential causes of AKI in settings such as sepsis, including drug-induced interstitial nephritis or glomerulonephritis. These and other causes of intrinsic AKI can be catalogued anatomically according to the major site of renal parenchymal damage: glomeruli, tubulointerstitium, and vessels, although there is frequently overlap in tissue compartment involvement. For example, glomerulonephritis can alter efferent arteriolar blood flow, which then reduces capillary perfusion to a region of the nephron leading to cell death, obstruction of the lumen with cellular debris, and impaired tubular function.

SEPSIS-ASSOCIATED AKI

In the United States, >1 million cases of sepsis occur each year. AKI complicates >50% of cases of severe sepsis and greatly increases the risk of death. Sepsis is also a very important cause of AKI in the developing world. AKI also predisposes to sepsis. Decreases in GFR with sepsis can occur even in the absence of overt hypotension, although many cases of severe AKI typically occur in the setting of hemodynamic compromise requiring vasopressor support. Reduced urine output is common in sepsis-induced AKI. While there can be tubular injury associated with AKI in sepsis as manifest by the presence of tubular debris and casts in the urine, postmortem examinations of kidneys from individuals with severe sepsis suggest that other factors, perhaps related to inflammation, mitochondrial dysfunction, and interstitial edema, contribute to the pathophysiology of sepsis-induced AKI.

The hemodynamic effects of sepsis—arising from generalized arterial vasodilation, mediated in part by cytokines that upregulate the expression of inducible NO synthase in the vasculature—can lead to a

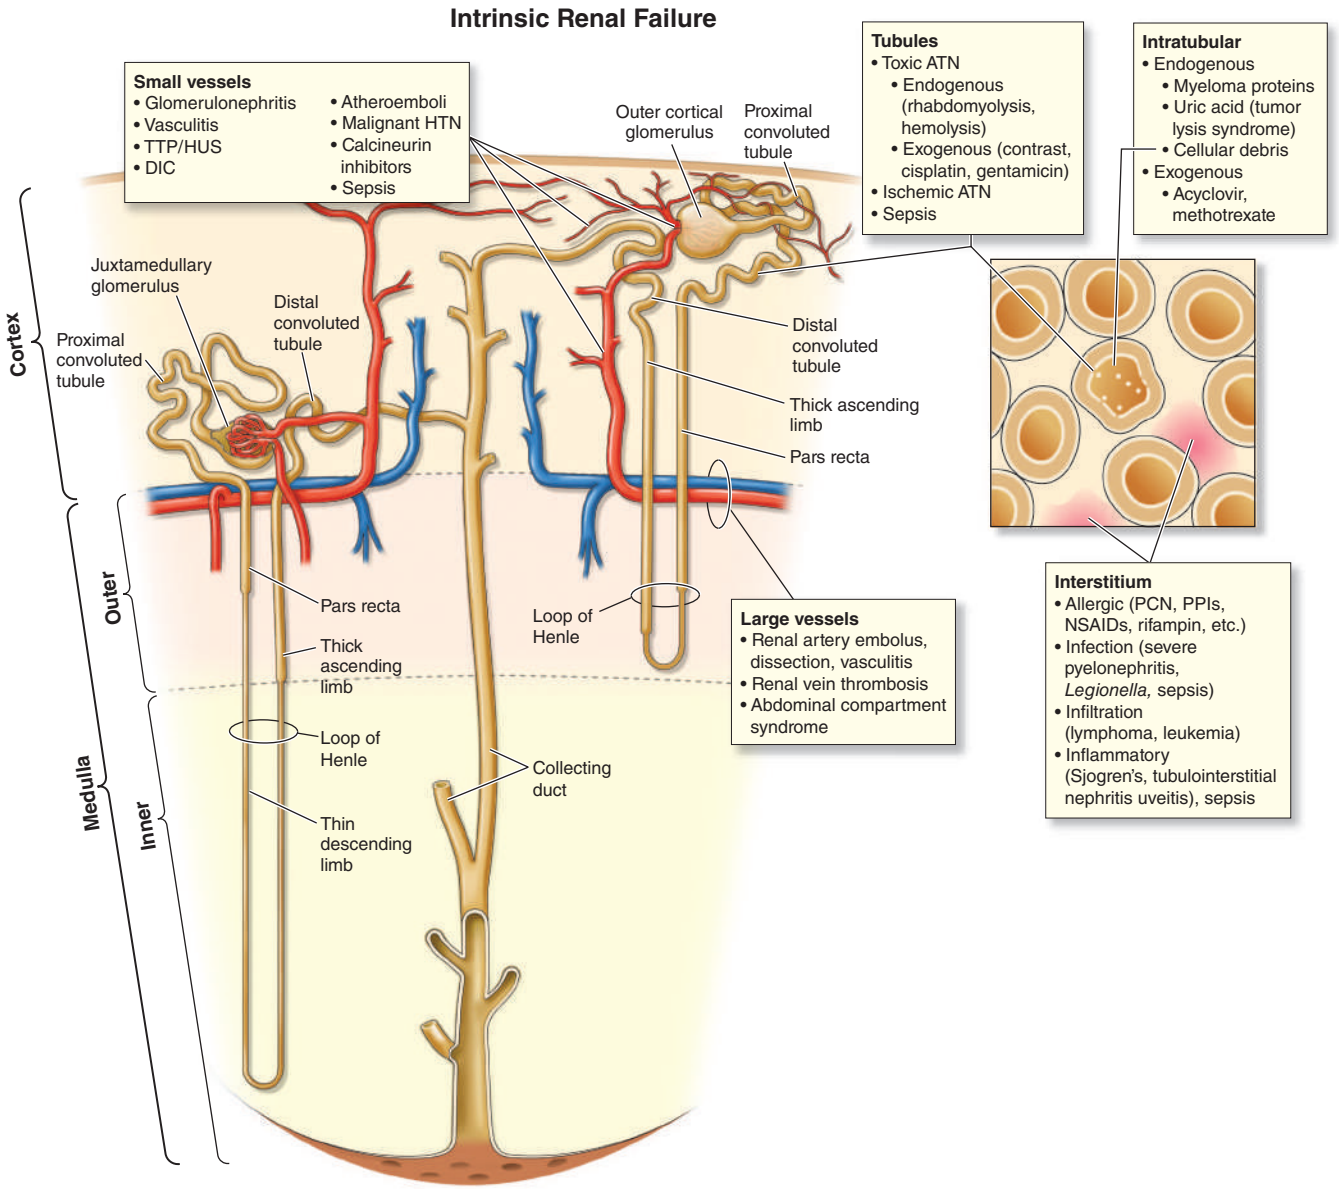

FIGURE 321-3 Major causes of intrinsic acute kidney injury. ATN, acute tubular necrosis; DIC, disseminated intravascular coagulation; HTN, hypertension; PCN, penicillin; PPI, proton pump inhibitors; TINU, tubulointerstitial nephritis-uveitis; TTP/HUS, thrombotic thrombocytopenic purpura/hemolytic-uremic syndrome.

reduction in GFR. The operative mechanisms may be excessive efferent arteriole vasodilation, particularly early in the course of sepsis, or renal vasoconstriction from activation of the sympathetic nervous system, the renin-angiotensin-aldosterone system, or increased levels of vasopressin or endothelin. Sepsis may lead to endothelial damage, which results in increased microvascular leukocyte adhesion and migration, thrombosis, permeability, increased interstitial pressure, reduction in local flow to tubules, and activation of reactive oxygen species, all of which may injure renal tubular cells.

AKI can be an important complication of viral infections, such as hantavirus, dengue virus, or SARS-CoV-2. The pathophysiology of AKI due to viral infections remains incompletely understood. As an example, some have reported infection of the kidney with SARS-CoV-2, whereas others have found less direct involvement. SARS-CoV-2 is associated with a large release of cytokines into the circulation ("cytokine storm"), which may cause diffuse intrarenal vasoconstriction. Finally, there is a generalized hypercoagulable state associated with SARS-CoV-2 that may contribute to the impairment of intrarenal blood flow.

ISCHEMIA-ASSOCIATED AKI

Healthy kidneys receive 20% of the cardiac output and account for 10% of resting oxygen consumption, despite constituting only 0.5% of the human body mass. The kidneys are also the site of one of the most hypoxic regions in the body, the renal medulla. The outer medulla is particularly vulnerable to ischemic damage because of the architecture of the blood vessels that supply oxygen and nutrients to the tubules. In the outer medulla, enhanced leukocyte-endothelial interactions in the small vessels lead to inflammation and reduced local blood flow to the metabolically very active S3 segment of the proximal tubule, which depends on oxidative metabolism for survival. Mitochondrial dysfunction leads to impaired oxidative phosphorylation with less efficient adenosine triphosphate (ATP) generation and mitochondrial release of reactive oxygen species, both of which play a role in renal tubular injury. Transient ischemia alone in a normal kidney is usually not sufficient to cause severe AKI, as evidenced by the relatively low risk of severe AKI even after total interruption of renal blood flow during suprarenal aortic clamping or cardiac arrest. Prerenal azotemia and ischemia-associated AKI represent a continuum of the manifestations of renal hypoperfusion leading to ATN. Persistent preglomerular vasoconstriction may be a common underlying cause of the reduction in GFR seen in AKI; implicated factors for vasoconstriction include activation of tubuloglomerular feedback from enhanced delivery of solute to the macula densa following proximal tubule injury and reduced reabsorption, increased basal vascular tone and reactivity to vasoconstrictive agents, and decreased vasodilator responsiveness. Other contributors to low GFR include backleak of filtrate across damaged and denuded tubular epithelium and mechanical obstruction of tubules from necrotic debris (Fig. 321-4).

Postoperative AKI Ischemia-associated AKI is a serious complication in the postoperative period, especially after major operations involving significant blood loss and intraoperative hypotension. The procedures most commonly associated with AKI are cardiac surgery with cardiopulmonary bypass (particularly for combined valve and bypass procedures), vascular procedures with aortic cross clamping, and intraperitoneal procedures. Severe AKI requiring dialysis occurs in ~1% of cardiac and vascular surgery procedures. The risk of severe AKI has been less well studied for major intraperitoneal procedures but appears to be of comparable magnitude. Common risk factors for postoperative AKI include underlying CKD, older age, diabetes mellitus, congestive heart failure, and emergency procedures. The pathophysiology of AKI following cardiac surgery is multifactorial. Major AKI risk factors are common in the population undergoing cardiac or vascular surgery. Over time, more of these surgical procedures are performed on older patients with comorbidities that predispose them to AKI and hasten progression of end-stage kidney disease (ESKD) if they develop AKI. Longer duration of cardiopulmonary bypass is a risk factor for AKI. In addition to ischemic injury from sustained hypoperfusion, cardiopulmonary bypass may cause AKI through a number of mechanisms including extracorporeal circuit activation of leukocytes and inflammatory processes, hemolysis with resultant pigment nephropathy (see below), and aortic injury with resultant atheroemboli. AKI from atheroembolic disease, which can also occur following percutaneous catheterization of the aorta, or spontaneously, is due to cholesterol crystal embolization resulting in partial or total occlusion of multiple small arteries within the kidney. Over time, a foreign body reaction can result in intimal proliferation, giant cell formation, and further narrowing of the vascular lumen, accounting for the generally subacute (over a period of weeks rather than days) decline in renal function.

Burns and Acute Pancreatitis Extensive fluid losses into the extravascular compartments of the body frequently accompany severe burns and acute pancreatitis. AKI is an ominous complication of burns, affecting 25% of individuals with >10% total body surface area involvement. In addition to severe hypovolemia resulting in decreased cardiac output and increased neurohormonal activation, burns and acute pancreatitis both lead to dysregulated inflammation and an increased risk of sepsis and acute lung injury, all of which may facilitate the development and progression of AKI. Individuals undergoing massive fluid resuscitation for trauma, burns, and acute pancreatitis can also develop abdominal compartment syndrome, where markedly elevated intraabdominal pressures, usually >20 mmHg, lead to renal vein compression and reduced GFR. Drug nephrotoxicity is also an important contributor to AKI. Mortality is much higher in patients who develop AKI.

Diseases of the Vasculature Leading to Ischemia These diseases can compromise oxygen and metabolic substrate delivery to the tubules and glomeruli. Microvascular causes of AKI include the thrombotic microangiopathies (due to cocaine, certain chemotherapeutic agents, antiphospholipid antibody syndrome, radiation nephritis, malignant hypertensive nephrosclerosis, thrombotic thrombocytopenic purpura/hemolytic-uremic syndrome [TTP-HUS]), scleroderma, some chemotherapeutic agents, and atheroembolic disease. Large-vessel diseases associated with AKI include renal artery dissection,

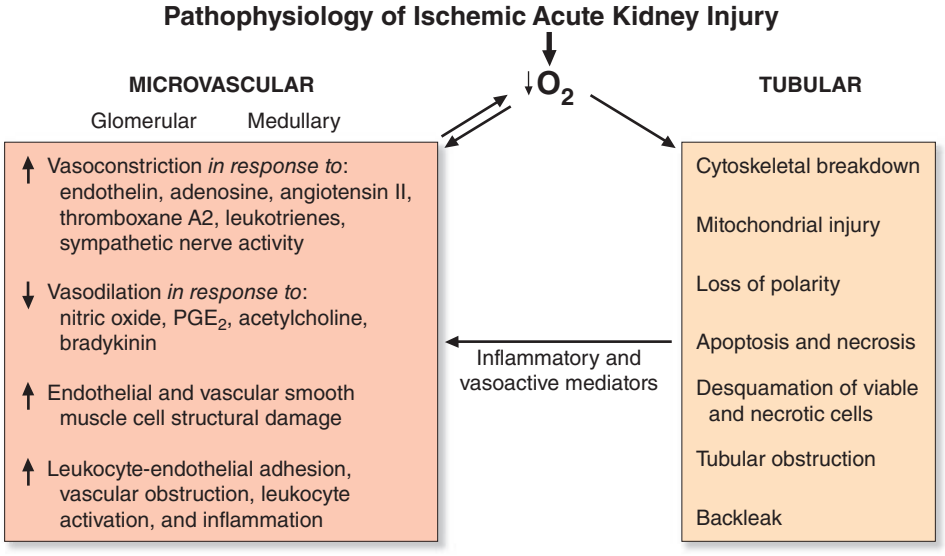

FIGURE 321-4 Interacting microvascular and tubular events contributing to the pathophysiology of ischemic acute kidney injury. PGE_2, prostaglandin E_2. *(Reproduced with permission from JV Bonventre, JM Weinberg. J Am Soc Nephrol. 14:2199, 2003.)*

thromboembolism, or thrombosis, and renal vein compression or thrombosis.

NEPHROTOXIN-ASSOCIATED AKI

The kidney has very high susceptibility to nephrotoxic agents due to extremely high blood perfusion and concentration of filtered substances along the nephron where filtrate water is reabsorbed. Nephrotoxic injury occurs in response to a number of pharmacologic compounds with diverse structures, endogenous substances, and environmental exposures. All structures of the kidney are vulnerable to toxic injury, including the tubules, interstitium, vasculature, and collecting system. As with other forms of AKI, risk factors for nephrotoxicity include older age, CKD, and prerenal azotemia. Hypoalbuminemia may increase the risk of some forms of nephrotoxin-associated AKI due to increased free circulating drug concentrations.

Contrast Agents Iodinated contrast agents used for cardiovascular and computed tomography (CT) imaging have been implicated as a cause of AKI. Many question whether AKI in response to contrast agents represents an important consequence of contrast studies. It is likely to have been diagnosed too frequently in the past, particularly in individuals who had many risk factors for AKI, making the cause difficult to identify. The terminology has changed so that the former "contrast nephropathy" has been replaced by "contrast-associated AKI" or "contrast-induced AKI" (CI-AKI), with the latter representing a smaller subgroup of the former. The occurrence of CI-AKI is negligible in those with normal renal function but increases in the setting of CKD, particularly in individuals with diabetic kidney disease. The most common clinical course of contrast nephropathy is characterized by a rise in SCr beginning 24–48 h following exposure, peaking within 3–5 days, and resolving within 1 week. More severe, dialysis-requiring AKI is uncommon except in the setting of significant preexisting CKD, often in association with congestive heart failure or other coexisting causes for ischemia-associated AKI. Patients with multiple myeloma and/or renal disease are particularly susceptible. Other diagnostic agents implicated as a cause of AKI are high-dose gadolinium used for magnetic resonance imaging (MRI) and oral sodium phosphate solutions used as bowel purgatives. Gadolinium has been associated with development of nephrogenic systemic fibrosis (NSF) in subjects with advanced kidney disease or AKI, but the majority of these cases were associated with group I gadolinium-based contrast media, which are rarely used now in the United States and have been withdrawn from the market in many other countries. The risk of AKI associated with standard doses of group II gadolinium-based contrast media is very low.

Antibiotics Several antimicrobial agents are commonly associated with AKI. *Vancomycin* may be associated with AKI from tubular injury, particularly when trough levels are high and when used in combination with other nephrotoxic antibiotics. Vancomycin can also crystalize in tubules and cause intratubular obstruction. *Aminoglycosides* and *amphotericin B* both cause tubular necrosis. Nonoliguric AKI (i.e., with a urine volume >400 mL/d) accompanies 10–30% of courses of aminoglycoside antibiotics, even when plasma levels are in the therapeutic range. Aminoglycosides are freely filtered across the glomerulus and then accumulate within the renal cortex, where concentrations can greatly exceed those of the plasma. AKI typically manifests after 5–7 days of therapy and can present even after the drug has been discontinued. Hypomagnesemia is a common finding.

Amphotericin B causes renal vasoconstriction from an increase in tubuloglomerular feedback as well as direct tubular toxicity mediated by reactive oxygen species. Nephrotoxicity from amphotericin B is dose and duration dependent. This drug binds to tubular membrane cholesterol and introduces pores. Clinical features of amphotericin B nephrotoxicity include polyuria, hypomagnesemia, hypocalcemia, and nongap metabolic acidosis.

Acyclovir can precipitate in tubules and cause AKI by tubular obstruction, particularly when given as an intravenous bolus at high doses (500 mg/m^2) or in the setting of hypovolemia. *Foscarnet, pentamidine, tenofovir*, and *cidofovir* are also frequently associated with AKI due to tubular toxicity. AKI secondary to acute interstitial nephritis can occur as a consequence of exposure to many antibiotics, including *penicillins, cephalosporins, quinolones, sulfonamides*, and *rifampin*.

Chemotherapeutic Agents *Cisplatin* and *carboplatin* are accumulated by proximal tubular cells and cause necrosis and apoptosis. Intensive hydration regimens have reduced the incidence of cisplatin nephrotoxicity, but it remains a dose-limiting toxicity. *Ifosfamide* may cause hemorrhagic cystitis and tubular toxicity, manifested as type II renal tubular acidosis (Fanconi syndrome), polyuria, hypokalemia, and a modest decline in GFR. Antiangiogenesis agents, such as *bevacizumab*, can cause proteinuria and hypertension via injury to the glomerular microvasculature (thrombotic microangiopathy). Other antineoplastic agents such as mitomycin C and gemcitabine may cause thrombotic microangiopathy with resultant AKI. Immune checkpoint inhibitors, such as *ipilimumab*, *tremelimumab*, *nivolumab*, and *pembrolizumab* can cause immune-related adverse events, often manifesting in the kidney as acute interstitial nephritis. Lower GFR, proton pump inhibitor use, and extrarenal immune-related adverse events are predisposing risk factors for AKI secondary to immune checkpoint inhibitors. The checkpoint inhibitors result in hyperactivity of the immune system triggered by these agents.

Toxic Ingestions Ethylene glycol, present in automobile antifreeze, is metabolized to oxalic acid, glycolaldehyde, and glyoxylate, which may cause AKI through direct tubular injury and tubular obstruction. Diethylene glycol is an industrial agent that has caused outbreaks of severe AKI around the world due to adulteration of pharmaceutical preparations. The metabolite 2-hydroxyethoxyacetic acid (HEAA) is thought to be responsible for tubular injury. Melamine contamination of foodstuffs has led to nephrolithiasis and AKI, either through intratubular obstruction or possibly direct tubular toxicity. Aristolochic acid was found to be the cause of "Chinese herb nephropathy" and "Balkan nephropathy" due to its contamination of medicinal herbs or farming. The list of environmental toxins is likely to grow and contribute to a better understanding of previously catalogued "idiopathic" chronic tubular interstitial disease, a common diagnosis in both the developed and developing world.

Endogenous Toxins AKI may be caused by a number of endogenous compounds, including myoglobin, hemoglobin, uric acid, and myeloma light chains. Myoglobin can be released by injured muscle cells, and hemoglobin can be released during massive hemolysis leading to pigment nephropathy. Rhabdomyolysis may result from traumatic crush injuries, muscle ischemia during vascular or orthopedic surgery, compression during coma or immobilization, prolonged seizure activity, excessive exercise, heat stroke or malignant hyperthermia, infections, metabolic disorders (e.g., hypophosphatemia, severe hypothyroidism), and myopathies (drug-induced, metabolic, or inflammatory). Pathogenic factors contributing to AKI upon exposure to endogenous toxins include intrarenal vasoconstriction, direct proximal tubular toxicity, and mechanical obstruction of the distal nephron lumen when myoglobin or hemoglobin precipitates with Tamm-Horsfall protein (uromodulin, the most common protein in urine and produced in the thick ascending limb of the loop of Henle), a process favored by acidic urine. Tumor lysis syndrome may follow initiation of cytotoxic therapy in patients with high-grade lymphomas and acute lymphoblastic leukemia; massive release of uric acid (with serum levels often exceeding 15 mg/dL) leads to precipitation of uric acid in the renal tubules and AKI **(Chap. 75)**. Other features of tumor lysis syndrome include hyperkalemia and hyperphosphatemia. The tumor lysis syndrome can also occasionally occur spontaneously or with treatment for solid tumors or multiple myeloma. Myeloma light chains can also cause AKI by glomerular damage and/or direct tubular toxicity and by binding to Tamm-Horsfall protein to form obstructing intratubular casts. Hypercalcemia, which can also be seen in multiple myeloma, may cause AKI by intense renal vasoconstriction and inhibition of sodium and water reabsorption in the nephron with resultant volume depletion.

Other Causes of Acute Tubulointerstitial Disease Leading to AKI While many drugs result in toxin-induced injury to the nephron with

subsequent inflammation, drugs can also lead to the development of an allergic response characterized by an inflammatory infiltrate, sometimes associated with blood and urinary eosinophilia. Proton pump inhibitors and NSAIDs are commonly used drugs that have been associated with acute tubulointerstitial nephritis. AKI may be also caused by severe infections and infiltrative malignant or nonmalignant (e.g., sarcoidosis) diseases with tubulointerstitial disease.

Anticoagulant-Related Nephropathy Excessive anticoagulation with warfarin or other classes of anticoagulants has been reported to cause AKI through glomerular hemorrhage resulting in the formation of obstructing red blood cell casts within the kidney tubule and tubular injury.

Glomerulonephritis Diseases involving the glomerular podocytes, mesangial, and/or endothelial cells can lead to AKI by compromising the filtration barrier and blood flow within the renal circulation. Although glomerulonephritis is a less common (~5%) cause of AKI, early recognition is particularly important because the diseases can respond to timely treatment with immunosuppressive agents or therapeutic plasma exchange, and the treatment may reverse the AKI and decrease subsequent longer term injury.

POSTRENAL AKI

(See also Chap. 331.) Postrenal AKI occurs when the normally unidirectional flow of urine is acutely blocked either partially or totally, leading to increased retrograde hydrostatic pressure and interference with glomerular filtration. Obstruction to urinary flow may be caused by functional or structural derangements anywhere from the renal pelvis to the tip of the urethra (Fig. 321-5). Normal urinary flow rate does not rule out the presence of partial obstruction, because the GFR is normally two orders of magnitude higher than the urinary flow rate and hence a preservation of urine output may be misleading in hiding the postrenal partial obstruction. For moderate to severe AKI to occur in individuals with two healthy functional kidneys, obstruction must affect both kidneys in order to observe large increases in SCr, unless there is asymmetric kidney function with one chronically diseased. Unilateral obstruction may cause AKI in the setting of significant underlying CKD with loss of renal reserve or, in rare cases, from reflex vasospasm of the contralateral kidney. Bladder neck obstruction is a common cause of postrenal AKI. This can be due to prostate disease (benign prostatic hypertrophy or prostate cancer), neurogenic bladder, or therapy with anticholinergic drugs. Obstructed bladder catheters can cause postrenal AKI if not recognized. Other causes of lower tract obstruction are blood clots, calculi, and urethral strictures. Ureteric obstruction can occur from intraluminal obstruction (e.g., calculi, blood clots, sloughed renal papillae), infiltration of the ureteric wall (e.g., neoplasia), or external compression (e.g., retroperitoneal fibrosis, neoplasia, abscess, or inadvertent surgical damage). The pathophysiology of postrenal AKI involves hemodynamic alterations triggered by an abrupt increase in intratubular pressures. An initial period of hyperemia from afferent arteriolar dilation is followed by intrarenal vasoconstriction from the generation of angiotensin II, thromboxane A2, and vasopressin, and a reduction in NO production. Secondary reductions in glomerular function are due to underperfusion of glomeruli and, possibly, changes in the glomerular ultrafiltration coefficient.

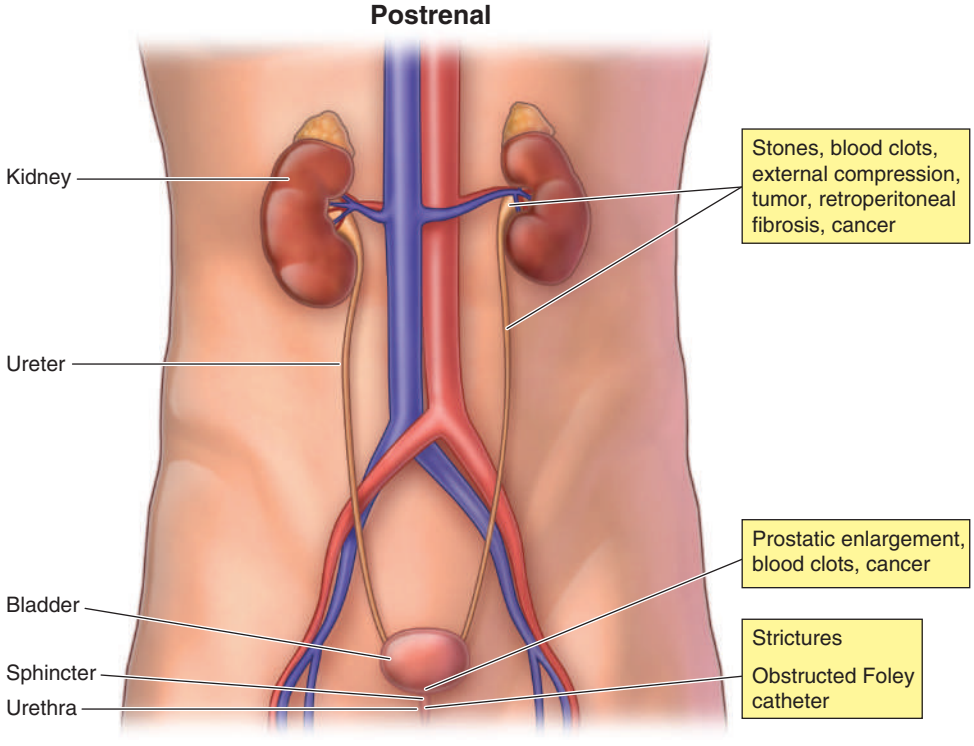

FIGURE 321-5 Anatomic sites and causes of obstruction leading to postrenal acute kidney injury.

DIAGNOSTIC EVALUATION (TABLE 321-2)

As described previously, AKI is defined by an elevation in the SCr concentration from baseline of at least 0.3 mg/dL within 48 h or at least 50% within 1 week, or a reduction in urine output to <0.5 mL/kg per h for longer than 6 h. Serum cystatin C is increasingly being used to estimate GFR and may have a role in AKI diagnosis; both SCr and cystatin C have distinct non-GFR determinants that can influence their sensitivity and specificity. As indicated previously, some patients with AKI will not have tubular or glomerular damage (e.g., prerenal azotemia). The distinction between AKI and CKD is important for proper diagnosis and treatment. CKD is defined by an estimated GFR <60 mL/min per 1.73 m^2 or an albumin-to-creatinine ratio (ACR) of >30 mg/g for a period of at least 3 months. If the diagnosis of AKI is made and renal dysfunction persists for more than a week but not yet 3 months, then some refer to this renal dysfunction as acute kidney disease. The distinction between AKI and CKD is straightforward when a recent baseline SCr concentration is available, but more difficult in the many instances in which the baseline is unknown. In such cases, clues suggestive of CKD can come from radiologic studies (e.g., small, shrunken kidneys with cortical thinning on renal ultrasound) or laboratory tests such as normocytic anemia in the absence of blood loss or secondary hyperparathyroidism with hyperphosphatemia and hypocalcemia, consistent with CKD. No set of tests, however, can rule out AKI superimposed on CKD because AKI is a frequent complication in patients with CKD, further complicating the distinction. Serial blood tests showing a continued substantial rise of SCr represent clear evidence of AKI. Once the diagnosis of AKI is established, its cause needs to be determined because the elevation of SCr or reduction in urine output can be due to a large number of physiologic and pathophysiologic processes, as described previously. Increasingly, the electronic medical record is being utilized for automated alerts to identify AKI and artificial intelligence approaches for AKI prediction. The role of automated alerts and artificial intelligence to predict and/or identify AKI is an area of active investigation.

HISTORY AND PHYSICAL EXAMINATION

The clinical context, careful history taking, and physical examination often narrow the differential diagnosis for the cause of AKI. Prerenal azotemia should be suspected in the setting of vomiting, diarrhea, glycosuria causing polyuria, and several medications

TABLE 321-2 Major Causes, Clinical Features, and Diagnostic Studies for Prerenal and Intrinsic Acute Kidney Injury

ETIOLOGY	CLINICAL FEATURES	LABORATORY FEATURES	COMMENTS
Prerenal azotemia	History of poor fluid intake or fluid loss (hemorrhage, diarrhea, vomiting, sequestration into extravascular space); NSAID/ACE-I/ARB; heart failure; evidence of volume depletion (tachycardia, absolute or postural hypotension, low jugular venous pressure, dry mucous membranes), decreased effective circulatory volume (cirrhosis, heart failure)	BUN/creatinine ratio above 20, FeNa <1%, hyaline casts in urine sediment, urine specific gravity >1.018, urine osmolality >500 mOsm/kg	Low FeNa, high specific gravity and osmolality may not be seen in the setting of CKD, diuretic use; BUN elevation out of proportion to creatinine may alternatively indicate upper GI bleed or increased catabolism. Response to restoration of hemodynamics is most diagnostic.
Sepsis-associated AKI	Sepsis, sepsis syndrome, or septic shock; overt hypotension not always seen in mild to moderate AKI	Positive culture from normally sterile body fluid or other test confirming infection; urine sediment often contains granular casts, renal tubular epithelial cell casts	FeNa may be low (<1%), particularly early in the course, but is usually >1% with osmolality <500 mOsm/kg
Ischemia-associated AKI	Systemic hypotension, often superimposed upon sepsis and/or reasons for limited renal reserve such as older age, CKD	Urine sediment often contains granular casts, renal tubular epithelial cell casts; FeNa typically >1%	
Nephrotoxin-Associated AKI: Endogenous			
Rhabdomyolysis	Traumatic crush injuries, seizures, immobilization	Elevated myoglobin, creatine kinase; urine heme positive with few red blood cells	FeNa may be low (<1%)
Hemolysis	Recent blood transfusion with transfusion reaction	Anemia, elevated LDH, low haptoglobin	FeNa may be low (<1%); evaluation for transfusion reaction
Tumor lysis	Recent chemotherapy	Hyperphosphatemia, hypocalcemia, hyperuricemia	
Multiple myeloma	Age >60 years, constitutional symptoms, bone pain	Monoclonal spike in urine or serum electrophoresis; elevated serum free light chains, low anion gap; anemia	Bone marrow or renal biopsy can be diagnostic
Nephrotoxin-Associated AKI: Exogenous			
Contrast nephropathy	Exposure to iodinated contrast	Characteristic course is rise in SCr within 1–2 d, peak within 3–5 d, recovery within 7 d	FeNa may be low (<1%)
Tubular injury	Aminoglycoside antibiotics, cisplatin, tenofovir, vancomycin, zoledronate, ethylene glycol, aristolochic acid, and melamine (to name a few)	Urine sediment often contains granular casts, renal tubular epithelial cell casts. FeNa typically >1%.	Can be oliguric or nonoliguric
Other Causes of Intrinsic AKI			
Glomerulonephritis/vasculitis	Variable **(Chap. 326)** features include skin rash, arthralgias, sinusitis (AGBM disease), lung hemorrhage (AGBM, ANCA, lupus), recent skin infection or pharyngitis (poststreptococcal), thrombotic microangiopathies including those related to drugs, such as cocaine, anti-VEGF agents, genetic abnormalities of the complement pathways	ANA, ANCA, Anti-GBM antibody, hepatitis serologies, cryoglobulins, blood culture, complement abnormalities, ASO titer (abnormalities of these tests depending on etiology)	Kidney biopsy may be necessary
Tubulointerstitial nephritis	Drugs are responsible for about 75% of the biopsy-proven acute interstitial nephritis, which involves tubules in most cases. Examples of causes include antibiotics, PPIs, immune checkpoint inhibitors. Non-drug-related causes include tubulointerstitial nephritis-uveitis (TINU) syndrome, lupus, viral infection (e.g., COVID, HIV, hantavirus), and *Legionella* infection.	Eosinophilia, sterile pyuria; often nonoliguric	Urine eosinophils have limited diagnostic accuracy; kidney biopsy may be necessary
TTP/HUS	Neurologic abnormalities and/or AKI; recent diarrheal illness; use of calcineurin inhibitors; pregnancy or postpartum; spontaneous	Schistocytes on peripheral blood smear, elevated LDH, anemia, thrombocytopenia	"Typical HUS" refers to AKI with a diarrheal prodrome, often due to Shiga toxin released from *Escherichia coli* or other bacteria; "atypical HUS" is due to inherited or acquired complement dysregulation. Diagnosis may involve screening for ADAMTS13 activity, Shiga toxin–producing *E. coli*, genetic evaluation of complement regulatory proteins, and kidney biopsy.
Atheroembolic disease	Recent manipulation of the aorta or other large vessels; may occur spontaneously or after anticoagulation; retinal plaques, palpable purpura, livedo reticularis, GI bleed	Hypocomplementemia, eosinophiluria (variable), variable amounts of proteinuria	Skin or kidney biopsy can be diagnostic
Postrenal AKI	History of kidney stones, prostate disease, obstructed bladder catheter, retroperitoneal or pelvic neoplasm	No specific findings other than AKI; may have pyuria or hematuria	Imaging with computed tomography or ultrasound

Abbreviations: ACE-I, angiotensin-converting enzyme inhibitor-I; AGBM, antiglomerular basement membrane; AKI, acute kidney injury; ANA, antinuclear antibody; ANCA, antineutrophilic cytoplasmic antibody; ARB, angiotensin receptor blocker; ASO, antistreptolysin O; BUN, blood urea nitrogen; CKD, chronic kidney disease; FeNa, fractional excretion of sodium; GI, gastrointestinal; LDH, lactate dehydrogenase; NSAID, nonsteroidal anti-inflammatory drug; PPI, proton pump inhibitors; TTP/HUS, thrombotic thrombocytopenic purpura/hemolytic-uremic syndrome.

including diuretics, NSAIDs, ACE inhibitors, and ARBs. Physical signs of orthostatic hypotension, tachycardia, reduced jugular venous pressure, decreased skin turgor, and dry mucous membranes are often present in prerenal azotemia. Congestive heart failure, liver disease, and nephrotic syndrome can be associated with reductions in renal blood flow and/or alterations in intrarenal hemodynamics leading to reduced GFR. Extensive vascular disease raises the possibility of renal artery disease, especially if kidneys are known to be asymmetric in size. Atheroembolic disease can be associated with livedo reticularis and other signs of emboli to the legs. The presence of sepsis is an important clue to causation, although, as described above, the detailed pathophysiology may be multifactorial.

A history of prostatic disease, nephrolithiasis, or pelvic or paraaortic malignancy would suggest the possibility of postrenal AKI. Whether or not symptoms are present early during obstruction of the urinary tract depends on the location of obstruction. Colicky flank pain radiating to the groin suggests acute ureteric obstruction. Nocturia and urinary frequency or hesitancy can be seen in prostatic disease. Abdominal fullness and suprapubic pain can accompany bladder enlargement. Definitive diagnosis of obstruction requires radiologic investigations.

A careful review of all medications is imperative in the evaluation of an individual with AKI. Not only are medications frequently a nephrotoxic cause of AKI, but doses of administered medications must be adjusted for reductions in kidney function. In this regard, it is important to recognize that reductions in true GFR are not reflected by equations that estimate GFR because those equations are dependent on SCr and the patient being in a steady state. With AKI, changes in SCr will lag behind changes in filtration rate. Allergic interstitial nephritis may be accompanied by fever, arthralgias, and a pruritic erythematous rash. The absence of systemic features of hypersensitivity, however, does not exclude the diagnosis of interstitial nephritis, and a kidney biopsy should be considered for definitive diagnosis when the cause of AKI is not apparent from the clinical presentation.

AKI accompanied by palpable purpura, pulmonary hemorrhage, or sinusitis raises the possibility of systemic vasculitis with glomerulonephritis. A history of autoimmune disease, such as systemic lupus erythematosus, should lead to consideration of the possibility that the AKI is related to worsening of this underlying disease. Pregnancy should lead to the consideration of preeclampsia as a pathophysiologic contributor to the AKI. A tense abdomen should prompt consideration of acute abdominal compartment syndrome, a diagnosis facilitated by measurement of bladder pressure. Signs and/or symptoms of limb ischemia may be clues to the diagnosis of rhabdomyolysis.

URINE FINDINGS

Complete anuria early in the course of AKI is uncommon except in the following situations: complete urinary tract obstruction, renal artery occlusion, overwhelming septic shock, severe ischemia (often with cortical necrosis), or severe proliferative glomerulonephritis or vasculitis. A reduction in urine output (oliguria, defined as <400 mL/24 h) usually denotes more severe AKI (i.e., lower GFR) than when urine output is preserved. Oliguria is associated with worse clinical outcomes in AKI. Preserved urine output can be seen in nephrogenic diabetes insipidus characteristic of long-standing urinary tract obstruction, tubulointerstitial disease, or nephrotoxicity from cisplatin or aminoglycosides, among other causes. Red or brown urine may be seen with or without gross hematuria; if the color persists in the supernatant after centrifugation, then pigment nephropathy from rhabdomyolysis or hemolysis should be suspected.

The urinalysis and urine sediment examination are invaluable tools, but they require clinical correlation because of generally limited sensitivity and specificity **(see Fig. 321-6 and Chap. A4)**. In the absence of preexisting proteinuria from CKD, AKI secondary to ischemia or nephrotoxins leads to mild proteinuria (<1 g/d). Greater proteinuria in AKI suggests damage to the glomerular ultrafiltration barrier or excretion of small molecular weight proteins such as myeloma light chains; the latter are not detected with conventional urine dipsticks (which detect albumin) and require the sulfosalicylic acid test or immunoelectrophoresis. Atheroemboli can cause a variable degree of proteinuria. Heavy proteinuria ("nephrotic range," >3.5 g/d) can occasionally be seen in glomerulonephritis, vasculitis, or toxins/medications that can affect the glomerulus as well as the tubulointerstitium (e.g., NSAIDs). AKI can also complicate cases of minimal change disease, a cause of the nephrotic syndrome often associated with low serum albumin concentrations **(Chap. 320)**.

Prerenal azotemia may present with hyaline casts or an unremarkable urine sediment examination. Postrenal AKI may also be associated with an unremarkable sediment, but hematuria and pyuria may be seen depending on the cause of obstruction. AKI from ATN due to ischemic injury, sepsis, or certain nephrotoxins has characteristic urine sediment

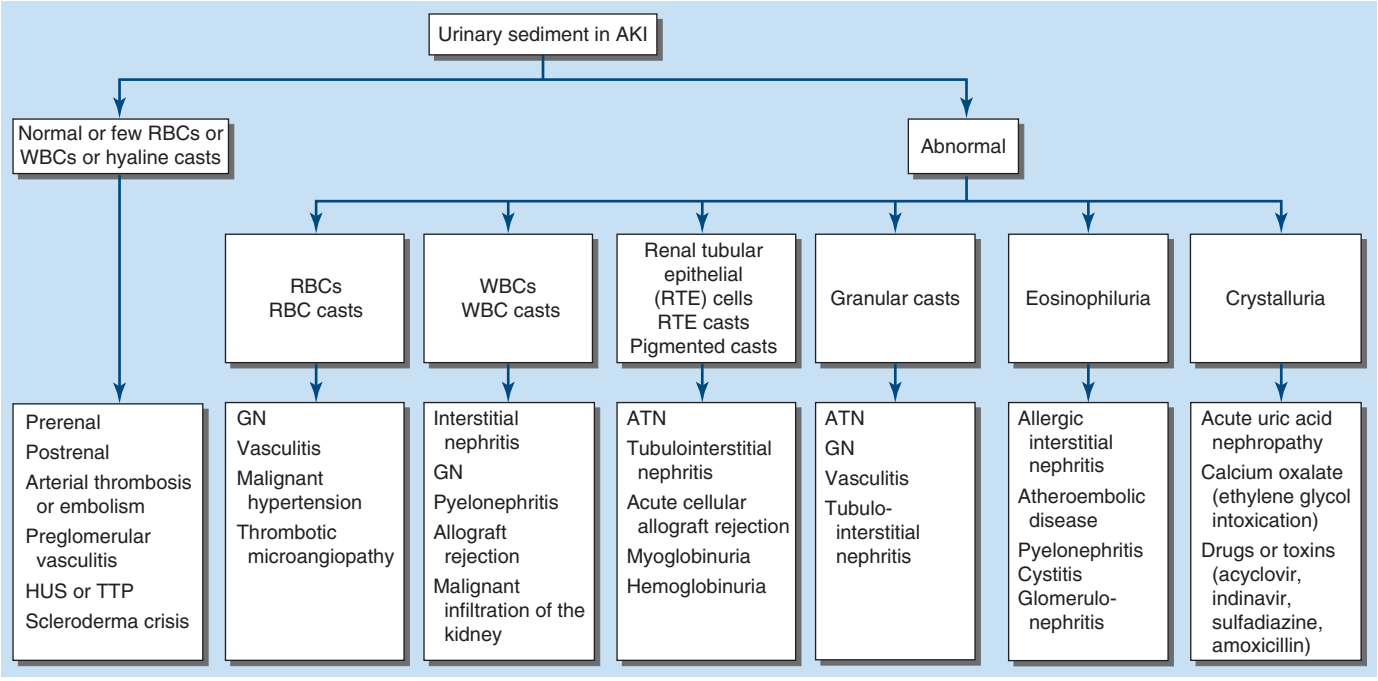

FIGURE 321-6 Interpretation of urinary sediment findings in acute kidney injury (AKI). ATN, acute tubular necrosis; GN, glomerulonephritis; HUS, hemolytic-uremic syndrome; RBCs, red blood cells; RTE, renal tubular epithelial; TTP, thrombotic thrombocytopenic purpura; WBCs, white blood cells. *(Adapted from L Yang, JV Bonventre: Diagnosis and clinical evaluation of acute kidney injury. In Comprehensive Nephrology, 4th ed. J Floege et al [eds]. Philadelphia, Elsevier, 2010.)*

findings: pigmented "muddy brown" granular casts and tubular epithelial cell casts. These findings may be absent in >20% of cases, however. Glomerulonephritis may lead to dysmorphic red blood cells or red blood cell casts. Interstitial nephritis may lead to white blood cell casts. The urine sediment findings overlap somewhat in glomerulonephritis and interstitial nephritis, and a diagnosis is not always possible on the basis of the urine sediment alone. Urine eosinophils have a limited role in differential diagnosis; they can be seen in interstitial nephritis, pyelonephritis, cystitis, atheroembolic disease, or glomerulonephritis. Crystalluria may be important diagnostically. The finding of oxalate crystals in AKI should prompt an evaluation for ethylene glycol toxicity. Abundant uric acid crystals may be seen in tumor lysis syndrome.

BLOOD LABORATORY FINDINGS

Certain forms of AKI are associated with characteristic patterns in the rise and fall of SCr. Prerenal azotemia typically leads to modest rises in SCr that return to baseline with improvement in hemodynamic status. In comparison, atheroembolic disease usually manifests with more subacute rises in SCr, although severe AKI with rapid increases in SCr can occur in this setting. With many of the epithelial cell toxins such as aminoglycoside antibiotics and cisplatin, the rise in SCr is characteristically delayed for 3–5 days to 2 weeks after initial exposure.

A complete blood count may provide diagnostic clues. Anemia is common in AKI and is usually multifactorial in origin. It is not related to an effect of AKI solely on production of red blood cells because this effect in isolation takes longer to manifest. Myeloma can be diagnosed with serum immunoelectrophoresis or free light chain assay, and it can often be suspected if the blood anion gap is low due to unmeasured cationic proteins. Peripheral eosinophilia can accompany interstitial nephritis, atheroembolic disease, polyarteritis nodosa, and Churg-Strauss vasculitis. Severe anemia in the absence of bleeding may reflect hemolysis, multiple myeloma, or thrombotic microangiopathy (e.g., HUS or TTP). Other laboratory findings of thrombotic microangiopathy include thrombocytopenia, schistocytes on peripheral blood smear, elevated lactate dehydrogenase level, and low haptoglobin content. Evaluation of patients suspected of having TTP or HUS includes measurement of levels of the von Willebrand factor cleaving protease (ADAMTS13) and testing for Shiga toxin–producing *Escherichia coli*. "Atypical HUS" constitutes the majority of adult cases of HUS; genetic testing is important because it is estimated that 60–70% of atypical HUS patients have mutations in genes encoding proteins that regulate the alternative complement pathway.

AKI often leads to hyperkalemia, hyperphosphatemia, and hypocalcemia. Marked hyperphosphatemia with accompanying hypocalcemia may suggest rhabdomyolysis or tumor lysis syndrome. Serum creatine kinase and uric acid levels are often elevated in rhabdomyolysis, while tumor lysis syndrome can be associated with normal or marginally elevated creatine kinase and markedly elevated serum uric acid. The anion gap may be increased with any cause of uremia due to retention of anions such as phosphate, hippurate, sulfate, and urate. The co-occurrence of an increased anion gap and an osmolal gap may suggest ethylene glycol poisoning, which may also cause oxalate crystalluria and oxalate deposition in kidney tissue. As discussed previously, low anion gap may provide a clue to the diagnosis of multiple myeloma due to the presence of unmeasured cationic proteins. Laboratory blood tests helpful for the diagnosis of glomerulonephritis and vasculitis include depressed complement levels and high titers of antinuclear antibodies (ANAs), antineutrophil cytoplasmic antibodies (ANCAs), antiglomerular basement membrane (anti-GBM) antibodies, and cryoglobulins. It is important to diagnose glomerulonephritis or myeloma early in the course of AKI since effective therapies (e.g., immunosuppression or chemotherapy) are now available for some of the causes. In general, however, the therapies are less effective when severe kidney injury has progressed.

RENAL FAILURE INDICES

Several indices have been used to help differentiate prerenal azotemia from intrinsic AKI when the tubules are malfunctioning. The low tubular flow rate and increased renal medullary recycling of urea seen in prerenal azotemia may cause a disproportionate elevation of the blood urea nitrogen (BUN) compared to creatinine. Other causes of disproportionate BUN elevation need to be kept in mind, however, including upper gastrointestinal bleeding, hyperalimentation, increased tissue catabolism, and glucocorticoid use.

The FeNa is the fraction of the filtered sodium load that is not reabsorbed by the tubules and is a measure of both the kidney's ability to reabsorb sodium as well as endogenously and exogenously administered factors that affect tubular reabsorption. As such, it depends on sodium intake, effective intravascular volume, GFR, diuretic intake, and intact tubular reabsorptive mechanisms. With prerenal azotemia, the FeNa may be <1%, suggesting avid tubular sodium reabsorption. In patients with CKD, a FeNa significantly >1% can be present due to tubular dysfunction in the reabsorption of sodium, despite a superimposed prerenal state. The FeNa may also be >1% despite hypovolemia due to treatment with diuretics. Low FeNa is often seen early in glomerulonephritis and other disorders and, hence, should not be taken as prima facie evidence of prerenal azotemia. Low FeNa is therefore suggestive of, but not synonymous with, effective intravascular volume depletion, and should not be used as the sole guide for volume management. The response of urine output to crystalloid or colloid fluid administration may be both diagnostic and therapeutic in prerenal azotemia. In ischemic AKI, the FeNa is frequently >1% because of tubular injury and resultant impaired ability to reabsorb sodium. Several causes of ischemia-associated and nephrotoxin-associated AKI can present with FeNa <1%, however, including sepsis (often early in the course), rhabdomyolysis, and contrast nephropathy. FeNa has the most utility in oliguric patients who are not given diuretics and do not have CKD.

The ability of the kidney to produce a concentrated urine is dependent upon many factors and relies on good blood flow and tubular function in multiple regions of the kidney. In the patient not taking diuretics and with good baseline kidney function, urine osmolality may be >500 mOsm/kg in prerenal azotemia, consistent with an intact medullary concentration gradient and elevated serum vasopressin levels causing water reabsorption by passive diffusion from the collecting duct into a concentrated medullary interstitium, resulting in concentrated urine. In elderly patients and those with CKD, however, baseline concentrating defects may exist, making urinary osmolality unreliable in many instances. Concentrating ability may also be maintained early in the course of glomerular disease when the tubules are not yet affected. Loss of concentrating ability (<350 mOsm/kg) is common in most forms of AKI that affect the tubules and interstitium, but this finding is not specific.

RADIOLOGIC EVALUATION

Postrenal AKI should always be considered in the differential diagnosis of AKI because treatment is usually successful if instituted early. Simple bladder catheterization can rule out urethral obstruction. Imaging of the urinary tract with renal ultrasound or CT scan should be undertaken to investigate obstruction in individuals with AKI unless an alternate diagnosis is apparent. Findings of obstruction include dilation of the collecting system and hydroureteronephrosis. Obstruction can be present without radiologic abnormalities in the setting of volume depletion, retroperitoneal fibrosis, encasement with tumor, and also early in the course of obstruction. If a high clinical index of suspicion for obstruction persists despite normal imaging, antegrade or retrograde pyelography should be performed. Imaging may also provide additional helpful information about kidney size and echogenicity to assist in the distinction between AKI versus CKD. In CKD, kidneys are usually smaller unless the patient has diabetic nephropathy, HIV-associated nephropathy, or infiltrative diseases. Normal-sized kidneys are expected in AKI. Enlarged kidneys in a patient with AKI suggest the possibility of acute interstitial nephritis or infiltrative diseases. Vascular imaging may be useful if venous or arterial obstruction is suspected.

KIDNEY BIOPSY

If the cause of AKI is not apparent based on the clinical context, physical examination, laboratory studies, and radiologic evaluation, kidney biopsy should be considered. The kidney biopsy can provide definitive diagnostic and prognostic information about acute kidney disease and CKD. The procedure is most often used in AKI when prerenal azotemia,

postrenal AKI, and ischemic or nephrotoxic AKI have been deemed unlikely and other possible diagnoses are being considered such as glomerulonephritis, vasculitis, interstitial nephritis, myeloma kidney, HUS and TTP, and allograft dysfunction. Kidney biopsy is associated with a risk of bleeding, which can be severe and organ- or life-threatening in patients with thrombocytopenia or coagulopathy, but the diagnostic and prognostic information obtained can be invaluable.

NOVEL BIOMARKERS

BUN, SCr, and cystatin C are functional biomarkers of glomerular filtration rather than tissue injury biomarkers and, therefore, may be suboptimal for the diagnosis of actual parenchymal kidney damage. Filtration markers are also relatively slow to rise after kidney injury. Several urine and blood biomarkers have been investigated and show promise for earlier and accurate diagnosis of AKI and for predicting AKI prognosis. In cases of oliguric AKI, the urinary flow rate in response to bolus intravenous furosemide 1.0–1.5 mg/kg can be used as a prognostic test: urine output <200 mL over 2 h after intravenous furosemide may identify patients at higher risk of progression to more severe AKI and the need for renal replacement therapy. The severity or risk of progressive AKI may also be reflected in findings on urine microscopy. In one study involving review of fresh urine sediments by board-certified nephrologists, a greater number of renal tubular epithelial cells and/or granular casts in the urine sediment was associated with both the severity and worsening of AKI. Protein biomarkers of kidney injury have also been identified in animal models of AKI and have been used in humans and found to be particularly useful in toxicity identification. *Kidney injury molecule-1* (KIM-1) is a type 1 transmembrane protein that is abundantly expressed in proximal tubular cells injured by ischemia or multiple, distinct nephrotoxins, such as cisplatin. KIM-1 is not expressed in appreciable quantities in the absence of tubular injury or in extrarenal tissues. KIM-1 can be detected after ischemic or nephrotoxic injury in the urine and plasma. *Neutrophil gelatinase associated lipocalin* (NGAL, also known as lipocalin-2 or siderocalin) is another biomarker of AKI. NGAL was first discovered as a protein in granules of human neutrophils. NGAL can bind to iron siderophore complexes and may have tissue-protective effects in the proximal tubule. NGAL is highly upregulated after inflammation and kidney injury and can be detected in the plasma and urine within 2 h of cardiopulmonary bypass–associated AKI. Soluble urokinase plasminogen activator receptor (suPAR) is a signaling glycoprotein expressed in multiple cell types and thought to be involved in the pathogenesis of certain kidney diseases; suPAR has been measured in the plasma and found to predict the subsequent development of AKI. In 2014, the U.S. Food and Drug Administration (FDA) approved the marketing of a test based on the combination of the urinary concentrations of two cell-cycle arrest biomarkers, insulin-like growth factor binding protein 7 (IGFBP7) and tissue inhibitor of metalloproteinase-2 (TIMP-2) as predictive biomarkers for higher risk of the development of moderate to severe AKI in critically ill patients. In 2023, the FDA also approved the use of NGAL for the early identification of AKI in pediatric patients. Biomarkers may also be helpful in distinguishing tubulointerstitial nephritis where interstitial inflammation plays a dominant role from other causes of AKI that primarily affect the glomeruli or the tubule where inflammation also exists but may be less dominant. One such marker, CXCL9, has recently been reported. The optimal use of AKI biomarkers in clinical settings is an area of ongoing investigation.

COMPLICATIONS OF AKI

The kidney plays a central role in homeostatic control of volume status, blood pressure, plasma electrolyte composition, acid-base balance, and the excretion of nitrogenous and other waste products. Complications associated with AKI are, therefore, protean, and depend on the severity of AKI and other associated conditions. Mild to moderate AKI may be entirely asymptomatic, particularly early in the course.

UREMIA

Buildup of nitrogenous waste products, manifested as an elevated BUN concentration, is a hallmark of AKI. BUN itself poses little direct toxicity at levels <100 mg/dL. In more severe AKI or when, as is often the case, AKI is on the backdrop of CKD, mental status changes and bleeding complications can arise. Other toxins normally cleared by the kidney may be responsible for the symptom complex known as uremia, which literally means "urine in the blood." Urea has direct and indirect toxic effects. There are increased blood levels of parathyroid hormone, advanced glycosylation end products, and many other "middle molecules" that contribute to the uremic syndrome. Few of the many possible uremic toxins have been definitively identified. The correlation of filtration markers or BUN concentrations with uremic symptoms is extremely variable, due in part to differences in generation rates across individuals.

HYPERVOLEMIA AND HYPOVOLEMIA

Expansion of extracellular fluid volume is a major complication of oliguric and anuric AKI, due to impaired salt and water excretion. The result can be weight gain, dependent edema, increased jugular venous pressure, and pulmonary edema. AKI may also induce or exacerbate acute lung injury characterized by increased vascular permeability and inflammatory cell infiltration in lung parenchyma. Recovery from AKI is often heralded by an increase in urine output. This "polyuric" phase of recovery may be due to an osmotic diuresis from retained urea and other waste products as well as delayed recovery of tubular reabsorptive functions.

HYPONATREMIA

Abnormalities in plasma electrolyte composition can be mild or life-threatening. The dysfunctional kidney has limited ability to regulate electrolyte balance. Administration of excessive hypotonic crystalloid or isotonic dextrose solutions can result in hypoosmolality and hyponatremia, which, if severe, can cause neurologic abnormalities, including seizures.

HYPERKALEMIA

An important complication of AKI is hyperkalemia. Marked hyperkalemia is particularly common in rhabdomyolysis, hemolysis, and tumor lysis syndrome due to release of intracellular potassium from damaged cells. Muscle weakness may be a symptom of hyperkalemia. Potassium affects the cellular membrane potential of cardiac and neuromuscular tissues. The more serious complication of hyperkalemia is due to effects on cardiac conduction, leading to potentially fatal arrhythmias.

ACIDOSIS

Metabolic acidosis, usually accompanied by an elevation in the anion gap, is common in AKI, and can further complicate acid-base and potassium balance in individuals with other causes of acidosis, including sepsis, diabetic ketoacidosis, or respiratory acidosis.

HYPERPHOSPHATEMIA AND HYPOCALCEMIA

AKI can lead to hyperphosphatemia, particularly in highly catabolic patients or those with AKI from rhabdomyolysis, hemolysis, and tumor lysis syndrome. Metastatic deposition of calcium phosphate can lead to hypocalcemia. AKI-associated hypocalcemia may also arise from derangements in the vitamin D–parathyroid hormone–fibroblast growth factor-23 axis. Hypocalcemia is often asymptomatic but can lead to perioral paresthesias, muscle cramps, seizures, carpopedal spasms, and prolongation of the QT interval on electrocardiography. Calcium levels should be corrected for the degree of hypoalbuminemia, if present, or ionized calcium levels should be followed. Mild, asymptomatic hypocalcemia does not require treatment.

BLEEDING

Hematologic complications of AKI include anemia and bleeding, both of which are exacerbated by coexisting disease processes such as sepsis, liver disease, and disseminated intravascular coagulation. Direct hematologic effects from AKI-related uremia include decreased erythropoiesis and platelet dysfunction.

INFECTIONS

Infections are a common precipitant of AKI and also a dreaded complication of AKI. Impaired host immunity has been described in ESKD and may be operative in severe AKI.

CARDIAC COMPLICATIONS

The major cardiac complications of AKI are arrhythmias, pericarditis, and pericardial effusion. In addition, volume overload and uremia may lead to cardiac injury and impaired cardiac function. In animal studies, cellular apoptosis and capillary vascular congestion as well as mitochondrial dysfunction have been described in the heart after renal ischemia reperfusion.

MALNUTRITION

AKI is often a severely hypercatabolic state, and therefore, malnutrition is a major complication.

PREVENTION AND TREATMENT OF AKI

The management of individuals with and at risk for AKI varies according to the underlying cause (Table 321-3). Common to all are several principles. Optimization of hemodynamics, correction of fluid and electrolyte imbalances, discontinuation of nephrotoxic medications, and dose adjustment of administered medications are all critical. Common causes of AKI such as sepsis and ischemic ATN do not yet have specific therapies once injury is established, but meticulous clinical attention is needed to support the patient until (if) AKI resolves. The kidney possesses remarkable capacity to repair itself after even severe, dialysis-requiring AKI, when baseline renal function was previously intact. However, many patients with AKI, particularly when superimposed on preexisting CKD, undergo maladaptive repair processes and do not recover fully and may remain dialysis dependent. It has become increasingly apparent that AKI predisposes to accelerated progression of CKD, and CKD is an important risk factor for AKI.

Prerenal Azotemia Prevention and treatment of prerenal azotemia require optimization of renal perfusion. In AKI, oliguria alone is not an indication for fluid administration. Intravascular hypovolemia should be the only indication. The composition of replacement fluids should be targeted to the type of fluid lost. Severe acute blood loss should be treated with packed red blood cells. Crystalloids are in general favored over colloid-containing solutions (e.g., hyperoncotic albumin-containing solutions, which are still commonly used for volume resuscitation in liver failure). The colloidal solution hydroxyethyl starch is no longer available for hospitalized patients, due in part to concerns over increased risk of AKI. The most commonly used crystalloid solution is 0.9% saline. Other options are buffered crystalloid solutions (e.g., Ringer's lactate, Hartmann's solution, Plasma-Lyte). The choice between 0.9% saline or buffered crystalloid solutions can be based on serum electrolyte (e.g., some buffered crystalloid solutions are slightly hypotonic to plasma water and may be preferred for patients with hypernatremia; 0.9% saline can cause or exacerbate hyperchloremic metabolic acidosis and can be used in those with metabolic alkalosis; bicarbonate-containing solutions like dextrose water with 150 mEq sodium bicarbonate can be used in those with metabolic acidosis).

Optimization of cardiac function in AKI may require use of inotropic agents, preload- and afterload-reducing agents, antiarrhythmic drugs, and mechanical aids such as ventricular assist devices. Invasive hemodynamic monitoring to guide therapy may be necessary.

Cirrhosis and Hepatorenal Syndrome Fluid management in individuals with cirrhosis, ascites, and AKI is challenging because of the frequent difficulty in ascertaining intravascular volume status. Administration of intravenous fluids as a volume challenge may be required diagnostically as well as therapeutically. Excessive volume administration may, however, result in worsening ascites and pulmonary compromise in the setting of hepatorenal syndrome or AKI due to superimposed spontaneous bacterial peritonitis. Peritonitis should be ruled out by inflammatory cell count and culture of ascitic fluid. Albumin may prevent AKI in those treated with antibiotics for spontaneous bacterial peritonitis. The definitive treatment of the hepatorenal syndrome is orthotopic liver transplantation. Bridge therapies that have shown promise include norepinephrine, terlipressin (a vasopressin analogue), or combination therapy with octreotide (a somatostatin analogue) and midodrine (an α_1-adrenergic agonist), in combination with intravenous albumin (25–50 g, maximum 100 g/d).

Intrinsic AKI Several agents have been tested and have failed to show benefit in the treatment of acute tubular injury. These include atrial natriuretic peptide, low-dose dopamine, endothelin antagonists, erythropoietin, prostaglandin analogues, antioxidants, antibodies against leukocyte adhesion molecules, growth factors,

TABLE 321-3 Management of Acute Kidney Injury

General Issues

1. Optimization of systemic and renal hemodynamics through volume resuscitation and judicious use of vasopressors
2. Maintain mean arterial pressure >65 mmHg
3. Elimination of nephrotoxic agents (e.g., ACE inhibitors, ARBs, NSAIDs, aminoglycosides, chemotherapeutic agents, checkpoint inhibitors, antibiotics) if possible
4. Sufficient protein and calorie intake (20–30 kcal/kg per day) to avoid negative nitrogen balance. Nutrition should be provided by the enteral route if oral intake is not possible.
5. Initiation of renal replacement therapy when indicated

Specific Issues

1. Nephrotoxin-specific
   a. Rhabdomyolysis: aggressive intravenous fluids; consider forced alkaline diuresis
   b. Tumor lysis syndrome: aggressive intravenous fluids and allopurinol or rasburicase
2. Volume overload
   a. Salt and water restriction
   b. Diuretics
   c. Ultrafiltration
3. Hyponatremia
   a. Restriction of enteral free water intake, minimization of hypotonic intravenous solutions including those containing dextrose
   b. Hypertonic saline is rarely necessary in AKI. Vasopressin antagonists are generally not needed.
4. Hyperkalemia
   a. Restriction of dietary potassium intake
   b. Discontinuation of potassium-sparing diuretics, ACE inhibitors, ARBs, NSAIDs
   c. Loop diuretics to promote urinary potassium loss
   d. Potassium-binding molecules (sodium zirconium cyclosilicate) or ion-exchange resins (patiromer, sodium or calcium polystyrene sulfonate)
   e. Insulin and glucose to promote entry of potassium intracellularly
   f. Inhaled beta-agonist therapy to promote entry of potassium intracellularly
   g. Calcium gluconate or calcium chloride (1 g) to stabilize the myocardium
5. Metabolic acidosis
   a. Sodium bicarbonate (if pH <7.2 to keep serum bicarbonate >15 mmol/L)
   b. Renal replacement therapy
6. Hyperphosphatemia
   a. Restriction of dietary phosphate intake
   b. Phosphate binding agents (calcium acetate, sevelamer hydrochloride, aluminum hydroxide—taken with meals)
7. Hypocalcemia
   a. Calcium carbonate or calcium gluconate if symptomatic
8. Hypermagnesemia
   a. Discontinue Mg^{2+}-containing antacids
9. Hyperuricemia
   a. Acute treatment is usually not required except in the setting of tumor lysis syndrome (see above)
10. Drug dosing
    a. Careful attention to dosages and frequency of administration of drugs, adjustment for degree of renal failure
    b. Note that serum creatinine concentration may overestimate renal function in the non-steady-state characteristic of patients with AKI

Abbreviations: ACE, angiotensin-converting enzyme; AKI, acute kidney infection; ARBs, angiotensin receptor blockers; NSAIDs, nonsteroidal anti-inflammatory drugs.

intra-aortic mesenchymal stem cells, and small interfering RNAs to inhibit p53-mediated cell death, among many others. Most studies have used changes in SCr to identify AKI; kidney injury biomarkers described previously may provide an opportunity to test agents with greater sensitivity.

AKI due to acute glomerulonephritis or vasculitis may respond to immunosuppressive agents, anticomplement therapies, and/or plasmapheresis (Chap. 320). Allergic interstitial nephritis due to medications requires discontinuation of the offending agent. Glucocorticoids have been used but not tested in randomized trials, in cases where AKI persists or worsens despite discontinuation of the suspected medication. AKI due to scleroderma (scleroderma renal crisis) should be treated with ACE inhibitors. Idiopathic TTP is a medical emergency and should be treated promptly with plasma exchange. Pharmacologic blockade of complement activation may be effective in atypical HUS.

Early and aggressive volume repletion is mandatory in patients with rhabdomyolysis, who may initially require 10 L of fluid per day. Alkaline fluids (e.g., 75 mmol/L sodium bicarbonate added to 0.45% saline) may be beneficial in preventing tubular injury and cast formation but carry the risk of worsening hypocalcemia. Diuretics may be used if fluid repletion is adequate but unsuccessful in achieving urinary flow rates of 200–300 mL/h. There is no specific therapy for established AKI in rhabdomyolysis, other than dialysis in severe cases or general supportive care to maintain fluid and electrolyte balance and tissue perfusion. Careful attention must be focused on calcium and phosphate status because of precipitation in damaged tissue and release when the tissue heals.

Postrenal AKI Prompt recognition and relief of urinary tract obstruction can forestall the development of permanent structural damage induced by urinary stasis. The site of obstruction defines the treatment approach. Transurethral or suprapubic bladder catheterization may be all that is needed initially for urethral strictures or functional bladder impairment. Ureteric obstruction may be treated by percutaneous nephrostomy tube placement or ureteral stent placement. Relief of obstruction is usually followed by an appropriate diuresis for several days. In rare cases, severe polyuria persists due to tubular dysfunction and may require continued administration of intravenous fluids and electrolytes for a period of time.

SUPPORTIVE MEASURES FOR AKI

Volume Management Hypervolemia in oliguric or anuric AKI may be life threatening due to acute pulmonary edema, especially because many patients have coexisting pulmonary disease, and AKI likely increases pulmonary vascular permeability. Fluid and sodium should be restricted, and diuretics may be used to increase the urinary flow rate. There is no evidence that increasing urine output itself improves the natural history of AKI, but diuretics may help to avoid the need for dialysis in some cases. In severe cases of volume overload, furosemide may be given as a bolus (200 mg) followed by an intravenous drip (10–40 mg/h), with or without a thiazide diuretic. In decompensated heart failure, stepped diuretic therapy was found to be superior to ultrafiltration in preserving renal function. Dopamine in low doses may transiently increase salt and water excretion by the kidney in prerenal states, but clinical trials have failed to show any benefit in patients with intrinsic AKI. Because of the risk of arrhythmias and potential bowel ischemia, the risks of dopamine outweigh the benefits if used specifically for the treatment or prevention of AKI.

Electrolyte and Acid-Base Abnormalities The treatment of dysnatremias and hyperkalemia is described in Chap. 56. Metabolic acidosis associated with AKI is generally not treated unless severe (pH <7.20 and serum bicarbonate <15 mmol/L). Acidosis can be treated with oral or intravenous sodium bicarbonate (Chap. 58), but overcorrection should be avoided because of the possibility of metabolic alkalosis, hypocalcemia, hypokalemia, and volume overload. Hyperphosphatemia is common in AKI and can usually be treated by limiting intestinal absorption of phosphate using phosphate binders (calcium carbonate, calcium acetate, lanthanum, sevelamer, or aluminum hydroxide). Symptomatic hypocalcemia should be treated with calcium gluconate or calcium chloride. Ionized calcium should be monitored rather than total calcium when hypoalbuminemia is present.

Malnutrition Increased catabolism with protein energy wasting is common in severe AKI, particularly in the setting of multisystem organ failure. Inadequate nutrition may lead to starvation ketoacidosis and protein catabolism. Excessive nutrition may increase the generation of nitrogenous waste and lead to worsening azotemia. Total parenteral nutrition requires large volumes of fluid administration and may complicate efforts at volume control. According to the KDIGO guidelines, patients with AKI should achieve a total energy intake of 20–30 kcal/kg per day. Protein intake should vary depending on the severity of AKI: 0.8–1.0 g/kg per day in noncatabolic AKI without the need for dialysis; 1.0–1.5 g/kg per day in patients on dialysis; and up to a maximum of 1.7 g/kg per day if hypercatabolic and receiving continuous renal replacement therapy. Trace elements and water-soluble vitamins should also be supplemented in AKI patients treated with dialysis and continuous renal replacement therapy.

Anemia The anemia seen in AKI is usually multifactorial and is not improved by erythropoiesis-stimulating agents, due to their delayed onset of action and the presence of bone marrow resistance in critically ill patients. Uremic bleeding may respond to desmopressin or estrogens but may require dialysis for treatment in the case of long-standing or severe uremia. Gastrointestinal prophylaxis with proton pump inhibitors or histamine (H_2) receptor blockers is required. It is important to recognize, however, that proton pump inhibitors have been associated with AKI due to interstitial nephritis, a relationship that is increasingly being recognized. Venous thromboembolism prophylaxis is important and should be tailored to the clinical setting; low-molecular-weight heparins and factor Xa inhibitors have unpredictable pharmacokinetics in severe AKI and should generally be avoided if possible.

Dialysis Indications and Modalities (See also Chap. 323.) Dialysis is indicated when medical management fails to control volume overload, hyperkalemia, or acidosis; in some toxic ingestions; and when there are severe complications of uremia (asterixis, pericardial rub or effusion, encephalopathy, uremic bleeding). Late initiation of dialysis carries the risk of avoidable volume, electrolyte, and metabolic complications of AKI. On the other hand, initiating dialysis too early may unnecessarily expose individuals to intravenous lines and invasive procedures, with the attendant risks of infection, bleeding, procedural complications, and hypotension. In randomized controlled trials, earlier versus later initiation of dialysis has not been demonstrated to improve survival and may increase the risk of adverse events. The initiation of dialysis should not, however, await the development of a life-threatening complication of renal failure. Many nephrologists initiate dialysis for AKI empirically when the BUN exceeds a certain value (e.g., 100 mg/dL) in patients without clinical signs of recovery of kidney function. The available modes for renal replacement therapy in AKI require either access to the peritoneal cavity (for peritoneal dialysis) or the large blood vessels (for hemodialysis, hemofiltration, and other hybrid procedures). Small solutes are removed across a semipermeable membrane down their concentration gradient ("diffusive" clearance) and/or along with the movement of plasma water ("convective" clearance). Hemodialysis can be used intermittently or continuously and can be done through convective clearance, diffusive clearance, or a combination of the two. Vascular access is through the femoral, internal jugular, or subclavian veins. Hemodialysis is an intermittent procedure that removes solutes through diffusive and convective clearance. Hemodialysis is typically performed 3–4 h per day, three to four times per week, and is the most common form of renal replacement therapy for AKI. One of the major complications of hemodialysis is hypotension, particularly in the critically ill, which can perpetuate AKI by causing ischemic injury to the recovering organ.

Continuous intravascular procedures were developed in the early 1980s to treat hemodynamically unstable patients without inducing the rapid shifts of volume, osmolarity, and electrolytes characteristic of intermittent hemodialysis. Continuous renal replacement therapy (CRRT)

can be performed by convective clearance (continuous venovenous hemofiltration [CVVH]), in which large volumes of plasma water (and accompanying solutes) are forced across the semipermeable membrane by means of hydrostatic pressure; the plasma water is then replaced by a physiologic crystalloid solution. CRRT can also be performed by diffusive clearance (continuous venovenous hemodialysis [CVVHD]), a technology similar to hemodialysis except at lower blood flow and dialysate flow rates. A hybrid therapy combines both diffusive and convective clearance (continuous venovenous hemodiafiltration [CVVHDF]). To achieve some of the advantages of CRRT without the need for 24-h staffing of the procedure, some physicians favor slow low-efficiency dialysis (SLED) or extended daily dialysis (EDD). In this therapy, blood flow and dialysate flow are higher than in CVVHD, but the treatment time is reduced to ≤12 h. The choice of modality is often dictated by the immediate availability of technology and the expertise of medical staff.

The optimal dose of dialysis for AKI for any particular patient is not clear. Daily intermittent hemodialysis and high-dose CRRT do not confer a demonstrable survival or renal recovery advantage, but care should be taken to avoid undertreatment. Studies have failed to show that continuous therapies are superior to intermittent therapies when measuring survival rates. If available, CRRT is often preferred in patients with severe hemodynamic instability, cerebral edema, or significant volume overload.

Peritoneal dialysis can be performed through a temporary intraperitoneal catheter. It is rarely used in the United States for AKI in adults (although it was "rediscovered" during the COVID-19 pandemic owing to inadequate numbers of continuous and intermittent hemodialysis machines). Peritoneal dialysis has enjoyed widespread use internationally, particularly when hemodialysis technology is not as readily available. Dialysate solution is instilled into and removed from the peritoneal cavity at regular intervals in order to achieve diffusive and convective clearance of solutes across the peritoneal membrane; ultrafiltration of water is achieved by the presence of an osmotic gradient across the peritoneal membrane achieved by high concentrations of dextrose in the dialysate solution. Because of its continuous nature, it is often better tolerated than intermittent procedures like hemodialysis in hypotensive patients. Peritoneal dialysis may not be sufficient for hypercatabolic patients due to inherent limitations in dialysis efficacy.

OUTCOME AND PROGNOSIS

The development of AKI is associated with a significantly increased risk of in-hospital and long-term mortality, longer length of stay, and increased costs. AKI is also associated with an increased risk of later cardiovascular disease events, though the mechanisms are not well understood. Prerenal azotemia, with the exception of the cardiorenal and hepatorenal syndromes, and postrenal azotemia carry a better prognosis than most cases of intrinsic AKI. The kidneys may recover even after severe, dialysis-requiring AKI. Survivors of an episode of AKI requiring temporary dialysis, however, are at extremely high risk for progressive CKD, and up to 10% may develop ESKD requiring dialysis or transplantation. AKI and CKD are increasingly seen as interrelated syndromes: CKD is a major risk factor for the development of AKI, and AKI is a risk factor for the future development of CKD. Measurement of albuminuria after an AKI episode can help predict the risk of kidney disease progression and can serve as a valuable risk-stratification tool. Postdischarge care after AKI under the supervision of a nephrologist for aggressive secondary prevention of kidney disease is prudent.

322 Chronic Kidney Disease

Joanne M. Bargman, Karl L. Skorecki

Chronic kidney disease (CKD) encompasses a spectrum of pathophysiologic processes associated with abnormal kidney function, often with a progressive decline in glomerular filtration rate (GFR). The risk of worsening CKD is closely linked to the GFR, its trajectory over time, and the quantity of urinary albumin excretion (albuminuria). **Figure 322-1** provides a staging of CKD stratified by the estimated risk for further progressive decline of GFR based on these parameters.

The dispiriting term *end-stage renal disease* represents a stage of CKD where the accumulation of toxins, fluid, and electrolytes normally excreted by the kidneys leads to death unless the toxins are removed by renal replacement therapy by means of dialysis or kidney transplantation. These interventions are discussed in **Chaps. 323 and 325**. End-stage renal disease will be supplanted in this chapter by the term *stage 5 CKD*.

PATHOPHYSIOLOGY OF CKD

The pathophysiology of CKD involves two broad mechanisms of damage: (1) specific initiating mechanisms particular to the underlying etiology (e.g., genetic abnormalities in development, immune complex deposition, inflammation, metabolic, microvascular perturbation, or toxin exposure affecting vascular, glomerular, or tubulointerstitial compartments of the kidney), and (2) nonspecific mechanisms involving hyperfiltration and hypertrophy of the remaining viable nephrons, which are common consequences of long-term reduction of renal mass, irrespective of underlying etiology. The responses to reduction in nephron number are mediated by vasoactive hormones, cytokines, and growth factors. Eventually, the short-term adaptations of hyperfiltration and hypertrophy to maintain GFR become maladaptive as the increased pressure and flow within the nephron predisposes to distortion of glomerular architecture, abnormal podocyte function, and disruption of the filtration barrier, leading to sclerosis and dropout of the remaining nephrons. Increased intrarenal activity of the renin-angiotensin system (RAS) together with reduced tubuloglomerular feedback appears to contribute both to the initial compensatory hyperfiltration and to the subsequent maladaptive hypertrophy and sclerosis **(Fig. 322-2)**. This process explains why a reduction in functioning nephron number from initial injuries may lead to a progressive decline in kidney function over many years.

IDENTIFICATION OF RISK FACTORS AND STAGING OF CKD

There has been significant progress in the identification of risk factors that increase the risk for CKD, even in individuals with normal GFR and often years prior to the development of overt kidney impairment **(Table 322-1)**.

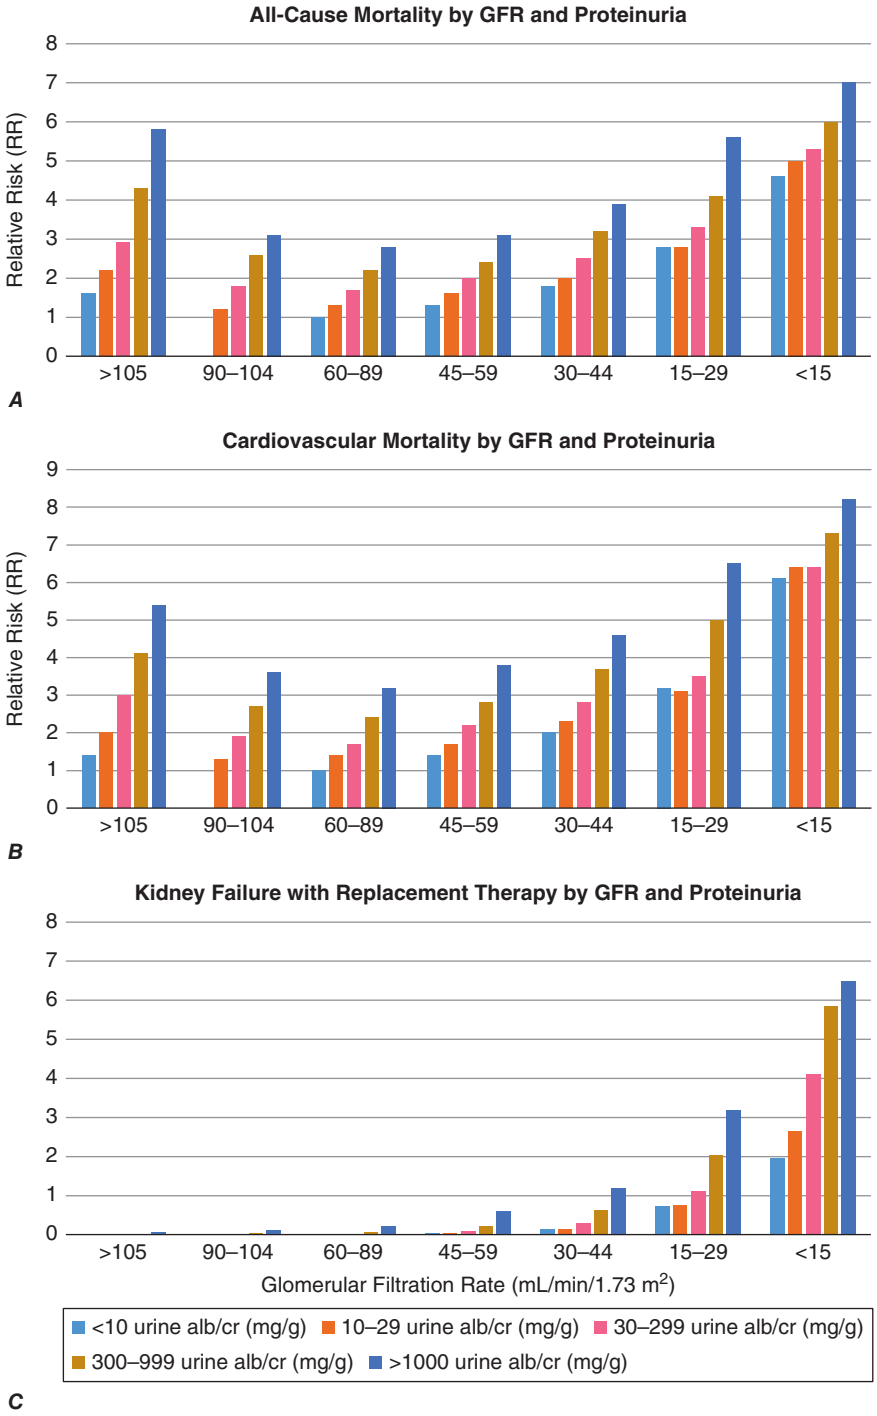

FIGURE 322-1 Kidney Disease Improving Global Outcome (KDIGO) classification of chronic kidney disease (CKD). Glomerular filtration rate (GFR) and Increasing albuminuria correspond to increasing risk of All-Cause Mortality (***A***), Cardiovascular Mortality (***B***) and Progression of CKD (***C***). *(Figure created using data from ME Grams et al: JAMA 330:1266, 2023.)*

Adults with such risk factors should be monitored yearly for urinary albumin excretion level, decline in estimated GFR (eGFR), and blood pressure, so that a clinical reno-protective management pathway can be planned. More recently, identified risk factors for which there is now a consensus include tobacco use, increased body mass index (BMI) and sedentary lifestyle, a past episode of clinically recovered acute kidney injury (AKI), and many forms of apparently recovered childhood and adolescent kidney disease.

There is also an increasing awareness of the role of genetic risk factors, which may account for up to 20% of adult-onset CKD, depending on the clinical phenotype, family background, demographic history, and population ancestry. Many rare inherited forms of CKD follow a Mendelian inheritance pattern, sometimes as part of a systemic syndrome, with the most common in this category being autosomal dominant polycystic kidney disease (ADPKD). In addition, it is now appreciated that many unique, kindred-specific, site-specific copy number variants and microdeletions, as well as functional single nucleotide variants at >300 genetic loci known to harbor systemic and kidney-only disease pathogenic mutations with high penetrance, also contribute to pleiotropic presentations of CKD (Table 322-2). Many of the genes with identified CKD-causing mutations are expressed in the podocytes of the glomeruli or in the glomerular basement membrane, but others are expressed in tubule segments associated with a primary tubulointerstitial process and secondary glomerular injury.

In addition to these high penetrance mutations, DNA sequence variants with partial penetrance for causation or progression of CKD have been identified and often require an acquired second hit for emergence of disease. A striking example is the finding of allelic versions of the *APOL1* gene, of sub-Saharan African population ancestry, which contributes to the several-fold higher frequency of certain common

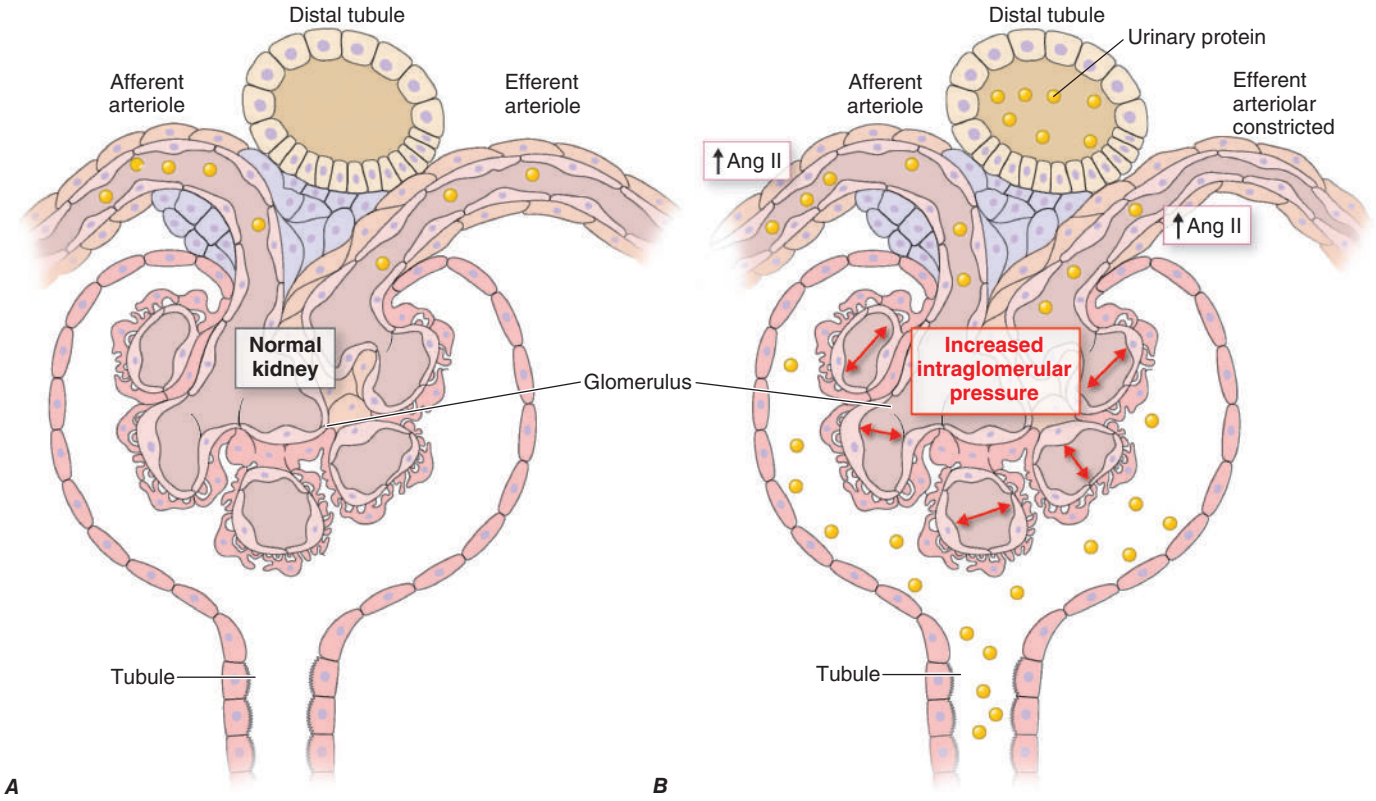

FIGURE 322-2 Schematic representation of the effect of intraglomerular hypertension on nephron survival.

etiologies of nondiabetic CKD (e.g., focal segmental glomerulosclerosis, HIV- and SARS-CoV-2–associated nephropathy, CKD with hypertension, lupus nephritis) observed among African and Hispanic Americans in major regions of continental Africa and the global African diaspora. The prevalence in West African populations seems to have arisen as an evolutionary adaptation conferring protection from tropical pathogens. As in other common diseases with a heritable component, acquired triggers (e.g., increased levels of interferon-γ and other cytokines) can transform genetic risk into disease. In addition to these single-gene loci, recent studies have identified genome-wide patterns of DNA sequence variants that confer increased risk for CKD. These include risk alleles associated with idiopathic IgA and idiopathic membranous glomerulopathy.

Staging of CKD (Fig. 322-1) is based on both GFR and on urinary albumin excretion rate and is key to understanding the emergence of symptoms, for determining the risk and rate of CKD progression and complications, and for determining indications for medical intervention. GFR is estimated (eGFR) rather than directly measured, using equations that include serum creatinine concentration and various other individual patient parameters, in place of timed urine collections, which have proven cumbersome and unreliable. U.S.-based national professional societies have recommended utilizing the equations shown in **Table 322-3**. eGFR determination in CKD is valid only if the patient is in steady state, that is, the serum creatinine is neither rising nor falling over days. The newly recommended equations no longer include a parameter that adjusts for differences in creatinine production based on continental ancestry (race-free eGFR estimation equations). However, in some situations where precise estimation of GFR might affect medication dosing or other individual clinical decisions, it is reasonable to include an estimated adjustment based on various parameters that could modify creatinine production downward (e.g., loss of a limb) or upward (increased muscle mass) or, in some cases, revert to measure timed creatinine production rates or use of the more costly and less widely available marker cystatin-C, which is not affected by variables that influence creatinine production.

The normal annual mean decline in GFR with age from the peak GFR (~120 mL/min per 1.73 m^2) attained during the third decade of life is ~1 mL/min per year per 1.73 m^2, reaching a mean value of 70 mL/min per 1.73 m^2 at age 70, with considerable interindividual variability. Although reduced GFR is expected with aging, the lower GFR signifies a true loss of kidney function with attendant consequences in terms of risk of CKD complications and requirement for dose adjustment of medications. The mean GFR is lower in women than in men, though men are at greater risk for CKD than women. A woman in her eighties with a laboratory report of serum creatinine in the normal range may have a GFR of <50 mL/min per 1.73 m^2. Relatedly, even a mild elevation in serum creatinine concentration often signifies a substantial reduction in GFR in older individuals. It is not entirely clear as yet as to whether advancing age as a risk factor for progressive CKD is independent of such age-related reduction in the measure of eGFR.

Measurement of albuminuria is also helpful for monitoring nephron injury and the response to therapy in many forms of CKD, especially chronic glomerular diseases. The cumbersome 24-h urine collection has been replaced by measurement of urinary albumin-to-creatinine ratio (UACR) in one and preferably several spot first-morning urine samples as a measure pointing to glomerular injury. Even in patients with negative conventional urinary dipstick tests for protein, persistent UACR >2.5 mg/mmol (male) or >3.5 mg/mmol (female) on two to three occasions serves as a marker not only for early detection of primary kidney disease but for systemic microvascular disease as well.

A Kidney Failure Risk (KFR) equation has been devised to predict the risk of progression to stage 5 dialysis-dependent kidney disease. The equation is available on many sites online (for example, *www.kidneyfailurerisk.com*) and uses age, sex, region (North American or non–North American), GFR, and UACR. It has been validated in several cohorts around the world, although the risk for progression appears to be greater in North America, accounting for the regional adjustment in the equation.

Stages 1 and 2 CKD are usually asymptomatic, such that the recognition of CKD occurs more often as a result of laboratory testing in clinical settings other than suspicion of kidney disease. Moreover, in the absence of the risk factors noted above, population-wide screening is not recommended. With progression to CKD stages 3 and 4, clinical and laboratory complications become more prominent. Virtually all organ systems are affected, but the most evident complications include

TABLE 322-1 Risk Factors for Chronic Kidney Disease (CKD)[a]

Noncommunicable Diseases
Diabetes
Increased BMI
Autoinflammatory disease (e.g., lupus, vasculitis, cancer immunotherapy)
Nephrotoxic exposure (including many antineoplastic therapies)
Hypertension (risk, cause, or consequence)
Communicable Diseases
Streptococcal infection
Mycobacterial infection
HIV infection (HIVAN)
SARS-CoV-2
HBV, HCV
Demographic, Anthropomorphic, Ancestry, Geographic
Age
Male sex
Population ancestry
Region-specific CKD risk of uncertain etiology (e.g., Central America, Sri Lanka, and indigenous peoples of Australia and New Zealand)
Family history of kidney disease
Genetic
Monogenic inheritance with (1) high penetrance or (2) low to medium penetrance
Polygenic risk factors
Childhood-Related Risk Factors
Premature and SGA birth
Persistent asymptomatic microscopic hematuria
Childhood kidney disease (even resolved)
Treated childhood cancer
Lifestyle
Tobacco use
Sedentary lifestyle
Other
Prior acute kidney injury
Preeclampsia
Kidney donation (or other acquired nephrectomy)

[a]Not biomarkers.

Abbreviations: BMI, body mass index; HBV, hepatitis B virus; HCV, hepatitis C virus; HIVAN, HIV-associated nephropathy; SGA, small for gestational age.

anemia with easy fatigability; decreased appetite with progressive malnutrition; abnormalities in calcium, phosphorus, and mineral-regulating hormones, such as $1,25(OH)_2D_3$ (calcitriol), parathyroid hormone (PTH), and fibroblast growth factor 23 (FGF-23); and abnormalities in sodium, potassium, water, and acid-base homeostasis. Many patients, especially older individuals, will have eGFR values compatible with stage 2 or 3 CKD. However, the majority of these patients will show no further deterioration of kidney function. In this setting, it is advised to recheck kidney function, and if it is stable and not associated with proteinuria, the patient can usually be followed with interval repeat testing without referral to a nephrologist. If repeat testing shows declining GFR, albuminuria, or uncontrolled hypertension, referral to a nephrologist is appropriate. If the patient progresses to stage 5 CKD (GFR <15 mL/min), toxins accumulate such that patients usually experience a disturbance in their activities of daily living, well-being, nutritional status, and water and electrolyte homeostasis, eventuating in the uremic syndrome.

ETIOLOGY AND EPIDEMIOLOGY

It has been estimated from population data that at least 6% of the adult population in the United States has CKD at stages 1 and 2. An additional 4.5% of the U.S. population is estimated to have stages 3 and 4 CKD. Table 322-4 lists the five most frequent clinical categories of CKD, cumulatively accounting for >90% of the CKD disease burden worldwide. The relative contribution of each category varies among different geographic regions. The most frequent cause of CKD in North America and Europe is diabetic nephropathy, most often secondary to type 2 diabetes mellitus. Patients with newly diagnosed CKD often have hypertension. When no overt evidence for a primary glomerular or tubulointerstitial kidney disease process is present, CKD is frequently attributed to hypertension. However, it is now appreciated that some of these patients may have a subclinical primary glomerulopathy, such as focal segmental or global glomerulosclerosis, and the elevated blood pressure is a consequence of the kidney disease. In other patients, progressive nephrosclerosis and hypertension are the renal correlates of a systemic vascular disease, often also involving large and small vessels elsewhere, such as the heart and brain. This latter combination is especially common in older patients, among whom chronic kidney ischemia as a cause of CKD may be underdiagnosed.

PATHOPHYSIOLOGY AND BIOCHEMISTRY OF UREMIA

Uremia is the syndrome with symptoms, signs, and accompanying disturbances in laboratory measurements that result from reduced kidney

TABLE 322-3 Recommended Equations for Estimation of Glomerular Filtration Rate (GFR) Using Serum Creatinine Concentration (S_{Cr}), Age, Sex, Race, and Body Weight

1. Equation from the Modification of Diet in Renal Disease Study
Estimated GFR (mL/min per 1.73 m^2) = $1.86 \times (S_{Cr})^{-1.154} \times (age)^{-0.203}$
Multiply by 0.742 for women
Multiply by 1.21 for African ancestry (currently under review)
2. CKD-EPI Equation
$GFR = 141 \times \min(S_{Cr}/kappa, 1)^{\alpha} \times \max(S_{Cr}/kappa, 1)^{-1.209} \times 0.993^{Age}$
Multiply by 1.018 for women
Multiply by 1.159 for African ancestry (currently under review)
where S_{Cr} is serum creatinine in mg/dL, kappa is 0.7 for females and 0.9 for males, α is –0.329 for females and –0.411 for males, min indicates the minimum of S_{Cr}/kappa or 1, and max indicates the maximum of S_{Cr}/kappa or 1.

function. Although serum urea and creatinine concentrations rise with reduced excretory capacity of the kidneys, accumulation of these two molecules themselves does not account for the symptoms and signs that characterize the uremic syndrome. Large numbers of solutes that accumulate when GFR declines have been implicated. These include water-soluble, hydrophobic, protein-bound, charged, and uncharged nitrogen-containing nonvolatile products of metabolism. It is thus evident that the serum concentrations of urea and creatinine should be viewed as being readily measured but very incomplete surrogate markers for retained toxins, and monitoring the levels of urea and creatinine in the patient with impaired kidney function represents a vast oversimplification of the uremic state.

The uremic syndrome involves more than renal excretory failure. A host of metabolic and endocrine functions normally performed by the kidneys are also impaired and can result in anemia, malnutrition, and abnormal metabolism of carbohydrates, fats, and proteins. Furthermore, plasma levels of many hormones, including PTH, FGF-23, insulin, glucagon, steroid hormones including vitamin D and sex hormones, and prolactin change with CKD as a result of reduced excretion, decreased degradation, or abnormal regulation. Finally, CKD is associated with increased systemic inflammation. Elevated levels of C-reactive protein are detected along with other acute-phase reactants, whereas levels of so-called negative acute-phase reactants, such as albumin and fetuin, decline. Thus, the inflammation associated with CKD is important in the malnutrition-inflammation-atherosclerosis/calcification syndrome, which contributes in turn to the acceleration of vascular disease and morbidity associated with advanced kidney disease.

In summary, the pathophysiology of the uremic syndrome can be divided into manifestations in three spheres of dysfunction: (1) those consequent to the accumulation of toxins that normally undergo renal excretion; (2) those consequent to the loss of other kidney functions, such as fluid and electrolyte homeostasis and hormone regulation; and (3) progressive systemic inflammation and its vascular and nutritional consequences.

CLINICAL AND LABORATORY MANIFESTATIONS OF CKD AND UREMIA

FLUID, ELECTROLYTE, AND ACID-BASE DISORDERS

Sodium and Water Homeostasis With normal kidney function, excretion of filtered sodium and water matches intake. Many forms of kidney disease disrupt this balance such that dietary intake of sodium exceeds its excretion, leading to sodium retention and attendant extracellular fluid volume (ECFV) expansion. This expansion may contribute to hypertension, which itself can accelerate nephron hyperfiltration and injury. As long as water intake does not exceed the capacity for renal water clearance, the ECFV expansion will be isonatric and the patient will have a normal plasma sodium concentration. Hyponatremia is not commonly seen in CKD patients, but when present, often responds to water restriction. The patient with ECFV expansion should be counseled regarding salt restriction. While the thiazide diuretic chlorthalidone alone has been shown to reduce elevated blood pressure in some patients even with stage 4 CKD, administration of loop diuretics, including furosemide, bumetanide, or torsemide, may be needed to manage sodium accumulation. Resistance to loop diuretics in CKD often mandates use of higher doses than those used in patients with normal GFR. The combination of loop diuretics with metolazone may be helpful. Diuretic resistance with intractable edema and hypertension in advanced CKD may serve as an indication to initiate dialysis.

Rarely, patients with CKD may have impaired renal conservation of sodium and water. When an extrarenal cause for fluid loss, such as gastrointestinal (GI) loss, is present, these patients may be prone to ECFV depletion because of the inability of the failing kidney to reclaim filtered sodium adequately. Any depletion of ECFV, whether due to GI losses, renal sodium loss, or overzealous diuretic therapy, can further compromise kidney function through hypoperfusion, or a "prerenal" state, leading to acute-on-chronic kidney failure. In this setting, holding or adjusting the diuretic dose or rarely even cautious volume repletion with normal saline may return the ECFV to normal and restore renal function to baseline. Many patients are given a "sick day" warning, wherein should they experience volume depletion, for example from vomiting or diarrhea, they are told to not take their diuretics or other antihypertensive medications until they resume eating and drinking normally.

Potassium Homeostasis In CKD, the decline in GFR is not necessarily accompanied by a parallel decline in urinary potassium excretion, which is predominantly mediated by aldosterone-dependent secretion in the distal nephron. Another defense against potassium retention in these patients is augmented potassium excretion in the GI tract. Notwithstanding these two homeostatic responses, hyperkalemia may be precipitated in certain settings. These include increased dietary potassium intake, hemolysis, transfusion of stored red blood cells, and metabolic acidosis. Importantly, a host of medications can inhibit renal potassium excretion and lead to hyperkalemia. The most important medications in this respect include the RAS inhibitors and spironolactone and other potassium-sparing diuretics such as amiloride, eplerenone, and triamterene, as well as the new nonsteroidal mineralocorticoid receptor antagonists. As will be outlined below, several of these are major agents in the medical management armamentarium to slow or prevent progression of CKD. The benefits of the RAS inhibitors in ameliorating hyperfiltration and progression of CKD and mitigating cardiovascular complications very often favor their cautious and judicious use with very close monitoring of plasma potassium concentration. Coadministration of potassium-lowering agents may allow for the use of RAS inhibitors with reduced risk of hyperkalemia. Gratifyingly, the gliflozin diuretics, administrated even in advanced stages of CKD, seem to have counterbalancing effects on kidney potassium handling that result in net preservation of potassium homeostasis.

Certain causes of CKD can be associated with earlier and more severe disruption of potassium secretory mechanisms in the distal nephron, out of proportion to the decline in GFR. These include conditions associated with hyporeninemic hypoaldosteronism, such as diabetes, and renal diseases that preferentially affect the distal nephron, such as obstructive uropathy and sickle cell nephropathy.

Hypokalemia is not common in CKD and usually reflects markedly reduced dietary potassium intake, especially in association with excessive diuretic therapy or concurrent GI losses. The use of potassium supplements and potassium-sparing diuretics may be risky in patients with impaired renal function and needs to be monitored closely.

Metabolic Acidosis Metabolic acidosis is a common disturbance in CKD. The majority of patients can still acidify the urine, but they produce less ammonia and, therefore, cannot excrete the quantity of protons required to maintain acid-base balance in most diets. Hyperkalemia, if present, further depresses ammonia production. The combination of hyperkalemia and hyperchloremic metabolic acidosis is often present, even at earlier stages of CKD, in patients with diabetic nephropathy or in those with predominant tubulointerstitial disease including obstructive uropathy. With further declining GFR, the total urinary net daily acid excretion may be severely limited to <30–40 mmol, and the accumulation of anions of retained organic acids can then lead to an anion-gap metabolic acidosis. Thus, the non-anion-gap metabolic acidosis seen in earlier stages of CKD may be complicated by the addition of an anion-gap metabolic acidosis as CKD progresses. In most patients, the metabolic acidosis is mild; the pH is rarely <7.32

and can usually be corrected with oral sodium bicarbonate supplementation. Studies have suggested that even modest degrees of metabolic acidosis may be associated with the development of protein catabolism and progression of CKD.

TREATMENT

Fluid, Electrolyte, and Acid-Base Disorders

Dietary salt restriction and the use of loop diuretics, occasionally in combination with metolazone, may be needed to maintain euvolemia. Water restriction is indicated only if there is hyponatremia.

Hyperkalemia often responds to dietary restriction of potassium, the use of kaliuretic diuretics, and both avoidance of potassium supplements (including occult sources, such as dietary salt substitutes) and monitoring with dose adjustment, or at times avoidance of potassium-retaining medications, which are often prescribed to slow CKD progression or afford cardioprotection (RAS inhibitors, steroidal or nonsteroidal mineralocorticoid antagonists). Kaliuretic diuretics promote urinary potassium excretion, whereas potassium-binding resins, such as calcium resonium, sodium polystyrene, or the newer agents patiromer and calcium zirconium cyclosilicate, promote potassium loss through the GI tract and may reduce the incidence of hyperkalemia. Intractable hyperkalemia is an indication (although uncommon) to consider institution of dialysis in a CKD patient. The renal tubular acidosis and subsequent anion-gap metabolic acidosis in progressive CKD will respond to alkali supplementation. Recent studies suggest that this replacement should be considered when the serum bicarbonate concentration falls below 20–23 mmol/L to avoid the protein catabolic state seen with even mild degrees of metabolic acidosis. Relatedly, a recent study suggested that bicarbonate supplementation in stages 3–5 CKD was also associated with slower progression to dialysis. The sodium load in sodium bicarbonate supplementation needs to be taken into account when ECFV expansion is present.

DISORDERS OF CALCIUM AND PHOSPHATE METABOLISM

The principal complications of abnormalities of calcium and phosphate metabolism in CKD occur in the skeleton and the vascular bed, with occasional involvement of soft tissues. It is likely that disorders of bone turnover and disorders of vascular and soft tissue calcification are related to each other.

Bone Manifestations of CKD The major disorders of bone disease can be classified into those associated with high bone turnover with increased PTH levels (including osteitis fibrosa cystica, the classic lesion of secondary hyperparathyroidism), osteomalacia due to reduced vitamin D effect, and low bone turnover with low or normal PTH levels (adynamic bone disease) or often some combination of the foregoing.

The pathophysiology of secondary hyperparathyroidism and the consequent high-turnover bone disease is related to abnormal mineral metabolism through the following series of interrelated mechanisms: (1) declining GFR leads to reduced excretion of phosphate and, thus, phosphate retention; (2) the retained phosphate stimulates increased synthesis of both FGF-23 by osteocytes and of PTH and also stimulates growth of parathyroid gland mass; and (3) decreased levels of ionized calcium, which results from decreased levels of renal calcitriol production due to phosphate retention and elevated levels of FGF-23, which also increases degradation of calcitriol. Low calcitriol levels contribute to hyperparathyroidism, both by leading to hypocalcemia and also by a direct effect on PTH gene transcription. In addition, the normal inhibitory effect of FGF-23 on PTH production, which is Klotho-dependent, is also attenuated in CKD. These changes start to occur when the GFR falls below 60 mL/min, though some studies point to retention of phosphate as an event antedating measurable reduction in GFR, together with early elevation of FGF-23 as well. FGF-23 is part of a family of phosphatonins that promotes phosphate excretion, and high levels of FGF-23 are an independent risk factor for left ventricular hypertrophy and are associated with increased mortality in CKD, dialysis, and kidney transplant patients.

Hyperparathyroidism stimulates bone turnover and leads to osteitis fibrosa cystica. Bone histology shows abnormal osteoid, bone and bone marrow fibrosis, and, in advanced stages, the formation of bone cysts, sometimes with hemorrhagic elements so that they appear brown in color; hence, the term *brown tumor*. Clinical manifestations of severe hyperparathyroidism include bone pain and fragility, brown tumors with compression syndromes, and resistance to erythropoiesis-stimulating agents (ESA) in part related to the bone marrow fibrosis. Furthermore, PTH itself is considered a uremic toxin, and high levels are associated with muscle weakness, fibrosis of cardiac muscle, and constitutional symptoms.

Adynamic bone disease is increasing in prevalence, especially among diabetics and older patients. It is characterized by reduced bone volume and mineralization and may result from excessive suppression of PTH production, chronic inflammation, or both. Suppression of PTH can result from the use of vitamin D preparations or from excessive calcium exposure in the form of calcium-containing phosphate binders or high-calcium dialysis solutions.

Complications of adynamic bone disease include an increased incidence of fracture and bone pain and an association with increased vascular and cardiac calcification. Occasionally, the calcium will precipitate in the soft tissues into large concretions termed *tumoral calcinosis* **(Fig. 322-3)**. Patients with adynamic bone disease often experience the most severe symptoms of musculoskeletal pain, owing to the inability to repair the microfractures that occur normally as a part of healthy skeletal homeostasis with regular physical activity. Patients with advanced CKD experience more frequent fractures than their age-matched controls. Osteomalacia is a distinct process, consequent to reduced production and action of $1,25(OH)_2D_3$, leading to accumulation of nonmineralized osteoid.

Calcium, Phosphorus, and the Cardiovascular System There is a strong association between hyperphosphatemia and increased cardiovascular mortality in patients with CKD. Hyperphosphatemia and hypercalcemia are associated with increased vascular calcification, but it is unclear whether the excessive mortality is mediated by this mechanism. Studies using computed tomography (CT) and electron-beam CT scanning show that CKD patients have calcification in the media of coronary arteries and heart valves that appears to be orders of magnitude greater than that in patients without kidney disease. The magnitude of the calcification is proportional to age and hyperphosphatemia and is also associated with low PTH levels and low bone turnover. It is possible, that in CKD patients, ingested calcium cannot be incorporated into bones with low turnover, and therefore, is deposited at

FIGURE 322-3 Tumoral calcinosis. This patient was on hemodialysis for many years and was nonadherent to dietary phosphorus restriction or the use of phosphate binders. He was chronically severely hyperphosphatemic. He developed an enlarging painful mass on his arm that was extensively calcified.

FIGURE 322-4 Calciphylaxis. This peritoneal dialysis patient was on chronic warfarin therapy for atrial fibrillation. She noticed a small painful nodule on the abdomen that was followed by progressive skin necrosis and ulceration of the anterior abdominal wall. She was treated with hyperbaric oxygen, intravenous thiosulfate, and discontinuation of warfarin, with slow resolution of the ulceration.

extraosseous sites, such as the vascular bed and soft tissues. There is a similar association between osteoporosis and vascular calcification in the general population. Finally, hyperphosphatemia can induce a change in gene expression in vascular cells to an osteoblast-like profile, leading to vascular calcification and even ossification.

Other Complications of Abnormal Mineral Metabolism Calciphylaxis is a devastating condition seen almost exclusively in patients with advanced CKD. It is heralded by painful livedo reticularis and subcutaneous nodules that advance to patches of ischemic necrosis, especially on the legs, thighs, abdomen, and breasts **(Fig. 322-4)**. Pathologically, there is evidence of vascular occlusion in association with extensive vascular and soft tissue calcification. It appears that this condition is increasing in incidence. Originally it was ascribed to severe abnormalities in calcium and phosphorus control in dialysis patients, usually associated with advanced hyperparathyroidism. However, more recently, calciphylaxis has been seen with increasing frequency in the absence of severe hyperparathyroidism. Warfarin is still used in some CKD patients in whom several members of the direct oral anticoagulant (DOAC) family of drugs are contraindicated, and one of the effects of warfarin therapy is to decrease the vitamin K–dependent activation of matrix GLA protein. This latter protein is important in preventing vascular calcification. Thus, warfarin treatment is considered a risk factor for calciphylaxis, and if a patient develops this syndrome, this medication should be discontinued and alternative means of anticoagulation should be chosen, depending on the specific underlying indication for anticoagulation.

TREATMENT

Disorders of Calcium and Phosphate Metabolism

The optimal management of secondary hyperparathyroidism and osteitis fibrosa is prevention. Once the parathyroid gland mass is very large, it is difficult to control the disease. Careful attention should be paid to the plasma phosphate concentration in CKD patients, who should be counseled on a low-phosphate diet as well as the appropriate use of phosphate-binding agents, which are taken with meals and complex dietary phosphate to limit its GI absorption. Examples of phosphate binders are calcium acetate and calcium carbonate. A major side effect of calcium-based phosphate binders is calcium accumulation and hypercalcemia, especially in patients with low-turnover bone disease. Sevelamer and lanthanum are non-calcium-containing polymers that also function as phosphate binders; they do not predispose CKD patients to hypercalcemia and may attenuate calcium deposition in the vascular bed. Tenapanor is a sodium-proton inhibitor that decreases GI phosphate absorption and may be useful to manage hyperphosphatemia in CKD and dialysis patients.

Calcitriol exerts a direct suppressive effect on PTH secretion and also indirectly suppresses PTH secretion by raising the concentration of ionized calcium. However, calcitriol therapy may result in hypercalcemia and/or hyperphosphatemia through increased GI absorption of these minerals. Certain analogues of calcitriol are available (e.g., paricalcitol) that suppress PTH secretion with less attendant hypercalcemia.

Recognition of the role of the extracellular calcium-sensing receptor has led to the development of calcimimetic agents that enhance the sensitivity of parathyroid cells to the suppressive effect of calcium. This class of drug, which includes cinacalcet and etelcalcetide, produces a dose-dependent reduction in PTH and plasma calcium concentration in some patients.

Current National Kidney Foundation Kidney Disease Outcomes Quality Initiative guidelines recommend a target PTH level between 2 and 9 times the upper limit of normal, recognizing that very low PTH levels are associated with adynamic bone disease and possible consequences of fracture and ectopic calcification.

For CKD patients requiring anticoagulation, careful assessment of the indication and choice and dosing of medication appropriate for reduced renal clearance, with avoidance of warfarin, should be considered to reduce the risk of calciphylaxis.

CARDIOVASCULAR ABNORMALITIES

Cardiovascular disease is the leading cause of morbidity and mortality in patients at every stage of CKD. The incremental risk of cardiovascular disease in those with CKD compared to the age- and sex-matched general population ranges from 10- to 200-fold, depending on the stage of CKD. As a result, most patients with CKD succumb to cardiovascular disease before ever reaching stage 5 CKD. Between 30 and 45% of those patients who do reach stage 5 CKD have advanced significant cardiovascular complications.

Vascular Disease The increased prevalence of vascular disease in CKD patients derives from both traditional ("classic") and nontraditional (CKD-related) risk factors. Traditional risk factors include hypertension, diabetes mellitus, hypervolemia, dyslipidemia, sympathetic overactivity, and hyperhomocysteinemia. The CKD-related risk factors comprise anemia, hyperphosphatemia, hyperparathyroidism, increased FGF-23, sleep apnea, and systemic inflammation. The inflammatory state appears to accelerate vascular occlusive disease, and low levels of fetuin may permit more rapid vascular calcification, especially in the face of hyperphosphatemia. Other abnormalities seen in CKD may augment myocardial ischemia, including left ventricular hypertrophy and microvascular disease. It is noteworthy that both high and low ejection fraction congestive heart failure, left ventricular hypertrophy, systemic hypertension, and pulmonary hypertension are no less prominent than coronary ischemia as causes of cardiovascular mortality in patients with advanced stages of CKD.

Cardiac troponin levels are frequently elevated in CKD without evidence of acute ischemia. The elevation complicates the diagnosis of acute myocardial infarction in this population. Serial measurements may be needed. Therefore, the trend in levels over the hours after presentation may be more informative than a single, elevated level. Interestingly, consistently elevated levels are an independent prognostic factor for adverse cardiovascular events.

Heart Failure Abnormal cardiac function secondary to myocardial ischemia, left ventricular hypertrophy, diastolic dysfunction, and frank cardiomyopathy, in combination with salt and water retention, often results in heart failure or even pulmonary edema. Heart failure can occur with preserved (diastolic dysfunction) or reduced (systolic dysfunction) ejection fraction. A form of "low-pressure" pulmonary edema can also occur in advanced CKD, manifesting as shortness of breath and a "bat wing" distribution of alveolar edema fluid on chest x-ray. This finding can occur even in the absence of ECFV overload

and is associated with normal or mildly elevated pulmonary venous pressure. This process has been ascribed to increased permeability of alveolar capillary membranes as a manifestation of the uremic state, and it responds to dialysis. Other CKD-related risk factors, including anemia and sleep apnea, may contribute to the risk of heart failure.

Hypertension and left ventricular hypertrophy are common complications of CKD. Hypertension usually develops early during the course of CKD and is associated with adverse outcomes, including the development of ventricular hypertrophy and a more rapid loss of renal function. Left ventricular hypertrophy and dilated cardiomyopathy are among the strongest risk factors for cardiovascular morbidity and mortality in patients with CKD and are thought to be related primarily, but not exclusively, to prolonged hypertension and ECFV overload. In addition, anemia and the placement of an arteriovenous fistula for hemodialysis can generate a high cardiac output state and consequent high-output heart failure.

It is important to note that in advanced stages of CKD, the presence of an advanced malnutrition-inflammation state can actually reverse the elevation of classic cardiovascular risk factors such as hypertension and hyperlipidemia and is associated in such patients with reduced left ventricular function, loss of body weight, and a poor prognosis.

The use of exogenous ESAs can increase blood pressure and the requirement for antihypertensive drugs. Chronic ECFV overload is also a contributor to hypertension, and improvement in blood pressure can often be seen with the use of dietary sodium restriction and diuretics, and when refractory, hypertension can serve as an indication of initiating renal replacement therapy. Nevertheless, because of activation of the RAS and other disturbances in the balance of vasoconstrictors and vasodilators, some patients remain hypertensive, despite careful attention to ECFV status.

TREATMENT

Cardiovascular Abnormalities

MANAGEMENT OF HYPERTENSION

The overarching goal of hypertension therapy in CKD is to prevent the extrarenal complications of high blood pressure, such as cardiovascular disease and stroke. National guideline panels recommend that in CKD patients with diabetes or proteinuria >1 g per 24 h, blood pressure should be reduced to <130/80 mmHg, if achievable without prohibitive adverse effects. Salt restriction should be the first line of therapy. When volume management alone is not sufficient, the choice of antihypertensive agent is similar to that in the general population. Angiotensin-converting enzyme (ACE) inhibitors and angiotensin receptor blockers (ARBs) appear to slow the rate of decline of kidney function in a manner that extends beyond reduction of systemic arterial pressure and that involves reduction in the intraglomerular hyperfiltration and hypertension by disproportionately reducing glomerular efferent arteriolar vasoconstriction. Occasionally, introduction of ACE inhibitors and ARBs can actually precipitate an episode of AKI, especially when used in combination in patients with ischemic renovascular disease.

More commonly, a slight reduction of GFR (<30% of baseline) may actually signify a salutary reduction in intraglomerular hypertension and hyperfiltration and, if stable over time, can be tolerated with continued monitoring. With progressive CKD, RAS inhibitors can be continued with careful monitoring. Careful clinical studies have shown that even in patients with an eGFR <30 mL/min, continuation of these agents was not associated with any signal for harm compared to those in whom the drugs were stopped and that discontinuing RAS inhibitors in CKD was associated with an increased risk of death or cardiovascular events but a lower incidence of starting kidney replacement therapy. Since the use of ACE inhibitors and ARBs may also be complicated by the development of hyperkalemia, the concomitant use of kaliuretic diuretics (e.g., furosemide with metolazone) or a potassium-lowering GI tract binder, such as patiromer, can improve potassium excretion in addition to improving blood pressure control. Likewise, if gliflozins are implemented in renoprotection, then these may also assist in potassium homeostasis. Potassium-sparing diuretics, such as amiloride and triamterene, should be avoided in most patients, and steroidal (e.g., spironolactone) or nonsteroidal (finerenone) mineralocorticoid receptor blockers should be accompanied by careful monitoring of serum potassium concentration, weighing potential cardiovascular and renoprotective benefits against risk for lethal hyperkalemia.

The recent movement to even lower blood pressure targets in the general population may not be applicable to patients with CKD, who often lack autoregulation to maintain GFR in the face of low perfusion pressure. If a patient experiences sudden decline in kidney function with intensification of antihypertensive therapy, consideration should be given to reducing therapy.

MANAGEMENT OF CARDIOVASCULAR DISEASE

There are many strategies available to treat the traditional and nontraditional risk factors in CKD patients. Although these have proved effective in the general population, there is little evidence for their benefit in patients with the most advanced stages of CKD. Certainly, hypertension and dyslipidemia promote atherosclerotic disease and are treatable complications of CKD. Renal disease complicated by nephrotic syndrome is associated with a very atherogenic lipid profile and hypercoagulability, which increases the risk of occlusive vascular disease. Because diabetes mellitus and hypertension are frequently associated with advanced CKD, it is not surprising that cardiovascular disease is the most frequent cause of death in dialysis patients. The use of the gliflozins (sodium-glucose cotransporter 2 [SGLT2] inhibitors) in patients with and without diabetes mellitus is quickly becoming a mainstay for both kidney protection, with marked amelioration of GFR reduction, and a reduction in cardiovascular events, including heart failure, even in advanced stages of CKD (including stage 4).

Pericardial Disease Chest pain with respiratory accentuation, accompanied by a friction rub, is diagnostic of pericarditis. Classic electrocardiographic abnormalities include PR-interval depression and diffuse ST-segment elevation. Pericarditis can be accompanied by pericardial effusion that is seen on echocardiography and can rarely lead to tamponade. However, the pericardial effusion can be asymptomatic, and pericarditis can be seen without significant effusion.

Pericarditis is observed in advanced uremia and, with the advent of timely initiation of dialysis, is not as common as it once was. It is now more often observed in underdialyzed, nonadherent patients than in those starting dialysis.

TREATMENT

Pericardial Disease

Uremic pericarditis is an absolute indication for the urgent initiation of dialysis or for intensification of the dialysis prescription in those already receiving dialysis. Because of the propensity to hemorrhage in pericardial fluid, hemodialysis should be performed without heparin. A pericardial drainage procedure should be considered in patients with recurrent pericardial effusion, especially with echocardiographic signs of impending tamponade. Nonuremic causes of pericarditis and effusion include viral, malignant, tuberculous, and autoimmune etiologies. It may also be seen after myocardial infarction and as a complication of treatment with the antihypertensive drug minoxidil. Consideration could be given to the use of colchicine or nonsteroidal anti-inflammatory drugs, although the latter agents could adversely affect renal function.

HEMATOLOGIC ABNORMALITIES

Anemia A normocytic, normochromic anemia is observed as early as stage 3 CKD and is almost universal by stage 4. The primary cause is insufficient production of erythropoietin (EPO) by the diseased kidneys, together with reduced erythrocyte lifespan and other factors. **(See Table 322-5.)**

TABLE 322-5 Causes of Anemia in Chronic Kidney Disease
Relative deficiency of erythropoietin
Diminished red blood cell survival
Bleeding diathesis
Iron deficiency due to poor dietary absorption and gastrointestinal blood loss
Hyperparathyroidism/bone marrow fibrosis
Chronic inflammation
Folate or vitamin B_{12} deficiency
Hemoglobinopathy
Comorbid conditions: hypo-/hyperthyroidism, pregnancy, HIV-associated disease, autoimmune disease, immunosuppressive drugs

Causes of Anemia in Chronic Kidney Disease The anemia of CKD is associated with a number of adverse pathophysiologic consequences, including decreased tissue oxygen delivery and utilization, increased cardiac output, ventricular dilation, and ventricular hypertrophy. Clinical manifestations include fatigue and diminished exercise tolerance, angina, heart failure, decreased cognition and mental acuity, and impaired host defense against infection. In addition, anemia may play a role in growth restriction in children with CKD. Although many studies in CKD patients have found that anemia and resistance to exogenous ESAs are associated with a poor prognosis, the relative contribution to a poor outcome of the low hematocrit itself, versus inflammation as a cause of the anemia and ESA resistance, remains unclear.

TREATMENT

Anemia

The availability of recombinant human ESA has been one of the most significant advances in the care of renal patients since the introduction of dialysis and renal transplantation. Its routine use has obviated the need for regular blood transfusions in severely anemic CKD patients, thus dramatically reducing the incidence of transfusion-associated infections, iron overload, and the development of alloantibodies that can sensitize patients to donor kidney antigens and render kidney transplantation more problematic.

Adequate bone marrow iron stores should be available before treatment with ESA is initiated. Iron supplementation is usually essential to ensure an optimal response to ESA in patients with CKD because the demand for iron by the marrow frequently exceeds the amount of iron that is immediately available for erythropoiesis (measured by percent transferrin saturation), as well as the amount in iron stores (measured by serum ferritin). For the CKD patient not yet on dialysis or the patient treated with peritoneal dialysis, oral iron supplementation should be attempted. If there is GI intolerance or poor GI absorption, the patient may have to undergo IV iron infusion, keeping in mind that parenteral iron therapy can increase the susceptibility to bacterial infections and that the adverse effects of free serum iron are still under investigation. In addition to iron, an adequate supply of other major substrates and cofactors for red cell production must be ensured, including vitamin B_{12} and folate. Anemia resistant to recommended doses of ESA in the face of adequate iron stores may be due to some combination of the following: acute or chronic inflammation, inadequate dialysis, severe hyperparathyroidism, chronic blood loss or hemolysis, chronic infection, or malignancy.

A new class of agents to treat the anemia of CKD are the prolyl-hydroxylase inhibitors of endogenous hypoxia-inducible factors (HIFs). This inhibition leads to an increase in both endogenous production of EPO and an increase in GI absorption of iron. While studies comparing HIF inhibitors to ESAs have demonstrated similar effectiveness, some safety considerations remain to be clarified in the realms of cardiovascular, retinal vessel, and possibly tumor vasculogenesis.

Randomized, controlled trials of ESAs in CKD have failed to show an improvement in cardiovascular outcomes with this therapy. Indeed, there has been an indication that the use of ESAs in CKD may be associated with an increased risk of stroke in those with type 2 diabetes or an increase in thromboembolic events and perhaps a faster progression of renal decline.

Therefore, any benefit in terms of improvement of anemic symptoms needs to be balanced against such potential cardiovascular risk. Since normalization of the hemoglobin concentration has not been demonstrated to be of benefit to CKD patients, current practice is to target a hemoglobin concentration of 100–115 g/L.

Abnormal Hemostasis Patients with later stages of CKD may have a prolonged bleeding time, decreased activity of platelet factor III, abnormal platelet aggregation and adhesiveness, and impaired prothrombin consumption. Clinical manifestations include an increased tendency to bleeding and bruising, prolonged bleeding from surgical incisions, menorrhagia, and GI bleeding. Interestingly, CKD patients also have a greater susceptibility to thromboembolism, especially if they have renal disease that includes nephrotic-range proteinuria. The latter condition results in hypoalbuminemia and renal loss of anticoagulant factors, which can lead to a thrombophilic state.

TREATMENT

Abnormal Hemostasis

Abnormal bleeding time and coagulopathy in patients with renal failure may be reversed temporarily with desmopressin (DDAVP), cryoprecipitate, IV conjugated estrogens, blood transfusions, and ESA therapy. Rarely with refractory and life-threatening bleeding, tranexamic acid and epsilon aminocaproic acid have also been used for hemostasis control. Optimal dialysis will usually correct a prolonged bleeding time.

Given the coexistence of bleeding disorders and a propensity to thrombosis that is unique in the CKD patient, decisions about anticoagulation that have a favorable risk-benefit profile in the general population may not be applicable to the patient with advanced CKD. One example is warfarin anticoagulation for atrial fibrillation; the decision to anticoagulate should be made on an individual basis in the CKD patient because there appears to be a greater risk of bleeding complications, as well as the consideration of precipitating calciphylaxis.

Certain anticoagulants, such as fractionated low-molecular-weight heparin, may need to be avoided or dose-adjusted in these patients, with monitoring of factor Xa activity where available. It is often more prudent to use conventional unfractionated heparin, titrated to the measured partial thromboplastin time, in hospitalized patients requiring an alternative to warfarin anticoagulation. Most of the new classes of oral anticoagulants are eliminated by the kidneys, although apixaban in either full or reduced dose is being used more often in CKD and dialysis patients **(Chap. 123)**.

NEUROMUSCULAR ABNORMALITIES

Central nervous system (CNS), peripheral, and autonomic neuropathy, as well as abnormalities in muscle structure and function, are all well-recognized complications of CKD. Subtle clinical manifestations of uremic neuromuscular disease usually become evident at stage 3 CKD.

Early manifestations of CNS complications include mild disturbances in memory and disturbances in concentration and sleep. Neuromuscular irritability, including hiccups, cramps, and twitching, becomes evident at later stages. In advanced untreated kidney failure, asterixis, myoclonus, seizures, and coma can be seen.

Peripheral neuropathy usually becomes clinically evident after the patient reaches stage 4 CKD, although electrophysiologic and histologic evidence occurs earlier. Initially, sensory nerves are involved more than motor, lower extremities more than upper, and distal parts of the extremities more than proximal. The "restless leg syndrome" is characterized by ill-defined sensations of sometimes debilitating discomfort in the legs and feet relieved by frequent leg movement. Evidence of peripheral neuropathy without another cause (e.g., diabetes

mellitus or iron deficiency) is an indication for starting renal replacement therapy. Many of the complications described above will resolve with dialysis, although some may persist.

GASTROINTESTINAL AND NUTRITIONAL ABNORMALITIES

Uremic fetor, a urine-like odor on the breath, derives from the breakdown of urea to ammonia in saliva and is often associated with an unpleasant metallic taste (dysgeusia). Gastritis, peptic disease, and mucosal ulcerations at any level of the GI tract occur in uremic patients and can lead to abdominal pain, nausea, vomiting, and GI bleeding. These patients are also prone to constipation, which can be worsened by the administration of calcium and iron supplements. The retention of uremic toxins also leads to anorexia, nausea, and vomiting.

Protein restriction may be useful to decrease nausea and vomiting; however, it may put the patient at risk for malnutrition and should be carried out, if possible, in consultation with a registered dietitian specializing in the management of CKD patients. Weight loss and protein-energy malnutrition, consequences of low protein and caloric intake, are common in advanced CKD and are often an indication for initiation of renal replacement therapy. Metabolic acidosis and the activation of inflammatory cytokines can promote protein catabolism. A number of indices are useful in nutritional assessment and include dietary history, including food diary, and subjective global assessment; edema-free body weight; and measurement of urinary protein nitrogen appearance. Dual-energy x-ray absorptiometry bioimpedance analysis is now widely used to estimate lean body mass versus fluid weight. Nutritional guidelines for patients with CKD are summarized in the "Treatment" section.

ENDOCRINE-METABOLIC DISTURBANCES

Glucose metabolism is impaired in CKD. However, fasting blood glucose is usually normal or only slightly elevated, and mild glucose intolerance does not require specific therapy. Because the kidney contributes to insulin removal from the circulation, plasma levels of insulin are slightly to moderately elevated in most uremic patients, both in the fasting and postprandial states. Because of this diminished renal degradation of insulin, patients on insulin therapy may need progressive reduction in dose as their renal function worsens. Many antihyperglycemic agents, including the gliptins, require dose reduction in renal failure, and some, such as metformin and sulfonylureas, are contraindicated when the GFR is less than half of normal. The gliflozins, discussed above, that inhibit sodium-glucose transport in the proximal tubule result in glucose lowering, accompanied by striking reductions in kidney function decline and in cardiovascular events. The stabilization of GFR in many patients with this therapeutic intervention represents a major, important added beneficial effect of these drugs. Their long-term stabilizing effect on GFR and urine albumin excretion appears to result from correction of hyperfiltration early in type 2 diabetes mellitus via reactivation of the tubuloglomerular feedback loop. This represents a fortunate convergence of pathophysiology of glomerular hyperfiltration in diabetes with drug discovery. A similar effect on hyperfiltration by residual nephrons in certain nondiabetic forms of CKD may explain the salutary role of this class of medications more broadly in CKD. Other studies have also pointed to a more direct effect on proximal tubule metabolic pathways that alleviate cell injury.

In women with CKD, estrogen levels are low, and menstrual abnormalities, infertility, and inability to carry pregnancies to term are common. When the GFR has declined to ~40 mL/min, pregnancy is associated with a high rate of spontaneous abortion, with only ~20% of pregnancies leading to live births, and pregnancy may hasten the progression of the kidney disease itself. Women with CKD who are contemplating pregnancy should consult first with a nephrologist in conjunction with an obstetrician specializing in high-risk pregnancy. Men with CKD have reduced plasma testosterone levels, and sexual dysfunction and oligospermia may supervene. Sexual maturation may be delayed or impaired in adolescent children with CKD, even among those treated with dialysis. Many of these abnormalities improve or reverse with intensive dialysis or with successful renal transplantation.

DERMATOLOGIC ABNORMALITIES

Abnormalities of the skin are prevalent in progressive CKD. Pruritus is quite common and one of the most vexing manifestations of the uremic state. In advanced CKD, even on dialysis, patients may become more pigmented, and this is felt to reflect the deposition of retained pigmented metabolites, or urochromes. Although many of the cutaneous abnormalities improve with dialysis, pruritus is often tenacious. The first lines of management are to rule out unrelated skin disorders, such as scabies, and to treat hyperphosphatemia, which can cause itch. Local moisturizers, mild topical glucocorticoids, oral antihistamines, and ultraviolet radiation have been reported to be helpful. Agonists of kappa opioid receptors can reduce pruritus intensity and improve quality of life.

A skin condition unique to CKD patients called nephrogenic fibrosing dermopathy consists of progressive subcutaneous induration, especially on the arms and legs. The condition is seen very rarely in patients with CKD who have been exposed to the magnetic resonance contrast agent gadolinium. Current recommendations are that patients with CKD stage 3 (GFR 30–59 mL/min) should minimize exposure to gadolinium and those with CKD stages 4–5 (GFR <30 mL/min) should avoid the use of gadolinium agents unless it is medically necessary. However, no patient should be denied an imaging investigation that is critical to management, and under such circumstances, rapid removal of gadolinium by hemodialysis (even in patients not yet receiving renal replacement therapy) shortly after the procedure may mitigate this sometimes devastating complication. Newer forms of gadolinium are not associated with this complication, and it remains to be seen if caution about their use will remain relevant.

EVALUATION AND MANAGEMENT OF PATIENTS WITH CKD

INITIAL APPROACH

History and Physical Examination Symptoms and overt signs of kidney disease are often subtle or absent until renal failure supervenes. Thus, the diagnosis of kidney disease often surprises patients and may lead to denial, especially given that pain in the region of the kidneys and decrease in urinary volume are not clinical features. Particular aspects of the history that are germane to renal disease include a history of hypertension (which can cause CKD or more commonly be a consequence of CKD), diabetes mellitus, abnormal urinalyses, and preeclampsia or early pregnancy loss. A careful drug history should be elicited. Drugs to consider include nonsteroidal anti-inflammatory agents, cyclooxygenase-2 (COX2) inhibitors, antimicrobials, chemotherapeutic agents, antiretroviral agents, proton pump inhibitors, phosphate-containing bowel cathartics, and lithium. In evaluating the uremic syndrome, questions about appetite, weight loss, nausea, hiccups, peripheral edema, muscle cramps, pruritus, and restless legs are especially helpful. A family history of kidney disease, together with assessment of manifestations in other organ systems such as auditory, visual, and integumentary, may lead to the diagnosis of a heritable form of CKD (e.g., Alport's or Fabry's disease, cystinosis) or shared environmental exposure to nephrotoxic agents (e.g., heavy metals, aristolochic acid). It should be noted that clustering of CKD, sometimes of different etiologies, is often observed within families.

The physical examination should focus on blood pressure and target organ damage from hypertension. Fundoscopy is especially important in the diabetic patient, because it may show evidence of diabetic retinopathy, which is associated with diabetic nephropathy. Other manifestations of CKD include edema and sensory polyneuropathy. The finding of asterixis or a pericardial friction rub not attributable to other causes signifies the presence of the uremic syndrome.

Laboratory Investigation Laboratory studies should focus on a search for clues to an underlying causative or aggravating disease process and on the degree of renal damage and its consequences. Serum and urine protein electrophoresis, looking for multiple myeloma, should be obtained in all patients >35 years old with unexplained CKD, especially if there is associated anemia and elevated, or even

inappropriately normal, serum calcium concentration in the face of renal insufficiency. In the presence of hematuria or proteinuria, autoimmune diseases such as lupus and underlying infectious etiologies such as hepatitis B and C and HIV should be tested. Serial measurements of renal function should be obtained to determine the pace of deterioration and ensure that the disease is truly chronic, rather than acute or subacute and hence potentially reversible. Serum concentrations of calcium, phosphorus, and PTH should be measured to evaluate metabolic bone disease. Hemoglobin concentration, iron, vitamin B_{12}, and folate should also be evaluated. A 24-h urine collection may be helpful, because protein excretion >300 mg may be an indication for therapy with ACE inhibitors, ARBs, and SGLT2 inhibitors and also is associated with a higher risk of progression. If the patient has difficulty in carrying out a 24-h urine collection, a random urine albumin/creatinine or protein/creatinine is less accurate than a well-done 24-h collection but less cumbersome.

Imaging Studies The most useful imaging study is a renal ultrasound, which can verify the presence of two kidneys, determine if they are symmetric, provide an estimate of kidney size, and rule out renal masses and evidence of obstruction. Because it takes time for kidneys to shrink as a result of chronic disease, the finding of bilaterally small kidneys supports the diagnosis of CKD of long-standing duration. If the kidney size is normal, it is possible that the kidney disease is acute or subacute. The exceptions are diabetic nephropathy (where kidney size is increased at the onset of diabetic nephropathy before CKD supervenes), amyloidosis, and HIV nephropathy, where kidney size may be normal in the face of CKD. Polycystic kidney disease that has reached some degree of renal failure will almost always present with enlarged kidneys with multiple cysts **(Chap. 327)**. A discrepancy >1 cm in kidney length suggests either a unilateral developmental abnormality or a disease process or renovascular disease with arterial insufficiency affecting one kidney more than the other. The diagnosis of renovascular disease can be undertaken with different techniques, including Doppler sonography, nuclear medicine studies, or CT or magnetic resonance imaging (MRI) studies. If there is a suspicion of reflux nephropathy (recurrent childhood urinary tract infection, asymmetric renal size with scars on the renal poles), a voiding cystogram may be indicated. However, in most cases, by the time the patient has CKD, the reflux has resolved, and even if still present, repair does not improve renal function. Radiographic contrast imaging studies are not particularly helpful in the investigation of CKD. Intravenous or intraarterial dye should be avoided where possible in the CKD patient, especially with diabetic nephropathy, because of the risk of radiographic contrast dye–induced renal failure. When unavoidable, appropriate precautionary measures include avoidance of hypovolemia at the time of contrast exposure, minimization of the dye load, and choice of radiographic contrast preparations with the least nephrotoxic potential. Additional measures thought to attenuate contrast-induced worsening of renal function include judicious administration of sodium bicarbonate–containing solutions and N-acetylcysteine, although these agents may not be as effective as previously thought.

Kidney Biopsy In the patient with bilaterally small kidneys, renal biopsy is not advised because (1) it is technically difficult and has a greater likelihood of causing bleeding and other adverse consequences, (2) there is usually so much scarring that the underlying disease may not be apparent, and (3) the window of opportunity to render disease-specific therapy has passed. Other contraindications to renal biopsy include uncontrolled hypertension, active urinary tract infection, bleeding diathesis (including ongoing anticoagulation), and severe obesity. Ultrasound-guided percutaneous biopsy is the favored approach, but a surgical or laparoscopic approach can be considered, especially in the patient with a single kidney where direct visualization and control of bleeding are crucial. In the CKD patient in whom a kidney biopsy is indicated (e.g., suspicion of a concomitant or superimposed active process or in the face of accelerated loss of GFR), the bleeding time should be measured, and if increased, desmopressin should be administered immediately prior to the procedure.

A brief run of hemodialysis (without heparin) may also be considered prior to renal biopsy to normalize the bleeding time.

ESTABLISHING THE DIAGNOSIS AND ETIOLOGY OF CKD

The most important initial diagnostic step is to distinguish newly diagnosed CKD from acute or subacute renal failure, because the latter two conditions may respond to targeted therapy. Previous measurements of serum creatinine concentration are particularly helpful in this regard. Normal values from recent months or even years suggest that the current extent of renal dysfunction could be more acute, and hence reversible, than might otherwise be appreciated. In contrast, elevated serum creatinine concentration in the past suggests that the renal disease represents a chronic process. Even if there is evidence of chronicity, there is the possibility of a superimposed acute process (e.g., ECFV depletion, urinary infection or obstruction, or nephrotoxin exposure) supervening on the chronic condition. If the history suggests multiple systemic manifestations of recent onset (e.g., fever, polyarthritis, rash), it should be assumed that renal insufficiency is part of an acute systemic illness.

Although kidney biopsy can usually be performed in early CKD (stages 1–3), it is not always indicated. For example, in a patient with a history of type 1 diabetes mellitus for 15–20 years with retinopathy, nephrotic-range proteinuria, and absence of hematuria, the diagnosis of diabetic nephropathy is very likely and biopsy is usually not necessary. However, if there is another finding not typical of diabetic nephropathy, such as hematuria or white blood cell casts, or absence of diabetic retinopathy, some other disease may be present and a biopsy may be indicated.

In the absence of a clinical diagnosis, kidney biopsy may be the only recourse to establish an etiology in early-stage CKD. However, as noted above, once the CKD is advanced and the kidneys are small and scarred, there is little utility and significant risk in attempting to arrive at a specific diagnosis.

Genetic testing is increasingly entering the repertoire of diagnostic tests since the patterns of injury and kidney morphologic abnormalities often reflect overlapping causal mechanisms, whose origins can sometimes be attributed to a genetic predisposition or cause (Table 322-2). The increased application of genetic testing has often yielded surprising diagnoses that deviate from the cause of CKD suggested by clinical or even kidney pathology alone. Given this realization and the cumulative significant contribution of monogenic disease etiologies, consideration is now given to large CKD gene panels, chromosomal microarrays, whole exome or even whole genome sequencing, and other advanced genetic analysis technologies in the evaluation and management of CKD. Suggested indications for such genetic evaluation in patients without a clinically evident etiology and course include family history (family member[s] with unexplained kidney failure, dialysis, or kidney transplant recipient; family member affected with maturity-onset diabetes of the young, kidney disease together with psychiatric morbidity, hearing or vision loss, autism spectrum disorder, developmental delay, and/or intellectual disability; multiple family members affected with similar phenotype); parental consanguinity; extrarenal involvement (dysmorphic facial features, autism spectrum disorder, developmental delay, and/or intellectual disability); multiple congenital structural kidney anomalies; steroid-resistant nephrotic syndrome; persistent active clinical or laboratory manifestations of glomerulonephritis or glomerular endotheliopathy; imaging consistent with cystic kidney diseases/ciliopathies; young adult onset of unexplained progressive CKD; consideration of *APOL1*-mediated kidney disease; and unexplained kidney failure prior to kidney transplantation.

TREATMENT

Chronic Kidney Disease

Therapy for CKD can be divided into interventions that are directed at the specific etiology and those that attenuate progression related to the common pathway of glomerular hyperfiltration, which

perpetuates kidney injury following reduced nephron mass, as discussed below. Treatments aimed at causes of CKD related to systemic diseases are discussed in the respective chapters. Recent developments in the etiology-directed therapy of CKD include the emergence of genome-specific therapies for certain patients with ADPKD **(Chap. 327)**, siRNA therapy (lumasiran) for type 1 hyperoxaluria, and highly specific inhibitors for *APOL1*-mediated kidney disease (AMKD). Inaxaplin, a specific inhibitor of APOL1 channel function, has been shown to decrease urine protein excretion in patients with focal segmental glomerulosclerosis caused by the high-risk genotypes at the *APOL1* gene. In the absence of validated and specific biomarkers of imminent or ongoing kidney injury, the optimal timing for such specific therapies is usually well before there has been a measurable decline in GFR and certainly before CKD is established. It is helpful to measure sequentially and plot the rate of decline of GFR in all patients. Any acceleration in the rate of decline should prompt a search for superimposed acute or subacute processes that may be reversible. These include ECFV depletion, uncontrolled hypertension, urinary tract infection, new obstructive uropathy, exposure to nephrotoxic agents (e.g., nonsteroidal anti-inflammatory drugs [NSAIDs] or radiographic dye), and reactivation or flare of the original disease, such as lupus or vasculitis.

SLOWING THE PROGRESSION OF CKD

There is variation in the rate of decline of GFR among patients with CKD. However, the several established and newer available interventions should be strongly considered in an effort to stabilize or slow the decline of renal function in most patients with reduced nephron mass at risk for progression from increased intraglomerular pressure and hyperfiltration as described above. Fortunately, these very same interventions also reduce cardiovascular complications of CKD and are therefore expected to greatly alleviate the global burden of CKD in the coming years to decades.

Reducing Intraglomerular Hypertension and Proteinuria Increased intraglomerular filtration pressures and glomerular hypertrophy develop as a response to loss of nephron number. This response is maladaptive as it promotes the ongoing decline of kidney function even if the inciting process has been treated or spontaneously resolved. Control of glomerular hypertension is important in slowing the progression of CKD. Moreover, elevated blood pressure increases proteinuria by increasing its flux across the glomerular capillaries. Conversely, the renoprotective effect of antihypertensive medications is gauged through the consequent reduction of proteinuria. Thus, the more effective a given treatment is in lowering protein excretion, the greater is the subsequent impact on protection from decline in GFR. This observation is the basis for the treatment guideline establishing 130/80 mmHg as a target blood pressure in proteinuric CKD patients.

Several controlled studies have shown that ACE inhibitors and ARBs are effective in slowing the progression of renal failure in patients with advanced stages of both diabetic and nondiabetic CKD, in large part through effects on efferent vasodilatation and the subsequent decline in glomerular hypertension. The combination of these two classes should be avoided, due to a demonstrated greater incidence of AKI and adverse cardiac events from such combination therapy. While a nonprogressive decrease in eGFR of up to 30% may be a tolerable reflection of effective unloading of glomerular hyperfiltration, a progressive increase in serum creatinine concentration with these agents may suggest the presence of renovascular disease within the large or small arteries.

Together with efferent arteriolar vasodilation, afferent vasoconstriction should reduce intraglomerular pressure. Indeed, gliflozins, which are a family of inhibitors of SGLT2 transporters in the proximal tubule, result in precisely this glomerular response by activating tubuloglomerular feedback **(Fig. 322-5)** and are indicated in slowing the decline of GFR in both diabetic and nondiabetic kidney disease. Other more direct cellular protective mechanisms of the gliflozins have been invoked in kidney and other tissues. This class of agents also has been demonstrated to reduce major cardiovascular events in CKD patients. Recent studies have also shown that the glucagon-like peptide receptor agonists reduce major cardiovascular events and CKD in at-risk patients.

Among the calcium channel blockers, diltiazem and verapamil may exhibit superior antiproteinuric and renoprotective effects compared to the dihydropyridines. At least two different categories of response can be considered: one in which progression is strongly associated with systemic and intraglomerular hypertension and proteinuria (e.g., diabetic nephropathy, glomerular diseases) and in which ACE inhibitors and ARBs are recommended choices, and another in which proteinuria is mild or absent initially (e.g., ADPKD and other tubulointerstitial diseases), where the contribution of intraglomerular hypertension is less prominent and other antihypertensive agents can be useful for control of systemic hypertension.

MANAGING OTHER COMPLICATIONS OF CKD

Medication Dose Adjustment Although the loading dose of most drugs is not affected by CKD because renal elimination is not used in the calculation, the maintenance doses of many drugs will need to

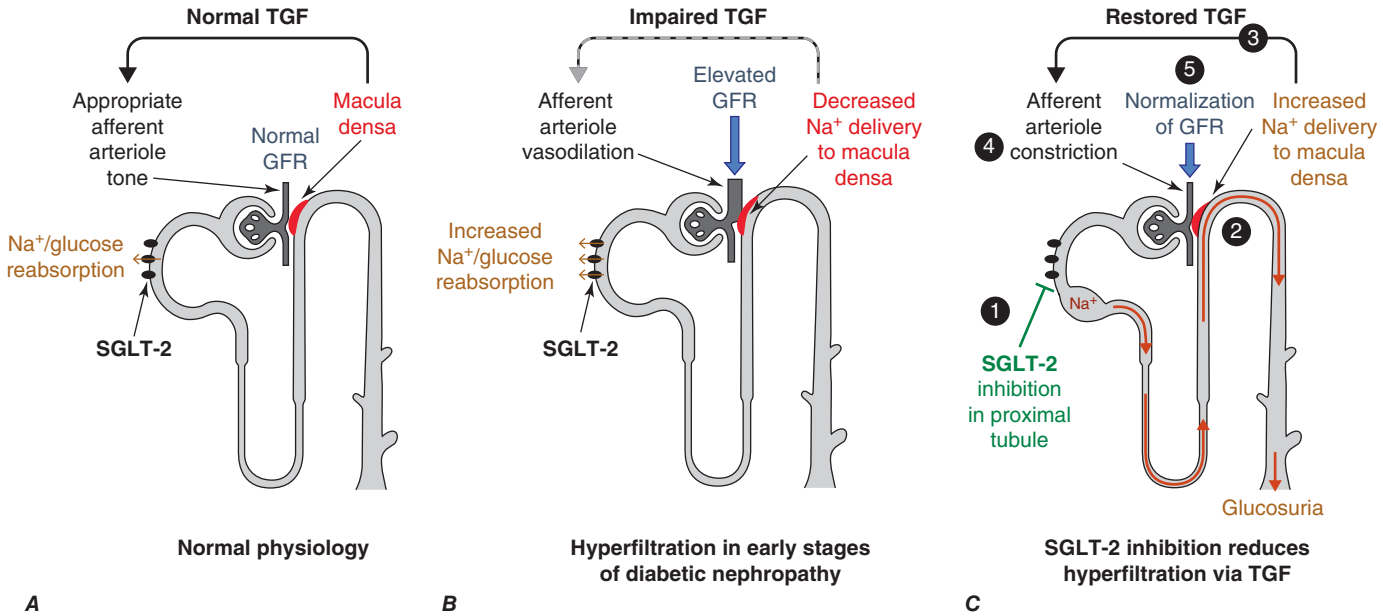

FIGURE 322-5 The postulated role of the gliflozins in generating tubuloglomerular feedback (TGF) to reduce intraglomerular hypertension. *(Reproduced with permission from DZ Cherney et al: Cherney et al: Circulation 129:587, 2014.)*

be adjusted. For those agents in which >70% excretion is by a non-renal route, such as hepatic elimination, dose adjustment may not be needed. Some drugs that should be avoided include metformin, meperidine, and oral antihyperglycemics that are eliminated by the kidney. NSAIDs including COX2 inhibitors should be avoided because of the risk of further worsening of kidney function. Many antibiotics, antihypertensives, and antiarrhythmics may require a reduction in dosage or change in the dose interval. Several online Web-based databases for dose adjustment of medications according to stage of CKD or estimated GFR are available (e.g., *http://www.globalrph.com/index_renal.htm*). Nephrotoxic radiocontrast agents and gadolinium should be used according to strict guidelines when medically necessary, as discussed above.

PREPARATION FOR RENAL REPLACEMENT THERAPY

(See also Chap. 325.) Temporary relief of symptoms and signs of impending uremia, such as anorexia, nausea, vomiting, lassitude, and pruritus, may sometimes be achieved with dietary protein restriction. However, this diet carries a risk of malnutrition; thus, plans for more long-term management should be in place.

Maintenance dialysis and kidney transplantation have extended the lives of hundreds of thousands of patients with CKD worldwide. Clear indications for initiation of renal replacement therapy for patients with CKD include anorexia and nausea not attributable to reversible causes such as peptic ulcer disease, evidence of malnutrition, and fluid and electrolyte abnormalities, principally hyperkalemia or ECFV overload, that are refractory to other measures. Encephalopathy and pericarditis are very late complications, so it is now rare that they serve as indications for initiation of renal replacement therapy.

Recommendations for the Optimal Time for Initiation of Renal Replacement Therapy Because of the individual variability in the severity of uremic symptoms and renal function, it is ill-advised to assign an arbitrary urea nitrogen or creatinine level to the need to start dialysis. Moreover, patients may become accustomed to chronic uremia and deny symptoms, only to find that they feel better with dialysis and realize in retrospect how poorly they were feeling before its initiation.

Previous studies suggested that starting dialysis before the onset of severe symptoms and signs of uremia was associated with prolongation of survival. This led to the concept of "healthy" start and is congruent with the philosophy that it is better to keep patients feeling well rather than allowing them to become ill with uremia and then attempting to return them to better health with dialysis or transplantation. Although recent studies have not confirmed an association of early-start dialysis with improved patient survival, there may be merit in this approach for some patients. At a practical level, advanced preparation may help to avoid problems with the dialysis process itself (e.g., a poorly functioning fistula for hemodialysis or malfunctioning peritoneal dialysis catheter) and, thus, preempt the morbidity associated with resorting to the insertion of temporary hemodialysis access with its attendant risks of sepsis, bleeding, thrombosis, and association with accelerated mortality.

Patient Education Social, psychological, and physical preparation for the transition to renal replacement therapy and the choice of the optimal initial modality are best accomplished with a gradual approach involving a multidisciplinary team. Along with conservative measures discussed in the sections above, it is important to prepare patients with an intensive educational program, explaining the likelihood and timing of initiation of renal replacement therapy and the various forms of therapy available and the option of nondialytic conservative care. The more knowledgeable that patients are about hemodialysis (both in-center and home-based), peritoneal dialysis, and kidney transplantation, the easier and more appropriate will be their decisions. Patients who are provided with education are more likely to choose home-based dialysis therapy. This approach is of societal benefit because home-based therapy is less expensive in most jurisdictions and is associated with improved quality of life. The educational programs should be commenced no later than stage 4 CKD so that the patient has sufficient time and cognitive function to learn the important concepts, make informed choices, and implement preparatory measures for renal replacement therapy.

Exploration of social support is also important. Early education of family members for selection and preparation of a home dialysis helper or a biologically or emotionally related potential living kidney donor should occur long before the onset of symptomatic renal failure.

Kidney transplantation **(Chap. 325)** offers the best potential for complete rehabilitation because dialysis replaces only a small fraction of the kidneys' filtration function and none of the other renal functions, including endocrine and anti-inflammatory effects. Generally, kidney transplantation follows a period of dialysis treatment, although preemptive kidney transplantation (usually from a living donor) can be carried out if it is certain that the renal failure is irreversible and, under such circumstances, is preferred to transplanting after a period of dialysis.

IMPLICATIONS FOR GLOBAL HEALTH

In contrast to the natural decline and successful eradication of many devastating infectious diseases, there is rapid growth in the prevalence of metabolic and vascular disease in developing countries. Diabetes mellitus is becoming increasingly prevalent in these countries, perhaps due in part to change in dietary habits, diminished physical activity, and weight gain. Therefore, it follows that there will be a proportionate increase in vascular and renal disease. According to a recent analysis, in the absence of effective implementation of significant preventive and therapeutic inroads, a forecasting analysis for the U.S. population suggests that the number of global years of life lost (YLLs) due to CKD is expected to rise from a prior value of ~26 million in 2016 to 52.5 million in 2040, accompanied by a rise in mortality from 1.2 million in 2016 to 3.1 million in 2040. These increases are predicted to move CKD in the YLL rankings from 16th in 2016 to 5th in 2040. This rise will be disproportionately large in many other regions of the world where CKD prevalence is already rising at alarming rates due to population aging and the rapid increase in diabetes, hypertension, and obesity.

Health care agencies must plan for improved screening of high-risk individuals for early detection, prevention, and treatment plans in these nations and must start considering options for improved availability of renal replacement therapies.

There is also increasing recognition of endemic nephropathies in developing countries that particularly target young males working in agriculture. The extent of morbidity and mortality associated with these nephropathies is only starting to be appreciated. It is unclear what the cause is, but population genetic risk, endemic nephrotoxins, exposure to pesticides, NSAID use, and chronic volume depletion have all been suggested to contribute. Global warming and air pollution have also been implicated in the development of kidney diseases.

323 Dialysis in the Treatment of Kidney Failure

Kathleen D. Liu, Glenn M. Chertow

Dialysis may be required for the treatment of either acute or chronic kidney disease (CKD). The use of continuous renal replacement therapies (CRRTs) and prolonged intermittent renal replacement therapy (PIRRT)/slow low-efficiency dialysis (SLED) is specific to the management of acute kidney injury/acute kidney disease and is discussed in **Chap. 321**. These modalities are performed continuously (CRRT) or over 6–12 h per session (PIRRT/SLED), in contrast to the 3–4 h of an intermittent hemodialysis session. Advantages and disadvantages of CRRT and PIRRT/SLED are discussed in **Chap. 321**.

Peritoneal dialysis is rarely used in developed countries for the treatment of acute kidney injury/acute kidney disease because of the increased risk of infection and (as will be discussed in more detail below) less efficient clearance per unit of time. The focus of this chapter will be on the use of peritoneal and hemodialysis for end-stage kidney disease (ESKD).

With the widespread availability of dialysis, the lives of hundreds of thousands of patients with ESKD have been prolonged. In the United States alone, there are now >800,000 patients with treated ESKD (kidney failure requiring dialysis or transplantation), the vast majority of whom require dialysis. Since 2000, the prevalence of treated ESKD has increased 65%, which predominantly reflects enhanced survival of patients receiving dialysis. The crude incidence rate for treated ESKD in the United States is 363 cases per million population per year; this incidence has slowly fallen over time. ESKD is disproportionately higher in African Americans as compared with white Americans. In the United States, the leading cause of ESKD is diabetes mellitus, currently accounting for ~45% of newly diagnosed cases of ESKD. Approximately 30% of patients have ESKD that has been attributed to hypertension, although it is unclear whether in these cases hypertension is the cause or a consequence of vascular disease or other unknown causes of kidney failure. Other prevalent causes of ESKD include glomerulonephritis, polycystic kidney disease, and obstructive uropathy. A fraction of the excess incidence of ESKD in African Americans is likely related to transmission of high-risk alleles for the *APOL1* gene.

Globally, mortality rates for patients with ESKD are lowest in Europe and Japan but very high in the developing world because of the limited availability of dialysis. In the United States, the mortality rate of patients on dialysis had decreased somewhat but remained extremely high prior to the COVID-19 pandemic. During the pandemic, there was a significant increase in the mortality of patients receiving hemodialysis or peritoneal dialysis, but we remove the point estimates. Deaths are due mainly to cardiovascular diseases and infections. Older age, male sex, nonblack race, diabetes mellitus, malnutrition, and underlying heart disease are important predictors of death.

TREATMENT OPTIONS FOR PATIENTS WITH ESKD

Commonly accepted criteria for initiating patients on maintenance dialysis include the presence of uremic symptoms, the presence of hyperkalemia unresponsive to conservative measures, persistent extracellular volume expansion despite diuretic therapy, acidosis refractory to medical therapy, a bleeding diathesis, and a creatinine clearance or estimated glomerular filtration rate (GFR) <10 mL/min per 1.73 m^2, although we should emphasize that there is no absolute level of serum creatinine, cystatin C, blood urea nitrogen (BUN), or estimated GFR that should be considered an absolute indication (see **Chap. 322** for estimating equations). Timely referral to a nephrologist for advanced planning and creation of a dialysis access, education about ESKD treatment options, and management of the complications of advanced CKD, including hypertension, anemia, metabolic acidosis, and disorders of bone and mineral metabolism, including secondary hyperparathyroidism, is advisable. Recent data have suggested that a sizable fraction of ESKD cases result following episodes of acute kidney injury, particularly among persons with underlying CKD. Furthermore, there is no benefit to initiating dialysis preemptively at a GFR of 10–14 mL/min per 1.73 m^2 compared to initiating dialysis for symptoms of uremia.

In ESKD, treatment options include hemodialysis (in a center or at home); peritoneal dialysis, as either continuous ambulatory peritoneal dialysis (CAPD) or continuous cyclic peritoneal dialysis (CCPD); or transplantation **(Chap. 325)**. Although there are significant geographic variations and differences in practice patterns, in-center hemodialysis remains the most common therapeutic modality for ESKD (>80% of patients) in the United States. In contrast to hemodialysis, peritoneal dialysis is continuous, but much less efficient in terms of solute clearance. While no large-scale clinical trials have been completed comparing outcomes among patients randomized to either hemodialysis or peritoneal dialysis, outcomes associated with both therapies are similar in most reports, and the decision of which modality to select is often based on personal preferences and quality-of-life considerations.

HEMODIALYSIS

Hemodialysis relies on the principles of solute diffusion across a semipermeable membrane. Movement of by-products of metabolism (often referred to as "waste products" or "toxins"—terms that may understandably create anxiety in patients) takes place down a concentration gradient from the circulation into the dialysate. The rate of diffusive transport increases in response to several factors, including the magnitude of the concentration gradient, the membrane surface area, and the mass transfer coefficient of the membrane. The latter is a function of the porosity and thickness of the membrane, the size of the solute molecule, and the conditions of flow on the two sides of the membrane. According to laws of diffusion, the larger the molecule, the slower is its rate of transfer across the membrane. A small molecule, such as urea (60 Da), undergoes substantial clearance, whereas a larger molecule, such as creatinine (113 Da), is cleared less efficiently. In addition to diffusive clearance, movement of waste products from the circulation into the dialysate may occur as a result of ultrafiltration. Convective clearance occurs because of solvent drag, with solutes being swept along with water across the semipermeable dialysis membrane.

THE DIALYZER

There are three essential components to hemodialysis: the dialyzer, the composition and delivery of the dialysate, and the blood delivery system **(Fig. 323-1)**. The dialyzer is a plastic chamber with the ability to perfuse blood and dialysate compartments simultaneously at very high flow rates. The hollow-fiber dialyzer is the most common in use in the United States. These dialyzers are composed of bundles of capillary tubes through which blood circulates while dialysate travels on the outside of the fiber bundle. Virtually all dialyzers now manufactured in the United States are "biocompatible" synthetic membranes derived from polysulfone or related compounds (versus older cellulose "bioincompatible" membranes that activated the complement cascade). The frequency of reprocessing and reuse of hemodialyzers and blood lines varies across the world. In general, as the cost of disposable supplies has decreased, the use of single-use dialyzers has increased. In the United States, reprocessing of dialyzers is now extremely rare. Formaldehyde, peracetic acid–hydrogen peroxide, glutaraldehyde, and bleach have all been used as reprocessing agents.

DIALYSATE

The potassium concentration of dialysate may be varied from 0–4 mmol/L depending on the predialysis serum potassium concentration. The use of 0- or 1-mmol/L potassium dialysate is becoming much less common owing to data suggesting that patients who undergo treatments with very low potassium dialysate have an increased risk of sudden death, perhaps due to arrhythmias in the setting of potassium shifts. The usual dialysate calcium concentration is 1.25 mmol/L (2.5 mEq/L), although modification may be required in selected settings (e.g., higher dialysate calcium concentrations may be used in patients with hypocalcemia

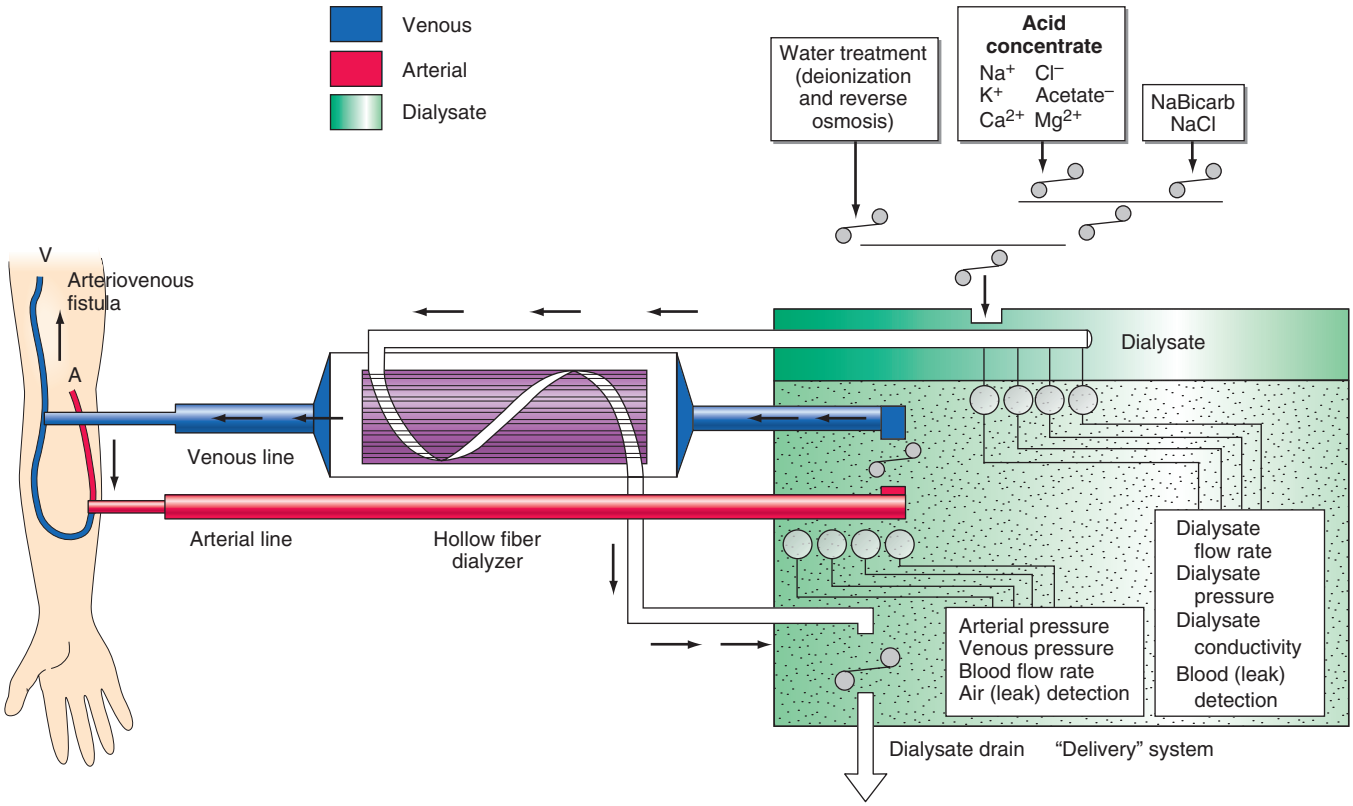

FIGURE 323-1 Schema for hemodialysis.

associated with secondary hyperparathyroidism or with "hungry bone syndrome" following parathyroidectomy). The usual dialysate sodium concentration is 135–140 mmol/L. In patients who frequently develop hypotension during their dialysis run, "sodium modeling" to counterbalance urea-related osmolar gradients may be employed. With sodium modeling, the dialysate sodium concentration is gradually lowered from the range of 145–155 mmol/L to isotonic concentrations (135–140 mmol/L) near the end of the dialysis treatment, typically declining either in steps or in a linear or exponential fashion. However, higher dialysate sodium concentrations and sodium modeling may predispose patients to positive sodium balance and increased thirst; thus, these strategies to ameliorate intradialytic hypotension may be undesirable in patients with hypertension or in patients with large interdialytic weight gains. Because patients are exposed to ~120 L of water during each dialysis treatment, water used for the dialysate is subjected to filtration, softening, deionization, and, ultimately, reverse osmosis to remove microbiologic contaminants and dissolved ions.

BLOOD DELIVERY SYSTEM

The blood delivery system is composed of the extracorporeal circuit and the dialysis access. The dialysis machine consists of a blood pump, dialysis solution delivery system, and various safety monitors. The blood pump moves blood from the access site, through the dialyzer, and back to the patient. The blood flow rate typically ranges from 250–450 mL/min, depending on the type and integrity of the vascular access and needle gauge. Negative hydrostatic pressure on the dialysate side can be manipulated to achieve desirable fluid removal or *ultrafiltration*. Dialysis membranes have different ultrafiltration coefficients (i.e., mL removed/min per mmHg) so that along with hydrostatic changes, fluid removal can be varied. The dialysis solution delivery system dilutes the concentrated dialysate with water and monitors the temperature, conductivity, and flow of dialysate.

DIALYSIS ACCESS

The fistula, graft, or catheter through which blood is obtained for hemodialysis is often referred to as a *hemodialysis (or vascular) access*. A native fistula created by the anastomosis of an artery to a vein (e.g., the Brescia-Cimino fistula, in which the cephalic vein at the wrist is anastomosed end-to-side to the radial artery) results in arterialization of the vein. This facilitates its subsequent use in the placement of large needles (typically 15 or 16 gauge) to access the circulation. Fistulas have the highest long-term patency rate of all hemodialysis access options. For patients in whom fistulas fail to mature or in patients whose vasculature does not allow creation of a successful fistula (i.e., poor arterial inflow or recipient veins of inadequate caliber), patients undergo placement of an arteriovenous graft (i.e., the interposition of prosthetic material, usually polytetrafluoroethylene, between an artery and a vein) or a tunneled hemodialysis catheter. Nephrologists, vascular surgeons, and health care policymakers in the United States have encouraged creation of arteriovenous fistulas in a larger fraction of patients (the "fistula first" initiative). Unfortunately, even when created, arteriovenous fistulas may not mature sufficiently to provide reliable access to the circulation, or they may thrombose early in their development.

The most important complication of arteriovenous grafts is thrombosis of the graft and graft failure, due principally to intimal hyperplasia at the anastomosis between the graft and recipient vein. When grafts (or fistulas) fail, catheter-guided angioplasty can be used to dilate stenoses; monitoring of venous pressures on dialysis and of access flow, although not universally performed, may assist in the early recognition of impending vascular access failure. In addition to increased rates of access failure, grafts and (in particular) catheters are associated with much higher rates of infection than fistulas.

Intravenous large-bore catheters are often used in patients with acute renal failure and CKD. For persons on maintenance hemodialysis, tunneled catheters (either two separate catheters or a single catheter with two lumens) are often used when arteriovenous fistulas and grafts have failed or are not feasible due to anatomic considerations. These catheters are tunneled under the skin; the tunnel reduces bacterial translocation from the skin, resulting in a lower infection rate than with nontunneled temporary catheters. Most tunneled catheters are placed in the internal jugular veins; the external jugular, femoral, and subclavian veins may also be used. Infection, venous thrombosis, and venous stenosis resulting in swelling of the extremity or superior vena cava syndrome are complications best avoided by limiting the time during which catheters are employed.

Nephrologists, interventional radiologists, and vascular surgeons generally prefer to avoid placement of catheters into the subclavian

veins; while flow rates are usually excellent, subclavian stenosis is a frequent complication and, if present, will likely prohibit permanent vascular access (i.e., a fistula or graft) in the ipsilateral extremity. Infection rates may be higher with femoral catheters. For patients with multiple vascular access complications and no other options for permanent vascular access, tunneled catheters may be the last "lifeline" for hemodialysis. Translumbar or transhepatic approaches into the inferior vena cava may be required if the superior vena cava or other central veins draining the upper extremities are stenosed or thrombosed.

GOALS OF DIALYSIS

The hemodialysis procedure consists of pumping heparinized blood through the dialyzer at a flow rate of 250–450 mL/min, while dialysate flows in an opposite *counter-current* direction at 500–800 mL/min. The efficiency of dialysis is determined by blood and dialysate flow through the dialyzer as well as dialyzer characteristics (i.e., its efficiency in removing solute). The *dose* of dialysis, which is currently defined as a derivation of the fractional urea clearance during a single treatment, is further governed by patient size (in particular, the total body water or urea volume of distribution, which resides to large extent in the skeletal muscle), residual kidney function, dietary protein intake, the degree of anabolism or catabolism, and the presence of comorbid conditions, including, in particular, heart failure.

Since the landmark studies of Sargent and Gotch relating the measurement of the dose of dialysis using urea concentrations with morbidity in the National Cooperative Dialysis Study, the *delivered* dose of dialysis has been measured and considered as a quality assurance and improvement tool. While the fractional removal of urea nitrogen and derivations thereof are considered to be the standard methods by which "adequacy of dialysis" is measured, a large multicenter randomized clinical trial (the HEMO study) failed to show a difference in mortality associated with a large difference in per-session urea clearance. Current targets include a urea reduction ratio (the fractional reduction in blood urea nitrogen per hemodialysis session) of >65–70% and a total body water–indexed clearance × time product (Kt/V) >1.2 or 1.05, depending on whether urea concentrations are "equilibrated." For the majority of patients with ESKD, 9–12 h of dialysis are required each week, usually divided into three equal sessions. Several studies have suggested that longer hemodialysis session lengths may be beneficial (independent of urea clearance), although these studies are confounded by a variety of patient characteristics, including body size and nutritional status. Hemodialysis "dose" should be individualized, and factors other than the urea nitrogen should be considered, including the adequacy of ultrafiltration or fluid removal and control of hyperkalemia, hyperphosphatemia, and metabolic acidosis. A randomized clinical trial comparing hemodialysis performed 6 versus 3 times per week (the Frequent Hemodialysis Network Daily Trial) demonstrated improved control of hypertension and hyperphosphatemia, reduced left ventricular mass, and improved self-reported physical health with more frequent hemodialysis. Secondary analyses also demonstrated improvements in other metrics of health-related quality of life, including improved self-reported general health and a reduced "time to recovery" (time until usual activities can be resumed) among patients randomized to more frequent hemodialysis. A companion trial in which frequent nocturnal hemodialysis was compared to conventional hemodialysis at home showed no significant effect on left ventricular mass or self-reported physical health. Finally, an evaluation of the U.S. Renal Data System registry showed a significant increase in mortality and hospitalization for heart failure after the longer interdialytic interval that occurs over the dialysis "weekend."

COMPLICATIONS DURING HEMODIALYSIS

Hypotension is the most common acute complication of hemodialysis, particularly among patients with diabetes mellitus. Numerous factors appear to increase the risk of hypotension, including excessive ultrafiltration with inadequate compensatory vascular filling, impaired vasoactive or autonomic responses, osmolar shifts, overzealous use of antihypertensive agents, and reduced cardiac reserve. Patients with arteriovenous fistulas and grafts may develop high-output cardiac failure due to shunting of blood through the dialysis access; on rare occasions, this may necessitate ligation of the fistula or graft. The management of hypotension during dialysis consists of discontinuing ultrafiltration, the administration of 100–250 mL of isotonic saline, or administration of salt-poor albumin, although the latter is generally unavailable in outpatient settings. Hypotension during dialysis can frequently be prevented by careful evaluation of the dry weight and by ultrafiltration modeling, such that more fluid is removed at the beginning rather than the end of the dialysis procedure. Excessively rapid fluid removal (>13 mL/kg per h) should be avoided, as rapid fluid removal has been associated with adverse outcomes, including cardiovascular deaths. Additional maneuvers to prevent intradialytic hypotension include the performance of sequential ultrafiltration followed by dialysis, cooling of the dialysate during dialysis treatment, and avoiding heavy meals during dialysis. Midodrine, an oral selective α_1 adrenergic agent, has been advocated by some practitioners, although there is insufficient evidence of its safety and efficacy to support its routine use.

Muscle cramps during dialysis are also a common complication. The etiology of dialysis-associated cramps remains obscure. Changes in muscle perfusion because of excessively rapid volume removal or targeted removal below the patient's estimated dry weight often precipitate dialysis-associated cramps. Strategies that may be used to prevent cramps include reducing volume removal during dialysis, ultrafiltration profiling, and the use of sodium modeling (see above).

Anaphylactoid reactions to the dialyzer, particularly on its first use, have been reported, most frequently with the bioincompatible cellulosic-containing membranes, which are rarely used today. Dialyzer reactions can be divided into two types, A and B. Type A reactions are attributed to an IgE-mediated intermediate hypersensitivity reaction to ethylene oxide used in the sterilization of new dialyzers. This reaction typically occurs soon after the initiation of a treatment (within the first few minutes) and can progress to full-blown anaphylaxis. The type B reaction consists of a symptom complex of nonspecific chest and back pain, which appears to result from complement activation and cytokine release. These symptoms typically occur several minutes into the dialysis run and typically resolve over time with continued dialysis.

PERITONEAL DIALYSIS

In peritoneal dialysis, 1.5–3 L of a dextrose-containing solution is infused into the peritoneal cavity and allowed to dwell for a set period of time, usually 2–4 h. As with hemodialysis, metabolic by-products are removed through a combination of convective clearance generated through ultrafiltration and diffusive clearance down a concentration gradient. The clearance of solutes and water during a peritoneal dialysis exchange depends on the balance between the movement of solute and water into the peritoneal cavity versus absorption from the peritoneal cavity. The rate of diffusion diminishes with time and eventually stops when equilibration between plasma and dialysate is reached. Absorption of solutes and water from the peritoneal cavity occurs across the peritoneal membrane into the peritoneal capillary circulation and via peritoneal lymphatics into the lymphatic circulation. The rate of peritoneal solute transport varies from patient to patient and may be altered by the presence of infection (peritonitis), drugs, and physical factors such as position and exercise.

FORMS OF PERITONEAL DIALYSIS

Peritoneal dialysis may be carried out as CAPD, CCPD, or a combination of both. In CAPD, dialysate is manually infused into the peritoneal cavity and exchanged three to five times during the day. A nighttime dwell is frequently instilled at bedtime and remains in the peritoneal cavity through the night. In CCPD, exchanges are performed in an automated fashion, usually at night; the patient is connected to an automated cycler that performs a series of exchange cycles while the patient sleeps. The number of exchange cycles required to optimize peritoneal solute clearance varies by the peritoneal membrane characteristics; as with hemodialysis, solute clearance should be tracked to ensure dialysis "adequacy."

Peritoneal dialysis solutions are available in volumes typically ranging from 1.5–3 L. The major difference between the dialysate used for peritoneal dialysis rather than hemodialysis is that the hypertonicity of peritoneal dialysis solutions drives solute and fluid removal, whereas

solute removal in hemodialysis depends on concentration gradients, and fluid removal requires transmembrane pressure. Typically, dextrose at varying concentrations contributes to the hypertonicity of peritoneal dialysate. In some cases in which patients have developed severe protein-energy malnutrition or have struggled with insufficient ultrafiltration, amino acid–containing peritoneal dialysis solutions have been added to the CAPD or CCPD regimen. Icodextrin is a nonabsorbable carbohydrate that is frequently used in place of dextrose during a single daily exchange. Studies have demonstrated more efficient ultrafiltration with icodextrin than with dextrose-containing solutions. Icodextrin is typically used as the "last fill" for patients on CCPD or for the longest dwell in patients on CAPD. The most common additives to peritoneal dialysis solutions are heparin to prevent obstruction of the dialysis catheter lumen with fibrin and antibiotics during an episode of acute peritonitis. Insulin may also be added in patients with diabetes mellitus.

ACCESS TO THE PERITONEAL CAVITY

Access to the peritoneal cavity is obtained through a peritoneal catheter. Catheters used for maintenance peritoneal dialysis are flexible, being made of silicone rubber with numerous side holes at the distal end. These catheters usually have two Dacron cuffs. The scarring that occurs around the cuffs anchors the catheter and seals it from bacteria tracking from the skin surface into the peritoneal cavity; it also prevents the external leakage of fluid from the peritoneal cavity. The cuffs are placed in the preperitoneal plane and ~2 cm from the skin surface.

The *peritoneal equilibrium test* is a formal evaluation of peritoneal membrane characteristics that measures the transfer rates of creatinine and glucose across the peritoneal membrane. Patients are classified as low, low–average, high–average, and high transporters. Patients with rapid equilibration (i.e., high transporters) tend to absorb more glucose and lose efficiency of ultrafiltration with long daytime dwells. High transporters also tend to lose larger quantities of albumin and other proteins across the peritoneal membrane. In general, patients with rapid transporting characteristics require more frequent, shorter dwell-time exchanges, nearly always obligating use of a cycler. Slower (low and low–average) transporters tend to do well with fewer exchanges. The efficiency of solute clearance also depends on the volume of dialysate infused. Larger volumes allow for greater solute clearance, particularly with CAPD in patients with low and low–average transport characteristics.

As with hemodialysis, the optimal dose of peritoneal dialysis is unknown. Several observational studies have suggested that higher rates of urea and creatinine clearance (the latter generally measured in L/week) are associated with lower mortality rates and fewer uremic complications. However, a randomized clinical trial (Adequacy of Peritoneal Dialysis in Mexico [ADEMEX]) failed to show a significant reduction in mortality or complications with a relatively large increment in urea clearance. In general, patients on peritoneal dialysis do well when they retain residual kidney function. Rates of technique failure increase with years on dialysis and have been correlated with loss of residual function to a greater extent than loss of peritoneal membrane capacity. For some patients in whom CCPD does not provide sufficient solute clearance, a hybrid approach can be adopted where one or more daytime exchanges are added to the CCPD regimen. While this approach can enhance solute clearance and prolong a patient's capacity to remain on peritoneal dialysis, the burden of the hybrid approach can be overwhelming.

COMPLICATIONS DURING PERITONEAL DIALYSIS

The major complications of peritoneal dialysis are peritonitis, catheter-associated nonperitonitis infections, weight gain and other metabolic disturbances, and residual uremia (especially among patients with little or no residual kidney function).

Peritonitis typically develops when there has been a break in sterile technique during one or more of the exchange procedures. Peritonitis is usually defined by an elevated peritoneal fluid leukocyte count ($100/mm^3$, of which at least 50% are polymorphonuclear neutrophils); these cutoffs are lower than in spontaneous bacterial peritonitis because of the presence of dextrose in peritoneal dialysis solutions and rapid bacterial proliferation in this environment without antibiotic therapy. The clinical presentation typically consists of pain and cloudy dialysate, often with fever and other constitutional symptoms. The most common culprit organisms are gram-positive cocci, including *Staphylococcus*, reflecting the origin from the skin. Gram-negative rod infections are less common; fungal and mycobacterial infections can be seen in selected patients, particularly after antibacterial therapy. Most cases of peritonitis can be managed either with intraperitoneal or oral antibiotics, depending on the organism; many patients with peritonitis do not require hospitalization. In cases where peritonitis is due to hydrophilic gram-negative rods (e.g., *Pseudomonas* spp.) or yeast, antimicrobial therapy is usually not sufficient, and catheter removal is required to ensure complete eradication of infection. Nonperitonitis catheter-associated infections (often termed *tunnel infections*) vary widely in severity. Some cases can be managed with local antibiotic or silver nitrate administration, while others are severe enough to require parenteral antibiotic therapy and catheter removal.

Peritoneal dialysis is associated with a variety of metabolic complications. Albumin and other proteins can be lost across the peritoneal membrane in concert with the loss of metabolic wastes. Hypoproteinemia obligates a higher dietary protein intake in order to maintain nitrogen balance. Hyperglycemia and weight gain are also common complications of peritoneal dialysis. Several hundred calories in the form of dextrose are absorbed each day, depending on the concentration of dextrose employed. Patients receiving peritoneal dialysis, particularly those with diabetes mellitus, are prone to other complications of insulin resistance, including hypertriglyceridemia. On the positive side, the continuous nature of peritoneal dialysis usually allows for a more liberal diet due to continuous removal of potassium and phosphorus—two major dietary components whose accumulation can be hazardous in ESKD.

LONG-TERM OUTCOMES IN ESKD

Cardiovascular disease constitutes the major cause of death in patients with ESKD. Cardiovascular mortality and event rates are higher in patients receiving dialysis than in patients posttransplantation, although rates are extraordinarily high in both populations. The underlying cause of cardiovascular disease is unclear but may be related to shared risk factors (e.g., diabetes mellitus, hypertension, atherosclerotic and arteriosclerotic vascular disease), chronic inflammation, massive changes in extracellular volume (especially with high interdialytic weight gains), inadequate treatment of hypertension, dyslipidemia, anemia, dystrophic (vascular) calcification, and, perhaps, alterations in cardiovascular dynamics during the dialysis treatment. Few studies have targeted cardiovascular risk reduction in patients with ESKD; none has demonstrated consistent benefit. Two clinical trials of statin agents in ESKD demonstrated significant reductions in low-density lipoprotein (LDL) cholesterol concentrations but no significant reductions in death or cardiovascular events (Die Deutsche Diabetes Dialyse Studie [4D] and AURORA studies). The Study of Heart and Renal Protection (SHARP), which included patients on dialysis and others with non-dialysis-requiring CKD, showed a 17% reduction in the rate of major cardiovascular events or cardiovascular death with simvastatin-ezetimibe treatment. Most experts recommend conventional cardioprotective strategies (e.g., lipid-lowering agents, aspirin, inhibitors of the renin-angiotensin-aldosterone system, and β-adrenergic antagonists) in patients receiving dialysis based on the patients' cardiovascular risk profile, which appears to be increased by more than an order of magnitude relative to persons unaffected by kidney disease. To date, sodium-glucose cotransporter 2 (SGLT-2) inhibitors and glucagon-like peptide 1 (GLP-1) receptor agonists have not been formally studied in the context of ESKD for cardiovascular risk reduction. Other complications of ESKD include a high incidence of infection, progressive debility and frailty, protein-energy malnutrition, and impaired cognitive function.

GLOBAL PERSPECTIVE

The incidence of ESKD is increasing worldwide with longer life expectancies and improved care of infectious and cardiovascular diseases. The management of ESKD varies widely by country and within

country by region, and it is influenced by economic and other major factors. In general, peritoneal dialysis is more commonly performed in poorer countries owing to its lower expense and the high cost of establishing in-center hemodialysis units.

324 Interventional Nephrology

Dirk M. Hentschel

Interventional nephrology is a procedure-oriented subspecialty with a focus on dialysis access for peritoneal and hemodialysis, typically performed under fluoroscopy. Ultrasound (US) evaluation of dialysis access is common, and some practitioners perform renal and renal artery US evaluation as well as renal biopsies. Endovascular creation of arteriovenous fistulas (AVFs) is a recent addition to the procedural spectrum; (open) surgical access creation by nephrologists is limited to very few centers in the United States, while common in China, Germany, India, and Italy.

Interventional nephrologists (INs) usually provide patient care in multidisciplinary teams that include clinical nephrologists; access surgeons with vascular, transplant, or general surgery background; other interventionalists (with radiology or cardiology training); and dialysis unit access coordinators, nurses, and technicians involved in needle placement. Long-term preservation of venous and arterial vascular access options is one tenet of chronic kidney disease (CKD) care, leading INs to advocate for specific vascular access options (tunneled small-diameter catheters over peripherally inserted central catheters [PICCs]) and cardiac devices (epicardial rather than endovascular lead passage).

HISTORY

The history of vascular access for hemodialysis is closely tied to the history of dialysis. The first hemodialysis treatments in humans were performed in 1924 using glass needles to access the radial artery and return blood into the cubital vein. In 1943, a "rotating drum kidney" was used to dialyze a 29-year-old housemaid with CKD by surgical exposure of different arteries until she ran out of access sites after 12 treatments. The challenge of repetitive vascular access prevented dialysis from becoming a routine method for the treatment of CKD until the development of an arteriovenous Teflon shunt and then the development of an autogenous arterial-venous access (arteriovenous fistula, AVF) by side-to-side-anastomoses between the radial artery and the cephalic vein at the wrist (Cimino fistula). Catheter-based approaches for chronic renal replacement therapy (RRT) were designed initially in 1961 for hemodialysis and in 1968 for peritoneal dialysis, both using Dacron felt cuffs to protect against infection.

Material sciences have continued to evolve the development of grafts for use in hemodialysis. A modified bovine carotid artery biological graft was introduced in 1972, followed by the use of expanded polytetrafluoroethylene (ePTFE) grafts in 1976, and most recently in 2016, tissue-engineered blood vessels from human fibroblasts and endothelial cells. Some ePTFE grafts are modified with a silicone layer to allow for early cannulation within days of insertion. Ultra-high-pressure (up to 40 atm) angioplasty balloons are a mainstay of peripheral and central venous therapy, and Nitinol self-expanding stents and stent grafts serve as rescue tools for unsuccessful angioplasty as well as vessel rupture with extravasation. The role of drug-coated balloons in dialysis access care continues to be assessed, although greater cost and, to date, mixed clinical trial results have limited widespread use.

PHYSIOLOGY AND PATHOPHYSIOLOGY OF DIALYSIS ACCESS

Peritoneal Dialysis Peritoneal dialysis (PD) catheters can be placed fluoroscopically, peritoneoscopically, laparoscopically, and open surgically. Procedural success is typically linked to provider experience and procedural planning to optimize positioning of the PD catheter coil as this improves function and decreases drain pain and other complications. The internal cuff is placed within the rectus sheath just laterally to the linea alba, while the external PD catheter cuff should be located 2–4 cm from the skin exit site. Ingrowth of both cuffs ensures secure positioning of the catheter and allows water emersion. Over time, the peritoneal catheter can become encased in a fibrinous sheath, which, if limiting fluid flow during exchanges, can be disrupted by guidewire manipulation. Omental entrapment of the catheter often requires laparoscopic intervention; omentopexy at the time of PD catheter placement can prevent later entrapment. Repeated infections affect the permeability of the peritoneal membrane, as does long-term exposure to glucose-containing exchange solutions. Encapsulating peritoneal sclerosis is a late-stage complication of PD thought to be triggered by repeated peritonitis.

Hemodialysis Catheters Dialysis catheters are typically made of polyurethane that softens at body temperature but is sufficiently strong to allow for blood flow rates of 400–500 mL/min in each of two channels inside a 14.5–16 French design without collapse of the catheter lumen. Tunneled catheters have a cuff that creates a barrier between skin flora at the exit site and the sterile catheter tunnel leading into the fibrinous sheath covering the catheter from the vessel insertion point to its tip. The fibrinous sheath can extend too far, impeding catheter flow and necessitating exchange of the catheter with disruption of the sheath by balloon angioplasty. Catheter-related bacteremia is best treated with exchange of the catheter and disruption of any fibrinous sheath, although removal of the catheter and delayed reinsertion after several days is also successful. Catheter infection-related sepsis unresponsive to antibiotics requires removal of the catheter. Thrombotic occlusion and later sclerotic scarring of the vein at catheter insertion sites is common, however, and removal of a catheter may lead to loss of this access site. Catheter vessel wall contact points are thought to lead to central vein stenosis, which is more commonly observed in patients with catheter contact times of longer duration (>3 months). Catheter tip position in the large central veins instead of the right atrium causes additional injury from dynamic blood movement during dialysis treatments and should be corrected. A thrombus is commonly found attached to the catheter, often tethering the catheter to the vessel wall and right atrium. While some thrombi are mobile and dissolve with anticoagulation, a wall-tethered thrombus is often well organized

with cellular components and quite resistant to pharmacologic lysis. Clinically significant pulmonary embolism from catheter-associated thrombus is rare, and it may be that only intra-atrial thrombus >2 cm in diameter deserves active intervention.

Arteriovenous Graft and Fistulas During the first decades of hemodialysis for loss of renal function, U.S. patients were relatively young and without long-term systemic vascular disease. Creation of forearm Cimino AVFs was common, and access failure usually led to creation of a second AVF slightly higher up on the arm. As diabetes and hypertension with associated systemic arterial and venous vascular disease became more prevalent in the CKD population, placement of nonautogenous accesses (arteriovenous grafts [AVGs]) increased. In the mid-1990s, 65% of prevalent dialysis patients used an AVG for access. The United States was an international outlier in this regard, and studies associated increased mortality in U.S. dialysis patients with lower AVF prevalence. In the context of "Fistula First" and then "Fistula First, Catheter Last" campaigns, AVG prevalence decreased to its current value of <20%, while AVFs increased to near 65% prevalence. However, most centers still struggle with the challenging conditions of arteries and veins in these patients requiring that 75% of AVFs are now created in the upper arm, where the veins a priori are larger in diameter, and arteries can deliver higher blood flow rates due to large vessel diameter **(see Fig. 324-1)**.

To provide successful dialysis, an AVF or AVG has to provide at least the desired blood pump speed **(Chap. 323)** plus 100–200 mL/min to minimize recirculation and prevent collapse of the access. In the United States, this usually means flow in the 600–800 mL/min range. A fistula created using an artery with ≥2 mm diameter and a vein ≥3 mm will typically have flow volumes >500 mL/min when the systolic blood pressure is >100 mmHg. After creation of the arterial-venous anastomosis (or insertion of the AVG), blood flow increases significantly: brachial artery flow at rest is typically <50 mL/min, but after access creation, flow volume in AVFs increases within weeks to 800 mL/min, while flow volume in AVGs increases within minutes to 1000 mL/min. The increased flow changes the arterial shear stress profile and leads to enlargement of the artery over time. In AVGs, this process is limited by the graft itself, which typically is 6 mm in diameter and 35–40 cm long, and access flows remain in the 1200–1800 mL/min range. The access vein in AVFs in the right shear stress environment enlarges over time, often to >10 mm in diameter in the upper arm such that the artery continues to enlarge until a narrow segment in the venous conduit becomes flow limiting. Flow volumes in these mature upper arm AVFs are usually 1400–1800 mL/min, but after a few years can be as high as 2000–4000 mL/min. Forearm AVFs usually have lower flow volumes (500–700 mL/min) as the feeding radial artery is of smaller diameter and, in the context of systemic vascular disease in the United States, only increases in diameter over many years.

Increased flows and pressure in the venous segment of the access circuit combine to lead to "chronic dialysis access disease" that manifests differently for each type of the common long-term accesses in predetermined segments particularly prone to shear stress and needle insertion–related injury. AVGs develop venous anastomotic stenoses that recur with very short periodicity in the 3- to 4-month range. Stent grafts can effectively be deployed to extend patency for usually 1 year at the site, after which the buildup of pauci-cellular fibrous depositions at the stent edges requires re-angioplasty one to three times per year. Forearm radial-cephalic autogenous accesses of the Cimino type at the wrist are most prone to low flow due to juxta-anastomotic stenoses. Over time, these stenoses can stabilize, and with enlargement of the inflow artery, they effectively provide protection against excessive flows and their sequelae. "Snuff box" radial-cephalic fistulas require minimal mobilization of the cephalic vein with fewer juxta-anastomotic stenoses. However, the additional side branches and associated venous valves may present as stenosis and require ligation to allow cannulation (see below discussion of augmentation). Upper arm brachial-cephalic autogenous accesses typically develop stenoses in the cephalic arch, which recur in accelerated fashion after each angioplasty. Flexible stent grafts in the cephalic arch extend intraprocedural intervals usually to 9–12 months. Upper arm transposed brachial-basilic autogenous accesses develop stenoses in the swing point where the basilic vein is curved during a mobilization procedure to provide a location more lateral and closer to the skin to facilitate needle cannulation. Angioplasty and stent graft placement approaches extend patency. In both types of upper arm accesses, there are often prolonged periods with increased intra-access pressures due to outflow stenoses, which lead to enlargement of needle insertion site aneurysm as the skin heals in a pressurized, stretched state. Continued use of pressurized accesses leads to enlargement of needle sites, then thinning of the skin, scab formation, and, finally, full-thickness ulceration with often significant bleeding events. Recognizing the occurrence of outflow stenoses early

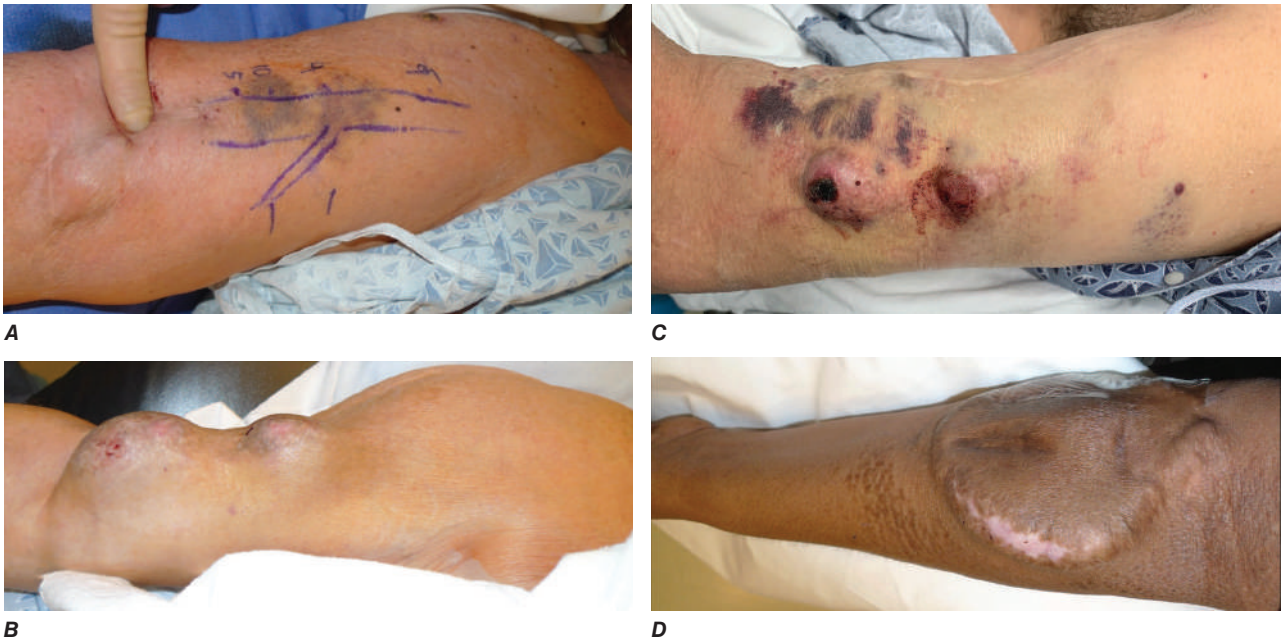

FIGURE 324-1 Dialysis access health depends on intra-access pressures and needle insertions. ***A.*** A right upper arm brachial-cephalic arteriovenous fistula (AVF) with two recurrences of clinically relevant inflow stenosis in 4 years has low-normal intra-access pressure before and after angioplasty; there is only minimal needle insertion site enlargement. ***B.*** In contrast, a right upper arm brachial-cephalic AVF with seven recurrences of cephalic arch outflow stenosis in 4-year cycles between states of high-normal to high intra-access pressures with notable needle insertion site enlargement. ***C.*** Focal needle insertions despite available graft segments led to penetrating skin ulcers over 3 years. ***D.*** Segmental needle rotation preserves skin integrity even after 7 years of arteriovenous graft (AVG) use.

is an important skill for nurses and technologists working in dialysis units to acquire in order to avoid irreversible loss of skin coverage and possible loss of the access.

High-access flow (>1500 mL/min) can lead to systemic complications, such as heart failure and pulmonary hypertension. Fistula inflow higher than outflow capacity leads to accelerated aneurysm formation and breakdown of skin coverage as intra-access pressures are increased over the ideal pressure of 20–35 mmHg. High-access flows are also associated with steal syndrome, typically ischemia of the hand. A variety of procedures have been described to reduce access flows, the most common being "banding," where typically a 2-0 Prolene suture is guided around the inflow and a 3- or 4-mm spacer and is tied snugly over the spacer to create an inflow stenosis.

APPROACH TO THE PATIENT

Physical Examination of Dialysis Access

The 2019 Kidney Disease Outcomes Quality Initiative (KDOQI) vascular access guidelines were developed under the tenet, "[t]he right access for the right patient at the right time." Progression of CKD is highly variable, many patients die from other causes before reaching end-stage renal disease (ESRD), and some AVFs require 6–12 months to mature to usability in patients with hypertension and diabetes, leading to uncertainty as to when to create AVFs. The more common need of upper arm accesses for interventions to maintain patency favors the creation of forearm accesses during the pre-ESRD period. The processes of care from vein mapping, surgery, follow-up visits after access creation, to availability and timing of open surgical or endovascular interventions have profound effects on the overall success rate needed to achieve mature and usable accesses and appear to be key factor in the highly variable outcomes across the United States.

A central skill in dialysis access evaluation is the physical examination. Five steps in the access examination capture all aspects of possible pathology: *Pulsatility* reflects the force of access expansion during systole and the degree of softening during diastole. Very high blood pressures will suggest increased pulsatility, but the access softens remarkably during diastole. An outflow stenosis will lead to increased pulsatility and reduced softening during diastole. An inflow stenosis will blunt the systolic component and create the impression of an "empty" access during diastole unless there is a coexisting outflow stenosis. The audible *flow murmur* can be characterized by pitch and continuity **(Video 324-1)**. A change in pitch toward higher frequency is typical at the site of a stenosis due to accelerated flow velocity at this site. A discontinuous flow murmur indicates that during diastole flow is so low that no audible shear force is created; this is the sign of a severe inflow or outflow stenosis. Typically, the stenotic inflow murmur is faint (like a whistle), whereas the stenotic outflow murmur can be coarse and loud (akin to a handsaw) **(Video 324-2)**. A *thrill* is palpable through the skin when the vessel is close enough to the surface and the flow high enough in relation to the diameter of the vessel to create vibration of the vessel wall. A continuous thrill can be a sign of a well-developed access, usually in the inflow segment, dissipating as the access vessel branches and takes a deeper course. In contrast, a discontinuous thrill is found with severe stenosis. An isolated thrill is also found focally immediately after a stenosis. The differentiation from a "healthy" thrill can be made by documenting a change in pulsatility at the site of the focal thrill, increased retrograde (inflow) and decreased antegrade (outflow). *Augmentation* is the engorgement of the body of the access (where needles are inserted) with occlusion of the outflow necessary for safe and successful needle insertions. An inflow stenosis will impair augmentation, as will side branches and collaterals between the occluding finger/tourniquet and the inflow. The location of side branches can be elucidated by moving the occluding finger closer toward the anastomosis until augmentation is achieved. With several collaterals, this may be a staged phenomenon. *Collapse of the access* with arm elevation (against gravity) is a measure of inflow and outflow capacity match or mismatch. A forearm access typically displays complete collapse, while upper arm accesses typically show only partial collapse. An outflow stenosis or very high inflow will decrease the degree of collapse; banding of an upper arm access or a natural flow-limiting stenosis may lead to complete collapse of an upper arm access.

Enlarged needle insertion sites (and any sites of suspected skin thinning) are best examined while occluding inflow: the completely empty access allows palpation of a firm, layered thrombus inside aneurysms as well as a better appreciation of the thickness of the overlying skin by rolling it between thumb and index finger. The chest wall and neck should be inspected for the presence of skin veins and venous distention, which are associated with central venous stenosis or occlusion, as is ipsilateral arm edema.

PRESERVATION OF VENOUS "REAL ESTATE"

Preserving access is a key care component for the patient with advancing CKD. Approximately 8–10% of this population has the need for cardiac rhythm management devices (CRMDs) that can lead to loss of the upper arm cephalic vein as well as central venous stenoses and occlusions around device leads. Planning for which side a future autogenous access is to be placed and where a CRMD is located is recommended in all cases. CKD patients also have an increased frequency of hospitalizations, some of which require intravenous access beyond the hospital stay for antibiotics, nutritional support, or hydration. Avoiding PICCs in a patient with CKD stage 3 or 3b and higher and, instead, using internal (or external) jugular vein tunneled small-diameter catheters preserves arm veins for long-term access creation. Arterial access points for cardiac procedures should be chosen with AVF creation in mind.

Approach to the dialysis access of patients with a kidney transplant depends on the function of the transplanted kidney, the risk of recurrence of kidney disease in the transplant, the ability to limit access flow over time while maintaining patency, and the potential benefit of the AVF for blood pressure control.

VIDEO 324-1 Flow murmur of an upper arm brachial-cephalic autogenous access (arteriovenous fistula [AVF]) with a juxta-anastomotic stenosis. The sound is discontinuous as the stenosis is severe enough that only during systole is the flow volume high enough to create audible turbulence. There also is a high-pitch component of the murmur due to the high flow velocity during the peak of the flow cycle.

VIDEO 324-2 Flow murmur of an upper arm brachial-cephalic autogenous access (arteriovenous fistula [AVF]) with a juxta-anastomotic stenosis after angioplasty. The sound is now continuous with systolic-diastolic modulation. There is an even pitch, overall lower than the pitch associated with peak flow in the setting of an untreated stenosis.

325 Kidney Transplantation

Jamil R. Azzi, Naoka Murakami, Anil K. Chandraker

Kidney transplantation is the treatment of choice for patients with end-stage kidney disease (ESKD). Worldwide, tens of thousands of kidney transplants have been performed, and >220,000 patients are living with a functioning kidney transplant in the United States today. The first successful kidney transplant was performed in Boston in 1954 between identical twins. The introduction of immunosuppressive therapies such as azathioprine and prednisone in the 1960s established kidney transplantation across nonidentical individuals (allografts). During the 1970s and 1980s, the success rate at the 1-year mark for deceased-donor allografts markedly improved after the introduction of calcineurin inhibitors. Currently, 1-year survival rates for living-donor and deceased-donor allografts are 98 and 93%, respectively, in the United States. However, long-term survival has not improved as much over time, and the average allograft survival time is 19 and 12 years for living-donor and deceased-donor grafts, respectively.

Age-related mortality rates after transplantation are highest in the first year due to the surgical risks: 2% for ages 18–34 years, 3% for ages 35–49 years, and 6.8% for ages ≥50–60 years. Despite this, the actual survival benefit of transplantation compared to chronic dialysis becomes apparent within days to months following transplantation, even after risk adjustments for age, diabetes, and cardiovascular status. While the loss of kidney transplant due to acute rejection is now a rare event, most allografts eventually succumb at varying rates to a chronic process consisting of interstitial fibrosis, tubular atrophy, vasculopathy, and glomerulopathy, the pathogenesis of which in varying degrees is likely a combination of an alloimmune response, drug toxicity, and the result of a variety of other insults. Overall, transplantation results in an improved life expectancy with a higher quality of life compared to patients who remain on dialysis.

RECENT ACTIVITY AND RESULTS

In 2022, >19,000 deceased-donor kidney transplants and approximately 6000 living-donor transplants were performed in the United States, with the ratio of deceased-donor to living-donor transplants remaining stable over the past few years. As the number of patients with ESKD increases, the number of patients on the transplant waitlist also increases. The donor shortage remains a critical challenge; as of 2022, there were nearly 139,000 adult kidney transplant candidates on the waiting list, with 25,000 patients being transplanted yearly. This imbalance is set to worsen over the coming years with the predicted increased rates of kidney failure associated with obesity and diabetes worldwide. In an attempt to increase utilization of marginal kidneys and allocate organs equitably, a new allocation system within the United States was implemented in 2014. The guiding principles of the changes were to offer an opportunity for transplantation to patients who were highly sensitized and, thus, less likely to find a suitable donor, while at the same time allowing patients expected to survive the longest to receive the best-quality deceased donor organs. The Kidney Donor Profile Index (KDPI) score, which ranges from 0 to 100%, was introduced to estimate the potential risk of graft failure after kidney transplant based on 10 donor factors. The lower KDPI values are associated with higher expected posttransplant survival. Hence, the kidneys with a KDPI <20% are allocated to the 20% of the potential recipients with the highest expected posttransplant survival. Kidneys with a KDPI >85% (previously called expanded criteria donor [ECD] kidneys) are directed toward patients who are expected to fare less well on dialysis and would benefit from being transplanted earlier even if it means accepting a lower-quality organ.

In 2021, a new distance-based kidney allocation policy was introduced. Under this policy, deceased-donor kidneys are to be offered first to candidates listed at transplant hospitals within 250 nautical miles of the donor hospitals. While intended to reduce geographic disparities in access to kidney transplantation, this program has resulted in more complex organ sharing, unintended higher kidney discard rates, and increased cold ischemia time. A variety of other means to increase the donor pool and equity have also become more popular. Kidneys from donors after cardiac death (DCD) are now commonly used to overcome the demand for organs, consisting of 30% of total deceased kidney transplants **(Table 325-1)**. Furthermore, with the advancement of the direct-acting antiviral therapies for hepatitis C virus (HCV), transplantation from HCV-positive donors to HCV-positive or -negative recipients has been performed since 2017 in order to increase the donor pool. Now this practice is becoming more common, consisting of 9% of deceased kidney transplants. Recently, the HOPE (Human Immunodeficiency Virus [HIV] Organ Policy Equity) Act authorized organ donation from HIV-positive candidates, and >100 transplants have been performed. As patients with blood group B wait longer for deceased donor offers, eligible B blood type candidates who have low anti-A titer are eligible for an allograft from A blood type donors. This helps improve access and reduce disparities in wait time for minorities, especially for the African-American ESKD population, in whom blood type B is more common than in other ethnicities. Finally, with recent advances in gene editing technology, xenotransplantation is becoming a more realistic endeavor. Using kidneys from genetically engineered pigs, three experimental kidney transplantations into brain-dead recipients were performed in 2022. There are still multiple issues to overcome, including xenoimmunity, transmission of zoonosis, and ethical challenges, but xenotransplantation has the potential to provide an unlimited source of organs.

The overall results of transplantation are presented in **Table 325-2**. At the 1-year mark, allograft survival is higher for living-donor recipients. This is most likely related to less ischemic injury of the transplant organ. The introduction of more effective immunosuppression and more accurate matching between recipients and donors has almost equalized the risk of graft rejection in the majority of patients within the first year. At 5- and 10-year follow-up, however, there remains a steeper decline in survival of those with deceased-donor kidneys.

RECIPIENT EVALUATION

Virtually all patients with ESKD benefit from transplantation with a longer life expectancy and a better quality of life. While the mortality rate after transplantation is highest in the first year due to perioperative complications, recipient evaluation is critical in identifying patients at risk. It involves a multidisciplinary approach that requires thorough medical, surgical, social, and psychosocial evaluations to identify the risk factors that prohibit transplantation or mandate treatment before proceeding, as well as ensuring the appropriate use of limited organs.

There are a few absolute contraindications to kidney transplantation: chronic illness that limits predicted survival for <2 years, active malignancy, active infection, psychosocial issues affecting adherence to the medical care, and active substance abuse. Cardiovascular risk assessment is crucial during both the perioperative and postoperative periods. Patients with ESKD are at higher cardiovascular mortality risk,

TABLE 325-1 Definition of a Non-Heart-Beating Donor (Donation After Cardiac Death[a] [DCD])

I: Brought in dead
II: Unsuccessful resuscitation
III: Awaiting cardiac arrest
IV: Cardiac arrest after brainstem death
V: Cardiac arrest in a hospital patient

[a]Kidneys can be used for transplantation from categories II–V but are commonly only used from categories III and IV. The survival of these kidneys has not been shown to be inferior to that of deceased-donor kidneys.

Note: Kidneys can both have a Kidney Donor Profile Index (KDPI) score >85% and be DCD. High KDPI kidneys have been shown to have a poorer survival, and there is a separate shorter waiting list for those kidneys. They are generally utilized for patients for whom the benefits of being transplanted earlier outweigh the associated risks of using a lower-quality kidney.

TABLE 325-2 Mean Rates of Graft and Patient Survival for Kidneys Transplanted in the United States from 1999 to 2018[a]

	1-YEAR FOLLOW-UP		5-YEAR FOLLOW-UP		10-YEAR FOLLOW-UP	
	GRAFTS, %	PATIENTS, %	GRAFTS, %	PATIENTS, %	GRAFTS, %	PATIENTS, %
Deceased donor	94	95	76	77	54	67
Living donor	98	99	87	87	70	83

[a]All patients transplanted are included, and the follow-up unadjusted survival data from the 1-, 5-, and 10-year periods are presented to show the attrition rates over time within the two types of organ donors.

Source: Data from Summary Tables, 2021 Annual Reports, Scientific Registry of Transplant Recipients.

and thorough cardiovascular evaluation for coronary artery diseases, valvular diseases, and heart failure is critical.

At most centers, there is no official age limit for transplantation, with >20% of waitlisted candidates currently being older than 65. However, overall physical and cognitive function of the candidates needs to be fully assessed. While history of malignancy itself is not a contraindication for kidney transplantation, potential recipients should be treated to ensure cancer-free wait time of 2–5 years depending on the type and stages of malignancy to decrease the risk of cancer recurrence. Latent or indolent infection (HIV, hepatitis B or C, tuberculosis) should be a routine part of the candidate workup. While historically transplant centers considered overt AIDS and active hepatitis absolute contraindications to transplantation because of the high risk of opportunistic infection, with the introduction of potent antiviral regimens, many centers are now transplanting individuals with hepatitis and HIV infection under strict protocols.

One of the few "immunologic" contraindications to transplantation is the presence of preformed antibodies against the donor kidney at the time of the anticipated transplant that can cause hyperacute rejection. Those harmful antibodies include natural antibodies against the ABO blood group antigens and antibodies against human leukocyte antigen (HLA) class I (A, B, C) or class II (DR, DQ, DP) antigens. These antibodies are routinely excluded by proper screening of the candidate's ABO compatibility and direct cytotoxic cross-matching of candidate serum with lymphocytes of the donor. Removal of these antibodies directed at donor tissue through a variety of strategies (desensitization) is now routinely performed with varying levels of success.

TISSUE TYPING AND CLINICAL IMMUNOGENETICS

Matching of HLA major histocompatibility complex antigens **(Chap. 361)** is an important criterion for the selection of donors. Each mammalian species has a single chromosomal region that encodes the major histocompatibility antigens, and this region on the human chromosome 6 codes the HLA genes. HLA is highly polymorphic; therefore, it can be an immunologic target of organ rejection when mismatched between the donor and the recipient. Historically, HLA antigens have been defined by serologic techniques by adding sera of a recipient (potentially containing anti-HLA antibodies) with a "library" of leukocytes with known serotypes. However, currently, molecular typing of HLA by genomic sequencing is almost universally used. Other "minor," non-HLA antigens may also elicit an alloimmune response in addition to the ABH(O) antigens and endothelial antigens that are not expressed on lymphocytes. The number of HLA antigen mismatches in A, B, and DR loci correlates with allograft survival; the more mismatches, the higher is the risk of allograft rejection. Nevertheless, some HLA-identical renal allografts are rejected, often within the first few weeks after transplantation. These observations may represent prior sensitization to non-HLA antigens. Non-HLA minor antigens are relatively weak when initially encountered and are, therefore, suppressible by conventional immunosuppressive therapy. If prior exposure to the antigen and priming of the recipient immune system have occurred, secondary exposure at the time of transplantation may lead to an immune response refractory to treatment. More recently, a genetics study of donor-recipient pairs revealed that non-HLA antigen polymorphisms in the LIMS-1 locus can contribute to the risk of acute rejection; more of these non-HLA antigens are likely to be discovered.

DONOR EVALUATION

LIVING-DONOR EVALUATION

Living kidney donors experience the immediate risk of surgery and the long-term potential risk of developing kidney dysfunction prematurely; thus, the basic principle of "first, do no harm" **(Chap. 12)** is important. Therefore, donor evaluation must take every effort to exclude any medical conditions that may cause morbidity and mortality after kidney donation, such as hypertension, diabetes, and/or proteinuria. Although studies have shown that the risk of ESKD after kidney donation is not greater than that of the general population, donation is associated with a small but significant potential lifetime risk of ESKD (0.3–0.4%; absolute risk increased by 0.2–0.3% compared to that of healthy nondonors). The mechanism of premature renal failure is thought to be due to increased blood flow and hyperfiltration injury in the remaining kidney. There are a few reports of the development of hypertension, proteinuria, and even lesions of focal segmental sclerosis in donors over long-term follow-up. In family members of type 1 diabetics, anti-insulin and anti-islet cell antibodies should be measured, and a glucose tolerance test should be performed. African-American donors have a higher risk of ESKD after donation (in line with their higher risk of kidney failure in general), and the genetic screening for APOL1 risk alleles may be appropriate **(Chap. 326)**. Additionally, as more robust genetic testing becomes available, predonation genetic testing per protocol is being introduced to stratify the risks of kidney donors. From the surgical perspective, selective renal arteriography is essential to reveal any anatomic anomaly and to assess the size imbalance and laterality of donor kidneys. In most cases, donor nephrectomy is performed laparoscopically to minimize the surgical scar and to enhance a faster postsurgical recovery. Lastly, although financial and nonfinancial conflicts of interest between kidney donors and recipients are strictly prohibited, removing financial disincentives is increasingly accepted to reduce barriers toward living donation, and legislative efforts to protect kidney donors are ongoing **(Chap. 12)**.

DECEASED-DONOR EVALUATION

Deceased donors should be free of malignant neoplastic disease, hepatitis, and HIV owing to possible transmission to the recipient, although under certain circumstances, HCV- and HIV-positive organs may be used. Increased risk of graft failure exists when the donor is elderly or has acute kidney injury or when the kidney experiences a prolonged period of ischemia.

In the United States, there is a national system of regulations, allocation support, and outcomes analysis for kidney transplantation called the Organ Procurement Transplant Network. Studies have shown that deceased-donor kidneys can be maintained for up to 48 h on cold pulsatile perfusion or on ice before being used for transplantation. Normothermic perfusion of donated organs has been studied, but it has not been part of clinical care as of yet. Generally, an ischemic time of <24 h is preferred; this approach permits adequate time for typing, cross-matching, transportation, and selection issues to be resolved.

PRESENSITIZATION

The presence of antibodies against donor antigens, either HLA or non-HLA, can be a potential cause of allograft injury after transplantation, and, hence, it is important to perform crossmatching prior to transplantation. For the purposes of crossmatching, donor T lymphocytes, which express class I but not class II HLA, are used as a surrogate target for detection of circulating anti–class I (HLA-A and -B) antibodies

in the recipient. Note that T cells are used as surrogate cells to detect class I HLA as a matter of convenience and this is unrelated to the risk of "T cell–mediated" rejection. A positive cytotoxic crossmatch of recipient serum with donor T lymphocytes indicates the presence of preformed donor-specific anti-HLA class I antibodies and is usually predictive of an acute vasculitic event termed *hyperacute rejection*. This finding represents the only widely accepted absolute immunologic contraindication for kidney transplantation. Recently, an increasing number of tissue-typing laboratories have shifted to a more sensitive flow cytometric crossmatch assay, which detects the presence of anti-HLA IgG antibodies that are not necessarily detected on a cytotoxic crossmatch assay and may not be an absolute contraindication to transplantation. The known sources of sensitization are blood transfusion, a prior transplant, pregnancy, and less commonly, vaccination or infection.

Preformed anti–class II (HLA-DR and -DQ) antibodies against the donor also carry a higher risk of graft loss, particularly in recipients who have suffered early loss of a prior kidney transplant. B lymphocytes (again, used for convenience), which express both class I and class II HLA, are used as a surrogate target in these assays. Some non-HLA antigens restricted in expression to endothelium and monocytes have been described, but their clinical relevance is not well established. A series of minor histocompatibility antigens do not elicit antibodies, and sensitization to these antigens is detectable only by cytotoxic T cells, an assay too cumbersome for routine use. Recent studies revealed the importance of "eplet" matching in antigen recognition. Eplets are short sequences of polymorphic amino acids on the surface of HLA antigens, recognized by HLA antibodies, and can be shared among different HLA antigens. Especially in class II HLA DQ loci, eplet mismatches are shown to be important risk factors for acute rejection.

Desensitization prior to transplantation by reducing the level of anti-donor antibodies utilizing plasmapheresis and/or the administration of pooled immunoglobulin (IV immunoglobulin [IVIG]) has been useful in reducing the risk of hyperacute rejection following transplantation. In addition, kidney paired donation programs where living donor kidneys are swapped so each recipient receives a compatible transplant organ are increasingly popular to transplant presensitized candidates safely.

IMMUNOLOGY OF REJECTION

Both T cell–mediated and antibody-mediated effector mechanisms can play roles in kidney transplant rejection.

T cell–mediated rejection is caused by recipient T lymphocytes that respond to donor HLA antigens expressed within the transplanted organ. CD4+ lymphocytes respond to class II (HLA-DR) incompatibility by proliferating and releasing proinflammatory cytokines that augment the proliferative response of the immune system. CD8+ cytotoxic lymphocytes respond primarily to class I (HLA-A, -B) antigens and mature into cytotoxic effector cells that cause organ damage through direct contact and lysis of donor target cells. Full T-cell activation requires not only T-cell receptor binding to the alloantigens presented by self or donor HLA molecules (known as indirect and direct presentation, respectively) but also engagement of costimulatory molecules such as CD28 on T cells and CD80 and CD86 ligands on antigen-presenting cells **(Fig. 325-1)**. Signaling through both of these pathways induces activation of the kinase activity of calcineurin, which, in turn, activates transcription factors leading to upregulation of multiple genes, including interleukin (IL) 2 and interferon γ. IL-2 signals through the target of rapamycin (TOR) to induce cell proliferation in an autocrine fashion.

Antibody-mediated rejection is caused by circulating antibodies against donor antigens. After transplantation, donor-derived antigens are delivered to the recipient's draining lymph nodes and activate an alloimmune response. A subset of CD4+ T cells called follicular helper T cells (Tfh) are activated and promote differentiation of B cells into antibody-secreting plasma cells. Plasma cells produce donor-targeting antibodies against HLA and non-HLA antigens, which can deposit in allograft kidney and cause injury via complement-dependent and independent mechanisms. C4d deposition in peritubular capillaries and glomerular basement membrane is a footprint of complement activation and is one of the diagnostic criteria of antibody-mediated rejection, together with the presence of circulating donor-specific antibody.

IMMUNOSUPPRESSIVE TREATMENT

Kidney transplant recipients need to take immunosuppressive drugs for life, except identical twins or simultaneous bone marrow–kidney transplant recipients. Currently clinically available immunosuppressive therapies suppress all immune responses nonspecifically, including those to exogenous pathogens (bacteria, viruses, and fungi) and even malignant tumors, and tend to spare memory immune responses. Immunosuppressive agents are divided into induction and maintenance agents. Those currently in clinical use are listed in **Table 325-3**.

INDUCTION THERAPY

Induction therapy is given to most kidney transplant recipients in the United States at the time of transplant to reduce the risk of early acute rejection and to minimize or eliminate the use of either steroids or

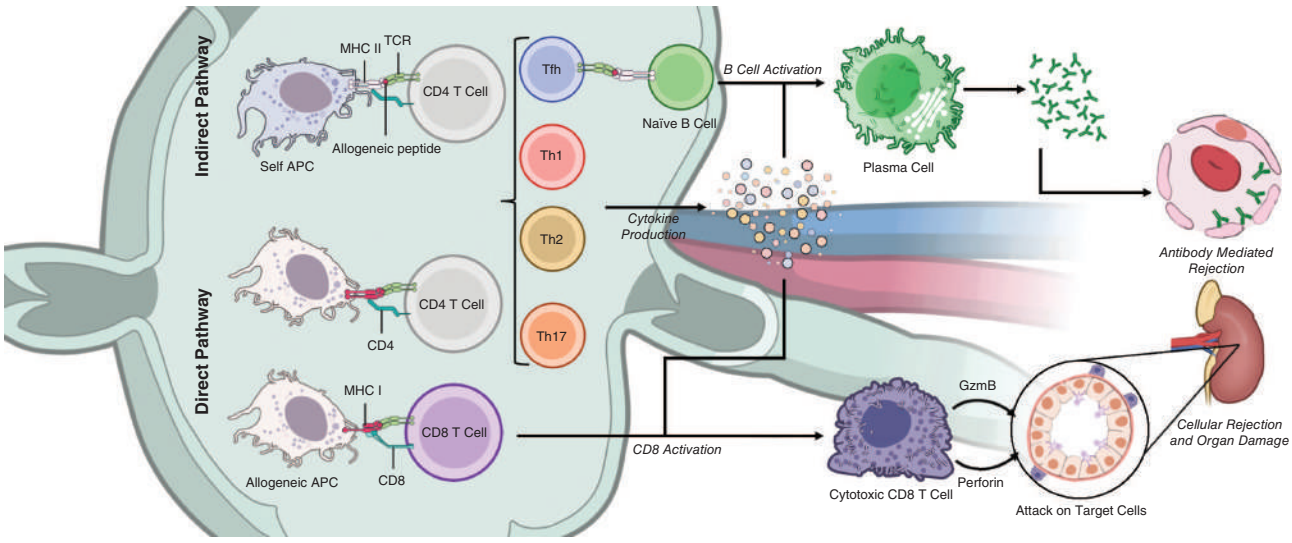

FIGURE 325-1 Recognition pathways for major histocompatibility complex (MHC) antigens. Graft rejection is initiated by CD4 helper T lymphocytes (T_H) having antigen receptors that bind to specific complexes of peptides and MHC class II molecules on antigen-presenting cells (APC). In transplantation, in contrast to other immunologic responses, there are two sets of T-cell clones involved in rejection. In the direct pathway, the class II MHC of donor allogeneic APCs is recognized by CD4 T_H cells that bind to the intact MHC molecule, and class I MHC allogeneic cells are recognized by CD8 T cells. The latter generally proliferate into cytotoxic cells (T_C). In the indirect pathway, the incompatible MHC molecules are processed into peptides that are presented by the self-APCs of the recipient. The indirect, but not the direct, pathway is the normal physiologic process in T-cell recognition of foreign antigens. Once T_H cells are activated, they proliferate and, by secretion of cytokines and direct contact, exert strong helper effects on macrophages, TC, and B cells. *(Courtesy of Andrew Badoui and Nadim Al Rahy.)*

TABLE 325-3 Maintenance Immunosuppressive Drugs

AGENT	PHARMACOLOGY	MECHANISMS	SIDE EFFECTS
Glucocorticoids	Increased bioavailability with hypoalbuminemia and liver disease; prednisone/prednisolone generally used	Binds cytosolic receptors and heat shock proteins. Blocks transcription of IL-1, -2, -3, -6, TNF-α, and IFN-γ	Hypertension, glucose intolerance, dyslipidemia, osteoporosis
Cyclosporine (CsA)	Lipid-soluble polypeptide, variable absorption, microemulsion more predictable	Trimolecular complex with cyclophilin and calcineurin → block in cytokine (e.g., IL-2) production; however, stimulates TGF-β production	Nephrotoxicity, hypertension, dyslipidemia, glucose intolerance, hirsutism/hyperplasia of gums
Tacrolimus	Macrolide, well absorbed	Trimolecular complex with FKBP-12 and calcineurin → block in cytokine (e.g., IL-2) production; may stimulate TGF-β production	Similar to CsA, but hirsutism/hyperplasia of gums unusual, and diabetes more likely
Azathioprine	Mercaptopurine prodrug	Hepatic metabolites inhibit purine synthesis	Marrow suppression (WBC > RBC > platelets)
Mycophenolate mofetil/sodium	Metabolized to mycophenolic acid	Inhibits purine synthesis via inosine monophosphate dehydrogenase	Diarrhea/cramps; dose-related liver and marrow suppression is uncommon
Sirolimus/everolimus	Macrolide, poor oral bioavailability	Complexes with FKBP-12 and then blocks p70 S6 kinase in the IL-2 receptor pathway for proliferation	Hyperlipidemia, thrombocytopenia
Belatacept	Fusion protein, intravenous injections	Binds CD80 and CD86, prevents CD28 binding and T-cell activation	Posttransplant lymphoproliferative disease (PTLD)

Abbreviations: FKBP-12, FK506 binding protein 12; IFN, interferon; IL, interleukin; RBC, red blood cells; TGF, transforming growth factor; TNF, tumor necrosis factor; WBC, white blood cells.

calcineurin inhibitors and their associated toxicities. Induction therapy consists of antibodies that could be depleting or nondepleting.

Depleting Agents Antithymocyte globulin (ATG) is a lymphocyte-depleting agent. Peripheral human lymphocytes, thymocytes, or lymphocytes from spleens or thoracic duct fistulas are injected into horses or rabbits to produce antilymphocyte serum, from which the immunoglobulin fraction is then separated. Those polyclonal antibodies induce lymphocyte depletion, and the immune system may take several months, if not years, to fully recover.

Monoclonal antibodies against defined lymphocyte subsets offer a more precise and standardized form of therapy. Alemtuzumab is directed against CD52, widely expressed on immune cells such as B and T cells, natural killer cells, macrophages, and some granulocytes.

Nondepleting Agents Another more selective approach is to target the 55-kDa alpha chain of the IL-2 receptor, which is expressed only on activated T cells. This approach is used as prophylaxis for (but not treatment of) acute rejection in the immediate posttransplant period and is effective at decreasing the early acute rejection rate with few adverse side effects.

MAINTENANCE THERAPY

The most frequently used combination is a calcineurin inhibitor (CNI), usually tacrolimus, and an antimetabolite, usually mycophenolic acid, with or without early steroid withdrawal. Belatacept is a co-stimulatory bocking antibody, used as an alternative to long-term toxic CNI therapy. The mammalian TOR (mTOR) inhibitors sirolimus and everolimus are infrequently used as first-line maintenance immunosuppression.

Antimetabolites *Azathioprine* is a prodrug that must first be activated to form thioguanine nucleotides. Thiopurine *S*-methyltransferase (TPMT) inactivates azathioprine. Patients with two nonfunctional TPMT alleles experience life-threatening myelosuppression when treated with azathioprine, and those who carry one nonfunctional TPMT allele may also have significant side effects; therefore, the U.S. Food and Drug Administration (FDA) recommends TPMT genotyping or phenotyping before starting treatment with azathioprine. Azathioprine, which inhibits synthesis of DNA and RNA and thereby inhibits T-cell proliferation, was the keystone of immunosuppressive therapy in kidney transplant recipients until the 1990s but has been replaced by more effective agents. Concomitant use of allopurinol is best avoided and, if used, very carefully monitored, owing to inhibition of xanthine oxidase.

Mycophenolate mofetil and *mycophenolate sodium*, both of which are metabolized to mycophenolic acid, are now used in place of azathioprine based on superior efficacy. Mycophenolic acid has a similar mode of action as azathioprine and is associated with a mild degree of gastrointestinal toxicity but less bone marrow suppression.

Steroids *Glucocorticoids* are important adjuncts to immunosuppressive therapy and used as both induction and maintenance therapy. In general, methylprednisolone 250–500 mg is given immediately before or at the time of transplantation, and the dose is tapered to 20 mg within a week. The side effects of the glucocorticoids, particularly impairment of wound healing and predisposition to infection, make it desirable to taper the dose as rapidly as possible in the immediate postoperative period. Early discontinuation or avoidance of steroids is common to avoid long-term adverse effects on bone, skin, and glucose metabolism. Most patients whose renal function is stable after 6 months or a year do not require large doses of prednisone; maintenance doses of 5–10 mg per day are the rule. A major effect of steroids is preventing the release of IL-6 and IL-1 by monocytes-macrophages.

Calcineurin Inhibitors *Cyclosporine* is a fungal peptide with potent immunosuppressive activity. It acts on the calcineurin pathway to inhibit transcription of IL-2 and other proinflammatory cytokines, thereby inhibiting T-cell proliferation. It works synergistically with glucocorticoids and mycophenolate. Among its toxic effects (nephrotoxicity, hepatotoxicity, hirsutism, tremor, gingival hyperplasia, and diabetes), nephrotoxicity presents a serious management problem and is further discussed below.

Tacrolimus (FK506) is a fungal macrolide that has the same mode of action as cyclosporine as well as a similar side effect profile; it does not, however, produce hirsutism or gingival hyperplasia; in contrast, it can be associated with hair loss. Posttransplant diabetes mellitus more commonly occurs with tacrolimus. An extended-release formulation of tacrolimus is now available and is given once daily. Owing to its nephrotoxicity and narrow therapeutic window, the drug level of CNIs should be monitored, and drug–drug interactions should be carefully examined. Antibiotics and antifungals (e.g., erythromycin, ketoconazole, fluconazole) and nondihydropyridine calcium channel blockers (e.g., diltiazem, verapamil) inhibit the activity of cytochrome P450 C3A enzyme and cause elevated levels of CNIs. On the other hand, antiepileptics, such as phenytoin and carbamazepine, increase metabolism, resulting in lower levels.

mTOR Inhibitors *Sirolimus* (previously called rapamycin) is another fungal macrolide but has a different mode of action from tacrolimus; i.e., it inhibits T-cell growth factor signaling pathways, preventing the response to IL-2 and other cytokines. Sirolimus can be used in conjunction with cyclosporine or tacrolimus, or with mycophenolic acid, to avoid the use of CNIs.

Everolimus is another mTOR inhibitor with similar mechanism of action as *sirolimus* but with better bioavailability. mTOR inhibitors are modestly tolerated and are associated with gastrointestinal disturbance, stomatitis, mucositis, and pneumonitis. Poor wound healing associated with mTOR inhibitors makes them less preferable agents during the perisurgical period. While the PI3K-mTOR is the most commonly

mutated cellular pathway in malignant cells, mTOR inhibitors have been used more frequently in transplant patients who develop cancers, in particular recurrent skin cancers.

Belatacept *Belatacept* is a fusion protein composed of the Fc fragment of human IgG1 immunoglobulin and the extracellular domain of cytotoxic T-lymphocyte associated protein 4 (CTLA-4). It binds to its costimulatory ligands (CD80 and CD86) on antigen-presenting cells, interrupting their binding to CD28 on T cells. This inhibition leads to T-cell anergy and apoptosis. Belatacept is FDA approved for kidney transplant recipients and is given monthly as an intravenous infusion. The 7-year follow-up of the Belatacept Evaluation of Nephroprotection and Efficacy as First-Line Immunosuppression Trial (BENEFIT) showed improved patient and graft survival for the belatacept-treated group compared to patients treated with cyclosporine, despite short-term risks of higher rates of acute rejection.

CLINICAL COURSE AND MANAGEMENT OF THE RECIPIENT

Adequate hemodialysis should be performed within 48 h prior to the surgery as needed to control serum potassium to prevent cardiac arrhythmias. During the transplantation surgery, the kidney allograft is usually placed in the recipient's iliac fossa using a retroperitoneal approach. An anastomosis is made between donor renal artery and recipient external iliac artery and donor renal vein to recipient external iliac vein. The donor ureter is anastomosed to the recipient bladder mucosa. Native kidney nephrectomy is rarely performed except in the case of an extremely enlarged polycystic kidney or chronic pyelonephritis. In many cases, especially after living kidney transplantation, the allograft starts to produce urine immediately after anastomosis. The allograft often has some degree of acute tubular injury due to ischemia, which accounts for postoperative diuresis. Large amounts of sodium, potassium, and water may be lost postoperatively, which requires close monitoring and replacement. The recipient's serum creatinine should start to fall as the allograft starts to function, and recovery usually occurs within 2 weeks, although periods as long as 6 weeks have been reported. Slow recovery or oliguria should prompt an allograft biopsy because superimposition of rejection on acute tubular injury is common and difficult to distinguish without an allograft biopsy. Induction immunosuppression therapy and maintenance steroids and antimetabolites start on the day of surgery, and it is usually safe to delay introduction of a CNI for a few days if a lymphocyte-depleting induction agent is used. **Figure 325-2** illustrates a typical algorithm followed by transplant centers for early posttransplant management of recipients at high or low risk of early renal dysfunction.

MANAGEMENT OF REJECTION

Early diagnosis of rejection allows prompt institution of therapy to preserve allograft function and prevent irreversible damage. Clinical

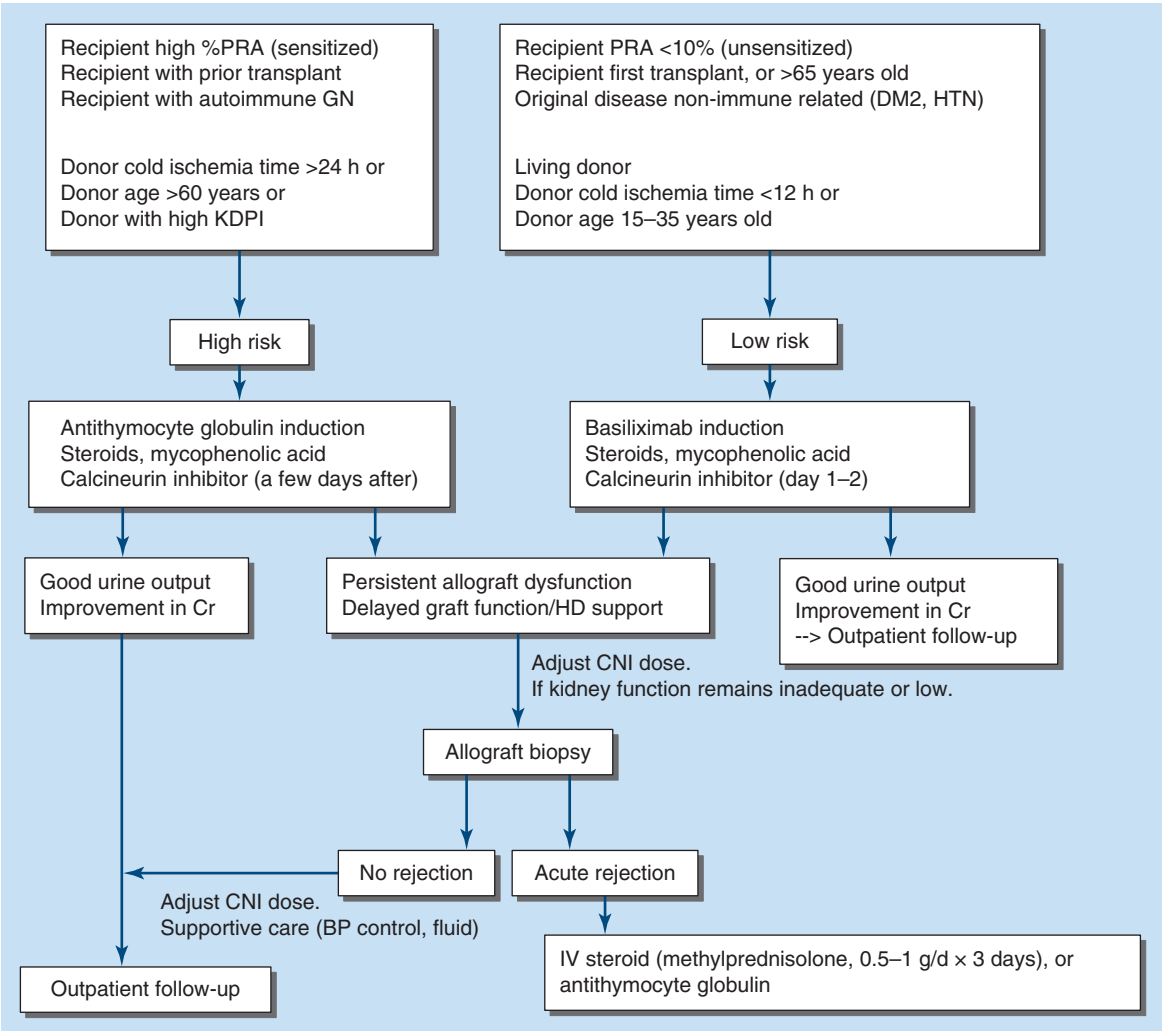

FIGURE 325-2 A typical algorithm for early posttransplant care of a kidney recipient. If any of the recipient or donor "high-risk" factors exist, more aggressive management is called for. Low-risk patients can be treated with a standard immunosuppressive regimen with no or less-potent induction therapy (e.g., basiliximab). Patients at higher risk of rejection or early ischemic transplant dysfunction are often induced with an antithymocyte globulin to provide more potent early immunosuppression or to spare calcineurin use in the immediate posttransplant period. When there is early transplant dysfunction, prerenal, obstructive, and vascular causes must be ruled out by ultrasonographic examination. The panel reactive antibody (PRA) is a quantitation of how much antibody is present in a candidate against a panel of cells representing the distribution of antigens in the donor pool. BP, blood pressure; CNI, calcineurin inhibitor; Cr, creatinine; DM2, type 2 diabetes; GN, glomerulonephritis; HD, hemodialysis; HTN, hypertension; KDPI, Kidney Donor Profile Index.

evidence of rejection is rarely characterized by fever, swelling, and tenderness over the allograft. Rejection may present only with a rise in serum creatinine, with or without a reduction in urine volume. The focus should be on ruling out other causes of functional deterioration, such as acute tubular injury, calcineurin toxicity, BK nephropathy, and recurrent glomerular diseases.

Doppler ultrasonography is useful in ascertaining changes in the allograft vasculature and in blood flow. Thrombosis of the renal vein occurs rarely; it may be reversible if it is caused by technical factors and intervention is prompt. Diagnostic ultrasound is also helpful in identifying urinary obstruction or the presence of perirenal collections of urine (urinoma), blood (hematoma), or lymph (lymphocele).

Allograft biopsy is the gold standard for diagnosis of acute T cell–mediated and antibody-mediated rejection. Acute T cell–mediated rejection is diagnosed by the presence of immune cell infiltration in the interstitial, tubular, or vascular compartments, according to the Banff classification. Treatment of T cell–mediated rejection involves a high-dose steroid, e.g., IV administration of methylprednisolone, 500–1000 mg daily for 3 days. Failure to respond is an indication for antibody therapy, usually with ATG.

Evidence of antibody-mediated rejection is present when endothelial injury and deposition of complement component C4d is detected in peritubular capillaries. This is usually accompanied by detection of the circulating donor-specific antibody in the recipient's blood. Treatment of antibody-mediated rejection remains a challenge, and aggressive use of plasmapheresis, IVIG, anti-CD20 monoclonal antibody (rituximab) to target B lymphocytes, and bortezomib to target antibody-producing plasma cells is indicated. Recently, noninvasive biomarkers such as circulating donor-derived cell-free DNA, urine chemokine markers (e.g., CXCL9), and characterization of the urine exosome have been used as adjunct diagnostic markers for rejection. Future studies to identify prognostic, noninvasive biomarkers that predict response to therapy, that risk stratify, and that provide personalized immunosuppression strategies will be needed.

MANAGEMENT OF CHRONIC COMPLICATIONS

Cardiovascular events (29%), infection (18%), and malignancy (17%) are the major causes of death in kidney transplant recipients. Typical time courses of opportunistic infections after transplantation are shown in **Table 325-4**.

The signs and symptoms of infection may be atypical due to immunosuppression, which makes diagnosis challenging. In addition to commensal infections, opportunistic infections should be considered based on the clinical presentation. Diagnostic measures such as culture (blood, urine, drain fluids), viral load in plasma, and imaging (allograft ultrasound and computed tomography [CT]) should be obtained. Overall therapy involves adequate source control, anti-microorganism therapy, and reduction of immunosuppression.

Pneumocystis jirovecii is a rare but critical opportunistic infection **(Chap. 227)**. Aggressive diagnostic procedures, including transbronchial and open-lung biopsy, are frequently indicated.

TABLE 325-4 The Most Common Opportunistic Infections in Renal Transplant Recipients

Peritransplant (<1 month)	Late (>6 months)
Wound infections	*Aspergillus*
Herpesvirus	*Nocardia*
Oral candidiasis	BK virus (polyoma)
Urinary tract infection	Herpes zoster
Early (1–6 months)	Hepatitis B
Pneumocystis carinii	Hepatitis C
Cytomegalovirus	
Legionella	
Listeria	
Hepatitis B	
Hepatitis C	

Trimethoprim-sulfamethoxazole (TMP-SMX) is the treatment of choice; amphotericin B has been used effectively in systemic fungal infections. Prophylaxis against *P. jirovecii* with daily low-dose TMP-SMX for 6 months is effective. Involvement of the oropharynx with *Candida* **(Chap. 222)** may be treated with local nystatin. Tissue-invasive fungal infections require treatment with systemic agents such as fluconazole or one of the newer antifungal agents. *Aspergillus* **(Chap. 223)**, *Nocardia* **(Chap. 179)**, and especially cytomegalovirus (CMV) **(Chap. 200)** infections also occur.

CMV infection is a serious complication after kidney transplantation associated with increased morbidity and mortality. While the seronegative recipients of seropositive donors are at the highest risk, presentation varies from asymptomatic CMV viremia to a systemic syndrome (fever, leukopenia) and tissue-specific manifestation (hepatitis, gastroenteritis, and retinopathy). Plasma viral load and a rise in IgM antibodies to CMV are diagnostic. Valganciclovir has proved effective in both prophylaxis and treatment of CMV disease. Acyclovir is an effective therapy for herpes simplex virus infections.

BK virus is a latent polyomavirus that lies dormant in the kidney and urothelial tract and can be activated in the setting of immunosuppression. Reactivation of BK, if left untreated, will lead to progressive fibrosis and loss of the graft within 1 year in most cases. However, as risk of reactivation of BK infection is associated with the overall degree of immunosuppression, in most cases, BK infection can be managed by regular testing of BK viral load and judicious reduction of maintenance immunosuppression. Renal biopsy can be useful in examining for the presence of interstitial nephritis, tubular cytopathic changes of BK nephropathy, and viral antigens in the allograft. In difficult to treat cases beyond reduction in immunosuppression, a variety of therapies including leflunomide, cidofovir, and quinolone antibiotics (which are effective against polyoma helicase) and IVIG have been tried but with inconsistent results.

CHRONIC LESIONS OF THE TRANSPLANTED KIDNEY

Although current 1-year transplant survival is excellent, most recipients experience a progressive decline in kidney function over time thereafter. Chronic renal transplant dysfunction can be caused by chronic active antibody-mediated rejection, recurrent glomerular disease, hypertension, CNI nephrotoxicity, secondary focal glomerulosclerosis, or a combination of these pathophysiologies. Chronic vascular changes with intimal proliferation and medial hypertrophy are commonly found. Control of systemic and intrarenal hypertension with calcium channel blockers is thought to have a beneficial influence on the rate of progression of chronic allograft dysfunction. Kidney allograft biopsy can distinguish subacute cellular rejection from recurrent disease or secondary focal sclerosis.

MALIGNANCY

The incidence of tumors in patients on immunosuppressive therapy is 5–6%, or ~100 times greater than that in the general population in the same age range. The most common lesions are cancer of the skin and lips. Hence, surveillance for skin cancers and protection from ultraviolet radiation are necessary. Solid organ transplant recipients are at higher risk to develop posttransplant lymphoproliferative disease, most frequently seen early (<1 year) or late (7–10 years) after transplantation. Most cases are associated with Epstein-Barr virus infection, and the prognosis is poor. The overall malignancy risks are increased in proportion to the total immunosuppressive load administered and the time elapsed since transplantation. Treatment of cancer after transplant involves the reduction of immunosuppression, surgery, conventional cytotoxic chemotherapy, and radiotherapy. Cancer immunotherapy is associated with a high risk of allograft rejection (30–40%), and the multidisciplinary risk-benefit discussion should be made before the initiation of therapy.

OTHER COMPLICATIONS

Both chronic dialysis and renal transplant patients have a higher incidence of death from myocardial infarction and stroke than the

population at large, and this is particularly true of diabetic patients. Contributing factors are the use of glucocorticoids and sirolimus, as well as hypertension. Recipients of renal transplants have a high prevalence of coronary artery and peripheral vascular diseases. The percentage of deaths from these causes has been slowly rising as the numbers of transplanted diabetic patients and the average age of recipients increase. More than 30% of kidney transplant recipient mortality is attributable to cardiovascular disease. Strict control of blood pressure and blood sugar and lipid levels is essential in this population.

Hypertension may be caused by (1) native kidney disease, (2) rejection activity in the transplant, (3) renal artery stenosis if an end-to-end anastomosis was constructed with an iliac artery branch, and (4) renal CNI toxicity, which may improve with reduction in dose. Calcium channel blockers are shown to improve long-term mortality. Amelioration of hypertension to the range of 120–130/70–80 mmHg should be the goal in all patients.

Hypercalcemia after transplantation may indicate failure of hyperplastic parathyroid glands to regress. Aseptic necrosis of the head of the femur when it occurs is probably due to preexisting hyperparathyroidism, with aggravation by glucocorticoid treatment. With improved management of calcium and phosphorus metabolism during chronic dialysis, the incidence of parathyroid-related complications has fallen dramatically. Persistent hyperparathyroid activity may require subtotal parathyroidectomy.

Although most transplant patients have robust production of erythropoietin and normalization of hemoglobin, *anemia* is commonly seen in the posttransplant period. Often the anemia is attributable to bone marrow–suppressant immunosuppressive medications such as azathioprine, mycophenolic acid, and mTOR inhibitors. Gastrointestinal bleeding is a common side effect of high-dose and long-term steroid administration. Many transplant patients have creatinine clearances of 30–50 mL/min and can be considered to have chronic renal insufficiency for anemia management, including supplemental erythropoietin.

Chronic hepatitis, particularly when due to hepatitis B virus, can be a progressive, fatal disease over a decade or so. Patients who are persistently hepatitis B surface antigen–positive are at higher risk, according to some studies, but the presence of HCV is also a concern when one embarks on a course of immunosuppression in a transplant recipient. However, the introduction of the new highly effective, direct-acting HCV antiviral medications reduced this risk significantly.

In conclusion, while kidney transplantation has progressed significantly toward the goals of longer patient survival and better quality of life, the field still has significant challenges and unmet needs. Advanced immunologic and genetic studies have led and will continue to lead us to detailed understanding of alloimmunity at the molecular level. Noninvasive biomarkers for monitoring and diagnosing rejection and novel therapeutic targets will continue to evolve. Further effort is needed to achieve equity and improve personalized care of kidney transplant recipients.

326 Glomerular Diseases

Julia B. Lewis, Eric G. Neilson

Two human kidneys harbor nearly 1.8 million glomerular capillary tufts. Each glomerular tuft resides within Bowman's space. The capsule circumscribing this space is lined by parietal epithelial cells that transition into tubular epithelia forming the proximal nephron or migrate into the tuft to replenish podocytes. The glomerular capillary tuft derives from an afferent arteriole that forms a branching capillary bed embedded in mesangial matrix **(Fig. 326-1)**. This capillary network funnels into an efferent arteriole, which passes filtered blood into cortical peritubular capillaries or medullary vasa recta that supply and exchange with a folded tubular architecture. Hence, the glomerular capillary tuft, fed and drained by arterioles, represents an arteriolar portal system. Fenestrated endothelial cells resting on a glomerular basement membrane (GBM) line glomerular capillaries. Delicate foot processes extending from epithelial podocytes shroud the outer surface of these capillaries, and adjacent podocytes interconnect to each other by slit-pore membranes forming a selective filtration barrier.

The glomerular capillaries filter 120–180 L/d of plasma water containing various solutes for reclamation or discharge by downstream tubules. Most large proteins and all cells are excluded from filtration by a physicochemical barrier governed by pore size and negative electrostatic charge. The mechanics of filtration and reclamation are quite complicated for many solutes **(Chap. 320)**. For example, in the case of serum albumin, the glomerulus is an imperfect barrier. Although albumin has a negative charge, which would tend to repel the negatively charged GBM, it only has a physical radius of 3.6 nm, while pores in the GBM and slit-pore membranes have a radius of 4 nm. Consequently, variable amounts of albumin inevitably cross the filtration barrier to be reclaimed by megalin and cubilin receptors along the proximal tubule. Remarkably, humans with normal nephrons excrete on average 8–10 mg of albumin in daily voided urine, ~20–60% of total excreted protein. This amount of albumin, and other proteins, can rise to gram quantities following glomerular injury.

The breadth of diseases affecting the glomerulus is expansive because the microenvironment supporting the glomerular capillaries can be injured in a variety of ways, producing many different lesions. Some order to this vast subject is brought by grouping all of these diseases into a smaller number of clinical syndromes.

PATHOGENESIS OF GLOMERULAR DISEASE

There are many forms of glomerular disease with pathogenesis variably linked to the presence of genetic mutations, infection, toxin exposure, autoimmunity, atherosclerosis, hypertension, emboli, thrombosis, or diabetes mellitus. Even after careful study, however, the cause often remains unknown, and the lesion is called *idiopathic*. Specific or unique features of pathogenesis are mentioned with the description of each of the glomerular diseases later in this chapter.

Some glomerular diseases result from genetic mutations producing familial disease or a founder effect: congenital nephrotic syndrome from mutations in *NPHS1* (nephrin) and *NPHS2* (podocin) affects the slit-pore membrane at birth, and *TRPC6* cation channel mutations produce *focal segmental glomerulosclerosis* (*FSGS*) in adulthood;

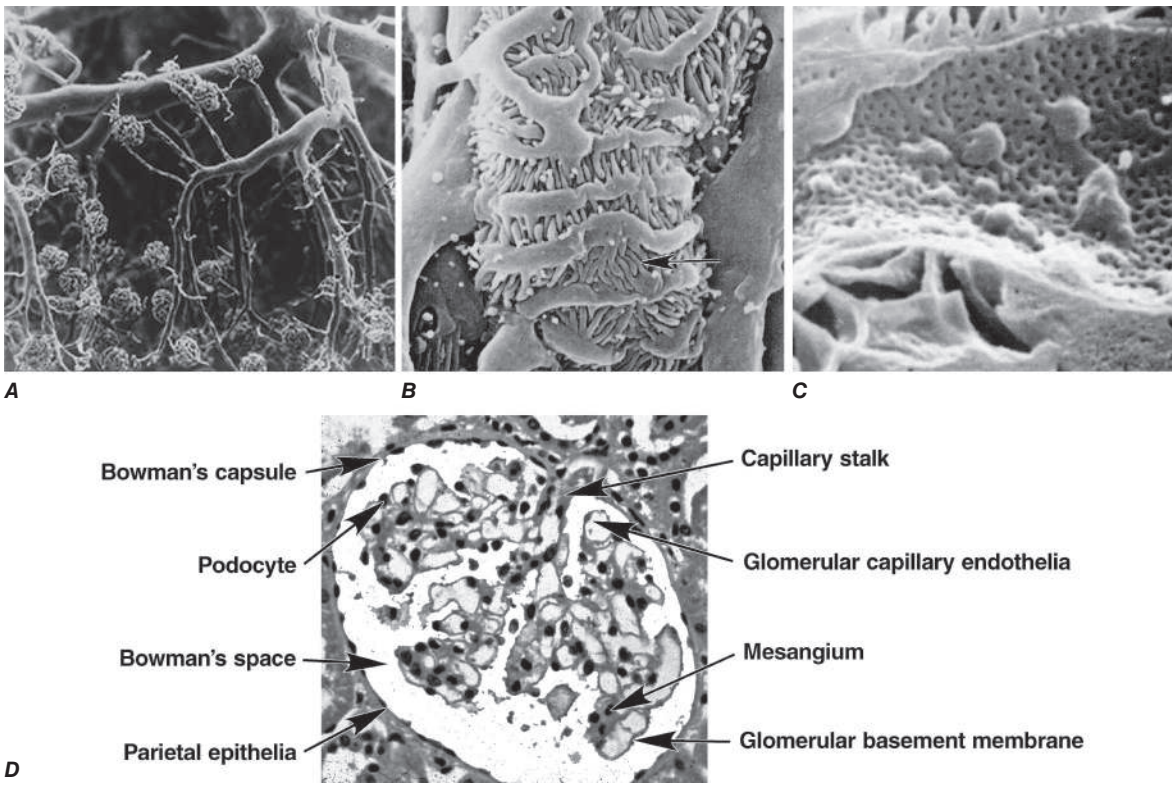

FIGURE 326-1 Glomerular architecture. ***A.*** The glomerular capillaries form from a branching network of renal arteries, arterioles leading to an afferent arteriole, glomerular capillary bed (tuft), and a draining efferent arteriole. *(From VH Gattone II et al: Hypertension 5:8, 1983.)* ***B.*** Scanning electron micrograph of podocytes that line the outer surface of the glomerular capillaries (*arrow* shows foot process). ***C.*** Scanning electron micrograph of the fenestrated endothelia lining the glomerular capillary. ***D.*** The various normal regions of the glomerulus on light microscopy. *(A–C: Courtesy of Dr. Vincent Gattone, Indiana University; with permission.)*

polymorphisms in the gene encoding apolipoprotein L1, *APOL1*, are a major risk for nearly 70% of African Americans with nondiabetic end-stage kidney disease (ESKD), particularly FSGS; monogenetic causes of FSGS are increasingly linked to early age of onset and to genes encoding type IV collagen in older adults, suggesting that much of FSGS may be hereditary; mutations in control of the complement pathway increasingly associate with various forms of *membranoproliferative glomerulonephritis* (*MPGN*) and C_3 glomerulopathies including dense deposit disease, or *atypical hemolytic-uremic syndrome* (*aHUS*); type II partial lipodystrophy from mutations in genes encoding lamin A/C or PPARγ causes a metabolic syndrome associated with MPGN; IgG3 subclass antibodies to antigens expressed on podocytes encoded by *PLAR2gc* indicate a poor prognosis in membranous nephropathy; Alport's syndrome, from mutations in the genes encoding for the α3, α4, or α5 chains of type IV collagen, produces *split basement membranes* with *glomerulosclerosis*; and lysosomal storage diseases, such as α-galactosidase A deficiency causing Fabry's disease and *N*-acetylneuraminic acid hydrolase deficiency causing nephrosialidosis, produce FSGS.

Systemic hypertension and atherosclerosis can produce pressure stress, ischemia, or lipid oxidants that lead to *chronic glomerulosclerosis*. *Malignant hypertension* can quickly complicate glomerulosclerosis with fibrinoid necrosis of arterioles and glomeruli, thrombotic microangiopathy, and acute kidney failure. *Diabetic nephropathy* is an acquired sclerotic injury associated with thickening of the GBM secondary to the long-standing effects of hyperglycemia, advanced glycosylation end products, and reactive oxygen species.

Inflammation of the glomerular capillaries is called *glomerulonephritis*. Most glomerular or mesangial antigens involved in *immune-mediated glomerulonephritis* are unknown **(Fig. 326-2)**. Glomerular epithelial or mesangial cells may shed or express epitopes that mimic other immunogenic proteins made elsewhere in the body. Bacteria, fungi, and viruses can directly infect the kidney, producing their own antigens. Autoimmune diseases such as idiopathic *membranous glomerulonephritis* (*MGN*) or MPGN are confined to the kidney, whereas systemic inflammatory diseases such as *lupus nephritis* or *granulomatosis with polyangiitis* spread to the kidney, causing secondary glomerular injury. *Antiglomerular basement membrane disease* producing Goodpasture's syndrome primarily injures both the lung and kidney because of the narrow distribution of the α3 NC1 domain of type IV collagen that is the target antigen.

Local activation of Toll-like receptors on glomerular cells, deposition of immune complexes, or complement injury to glomerular structures induces mononuclear cell infiltration, which subsequently leads to an adaptive immune response attracted to the kidney by local release of chemokines. Neutrophils, macrophages, and T cells are drawn by chemokines into the glomerular tuft, where they react with antigens and epitopes on or near somatic cells or their structures, producing more cytokines and proteases that damage the mesangium, capillaries, and/or the GBM. While the adaptive immune response is similar to that of other tissues, early T-cell activation plays an important role in the mechanism of glomerulonephritis. Antigens presented by class II major histocompatibility complex (MHC) molecules on macrophages and dendritic cells in conjunction with associative recognition molecules engage the CD4/8 T-cell repertoire.

Mononuclear cells by themselves can injure the kidney, but autoimmune events that damage glomeruli classically produce a humoral immune response. *Poststreptococcal glomerulonephritis, lupus nephritis*, and idiopathic *membranous nephritis* typically are associated with immune deposits along the GBM, while anti-GBM antibodies produce the linear binding of anti-GBM disease. Preformed circulating immune complexes can precipitate along the subendothelial side of the GBM, while other immune deposits form in situ on the subepithelial side. These latter deposits accumulate when circulating autoantibodies find their antigen trapped along the subepithelial edge of the GBM. Immune deposits in the glomerular mesangium may result from the deposition of preformed circulating complexes or in situ antigen-antibody interactions. Immune deposits stimulate the release of local proteases and activate the complement cascade, producing C_{5-9} attack complexes. In addition, local oxidants damage glomerular structures, producing proteinuria and effacement of the podocytes. Overlapping etiologies or pathophysiologic mechanisms can produce similar

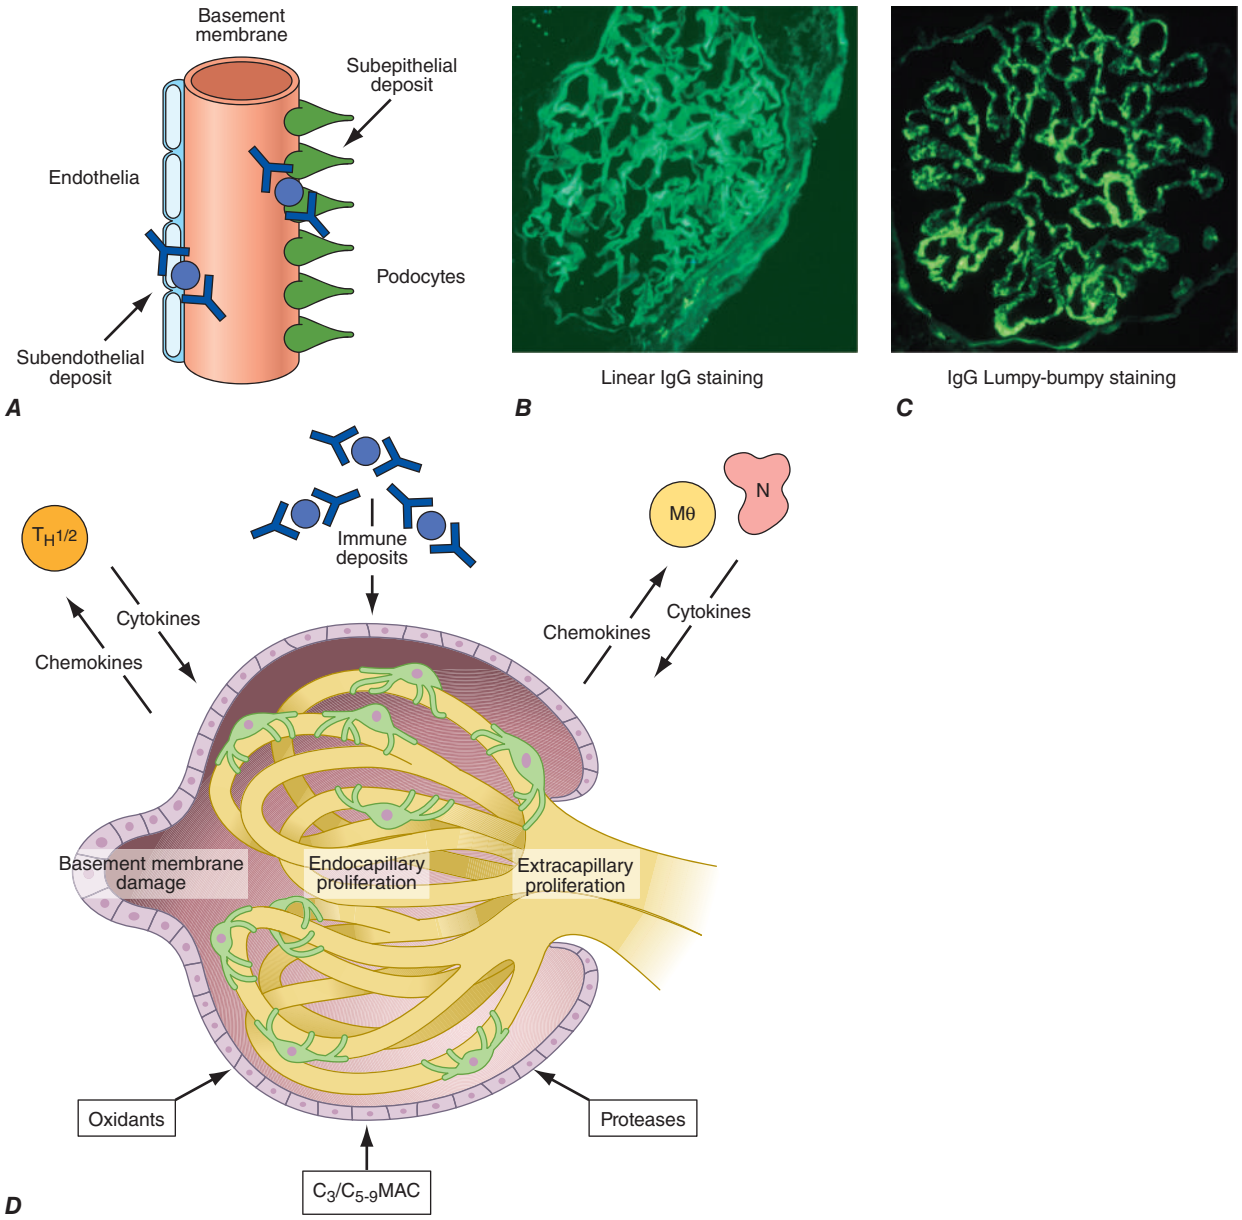

FIGURE 326-2 The glomerulus is injured by a variety of mechanisms. ***A.*** Preformed immune deposits can precipitate from the circulation and collect along the glomerular basement membrane (GBM) in the subendothelial space or can form in situ along the subepithelial space. ***B.*** Immunofluorescent staining of glomeruli with labeled anti-IgG demonstrating linear staining from a patient with anti-GBM disease or immune deposits from a patient with membranous glomerulonephritis. ***C.*** The mechanisms of glomerular injury have a complicated pathogenesis. Immune deposits and complement deposition classically draw macrophages and neutrophils into the glomerulus. T lymphocytes may follow to participate in the injury pattern as well. ***D.*** Amplification mediators as locally derived oxidants and proteases expand this inflammation, and depending on the location of the target antigen and the genetic polymorphisms of the host, basement membranes are damaged with either endocapillary or extracapillary proliferation.

glomerular lesions, suggesting that downstream molecular and cellular responses often converge toward common patterns of injury.

PROGRESSION OF GLOMERULAR DISEASE

Persistent glomerulonephritis that worsens kidney function is always accompanied by interstitial nephritis, renal fibrosis, and tubular atrophy. What is not so obvious, however, is that kidney failure in glomerulonephritis best correlates histologically with the appearance of tubulointerstitial nephritis rather than with the type of inciting glomerular injury.

Loss of kidney function due to interstitial damage is explained hypothetically by several mechanisms. The simplest explanation is that urine flow is impeded by tubular obstruction as a result of interstitial inflammation and fibrosis. Thus, obstruction of the tubules with debris or by extrinsic compression functionally results in aglomerular nephrons. A second mechanism suggests that interstitial changes, including interstitial edema or fibrosis, alter tubular and vascular architecture and thereby compromise the normal tubular transport of solutes and water from tubular lumen to vascular space. This failure increases the solute and water content of the tubule fluid, resulting in isosthenuria and polyuria. Adaptive mechanisms related to tubuloglomerular feedback also fail, resulting in a reduction of renin output from the juxtaglomerular apparatus trapped by interstitial inflammation. Consequently, the local vasoconstrictive influence of angiotensin II on the glomerular arterioles decreases, and filtration drops owing to a generalized decrease in arteriolar tone. A third mechanism involves changes in vascular resistance due to damage of peritubular capillaries. The cross-sectional volume of these capillaries is decreased by interstitial inflammation, edema, or fibrosis. These structural alterations in vascular resistance affect kidney function through two mechanisms. First, tubular cells are very metabolically active, and as a result, decreased perfusion leads to tubular ischemic injury. Second, impairment of glomerular arteriolar outflow leads to increased intravascular hypertension in less-involved glomeruli; this selective intraglomerular

hypertension aggravates and extends *mesangial sclerosis* and *glomerulosclerosis* to less-involved glomeruli. Regardless of the exact mechanism, early *acute tubulointerstitial nephritis* **(see Fig. A4-31)** suggests potentially recoverable kidney function, whereas the development of *chronic interstitial fibrosis* prognosticates permanent loss **(see Fig. A4-25)**.

Persistent damage to glomerular capillaries spreads to the tubulointerstitium in association with proteinuria. There is a hypothesis that efferent arterioles leading from inflamed glomeruli carry forward inflammatory mediators, which induces downstream interstitial nephritis, resulting in fibrosis. Glomerular filtrate from injured glomerular capillaries adherent to Bowman's capsule may also be misdirected to the periglomerular interstitium. Most nephrologists believe, however, that proteinuric glomerular filtrate forming tubular fluid is the primary route to downstream tubulointerstitial injury, although none of these hypotheses are mutually exclusive.

The simplest explanation for the effect of proteinuria on the development of interstitial nephritis is that increasingly severe proteinuria, carrying activated cytokines and lipoproteins producing reactive oxygen species, triggers a downstream inflammatory cascade in and around epithelial cells lining the tubular nephron. These effects induce T lymphocyte and macrophage infiltrates in the interstitial spaces along with fibrosis and tubular atrophy.

Tubules disaggregate following direct damage to their basement membranes, leading to more interstitial fibroblasts and fibrosis at the site of injury; recent comprehensive evidence suggests that renal fibroblasts increase through several mechanisms: epithelial or endothelial-mesenchymal transitions (15%), bone marrow–derived fibrocytes (35%), and the proliferation of resident fibroblasts (50%). Most renal myofibroblasts are formed from bone marrow fibrocytes or proliferating fibroblasts. Transforming growth factor β (TGF-β), fibroblast growth factor 2 (FGF-2), hypoxemia-inducible factor 1α (HIF-1α), and platelet-derived growth factor (PDGF) are particularly active in this transition. With persistent nephritis, fibroblasts multiply and lay down tenascin and a fibronectin scaffold for the polymerization of new interstitial collagen types I/III. These events form scar tissue through a process called fibrogenesis. In experimental studies, bone morphogenetic protein 7 and hepatocyte growth factor can reverse early fibrogenesis and preserve tubular architecture. When fibroblasts outdistance their survival factors, apoptosis occurs, and the permanent renal scar becomes acellular, leading to irreversible kidney failure.

APPROACH TO THE PATIENT

Glomerular Disease

HEMATURIA, PROTEINURIA, AND PYURIA

Patients with glomerular disease usually have some hematuria with varying degrees of proteinuria. Hematuria is typically asymptomatic. As few as 3–5 red blood cells in the spun sediment from first-voided morning urine is suspicious. The diagnosis of glomerular injury can be delayed because patients will not realize they have *microscopic hematuria*, and only rarely with the exception of IgA nephropathy and sickle cell disease is *gross hematuria* present. When working up microscopic hematuria, perhaps accompanied by minimal proteinuria (<500 mg/24 h), it is important to exclude anatomic lesions, such as malignancy of the urinary tract, particularly in older men. Microscopic hematuria may also appear with the onset of benign prostatic hypertrophy, interstitial nephritis, papillary necrosis, hypercalciuria, kidney stones, cystic kidney diseases, or renal vascular injury. However, when red blood cell casts **(see Fig. A4-38)** or dysmorphic red blood cells are found in the sediment, glomerulonephritis is likely. A mean of 8–10 mg/24 h of albumin appears in the urine in the absence of kidney disease. In early nephropathy, such as in diabetic nephropathy, proteinuria increases to 30–300 mg/24 h and is called microalbuminuria and represents the presence of kidney disease. Screening spot urine albumin/creatinine ratio (UACR) of >30 mg/g suggests a need for further investigation. Greater than 300 mg/24 h of albuminuria represents frank proteinuria and more advanced kidney disease **(Table 326-1)**.

Sustained proteinuria >1–2 g/24 h is also commonly associated with glomerular disease. Patients often will not know they have proteinuria unless they become edematous or notice foaming urine on voiding. *Sustained proteinuria* has to be distinguished from lesser amounts of so-called *benign proteinuria* in the normal population. (Table 326-1). This latter class of proteinuria is nonsustained, generally <1 g/24 h, and is sometimes called *functional* or *transient proteinuria*. Fever, exercise, obesity, sleep apnea, emotional stress, and congestive heart failure can explain transient proteinuria. Proteinuria only seen with upright posture is called *orthostatic proteinuria* and has a benign prognosis. Isolated proteinuria sustained over multiple clinic visits is found in many glomerular lesions. Proteinuria in most adults with glomerular disease is *nonselective*, containing albumin and a mixture of other serum proteins, whereas in children with *minimal change disease* (MCD), the proteinuria is *selective* and composed largely of albumin.

Some patients with inflammatory glomerular disease, such as acute poststreptococcal glomerulonephritis or MPGN, have *pyuria* characterized by the presence of considerable numbers of leukocytes. This latter finding has to be distinguished from urine infected with bacteria.

CLINICAL SYNDROMES

Various forms of glomerular injury can also be parsed into several distinct syndromes on clinical grounds **(Table 326-2)**. These syndromes, however, are not always mutually exclusive. There is an *acute nephritic syndrome* producing 1–2 g/24 h of proteinuria, hematuria with red blood cell casts, pyuria, hypertension, fluid retention, and a rise in serum creatinine associated with a reduction in glomerular filtration. If glomerular inflammation develops slowly, the serum creatinine will rise gradually over many weeks, but if the serum creatinine rises quickly, particularly over a few days, acute nephritis is sometimes called *rapidly progressive glomerulonephritis* (RPGN); the histopathologic term *crescentic glomerulonephritis* is the pathologic equivalent of the clinical presentation of RPGN. When patients with RPGN present with lung hemorrhage from Goodpasture's syndrome, antineutrophil cytoplasmic antibody (ANCA)–associated small-vessel vasculitis, lupus erythematosus, or cryoglobulinemia, they are often diagnosed as having a *pulmonary-renal syndrome*. *Nephrotic syndrome* describes the onset of heavy proteinuria (>3.0 g/24 h), hypertension, hypercholesterolemia, hypoalbuminemia, edema/anasarca, and microscopic hematuria; if only large amounts of proteinuria are present without clinical manifestations, the condition is sometimes called *nephrotic-range proteinuria*. The glomerular filtration rate (GFR) in these patients may initially be normal or, rarely, higher than normal, but with persistent hyperfiltration and continued nephron loss, it typically declines over months to years. Patients with a *basement membrane syndrome* either have genetically abnormal basement membranes (Alport's syndrome) or an autoimmune

[a]Can present as rapidly progressive glomerulonephritis (RPGN); sometimes called crescentic glomerulonephritis. [b]Can present as a malignant hypertensive crisis producing an aggressive fibrinoid necrosis in arterioles and small arteries with microangiopathic hemolytic anemia. [c]Can present with gross hematuria.

Abbreviations: AA, amyloid A; AL, amyloid L; ANCA, antineutrophil cytoplasmic antibodies; GBM, glomerular basement membrane.

response to basement membrane collagen IV (Goodpasture's syndrome) associated with microscopic hematuria, mild to heavy proteinuria, and hypertension with variable elevations in serum creatinine. *Glomerular-vascular syndrome* describes patients with vascular injury producing hematuria and moderate proteinuria. Affected individuals can have vasculitis, thrombotic microangiopathy, antiphospholipid syndrome, or, more commonly, a systemic disease such as atherosclerosis, cholesterol emboli, hypertension, sickle cell anemia, and autoimmunity. *Infectious disease–associated syndrome* is most important if one has a global perspective. Save for subacute bacterial endocarditis (SBE) in the Western Hemisphere, malaria and schistosomiasis may be the most common causes of glomerulonephritis throughout the world, closely followed by HIV and chronic hepatitis B and C. These infectious diseases produce a variety of inflammatory reactions in glomerular capillaries, ranging from nephrotic syndrome to acute nephritic injury, and urinalyses that demonstrate a combination of hematuria and proteinuria.

These six general categories of syndromes are usually determined at the bedside with the help of a history and physical examination, blood chemistries, kidney ultrasound, and urinalysis. These initial studies help frame further diagnostic workup that typically involves testing of the serum for the presence of various proteins (HIV and hepatitis B and C antigens) or antibodies (anti-GBM, antiphospholipid, antistreptolysin O [ASO], PLA2R, THSD7A, anti-DNAse, antihyaluronidase, ANCA, anti-DNA, cryoglobulins, anti-HIV, and anti-hepatitis B and C antibodies) or depletion of complement components (C_3 and C_4). The bedside history and physical examination can also help determine whether the glomerulonephritis is isolated to the kidney (*primary glomerulonephritis*) or is part of a systemic disease (*secondary glomerulonephritis*).

When confronted with an abnormal urinalysis and elevated serum creatinine, with or without edema or congestive heart failure, one must consider whether the glomerulonephritis is *acute* or *chronic*. This assessment is best made by careful history (last known urinalysis or serum creatinine during pregnancy or insurance physical, evidence of infection, or use of medication or recreational drugs), the size of the kidneys on ultrasound examination, and how the patient feels at presentation. Chronic glomerular disease often presents with decreased kidney size. Patients who quickly develop kidney failure are fatigued and weak and often have uremic symptoms associated with nausea, vomiting, fluid retention, and somnolence. Primary glomerulonephritis presenting with kidney failure that has progressed slowly, however, can be remarkably asymptomatic, as are patients with acute glomerulonephritis without much loss in kidney function. Once this initial information is collected, selected patients who are clinically stable, have adequate blood clotting parameters, and are willing and able to receive treatment are encouraged to have a kidney biopsy.

KIDNEY PATHOLOGY

A kidney biopsy in the setting of glomerulonephritis quickly identifies the type of glomerular injury and often suggests a course of treatment. The biopsy is processed for light microscopy using stains for *hematoxylin and eosin* (*H&E*) to assess cellularity and architecture, *periodic acid–Schiff* (*PAS*) to stain carbohydrate moieties in the membranes of the glomerular tuft and tubules, *Jones-methenamine silver* to enhance basement membrane structure, *Congo red* for amyloid deposits, and *Masson's trichrome* to identify collagen deposition and assess the degree of glomerulosclerosis and interstitial fibrosis. Biopsies are also processed for direct immunofluorescence using conjugated antibodies against IgG, IgM, and IgA to detect the presence of "lumpy-bumpy" immune deposits or "linear" IgG or IgA antibodies bound to GBM, antibodies against trapped complement proteins (C_3 and C_4), or specific antibodies against a relevant antigen (PLA2R, THSD7A, and DNAJB9). High-resolution electron microscopy can clarify the principal location of immune deposits and the status of the basement membrane.

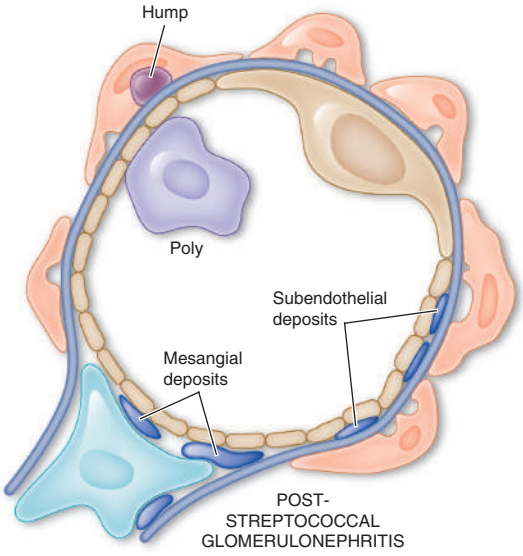
Each region of a kidney biopsy is assessed separately. By light microscopy, glomeruli (ideally 20) are reviewed individually for discrete lesions; <50% involvement is considered *focal*, and >50% is *diffuse*. Injury in each glomerular tuft can be *segmental,* involving a portion of the tuft, or *global,* involving most of the glomerulus. Glomeruli having *proliferative* characteristics show increased cellularity. When cells in the capillary tuft proliferate, it is called *endocapillary*, and when cellular proliferation extends into Bowman's space, it is called *extracapillary. Synechiae* are formed when epithelial podocytes attach to Bowman's capsule in the setting of glomerular injury; *crescents*, which in some cases may be the extension of synechiae, develop when fibrocellular/fibrin collections fill all or part of Bowman's space; and *sclerotic* glomeruli show acellular, amorphous accumulations of proteinaceous material throughout the tuft with loss of functional capillaries and normal mesangium. Since *age-related glomerulosclerosis* is common in adults, one can estimate the background percentage of sclerosis by dividing the patient's age in half and subtracting 10. Immunofluorescent and electron microscopy can detect the presence and location of *subepithelial, subendothelial, or mesangial* immune deposits, or *reduplication* or *splitting* of the basement membrane. In the other regions of the biopsy, the vasculature surrounding glomeruli and tubules can show *angiopathy, vasculitis*, the presence of *fibrils*, or *thrombi*. The tubules can be assessed for adjacency to one another; separation can be the result of edema, tubular dropout, or collagen deposition resulting from interstitial fibrosis. Interstitial fibrosis is an ominous sign of irreversibility and progression to kidney failure.

ACUTE NEPHRITIC SYNDROMES

Acute nephritic syndromes classically present with hypertension, hematuria, red blood cell casts, pyuria, and mild to moderate proteinuria. Extensive inflammatory damage to glomeruli causes a fall in GFR and eventually produces uremic symptoms with salt and water retention, leading to edema and hypertension.

POSTSTREPTOCOCCAL GLOMERULONEPHRITIS

Poststreptococcal glomerulonephritis is prototypical for *acute endocapillary proliferative glomerulonephritis*. The incidence of poststreptococcal glomerulonephritis has dramatically decreased in developed countries, and in these locations is typically sporadic. Acute nephritis in developing countries is epidemic and usually affects children between the ages of 2 and 14 years. In developed countries, it is more typical in the elderly, especially in association with debilitating conditions. It is more common in males, and the familial or cohabitant incidence is as high as 40%. Skin and more commonly throat infections with particular M types of streptococci (nephritogenic strains) antedate glomerular



disease. Antibiotic therapy does not reduce the occurrence of nephritis. Poststreptococcal glomerulonephritis due to pharyngitis develops 1–3 weeks after infection and 2–6 weeks after skin infection.

The kidney biopsy in poststreptococcal glomerulonephritis demonstrates hypercellularity of mesangial and endothelial cells; glomerular infiltrates of polymorphonuclear leukocytes; granular subendothelial immune deposits of IgG, IgM, C_3, C_4, and C_{5-9}; and subepithelial deposits, which appear as "humps" **(see Fig. A4-6)**. **(See Glomerular Schematic 1.)** Poststreptococcal glomerulonephritis is an immune-mediated disease involving putative streptococcal antigens, circulating immune complexes, and activation of the alternate complement pathway in association with cell-mediated injury. Leading candidate antigens from nephritogenic streptococci are a cationic cysteine proteinase known as streptococcal pyrogenic exotoxin B (SPEB) and NAPlr, the nephritis-associated plasmin receptor. The nephritogenic antigen SPEB has been demonstrated inside the subepithelial deposits.

The classic presentation is an acute nephritic picture with hematuria, pyuria, red blood cell casts, edema, hypertension, and oliguric acute kidney injury (AKI), which may be severe enough to appear as RPGN. Systemic symptoms of headache, malaise, anorexia, and flank pain (due to swelling of the renal capsule) are reported in as many as 50% of cases. Five percent of children and 20% of adults have proteinuria in the nephrotic range. In the first week of symptoms, 90% of patients will have a depressed CH_{50} and decreased levels of C_3 with normal levels of C_4. Positive rheumatoid factor (30–40%), cryoglobulins, circulating immune complexes (60–70%), and ANCA against myeloperoxidase (10%) are also reported. Positive cultures for streptococcal infection are inconsistently present (~25%) but the streptozyme test is positive in 80–95% of patients and includes antibodies to ASO, anti-DNAse, Altase, ASKase, and anti-NAD. Consequently, the diagnosis of poststreptococcal glomerulonephritis rarely requires a kidney biopsy. A subclinical disease is reported in some series to be 4–5 times as common as clinical nephritis, and these latter cases are characterized by asymptomatic microscopic hematuria with low serum C_3 complement levels.

Treatment is supportive, with control of hypertension, edema, and dialysis as needed. Antibiotic treatment for active streptococcal infection should be given to patients and their cohabitants. There is no role for immunosuppressive therapy, even in the setting of crescents. Recurrent poststreptococcal glomerulonephritis is rare despite repeated streptococcal infections. Early death is rare in children but does occur in the elderly. Complete resolution of the azotemia, hematuria, and proteinuria in the majority of children occurs within 3–6 weeks of the onset of nephritis, but 3–10% of children may have persistent microscopic hematuria, non-nephrotic proteinuria, or hypertension. Overall, the prognosis is good, with ESKD being very uncommon in children and adults. The prognosis in elderly patients is worse, with a high incidence of azotemia (up to 60%), nephrotic-range proteinuria, and ESKD.

Glomerular schematic 1

SUBACUTE BACTERIAL ENDOCARDITIS

Endocarditis-associated glomerulonephritis is typically a complication of SBE, particularly in patients who remain untreated for a long time, have negative blood cultures, or have right-sided endocarditis. Common comorbidities are valvular heart disease, intravenous drug use, hepatitis C, and diabetes mellitus. Glomerulonephritis is unusual in acute bacterial endocarditis because it takes 10–14 days to develop immune complex–mediated injury, by which time the patient has been treated, often with emergent surgery. Grossly, the kidneys in SBE have subcapsular hemorrhages with a "flea-bitten" appearance, and kidney biopsy reveals focal or diffuse proliferation with C3 (94%), IgG, and IgA staining, as well as mesangial, subendothelial, and subepithelial immune deposits. Commonly patients present with a clinical picture of RPGN and have crescents on biopsy. Embolic infarcts or septic abscesses may also be present. The pathogenesis hinges on the deposition of circulating immune complexes in the kidney with complement activation. Patients present with gross or microscopic hematuria, pyuria, and mild proteinuria, acute kidney injury, or RPGN with rapid loss of kidney function. A normocytic anemia, elevated erythrocyte sedimentation rate, hypocomplementemia, high titers of rheumatoid factor, type III cryoglobulins, circulating immune complexes, and ANCAs may be present. Levels of serum creatinine may be elevated at diagnosis, but with modern therapy, there is little progression to chronic kidney disease. Primary treatment is eradication of the infection with 4–6 weeks of antibiotics, and if accomplished expeditiously, the prognosis for kidney recovery is good. ANCA-associated vasculitis sometimes accompanies or is confused with SBE and should be ruled out, as the treatment is different.

As variants of persistent bacterial infection in blood-associated glomerulonephritis, infection-associated glomerulonephritis can occur in patients with ventriculoatrial and ventriculoperitoneal shunts; pulmonary, intraabdominal, pelvic, or cutaneous infections; and infected vascular prostheses. In developed countries, a significant proportion of cases afflict adults, especially the immunocompromised, and the predominant organism is *Staphylococcus*. The clinical presentation of these conditions is variable and includes proteinuria, microscopic hematuria, acute kidney injury, and hypertension. Serum complement levels are low, and there may be elevated levels of C-reactive proteins, rheumatoid factor, antinuclear antibodies, and cryoglobulins. Biopsy findings include membranoproliferative glomerulonephritis (MPGN), diffuse proliferative and exudative glomerulonephritis (DPGN), or mesangioproliferative glomerulonephritis, sometimes leading to RPGN. Treatment focuses on eradicating the infection, with most patients treated as if they have endocarditis. The prognosis is guarded.

LUPUS NEPHRITIS

Lupus nephritis is a common and serious complication of systemic lupus erythematosus (SLE). Clinical manifestations of kidney disease are present in 30% of patients at the time of diagnosis, and the majority will develop kidney abnormalities in the course of their disease. Lupus nephritis results from the deposition of circulating immune complexes composed of primarily DNA and anti-DNA, which activate the complement cascade, leading to complement-mediated damage, leukocyte infiltration, activation of procoagulant factors, and release of various cytokines. In situ immune complex formation also plays a role in kidney injury. These immune deposits may occur in the mesangial, subendothelial, and/or subepithelial spaces.

The clinical manifestations, course of disease, and treatment of lupus nephritis are closely linked to kidney pathology. The most common clinical sign of kidney disease is proteinuria, but hematuria, hypertension, varying degrees of kidney injury, and active urine sediment with red blood cell casts can all be present. Anti-dsDNA antibodies that fix complement correlate best with the presence of kidney disease. Hypocomplementemia is common in patients with acute lupus nephritis (70–90%), and declining complement levels may

TABLE 326-3 Classification for Lupus Nephritis

Class I	Minimal mesangial	Normal histology with mesangial deposits
Class II	Mesangial proliferation	Mesangial hypercellularity with expansion of the mesangial matrix
Class III	Focal nephritis	Focal endocapillary ± extracapillary hypercellularity with focal subendothelial immune deposits and mild mesangial expansion ± fibrinoid necrosis
Class IV	Diffuse nephritis	Diffuse endocapillary ± extracapillary hypercellularity with diffuse subendothelial immune deposits and mesangial alterations ± crescents ± fibrinoid necrosis
Class V	Membranous nephritis	Thickened basement membranes with diffuse subepithelial immune deposits; may occur with class III or IV lesions and is sometimes called mixed membranous and proliferative nephritis
Class VI	Sclerotic nephritis	Global sclerosis of nearly all glomerular capillaries

Note: Revised in 2004 by the International Society of Nephrology-Renal Pathology Society Study Group. Recommendation for revision 2018.

herald a flare. A kidney biopsy should be performed in most patients with kidney involvement to establish the histologic subtype, which guides therapy.

The World Health Organization (WHO) workshop in 1974 first outlined several distinct patterns of lupus-related glomerular injury, and this classification was modified in 2004. This version with ongoing refinement **(Table 326-3)** forms the basis for treatment recommendations. Class I nephritis describes normal glomerular histology by normal light microscopy with minimal mesangial deposits on immunofluorescent or electron microscopy. Class II designates mesangial immune complexes with *mesangial proliferation*. Both class I and II lesions are typically associated with minimal kidney manifestation and normal kidney function; nephrotic syndrome is rare. Patients with lesions limited to the renal mesangium have an excellent prognosis and need little or no therapy for their lupus nephritis.

The subject of lupus nephritis is presented under acute nephritic syndromes because of the aggressive and important proliferative lesions seen in class III–V kidney diseases **(see Figs. A4-14 and A4-15)**. Class III describes *focal lesions involving <50% of the glomeruli with proliferation or scarring*, often involving only a segment of the glomerulus. Class III lesions have the most varied course. Hematuria and proteinuria are present, and some patients also have an active urinary sediment, nephrotic syndrome, hypertension, and a decreased GFR. Patients with mild proliferation involving a small percentage of glomeruli respond well to therapy with steroids alone, and <5% progress to kidney failure over 5 years. Patients with more severe proliferation involving a greater percentage of glomeruli or include fibrinoid necrosis have a far worse prognosis and lower remission rates. Treatment of those patients is the same as that for class IV lesions. Class IV describes *diffuse lesions with >50% of the glomeruli involved and proliferative endocapillary lesions with or without extracapillary lesions that may be segmental (IV-S), involving <50% of the glomerular tuft, or global (IV-G), involving >50%.* Patients with class IV lesions commonly have high anti-DNA antibody titers, low serum complement, hematuria, red blood cell casts, proteinuria, hypertension, and decreased kidney function; 50% of patients have nephrotic-range proteinuria. Patients with crescents on biopsy often have a rapidly progressive decline in kidney function. Without treatment, this aggressive lesion has the worst kidney prognosis, with class IV-S worse than class IV-G. However, if a remission—defined as a return to near-normal kidney function and proteinuria ≤330 mg/dL per day—is achieved with treatment, kidney outcomes are excellent. Inducing a remission with administration of high-dose steroids and either cyclophosphamide or mycophenolate mofetil for 2–6 months, followed by maintenance therapy with lower doses of steroids and mycophenolate mofetil or azathioprine, best balances the likelihood of successful remission with the side effects of therapy. Voclosporin may also be used in combination with steroids and mycophenolate mofetil in patients with focal or diffuse lupus nephritis. Belimumab can also be added to standard maintenance therapy. There is no consensus on use of high-dose intravenous methylprednisolone versus oral prednisone, monthly intravenous cyclophosphamide versus daily oral cyclophosphamide, or other immunosuppressants such as cyclosporine, tacrolimus, or rituximab. Prolonged use of cyclophosphamide is avoided in patients of childbearing age.

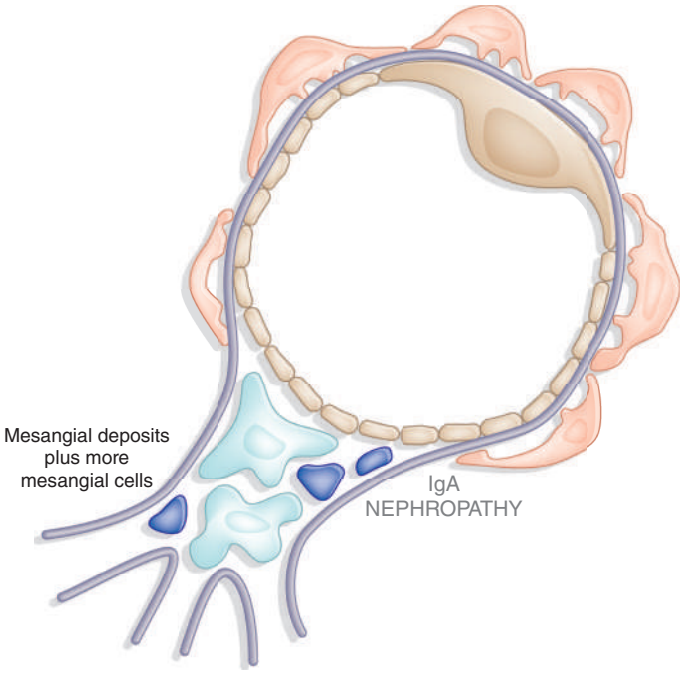
The class V lesion describes subepithelial immune deposits producing a *membranous pattern*; a subcategory of class V lesions is associated with proliferative lesions and is sometimes called *mixed membranous and proliferative disease* **(see Fig. A4-14)**; this category of injury is treated like class IV glomerulonephritis. Sixty percent of patients present with nephrotic syndrome or lesser amounts of proteinuria. Patients with lupus nephritis class V, like patients with primary membranous nephropathy, are predisposed to renal vein thrombosis and other thrombotic complications. A minority of patients with class V will present with hypertension and kidney dysfunction. There are conflicting data on the clinical course, prognosis, and appropriate therapy for patients with class V disease, which may reflect the heterogeneity of this group of patients. Patients with severe nephrotic syndrome, elevated serum creatinine, and a progressive course will probably benefit from therapy with steroids in combination with other immunosuppressive agents. Therapy with inhibitors of the renin-angiotensin system also may attenuate the proteinuria. Antiphospholipid antibodies present in lupus may result in glomerular microthromboses and a thrombotic microangiopathy. The kidney prognosis is worse despite anticoagulant therapy.

Patients with any of the above lesions also can transform to another lesion; hence, patients often require reevaluation, including repeat kidney biopsy. Lupus patients with class VI lesions have >90% *sclerotic glomeruli* and ESKD with interstitial fibrosis. Up to 20% of patients with lupus nephritis will reach end-stage disease, requiring dialysis or transplantation. Patients with lupus nephritis have a markedly increased mortality compared with the general population. Kidney transplantation usually performed after ~6 months of inactive disease results in allograft survival rates comparable to patients transplanted for other reasons.

ANTIGLOMERULAR BASEMENT MEMBRANE DISEASE

Patients who develop autoantibodies directed against glomerular basement antigens frequently develop a glomerulonephritis termed *anti-glomerular basement membrane* (*anti-GBM*) *disease*. When they present with lung hemorrhage and glomerulonephritis, they have a pulmonary-renal syndrome called *Goodpasture's syndrome*. The target epitopes for this autoimmune disease lie in the quaternary structure of α3 NC1 domain of collagen IV. Indeed, anti-GBM disease may be considered an autoimmune "conformeropathy" that involves the perturbation of quaternary structure of the α 345NC1 hexamer. MHC-restricted T cells initiate the autoantibody response because humans are not tolerant to the epitopes created by this quaternary structure. The epitopes are normally sequestered in the collagen IV hexamer and can be exposed by infection, smoking, oxidants, or solvents. Goodpasture's syndrome is rare and appears in two age groups: in young men in their late twenties and in men and women in their sixties and seventies. Younger patients are more likely to present with the full Goodpasture's syndrome, with hemoptysis, a sudden fall in hemoglobin, fever, dyspnea, and hematuria, and older patients are more likely to present with isolated glomerulonephritis. Those who present with lung hemorrhage as a group do better than older populations who have prolonged, asymptomatic kidney injury; presentation with oliguria is often associated with a particularly bad outcome. The performance of an urgent kidney biopsy is important in suspected cases of Goodpasture's syndrome to confirm the diagnosis and assess prognosis. Kidney biopsies typically show *focal or segmental necrosis* that later, with aggressive destruction of the capillaries by cellular proliferation, leads to crescent formation in Bowman's space **(see Fig. A4-17)**. As these lesions progress, there is concomitant interstitial nephritis with fibrosis and tubular atrophy.

The presence of anti-GBM antibodies and complement is recognized on biopsy by linear immunofluorescent staining for IgG (rarely IgA). In testing serum for anti-GBM antibodies, it is particularly important that the α3 NC1 domain of collagen IV alone be used as the target. This is because non-nephritic antibodies against the α1 NC1 domain are seen in paraneoplastic syndromes and cannot be discerned from assays that use whole basement membrane fragments as the binding target. Between 10 and 15% of sera from patients with Goodpasture's syndrome also contain ANCA antibodies against myeloperoxidase. Prognosis at presentation is worse if there are >50% crescents on kidney biopsy with advanced fibrosis, if serum creatinine is >5–6 mg/dL, if oliguria is present, or if there is a need for acute dialysis. Patients who present with hemoptysis should be treated for their lung hemorrhage, as it responds to plasmapheresis. Treated patients with less severe disease typically respond to 8–10 treatments of plasmapheresis accompanied by oral prednisone and cyclophosphamide. Maintenance therapy with low-dose immunosuppressants should be considered until antibody titers are negative. There are scarce data alternatively using rituximab or mycophenolate mofetil. Kidney transplantation should wait for 6 months and until serum antibodies are undetectable.



IgA NEPHROPATHY

Berger first described the glomerulonephritis now termed *IgA nephropathy*. It is classically characterized by episodic hematuria associated with the deposition of IgA in the mesangium. IgA nephropathy is one of the most common forms of glomerulonephritis worldwide. There is a male preponderance, a peak incidence in the second and third decades of life, and rare familial clustering. There are geographic differences in the prevalence of IgA nephropathy, with 30-45% prevalence along the Asian and Pacific Rim and 20% in southern Europe, compared to 10% in northern Europe and North America. This may reflect variation in detection or a true variation among racial and ethnic groups.

IgA nephropathy is predominantly a sporadic disease, but susceptibility to it has been shown uncommonly to have a genetic component depending on geography and the existence of "founder effects." No single causal gene has been identified. Clinical and laboratory evidence suggests close similarities between IgA vasculitis (formerly called Henoch-Schonlein purpura) and IgA nephropathy. IgA vasculitis is distinguished clinically from IgA nephropathy by prominent systemic symptoms, a younger age (<20 years old), preceding infection, and abdominal complaints. Deposits of IgA are also found in the glomerular mesangium in a variety of systemic diseases, including chronic liver disease, Crohn's disease, celiac disease, chronic bronchiectasis, idiopathic interstitial pneumonia, dermatitis herpetiformis, mycosis fungoides, ankylosing spondylitis, HIV infection, and Sjögren's syndrome. IgA deposition in these entities is not usually associated with clinically significant kidney disease. IgA-dominant *Staphylococcus*-associated infectious glomerulonephritis is associated with clinically significant kidney disease.

The pathognomonic finding on kidney biopsy is dominant or codominant mesangial IgA deposits, either alone or with IgG, IgM, or complement. **(See Glomerular Schematic 2.)** IgA deposits are typically J-chain containing polymeric IgA1. Abnormalities in the *O*-glycosylation of the hinge region of primarily polymeric IgA1 seem to best account for the pathogenesis. Synthesis of poorly galactosylated IgA1 results in exposure of *N*-acetyl-galactosamine in truncated IgA1 hinge regions, which is recognized by IgG or IgA1 antibodies leading to formation of immune complexes in the circulation or in situ after glomerular deposition of galactose-deficient IgA1 activating the complement system through the alternative and lectin pathways. Viral or other antigen exposure, or hereditary defects in alternative complement pathway proteins may affect the manifestation of disease. Despite the presence of elevated serum IgA levels in 20–50% of patients and IgA deposition in skin biopsies in 15–55% of patients, a kidney biopsy is necessary to confirm the diagnosis. Although the immunofluorescent pattern of IgA on kidney biopsy defines IgA nephropathy in the proper clinical context, a variety of histologic lesions may be seen on light microscopy **(see Fig. A4-8)**, including DPGN; *segmental sclerosis*; and, rarely, *segmental necrosis with cellular crescent formation*, which typically presents as RPGN.

Glomerular schematic 2

The two most common presentations of IgA nephropathy are persistent asymptomatic microscopic hematuria and recurrent episodes of macroscopic hematuria during or immediately following an upper respiratory infection, often accompanied by proteinuria. Nephrotic syndrome is uncommon. Proteinuria can also first appear late in the course of the disease. Rarely, patients present with acute kidney failure and a rapidly progressive clinical picture. IgA nephropathy can be a benign disease with some patients going into complete remission while others may have ongoing hematuria but well-preserved kidney function. Slow progression to ESKD is seen in only 25–30% of patients over 20–25 years. This risk varies considerably among populations. Cumulatively, risk factors for the loss of kidney function identified thus far account for <50% of the variation in observed outcome but include the presence of hypertension or proteinuria, the absence of episodes of macroscopic hematuria, male sex, and older age of onset. Mesangial hypercellularity (M), endocapillary hypercellularity (E), segmental glomerulosclerosis (S), tubular interstitial fibrosis (T), and crescents (C) have predictive value as established by the Oxford Classification and the MEST-C score. Several analyses in large populations of patients found persistent proteinuria for 6 months or longer to have the greatest predictive power for adverse kidney outcomes.

There is no agreement on optimal treatment. Both large studies that include patients with multiple glomerular diseases and small studies of patients with IgA nephropathy support the use of angiotensin-converting enzyme (ACE) inhibitors in patients with proteinuria or declining kidney function. Steroid treatment or other immunosuppressives have demonstrated conflicting results. An oral targeted-release formulation of budesonide has been shown to reduce proteinuria and improve preserved kidney function in patients with risk of rapid progression. In preliminary studies the sodium-glucose transport-2 inhibitor (SGLT2i) dapagliflozin and the endothelin antagonist sparsentan have reduced adverse kidney outcomes. Tonsillectomy and fish oil have also been suggested in small studies to benefit select patients. When presenting as RPGN, patients typically receive steroids, cytotoxic agents, and plasmapheresis.

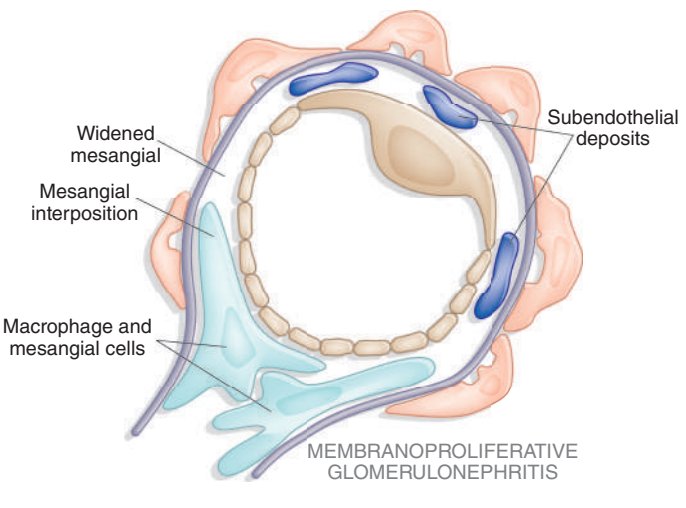
ANCA SMALL-VESSEL VASCULITIS

A group of patients with small-vessel vasculitis (arterioles, capillaries, and venules; rarely small arteries) and glomerulonephritis have circulating antineutrophil cytoplasmic autoantibodies (ANCAs); the most common antigen targets are proteinase 3 (PR3) and myeloperoxidase

(MPO) **(Chap. 375)**. ANCA are produced with the help of T cells and activate leukocytes and monocytes, which together damage the walls of small vessels. Endothelial injury also attracts more leukocytes and extends the inflammation. Granulomatosis with polyangiitis (GPA), microscopic polyangiitis (MPA), eosinophilic granulomatosis with polyangiitis (EGPA), and renal-limited vasculitis belong to this group because they are associated with ANCAs and have a *pauci-immune glomerulonephritis* given the absence or paucity of immune complex deposition. Patients with any of these diseases can have any combination of the above serum antibodies, but anti-PR3 antibodies are more common in GPA, and anti-MPO antibodies are more common in MPA or EGPA. Although each of these diseases has some unique clinical features, most features do not predict relapse or progression, and as a group, they are generally treated in the same way. Targeted determination of ANCA levels may be useful in monitoring response to therapy or if a relapse is clinically suspected. Since mortality is high without treatment, virtually all patients receive urgent treatment. Induction therapy usually includes glucocorticoids and either cyclophosphamide or rituximab. Plasmapheresis remains controversial but is generally recommended in rapidly progressive kidney failure or pulmonary hemorrhage, or with concomitantly positive anti-GBM antibodies. Remission is induced in 75–90% of patients, but clinical relapse is common (25–50%). There is evidence to support a reduced dose corticosteroid regimen with discontinuation at 16 weeks recommended. Additionally, novel complement antagonists may have a role as steroid sparing agents. Maintenance therapy is recommended for up to 1–2 years following remission and includes cyclophosphamide or rituximab, or in certain circumstances azathioprine or methotrexate.

Granulomatosis with Polyangiitis Patients with this disease classically present with fever, purulent rhinorrhea, nasal ulcers, sinus pain, polyarthralgias/arthritis, cough, hemoptysis, shortness of breath, hematuria, and subnephrotic proteinuria; occasionally, there may be cutaneous purpura and mononeuritis multiplex. Patients may present without kidney involvement, although most of these patients develop kidney injury later. Chest x-ray often reveals nodules and persistent infiltrates, sometimes with cavities. Biopsy of involved tissue will show a small-vessel vasculitis and adjacent noncaseating granulomas. Kidney biopsies during active disease demonstrate *segmental necrotizing glomerulonephritis* without immune deposits and have been classified as focal, mixed, crescentic, or sclerotic **(see Fig. A4-16)**. The disease is more common in patients exposed to silica dust and those with α_1-antitrypsin deficiency, which is an inhibitor of PR3. Relapse after achieving remission is common and is more common in patients with GPA than the other ANCA-associated vasculitis, necessitating diligent follow-up care. Although associated with an unacceptable high mortality rate without treatment, the greatest threat to patients is from adverse events often secondary to treatment rather than active vasculitis; this is particularly true in elderly patients in the first year of therapy. Patients should also be monitored long term for malignancy after immunosuppressive therapy.

Microscopic Polyangiitis Clinically, these patients present similarly to GPA, except they rarely have significant lung disease or destructive sinusitis. The distinction is made on biopsy, where the vasculitis in MPA is without granulomas. Some patients will also have injury limited to the capillaries and venules.



Eosinophilic Granulomatosis with Polyangiitis When small-vessel vasculitis is associated with peripheral eosinophilia, cutaneous purpura, mononeuritis, asthma, and allergic rhinitis, a diagnosis of EGPA is considered. Hypergammaglobulinemia, elevated levels of serum IgE, or the presence of rheumatoid factor sometimes accompanies the allergic state. Lung inflammation, including fleeting cough and pulmonary infiltrates, often precedes the systemic manifestations of disease by years; lung manifestations are rarely absent. A third of patients may have exudative pleural effusions associated with eosinophils. Small-vessel vasculitis and *focal segmental necrotizing glomerulonephritis* without immune deposits can be seen on kidney biopsy, usually absent of eosinophils or granulomas. The cause of is thought to be abnormal immune function, but the inciting factors are unknown.

C_3 GLOMERULOPATHIES

C_3 glomerulopathy is a recent disease classification that is defined by the glomerular accumulation of C_3 with little or no immunoglobulin and encompasses dense deposit disease (DDD), formerly MPGN type II (see below), and C_3 glomerulonephritis (C_3GN). DDD is defined morphologically by dense deposits forming ribbons in the GBM. In the absence of this specific morphology, the entity is categorized as C_3GN. Both are associated with the presence of a complement mutation believed to cause the kidney pathology, including mutations in the complement factor H regulatory (CFHR) protein genes. DDD is primarily a disease of children and young adults, whereas the other C_3 glomerulopathies are reported to present in an older age group (mean age 30). By definition, kidneys with C_3 glomerulopathy show sole or dominant staining for C_3 but can have variable light microscopy, with mesangial proliferative or membranoproliferative patterns seen most commonly. Morphologically, many cases are not distinguishable from recovering postinfectious glomerulonephritis. Low serum C3 and a dense thickening of the GBM containing ribbons of dense despits and C3 characterize DDD **(see Fig. A4-10)**. Patients with DDD present with proteinuria, which may be nephrotic range, and/or hematuria, which may be macroscopic or microscopic. Partial lipodystrophy and Drusen bodies in the retina may also be present. Prognosis is poor, with 50% of patients progressing to ESKD. C_3GN patients are clinically less well defined, but approximately two-thirds have hematuria and one-third have proteinuria. C_3 levels are low with normal C_4, and C_3 nephritic factor is present in most patients with DDD and less commonly in C_3GN. Abnormalities in factor H, soluble C5b-9, paraprotein detection, and specific CFHR genetic mutations should be assessed as well. Screening family members may be indicated. The optimal therapies remain undefined but include inhibition of the renin-angiotensin system, lipid lowering, steroids, and other immunosuppressants. Evidence suggests a benefit of therapy with eculizumab, a monoclonal antibody directed at C_5, which is activated by C_3.

MEMBRANOPROLIFERATIVE GLOMERULONEPHRITIS

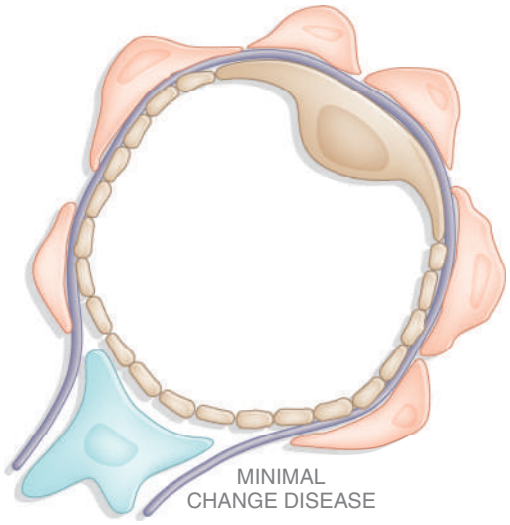
MPGN has been previously identified as a disease with the classification MPGN types I, II, and III; however, it is now considered a pattern of glomerular injury characterized by mesangial and subendothelial immune complexes, complement deposits and/or monoclonal protein deposits, or chronic endothelial cell injury. In addition to increased mesangial and endocapillary hypercellularity, there are thickened GBM's with interposition of cellular elements between the endothelial cell and the GBM creating double contours, sometimes call "tram-tracking" **(see Fig. A4-9). (See Glomerular Schematic 3.)** The MPGN pattern of injury can be seen with immune complex mediated diseases

including cryoglobulinemia, infection associated GN, and hepatitis C and B; complement mediated diseases including inherited or acquired dysregulation of complement (see C3G Glomerulopathies); and monoclonal immunoglobulin mediated diseases including light and heavy chain deposition diseases. The MPGN pattern of injury can be seen with unusual deposits as well including fibrillary glomerulonephritis. Each of these diseases have distinct findings on biopsy, natural history and treatments.

MESANGIOPROLIFERATIVE GLOMERULONEPHRITIS

Mesangioproliferative glomerulonephritis is characterized by expansion of the mesangium, sometimes associated with mesangial hypercellularity; thin, single contoured capillary walls; and mesangial immune deposits. Mesangioproliferative pathology may be seen in IgA nephropathy, *Plasmodium falciparum* malaria, resolving postinfectious glomerulonephritis, and class II nephritis from lupus, all of which can have a similar histologic appearance. With these secondary entities excluded, the diagnosis of *primary mesangioproliferative glomerulonephritis* is made in <15% of kidney biopsies.

NEPHROTIC SYNDROME



Nephrotic syndrome classically presents with heavy proteinuria, minimal hematuria, hypoalbuminemia, hypercholesterolemia, edema, and hypertension. If left undiagnosed or untreated, some of these syndromes will progressively damage enough glomeruli to cause a fall in GFR, producing kidney failure. Multiple studies have noted that the higher the 24-h urine protein excretion, the more rapid is the decline in GFR.

Therapies for various causes of nephrotic syndrome are noted under individual disease headings below. In general, all patients with hypercholesterolemia secondary to nephrotic syndrome should be treated with lipid-lowering agents because they are at increased risk for cardiovascular disease. Edema secondary to salt and water retention can be controlled with the use of diuretics, avoiding intravascular volume depletion. Venous complications secondary to the hypercoagulable state associated with nephrotic syndrome can be treated with anticoagulants. The losses of various serum binding proteins, such as thyroid-binding globulin, lead to alterations in functional tests. Lastly, proteinuria itself is hypothesized to be nephrotoxic, and treatment of proteinuria with inhibitors of the renin-angiotensin system and SGLT2i can lower urinary protein excretion and preserve kidney function across a wide range of chonic kidney diseases.

MINIMAL CHANGE DISEASE

MCD, sometimes known as *nil lesion,* causes 70–90% of nephrotic syndrome in childhood but only 10–15% of nephrotic syndrome in adults. MCD usually presents as a primary kidney disease but can be associated with several conditions, including Hodgkin's disease, allergies, use of nonsteroidal anti-inflammatory agents or lithium, infections, and other glomerular diseases. MCD on kidney biopsy shows no glomerular lesion by light microscopy and is negative for deposits by immunofluorescent microscopy or occasionally shows small amounts of IgM in the mesangium **(see Fig. A4-1). (See Glomerular Schematic 4.)** Electron microscopy, however, consistently demonstrates an effacement of the foot processes supporting the epithelial podocytes with weakening of slit-pore membranes. The pathogenesis of this lesion is unclear, although immune dysfunction is likely the initiating factor for MCD. Disturbances in T cell response may result in circulating glomerular permeability factors which directly affect the glomerular capillary wall, postulated to be T cell derived cytokines, such as IL13 and IL4. There is also evidence of increased CD80 on podocytes, promoting dysregulated interactions with T cells via T lymphocyte antigen-4 (CLTA-4). Other evidence supporting cell-mediated immunity includes the presence of preceding allergies, altered cell-mediated immunity during viral infections, and a high frequency of remissions with steroids. Evidence to suggest that there is a role for B cell dysfunction includes reports of patients with anti-nephrin antibodies and the successful treatment with the anti-CD20 monoclonal antibody, rituximab.

Glomerular schematic 4

MCD presents clinically with the abrupt onset of edema and nephrotic syndrome accompanied by acellular urinary sediment. Average urine protein excretion reported in 24 h is 10 g with severe hypoalbuminemia. Less common clinical features include hypertension (30% in children, 20–50% in adults), microscopic hematuria (20% in children, 33% in adults), atopy or allergic symptoms (40% in children, 30% in adults), and decreased kidney function (25–40%), which often returns to normal after remission of the nephrotic syndrome. The appearance of acute kidney failure in adults is often seen more commonly in patients with low serum albumin and intrarenal edema (nephrosarca) that is responsive to diuretics. This presentation must be distinguished from acute kidney failure secondary to hypovolemia. Acute tubular necrosis and interstitial inflammation are also reported. In children, the abnormal urine principally contains albumin with minimal amounts of higher-molecular-weight proteins and is sometimes called *selective proteinuria*. Although up to 30% of children have a spontaneous remission, most children today are treated with steroids; only children who are nonresponders are biopsied. Primary responders are patients who have a complete remission (<0.2 mg/24 h of proteinuria), often abruptly after a single course of prednisone; steroid-dependent patients relapse as their steroid dose is tapered. Frequent relapsers have two or more relapses in the 6 months following taper, and steroid-resistant patients fail to respond to steroid therapy. Adults are not considered steroid-resistant until after 4 months of therapy. Ninety to 95% of children will develop a complete remission after 8 weeks of steroid therapy, and 80–90% of adults will achieve complete remission, but the response is more delayed. Patients with steroid resistance may have FSGS on repeat biopsy. If the first kidney biopsy does not have a sample of deeper corticomedullary glomeruli, then the correct diagnosis of FSGS may be missed.

Relapses occur in 70–75% of children after the first remission, and early relapse predicts multiple subsequent relapses, as do high levels of basal proteinuria. The frequency of relapses decreases after puberty. Relapses are less common in adults but are more resistant to subsequent therapy. Prednisone is first-line therapy. Other immunosuppressive drugs, such as cyclophosphamide, mycophenolate mofetil, calcineurin inhibitors (CNIs), and rituximab are reserved for frequent relapsers, steroid-dependent patients, or steroid-resistant patients. CNIs can induce remission, but relapse is also common when withdrawn. The long-term prognosis in adults is less favorable when acute kidney failure or steroid resistance occurs.

FOCAL SEGMENTAL GLOMERULOSCLEROSIS

FSGS refers to a pattern of kidney injury characterized by segmental glomerular scars that involve some but not all glomeruli (focal); the clinical findings of FSGS largely manifest as proteinuria. When the secondary and genetic causes of FSGS are eliminated **(Table 326-4)**, the remaining patients are considered to have primary FSGS. FSGS

TABLE 326-4 Focal Segmental Glomerulosclerosis

Primary focal segmental glomerulosclerosis
Yet to be identified circulating permeable factor
Secondary focal segmental glomerulosclerosis
Adaptive response to hyperfiltration/reduced kidney mass, obesity
Viruses: HIV/hepatitis B/parvovirus/SARS-CoV-2
Hypertensive nephropathy
Reflux nephropathy
Cholesterol emboli
Drugs: Heroin/analgesics/bisphosphonates/ecstasy/interferon/anabolic steroids
Oligomeganephronia
Sickle cell disease
Radiation nephritis
Familial podocytopathies
NPHS1 mutation/nephrin
NPHS2 mutation/podocin
PLCE1 mutation/phospholipase Cε1
INF2 mutation/inverted formin 2
WT1 mutation/Wilms tumor
TRPC6 mutation/cation channel
ACTN4 mutation/actinin
α-Galactosidase A deficiency/Fabry's disease
N-Acetylneuraminic acid hydrolase deficiency/nephrosialidosis
Uncertain cause

is now recognized as the most common cause of primary glomerular disease in patients with ESKD in the US. The pathogenesis of FSGS has multiple possible mechanisms including a circulating permeability factor (primary FSGS), an adaptive response to glomerular hypertrophy or hyperfiltration, and podocyte abnormalities associated with direct toxic injury or genetic mutations. Risk polymorphisms at the *APOL1* locus expressed in podocytes are thought to predispose patients to FSGS.

The pathologic changes of FSGS are most prominent in glomeruli located at the corticomedullary junction **(see Fig. A4-2)**, so if the kidney biopsy specimen is from superficial tissue, the lesions can be missed, which sometimes leads to a misdiagnosis of MCD. The most frequent variant is FSGS not otherwise specified (NOS), previously called classic FSGS, which may occur in primary or secondary FSGS. In addition to focal and segmental scarring, other variants have been described, including *cellular* lesions with endocapillary hypercellularity and heavy proteinuria; *collapsing glomerulopathy* **(see Fig. A4-3)** with segmental or global glomerular collapse and a rapid decline in kidney function; a *perihilar* lesion **(see Fig. A4-4)**; or the *glomerular tip* lesion **(see Fig. A4-5)**, which is usually steroid responsive and has a favorable prognosis. **(See Glomerular Schematic 5.)**

FSGS can present with hematuria, hypertension, any level of proteinuria, and kidney injury. Nephrotic-range proteinuria and kidney injury are associated with a poor outcome, with 50% of patients reaching ESKD in 10 years. FSGS rarely remits spontaneously, but treatment-induced remission of proteinuria significantly improves prognosis. Treatment of patients with *FSGS* should include inhibitors of the renin-angiotensin system and SGLT2i. Patients with primary FSGS with nephrotic-range proteinuria can be treated with steroids but respond far less often and after a longer course of therapy than patients with MCD. Proteinuria remits in only 20–45% of patients receiving a course of steroids over 6–12 months. CNIs have been used in patients requiring a steroid sparing regimen. Limited evidence suggests the use of cyclosporine in steroid-responsive patients helps ensure remissions. Relapse frequently occurs after cessation of cyclosporine therapy, and CNIs themselves can lead to a deterioration of kidney function due to their nephrotoxic effects. A role for other agents that suppress the immune system such as rituximab or mycophenolate mofetil has not

Glomerular schematic 5

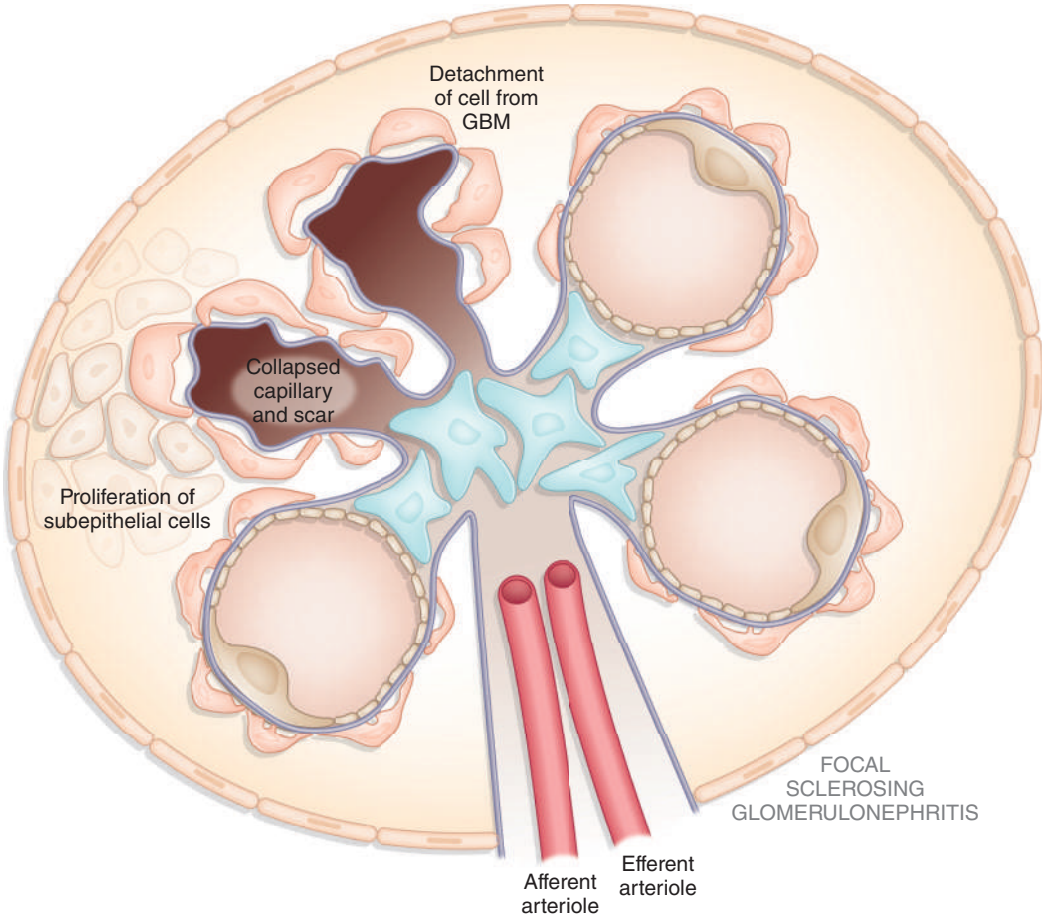


TABLE 326-5 Membranous Glomerulonephritis

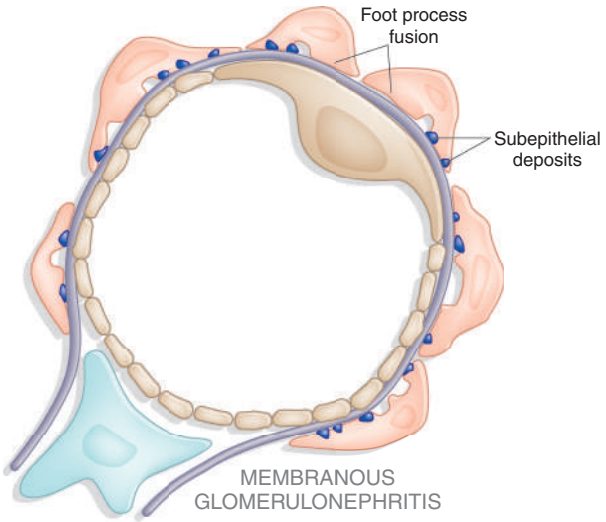
Primary/antigen-associated membranous glomerulonephritis
PLA2R, NELL1, THSD7A, Sema3B, PCDH7, HTRA1, EXT1, EXT2, NCAM1
Secondary membranous glomerulonephritis
Infection: Hepatitis B and C, syphilis, malaria, schistosomiasis, leprosy, filariasis
Cancer: Breast, colon, lung, stomach, kidney, esophagus, neuroblastoma
Drugs: Gold, mercury, penicillamine, nonsteroidal anti-inflammatory agents, probenecid, antitumor necrosis factor agents
Autoimmune diseases: Systemic lupus erythematosus, rheumatoid arthritis, primary biliary cirrhosis, dermatitis herpetiformis, bullous pemphigoid, myasthenia gravis, Sjögren's syndrome, Hashimoto's thyroiditis, IgG4 disease
Other systemic diseases: Fanconi's syndrome, sickle cell anemia, diabetes, Crohn's disease, sarcoidosis, Guillain-Barré syndrome, Weber-Christian disease, angiofollicular lymph node hyperplasia

Abbreviations: PLA2R, phospholipase A2 receptor; EXT1 and EXT2, exostosin 1 and 2; NCAM1, neural cell adhesion molecule 1; NELL1, neural epidermal growth factor-like 1; PCDH7, protocadherin 7; *Sema3B,* semaphorin 3B; THSD7A, thrombospondin type-1 domain containing 7A.

been established. FSGS recurs in 30% of kidney transplants, more commonly in primary FSGS, less commonly in secondary FSGS, and rarely in genetic FSGS. In recurrent posttransplant FSGS from presumed circulating factor, many patients will achieve a full or partial remission with plasmapheresis. The treatment of *secondary FSGS* typically involves treating the underlying cause and controlling proteinuria. There is no role for steroids or other immunosuppressive agents in secondary or genetic FSGS.

MEMBRANOUS GLOMERULONEPHRITIS



MGN, or *membranous nephropathy* as it is sometimes called, accounts for ~25% of cases of nephrotic syndrome in adults, with a peak incidence between the ages of 30 and 50 years and a male-to-female ratio of 2:1. MGN is most often primary in the absence of an identifiable associated disease, but with the identification of novel associated antigens **(see Table 326-5)**, this nomenclature may change particularly in children in whom these antigens are increasingly found. In 20–30% of cases, MGN is secondary and is associated with a malignancy (solid tumors of the breast, lung, colon), infection (hepatitis B, syphilis, malaria, schistosomiasis), rheumatologic disorders such as lupus or rheumatoid arthritis, IgG4 diseases, or drug exposure (see Table 326-5).

Uniform thickening of the basement membrane along the peripheral capillary loops is seen by light microscopy on kidney biopsy **(see Fig. A4-7)**; this thickening needs to be distinguished from that seen in diabetes and amyloidosis. **(See Glomerular Schematic 6.)** There may be characteristic "spikes" seen on silver stain due to the glomerular basement membrane reactivity to deposits. Immunofluorescence demonstrates diffuse granular deposits of IgG and C_3, and electron microscopy typically reveals electron-dense subepithelial deposits. While different stages (I–V) of progressive membranous lesions have been described, some published analyses indicate the degree of tubular atrophy or interstitial fibrosis is more predictive of progression than is the stage of glomerular disease. The presence of subendothelial deposits or the presence of tubuloreticular inclusions strongly points to a diagnosis of membranous lupus nephritis, which may precede the extrarenal manifestations of lupus. In 70–80% of cases of primary MGN, IgG_4 autoantibodies against the M-type phospholipase A_2 receptor circulate and bind to a conformational epitope present in the PLA2R on human podocytes, producing characteristic in situ deposits. The diagnosis of MGN may no longer require a kidney biopsy in the setting of anti-PLA2R antibody positivity, normal creatinine, and no identifiable other causes of MGN. THSD7A is another antigen localized on the podocyte surface that complexes with IgG_4, while NELL1 is the most common non-PLA2R antigen accounting for up to 16% of primary MGN cases. These novel antigens (see Table 326-5) along with PLA2R account for over 90% of cases of primary MGN. In most cases of secondary membranous nephropathy, autoantibodies to these antigens are absent, with rare reports of autoantibodies to PLA2R associated with hepatitis B, cancer, and sarcoidosis. Circulating deposits and glomerular deposits of these autoantibodies have correlated with the likelihood of a spontaneous remission, severity of primary MGN, and the response to therapy.

Eighty percent of patients with MGN present with nephrotic syndrome and nonselective proteinuria. Microscopic hematuria is seen but less commonly than in IgA nephropathy or FSGS. Spontaneous remissions occur in 20–33% of patients and often occur late in the course, making treatment decisions difficult. One-third of patients continue to have relapsing nephrotic syndrome but maintain normal kidney function, and approximately another third of patients develop kidney failure or die from the complications of nephrotic syndrome. Male gender, older age, hypertension, and the persistence of nephrotic-range proteinuria are associated with worse prognosis. Although thrombotic complications are a feature of all nephrotic syndromes, MGN has the highest reported incidences of renal vein thrombosis, pulmonary embolism, and deep-vein thrombosis. Prophylactic anticoagulation is controversial but has been recommended in select patients with hypoalbuminemia.

The treatment of edema, dyslipidemia, hypertension, and inhibition of the renin-angiotensin system and the use of SGLT2i is recommended. Therapy with immunosuppressive drugs is recommended for patients with primary MGN and persistent proteinuria. The choice of immunosuppressive drugs for therapy is controversial, however, patient risk stratification based on proteinuria, GFR, and serum albumin can help guide therapy choices with steroids and cyclophosphamide, CNIs or rituximab. Attaining remission is associated with a good long-term prognosis.

Glomerular schematic 6

DIABETIC NEPHROPATHY

Diabetic nephropathy is the single most common cause of chronic kidney disease in the United States and worldwide. The dramatic increase in the number of patients with diabetic nephropathy reflects the epidemic increase in obesity and type 2 diabetes mellitus. Approximately 40% of patients with diabetes develop nephropathy; the vast majority of patients with diabetic nephropathy will have type 2 diabetes due to the higher prevalence compared to type 1 diabetes.

Within 1–2 years after the onset of clinical diabetes, morphologic changes appear in the kidney. Thickening of the GBM is a sensitive indicator for the presence of diabetes but correlates poorly with the presence of nephropathy. The composition of the GBM is altered notably with a loss of heparan sulfate moieties that form the negatively charged filtration barrier resulting in increased filtration of serum proteins into the urine. The expansion of the mesangium due to the accumulation of extracellular matrix correlates with the clinical manifestations of diabetic nephropathy **(see stages in Fig. A4-24)**. This expansion in mesangial matrix is associated with the development of *mesangial sclerosis.* Some patients also develop eosinophilic, PAS^+ nodules called *nodular glomerulosclerosis* or *Kimmelstiel-Wilson nodules.*

Immunofluorescence microscopy often reveals the nonspecific deposition of IgG (at times in a linear pattern) or complement staining without immune deposits on electron microscopy. Prominent vascular changes are frequently seen with hyaline and hypertensive arteriosclerosis. This is associated with varying degrees of chronic glomerulosclerosis and tubulointerstitial changes. Kidney biopsies from patients with types 1 and 2 diabetic nephropathies with albuminuria are largely indistinguishable. Patients with type 2 diabetes without albuminuria are classified as having diabetic kidney disease as opposed to diabetic nephropathy and may have myriad pathologic findings.

Multiple lines of evidence support an important role for changes in glomerular hemodynamics including increases in glomerular capillary pressure and glomerular hyperfiltration in these pathologic changes. Hyperglycemia activates the renin-angiotensin-aldosterone system and alters insulin-like growth factor, reactive oxygen species, and endothelin 1. Diabetes upregulates the sodium-glucose cotransporters (SGLT1 and SGLT2) in the proximal tubule, resulting in decreased distal delivery of sodium to the macula densa and further glomerular hyperfiltration. Sustained glomerular hypertension increases matrix production and alterations in the GBM with disruption in the filtration barrier. Other factors that alter matrix production include the accumulation of advanced glycosylation end products, circulating factors including growth hormone, connective tissue growth factor, TGF-β, and dyslipidemia.

The natural history of diabetic nephropathy has been historically well characterized in the ~40% of diabetics who develop it as a progression from glomerular hyperfiltration and renal hypertrophy to increasing albuminuria followed by declining GFR and ESKD. However, since the onset of type 1 diabetes is readily identifiable and the onset of type 2 diabetes is not, a patient newly diagnosed with type 2 diabetes may present with *advanced diabetic nephropathy*. Albuminuria and decreased GFR are potent risk factors for cardiovascular disease, with some patients dying before they reach ESKD. Furthermore, contemporary studies reveal that up to 24% of patients with type 1 diabetes and 50% with type 2 diabetes and chronic kidney disease may be normoalbuminuric. It is unknown whether this alteration in the natural history reflects contemporary effective interventions or perhaps other kidney diseases that happen to occur in patients with diabetes. The degree of early glomerular hyperfiltration does correlate with the development of albuminuria and declining GFR. Albuminuria in the range of 30–300 mg/24 h is called *microalbuminuria* (Table 326-1). Microalbuminuria appears 5–10 years after the onset of diabetes. It is currently recommended to test patients with type 1 disease for microalbuminuria 5 years after diagnosis of diabetes and yearly thereafter. Patients with type 2 diabetes should be tested for microalbuminuria at time of diagnosis followed by annual monitoring. Microalbuminuria classically progresses over 5–10 years to proteinuria and declining GFR, but in contemporary studies, greater heterogeneity is reported with regression to normoalbuminuria. Albuminuria remains the single most important predictor of a faster decline in GFR. Regression of albuminuria with a treatment intervention is a good prognostic sign. Proteinuria in diabetic nephropathy can be variable, ranging from 500 mg to 25 g/24 h. More than 90% of patients with type 1 diabetes and nephropathy have diabetic retinopathy, so the absence of retinopathy in type 1 patients with proteinuria should prompt consideration of a diagnosis other than diabetic nephropathy; only 60% of patients with type 2 diabetes with nephropathy have diabetic retinopathy. There is a significant correlation between the presence of retinopathy and the presence of Kimmelstiel-Wilson nodules. Even with advanced chronic kidney disease, patients with diabetic nephropathy will have enlarged kidneys. Using the above data, and in the absence of other clinical or serologic data suggesting another disease, diabetic nephropathy is usually diagnosed without a kidney biopsy. The risk of progression to ESKD is influenced by treatment and other risk factors, and reports vary from a decline of 1.8–14 mL/min per year. Survival on dialysis is worse for patients with diabetes. Kidney transplantation results in better survival.

Good evidence supports the benefits of blood sugar and blood pressure control, inhibitors of the renin-angiotensin-aldosterone system (RAAS), and inhibitors of SGLT2 in slowing the progression of diabetic nephropathy. In patients with type 1 diabetes, intensive control of blood sugar clearly prevents the development or progression of diabetic nephropathy. The evidence for benefit of intensive blood glucose control in patients with type 2 diabetes is less certain.

Controlling systemic blood pressure decreases kidney and cardiovascular adverse events in this high-risk population. The vast majority of patients with diabetic nephropathy require three or more antihypertensive drugs to achieve this goal. Drugs that inhibit the RAAS (ACE inhibitors, angiotensin receptor blockers [ARBs]) have been shown in large clinical trials to slow the progression of diabetic nephropathy at early (microalbuminuria) and late (proteinuria with reduced glomerular filtration) stages, independent of their effects on systemic blood pressure. Finerenone, a nonsteroidal mineralocorticoid receptor antagonist, therapy in patients with diabetes and nephropathy on ACEi or ARB improved cardiovascular and kidney outcomes. In patients with type 2 diabetes and kidney disease, the risk of kidney failure and cardiovascular events was lower in those receiving SGLT2 inhibitors in addition to ACE inhibitors or ARBs.

GLOMERULAR DEPOSITION DISEASES

Plasma cell dyscrasias producing excess light chain (80%), heavy chain (10%) or both immunoglobulins can lead to the formation of glomerular and tubular deposits. The same is true for the accumulation of serum amyloid A protein fragments and monoclonal gammopathy of renal significance (MGRS). This broad group of proteinuric patients has *glomerular deposition disease*.

Light Chain Deposition Disease The biochemical characteristics of nephrotoxic light chains produced in patients with light chain malignancies confer kidney injury; that of either *cast nephropathy* **(see Fig. A4-21)**, which causes kidney injury but not heavy proteinuria or amyloidosis, or light chain deposition disease (LCDD) **(see Fig. A4-20)**, which produces proteinuria with kidney injury. These latter patients produce kappa light chains that do not have the biochemical features necessary to form amyloid fibrils. Instead, they self-aggregate and form granular deposits along the glomerular capillary and mesangium or, more prominently, in the tubular basement membrane and Bowman's capsule. Light chain deposits are not fibrillar and do not stain with Congo red, but they are easily detected with anti–light chain antibody. A combination of the light chain rearrangement, self-aggregating properties at neutral pH, and abnormal metabolism probably contributes to the deposition. Multiple myeloma, Waldenström's macroglobulinemia, or lymphoma may be present, as well as heart, liver, and pulmonary involvement. The monoclonal protein may be found with serum electrophoresis or with serum free light chain analysis. Nephrotic syndrome may develop, and ~70% of patients progress to dialysis. Treatment for LCDD is treatment of the primary disease. Less commonly, the deposits may be composed of heavy chains only (HCDD) or both ligh and heavy chains (LHCDD); both diseases have similar clinical characteristics to LCDD.

Monoclonal Gammopathy of Renal Significance In MGRS, a monoclonal immunoglobulin secreted by a nonmalignant or premalignant B cell or plasma cell clone results in monoclonal deposits in the kidney which can manifest as proteinuria and ESKD. Treatment is controversial but may include chemotherapy.

Renal Amyloidosis Most *renal amyloidosis* is either the result of primary fibrillar deposits of immunoglobulin light chains known as amyloid L (AL) or secondary to fibrillar deposits of serum amyloid A (AA) protein fragments **(Chap. 117)**. Hereditary amyloidosis is rare. Even though AA and AL amyloid occur for different reasons, their clinicopathophysiology is quite similar. Amyloid infiltrates the liver, heart, peripheral nerves, carpal tunnel, upper pharynx, and kidney, ultimately producing restrictive cardiomyopathy, hepatomegaly, macroglossia, and heavy proteinuria sometimes associated with renal vein thrombosis. In contrast to LCDD, amyloid kidney deposits are fibrillar, stain with Congo red, and contain predominantly the variable region of lambda chains **(see Fig. A4-19)**. In systemic AL amyloidosis, also

called *primary amyloidosis,* light chains produced in excess by clonal plasma cell dyscrasias are made into fragments by macrophages that aggregate into amyloid fibrils. Approximately 10% of patients have overt myeloma as defined by CRAB (hypercalcemia, renal insufficiency, anemia, or lytic bone lesions). Nephrotic syndrome is common and ~20% of patients progress to dialysis. AA amyloidosis is sometimes called *secondary amyloidosis* and is due to deposition of β-pleated sheets of serum amyloid A protein, an acute phase reactant. Fragments of serum amyloid A protein increase and self-aggregate by attaching to receptors for advanced glycation end products in the extracellular environment. Patients with AA amyloid have associated inflammatory diseases including autoimmune diseases, chronic infections, and genetic autoinflammatory diseases. An increasing proportion of patients have unidentified chronic inflammation; this may reflect better treatments for the previously associated diseases or a rise in chronic inflammation due to obesity. Nephrotic syndrome is common, and ~40–60% of patient's progress to dialysis. Serum-free light chain analysis is useful in the early diagnosis and follow-up of disease progression. Biopsy of involved liver or kidney is diagnostic 90% of the time when the pretest probability is high; abdominal fat pad aspirates are positive ~70% of the time, but apparently less so when looking for AA amyloid. Amyloid deposits are distributed along blood vessels and in the mesangial regions of the kidney. The recommended treatment for primary amyloidosis is melphalan followed by autologous hematopoietic cell transplantation (HCT) which can achieve remission, however relapses are common. Patients who are not candidates for HCT often receive bortezomib-based regimens. Secondary amyloidosis is relentless unless the primary disease can be controlled. Drugs in development that disrupt the formation of fibrils may be available in the future.

Fibrillary and Immunotactoid Glomerulopathies Fibrillary and immunotactoid glomerulopathies are rare (<1.0% of kidney biopsies), morphologically defined diseases characterized by glomerular accumulation of nonbranching randomly arranged fibrils that are Congo red negative **(see Fig. A4-18)**. Fibrillary glomerulopathy accounts for 85–90% of cases and is identified by the presence of the protein DnaJ heat shock protein family member B9 (DNAJB9) in the glomeruli, which is absent in the rarer immunotactoid glomerulopathy. In both, glomerular and mesangial deposits contain oligoclonal or oligotypic immunoglobulins and complement, with 12- to 24-nm fibrils randomly arranged in fibrillary glomerulopathy and 16 to 52-nm fibrils organized into microtubules in immunotactoid glomerulopathy. The cause of this "nonamyloid" glomerulopathy is mostly idiopathic; reports of fibrillary glomerulonephritis describe associations with malignancy, autoimmune disease, and monoclonal gammopathy. Immunotactoid glomerulopathy has been associated with lymphoma or plasma cell disorders. Both disorders appear in adults aged 40–80 years old, with moderate to heavy proteinuria (100%), hematuria (70%), kidney injury (50%), a wide variety of histologic lesions, and ESKD within 2 to 6 years in 50% of patients. Most patients have disease limited to the kidney. Patients should be screened for associated disorders. There is no consensus on treatment of this uncommon disorder, although rituximab has been reported to remit proteinuria. These diseases can recur in the kidney transplant.

FABRY'S DISEASE

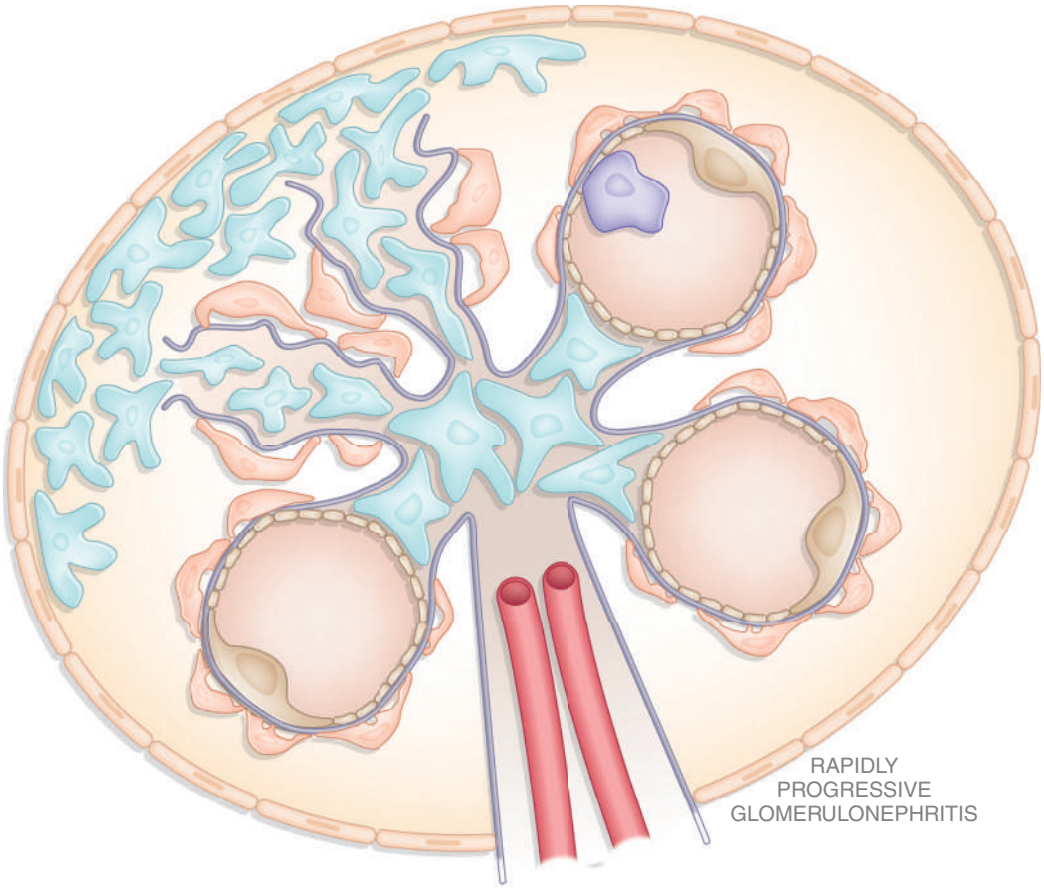
Fabry's disease is an X-linked inborn error of globotriaosylceramide metabolism secondary to deficient lysosomal α-galactosidase A (alpha-Gal A) activity, resulting in excessive intracellular storage of globotriaosylceramide. Affected organs include the vascular endothelium, heart, brain, and kidneys. Classically, Fabry's disease presents in childhood in males with acroparesthesias, angiokeratomas commonly in groin and periumbilical areas, abdominal pain, cornea verticillate, and hypohidrosis. Over time, male patients develop cardiac involvement, cerebrovascular disease, and kidney injury, with an average age of death around 50 years of age. Female heterozygotes with unfavorable X inactivation present with mild single-organ involvement or rarely severe manifestations including kidney failure but do so later in life than males. Kidney biopsy reveals enlarged glomerular visceral epithelial cells packed with small clear vacuoles containing globotriaosylceramide; vacuoles may also be found in parietal and tubular epithelia **(see Fig. A4-22)**. These vacuoles of electron-dense materials in parallel arrays (zebra bodies) are easily seen on electron microscopy. Ultimately, kidney biopsies reveal FSGS. The nephropathy of Fabry's disease typically presents in the third decade as mild to moderate proteinuria, sometimes with microscopic hematuria or nephrotic syndrome. Urinalysis may reveal oval fat bodies and birefringent glycolipid globules under polarized light (Maltese cross). Measurement of alpha-Gal A activity and mutational analysis of the gene is diagnostic, with kidney biopsies sometimes helpful. Progression to ESKD occurs by the fourth or fifth decade. Treatment with inhibitors of the renin-angiotensin system is recommended. Treatment with recombinant agalsidase alpha or beta or migalastat, a chaperone that facilitates trafficking of alpha-Gal A, clears microvascular endothelial deposits of globotriaosylceramide from the kidneys, heart, and skin. In patients with advanced organ involvement including chronic kidney disease, progression of disease occurs despite enzyme replacement therapy. Variable responses to enzyme therapy may be due to the occurrence of neutralizing antibodies or differences in uptake of the enzyme. Graft and patient survival following kidney transplantation in patients with Fabry's disease are similar to those of other causes of ESKD.

PULMONARY-RENAL SYNDROMES

Several diseases can present with catastrophic hemoptysis and glomerulonephritis associated with varying degrees of kidney injury. The usual causes include Goodpasture's syndrome, granulomatosis with polyangiitis, microscopic polyangiitis, Churg-Strauss vasculitis, and, rarely, Henoch-Schönlein purpura or cryoglobulinemia. Each of these diseases can also present without hemoptysis and are discussed in detail earlier in "Acute Nephritic Syndromes." **(See Glomerular Schematic 7.)** Pulmonary bleeding in this setting is life-threatening and often results in airway intubation, and acute kidney injury may require dialysis. Diagnosis is difficult initially because biopsies and serologic testing take time. Treatment with plasmapheresis and methylprednisolone is often empirical and temporizing until results of testing are available.

BASEMENT MEMBRANE SYNDROMES

All kidney epithelia, including podocytes, rest on basement membranes assembled into a planar surface through the interweaving of collagen IV with laminins, nidogen, and sulfated proteoglycans. Structural abnormalities in GBM associated with hematuria are characteristic of several familial disorders related to the expression of collagen IV genes. The extended family of collagen IV contains six chains, which are expressed in different tissues at different stages of embryonic development. All epithelial basement membranes early in human development are composed of interconnected triple-helical protomers rich in α1.α1.α2(IV) collagen. Some specialized tissues undergo a developmental switch replacing α1.α1.α2(IV) protomers with an α3.α4.α5(IV) collagen network; this switch occurs in the kidney (glomerular and tubular basement membrane), lung, testis, cochlea, and eye, while an α5.α5.α6(IV) network appears in skin, smooth muscle, and esophagus and along Bowman's capsule in the kidney. This switch probably occurs because the α3.α4.α5(IV) network is more resistant to proteases and ensures the structural longevity of critical tissues. When basement membranes are the target of glomerular disease, they produce moderate proteinuria, some hematuria, and progressive kidney failure.



ANTI-GBM DISEASE

Autoimmune disease where antibodies are directed against the α3 NC1 domain of collagen IV produces an *anti-GBM disease* often associated with RPGN and/or a pulmonary-renal syndrome called *Goodpasture's syndrome*. Discussion of this disease is covered earlier in "Acute Nephritic Syndromes."

ALPORT'S SYNDROME

Classically, patients with Alport's syndrome develop hematuria, and mild proteinuria (<1–2 g/24 h), which appears late in the course,

Glomerular schematic 7

followed by chronic glomerulosclerosis leading to kidney failure in association with sensorineural deafness. Some patients develop lenticonus of the anterior lens capsule, "dot and fleck" retinopathy, and rarely, leiomyomatosis. Approximately 80–85% of patients with Alport's syndrome have an X-linked inheritance of mutations at the *COL4A5* locus affecting in the α5(IV) collagen chain on chromosome Xq22–24. Female carriers have variable penetrance depending on the type of mutation or the degree of mosaicism created by X inactivation. Mutations on chromosome 2q35-37 at the *COL4A3* and *COL4A4* loci of the α3(IV) and α4(IV) chains, respectively, are associated with autosomal recessive (AR) disease and less commonly autosomal dominant (AD) disease. With use of next generation sequencing, AD disease is now noted to likely occur more frequently than previously thought.

Pedigrees with the X-linked syndrome are quite variable in their rate and frequency of tissue damage leading to organ failure. There is strong correlation between genotype and phenotype regarding risk of disease progression in males; truncating variants, including large deletions and nonsense mutations, are associated with rapidly progressive disease with ESKD by age 30 in up to 90% of males. By contrast, those with missense or splice variants may not deteriorate until after the age of 30 with mild or late deafness. Early severe deafness, lenticonus, or proteinuria suggests a poorer prognosis. Usually females from X-linked pedigrees have only microhematuria, but up to 25% of carrier females have been reported to have more severe kidney manifestations. Pedigrees with the AR form of the disease have severe early disease in both females and males with asymptomatic parents.

Clinical evaluation should include a careful eye examination and hearing tests. However, the absence of extrarenal symptoms does not rule out the diagnosis. Genetic testing can be used for the diagnosis of Alport's syndrome and the demonstration of the mode of inheritance. In certain cases with high clinical suspicion or family history of Alport's, genetic testing alone may be sufficient for diagnosis. Since α5(IV) collagen is expressed in the skin, some X-linked Alport's patients can be diagnosed with a skin biopsy revealing the lack of the α5(IV) collagen chain on immunofluorescent analysis. Patients with mutations in α3(IV) or α4(IV) require a kidney biopsy. Early in their disease, Alport's patients typically have thin basement membranes on kidney biopsy **(see Fig. A4-23)**, which thicken over time into multilamellations surrounding lucent areas that often contain granules of varying density—the so-called split basement membrane. In any Alport's kidney, there are areas of thinning mixed with splitting of the GBM. Tubules drop out, glomeruli scar, and the kidney eventually succumbs to interstitial fibrosis. All affected members of a family with X-linked Alport's syndrome should be identified and followed, including mothers of affected males. Primary treatment is control of systemic hypertension and use of ACE inhibitors and possibly SGLT2i to slow kidney disease progression. Although patients who receive kidney allografts usually develop anti-GBM antibodies directed toward the collagen epitopes absent in their native kidney, overt Goodpasture's syndrome is rare and graft survival is good.

THIN BASEMENT MEMBRANE DISEASE

Thin basement membrane disease (TBMD), a relatively common disorder characterized by persistent or intermittent hematuria, which is usually microscopic hematuria and rarely macroscopic hematuria with flank pain. It is not typically associated with proteinuria, hypertension, or loss of kidney function or extrarenal disease. TBMD is often familial, with pedigrees exhibiting an autosomal dominant pattern. It usually presents in childhood in multiple family members and has also been called *benign familial hematuria*. Many cases of TBMD have genetic defects in type IV collagen; in contrast to Alport's syndrome, the disease behaves as an autosomal dominant disorder that in ~40% of families segregates with the *COL(IV)* α3/*COL(IV)* α4 loci. Mutations in these loci can result in a spectrum of disease, ranging from TBMD to autosomal dominant or recessive Alport's. The GBM shows diffuse thinning compared to normal values for the patient's age in otherwise normal biopsies **(see Fig. A4-23)**. The vast majority of patients have a benign course.

NAIL-PATELLA SYNDROME

Patients with nail-patella syndrome develop iliac horns on the pelvis and dysplasia of the dorsal limbs involving the patella, elbows, and nails, variably associated with neural-sensory hearing impairment, glaucoma, and abnormalities of the GBM and podocytes, leading to hematuria, proteinuria, and FSGS. The syndrome is autosomal dominant, with haploinsufficiency for the LIM homeodomain transcription factor LMX1B; pedigrees are extremely variable in the penetrance for all features of the disease. LMX1B regulates the expression of genes encoding α3 and α4 chains of collagen IV, interstitial type III collagen, podocin, and CD2AP that help form the slit-pore membranes connecting podocytes. Mutations in the LIM domain region of *LMX1B* associate with glomerulopathy in 30–40% of patients and rarely progress to ESKD. Proteinuria or isolated hematuria is discovered throughout life but usually by the third decade. Genetic testing can confirm the diagnosis. Treatment is nonspecific, but renin-angiotensin system inhibition is recommended. Patients with ESKD do well with transplantation.

GLOMERULAR-VASCULAR SYNDROMES

A variety of diseases result in classic vascular injury to the glomerular capillaries. Most of these processes also damage blood vessels elsewhere in the body. The group of diseases discussed here lead to vasculitis, renal endothelial injury, thrombosis, ischemia, and/or lipid-based occlusions.

ATHEROSCLEROTIC NEPHROPATHY

Aging in the developed world is commonly associated with the occlusion of coronary and systemic blood vessels. When the renal arterial circulation is involved, the glomerular microcirculation is damaged, leading to *chronic nephrosclerosis*. Several aggressive lipid disorders can accelerate this process, but most of the time, atherosclerotic progression to chronic nephrosclerosis is associated with poorly controlled hypertension.

HYPERTENSIVE NEPHROSCLEROSIS

Systemic hypertension causes permanent damage to the kidneys in ~6% of patients with elevated blood pressure. As many as 27% of patients with ESKD have hypertension as a primary cause, and it is the second most common cause of ESKD after diabetic nephropathy in the US. Risk alleles associated with *APOL1,* a functional gene for apolipoprotein L1 expressed in podocytes are associated with an increased risk of ESKD. Other associated risk factors for progression to end-stage kidney disease include increased age, male gender, smoking, hypercholesterolemia, duration of hypertension, low birth weight, and preexisting kidney injury. Kidney biopsies in patients with hypertension, microhematuria, and moderate proteinuria demonstrate arteriolosclerosis, chronic nephrosclerosis, and interstitial fibrosis in the absence of immune deposits **(see Fig. A4-25)**. Based on a careful history, physical examination, urinalysis, and some serologic testing, the diagnosis of chronic nephrosclerosis is usually inferred without a biopsy. Recent studies suggest, in the absence of diabetes, adults with hypertension and cardiovascular risk factors benefit from achieving a systolic blood pressure <120 mmHg, compared to <140 mmHg. In the presence of kidney disease, most patients begin antihypertensive therapy with two drugs, classically a thiazide diuretic and an ACE inhibitor; most will require three drugs. There is strong evidence in a study with self-identified African Americans with hypertensive nephrosclerosis that therapy initiated with an ACE inhibitor can slow the rate of decline in kidney function independent of effects on systemic blood pressure. Malignant acceleration of hypertension complicates the course of chronic nephrosclerosis, particularly in the setting of scleroderma or cocaine use **(see Fig. A4-28)**. The hemodynamic stress of malignant hypertension leads to fibrinoid necrosis of small blood vessels, thrombotic microangiography, a nephritic urinalysis, and AKI. In the setting of kidney injury, chest pain, or papilledema, the condition is treated as a hypertensive emergency.

CHOLESTEROL EMBOLI

Aging patients with clinical complications from atherosclerosis sometimes shower cholesterol crystals into the circulation following an endovascular procedure with manipulation of the aorta or with use of systemic anticoagulation. Less commonly, spontaneous emboli can occur and may shower acutely or shower subacutely which is somewhat more silently. Irregular emboli trapped in the microcirculation produce ischemic damage that induces an inflammatory reaction. Depending on the location of the atherosclerotic plaques releasing these cholesterol fragments, one may see cerebral transient ischemic attacks; livedo reticularis in the lower extremities; Hollenhorst plaques in the retina with visual field cuts; necrosis of the toes; and acute glomerular capillary injury leading to FSGS sometimes associated with hematuria, mild proteinuria, and loss of kidney function, which typically progresses over a few years. Occasional patients have fever, eosinophilia, or eosinophiluria. A skin biopsy of an involved area may be diagnostic. Since tissue fixation dissolves the cholesterol, one typically sees only residual, biconvex clefts in involved vessels **(see Fig. A4-26)**. There is no therapy to reverse embolic occlusions, and steroids do not help. Controlling blood pressure and lipids and cessation of smoking are usually recommended for prevention.

SICKLE CELL DISEASE

Sickle cell disease (SCD) is an autosomal recessive disease that occurs due to a mutation in the hemoglobin β-chain (HβS). Clinical disease occurs in homozygous patients (SS) or heterozygous patients in the presence of an abnormal or missing β-chain (SC, HbSβ). Under certain circumstances (i.e., hypoxia, hypovolemia, acidity, hyperosmolality), HbS polymerizes which causes the red blood cell shape to distort. These cells attach to endothelia, causing obstruction as well as other changes to the vasculature that produce acute and chronic vaso-occlusion disease in many organs, including the kidney. The major site of injury in the kidney is the renal medulla, an area supplied by the vasa recta capillaries that promotes sickling due to the relative hypoxic, acidotic, and hypertonic environment. Repeated injury overtime produces chronic organ damage leading to sickle cell nephropathy (SCN). Early changes of SCN include glomerular hyperfiltration, albuminuria, and both micro- and macro-hematuria. Nearly all SCD patients have concentrating defects which cause hyposthenuria and can lead to severe dehydration. Later changes include papillary necrosis, renal infarction, interstitial nephritis, proteinuria, and FSGS. Rarely patients may present with MPGN. Several genetic risk factors have been identified that may increase risk for progression of CKD, including *APOL1* gene variants. Treatment is directed at reducing the frequency of vaso-occlusive events and administering ACE inhibitors/ARBs and hydroxyurea in the hope of delaying a progressive decline in kidney function. Management of anemia in SCN patients is complex and may require high doses of erythropoiesis-stimulating agents. A number of patients will develop progressive CKD, and one study found that 20% of SCD patients develop ESKD before the age of 30. SCD patients with ESKD have poor prognosis on kidney replacement therapy (KRT), with a mean time to death of 4 years. Prognosis for ESKD patients improves after kidney transplant with 7 year survival of 67%.

Sickle cell trait occurs in patients with one HbS and one normal hemoglobin. Although individuals usually do not experience vaso-occlusive symptoms, most will gradually develop hyposthenuria due to subclinical infarction of the renal medulla and a consequent loss of concentrating ability. They may experience hematuria and are at higher risk for renal medullary carcinoma than SCD patients.

THROMBOTIC MICROANGIOPATHIES

Thrombotic microangiopathy (TMA) refers to a pathologic lesion that causes thrombocytopenia and microangiopathic hemolytic anemia with schistocytes. *Thrombotic thrombocytopenic purpura* (TTP), Shiga toxin–mediated *hemolytic-uremic syndrome* (HUS), and complement-mediated HUS represent a spectrum of primary TMAs that share these features and may have concurrent fever, kidney failure, and neurologic disturbances. HUS is suspected with patients have more severe kidney injury while TTP is suspected in adults with neurologic disease and more severe thrombocytopenia. On examination of kidney tissue, there is evidence of *glomerular capillary endotheliosis* associated with platelet thrombi, damage to the capillary wall, and formation of fibrin

TABLE 326-6 Thrombotic Microangiopathies

Primary thrombotic microangiopathy
TTP
Shiga-toxin HUS
Complement-mediated HUS
Secondary thrombotic microangiopathy
Pregnancy related: preeclampsia, HELLP (*h*emolysis, *e*levated *l*iver enzymes, and *l*ow *p*latelet count syndrome), postpartum (thought to be complement mediated)
Drug induced: oral contraceptives or quinine, calcineurin inhibitors, antiplatelet agents (ticlopidine and clopidogrel), drugs of abuse (cocaine, IV use of oxycodone)
Kidney transplant patients given OKT3 for rejection
Malignant hypertension
Autoimmune: antiphospholipid syndrome, lupus, scleroderma
Infections: HIV, pneumococcal, CMV
Cobalamin deficiency

Abbreviations: CMV, cytomegalovirus; HUS, hemolytic-uremic syndrome; TTP, thrombotic thrombocytopenic purpura.

material in and around glomeruli **(see Fig. A4-27)**. These tissue findings are similar to what is seen in secondary TMA, which includes a broad group of conditions known to be associated with TMA **(see Table 326-6)**.

Shiga toxin–mediated HUS is caused by a toxin released by *Escherichia coli* 0157:H7 and occasionally by *Shigella dysenteriae*. This Shiga toxin (verotoxin) directly injures endothelia, enterocytes, and kidney cells, causing apoptosis, platelet clumping, and intravascular hemolysis by binding to the glycolipid receptors (Gb3). These receptors are more abundant along endothelia in children compared to adults. Shiga toxin also inhibits the endothelial production of ADAMTS13. In familial cases of adult TTP, there is a genetic deficiency of the ADAMTS13 metalloprotease that cleaves large multimers of von Willebrand's factor (VWF). In the absence of ADAMTS13, these large multimers cause platelet clumping and intravascular hemolysis. An antibody to ADAMTS13 is found in many sporadic cases of adult TTP. Patients can be tested for ADAMTS13 activity, and if low, the presence of antibodies to ADAMTS13 distinguishes the deficiency from the immune-mediated disease. Complement-mediated HUS, previously referred to as atypical HUS, is thought to occur when there is a hereditary deficiency or antibody to a regulatory protein in the alternative complement pathway leading to overactivation. The treatment of adult TTP with ADAMTS13 antibodies is daily plasmapheresis, which can be lifesaving. Plasmapheresis with fresh frozen plasma is given until the platelet count rises, or longer for relapsing patients. There is an anecdotal role in relapsing patients for splenectomy. Refractory or relapsing patients may benefit from steroids, immunosuppressive drugs such as rituximab, or caplacizumab, a monoclonal antibody that blocks interaction between VWF and platelets. In the absence of ADAMTS13 antibodies, patients with a genetic deficiency of ADAMTS13 production can be treated with fresh frozen plasma alone. Patients with Shiga toxin–mediated HUS are treated primarily with supportive care because antibiotics are thought to accelerate the release of the toxin and the diarrhea is usually self-limited. Patients with complement-mediated HUS are treated with anticomplement therapy, such as eculizumab or ravulizumab.

ANTIPHOSPHOLIPID ANTIBODY SYNDROME (SEE CHAP. 369)

GLOBAL CONSIDERATIONS

INFECTIOUS DISEASE–ASSOCIATED SYNDROMES

A number of infectious diseases will injure the glomerular capillaries as part of a systemic reaction producing an immune response or from direct infection of kidney tissue. Evidence of this immune response is collected by glomeruli in the form of immune deposits that damage the kidney, producing moderate proteinuria and hematuria. A high prevalence of many of these infectious diseases in developing countries results in infection-associated kidney disease being the most common cause of glomerulonephritis in many parts of the world.

Poststreptococcal Glomerulonephritis This form of glomerulonephritis is one of the classic complications of streptococcal infection. The discussion of this disease can be found earlier, in the section "Acute Nephritic Syndromes."

Subacute Bacterial Endocarditis Kidney injury from persistent bacteremia absent the continued presence of a foreign body, regardless of cause, is treated presumptively as if the patient has endocarditis. The discussion of this disease can be found earlier, in the section "Acute Nephritic Syndromes."

Human Immunodeficiency Virus Kidney disease is an important complication of HIV disease. About 50% of HIV-infected patients with kidney disease have HIV-associated nephropathy (HIVAN) on biopsy. The lesion in HIVAN is FSGS, characteristically revealing a collapsing glomerulopathy **(see Fig. A4-3)** with visceral epithelial cell swelling, microcystic dilatation of renal tubules, and tubuloreticular inclusion. Renal epithelial cells express replicating HIV virus, but host immune responses also play a role in the pathogenesis. HIVAN is thought to be linked to *APOL1* risk variants. HIV immune complex kidney disease (HIVICK) is a group of immune complex–mediated glomerular lesions seen in HIV patients that, on biopsy, can look like a constellation of other glomerular lesions, including postinfectious glomerulonephritis, MGN, MPGN, DPGN, MCD, and IgA nephropathy. The HIVICK effect is a complication of active HIV viremia.

HIV patients with FSGS typically present with nephrotic-range proteinuria and hypoalbuminemia, but unlike patients with other etiologies for nephrotic syndrome, they do not commonly have hypertension, edema, or hyperlipidemia. Kidney ultrasound also reveals large, echogenic kidneys despite the finding that kidney function in some patients declines rapidly. Treatment with inhibitors of the renin-angiotensin system decreases the proteinuria. Effective antiretroviral therapy benefits both the patient and the kidney and improves survival of HIV-infected patients with HIVAN and, in some cases, HIVICK-associated chronic kidney disease or ESKD. In HIV-infected patients not yet on therapy, the presence of HIVAN is an indication to initiate therapy. Following the introduction of antiretroviral therapy, survival on dialysis for the HIV-infected patient has improved dramatically. Kidney transplantations in HIV-infected patients without detectable viral loads or histories of opportunistic infections provide a better survival benefit over dialysis. Following transplantation, patient and graft survival are similar to the general transplant population despite frequent rejections.

Hepatitis B and C Typically, infected patients present with microscopic hematuria, nonnephrotic or nephrotic-range proteinuria, and hypertension. There is a close association between hepatitis B infection and polyarteritis nodosa, with vasculitis appearing generally in the first 6 months following infection. Kidney manifestations include renal artery aneurysms, renal infarction, and ischemic scars. Alternatively, the hepatitis B carrier state can produce an MGN with predominant IgG1 deposition that is more common in children than adults or MPGN that is more common in adults than in children. Kidney histology is indistinguishable from idiopathic MGN or MPGN. Viral antigens, most commonly HBeAG, are found in the kidney deposits. Cryoglobulinemic glomerulonephritis has also been reported. Treatment is with antiviral agents. Children have a better prognosis than adults.

Up to 30% of patients with chronic hepatitis C infection have some kidney manifestations. Patients often present with type II mixed cryoglobulinemia, nephrotic syndrome, microscopic hematuria, abnormal liver function tests, depressed C_3 levels, anti–hepatitis C virus (HCV) antibodies, and viral RNA in the blood. The lesions most commonly seen, in order of decreasing frequency, are cryoglobulinemic glomerulonephritis, MGN, and MPGN, but polyarteritis nodosa (PAN), IgA nephropathy, and FSGS have been reported. With the availability of direct-acting antivirals, which can achieve a viral remission in >95% of

patients, the prevalence of glomerular disease in HCV patients should decline. These drugs are currently the treatment of choice for patients with HCV-related MPGN or PAN.

SARS-CoV-2 The novel coronavirus, SARS-CoV-2, is associated with several complications related to kidney disease including acute kidney injury, chronic kidney disease, and, rarely, glomerular diseases. The glomerular lesions reported in patients with COVID-19 include FSGS, minimal change disease, membranous nephropathy, ANCA-associated vasculitis, anti-GBM disease, IgA nephropathy and thrombotic microangiopathy. The glomerular disease most commonly associated with COVID-19 is collapsing glomerulopathy, a morphologic variant of FSGS, also referred to as COVID-associated nephropathy (COVAN). Patients may present with new onset nephrotic syndrome or nephrotic range proteinuria with AKI. There have been case reports of *de novo* glomerular disease and relapse of pre-existing glomerular disease following administration of COVID-19 mRNA vaccines, although evidence for causal link is not well established. The use of immunosuppression therapy may be considered in patients with severe nephrotic syndrome or persistent disease despite resolution of infection, however there is limited data to guide treatment recommendations.

Other Viruses Other viral infections are occasionally associated with glomerular lesions, but cause and effect are not well established. These viral infections and their respective glomerular lesions include cytomegalovirus producing MPGN or FSGS; influenza and anti-GBM disease; measles-associated endocapillary proliferative glomerulonephritis, with measles antigen in the capillary loops and mesangium; parvovirus causing mild proliferative or mesangioproliferative glomerulonephritis or FSGS; mumps and mesangioproliferative glomerulonephritis; Epstein-Barr virus producing MPGN, diffuse proliferative nephritis, or IgA nephropathy; dengue hemorrhagic fever causing endocapillary proliferative glomerulonephritis; Hanta virus and mesangial proliferative glomerulonephritis; and coxsackievirus producing *focal glomerulonephritis* or DPGN.

Syphilis Secondary syphilis, with rash and constitutional symptoms, develops weeks to months after the chancre first appears and occasionally presents with the nephrotic syndrome from MGN caused by subepithelial immune deposits containing treponemal antigens. Neuron-derived neurotrophic factor has also been identified as an antigenic target. Other lesions have also rarely been described, including interstitial syphilitic nephritis. The diagnosis is confirmed with nontreponemal and treponemal tests for *Treponema pallidum*. The kidney lesion responds to treatment with penicillin or an alternative drug, if allergic. Additional testing for other sexually transmitted diseases is an important part of disease management.

Leprosy Despite aggressive eradication programs, new cases of leprosy appear primarily in developing countries. The diagnosis is best made in patients with multiple skin lesions accompanied by sensory loss in affected areas, using skin smears showing paucibacillary or multibacillary infection (WHO criteria). Leprosy is caused by infection with *Mycobacterium leprae* and can be classified by Ridley-Jopling criteria into various types: tuberculoid, borderline tuberculoid, mid-borderline and borderline lepromatous, and lepromatous. Kidney involvement in leprosy is related to the quantity of bacilli in the body, and the kidney is one of the target organs during splanchnic localization. In some series, all cases with borderline lepromatous and lepromatous types of leprosy have various forms of kidney involvement including FSGS, mesangioproliferative glomerulonephritis, or renal amyloidosis; much less common are DPGN and MPGN. Treatment of the infection with multidrug therapy can reduce the incidence of kidney disease or produce remission of the kidney disease.

Malaria There are 300–500 million incident cases of malaria each year worldwide, and the kidney is commonly involved. Glomerulonephritis is due to immune complexes containing malarial antigens that are implanted in the glomerulus. In malaria from *P. falciparum*, mild proteinuria is associated with subendothelial deposits, mesangial deposits, and mesangioproliferative glomerulonephritis that usually resolve with treatment. In quartan malaria from infection with *Plasmodium malariae*, children are more commonly affected and kidney involvement is more severe. Transient proteinuria and microscopic hematuria can resolve with treatment of the infection. However, resistant nephrotic syndrome with progression to ESKD over 3–5 years does happen, as <50% of patients respond to steroid therapy. Affected patients with nephrotic syndrome have thickening of the glomerular capillary walls, with subendothelial deposits of IgG, IgM, and C_3 associated with a sparse membranoproliferative lesion. The rare mesangioproliferative glomerulonephritis reported with *Plasmodium vivax* or *Plasmodium ovale* typically has a benign course. Acute kidney injury can often complicate these glomerulopathies.

Schistosomiasis Schistosomiasis affects >300 million people worldwide and primarily involves the urinary and gastrointestinal tracts. Glomerular involvement varies with the specific strain of schistosomiasis; *Schistosoma mansoni* is most commonly associated with clinical kidney disease, and the glomerular lesions can be classified as follows: class I is a *mesangioproliferative glomerulonephritis*; class II is an *extracapillary proliferative glomerulonephritis*; class III is a *membranoproliferative glomerulonephritis*; class IV is a *focal segmental glomerulonephritis*; and class V is *amyloidosis*. Classes I–II often remit with treatment of the infection, but class III and IV lesions are associated with IgA immune deposits and progress despite antiparasitic and/or immunosuppressive therapy.

Other Parasites Kidney involvement with toxoplasmosis infections is rare. When it occurs, patients present with nephrotic syndrome and have a histologic picture of MPGN. Fifty percent of patients with leishmaniasis will have mild to moderate proteinuria and microscopic hematuria, but decreased GFR is rare. Acute DPGN, MGN, and mesangioproliferative glomerulonephritis have all been observed on biopsy. Filariasis and trichinosis are caused by nematodes and are sometimes associated with glomerular injury presenting with proteinuria, hematuria, and a variety of histologic lesions that typically resolve with eradication of the infection.

327 Polycystic Kidney Disease and Other Inherited Disorders of Tubule Growth and Development

Jing Zhou, Martin R. Pollak

The polycystic kidney diseases are a group of genetically heterogeneous disorders and a leading cause of kidney failure. The autosomal dominant form of polycystic kidney disease (ADPKD) is the most common life-threatening monogenic disease, affecting 12 million people worldwide. The autosomal recessive form of polycystic kidney disease (ARPKD) is rarer but affects the pediatric population. Kidney cysts are often seen in a wide range of syndromic diseases. Recent studies have shown that defects in the structure or function of the primary cilia may underlie this group of genetic diseases collectively termed *ciliopathies* (Table 327-1).

AUTOSOMAL DOMINANT POLYCYSTIC KIDNEY DISEASE

Etiology and Pathogenesis (Fig. 327-1) ADPKD is characterized by progressive formation of epithelial lined cysts in the kidney. Although cysts occur in only 5% of the tubules in the kidney, the enormous growth of these cysts ultimately leads to the loss of normal surrounding tissues and loss of renal function. The cellular defects in ADPKD that have been known for a long time are increased cell proliferation and fluid secretion, decreased cell differentiation, and abnormal extracellular matrix. ADPKD is caused by mutations in *PKD1* and *PKD2*, which, respectively, code for polycystin-1 (PC1) and polycystin-2 (PC2). PC1 is a large 11-transmembrane protein that functions like a G protein–coupled receptor. PC2 is a calcium-permeable six-transmembrane protein that structurally belongs to the transient receptor potential (TRP) cation channel family. PC1 and PC2 are widely expressed in almost all tissues and organs. PC1 expression is high in development and low in the adult, whereas PC2 expression is relatively constant. PC1/2 are found on the primary cilium, a hair-like structure present on the apical membrane of a cell, in addition to the cell membranes and cell–cell junctions of tubular epithelial cells. Defects in the primary cilia are linked to a wide spectrum of human diseases, collectively termed *ciliopathies*. The most common phenotype shared by many ciliopathies is kidney cysts. PC1 and PC2 bind to each other via their respective C-terminal tails to form a receptor-channel complex and regulate each other's function. Recent evidence suggests a 1:3 stoichiometry for PC1:PC2 in the PC1/2 channel complex. The PC1/2 protein complex serves as a mechanosensor or chemical sensor and regulates calcium and G-protein signaling. The PC1/2 protein complex may also directly regulate a number of cellular functions, including the cell cycle, the actin cytoskeleton, planar cell polarity (PCP), and cell migration. This protein complex has also

TABLE 327-1 Inherited Diseases Commonly Associated with a Cystic Phenotype

DISEASE	MODE OF INHERITANCE	RENAL ABNORMALITIES	OTHER CLINICAL FEATURES	GENES
Autosomal dominant polycystic kidney disease	AD	Bilaterally enlarged kidneys with cortical and medullary cysts	Liver, pancreatic cysts, hypertension, subarachnoid hemorrhage	*PKD1, PKD2*
Autosomal dominant polycystic kidney disease-like	AD	Normal to smaller sized kidneys with fewer cortical and medullary cysts	Liver cysts at variable degree (from absent to severe)	*GANAB, DNAJB11*
Autosomal recessive polycystic kidney disease	AR	Distal and collecting duct cysts	Oligohydramnios if severe, hypertension, ascending cholangitis, liver fibrosis	*PKHD1*
Autosomal dominant tubulointerstitial kidney disease	AD	Small fibrotic kidneys; medullary cysts	In adults, gout	*UMOD, MUC1, REN, HNF1β, SEC61A1*
Renal cysts and diabetes syndrome	AD	Kidney cysts, aberrant nephrogenesis, irregular collecting systems, abnormal renal calyces, hyperuricemic nephropathy. Highly variable.	Diabetes	*HNF1B*
Nephronophthisis	AR	Small fibrotic kidneys; medullary cysts	Growth retardation, anemia (In syndromic forms: visual loss, liver fibrosis, cerebellar ataxia, other)	*NPHP1-20, IQCB1, CEP290, GLIS2, RPGRIP1L, NEK8, SDCCAG8, TMEM67, TTC21B*
Senior-Loken syndrome	AR	Renal cysts	Juvenile nephronophthisis, Leber amaurosis	*NPHP1-6, SDCCAG8*
Leber congenital amaurosis	AR	Renal cysts	Visual impairment in first year of life; pigmentary retinopathy	*GUCY2D, RPE65, LCA3-14*
Meckel-Gruber syndrome	AR	Cortical and medullary cysts	CNS anomalies, polydactyly, congenital heart defects	*MKS1, TMEM216, TMEM67, TMEM231, TMEM107, CEP290, RPGRIP1L, CC2D2A, TCTN2, B9D1, B9D2, NPHP3, KIF14*
Bardet-Biedl syndrome	AR	Renal cysts	Obesity, polydactyly, retinitis pigmentosa, anosmia, congenital heart defects, intellectual disability	*BBS1, 2, ARL6, BBS4,5, MKKS, BBS7, TTC8, BBS9, 10, TRIM32, BBS12, MKS1, CEP290, C2ORF86*
Oral-facial-digital syndrome type I	X-linked dominant	Renal cysts	Oral cavity, face, and digit anomalies; CNS abnormalities; cystic kidney disease; X-linked with male lethality, primary ciliary dyskinesia	*OFD1*
Tuberous sclerosis	AD	Renal cysts	Angiomyolipomas; renal cell carcinoma Facial angiofibromas; CNS hamartomas	*TSC1, TSC2*
Von Hippel-Lindau disease	AD	Renal cysts	Renal cell carcinoma, retinal angiomas; CNS hemangioblastomas; pheochromocytomas	*VHL*

Abbreviations: AD, autosomal dominant; AR, autosomal recessive; CNS, central nervous system.

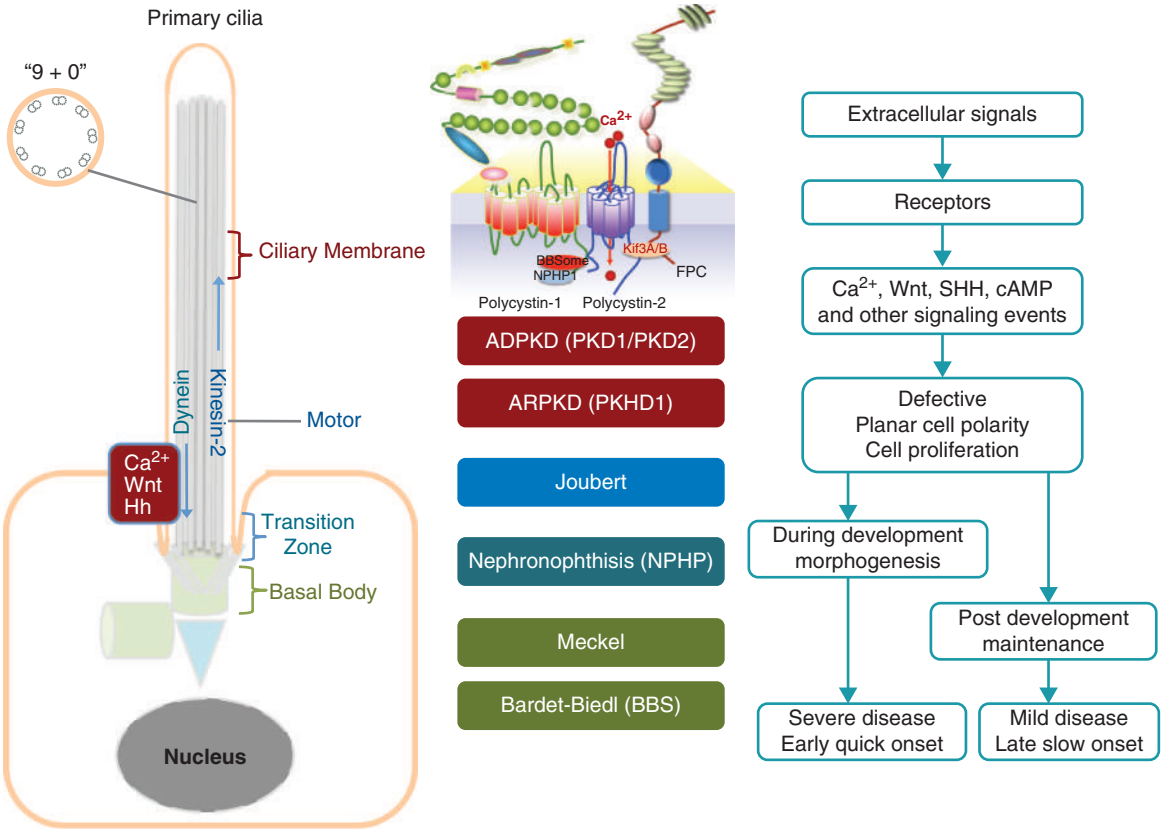

FIGURE 327-1 Scheme of the primary cilium and cystic kidney disease proteins. ***Left:*** A scheme of the primary cilium. Primary cilia share a "9+0" organization of microtubule doublets. Proteins are transported into the cilium by motor protein kinesin 2 and transported out of the cilium by dynein. The cilium is connected to the basal body through the transition zone. ***Middle:*** Topology of ADPKD and ARPKD proteins polycystin 1, polycystin 2, and FPC is shown. Localizations of disease proteins in the cilium, the transition zone, and the basal body are color coded. ***Right:*** Potential disease mechanisms due to cilium-mediated signaling events.

been implicated in regulating a number of signaling pathways, including Wnt, mammalian target of rapamycin (mTOR), STAT3, cMET, phosphoinositide 3-kinase (PI3K/Akt), G protein–coupled receptor (GPCR), and epidermal growth factor receptor (EGFR), as well as in the localization and activity of cystic fibrosis transmembrane conductance regulator (CFTR). One hypothesis is that loss of ciliary function of PC1 and PC2 leads to aberrant calcium signaling and a subsequent increase of adenylyl cyclase activity and decrease of phosphodiesterase activity, which, in turn, causes increased cellular cAMP. Increased cAMP promotes protein kinase A activity, among other effectors, and, in turn, leads to cyst growth by promoting proliferation and fluid secretion of cyst-lining cells through chloride and aquaporin channels in ADPKD kidneys.

ADPKD is inherited as an autosomal dominant trait with complete penetrance but variable expressivity. The disease affects all ethnic groups worldwide with an estimated prevalence of 1:1000 to 1:400. Only half of the patients with ADPKD are clinically diagnosed during their lifetimes. ADPKD is genetically heterogeneous. The first disease gene (*PKD1*) was localized to the region of the alpha-globin gene on chromosome 16p13 in 1985, and a second disease gene (*PKD2*) locus was mapped to chromosome 4q21-q23 in 1993. Mutations of *PKD1* and *PKD2* are responsible for ~85% and ~15% of ADPKD cases, respectively. However, patients with *PKD2* mutations may be >15% because they tend to have milder clinical disease and, as a result, are underdiagnosed. Embryonic lethality of *Pkd1* and *Pkd2* knockout mice suggests human homozygotes may be lethal and thus not clinically recognized.

PKD1 is comprised of 46 exons occupying ~52 kb of genomic DNA. It produces a ~14 kb transcript that encodes polycystin-1, a protein of ~4300 amino acids. A feature of the *PKD1* gene is that the 5′ three-quarters of *PKD1* have been duplicated at six other sites on chromosome 16p, and many of them produce mRNA transcripts, which provides a major challenge for genetic analysis of the duplicated region. *PKD2* is a single-copy gene with 15 exons producing a ~5.3 kb mRNA transcript that encodes polycystin-2, a protein of 968 amino acids. Two additional genes, *GANAB* and *DNAJB11*, have been found in patients with autosomal dominant form of polycystic kidney disease. The *GANAB* gene encodes the glucosidase IIa subunit, and the *DNAJB11* gene produces a cofactor of BiP, a key chaperone in the endoplasmic reticulum controlling folding, trafficking, and degradation of secreted and membrane proteins. Both proteins appear to affect PC1 trafficking. However, these mutations have only been found in a very small number of families.

In ADPKD patients, every cell carries a germline mutant allele of either *PKD1* or *PKD2*. However, cysts develop in only a small fraction of the nephrons. Cysts are thought to originate from clonal growth of single cells that have received a somatic "second hit" mutation in the "normal" allele of the *PKD1* or *PKD2* gene. Accumulating evidence in mouse models now shows that partial loss of function of the second allele of *Pkd1* in a proliferative environment is sufficient for cystogenesis, suggesting that a critical amount of *PKD1* is needed in a cell. Somatic inactivation of the second allele of *Pkd1* in adult mice results in very slow onset of cyst development in the kidney, but a "third hit," such as an additional genetic or epigenetic event, the inactivation of a growth suppressor gene, the activation of a growth promoting gene(s), or an event such as renal injury that activates the developmental program, may promote rapid cyst formation.

Clinical Manifestations ADPKD is characterized by the progressive bilateral formation of renal cysts. Focal renal cysts are typically detected in affected subjects aged <30 years. Hundreds to thousands of cysts are usually present in the kidneys of most patients in the fifth decade (Fig. 327-2). Enlarged kidneys can each reach a fourfold increase in length and weigh up to 20 times the normal weight. The clinical presentations of ADPKD are highly variable. While many patients are asymptomatic until the fourth to fifth decade of life and

FIGURE 327-2 Photograph showing a kidney from a patient with autosomal dominant polycystic kidney disease. The kidney has been cut open to expose the parenchyma and internal aspects of cysts.

are diagnosed by incidental discoveries of hypertension or abdominal masses, back or flank pain is a frequent symptom in ~60% of patients with ADPKD. The pain may result from renal cyst infection, hemorrhage, or nephrolithiasis. Gross hematuria resulting from cyst rupture occurs in ~40% of patients during the course of their disease, and many of them will have recurrent episodes. Flank pain and hematuria may coexist if the cyst that ruptures is connected with the collecting system. Proteinuria is usually a minor feature of ADPKD. Infection is the second most common cause of death for patients with ADPKD. Up to half of patients with ADPKD will have one or more episodes of renal infection during their lifetimes. An infected cyst and acute pyelonephritis are the most common renal infections often due to gram-negative bacteria, which are associated with fever and flank pain, with or without bacteremia. These complications and renal insufficiency often correlate with structural abnormality of the renal parenchyma. Mutations in *GANAB* and *DNAJB11* genes result in milder cystic kidney disease than that in classic ADPKD with small renal cysts and normal-sized kidneys. Sometimes patients with *GANAB* mutations present with autosomal dominant polycystic liver disease (ADPLD)-like phenotype. Patients with *DNAJB11* develop renal fibrosis, characteristic of autosomal dominant tubulointerstitial disease (ADTKD), discussed below. Kidney stones occur in ~20% of patients with ADPKD. Different from the general population, more than half of the stones in patients with ADPKD are composed of uric acid, with the remainder due to calcium oxalate. Distal acidification defects, abnormal ammonium transport, low urine pH, and hypocitraturia may be important in the pathogenesis of renal stones in ADPKD. Renal cell carcinoma is a rare complication of ADPKD with no apparent increased frequency compared to the general population. However, in ADPKD, these tumors are more often bilateral at presentation, multicentric, and sarcomatoid in type. Radiologic imaging is often not helpful in distinguishing cyst infection and cyst hemorrhage because of their complexity. Computed tomography (CT) scan and magnetic resonance imaging (MRI) are often useful in distinguishing a malignancy from a complex cyst. Cardiovascular complications are the major cause of mortality in patients with ADPKD. Hypertension is common and typically occurs before any reduction in glomerular filtration rate (GFR). Hypertension is a risk factor for both cardiovascular and kidney disease progression in ADPKD. Notably, some normotensive patients with ADPKD may also have left ventricular hypertrophy. Hypertension in ADPKD may result from the increased activation of the renin-angiotensin-aldosterone system, increased sympathetic nerve activity, and impaired endothelial cilium function–dependent relaxation of small resistant blood vessels.

The progression of ADPKD has striking inter- and intrafamilial variability. The disease can present as early as in utero, but end-stage renal disease (ESRD) typically occurs in late middle age. Risk factors include early diagnosis of ADPKD, hypertension, gross hematuria, multiple pregnancies, and large kidney size. Liver cysts derived from the biliary epithelia are the most common extrarenal complication. Polycystic liver disease associated with ADPKD is different from ADPLD, which is caused by mutations in at least two distinct genes (*PRKCSH* and *SEC63*) and does not progress to renal failure. Massive polycystic liver disease occurs almost exclusively in women with ADPKD, particularly those with multiple pregnancies. Heterozygous loss-of-function variants in *PKHD1, ALG8, GANAB*, and *SEC61B* are now found in ADPLD. *ALG8, GANAB,* and *SEC61B* all encode ER proteins that are involved in the same pathway as GIIβ and SEC63, and each appears to affect PC1 biogenesis.

Intracranial aneurysm (ICA) occurs four to five times more frequently in ADPKD patients than in the general population and causes high mortality. The disease gene products PC1 and PC2 may be directly responsible for defects in arterial smooth muscle cells and myofibroblasts. The focal nature and the natural history of ICA in ADPKD remain unclear. A family history of ICA is a risk factor of aneurysm rupture in ADPKD; whether hypertension and cigarette smoking are independent risk factors is not clear. About 20–50% of patients may experience "warning headaches" preceding the index episode of subarachnoid hemorrhage due to ruptured ICA. A CT scan is generally used as the first diagnostic test. A lumbar puncture may be used to confirm the diagnosis. The role of radiologic screening for ICA in asymptomatic patients with ADPKD remains unclear. ADPKD patients with a positive family history of ICAs may undergo presymptomatic screening of ICAs by magnetic resonance angiography. Other vascular abnormalities in ADPKD patients include diffuse arterial dolichoectasias of the anterior and posterior cerebral circulation, which can predispose to arterial dissection and stroke. Mitral valve prolapse occurs in up to 30% of patients with ADPKD, and tricuspid valve prolapse is less common. Other valvular abnormalities occurring with increased frequency in ADPKD patients include insufficiency of the mitral, aortic, and tricuspid valves. Most patients are asymptomatic, but some may progress and require valve replacement. The prevalence of colonic diverticulae and abdominal wall hernias is also increased in ADPKD patients.

Diagnosis A diagnosis is typically made from a positive family history consistent with autosomal dominant inheritance and multiple kidney cysts bilaterally. Renal ultrasonography is often used for presymptomatic screening of at-risk subjects and for evaluation of potential living-related kidney donors from ADPKD families. The presence of *at least two renal cysts (unilateral or bilateral)* is sufficient for diagnosis among at-risk subjects between 15 and 29 years of age with a sensitivity value of 96% and specificity value of 100%. The presence of *at least two cysts in each kidney* and *at least four cysts in each kidney*, respectively, is required for the diagnosis among at-risk subjects aged 30–59 years and aged ≥60 years with a sensitivity value of 100% and specificity value of 100%. This is because there is an increased frequency of developing simple renal cysts with age. Conversely, in subjects aged between 30 and 59 years, the absence of *at least two cysts in each kidney*, which is associated with a false-negative rate of 0%, can be used for disease exclusion. These criteria have a lower sensitivity for patients with a

PKD2 mutation because of a late onset of ADPKD2. CT scan and T2-MRI, with and without contrast enhancement, are more sensitive than ultrasonography and can detect cysts of smaller size. However, a CT scan exposes the patient to radiation and radiocontrast, which may cause serious allergic reactions and nephrotoxicity in patients with renal insufficiency. T2-MRI, with gadolinium as a contrast agent, has minimal renal toxicity and can detect cysts of only 2–3 mm in diameter. However, a large majority of cysts may still be below the detection level. Genetic testing by linkage analyses and mutational analyses is available for ambiguous cases. Because of the large size of the *PKD1* gene and the presence of multiple highly homologous pseudogenes, mutational analysis of the *PKD1* gene is difficult and costly. Application of new technologies such as paired-end next-generation sequencing with multiplexing individually bar-coded long-range polymerase chain reaction (PCR) libraries may reduce the costs and improve the sensitivity for clinical genetic testing.

TREATMENT

Autosomal Dominant Polycystic Kidney Disease

No specific treatment to prevent cyst growth or the decline of renal function has been approved by the U.S. Food and Drug Administration. Blood pressure control to a target of 140/90 mmHg is recommended according to the guidelines from the eighth report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC VIII report) for reducing cardiovascular complications in ADPKD and renal disease progression. More rigorous blood pressure control does not equal greater clinical benefits. Maintaining a target systolic blood pressure to 110 mmHg in patients with moderate or advanced disease may increase the risk of renal disease progression by reducing renal blood flow. Lipid-soluble antibiotics against common gram-negative enteric organisms include trimethoprim-sulfamethoxazole, quinolones, and chloramphenicol, and are preferred for cyst infection because most renal cysts are not connected to glomerular filtration and antibiotics that are capable of penetrating the cyst walls are likely to be more effective. Treatment often requires 4–6 weeks. The treatment of kidney stones in ADPKD includes standard measures such as analgesics for pain relief and hydration to ensure adequate urine flow. Management of chronic flank, back, or abdominal pain due to renal enlargement may include both pharmacologic (nonnarcotic and narcotic analgesics) and nonpharmacologic treatment (transcutaneous electrical nerve stimulation, acupuncture, and biofeedback). Occasionally surgical decompression of cysts may be necessary. More than half of ADPKD patients eventually require peritoneal dialysis, hemodialysis, or kidney transplantation. Peritoneal dialysis may not be suitable for some patients with massively enlarged polycystic kidneys due to the small intraabdominal space for efficient peritoneal exchange of fluid and solutes and increased chance of abdominal hernia and back pain. Patients with very large polycystic kidneys and recurrent renal cyst infection may require pretransplant nephrectomy or bilateral nephrectomy to accommodate the allograft and reduce the pain.

Specific treatment strategies for ADPKD have focused on slowing renal disease progression and lowering cardiovascular risk. For the latter, the main approach is to control blood pressure by inhibiting the renin-angiotensin-aldosterone system. The HALT PKD trial was set to evaluate the impact of intensive blockade of the renin-angiotensin-aldosterone system and levels of blood pressure control on progressive renal disease. This trial found that rigorous blood pressure control could slow cyst growth. Most approaches target the slowing of renal disease progression by inhibiting cell proliferation and fluid secretion. Several clinical trials have been conducted targeting cell proliferation: sirolimus and everolimus, inhibitors of the mTOR pathway; OPC31260 and tolvaptan, which inhibit cyclic adenosine monophosphate (cAMP) pathways by antagonizing the activation of vasopressin V2 receptor (V2R) in collecting ducts and reduces cell proliferation by decreasing renal cAMP levels; and somatostatin analogues, which reduce cAMP levels by binding to several GPCRs. The TAMPO and ALADIN trials showed that V2R antagonists and somatostatin analogues (octreotide-LAR groups), respectively, slowed the decline of renal function. Some side effects, such as liver function impairment, polydipsia, and diarrhea, have been observed for tolvaptan and cholecystitis for octreotide-LAR. A recent report also showed that tolvaptan reduces renal pain. DIPAK, a small multicenter European study, showed that nerve block may be used to relieve pain in ADPKD patients suffering with refractory chronic pain. A combination of different growth inhibitors may enhance efficacy and reduce side effects. Notably, treatments may vary depending on the patient population. For example, the U.S. Food and Drug Administration (FDA) has indicated tolvaptan to be only for patients at risk of rapidly progressing disease. Combining genotypic and imaging information may predict kidney growth rates and help in selecting this patient population. Several other trials are being conducted. For example, compounds targeting microRNAs regulating the production of PKD1 and PKD2 proteins are currently under phase I trials in patients with ADPKD. Additionally, daily caloric restriction and intermittent fasting are also being trialed in overweight and obese adult patients.

Additional preclinical studies in animal models include the use of inhibitors to nonreceptor tyrosine kinase Src, B-raf, cyclin-dependent kinase (CDK), transcription factors STAT3 and STAT6 (pyrimethamine and leflunomide), purinergic receptors, hepatocyte growth factor receptor, glucosylceramide, agonists to peroxisome proliferator-activated receptor-gamma (PPARγ) receptors (thiazolidinediones), and targeting microRNAs. Reprogramming the metabolic pathway through studies of transcription regulator super-enhancer as well as dietary control, including time-restricted feeding, has been shown in murine models to reduce cyst area, kidney fibrosis, inflammation, and injury. Branched-chain amino acids appear to enhance cyst development in a mouse model.

AUTOSOMAL RECESSIVE POLYCYSTIC KIDNEY DISEASE

Genetic Considerations ARPKD is a significant hereditary renal disease in childhood, with an estimated prevalence of 1 in 20,000 live births. A carrier frequency of up to 1:70 has been reported. Mutations in a single gene, *PKHD1*, are responsible for all the clinical presentations of ARPKD. *PKHD1*, localized on human chromosome region 6p21.1–6p12.2, is one of the largest genes in the genome, occupies ~450 kb of DNA, and contains at least 86 exons. It produces multiple alternatively spliced transcripts. The largest transcript encodes fibrocystin/polyductin (FPC), which is a large receptor-like integral membrane protein of 4074 amino acids. FPC has a single transmembrane, a large N-terminal extracellular region, and a short intracellular cytoplasmic domain. FPC is localized on the primary cilia of epithelia cells of cortical and medullary collecting ducts and cholangiocytes of bile ducts, similar to polycystins and several other ciliopathy proteins. FPC is also expressed on the basal body and plasma membrane. The large extracellular domain of FPC is presumed to bind to an as yet unknown ligand(s) and is involved in cell-cell and cell-matrix interactions. FPC interacts with ADPKD protein PC2 and may also participate in regulation of the mechanosensory function of the primary cilia, calcium signaling, and PCP, suggesting a common mechanism underlying cystogenesis between ADPKD and ARPKD. FPC is also found on the centrosomes and mitotic spindle and may regulate centrosome duplication and mitotic spindle assembly during cell division. A large number of various mutations have been found throughout *PKHD1* and are unique to individual families. Most patients are compound heterozygotes for *PKHD1* mutations. Patients with two truncation mutations appear to have an earlier onset of the disease.

Clinical Features Classic ARPKD is generally diagnosed in utero or within the neonatal period and characterized by greatly enlarged echogenic kidneys in diseased fetuses. Reduced fetal urine production

may contribute to oligohydramnios and pulmonary hypoplasia. About 30% of affected neonates die shortly after birth due to respiratory insufficiency. Close to 60% of mortality occurs within the first month of life. In the classic group, most patients are born with renal insufficiency and ESRD. However, infants often have a transient improvement in their GFR; death from renal insufficiency at this stage is rare. Some patients are diagnosed after the neonatal stage, which form the older group. Morbidity and mortality in this group often involve systemic hypertension, progressive renal insufficiency, and liver manifestations. The hallmarks of ARPKD liver disease are biliary dysgenesis due to a primary ductal plate malformation with associated periportal fibrosis, namely congenital hepatic fibrosis (CHF) and dilatation of intrahepatic bile ducts (Caroli disease). CHF and Caroli disease can then lead to portal hypertension exhibiting hepatosplenomegaly, variceal bleeding, and cholangitis. Some patients with the diagnosis of ARPKD at 1 year of age with nephromegaly exhibit slowly declining renal function over 20 years with only minimally enlarged kidneys at ESRD and markedly atrophic kidneys following renal transplantation. The slow progression of renal disease is likely due to increasing fibrosis rather than the development of cysts. Systemic hypertension is common in all ARPKD patients, even those with normal renal function.

Diagnosis Ultrasonography, CT, and MRI all can be used for diagnosis. Ultrasonography reveals large, echogenic kidneys with poor corticomedullary differentiation. The diagnosis can be made in utero after 24 weeks of gestation in severe cases. Macrocysts generally are not common at birth in ARPKD patients. The absence of renal cysts in either parent, particularly if they are >40 years of age, on ultrasonography helps distinguish ARPKD from ADPKD in older patients. Clinical, laboratory, or radiographic evidence of hepatic fibrosis, hepatic pathology demonstrating characteristic ductal plate abnormalities, family history of affected siblings, or parental consanguinity suggestive of autosomal recessive inheritance is helpful. The lack of mutational hot spots and the large and complex genomic structure of *PKHD1* make molecular diagnosis difficult; however, presymptomatic screen of other at-risk members in a family with already identified ARPKD mutations is straightforward and inexpensive.

TREATMENT

Autosomal Recessive Polycystic Kidney Disease

There is no specific therapy for ARPKD. Appropriate neonatal intensive care, blood pressure control, dialysis, and kidney transplantation increase survival into adulthood. Complications of hepatic fibrosis may necessitate liver transplantation. Patients with severe Caroli disease may need portosystemic shunting. Tolvaptan, an approved drug, functions by inhibiting the vasopressin pathway through the blockade of the vasopressin receptor 2 (V2). Preclinical studies conducted on a rat model of PKD, wherein the causative gene of ARPKD, *PKHD1*, is mutated, revealed promising results. These studies demonstrated a reduction in kidney cyst formation, decreased cyst cell growth, and preserved kidney function following tolvaptan administration. These findings suggest that the vasopressin pathway may contribute to the progression of renal manifestations in ARPKD. A multinational, multicenter phase 3 clinical trial is evaluating the safety and efficacy of the drug tolvaptan in treating infants and children with ARPKD. Upcoming therapies may target abnormal cell signaling mechanisms, as described above for ADPKD.

OTHER DISEASES CHARACTERIZED BY LARGE KIDNEY CYSTS

TUBEROUS SCLEROSIS

Tuberous sclerosis (TS) is a rare autosomal dominant syndrome caused by mutations in one of two genes, *TSC1*, encoding hamartin, or *TSC2*, encoding tuberin. Published estimates of prevalence vary widely, but it certainly occurs in <1:5000 births. Kidney cysts are a frequent feature of this condition, as are two other abnormalities of kidney growth, renal cell carcinoma and renal angiomyolipomas. TS is a syndrome affecting multiple organ systems. Other features of TS include benign growths in the nervous system, eyes, heart, lung, liver, and the skin. Essentially all TS patients have such skin lesions, and a large proportion of patients have neurologic and cognitive manifestations. Kidney cysts and their complications should be managed similarly to the management of these problems in the general population. The neurologic features of TS can be a source of significant morbidity.

The *TSC2* gene is adjacent to *PKD1* in the human genome. Some patients have deletions in their genomic DNA that inactivate these two genes. Such individuals may have manifestations of both ADPKD and TS. The majority of TS-causing mutations are found in TSC2.

Renal cysts are observed in about 20–30% of people with TS. The most common kidney finding in TS is the presence of angiomyolipomas. These growths tend to be multiple and bilateral. While they are usually benign, they may bleed. Surgical removal is often recommended as a prophylactic measure in people with angiomyolipomas >4 cm in diameter. The cysts in TS are radiographically similar to those seen in ADPKD. In contrast to ADPKD, there is a clearly increased risk of renal cell carcinoma in TS patients. Advances in imaging technology have improved the ability to detect TSC-related abnormalities, aiding in early diagnosis and treatment planning.

Regular periodic imaging is recommended in TS patients with kidney involvement to screen for the development of renal cell carcinoma. These cysts may rarely become large and hemorrhagic, occasionally requiring nephrectomy when nephron-sparing surgery is not possible. Although a rare problem, TS may lead to significant chronic kidney disease (CKD) and progress to end-stage kidney failure. Patients with TS and CKD typically have an unremarkable urine sediment and only small amounts of proteinuria.

Mechanistically, the *TSC1* and *TSC2* gene products tuberin and hamartin interact physically. This protein complex is localized to the base of the cilia and inhibits intracellular signaling processes mediated by mTOR, leading to abnormal growth in a number of tissues. Everolimus, an mTOR inhibitor, has been approved in the United States for treatment of TSC-associated kidney tumors as well as nonkidney manifestations of TS. mTOR inhibitors are now considered first-line treatment for TS.

VON HIPPEL-LINDAU DISEASE

Von Hippel-Lindau disease (VHL) is an inherited cancer syndrome with renal manifestations. VHL is an autosomal dominant condition caused by mutations in the VHL tumor-suppressor gene. The VHL protein plays a critical role in the regulation of hypoxia pathways and oxygen sensing via the transcription factor hypoxia-inducible factor (HIF). Like many other autosomal dominant cancer syndromes, VHL is recessive at the cellular level: a somatic mutation in the second VHL allele leads to loss of VHL in the cell and abnormal growth. Kidney manifestations of VHL include multiple bilateral kidney cysts and renal cell carcinomas. Kidney cysts and carcinoma affect the majority of VHL patients. Nonrenal features of VHL include pheochromocytomas, cerebellar hemangioblastomas, and retinal hemangiomas. While much rarer than ADPKD, VHL is an entity that should be considered in the differential diagnosis of an individual with newly recognized kidney cysts.

In these patients, annual screening of the kidneys by imaging with CT or MRI scanning is recommended for early detection of renal cell carcinomas. Increasingly, nephron-sparing surgical approaches are being used for removal of cancerous lesions in order to preserve kidney function. The HIF inhibitor belzutifan has been approved for VHL-associated renal cell carcinoma.

OTHER INHERITED DISEASES OF TUBULE GROWTH AND DEVELOPMENT

ADPKD is by far the most common adult-onset single-gene form of adult-onset kidney disease. The large cysts that are sometimes seen in VHL and TS are similar in appearance to the cysts seen in ADPKD. A variety

of other inherited disorders affecting primarily tubule and renal interstitial function can lead to CKD and eventual end-stage kidney disease in the absence of large tubule-derived cysts.

Inherited diseases affecting the tubulointerstitial compartment of the kidney can lead to secondary glomerular stress and glomerulosclerosis with some degree of concomitant proteinuria. Similarly, disorders of glomerular function will typically lead to secondary interstitial fibrosis and tubule atrophy. From a clinical perspective, therefore, distinguishing between a genetic disease of the renal tubules and a disease of the glomerulus may not be easy, particularly in the absence of a gross phenotype such as large kidney cysts. In recent years, DNA sequencing panels have greatly improved the ability to make rapid and accurate genetic diagnoses of the underlying cause of many kidney disease, including diseases characterized by cysts, tumors, and other growth abnormalities.

AUTOSOMAL DOMINANT TUBULOINTERSTITIAL KIDNEY DISEASE (MEDULLARY CYSTIC KIDNEY DISEASE)

The term *autosomal dominant tubulointerstitial kidney disease* (ADTKD) has replaced the phrase *medullary cystic kidney disease* (MCKD) as the preferred designation for a group of autosomal dominant disorders characterized by progressive kidney failure and a benign urine sediment. Despite the old nosology, kidney cysts are not invariably present. Older literature often grouped MCKD together with the childhood-onset disorders known as the nephronophthises, but these are distinct clinical and genetic entities.

ADTKD-MUC1 Patients with medullary cystic kidney disease type I (MCKD I) have mutations in the mucin 1 gene *MUC1*. In contrast to MCKD II patients, individuals with MCKD I do not have elevated uric acid levels. The disease-causing *MUC1* mutations that have been reported all alter a highly repetitive region within the *MUC1* gene. This leads to the production of a large "neoprotein" fragment that has toxic effects on the kidney tubule.

Clinically, patients with MCKD I exhibit slowly progressive CKD in adulthood, with only minimal amounts of increased urine protein and occasional renal cysts seen on ultrasound examination. Kidney histology shows tubulointerstitial fibrosis and tubular atrophy. Disease does not recur in transplanted kidneys.

ADTKD-UMOD ADTKD-UMOD (also called MCKD II) is caused by mutations in the *UMOD* gene, which encodes the protein uromodulin, also known as Tamm-Horsfall protein. Uromodulin is also found on the centrosome, the mitotic spindle, and the primary cilia; it colocalizes with nephrocystin-1 and KIF3A on the cilia. *UMOD* mutations also cause the conditions that have been referred to as familial juvenile hyperuricemic nephropathy (HNFJ1) and glomerulocystic kidney disease (GCKD), although it does not seem that these different names represent clearly distinct disorders. The term *uromodulin-associated kidney disease* (UAKD) has been suggested as a better name for MCKD II and the various other related *UMOD*-associated diseases. Despite the name, kidney cysts are not a common feature of MCKD II. MCKD II should be suspected clinically in patients with a family history of late-onset kidney disease, benign urine sediments, absence of significant proteinuria, and hyperuricemia. Large genome-wide association studies have suggested that certain common noncoding sequence variants in *UMOD* are associated with a moderately increased risk of CKD in the general population. *UMOD*-associated disease is often associated with gout. The features of UMOD-associated kidney disease are fairly nonspecific, and the diagnosis should be made by genetic testing.

Other Forms of Familial Tubulointerstitial Kidney Disease A small number of families have been identified with ADTKD and hyperuricemia who lack *UMOD* mutations. Some of these families carry disease-segregating mutations in the renin gene *REN* (disease designation ADTKD-REN). ADKTKD-REN patients demonstrate hyporeninemia with mild hyperkalemia and often have hyperuricemia and gout. Mutations in *HNF1β* and *SEC61A1* are even rarer causes of ADTKD.

Kidney biopsies in patients with any of the various forms of ADTKD typically show interstitial fibrosis. These histologic features are not diagnostic of any particular genetic entity, and the specific diagnosis must be made by other means. Genetic tests for alterations in specific genes and in large panels of kidney disease genes are available in the clinical setting. High cost and complexity in interpretation are the major barriers to the use of such testing.

Patients with autosomal dominant interstitial kidney disease, *UMOD* or *REN* mutations, and hyperuricemia and gout should be treated similarly to others with these findings, with uric acid–lowering agents, such as allopurinol or febuxostat.

NEPHRONOPHTHISIS

A large and growing number of genetically distinct but related sets of autosomal recessive disorders are referred to as nephronophthises, or nephronophthisis-related ciliopathies. These entities should not be confused with the adult-onset autosomal dominant MCKD discussed above, despite the often-confusing nomenclature seen in older medical literature. Each of the individual forms of nephronophthisis is quite rare, but together this category constitutes the most common inherited childhood form of kidney failure requiring kidney replacement therapy. Most individuals with nephronophthisis develop end-stage kidney disease.

Like ADPKD and ARPKD, the various genetically heterogeneous entities that fall under the category of nephronophthisis (NPHP) are disorders of ciliary function. Mutations in >90 genes have been identified that lead to NPHP under an autosomal recessive pattern of inheritance. Some of these gene defects cause limited kidney disease, while many cause ciliopathies characterized by multiple organ involvement. The various forms of NPHP share common features, including tubulointerstitial fibrosis, corticomedullary cysts, and progressive CKD, leading to renal failure. Proteinuria is absent or mild, and the urine sediment is not active.

NPHP is often divided into infantile, juvenile, and adolescent forms. The juvenile form is the most frequent, and usually caused by mutations in the *NPHP2* gene. The infantile form, usually caused by *NPHP2* mutations, is associated with end-stage kidney failure in early childhood. Patients with the adolescent form of NPHP typically develop end-stage kidney failure in early adulthood. Hypertension, if present, tends to be a late finding in the course of the NPHPs. The products of the NPHP genes are referred to as nephrocystins. *NPHP1* through *NPHP20* have been reported; some are referred to by other names as well.

NPHP can present as an isolated finding or be part of several multiorgan syndromes. Neurologic abnormalities are present in a significant number of patients. Bone and liver abnormalities are seen in some NPHP patients. Senior-Loken syndrome is defined by the presence of NPHP with retinitis pigmentosa. Joubert syndrome is defined by multiple neurologic findings, including hypoplasia of the cerebellar vermis. Some forms of this genetically heterogeneous syndrome include NPHP as a component.

The multisystem disease Bardet-Biedl syndrome (BBS) is a subset of the ciliopathies. BBS is defined clinically by a spectrum of features, including truncal obesity, cognitive impairment, retinal dystrophy, polydactyly, developmental urogenital abnormalities, and kidney cysts. The kidney phenotype is NPHP-like, with small cysts deriving from the tubules, tubulointerstitial and often secondary glomerular disease, and urine concentrating defects. To date, 26 BBS genes have been identified. BBS follows autosomal recessive inheritance.

The multiple genes and gene products (nephrocystins) that are responsible for NPHP are expressed in cilia, basal bodies, and the centrosomes of kidney tubule cells. It has been hypothesized that all of the NPHP gene defects lead to a clinical phenotype by interfering with the regulation of PCP.

There are no specific clinical tests that define NPHP. Genetic diagnosis has become fairly straightforward due to new DNA sequencing technologies and should be pursued as part of the diagnostic workup. There are no specific therapies for NPHP. Rather, therapy is aimed at treating signs of these diseases as well as those systemic abnormalities

seen with all CKDs. Chronic dialysis or kidney transplantation is eventually required for most NPHP-affected individuals.

KARYOMEGALIC TUBULOINTERSTITIAL NEPHRITIS

Karyomegalic tubulointerstitial nephritis is an exceptionally rare form of kidney disease with adult-onset progressive kidney failure. Kidney biopsy shows chronic tubulointerstitial nephritis, as well as interstitial fibrosis. This is a recessive disorder caused by inheritance of two mutant copies of the *FAN1* gene. *FAN1* encodes a component of a DNA repair machinery complex. Individuals with two mutant *FAN1* genes are genetically sensitized to the effect of DNA damage. Kidney histology shows karyomegaly in addition to the nonspecific findings of interstitial fibrosis and tubular atrophy.

MEDULLARY SPONGE KIDNEY

Medullary sponge kidney (MSK) is often grouped together with inherited disorders of the kidney affecting tubule growth and development, although it is usually a sporadic finding rather than an inherited phenotype. MSK is caused by developmental malformation and cystic dilatation of the renal collecting ducts. The medullary cysts seen in this entity can be quite variable in size.

MSK is usually a benign entity. The diagnosis of MSK is often made incidentally. In the past, the diagnosis of MSK was often made by intravenous pyelography (IVP). CT urography, which has replaced IVPs for much routine kidney imaging, is not as sensitive in detecting MSK.

MSK is associated with an increased frequency of calcium phosphate and calcium oxalate kidney stones. Altered flow characteristics in the kidney tubules may lead to the development of formation of a nidus for stone formation. Kidney stones in this group are treated the same as are kidney stones in the general population. MSK patients also often exhibit reduced kidney concentrating ability and an increased frequency of urinary tract infections.

CONGENITAL ABNORMALITIES OF THE KIDNEY AND URINARY TRACT

The structural abnormalities known as CAKUT (congenital abnormalities of the kidney and urinary tract) are a group of etiologically and phenotypically heterogeneous disorders. Some form of CAKUT is estimated to occur in up to 1 in 500 live births. Specific abnormalities classified as part of the CAKUT spectrum include kidney hypoplasia, kidney agenesis, ureteropelvic junction obstruction, and vesicoureteral reflux.

CAKUT can be the cause of clinically significant problems in both adults and children. However, it is a major contributor to kidney failure in children, accounting for more than one-third of end-stage kidney disease in this group.

CAKUT is typically a sporadic finding but can also cluster in families. Familial forms can be observed as parts of multisystem developmental syndromes. A growing list of specific genes have been identified that when mutated lead to both nonsyndromic and syndromic forms of CAKUT. For example, the branchio-oto-renal syndrome, characterized by developmental abnormalities in the neck, ears, and kidney, can be caused by mutations in the *EYA1* and *SIX1* genes. Mutations in the *PAX2* transcription factor gene can cause the autosomal dominant renal coloboma syndrome, characterized by optic nerve malformations and hypoplastic kidneys. A nontrivial fraction of children with CKD have an unsuspected genomic imbalance, often disrupting genes known to be relevant to CAKUT and kidney development. It is not uncommon for such genetic lesions to affect both kidney and neurocognitive function.

CAKUT can be caused by both environmental influences and genetic alterations. For example, renal tubular dysgenesis, defined by altered tubule development, can be caused by prenatal exposure of angiotensin-converting enzyme inhibitors or angiotensin receptor blockers.

MITOCHONDRIAL DISEASE

Inherited disorders of the mitochondrial genome (discussed elsewhere in this text **[see also Chap. 481]**) commonly affect kidney function. Thirteen of the genes involved in encoding components of the mitochondrial respiratory chain are located on the mitochondrial genome that is inherited maternally. The remainder of these components are encoded by the nuclear genome. These defects of oxidative phosphorylation may affect multiple organs and tissues.

Neuromuscular disease is the best recognized part of this complex phenotype. Kidney disease is now recognized as a common component, as well. Tubulointerstitial disease may be seen on kidney biopsy, and progression to kidney failure may occur. Glomerular involvement, manifest as proteinuria and glomerulosclerosis, can also develop. Changes in proximal tubule activity are the most common renal phenotype. Patients may have several defects in proximal tubule transport, including the Fanconi syndrome. Some patients may also have acidosis, hypophosphatemic rickets, hypercalciuria, glycosuria, and tubular proteinuria. Decreased urine concentrating ability is common.

DIAGNOSTIC CONSIDERTIONS

Recent studies using new DNA sequencing technologies suggest that variants in Mendelian kidney disease genes contribute to a nontrivial fraction of CKD cases, even when a clear Mendelian disease phenotype or family history of disease is lacking. Many studies also lead to the conclusion that various rare genetically mediated kidney diseases are difficult to categorize by phenotype alone. These diseases may mimic each other, an argument for using fairly large panels (or the entire genome) in genetic testing in the setting of kidney disease. The old and complicated nomenclature used to describe many human kidney diseases has largely been replaced by newer, genetically defined, categories.

GLOBAL CONSIDERATIONS

The disorders discussed above are all seen worldwide. In addition, a previously unrecognized epidemic of kidney disease is leading to very high rates of kidney failure in and near the western coast of Central America. This Mesoamerican nephropathy is particularly common in Nicaragua and El Salvador. Mesoamerican nephropathy patients do not have significant proteinuria, suggesting that this is a disease of the kidney tubules and interstitium. The causes are unknown, but it is thought that a combination of toxic environmental factors and heat stress underlie the development of this kidney disease, which has a striking male predominance. The fact that in many families a large fraction of the men have kidney disease has suggested that a strong genetic component is involved as well.

328 Tubulointerstitial Diseases of the Kidney

Laurence H. Beck, Jr., David J. Salant

Inflammation or fibrosis of the renal interstitium and atrophy of the tubular compartment are common consequences of diseases that target the glomeruli or vasculature. Distinct from these secondary phenomena, however, are a group of disorders that primarily affect the tubules and interstitium, with relative sparing of the glomeruli and renal vessels. Such disorders are conveniently divided into acute and chronic tubulointerstitial nephritis (TIN) (Table 328-1).

Acute TIN most often presents with acute kidney injury (Chap. 321). The acute nature of this group of disorders may be caused by aggressive inflammatory infiltrates that lead to tissue edema, tubular cell injury, and compromised tubular flow, or by frank obstruction of the tubules with casts, cellular debris, or crystals. There is sometimes flank pain due to distention of the renal capsule. Urinary sediment is often active with leukocytes and cellular casts but depends on the exact nature of the disorder in question.

The clinical features of chronic TIN are more indolent and may manifest with disorders of tubular function, including polyuria from impaired concentrating ability (nephrogenic diabetes insipidus), defective proximal tubular reabsorption leading to features of Fanconi's syndrome (glycosuria, phosphaturia, aminoaciduria, hypokalemia, and type II renal tubular acidosis [RTA] from bicarbonaturia), or non-anion-gap metabolic acidosis and hyperkalemia (type IV RTA) due to impaired ammoniagenesis, as well as progressive azotemia (rising creatinine and blood urea nitrogen [BUN]). There is often modest proteinuria (rarely >2 g/d) attributable to decreased tubular reabsorption of filtered proteins; however, nephrotic-range albuminuria may occur in some conditions due to the development of secondary focal segmental glomerulosclerosis (FSGS). Renal ultrasonography may reveal changes of "medical renal disease," such as increased echogenicity of the renal parenchyma with loss of corticomedullary differentiation, prominence of the renal pyramids, and cortical scarring in some conditions. The predominant pathology in chronic TIN is interstitial fibrosis with patchy mononuclear cell infiltration and widespread tubular atrophy, luminal dilation, and thickening of tubular basement membranes. Because of the nonspecific nature of the histopathology, biopsy specimens rarely provide a specific diagnosis. Thus, diagnosis relies on careful analysis of history, drug or toxin exposure, associated symptoms, and imaging studies.

ACUTE INTERSTITIAL NEPHRITIS

In 1897, Councilman reported eight cases of acute interstitial nephritis (AIN) in the Medical and Surgical Reports of the Boston City Hospital—three as a postinfectious complication of scarlet fever and two from diphtheria. Later, he described the lesion as "an acute inflammation of the kidney characterized by cellular and fluid exudation in the interstitial tissue, accompanied by, but not dependent on, degeneration of the epithelium; the exudation is not purulent in character, and the lesions may be both diffuse and focal." Today AIN is far more often encountered as an allergic reaction to a drug (Table 328-1). Immune-mediated AIN may also occur as part of a known autoimmune syndrome, but in some cases, there is no identifiable cause despite features suggestive of an immunologic etiology (Table 328-1).

ALLERGIC INTERSTITIAL NEPHRITIS

Although biopsy-proven AIN accounts for no more than ~15% of cases of unexplained acute kidney injury, this is likely a substantial underestimate of the true incidence. This is because potentially offending medications are more often identified and empirically discontinued in a patient noted to have a rising serum creatinine, without the benefit of a kidney biopsy to establish the diagnosis of AIN.

TABLE 328-1 Classification of the Causes of Tubulointerstitial Diseases of the Kidney

Acute Tubulointerstitial Disorders

Acute Interstitial Nephritis

Therapeutic agents

- Antibiotics (β-lactams, sulfonamides, quinolones, vancomycin, erythromycin, linezolid, minocycline, rifampin, ethambutol, acyclovir)
- Nonsteroidal anti-inflammatory drugs, COX-2 inhibitors
- Diuretics (rarely thiazides, loop diuretics, triamterene)
- Anticonvulsants (phenytoin, valproate, carbamazepine, phenobarbital)
- Immune modulators (immune checkpoint inhibitors, vedolizumab, lenalidomide)
- Miscellaneous (proton pump inhibitors, H_2 blockers, captopril, mesalazine, indinavir, allopurinol)

Infection

- Bacteria (*Streptococcus, Staphylococcus, Legionella, Salmonella, Brucella, Yersinia, Corynebacterium diphtheriae*)
- Viruses (EBV, CMV, hantavirus, polyomavirus, HIV)
- Miscellaneous (*Leptospira, Rickettsia, Mycoplasma, Histoplasma*)

Autoimmune

- Tubulointerstitial nephritis with uveitis (TINU)
- Sjögren's syndrome
- Systemic lupus erythematosus
- Granulomatous interstitial nephritis
- IgG4-related systemic disease
- Tubulointerstitial disease related to checkpoint inhibitors
- Anti-brush border disease (anti-LRP2 nephropathy)
- Idiopathic autoimmune interstitial nephritis

Acute Obstructive Disorders

- Light chain cast nephropathy ("myeloma kidney")
- Acute phosphate nephropathy
- Acute urate nephropathy

Chronic Tubulointerstitial Disorders

- Vesicoureteral reflux/reflux nephropathy
- Sickle cell disease
- Chronic exposure to toxins or therapeutic agents
- Analgesics, especially those containing phenacetin
- Lithium
- Heavy metals (lead, cadmium)
- Aristolochic acid (Chinese herbal and Balkan endemic nephropathies)
- Calcineurin inhibitors (cyclosporine, tacrolimus)
- Chronic interstitial nephritis in agricultural communities

Metabolic Disturbances

- Hypercalcemia and/or nephrocalcinosis
- Hyperuricemia
- Prolonged hypokalemia
- Hyperoxaluria
- Cystinosis (see Chap. 327)

Cystic and Hereditary Disorders (see Chap. 327)

- Polycystic kidney disease
- Nephronophthisis
- Autosomal dominant tubulointerstitial kidney disease (medullary cystic kidney disease)
- Medullary sponge kidney

Miscellaneous

- Aging
- Chronic glomerulonephritis
- Chronic urinary tract obstruction
- Ischemia and vascular disease
- Radiation nephritis (rare)

Abbreviations: CMV, cytomegalovirus; COX, cyclooxygenase; EBV, Epstein-Barr virus.

Clinical Features The classic presentation of AIN, namely, fever, rash, peripheral eosinophilia, and oliguric kidney injury occurring after 7–10 days of treatment with methicillin or another β-lactam antibiotic, is the exception rather than the rule. More often, patients are found incidentally to have a rising serum creatinine or present with symptoms attributable to acute kidney injury (Chap. 321). Atypical reactions can occur, most notably with nonsteroidal anti-inflammatory drug (NSAID)–induced AIN, in which fever, rash, and eosinophilia are rare, but acute kidney injury with heavy proteinuria is common. A particularly severe and rapid-onset AIN may occur upon reintroduction of rifampin after a drug-free period. More insidious reactions to the agents listed in Table 328-1 may lead to progressive tubulointerstitial damage. Examples include proton pump inhibitors and, rarely, sulfonamide and 5-aminosalicylate (mesalazine and sulfasalazine) derivatives and antiretrovirals. It is not clear if the association of proton pump inhibitors with incident chronic kidney disease involves an intermediate step of prolonged, subclinical interstitial nephritis.

Diagnosis The finding of otherwise unexplained kidney injury with or without oliguria and exposure to a potentially offending agent usually points to the diagnosis. Peripheral blood eosinophilia adds supporting evidence but is present in only a minority of patients. Urinalysis reveals pyuria with white blood cell casts and hematuria. Urinary eosinophils are neither sensitive nor specific for AIN; therefore, testing is not recommended. Kidney biopsy is generally not required for diagnosis but reveals extensive interstitial and tubular infiltration of leukocytes, including eosinophils.

TREATMENT

Allergic Interstitial Nephritis

Discontinuation of the offending agent often leads to reversal of the kidney injury. However, depending on the duration of exposure and degree of tubular atrophy and interstitial fibrosis that has occurred, the kidney damage may not be completely reversible. Glucocorticoid therapy may accelerate kidney recovery but is not required in most cases. It is best reserved for those cases with severe kidney injury in which dialysis is imminent and should be started promptly if kidney function continues to deteriorate despite stopping the offending drug; delay in initiating dialysis leads to worse long-term outcomes (Fig. 328-1 and Table 328-2).

TABLE 328-2 Indications for Corticosteroids and Immunosuppressives in Interstitial Nephritis

Absolute Indications
• Sjögren's syndrome
• Sarcoidosis
• SLE interstitial nephritis
• Adults with TINU
• Interstitial nephritis from IgG4-related disease
• Idiopathic and other granulomatous interstitial nephritis
Relative Indications
• Drug-induced or idiopathic AIN with:
◦ Rapid progression of renal failure
◦ Diffuse infiltrates on biopsy
◦ Impending need for dialysis
◦ Delayed recovery
• Children with TINU
• Postinfectious AIN with delayed recovery (?)

Abbreviations: AIN, acute interstitial nephritis; SLE, systemic lupus erythematosus; TINU, tubulointerstitial nephritis with uveitis.

Source: From Treatment of acute interstitial nephritis, S Reddy & DJ Salant: Renal Failure, 07 Jul 2009, Taylor and Francis. Reprinted by permission of the publisher: Taylor and Francis Ltd, *http://www.tandfonline.com*.

SJÖGREN'S SYNDROME

Sjögren's syndrome is a systemic autoimmune disorder that primarily targets the exocrine glands, especially the lacrimal and salivary glands, and thus results in symptoms, such as dry eyes and mouth, which constitute the "sicca syndrome" (Chap. 373). TIN with a predominant lymphocytic infiltrate is the most common renal manifestation of Sjögren's syndrome and can be associated with impaired kidney function, distal RTA, and nephrogenic diabetes insipidus. Diagnosis is strongly supported by positive serologic testing for anti-Ro (SS-A) and anti-La (SS-B) antibodies. A large proportion of patients with Sjögren's syndrome also have polyclonal hypergammaglobulinemia. Treatment

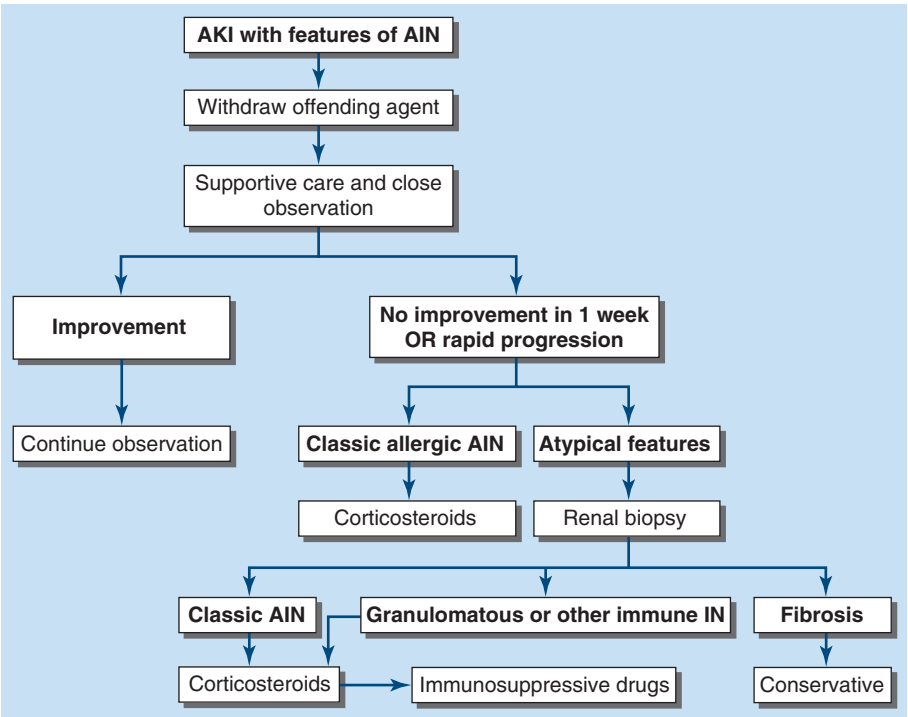

FIGURE 328-1 Algorithm for the treatment of allergic and other immune-mediated acute interstitial nephritis (AIN). AKI, acute kidney injury; IN, interstitial nephritis. See text for immunosuppressive drugs used for refractory or relapsing AIN. *(From Treatment of acute interstitial nephritis, S Reddy & DJ Salant: Renal Failure, 07 Jul 2009, Taylor and Francis. is initially with glucocorticoids, although patients may require maintenance therapy with azathioprine or mycophenolate mofetil to prevent relapse (Fig. 328-1 and Table 328-2).

TUBULOINTERSTITIAL NEPHRITIS WITH UVEITIS

Tubulointerstitial nephritis with uveitis (TINU) is a systemic autoimmune disease of unknown etiology. It accounts for <5% of all cases of AIN, affects females three times more often than males, and has a median age of onset of 15 years. Its hallmark feature, in addition to a lymphocyte-predominant interstitial nephritis **(Fig. 328-2)**, is a painful anterior uveitis, often bilateral and accompanied by blurred vision and photophobia. Diagnosis is often confounded by the fact that the ocular symptoms precede or accompany the kidney disease in only one-third of cases. Additional extrarenal features include fever, anorexia, weight loss, abdominal pain, and arthralgia. The presence of such symptoms as well as elevated creatinine, sterile pyuria, mild proteinuria, features of Fanconi's syndrome, and elevated erythrocyte sedimentation rate should raise suspicion for this disorder. Serologies suggestive of the more common autoimmune diseases are usually negative, and TINU is often a diagnosis of exclusion after other causes of uveitis and kidney disease, such as Sjögren's syndrome, Behçet's disease, sarcoidosis, and systemic lupus erythematosus, have been considered. Clinical symptoms are typically self-limited in children but are more apt to follow a relapsing course in adults. The renal and ocular manifestations generally respond well to oral glucocorticoids, although maintenance therapy with agents such as methotrexate, azathioprine, or mycophenolate may be necessary to prevent relapses (Fig. 328-1 and Table 328-2).

SYSTEMIC LUPUS ERYTHEMATOSUS

An interstitial mononuclear cell inflammatory reaction accompanies the glomerular lesion in most cases of class III or IV lupus nephritis **(Chap. 326)**, and deposits of immune complexes can be identified in tubular basement membranes in ~50% of cases. Occasionally, however, the tubulointerstitial inflammation predominates and may manifest with azotemia and type IV RTA rather than features of glomerulonephritis.

GRANULOMATOUS INTERSTITIAL NEPHRITIS

Some patients may present with features of AIN but follow a protracted and relapsing course. Kidney biopsy in such patients reveals a more chronic inflammatory infiltrate with granulomas and multinucleated giant cells. Most often, no associated disease or cause is found; however, some of these cases may have or subsequently develop the pulmonary, cutaneous, or other systemic manifestations of *sarcoidosis* such as hypercalcemia. Most patients experience some improvement in kidney function if treated early with glucocorticoids before the development of significant interstitial fibrosis and tubular atrophy (Table 328-2). Other immunosuppressive agents may be required for those who relapse frequently upon steroid withdrawal (Fig. 328-1). Tuberculosis should be ruled out before starting treatment because this too is a rare cause of granulomatous interstitial nephritis.

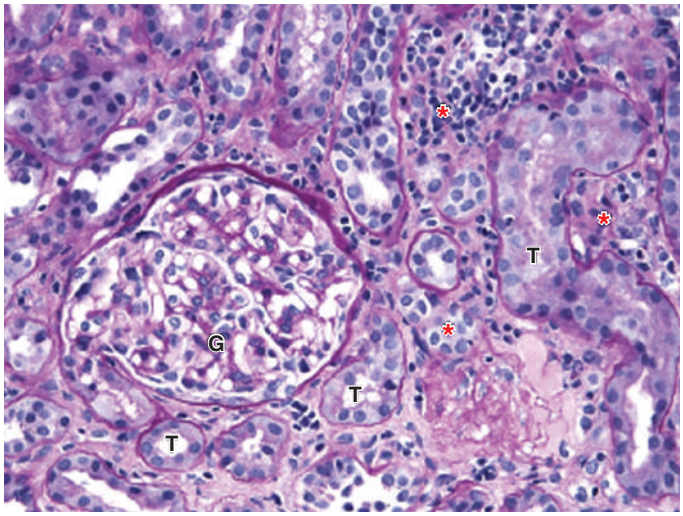

FIGURE 328-2 Acute interstitial nephritis (AIN) in a patient who presented with acute iritis, low-grade fever, erythrocyte sedimentation rate of 103, pyuria and cellular casts on urinalysis, and a newly elevated serum creatinine of 2.4 mg/dL. Both the iritis and AIN improved after intravenous methylprednisolone. This PAS-stained kidney biopsy shows a mononuclear cell interstitial infiltrate (*asterisks*) and edema separating the tubules (T) and a normal glomerulus (G). Some of the tubules contain cellular debris and infiltrating inflammatory cells. The findings in this biopsy are indistinguishable from those that would be seen in a case of drug-induced AIN. PAS, periodic acid–Schiff.

IgG4-RELATED SYSTEMIC DISEASE

A form of AIN characterized by a dense inflammatory infiltrate containing IgG4-expressing plasma cells can occur as a part of a syndrome known as IgG4-related systemic disease **(Chap. 380)**. Autoimmune pancreatitis, sclerosing cholangitis, retroperitoneal fibrosis, and a chronic sclerosing sialadenitis (mimicking Sjögren's syndrome) may variably be present as well. Fibrotic lesions that form pseudotumors in the affected organs soon replace the initial inflammatory infiltrates and often lead to biopsy or excision for fear of true malignancy. Although the involvement of IgG4 in the pathogenesis is not understood, glucocorticoids have been successfully used as first-line treatment in this group of disorders, once they are correctly diagnosed.

AIN ASSOCIATED WITH THE USE OF IMMUNE CHECKPOINT INHIBITORS

The use of immune checkpoint inhibitors has had a major impact in cancer care by disrupting mechanisms by which tumor cells elude the body's immune surveillance systems. However, such success comes at the cost of increasing the incidence of autoimmune phenomena. While dermatologic, gastrointestinal, and endocrine manifestations prevail, the kidney is impacted in 2% of cases with monotherapy and up to 5% when dual checkpoint inhibitor therapy is used. An acute rise in serum creatinine is typically noted within 15 weeks after starting therapy, although it can occur later during therapy or up to 2 months following the final dose. Biopsy, when performed, typically shows acute interstitial inflammation, although glomerular pathologies may also be found. Patients are often taking medications commonly known to cause acute drug-associated TIN such as proton pump inhibitors or NSAIDs. Treatment for severe acute kidney injury includes corticosteroids, discontinuation of potential inciting medications, and avoidance of further checkpoint inhibitor doses until the kidney function has recovered. Reinitiation of these agents for continued treatment of the underlying malignancy may be possible in some cases.

IDIOPATHIC AIN

Some patients present with typical clinical and histologic features of AIN but have no evidence of drug exposure or clinical or serologic features of an autoimmune disease. The presence in some cases of autoantibodies to a tubular antigen, similar to that identified in rats with an induced form of interstitial nephritis, suggests that an autoimmune response may be involved. Like TINU and granulomatous interstitial nephritis, idiopathic AIN is responsive to glucocorticoid therapy but may follow a relapsing course requiring maintenance treatment with another immunosuppressive agent (Fig. 328-1 and Table 328-2). Recently, cases have been identified in which autoantibodies that may be important in disease pathogenesis were seen to target antigens expressed by the collecting duct or proximal tubular brush border.

INFECTION-ASSOCIATED AIN

AIN may also occur as a local inflammatory reaction to microbial infection (Table 328-1) and should be distinguished from acute bacterial pyelonephritis **(Chap. 140)**. Acute bacterial pyelonephritis does not generally cause acute kidney injury unless it affects both kidneys or causes septic shock. Presently, infection-associated AIN is most often seen in immunocompromised patients, particularly kidney transplant recipients with reactivation of polyomavirus BK **(Chaps. 148 and 325)**. A significant increase in cases of acute TIN (without uveitis) or TINU has been noted in children after infection with SARS-CoV-2.

CRYSTAL DEPOSITION DISORDERS AND OBSTRUCTIVE TUBULOPATHIES

Acute kidney injury may occur when crystals of various types are deposited in tubular cells and interstitium or when they obstruct tubules. Impaired kidney function, often accompanied by flank pain from tubular obstruction, may occur in patients treated with sulfadiazine for toxoplasmosis, indinavir and atazanavir for HIV, and intravenous acyclovir for severe herpesvirus infections. Urinalysis reveals "sheaf of wheat" sulfonamide crystals, individual or parallel clusters of needle-shaped indinavir crystals, or red-green birefringent needle-shaped crystals of acyclovir. This adverse effect is generally precipitated by hypovolemia and is reversible with saline volume repletion and drug withdrawal. Distinct from the obstructive disease, a frank AIN from indinavir crystal deposition has also been reported.

Acute tubular obstruction is also the cause of oliguric kidney injury in patients with *acute urate nephropathy*. It typically results from severe hyperuricemia from tumor lysis syndrome in patients with lympho- or myeloproliferative disorders treated with cytotoxic agents but also may occur spontaneously before the treatment has been initiated **(Chap. 80)**. Uric acid crystallization in the tubules and collecting system leads to partial or complete obstruction of the collecting ducts, renal pelvis, or ureter. A dense precipitate of birefringent uric acid crystals is found in the urine, usually in association with microscopic or gross hematuria. Prophylactic allopurinol reduces the risk of uric acid nephropathy but is of no benefit once tumor lysis has occurred. Once oliguria has developed, attempts to increase tubular flow and solubility of uric acid with alkaline diuresis may be of some benefit; however, emergent treatment with hemodialysis or rasburicase, a recombinant urate oxidase, is usually required to rapidly lower uric acid levels and restore kidney function.

Calcium oxalate crystal deposition in tubular cells and interstitium may lead to permanent kidney dysfunction in patients who survive ethylene glycol intoxication, in patients with enteric hyperoxaluria from ileal resection or small-bowel bypass surgery, and in patients with hereditary hyperoxaluria **(Chap. 330)**. *Acute phosphate nephropathy* is an uncommon but serious complication of oral Phosphosoda used as a laxative or for bowel preparation for colonoscopy. It results from calcium phosphate crystal deposition in tubules and interstitium and occurs especially in subjects with underlying kidney disease and hypovolemia. Consequently, Phosphosoda should be avoided in patients with chronic kidney disease, and appropriately, the product is no longer widely available in the United States.

LIGHT CHAIN CAST NEPHROPATHY

Patients with multiple myeloma may develop acute kidney injury in the setting of hypovolemia, infection, or hypercalcemia or after exposure to NSAIDs or radiographic contrast media. The diagnosis of light chain cast nephropathy (LCCN)—commonly known as *myeloma kidney*—should be considered in patients who fail to recover when the precipitating factor is corrected or in any elderly patient with otherwise unexplained acute kidney injury.

In this disorder, filtered monoclonal immunoglobulin light chains (Bence-Jones proteins) form intratubular aggregates with secreted Tamm-Horsfall protein in the distal tubule. Casts, in addition to obstructing the tubular flow in affected nephrons, incite a giant cell or foreign-body reaction and can lead to tubular rupture, resulting in interstitial fibrosis **(Fig. 328-3)**. Although LCCN generally occurs in patients with known multiple myeloma and a large plasma cell burden, the disorder should also be considered as a possible diagnosis in patients who have known monoclonal gammopathy even in the absence of frank myeloma. Filtered monoclonal light chains may also cause less pronounced renal manifestations in the absence of obstruction, due to direct toxicity to proximal tubular cells and intracellular crystal formation. This may result in isolated tubular disorders such as RTA or full Fanconi's syndrome.

Diagnosis Clinical clues to the diagnosis include anemia, bone pain, hypercalcemia, and an abnormally narrow anion gap due to hypoalbuminemia and hypergammaglobulinemia. Urinary dipsticks detect albumin but not immunoglobulin light chains; however, laboratory detection of increased amounts of protein in a spot urine specimen and a negative dipstick result are highly suggestive that the urine contains Bence-Jones protein. Serum and urine should both be sent for protein electrophoresis and for immunofixation for the detection and identification of a potential monoclonal band. A sensitive method is available to detect urine and serum free light chains.

A hematoxylin-eosin–stained kidney biopsy shows many atrophic tubules filled with eosinophilic casts (consisting of Bence-Jones protein), which are surrounded by giant cell reactions. *(Courtesy of Dr. Michael N. Koss, University of Southern California Keck School of Medicine; with permission.)*

TREATMENT

Light Chain Cast Nephropathy

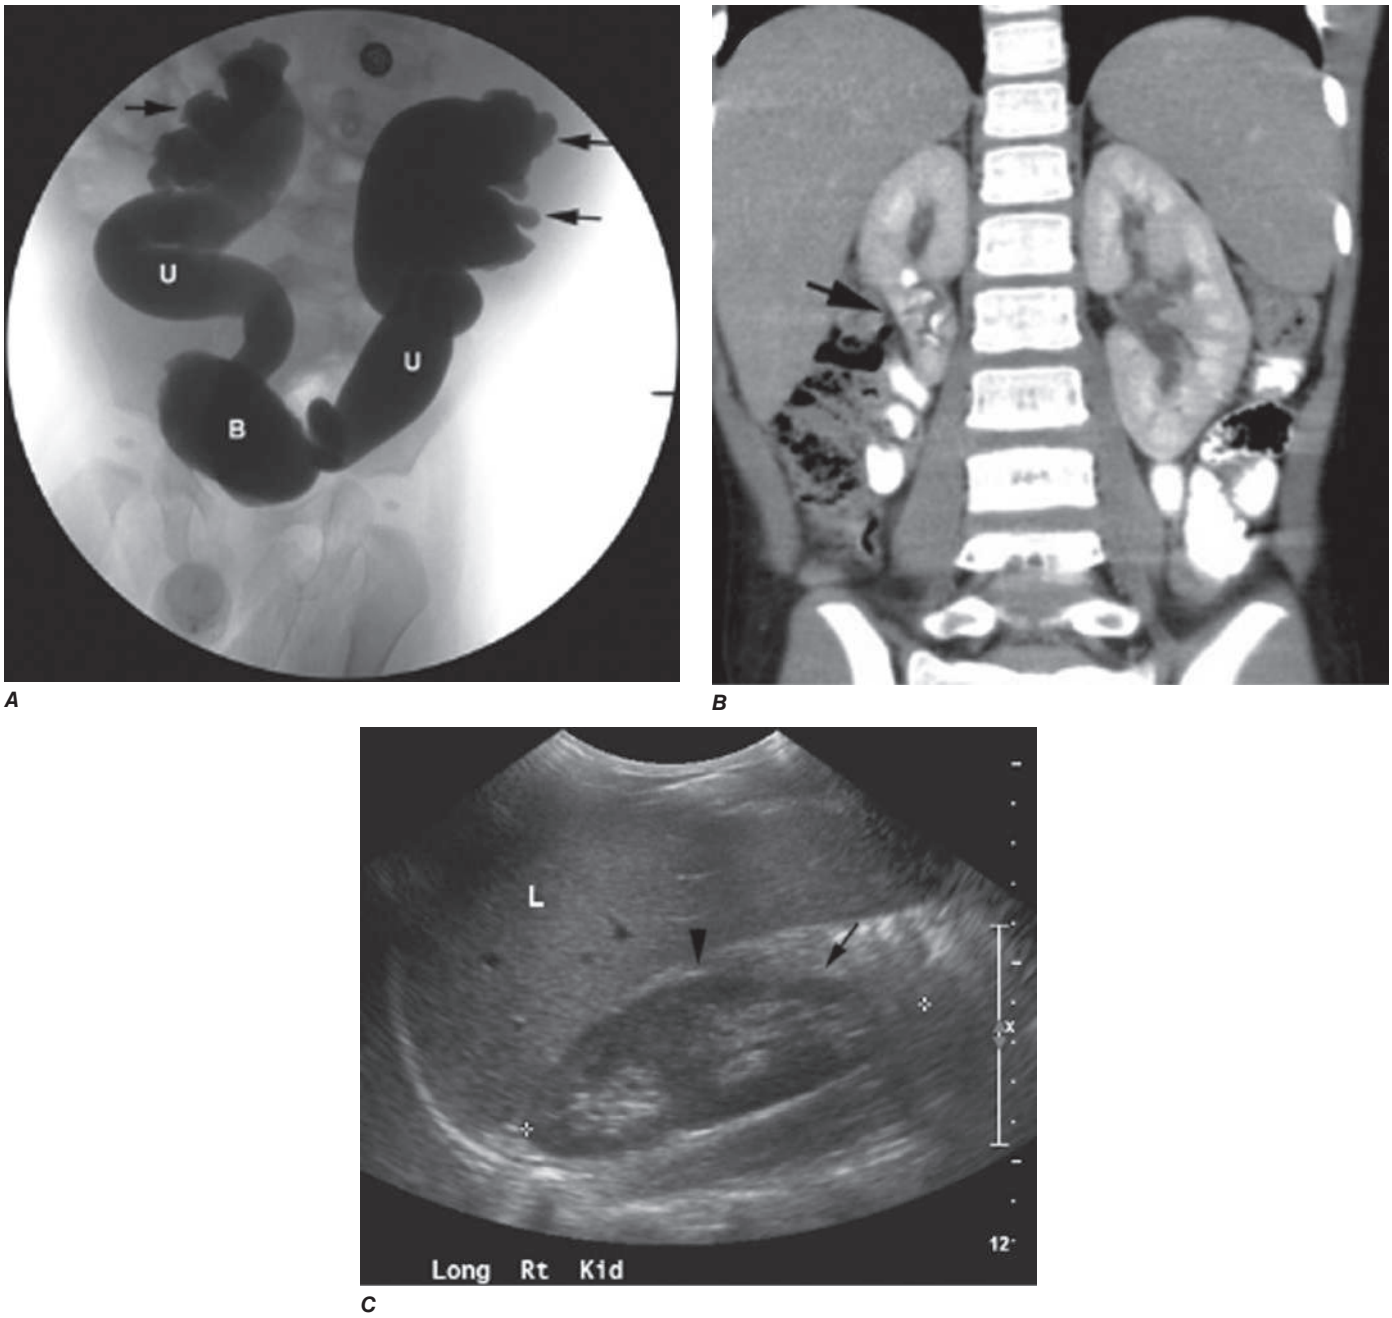
The goals of treatment are to correct precipitating factors such as hypovolemia and hypercalcemia, discontinue potential nephrotoxic agents, and treat the underlying plasma cell dyscrasia **(Chap. 116)**; plasmapheresis to remove light chains is of questionable value for LCCN.

LYMPHOMATOUS INFILTRATION OF THE KIDNEY

Interstitial infiltration by malignant B lymphocytes is a common autopsy finding in patients dying of chronic lymphocytic leukemia and non-Hodgkin's lymphoma; however, this is usually an incidental finding. Rarely, such infiltrates may cause massive enlargement of the kidneys and oliguric acute kidney injury. Although high-dose glucocorticoids and subsequent chemotherapy often result in recovery of kidney function, the prognosis in such cases is generally poor.

CHRONIC TUBULOINTERSTITIAL DISEASES

Improved occupational and public health measures, together with the banning of over-the-counter phenacetin-containing analgesics, has led to a dramatic decline in the incidence of chronic interstitial nephritis (CIN) from heavy metal—particularly lead and cadmium—exposure and analgesic nephropathy in North America. Today, CIN is most often the result of renal ischemia or secondary to a primary glomerular disease **(Chap. 326)**. Other important forms of CIN are the result of developmental anomalies or inherited diseases such as reflux nephropathy or sickle cell nephropathy and may not be recognized until adolescence or adulthood. Although it is impossible to reverse damage that has already occurred, further deterioration may be prevented or at least slowed in such cases by treating glomerular hypertension, a common denominator in the development of secondary FSGS and progressive loss of functioning nephrons. Therefore, awareness and early detection of patients at risk may prevent them from developing end-stage renal disease (ESRD).



VESICOURETERAL REFLUX AND REFLUX NEPHROPATHY

Reflux nephropathy is the consequence of vesicoureteral reflux (VUR) or other urologic anomalies in early childhood. It was previously called *chronic pyelonephritis* because it was believed to result from recurrent urinary tract infections (UTIs) in childhood. VUR stems from abnormal retrograde urine flow from the bladder into one or both ureters and kidneys because of mislocated and incompetent ureterovesical valves (Fig. 328-4). Although high-pressure sterile reflux may impair normal growth of the kidneys, when coupled with recurrent UTIs in early childhood, the result is patchy interstitial scarring and tubular atrophy. Loss of functioning nephrons leads to hypertrophy of the remnant glomeruli and eventual secondary FSGS. Reflux nephropathy often goes unnoticed until early adulthood when chronic kidney disease is detected during routine evaluation or during pregnancy. Affected adults are frequently asymptomatic but may give a history of prolonged bed-wetting or recurrent UTIs during childhood and may exhibit variable degrees of kidney injury as well as hypertension, mild to moderate proteinuria, and an unremarkable urine sediment. When both kidneys are affected, the disease often progresses inexorably over several years to ESRD, despite the absence of ongoing urinary infections or reflux. A single affected kidney may go undetected, except for the presence of hypertension. Kidney ultrasound in adults characteristically shows asymmetric small kidneys with irregular outlines, thinned cortices, and regions of compensatory hypertrophy (Fig. 328-4).

TREATMENT

Vesicoureteral Reflux and Reflux Nephropathy

While it was previously believed that maintenance of sterile urine in childhood limits scarring of the kidneys, a recent study found

A B C

FIGURE 328-4 Radiographs of vesicoureteral reflux (VUR) and reflux nephropathy. ***A.*** Voiding cystourethrogram in a 7-month-old baby with bilateral high-grade VUR evidenced by clubbed calyces (*arrows*) and dilated tortuous ureters (U) entering the bladder (B). ***B.*** Abdominal computed tomography scan (coronal plane reconstruction) in a child showing severe scarring of the lower portion of the right kidney (*arrow*). ***C.*** Sonogram of the right kidney showing loss of parenchyma at the lower pole due to scarring (*arrow*) and hypertrophy of the mid-region (*arrowhead*). *(Courtesy of Dr. George Gross, University of Maryland Medical Center; with permission.)*

no such benefit, at least for 2 years. Surgical reimplantation of the ureters into the bladder to restore competency is indicated in young children with persistent high-grade reflux but is ineffective and is not indicated in adolescents or adults after scarring has occurred. Aggressive control of blood pressure and/or glomerular hyperfiltration with an angiotensin-converting enzyme inhibitor (ACEI) or angiotensin receptor blocker (ARB) and other agents (e.g., sodium-glucose cotransporter 2 [SGLT2] inhibitors) is effective in reducing proteinuria and may significantly forestall further deterioration of kidney function.

SICKLE CELL NEPHROPATHY

The pathogenesis and clinical manifestations of sickle cell nephropathy are described in **Chap. 329**. Evidence of tubular injury may be evident in childhood and early adolescence in the form of polyuria due to decreased concentrating ability or type IV RTA years before there is significant nephron loss and proteinuria from secondary FSGS. Early recognition of these subtle renal abnormalities or development of microalbuminuria in a child with sickle cell disease may warrant consultation with a nephrologist and/or therapy with low-dose ACEIs. Papillary necrosis may result from ischemia due to sickling of red cells in the relatively hypoxemic and hypertonic medullary vasculature and present with gross hematuria and ureteric obstruction by sloughed ischemic papillae **(Table 328-3)**.

TUBULOINTERSTITIAL ABNORMALITIES ASSOCIATED WITH GLOMERULONEPHRITIS

Primary glomerulopathies are often associated with damage to tubules and interstitium. This may occasionally be due to the same pathologic process affecting the glomerulus and tubulointerstitium, as is the case with immune-complex deposition in lupus nephritis. More often, however, chronic tubulointerstitial changes occur as a secondary consequence of prolonged glomerular dysfunction. Potential mechanisms by which glomerular disease might cause tubulointerstitial injury include proteinuria-mediated damage to the epithelial cells, activation of tubular cells by cytokines and complement, or reduced peritubular blood flow leading to downstream tubulointerstitial ischemia, especially in the case of glomeruli that are globally obsolescent due to severe glomerulonephritis. It is often difficult to discern the initial cause of injury by kidney biopsy in a patient who presents with advanced kidney disease in this setting.

ANALGESIC NEPHROPATHY

Analgesic nephropathy results from the long-term use of compound analgesic preparations containing phenacetin (banned in the United States since 1983), aspirin, and caffeine. In its classic form, analgesic nephropathy is characterized by impaired kidney function, papillary necrosis (Table 328-3) attributable to the presumed concentration of the drug to toxic levels in the inner medulla, and a radiographic constellation of small, scarred kidneys with papillary calcifications. Patients may also have polyuria due to impaired concentrating ability and non-anion-gap metabolic acidosis from tubular damage. Shedding of a sloughed necrotic papilla can cause gross hematuria and ureteric colic due to ureteral obstruction. Individuals with ESRD as a result of analgesic nephropathy are at increased risk of a urothelial malignancy compared to patients with other causes of kidney failure.

ARISTOLOCHIC ACID NEPHROPATHY

Two seemingly unrelated forms of CIN, Chinese herbal nephropathy and Balkan endemic nephropathy, have recently been linked by the underlying etiologic agent aristolochic acid and are now collectively termed aristolochic acid nephropathy (AAN). In Chinese herbal nephropathy, first described in the early 1990s in young women taking traditional Chinese herbal preparations as part of a weight-loss regimen, one of the offending agents has been identified as aristolochic acid, a known carcinogen from the plant *Aristolochia*. Multiple *Aristolochia* species have been used in traditional herbal remedies for centuries and continue to be available despite official bans on their use in many countries. Molecular evidence has also implicated aristolochic acid in Balkan endemic nephropathy, a chronic TIN found primarily in towns along the tributaries of the Danube River and first described in the 1950s. Although the exact route of exposure is not known with certainty, contamination of local grain preparations with the seeds of *Aristolochia* species seems most likely. Aristolochic acid, after prolonged exposure, produces renal interstitial fibrosis with a relative paucity of cellular infiltrates. The urine sediment is bland, with rare leukocytes and only mild proteinuria. Anemia may be disproportionately severe relative to the level of kidney dysfunction. Definitive diagnosis of AAN requires two of the following three features: characteristic histology on kidney biopsy; confirmation of aristolochic acid ingestion; and detection of aristolactam-DNA adducts in kidney or urinary tract tissue. These latter lesions represent a molecular signature of aristolochic acid–derived DNA damage and often consist of characteristic A:T-to-T:A transversions. Due to this mutagenic activity, AAN is associated with a very high incidence of upper urinary tract urothelial cancers, with risk related to cumulative dose. Surveillance with computed tomography, ureteroscopy, and urine cytology is warranted, and consideration should be given to bilateral nephroureterectomy once a patient has reached ESRD.

TABLE 328-3 Major Causes of Papillary Necrosis

Analgesic nephropathy
Sickle cell nephropathy
Diabetes with urinary tract infection
Prolonged NSAID use (rare)

Abbreviation: NSAID, nonsteroidal anti-inflammatory drug.

KARYOMEGALIC INTERSTITIAL NEPHRITIS

Karyomegalic interstitial nephritis is an unusual form of slowly progressive chronic kidney disease with mild proteinuria, interstitial fibrosis, tubular atrophy, and oddly enlarged nuclei of proximal tubular epithelial cells. It has been linked to mutations in *FAN1*, a nuclease involved in DNA repair, which may render carriers of the mutation susceptible to environmental DNA-damaging agents.

LITHIUM-ASSOCIATED NEPHROPATHY

The use of lithium salts for the treatment of manic-depressive illness may have several renal sequelae, the most common of which is nephrogenic diabetes insipidus manifesting as polyuria and polydipsia. Lithium accumulates in principal cells of the collecting duct by entering through the epithelial sodium channel (ENaC), where it inhibits glycogen synthase kinase 3β and downregulates vasopressin-regulated aquaporin water channels. Less frequently, chronic TIN develops after prolonged (>10–20 years) lithium use and is most likely to occur in patients who have experienced repeated episodes of toxic lithium levels. Findings on kidney biopsy include interstitial fibrosis and tubular atrophy that are out of proportion to the degree of glomerulosclerosis or vascular disease, a sparse lymphocytic infiltrate, and small cysts or dilation of the distal tubule and collecting duct that are highly characteristic of this disorder. The degree of interstitial fibrosis correlates with both duration and cumulative dose of lithium. Individuals with lithium-associated nephropathy are typically asymptomatic, with minimal proteinuria, few urinary leukocytes, and normal blood pressure. Some patients develop more severe proteinuria due to secondary FSGS, which may contribute to further loss of kidney function.

TREATMENT

Lithium-Associated Nephropathy

Kidney function should be followed regularly in patients taking lithium, and caution should be exercised in patients with underlying kidney disease. The use of amiloride to inhibit lithium entry via ENaC has been effective to prevent and treat lithium-induced nephrogenic diabetes insipidus, but it is not clear if it will prevent lithium-induced CIN. Once lithium-associated nephropathy is detected, the discontinuation of lithium in attempt to forestall

further deterioration of kidney function can be problematic, as lithium is an effective mood stabilizer that is often incompletely substituted by other agents. Furthermore, despite discontinuation of lithium, chronic kidney disease in such patients is often irreversible and can slowly progress to ESRD. The most prudent approach is to monitor lithium levels frequently and adjust dosing to avoid toxic levels (preferably <1 meq/L). This is especially important because lithium is cleared less effectively as kidney function declines.

CALCINEURIN INHIBITOR NEPHROTOXICITY

The calcineurin inhibitor (CNI) immunosuppressive agents cyclosporine and tacrolimus can cause both acute and chronic kidney injury. Acute forms can result from vascular causes such as vasoconstriction or the development of thrombotic microangiopathy or can be due to a toxic tubulopathy. Chronic CNI-induced kidney injury is typically seen in solid organ (including heart-lung and liver) transplant recipients and manifests with a slow but irreversible reduction of glomerular filtration rate, with mild proteinuria and arterial hypertension. Hyperkalemia is a relatively common complication and is caused, in part, by tubular resistance to aldosterone. The histologic changes in kidney tissue include patchy interstitial fibrosis and tubular atrophy, often in a "striped" pattern. In addition, the intrarenal vasculature often demonstrates hyalinosis, and focal glomerulosclerosis can be present as well. Similar changes may occur in patients receiving CNIs for autoimmune diseases, although the doses are generally lower than those used for organ transplantation. Dose reduction or CNI avoidance appears to mitigate the chronic tubulointerstitial changes but may increase the risk of rejection and graft loss.

HEAVY METAL (LEAD) NEPHROPATHY

Heavy metals, such as lead or cadmium, can lead to a chronic tubulointerstitial process after prolonged exposure. The disease entity is no longer commonly diagnosed, because such heavy metal exposure has been greatly reduced due to the known health risks from lead and the consequent removal of lead from most commercial products and fuels. Nonetheless, occupational exposure is possible in workers involved in the manufacture or destruction of batteries, removal of lead paint, or manufacture of alloys and electrical equipment (cadmium) in countries where industrial regulation is less stringent. In addition, ingestion of moonshine whiskey distilled in lead-tainted containers has been one of the more frequent sources of lead exposure.

Early signs of chronic lead intoxication are attributable to proximal tubule dysfunction, particularly hyperuricemia as a result of diminished urate secretion. The triad of "saturnine gout," hypertension, and impaired kidney function should prompt a practitioner to ask specifically about lead exposure. Unfortunately, evaluating lead burden is not as straightforward as ordering a blood test; the preferred methods involve measuring urinary lead after infusion of a chelating agent or by radiographic fluoroscopy of bone. Several recent studies have shown an association between chronic low-level lead exposure and decreased kidney function, although either of these two factors may have been the primary event. In patients who have CIN of unclear origin and an elevated total body lead burden, repeated treatments of lead chelation therapy have been shown to slow the decline in kidney function.

METABOLIC DISORDERS

Disorders leading to excessively high or low levels of certain electrolytes and products of metabolism can also lead to chronic kidney disease if untreated.

CHRONIC URIC ACID NEPHROPATHY

The constellation of pathologic findings that represent *gouty nephropathy* is very uncommon nowadays and is more of historical interest than clinical importance, as gout is typically well managed with allopurinol and other agents. However, there is emerging evidence that hyperuricemia is an independent risk factor for the development of chronic kidney disease, perhaps through endothelial damage. The complex interactions of hyperuricemia, hypertension, and kidney failure are still incompletely understood.

Presently, gouty nephropathy is most likely to be encountered in patients with severe tophaceous gout and prolonged hyperuricemia from a hereditary disorder of purine metabolism. This should be distinguished from juvenile hyperuricemic nephropathy, a form of medullary cystic kidney disease caused by mutations in uromodulin (UMOD) **(Chap. 327)** and now grouped into the larger category of autosomal dominant tubulointerstitial kidney disease. Histologically, the distinctive feature of gouty nephropathy is the presence of crystalline deposits of uric acid and monosodium urate salts in the kidney parenchyma. These deposits not only cause intrarenal obstruction but also incite an inflammatory response, leading to lymphocytic infiltration, foreign-body giant cell reaction, and eventual fibrosis, especially in the medullary and papillary regions of the kidney. Since patients with gout frequently suffer from hypertension and hyperlipidemia, degenerative changes of the renal arterioles may constitute a striking feature of the histologic abnormality, out of proportion to the other morphologic defects. Clinically, gouty nephropathy is an insidious cause of chronic kidney disease. Early in its course, glomerular filtration rate may be near normal, often despite morphologic changes in medullary and cortical interstitium, proteinuria, and diminished urinary concentrating ability. Treatment with allopurinol and urine alkalinization is generally effective in preventing uric acid nephrolithiasis and the consequences of recurrent kidney stones; however, gouty nephropathy may be intractable to such measures. Furthermore, the use of allopurinol in asymptomatic hyperuricemia has not been consistently shown to improve kidney function.

HYPERCALCEMIC NEPHROPATHY

(See also Chap. 422) Chronic hypercalcemia, as occurs in primary hyperparathyroidism, sarcoidosis, multiple myeloma, vitamin D intoxication, or metastatic bone disease, can cause tubulointerstitial disease and progressive kidney injury. The earliest lesion is a focal degenerative change in renal epithelia, primarily in collecting ducts, distal tubules, and loops of Henle. Tubular cell necrosis leads to nephron obstruction and stasis of intrarenal urine, favoring local precipitation of calcium salts and infection. Dilation and atrophy of tubules eventually occur, as do interstitial fibrosis, mononuclear leukocyte infiltration, and interstitial calcium deposition (nephrocalcinosis). Calcium deposition may also occur in glomeruli and the walls of renal arterioles.

Clinically, the most striking defect is an inability to maximally concentrate the urine, due to reduced collecting duct responsiveness to arginine vasopressin and defective transport of sodium and chloride in the loop of Henle. Reductions in both glomerular filtration rate and renal blood flow can occur, both in acute and in prolonged hypercalcemia. Eventually, uncontrolled hypercalcemia leads to severe tubulointerstitial damage and overt kidney injury. Abdominal x-rays may demonstrate nephrocalcinosis as well as nephrolithiasis, the latter due to the hypercalciuria that often accompanies hypercalcemia.

Treatment consists of reducing the serum calcium concentration toward normal and correcting the primary abnormality of calcium metabolism **(Chap. 422)**. Acute kidney injury from acute hypercalcemia may be completely reversible. Gradual progressive kidney dysfunction related to chronic hypercalcemia, however, may not improve even with correction of the calcium disorder.

HYPOKALEMIC NEPHROPATHY

Patients with prolonged and severe hypokalemia from chronic laxative or diuretic abuse, surreptitious vomiting, or primary aldosteronism may develop a reversible tubular lesion characterized by vacuolar degeneration of proximal and distal tubular cells. Eventually, tubular atrophy and cystic dilation accompanied by interstitial fibrosis may ensue, leading to irreversible chronic kidney disease. Timely correction of the hypokalemia will prevent further progression, but persistent hypokalemia can cause ESRD.

GLOBAL PERSPECTIVE

The causes of AIN and CIN vary widely across the globe. Analgesic nephropathy continues to be seen in countries where phenacetin-containing compound analgesic preparations are readily available.

Adulterants in unregulated herbal and traditional medicaments pose a threat of toxic interstitial nephritis, as exemplified by aristolochic acid contamination of herbal slimming preparations. Contamination of food sources with toxins, such as an outbreak of nephrolithiasis and acute kidney injury from melamine contamination of infant milk formula, poses a continuing risk. Large-scale exposure to aristolochic acid remains prevalent in many Asian countries where traditional herbal medicine use is common. Although industrial exposure to lead and cadmium has largely disappeared as a cause of CIN in developed nations, it remains a risk for nephrotoxicity in countries where such exposure is less well controlled.

New endemic forms of chronic kidney disease continue to be described. In particular, nephropathies with features of CIN have been increasing in prevalence among Pacific coastal plantation workers in Central America (Mesoamerican nephropathy), Sri Lanka (Sri Lankan nephropathy), and southern India (Uddanam nephropathy). Together, these disorders have been called chronic interstitial nephritis of agricultural communities (CINAC) or chronic kidney disease of unknown etiology (CKDu) and may be related to repetitive episodes of heat exposure, dehydration, and volume depletion in the field workers. However, toxins, pesticides, and infective agents also remain as possible etiologic agents. Global warming and regional temperature variability have been proposed as contributors to these newly described forms of kidney disease, and tens of thousands of lives have been lost due to ESRD in these resource-poor areas in which renal replacement therapy is often not an option.

329 Thrombotic Renovascular Disorders

Elisabeth M. Battinelli, Rebecca L. Zon

The renal circulation is complex and is characterized by a highly perfused arteriolar network, reaching cortical glomerular structures adjacent to lower-flow vasa recta that descend into medullary segments. This chapter examines primary disorders of the microvessels, many of which are associated with thrombosis and hemolysis. Disorders of the larger vessels, including renal artery stenosis and atheroembolic disease, are discussed elsewhere (Chap. 289).

THROMBOTIC MICROANGIOPATHY

Thrombotic microangiopathy (TMA) is a pathologic lesion characterized by endothelial cell injury in the terminal arterioles and capillaries. Platelet and hyaline thrombi causing partial or complete occlusion are integral to the histopathology of TMA. TMA is usually accompanied by microangiopathic hemolytic anemia (MAHA) with its typical features of thrombocytopenia and schistocytes, but not always. In the kidney, TMA is characterized by swollen endocapillary cells (endotheliosis), fibrin thrombi, platelet plugs, arterial intimal fibrosis, and a membranoproliferative pattern in the glomerulus. Fibrin thrombi may extend into the arteriolar vascular pole, producing glomerular collapse and at times cortical necrosis. In kidneys that recover from acute TMA, secondary focal segmental glomerulosclerosis may develop. Thrombotic vascular diseases include thrombotic thrombocytopenic purpura (TTP), hemolytic-uremic syndrome (HUS), malignant hypertension, scleroderma renal crisis, antiphospholipid syndrome, preeclampsia/HELLP (*h*emolysis, *e*levated *l*iver enzymes, *l*ow *p*latelet count) syndrome, HIV infection, cancer-associated TMA, and microvascular disease associated with COVID-19.

HEMOLYTIC-UREMIC SYNDROME/THROMBOTIC THROMBOCYTOPENIC PURPURA

HUS and TTP are the prototypes for MAHA. Historically, HUS and TTP were distinguished mainly by their clinical and epidemiologic differences. TTP develops more commonly in adults and was thought to have more neurologic complications, while HUS occurs more frequently in children, particularly when associated with hemorrhagic diarrhea. However, atypical HUS (aHUS) can have its first appearance in adulthood, and neurologic involvement can be as common in HUS as in TTP. Currently, HUS and TTP can be differentiated etiologically and treated according to their specific pathophysiologic features.

Hemolytic-Uremic Syndrome HUS is loosely defined by the presence of MAHA and renal impairment. At least four variants are recognized. The most common is Shiga toxin–producing *Escherichia coli* (STEC) HUS, which is also known as D^+ (diarrhea-associated) HUS or enterohemorrhagic *E. coli* (EHEC) HUS. Most cases involve children <5 years of age, but adults also are susceptible, as evidenced by a 2011 outbreak in northern Europe. Diarrhea, often bloody, precedes MAHA within 1 week in >80% of cases. Abdominal pain, cramping, and vomiting are frequent, whereas fever is typically absent. Neurologic symptoms, including dysphasia, hyperreflexia, blurred vision, memory deficits, encephalopathy, perseveration, and agraphia, often develop, especially in adults. Seizures and cerebral infarction can occur in severe cases. STEC HUS is caused by the Shiga toxins (Stx1 and Stx2), which are also referred to as *verotoxins*. These toxins are produced by certain strains of *E. coli* and *Shigella dysenteriae*. In the United States and Europe, the most common STEC strain is O157:H7, but HUS has been reported with other strains ($O157/H^-$, $O111:H^-$, $O26:H11/H^-$, O145:H28, and O104:H4). After entry into the circulation, Shiga toxin binds to the glycolipid surface receptor globotriaosylceramide (Gb3), which is richly expressed on cells of the renal microvasculature. Upon binding, the toxin enters the cells, inducing inflammatory cytokines (interleukin 8 [IL-8], monocyte chemotactic protein 1 [MCP-1], and stromal cell–derived factor 1 [SDF-1]) and chemokine receptors (CXCR4 and CXCR7); this action results in platelet aggregation and the microangiopathic process. *Streptococcus pneumoniae* can also cause HUS. Certain strains produce a neuraminidase that cleaves the *N*-acetylneuraminic acid moieties normally covering the Thomsen-Friedenreich antigen on platelets and endothelial cells. Exposure of this cryptic antigen to preformed IgM results in severe MAHA.

aHUS or complement-mediated HUS is the result of complement dysregulation. The complement dysregulation can be congenital or acquired. The affected patients often have low C3 and normal C4 levels characteristic of alternative pathway activation. Factor H deficiency, the most common defect, has been linked to families with aHUS. Factor H competes with factor B to prevent the formation of C3bBb and acts as a cofactor for factor I, which proteolytically degrades C3b. More than 70 mutations of the factor H gene have been identified. Most are missense mutations that produce abnormalities in the C-terminus region, affecting its binding to C3b but not its concentration. Other mutations result in low levels or the complete absence of the protein. Deficiencies in other complement-regulatory proteins, such as factor I, factor B, membrane cofactor protein (CD46), C3, complement factor H (CFH)–related protein 1 (CFHR1), CFHR3, CFHR5, and thrombomodulin, have also been reported. Finally, an autoimmune variant of aHUS, DEAP (deficiency of CFHR plasma proteins and

CFH autoantibody positive) HUS, occurs when an autoantibody to factor H is formed. DEAP HUS is often associated with a deletion of an 84-kb fragment of the chromosome that encodes for CFHR1 and CFHR3. The autoantibody blocks the binding of factor H to C3b and surface-bound C3 convertase. Renal injury is often severe, resulting in end-stage renal disease. The severity of the renal injury and recurrence after kidney transplant depend on the complement regulatory protein.

Thrombotic Thrombocytopenic Purpura Traditionally, TTP is characterized by the pentad of MAHA, thrombocytopenia, neurologic symptoms, fever, and renal failure; however, <5% of individuals with immune-mediated TTP will have the full pentad. The pathophysiology of TTP involves the accumulation of ultra-large multimers of von Willebrand factor as a result of the absence or markedly decreased activity of the plasma protease ADAMTS13, a disintegrin and metalloproteinase with a thrombospondin type 1 motif, member 13. TTP is now defined as MAHA associated with ADAMTS13 activity of <5–10%. These ultra-large multimers form clots and shear erythrocytes, resulting in MAHA; however, the absence of ADAMTS13 alone may not by itself produce TTP. Often, an additional inflammatory trigger (such as infection, surgery, pancreatitis, or pregnancy) is required to initiate clinical TTP. This may be mediated by human neutrophil peptides that inhibit cleavage of von Willebrand factor by ADAMTS13. TTP can be congenital from ADAMTS13 mutation (cTTP) or acquired from autoantibody against ADAMTS13 protein (iTTP).

cTTP, also known as Upshaw-Schülman syndrome, is characterized by congenital deficiency of ADAMTS13. cTTP can start within the first weeks of life but, in some instances, may not present until adulthood, especially during pregnancy. Both environmental and genetic factors are thought to influence the development of cTTP. Plasma transfusion is an effective strategy for prevention and treatment. In iTTP, autoantibody to ADAMTS13 (IgG or IgM) either increases its clearance or inhibits its activity. Data from the Oklahoma TTP/HUS Registry suggest an iTTP incidence rate of 2.9 cases/10^6 patients in the United States. The median age of onset is 40 years. The incidence is more than nine times higher among blacks than nonblacks. Like that of systemic lupus erythematosus, the incidence of iTTP is nearly three times higher among women than among men. If untreated, iTTP has a mortality rate exceeding 90%. Even with modern therapy, 20% of patients die within the first month from complications of microvascular thrombosis.

Drug-induced TMA is a recognized complication of treatment with some chemotherapeutic agents, immunosuppressive agents, and quinine. Two different mechanisms are now recognized. Toxic or endothelial damage (pathologically similar to that of HUS) is the main cause of the TMA that develops in association with chemotherapeutic agents (e.g., proteasome inhibitors [bortezomib, carfilzomib, and ixazomib], mitomycin C, and gemcitabine) and immunosuppressive agents (cyclosporine, interferon, sirolimus, and tacrolimus). This process is usually dose-dependent. Alternatively, TMA may develop as a result of drug-induced autoantibodies. This form is less likely to be dose-dependent and can, in fact, occur after a single dose in patients with previous exposure (quinine). ADAMTS13 deficiency is found in fewer than half of patients with clopidogrel-associated TTP. Quinine appears to induce autoantibodies to granulocytes, lymphocytes, endothelial cells, and platelet glycoprotein Ib/IX or IIb/IIIa complexes, but not to ADAMTS13. Quinine-associated TTP is more common among women. TMA has also been reported with drugs that inhibit vascular endothelial growth factor, such as bevacizumab; the mechanism is not completely understood.

TREATMENT

Hemolytic-Uremic Syndrome/Thrombotic Thrombocytopenic Purpura

Treatment should be based on pathophysiology. iTTP and DEAP HUS respond to the combination of plasma exchange and prednisone. In addition to removing the autoantibodies, plasma exchange with fresh-frozen plasma replaces ADAMTS13. Twice-daily plasma exchanges with administration of rituximab may be effective in refractory cases. The use of caplacizumab, a monoclonal antibody fragment that binds to the A1 domain of von Willebrand factor, blocking its interaction with platelets, was recently shown to improve platelet count recovery and reduce the composite risk of death, disease exacerbation, and thromboembolic events. It is now approved for use in iTTP in conjunction with plasma exchange and immunosuppressive therapy. Plasma infusion is usually sufficient to replace the ADAMTS13 in cTTP. Plasma exchange should be considered if larger volumes are necessary. Additionally, newer medications are being studied and utilized in TTP, such as caplacizumab, a humanized monoclonal antibody fragment that binds to von Willebrand factor and blocks its interaction with platelet glycoproteins. Caplacizumab can be considered as an additive medication, especially in those with severe features of TTP or in cases with continued thrombocytopenia that does not respond to initial therapy.

Plasma infusion/exchange is effective in certain types of aHUS because it replaces complement-regulatory proteins. Eculizumab and ravulizumab, anti-C5 monoclonal antibodies, are approved for use in aHUS and have been shown to abort MAHA and improve renal function. Antibiotics and washed red cells should be given in neuraminidase-associated HUS, and plasmapheresis may be helpful; however, plasma and whole-blood transfusion should be avoided since these products contain IgM, which may exacerbate MAHA. Combined factor H and ADAMTS13 deficiency has been reported. The affected patients are generally less responsive to plasma infusion, an outcome that illustrates the complexity of the management of these cases.

Drug-induced TMA secondary to endothelial damage typically does not respond to plasma exchange and is treated primarily by discontinuing the use of the agent and, if refractory, a trial of C5 inhibitors. Similarly, STEC HUS should be treated with supportive measures as plasma exchange has not been found to be effective. Antimotility agents and antibiotics increase the incidence of HUS among children, but azithromycin may decrease the duration of bacterial shedding in adults.

HEMATOPOIETIC STEM CELL TRANSPLANTATION–ASSOCIATED THROMBOTIC MICROANGIOPATHY

Hematopoietic stem cell transplantation (HSCT)–associated TMA develops after allogeneic HSCT, with an incidence of ~8%. Etiologic factors include conditioning regimens, immunosuppression, infections, and graft-versus-host disease. Other risk factors include female sex and human leukocyte antigen (HLA)–mismatched donor grafts. HSCT-TMA usually occurs within the first 100 days of HSCT. **Table 329-1** lists definitions of HSCT-TMA currently used for clinical trials. Diagnosis may be difficult since thrombocytopenia, anemia, and renal insufficiency are common after HSCT. HSCT-TMA carries a high mortality rate (75% within 3 months). The majority of patients have >10% ADAMTS13 activity, and plasma exchange is beneficial in <25%

TABLE 329-1 Criteria for Establishing Microangiopathic Kidney Injury Associated with Hematopoietic Stem Cell Transplantation

INTERNATIONAL WORKING GROUP	BLOOD AND MARROW TRANSPLANT CLINICAL TRIALS NETWORK TOXICITY COMMITTEE
>4% schistocytes in the blood	RBC fragmentation and at least 2 schistocytes per high-power field
De novo, prolonged, or progressive thrombocytopenia	Concurrent increase in LDH above baseline
A sudden and persistent increase in LDH	Negative direct and indirect Coombs test
Decrease in hemoglobin or increased RBC transfusion requirement	Concurrent renal and/or neurologic dysfunction without other explanations
Decrease in haptoglobin concentration	

Abbreviations: LDH, lactate dehydrogenase; RBC, red blood cell.

of patients. Discontinuation of calcineurin inhibitors and treatment of infections or sinusoidal obstruction syndrome (if present) are recommended. There are increasing reports of successful use of eculizumab, but clinical trial data are lacking.

CANCER-ASSOCIATED TMA

When MAHA and thrombocytopenia are present, one should assess for evidence of malignancy and consider the diagnosis of cancer-associated TMA. The mechanism of TMA in cancer is thought to be tumor cell obstruction in the microvasculature leading to cell fragmentation and platelet consumption: TMAs in cancer can occur on initial diagnosis of the cancer or when the cancer becomes refractory, and have been identified in both solid malignancies and hematologic malignancies. Clinical features, such as bone pain and respiratory symptoms, have been found to occur more in cancer-associated TMA than in TTP. Additionally, compared to immune-mediated TTP, there is no role for plasma exchange, steroids, or other immunosuppression in cancer-associated TMA; instead, the management is treatment of the underlying malignancy.

HIV-RELATED THROMBOTIC MICROANGIOPATHY

HIV-related TMA is a complication encountered mainly before widespread use of highly active antiretroviral therapy. It is seen in patients with advanced AIDS and low CD4+ T-cell counts, although it can be the first manifestation of HIV infection. The presence of MAHA, thrombocytopenia, and renal failure is suggestive, but renal biopsy is required for diagnosis since other renal diseases are also associated with HIV infection. Thrombocytopenia may prohibit renal biopsy in some patients. The mechanism of injury is unclear, although HIV can induce apoptosis in endothelial cells. ADAMTS13 activity is not reduced in these patients. Cytomegalovirus co-infection may also be a risk factor. Effective antiviral therapy is key, while plasma exchange should be limited to patients who have evidence of TTP.

PROGRESSIVE SYSTEMIC SCLEROSIS (SCLERODERMA)

MAHA can also be present in scleroderma renal crisis, which is also characterized by acute kidney injury, abrupt onset of hypertension, and a normal urine sediment, although each of these aspects is not required for the diagnosis. Scleroderma renal crisis occurs in 12% of patients with diffuse systemic sclerosis but in only 2% of those with limited systemic sclerosis. Although MAHA is present in more than half of patients, coagulopathy is rare. Retinopathy and encephalopathy may accompany the hypertension. Salt and water retention with microvascular injury can lead to pulmonary edema. Cardiac manifestations, including myocarditis, pericarditis, and arrhythmias, denote an especially poor prognosis.

The renal lesion in scleroderma renal crisis is characterized by arcuate artery intimal and medial proliferation with luminal narrowing. This lesion is described as "onion-skinning" and can be accompanied by glomerular collapse due to reduced blood flow. Histologically, scleroderma renal crisis is indistinguishable from malignant hypertension, with which it can coexist. Fibrinoid necrosis and thrombosis are common. Before the availability of angiotensin-converting enzyme (ACE) inhibitors, the mortality rate for scleroderma renal crisis was >90% at 1 month. Introduction of renin-angiotensin system blockade has lowered the mortality rate to 30% at 3 years. Nearly two-thirds of patients with scleroderma renal crisis may require dialysis support, with recovery of renal function in 50% (median time, 1 year). Glomerulonephritis and vasculitis associated with antineutrophil cytoplasmic antibodies and systemic lupus erythematosus have been described in patients with scleroderma. An association has been found with a speckled pattern of antinuclear antibodies and with antibodies to RNA polymerases I and III. Anti-U3-RNP may identify young patients at risk for scleroderma renal crisis. Anticentromere antibody, in contrast, is a negative predictor of this disorder. Because of the overlap between scleroderma renal crisis and other autoimmune disorders, a renal biopsy is recommended for patients with atypical renal involvement, especially if hypertension is absent.

Treatment with ACE inhibition is the first-line therapy unless contraindicated. The goal of therapy is to reduce systolic and diastolic blood pressure by 20 mmHg and 10 mmHg, respectively, every 24 h until blood pressure is normal. Additional antihypertensive therapy may be given once the dose of drug for ACE inhibition is maximized. Angiotensin II receptor antagonists are less effective at preventing renal failure; thus, they are only recommended if the patient is intolerant of ACE inhibitors. ACE inhibition alone does not prevent scleroderma renal crisis, but it does reduce the impact of hypertension. In addition, it has been observed that patients on ACE inhibitors have a higher renal recovery rate after initiation of dialysis, and thus, ACE inhibitors are continued even after starting dialysis. Intravenous iloprost has been used in Europe for blood pressure management and improvement of renal perfusion. Kidney transplantation is not recommended for 2 years after the start of dialysis since delayed recovery may occur. Bosentan (endothelin-1 antagonist) and eculizumab have both been investigated for use in this disease.

ANTIPHOSPHOLIPID SYNDROME

Antiphospholipid syndrome (APLS) **(Chap. 369)** can be either primary or secondary, with the most common rheumatologic association being with systemic lupus erythematosus. It is characterized by a predisposition to systemic thrombosis (arterial and venous) and/or recurrent fetal loss mediated by antiphospholipid antibodies: anticardiolipin antibodies, lupus anticoagulant, and/or anti-β-2 glycoprotein I antibodies (antiβ2GPI). In addition to the antibody laboratory findings, classification criteria based on the 2023 American College of Rheumatology and European Alliance of Associations for Rheumatology include clinical features, such as macrovascular venous and arterial thromboses, microvascular thrombotic events, specific obstetric complications, cardiac valve abnormalities, and thrombocytopenia. Being positive for lupus anticoagulant, antiβ2GPI, and anticardiolipin antibodies ("triple positive") is associated with the highest thrombosis risk. APLS is the leading cause of stroke in patients <45 years old.

The vascular compartment within the kidney is the main site of renal involvement. Arteriosclerosis is commonly present in the arcuate and intralobular arteries. In the intralobular arteries, fibrous intimal hyperplasia characterized by intimal thickening secondary to intense myofibroblastic intimal cellular proliferation with extracellular matrix deposition is frequently seen along with onion-skinning. Arterial and arteriolar fibrous and fibrocellular occlusions are present in more than two-thirds of biopsy samples. Cortical necrosis and focal cortical atrophy may result from vascular occlusion. TMA is commonly present in renal biopsies, although signs of MAHA and platelet consumption are usually absent. TMA is especially common in the catastrophic variant of antiphospholipid syndrome, which is a life-threatening syndrome characterized by rapid onset of symptoms, multiorgan failure, and severe thrombotic events.

Treatment entails lifelong anticoagulation. For most individuals with APLS, warfarin is the preferred anticoagulant over direct oral anticoagulants (DOACs), with an international normalized ratio (INR) goal of 2–3. One can consider DOACs in a few, specific instances, such as a single venous thrombosis event or in those intolerant to warfarin, but never in those with arterial thrombotic events. Providers should have clear risk-benefit discussions with the patient if choosing a DOAC over warfarin given inferiority in many instances. In those with arterial thrombotic events, antiplatelet therapy is often a recommended addition to warfarin. Catastrophic APLS management includes anticoagulation, glucocorticoids, plasma exchange, and/or IV immunoglobulin (IVIG). Addition of rituximab and eculizumab can be considered, often in the refractory setting, although ongoing studies are evaluating earlier use of these agents.

HELLP SYNDROME

HELLP (*h*emolysis, *e*levated *l*iver enzymes, *l*ow *p*latelets) syndrome is a dangerous complication of pregnancy associated with microvascular injury. Occurring in 0.2–0.9% of all pregnancies and in 10–20% of women with severe preeclampsia, this syndrome carries a mortality rate of 7.4–34%. Most commonly developing in the third trimester, 20% of cases occur before week 28, and 30% occur postpartum. Although a strong association exists between HELLP syndrome and preeclampsia,

nearly 20% of cases are not preceded by recognized preeclampsia. Risk factors include abnormal placentation, family history, and elevated levels of fetal mRNA for FLT1 (vascular endothelial growth factor receptor 1) and endoglin. Patients with HELLP syndrome have higher levels of inflammatory markers (C-reactive protein, IL-1Ra, and IL-6) and soluble HLA-DR than do those with preeclampsia alone.

Renal failure occurs in half of patients with HELLP syndrome, although the etiology is not well understood. Limited data suggest that renal failure is the result of both preeclampsia and acute tubular necrosis. Proteinuria is present in 86–100% of cases. Renal histologic findings are those of TMA with endothelial cell swelling and occlusion of the capillary lumens, but luminal thrombi are typically absent. However, thrombi become more common in severe eclampsia and HELLP syndrome. Although renal failure is common, the organ that defines this syndrome is the liver. Subcapsular hepatic hematomas sometimes produce spontaneous rupture of the liver and can be life-threatening. Neurologic complications such as cerebral infarction, hemorrhage, and edema are other potentially life-threatening complications. Nonfatal complications include placental abruption, permanent vision loss due to Purtscher-like (hemorrhagic and vaso-occlusive vasculopathy) retinopathy, pulmonary edema, bleeding, and fetal demise.

Many features are shared by HELLP syndrome and MAHA. Diagnosis of HELLP syndrome is complicated by the fact that aHUS and TTP also can be triggered by pregnancy; in addition, complement gene mutations and complement pathway dysfunction are common (30–40%) among patients with HELLP syndrome. Patients with antiphospholipid syndrome also have an elevated risk of HELLP syndrome. A history of MAHA before pregnancy is of diagnostic value. Serum levels of ADAMTS13 activity are reduced (by 30–60%) in HELLP syndrome but not to the levels seen in TTP (<10%). Determination of the ratio of lactate dehydrogenase to aspartate aminotransferase may be helpful. This ratio is 13:1 in patients with HELLP syndrome and preeclampsia as opposed to 29:1 in patients without preeclampsia. Other markers, such as antithrombin III (decreased in HELLP syndrome but not in TTP) and D-dimer (elevated in HELLP syndrome but not in TTP), may also be useful. HELLP syndrome usually resolves spontaneously after delivery. Management includes administering magnesium sulfate for seizure prophylaxis and treating hypertension if present. A key component of treatment is delivery; timing of delivery is based on severity of symptoms and age of the fetus. In pregnancies with serious maternal or fetal complications, prompt delivery is recommended. In those without serious complications, the age of the fetus and fetal maturity can help distinguish between prompt delivery or a course of antenatal steroids. Plasma exchange has no benefit in HELLP but may be indicated if TTP has not yet been ruled out. Eculizumab has been reported to be effective in a small number of cases, but dosing, efficacy, and indications remain undetermined.

POEMS SYNDROME

POEMS syndrome is a systemic disease characterized by polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin changes, with polyneuropathy and monoclonal gammopathy being mandatory major criteria. Peripheral neuropathy often presents with severe motor-sensory deficit. Three other major criteria, at least one of which is required, are elevated vascular endothelial growth factor (VEGF) levels, evidence of Castleman disease, and sclerotic bone lesions. Patients also commonly have elevated IL-6. Another characteristic is that >95% of monoclonal light chain is of the lambda isotype. IgA also makes up ~50% of the monoclonal proteins involved. Organomegaly can involve any organ and often presents as lymphadenopathy. Other findings can include skin changes, thrombocytosis, polycythemia, papilledema, and volume overload. POEMS syndrome can occur with Castleman disease. In the kidney, the hypertrophy frequently is unilateral. One study suggests the difference in kidney size is due to unilateral contraction; however, a volumetric study showed that enlargement is responsible for the difference in kidney size in some patients. Glomerulomegaly is not uncommon. Lobular appearance, endothelial cell swelling, hypercellularity, mesangiolysis, microaneurysm, and glomerular enlargement are reminiscent of membranoproliferative glomerulonephritis. Most patients present with mild to moderate renal impairment and low-grade proteinuria. Progression to end-stage renal disease is rare.

SICKLE CELL NEPHROPATHY

Renal complications in sickle cell disease result from occlusion of the vasa recta in the renal medulla. The low partial pressure of oxygen and high osmolarity predispose to hemoglobin S polymerization and erythrocyte sickling. Sequelae include hyposthenuria, hematuria, and papillary necrosis (which can also occur in sickle trait). The kidney responds by increasing blood flow and glomerular filtration rate mediated by prostaglandins. This dependence on prostaglandins may explain the greater reduction of glomerular filtration rate by nonsteroidal anti-inflammatory drugs in these patients than in others. The glomeruli are typically enlarged. Intracapillary fragmentation and phagocytosis of sickled erythrocytes are thought to be responsible for the membranoproliferative glomerulonephritis–like lesion, and focal segmental glomerulosclerosis is seen in more advanced cases. Screening for sickle cell nephropathy should include blood pressure monitoring, urine studies for albumin-to-creatinine ratio, and metabolic panel. Proteinuria is present in 20–30%, and nephrotic-range proteinuria is associated with progression to renal failure. ACE inhibitors reduce proteinuria, although data are lacking on prevention of renal failure. Patients with sickle cell disease are also more prone to acute renal failure. The cause is thought to reflect microvascular occlusion associated with nontraumatic rhabdomyolysis, high fever, infection, and generalized sickling. Chronic kidney disease from sickle cell nephropathy is present in 25–33% of patients. Despite the frequency of renal disease, hypertension is significantly lower in patients with sickle cell disease compared to the general population of black individuals. Treatment can include medications, such as hydroxyurea, which has been shown to decrease vaso-occlusive events and lessen albuminuria. Two gene therapies for patients with sickle cell who have recurrent vaso-occlusive episodes and are >12 years old were approved in December 2023. Exagamglogene autotemcel uses CRISPR/Cas9 gene editing to modify *BCL11A* and increased fetal hemoglobin, whereas lovotibeglogene autotemcel uses lentiviral technology to produce a modified hemoglobin similar to hemoglobin A. Evaluation of outcomes in these individuals is ongoing.

RENAL VEIN THROMBOSIS

Renal vein thrombosis either can present with flank pain, tenderness, hematuria, rapid decline in renal function, and proteinuria or can be silent. Occasionally, renal vein thrombosis is identified during a workup for pulmonary embolism. The left renal vein is more commonly involved, and two-thirds of cases are bilateral. Etiologies can be divided into three broad categories: endothelial damage, venous stasis, and hypercoagulability. Homocystinuria, endovascular intervention, and surgery can produce vascular endothelial damage. Dehydration, which is more common among male patients, is a common cause of stasis in the pediatric population. Stasis also can result from compression and kinking of the renal veins from retroperitoneal processes such as retroperitoneal fibrosis and abdominal neoplasms. Thrombosis can occur throughout the renal circulation, including the renal veins, with antiphospholipid syndrome. Renal vein thrombosis can also be secondary to nephrotic syndrome, particularly membranous nephropathy. Other hypercoagulable states less commonly associated with renal vein thrombosis include proteins C and S, antithrombin deficiency, factor V Leiden, disseminated malignancy, and oral contraceptives. Severe nephrotic syndrome may also predispose patients to renal vein thrombosis.

Diagnostic screening can be performed with Doppler ultrasonography, which is more sensitive than ultrasonography alone. Computed tomography angiography is almost 100% sensitive. Magnetic resonance angiography is another option but is more expensive. Treatment for renal vein thrombosis consists of anticoagulation and therapy for the underlying cause. Endovascular thrombolysis may be considered in severe cases. Occasionally, nephrectomy may be undertaken for life-threatening complications. In patients who cannot receive anticoagulation, suprarenal inferior vena cava filters can be considered.

COVID-19 AND MICROVASCULAR DISEASE

The COVID-19 pandemic, cause by SARS-CoV-2, has led to many complications, including both macrovascular and microvascular thromboses. SARS-CoV-2 attaches to the cell membrane via interaction of the viral spike protein with the ACE2 protein and then enters the cell via endocytosis, leading to increased cytokine release, inflammatory cell activation, and cellular and tissue damage. Endothelial injury and dysfunction in the setting of COVID-19 have led to many microvascular phenotypes including renal injury, heart disease, liver complications, strokes, and respiratory distress syndrome. In response to SARS-CoV-2, endothelial exocytosis occurs, releasing von Willebrand factor and P-selectin from granules. Autopsy specimens have shown evidence of small-vessel occlusions in the heart, kidneys, and lungs. Certain factors related to microvascular damage, such as ADAMTS13, VEGF-A, and Angpt-2, have been shown to predict mortality. In the renal system, autopsies showed diffuse proximal tubule injury, which is thought to be due to the immune dysregulation and inflammatory cytokines, in addition to poor renal perfusion. In certain instances, viral particles have been observed in the tubular epithelium, although direct infection of SARS-CoV-2 in the kidney remains controversial. Having previous chronic kidney disease or diabetic nephropathy is a risk factor for developing acute kidney injury with COVID-19. Treatment includes antiviral medications and remdesivir, with these medications needing to be adjusted or avoided based on kidney function.

330 Nephrolithiasis

Gary C. Curhan

Nephrolithiasis, or kidney stone disease, is a common, painful, and costly condition. Each year, billions of dollars are spent on nephrolithiasis-related activity, with the majority of expenditures on surgical treatment of existing stones. While a stone may form due to crystallization of lithogenic factors in the upper urinary tract, it can subsequently move into the ureter and cause renal colic. Although nephrolithiasis is rarely fatal, patients who have had renal colic report that it is the worst pain they have ever experienced. The evidence on which to base clinical recommendations is not as strong as desired; nonetheless, most experts agree that the recurrence of most, if not all, types of stones can be prevented with careful evaluation and targeted recommendations. Preventive treatment may be lifelong; therefore, an in-depth understanding of this condition must inform the implementation of tailored interventions that are most appropriate for and acceptable to the patient.

There are several types of kidney stones. It is clinically important to identify the stone type, which informs prognosis and selection of the optimal preventive regimen. Calcium oxalate stones are most common (~75%); next, in order, are calcium phosphate (~15%), uric acid (~8%), struvite (~1%), and cystine (<1%) stones. Many stones are a mixture of crystal types (e.g., calcium oxalate and calcium phosphate) and also contain protein in the stone matrix. Rarely, stones are composed of medications, such as acyclovir, atazanavir, and triamterene. Stones that form as a result of an upper tract infection, if not appropriately treated, can have devastating consequences and lead to end-stage renal disease. Consideration should be given to teaching practitioners strategies to prevent recurrence of all stone types and the related morbidity.

EPIDEMIOLOGY

Nephrolithiasis is a global disease. Data suggest an increasing prevalence, likely due to Westernization of lifestyle habits (e.g., dietary changes, increasing body mass index). National Health and Nutrition Examination Survey data for 2007–2016 indicate that up to 20% of men and 10% of women will develop at least one stone during their lifetime. The prevalence is ~50% lower among black individuals than among whites. The incidence of nephrolithiasis (i.e., the rate at which previously unaffected individuals develop their first stone) also varies by age, sex, and race. Among white men, the peak annual incidence is ~3.5 cases/1000 at age 40 and declines to ~2 cases/1000 by age 70. Among white women in their thirties, the annual incidence is ~2.5 cases/1000; the figure decreases to ~1.5/1000 at age 50 and beyond. In addition to the medical costs associated with nephrolithiasis, this condition also has a substantial economic impact, as those affected are often of working age. Once an individual has had a stone, the prevention of a recurrence is essential. Published recurrence rates vary by the definitions and diagnostic methods used. Some reports have relied on symptomatic events, while others have been based on imaging. Most experts agree that radiographic evidence of a second stone should be considered to represent a recurrence, even if the stone has not yet caused symptoms.

ASSOCIATED MEDICAL CONDITIONS

Nephrolithiasis is a systemic disorder. Several conditions predispose to stone formation, including gastrointestinal malabsorption (e.g., Crohn's disease, gastric bypass surgery), primary hyperparathyroidism, obesity, type 2 diabetes mellitus, and distal renal tubular acidosis. A number of other medical conditions are more likely to be present in individuals with a history of nephrolithiasis, including hypertension, gout, cardiovascular disease, cholelithiasis, reduced bone mineral density, and chronic kidney disease.

Although nephrolithiasis does not directly cause upper urinary tract infections (UTIs), a UTI in the setting of an obstructing stone is a urologic emergency ("pus under pressure") and requires urgent intervention to reestablish drainage.

PATHOGENESIS

In the consideration of the processes involved in crystal formation, it is helpful to view urine as a complex solution. A clinically useful concept is *supersaturation* (the point at which the concentration product exceeds the solubility product). However, even though the urine in most individuals is supersaturated with respect to one or more types of crystals, the presence of inhibitors of crystallization prevents the majority of the population from continuously forming stones. The most clinically important inhibitor of calcium-containing stones is urine citrate. While the calculated supersaturation value does not perfectly predict stone formation, it is a useful guide as it integrates the multiple factors that are measured in a 24-h urine collection.

Recent studies have changed the paradigm for the site of initiation of stone formation. Renal biopsies of stone formers have revealed calcium phosphate in the renal interstitium. It is hypothesized that this calcium phosphate deposits at the thin limb of the loop of Henle and then extends down to the papilla and erodes through the papillary epithelium, where it provides a site for deposition of calcium oxalate and calcium phosphate crystals. The majority of calcium oxalate stones grow on calcium phosphate at the tip of the renal papilla (*Randall's plaque*). Tubular plugs of calcium phosphate may be the initiating event in calcium phosphate stone development. Thus, the process of stone formation may begin years before a clinically detectable stone is identified. The processes involved in interstitial deposition are under active investigation.

RISK FACTORS

Risk factors for nephrolithiasis can be categorized as dietary, nondietary, or urinary. These risk factors vary by stone type and clinical characteristics.

Dietary Risk Factors Patients who develop stones often change their diet; therefore, studies that retrospectively assess diet may be hampered by recall bias. Some studies have examined the relation between diet and changes in the lithogenic composition of the urine, often using calculated supersaturation. However, the composition of the urine does not perfectly predict risk, and not all components that modify risk are included in the calculation of supersaturation. Thus, dietary associations are best investigated by prospective studies that examine actual stone formation as the outcome. Dietary factors that are associated with an increased risk of nephrolithiasis include animal protein, oxalate, sodium, sucrose, and fructose. Dietary factors associated with a lower risk include calcium, potassium, phytate, and higher fluid intake.

CALCIUM The role of dietary calcium deserves special attention. Although in the distant past dietary calcium had been suspected of increasing the risk of stone disease, several prospective observational studies and a randomized controlled trial have demonstrated that higher dietary calcium intake is related to a *lower* risk of stone formation. The reduction in risk associated with higher calcium intake may be due to a reduction in intestinal absorption of dietary oxalate that results in lower urine oxalate. Low calcium intake is contraindicated as it increases the risk of stone formation and may contribute to lower bone density in stone formers.

Despite similar bioavailability, supplemental calcium may increase the risk of stone formation. The discrepancy between the risks from dietary calcium and calcium supplements may be due to the timing of supplemental calcium intake or to higher total calcium consumption leading to higher urinary calcium excretion.

OXALATE Urinary oxalate is derived from both endogenous production and absorption of dietary oxalate. Owing to its low and often variable bioavailability, much of the oxalate in food may not be readily absorbed. However, absorption may be higher in stone formers. Although observational studies demonstrate that dietary oxalate is only a weak risk factor for stone formation, urinary oxalate is a strong risk factor for calcium oxalate stone formation, and efforts to avoid high oxalate intake should thus be beneficial.

OTHER NUTRIENTS Several other nutrients have been studied and implicated in stone formation. Higher intake of animal protein may lead to increased excretion of calcium and uric acid as well as to decreased urinary excretion of citrate, all of which increase the risk of stone formation. Higher sodium and sucrose intake increases calcium excretion independent of calcium intake. Higher potassium intake decreases calcium excretion, and many potassium-rich foods increase urinary citrate excretion due to their alkali content. Other dietary factors that have been inconsistently associated with lower stone risk include magnesium and phytate.

Vitamin C supplements are associated with an increased risk of calcium oxalate stone formation in men, possibly owing to raised levels of oxalate in urine. Thus, male calcium oxalate stone formers should be advised to avoid high-dose vitamin C supplements. Although high doses of supplemental vitamin B_6 may be beneficial in selected patients with type 1 primary hyperoxaluria, the risk is not reduced in other patients.

FLUIDS AND BEVERAGES The risk of stone formation increases as urine volume decreases. When the urine output is <1 L/d, the risk of stone formation more than doubles. Fluid intake is the main determinant of urine volume, and the importance of fluid intake in preventing stone formation has been demonstrated in observational studies and in a randomized controlled trial. Observational studies of individual beverages have found that coffee, tea, beer, wine, and orange juice are associated with a reduced risk of stone formation. Sugar-sweetened beverage consumption may increase risk.

Nondietary Risk Factors Age, race, body size, and environment are important risk factors for nephrolithiasis. The incidence of stone disease is highest in middle-aged white men, but stones can form in infants as well as in the elderly. There is geographic variability, with the highest prevalence in the southeastern United States. Weight gain increases the risk of stone formation, and the increasing prevalence of nephrolithiasis in the United States may be due in part to the increasing prevalence of obesity. Environmental and occupational influences that may lead to lower urine volume, such as working in a hot environment or lack of ready access to water or a bathroom, are important considerations. Several observational studies, but not all, have reported that antibiotic use in early adulthood and middle age is associated with higher risk for nephrolithiasis in later life. The largest of these studies found an increased risk for five different classes of antibiotics.

Urinary Risk Factors

URINE VOLUME Lower urine volume results in higher concentrations of lithogenic factors and is a common and readily modifiable risk factor. A randomized trial has demonstrated the effectiveness of higher fluid intake in increasing urine volume and reducing the risk of stone recurrence.

URINE CALCIUM Higher urine calcium excretion increases the likelihood of formation of calcium oxalate and calcium phosphate stones. While the term *hypercalciuria* is often used, there is no cutoff that distinguishes between normal and abnormal urine calcium excretion. In fact, the relation between urine calcium and stone risk appears to be continuous; thus, the use of an arbitrary threshold should be avoided. Levels of urine calcium excretion are higher in individuals with a history of nephrolithiasis; however, the mechanisms remain poorly understood. Greater gastrointestinal calcium absorption is one important contributor, and greater bone turnover (with a resultant reduction in bone mineral density) may be another. Primary renal calcium loss, with lower serum calcium concentrations and elevated serum levels of parathyroid hormone (PTH) (and a normal 25-hydroxy vitamin D level), is rare.

URINE OXALATE Higher urine oxalate excretion increases the likelihood of calcium oxalate stone formation. As for urine calcium, no definition for "abnormal" urine oxalate excretion is widely accepted. Given that the relation between urine oxalate and stone risk is continuous, simple dichotomization of urine oxalate excretion is not helpful in assessing risk. The two sources of urine oxalate are endogenous generation and dietary intake. Dietary oxalate is the major contributor and also the source that can be modified. Notably, higher dietary calcium intake reduces gastrointestinal oxalate absorption and thereby reduces urine oxalate.

URINE CITRATE Urine citrate is a natural inhibitor of calcium-containing stones; thus, lower urine citrate excretion increases the risk of stone formation. Citrate reabsorption is influenced by the intracellular pH of proximal tubular cells. Metabolic acidosis, including that due to higher animal flesh intake, will lead to a reduction in citrate excretion by increasing reabsorption of filtered citrate. However, a notable proportion of patients have lower urine citrate for reasons that remain unclear.

URINE URIC ACID Higher urine levels of uric acid—a risk factor for uric acid stone formation—are found in individuals with excess purine consumption and rare genetic conditions that lead to overproduction of uric acid. This characteristic is not associated with the risk of calcium oxalate stone formation.

URINE pH Urine pH influences the solubility of some crystal types. Uric acid stones form when the urine pH is consistently ≤5.5, whereas calcium phosphate stones are more likely to form when the urine pH is ≥6.5. Cystine is more soluble at higher urine pH. Calcium oxalate stones are not influenced by urine pH.

Genetic Risk Factors The risk of nephrolithiasis is more than twofold greater in individuals with a family history of stone disease. This association is likely due to a combination of genetic predisposition and similar environmental exposures. While a number of rare monogenic disorders cause nephrolithiasis, genome-wide association studies have begun to reveal genetic contributors to common forms of stone disease.

The two most common and well-characterized rare monogenic disorders that lead to stone formation are primary hyperoxaluria and cystinuria. *Primary hyperoxaluria* is an autosomal recessive disorder that causes excessive endogenous oxalate generation by the liver, with consequent calcium oxalate stone formation and crystal deposition in organs. Intraparenchymal calcium oxalate deposition in the kidney can eventually lead to renal failure. *Cystinuria* is an autosomal recessive disorder that causes abnormal reabsorption of filtered basic amino acids. The excessive urinary excretion of cystine, which is poorly soluble, leads to cystine stone formation. Cystine stones are visible on plain radiographs and often manifest as staghorn calculi or multiple bilateral stones. Repeat episodes of obstruction and instrumentation can cause a reduction in the glomerular filtration rate (GFR).

APPROACH TO THE PATIENT

Nephrolithiasis

Evidence-based guidelines for the evaluation and treatment of nephrolithiasis have been published. Although there is limited evidence for several aspects, there are standard approaches to patients with acute and chronic presentations that can reasonably guide the clinical evaluation.

It typically requires weeks to months (and often much longer) for a kidney stone to grow to a clinically detectable size. Although the passage of a stone is a dramatic event, stone formation and growth are characteristically clinically silent. A stone can remain asymptomatic in the kidney for years or even decades before signs (e.g., hematuria) or symptoms (e.g., pain) become apparent. Thus, it is important to remember that the onset of symptoms, typically attributable to a stone moving into the ureter, does not provide insight into when the stone actually formed. The factors that induce stone movement are unknown.

CLINICAL PRESENTATION AND DIFFERENTIAL DIAGNOSIS

There are two common presentations for individuals with an acute stone event: renal colic and painless gross hematuria. *Renal colic* is a misnomer because pain typically does not subside completely; rather, it varies in intensity. When a stone moves into the ureter, the discomfort often begins with a sudden onset of unilateral flank pain.

The intensity of the pain can increase rapidly, and there are no alleviating factors. This pain, which is accompanied often by nausea and occasionally by vomiting, may radiate, depending on the location of the stone. If the stone lodges in the upper part of the ureter, pain may radiate anteriorly; if the stone is in the lower part of the ureter, pain can radiate to the ipsilateral testicle in men or the ipsilateral labium in women. Occasionally, a patient has gross hematuria without pain.

Other diagnoses may be confused with acute renal colic. If the stone is lodged at the right ureteropelvic junction, symptoms may mimic those of acute cholecystitis. If the stone blocks the ureter as it crosses over the right pelvic brim, symptoms may mimic acute appendicitis, whereas blockage at the left pelvic brim may be confused with acute diverticulitis. If the stone lodges in the ureter at the ureterovesical junction, the patient may experience urinary urgency and frequency. In female patients, the latter symptoms may lead to an incorrect diagnosis of bacterial cystitis; the urine will contain red and white blood cells, but the urine culture will be negative. An obstructing stone with proximal infection may present as acute pyelonephritis. A UTI in the setting of ureteral obstruction is a medical emergency that requires immediate restoration of drainage by placement of either a ureteral stent or a percutaneous nephrostomy tube. Other conditions to consider in the differential diagnosis include muscular or skeletal pain, herpes zoster, duodenal ulcer, abdominal aortic aneurysm, gynecologic conditions, ureteral stricture, and ureteral obstruction by materials other than a stone, such as a blood clot or sloughed papilla. Extraluminal processes can lead to ureteral compression and obstruction; however, because of the gradual onset, these conditions do not typically present with renal colic.

DIAGNOSIS AND INTERVENTION

Serum chemistry findings are typically normal, but the white blood cell count may be elevated. Examination of the urine sediment will usually reveal red and white blood cells and occasionally crystals **(Fig. 330-1)**. The absence of hematuria does not exclude a stone, particularly when urine flow is completely obstructed by a stone.

The diagnosis is often made on the basis of the history, physical examination, and urinalysis. Thus, it may not be necessary to wait for radiographic confirmation before treating the symptoms. The diagnosis is confirmed by an appropriate imaging study—preferably noncontrast helical computed tomography (CT), which is highly sensitive and allows visualization of uric acid stones (traditionally considered "radiolucent") **(Fig. 330-2)**. Helical CT detects stones as small as 1 mm that may be missed by other imaging modalities.

Typically, helical CT reveals a ureteral stone or evidence of recent passage (e.g., perinephric stranding or hydronephrosis), whereas a plain abdominal radiograph (kidney/ureter/bladder [KUB]) can miss a stone in the ureter or kidney, even if it is radiopaque, and does not provide information on obstruction. Abdominal ultrasound offers the advantage of avoiding radiation and provides information on hydronephrosis, but it is not as sensitive as CT and images only the kidney and possibly the proximal segment of the ureter; thus, most ureteral stones are not detectable by ultrasound.

Many patients who experience their first episode of colic seek emergent medical care. Randomized trials have demonstrated that parenterally administered nonsteroidal anti-inflammatory drugs (e.g., ketorolac) are just as effective as opioids in relieving symptoms and have fewer side effects. Excessive fluid administration has not been shown to be beneficial; therefore, the goal should be to maintain euvolemia. If the pain can be adequately controlled and the patient is able to take fluids orally, hospitalization can be avoided. Use of an alpha blocker may increase the rate of spontaneous stone passage.

Urologic intervention should be postponed unless there is evidence of UTI, a low probability of spontaneous stone passage (e.g., a stone measuring ≥6 mm or an anatomic abnormality), or intractable pain. A ureteral stent may be placed cystoscopically, but this procedure typically requires general anesthesia, and the stent can be quite uncomfortable, may cause gross hematuria, and may increase the risk of UTI.

If an intervention is indicated, the selection of the most appropriate intervention is determined by the size, location, and composition of the stone; the urinary tract anatomy; and the experience of the urologist. Extracorporeal shockwave lithotripsy (ESWL), the least invasive option, uses shockwaves generated outside the body to fragment the stone, but is being used less frequently. An endourologic approach, now more frequently used than ESWL,

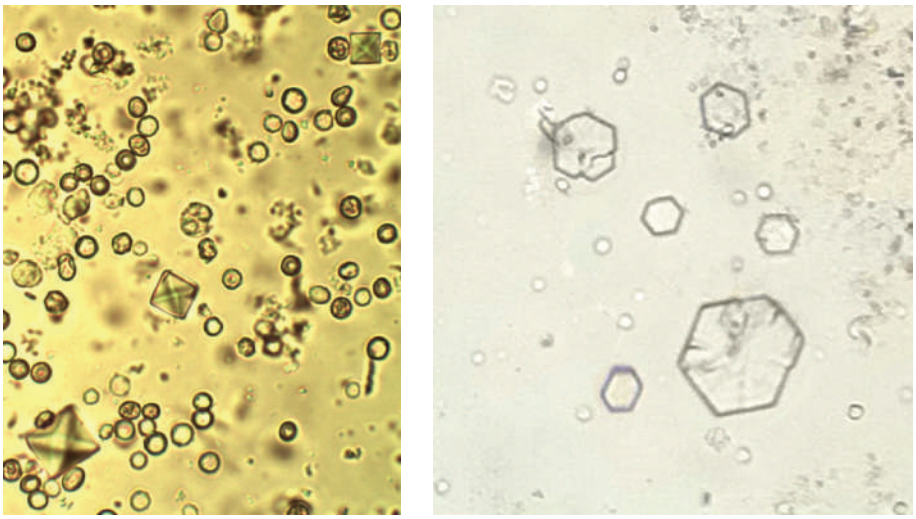

FIGURE 330-1 Urine sediment from a patient with calcium oxalate stones (*left*) and a patient with cystine stones (*right*). Calcium oxalate dihydrate crystals are bipyramidally shaped, and cystine crystals are hexagonal. *(Left panel image courtesy of Dr. Mark Perazella, Yale School of Medicine. Right panel image courtesy Dr. John Lieske, Mayo Clinic.)*

can remove a stone by basket extraction or laser fragmentation. For large upper-tract stones, percutaneous nephrostolithotomy has the highest likelihood of rendering the patient stone-free. Advances in urologic approaches and instruments have nearly eliminated the need for open surgical procedures such as ureterolithotomy or pyelolithotomy.

EVALUATION FOR STONE PREVENTION

More than half of first-time stone formers will have a recurrence within 10 years. A careful evaluation is indicated to identify predisposing factors, which can then be modified to reduce the risk of new stone formation or growth of existing renal stones. It is appropriate to proceed with an evaluation even after the first stone if the patient is interested because recurrences are common and are usually preventable with inexpensive lifestyle modifications or other treatments.

HISTORY

A detailed history, obtained from the patient and from a thorough review of medical records, should include the number and frequency of episodes (distinguishing stone passage from stone formation) and previous imaging studies, interventions, evaluations, and treatments. Inquiries about the patient's medical history should cover UTIs, gastric bypass surgery and other malabsorptive conditions, gout, hypertension, and diabetes mellitus. A family history of stone disease may reveal a genetic predisposition. A complete list of current prescription and over-the-counter medications as well as vitamin and mineral supplements is essential. The review of systems should focus on identifying possible etiologic factors related to low urine volume (e.g., high insensible losses) and gastrointestinal malabsorption as well as on ascertaining how frequently the patient voids during the day and overnight.

A large body of compelling evidence has demonstrated the important role of diet in stone disease. Thus, the dietary history should encompass information on usual dietary habits (meals and snacks), calcium intake, consumption of high-oxalate foods (spinach, rhubarb, potatoes), and fluid intake (including amount of specific beverages typically consumed). Amount and frequency of use of vitamin and mineral supplements should be carefully assessed.

An obstructing calculus, present in the distal left ureter at the level of S1, measures 10 mm in maximal dimension. There is severe left hydroureteronephrosis and associated left perinephric fat stranding. In addition, there is a nonobstructing 6-mm left renal calculus in the interpolar region. *(Image courtesy of Dr. Stuart Silverman, Brigham and Women's Hospital.)*

PHYSICAL EXAMINATION

The physical examination should assess weight, blood pressure, costovertebral angle tenderness, and lower-extremity edema as well as signs of other systemic conditions such as primary hyperparathyroidism and gout.

LABORATORY EVALUATION

If not recently measured, the following serum levels should be determined: electrolytes (to uncover hypokalemia or renal tubular acidosis), creatinine, calcium, phosphorus, and uric acid. The PTH level should be measured if indicated by elevated, high-normal, or low-normal serum and urine calcium concentrations. 25-Hydroxy vitamin D should be measured in concert with PTH to investigate the possible role of secondarily elevated PTH levels in the setting of vitamin D insufficiency.

The urinalysis, including examination of the sediment, can provide useful information. In individuals with asymptomatic residual renal stones, red and white blood cells are frequently present in urine. If there is concern about the possibility of an infection, a urine culture should be performed. The sediment may also reveal crystals (Fig. 330-1), which may help identify the stone type and also provide prognostic information as crystalluria is a strong risk factor for new stone formation.

The results from 24-h urine collections serve as the cornerstone on which therapeutic recommendations are based. Recommendations on lifestyle modification should be deferred until urine

collection is complete. As a baseline assessment, patients should collect at least two 24-h urine samples while consuming their usual diet and usual volume of fluid. The following factors should be measured: total volume, calcium, oxalate, citrate, uric acid, sodium, potassium, phosphorus, magnesium, pH, and creatinine. When available, the calculated supersaturation is also informative. There is substantial day-to-day variability in the 24-h excretion of many relevant factors; therefore, obtaining values from two collections is important before committing a patient to long-term lifestyle changes or medication. The interpretation of the 24-h urine results should take into account that the collections are usually performed on a weekend day when the patient is staying at home; an individual's habits may differ dramatically (beneficially or detrimentally) at work or outside the home. Specialized testing, such as calcium loading or restriction, is not recommended as it does not influence clinical recommendations.

Stone composition analysis is essential if a stone or fragment is available; patients should be encouraged to retrieve passed stones. The stone type cannot be determined with certainty from 24-h urine results, but pure uric acid stones can be identified by low Hounsfield units on CT.

IMAGING

The "gold standard" diagnostic test is helical CT without contrast. If not already performed during an acute episode, a low-dose renal-limited noncontrast CT should be considered to establish definitively the baseline stone burden. A suboptimal imaging study may not detect a residual stone that, if subsequently passed, would be mistaken for a new stone. In this instance, the preventive medical regimen might be unnecessarily changed as the result of a preexisting stone.

Recommendations for follow-up imaging should be tailored to the individual patient. While CT provides the best information, the radiation dose is higher than from other modalities; therefore, CT should be performed only if the results will lead to a change in clinical recommendations. Although less sensitive, renal ultrasound is typically used to minimize radiation exposure, with recognition of the limitations.

PREVENTION OF NEW STONE FORMATION

Recommendations for preventing stone formation depend on the stone type and the results of metabolic evaluation. After remediable secondary causes of stone formation (e.g., primary hyperparathyroidism) are excluded, the focus should turn to modification of the urine composition to reduce the risk of new stone formation. The urinary constituents and calculated urine supersaturation are continuous variables, and the associated risk is continuous; thus, there are no definitive thresholds. Dichotomization into "normal" and "abnormal" can be misleading and should be avoided.

For all stone types, consistently diluted urine reduces the likelihood of crystal formation. The urine volume should be at least 2 L/d. Because of differences in insensible fluid losses and fluid intake from food sources, the required total fluid intake will vary from person to person. Rather than specify how much to drink, it is more helpful to educate patients about how much *more* they need to drink in light of their 24-h urine volume. For example, if the daily urine volume is 1.5 L, then the patient should be advised to drink consistently at least 0.5 L more per day in order to increase the urine volume to the goal of 2 L/d.

RECOMMENDATIONS FOR SPECIFIC STONE TYPES

Calcium Oxalate Risk factors for calcium oxalate stones include higher urine calcium, higher urine oxalate, and lower urine citrate. This stone type is insensitive to urine pH in the physiologic range.

Individuals with higher urine calcium excretion tend to absorb a higher percentage of ingested calcium. Nevertheless, dietary calcium restriction is not beneficial and, in fact, is likely to be harmful (see "Dietary Risk Factors," above). In a randomized trial in men with high urine calcium and recurrent calcium oxalate stones, a diet containing 1200 mg of calcium and a low intake of sodium and animal protein significantly reduced subsequent stone formation compared with a low-calcium diet (400 mg/d). Excessive calcium intake (>1200 mg/d) should be avoided.

A thiazide diuretic, in doses higher than those used to treat hypertension, can substantially lower urine calcium excretion. Several randomized controlled trials, but not all, have demonstrated that thiazide diuretics can reduce calcium oxalate stone recurrence by ~50%. When a thiazide is prescribed, dietary sodium restriction is essential to obtain the desired reduction in urinary calcium excretion and minimize urinary potassium losses. While bisphosphonates may reduce urine calcium excretion in some individuals, there are only observational data to suggest whether this class of medication can reduce stone formation; therefore, bisphosphonates cannot be recommended solely for stone prevention at present, but they can be used to treat those individuals with low bone density.

A reduction in urine oxalate will, in turn, reduce the supersaturation of calcium oxalate. In patients with the common form of nephrolithiasis, avoiding high-dose vitamin C supplements is the only known strategy that reduces endogenous oxalate production. In patients with primary hyperoxaluria (type I), an siRNA-based therapy (lumasiran, nedosiran) can reduce oxalate generation in the liver.

Oxalate is a metabolic end product; therefore, any dietary oxalate that is absorbed will be excreted in the urine. Reducing absorption of exogenous oxalate involves two approaches. First, the avoidance of foods that contain high amounts of oxalate, such as spinach, rhubarb, almonds, and potatoes, is prudent. However, extreme oxalate restriction has not been demonstrated to reduce stone recurrence and could be harmful to overall health, given other health benefits of many foods that are erroneously considered to be high in oxalate. Second, the absorption of oxalate is reduced by higher calcium intake; therefore, individuals with higher-than-desired urinary oxalate should be counseled to consume adequate calcium. Oxalate absorption can be influenced by the intestinal microbiota, depending on the presence of oxalate-degrading bacteria. Currently, however, there are no available therapies to alter the microbiota that beneficially affect urinary oxalate excretion over the long term.

Citrate is a natural inhibitor of calcium oxalate and calcium phosphate stones. Increased consumption of foods rich in alkali (i.e., fruits and vegetables) can increase urine citrate. For patients with lower urine citrate in whom dietary modification does not adequately increase urine citrate, the addition of supplemental alkali (typically potassium citrate or bicarbonate) will lead to an increase in urinary citrate excretion. Sodium salts, such as sodium bicarbonate, while successful in raising urine citrate, are typically avoided due to the adverse effects of sodium on urine calcium excretion.

Past reports suggested that higher levels of urine uric acid may increase the risk of calcium oxalate stones, but more recent studies do not support this association. However, allopurinol reduced stone recurrence in one randomized controlled trial in patients with calcium oxalate stones and high urine uric acid levels. The lack of association between urine uric acid level and calcium oxalate stones suggests that a different mechanism underlies the observed beneficial effect of allopurinol in this setting.

Additional dietary modifications may be beneficial in reducing stone recurrence. Restriction of nondairy animal protein (e.g., meat, chicken, seafood) is a reasonable approach and may result in higher excretion of citrate and lower excretion of calcium. In addition, reducing sodium intake to <2.5 g/d may decrease urinary excretion of calcium. Sucrose and fructose intake should be minimized.

For adherence to a dietary pattern that is more manageable for patients than manipulating individual nutrients, the Mediterranean diet or the DASH (Dietary Approaches to Stop Hypertension) diet provides an appropriate and readily available option. Randomized trials have conclusively shown the DASH diet to reduce blood pressure. At present, only data from observational studies are available, but these demonstrate a strong and consistent inverse association between these healthy dietary patterns and risk of stone formation.

Calcium Phosphate Calcium phosphate stones share risk factors with calcium oxalate stones, including higher concentrations of urine calcium and lower concentrations of urine citrate, but additional factors deserve attention. Higher urine phosphate levels and higher urine pH (typically ≥6.5) are associated with an increased likelihood of calcium phosphate stone formation. Calcium phosphate stones are more common in patients with distal renal tubular acidosis and primary hyperparathyroidism.

There are no randomized trials on which to base preventive recommendations for calcium phosphate stone formers, so the interventions are focused on modification of the recognized risk factors. Thiazide diuretics (with sodium restriction) may be used to reduce urine calcium, as described above for calcium oxalate stones. In patients with low urine citrate levels, alkali supplements (e.g., potassium citrate or bicarbonate) may be used to increase urine citrate. However, the urine pH of these patients should be monitored initially because supplemental alkali can raise urine pH, thereby potentially increasing the risk of stone formation. Because these patients tend to have a urinary acidification defect, reducing the urine pH is not an option. Reduction of dietary phosphate may be beneficial by reducing urine phosphate excretion.

Uric Acid The two main risk factors for uric acid stones are persistently low urine pH and higher uric acid excretion. Urine pH is the predominant influence on uric acid solubility; therefore, the mainstay of prevention of uric acid stone formation entails increasing urine pH. Alkalinizing the urine can be achieved by increasing the intake of foods rich in alkali (e.g., fruits and vegetables) and reducing the intake of foods that produce acid (e.g., animal flesh). If necessary, supplementation with bicarbonate or citrate salts (preferably potassium-based) can be used to reach the recommended pH goal of 6.5 throughout the day and night.

Urine uric acid excretion is determined by uric acid generation. Uric acid is the end product of purine metabolism; thus, reduced consumption of purine-containing foods can lower urine uric acid excretion. It is noteworthy that the *serum* uric acid level is dependent on the fractional excretion of uric acid and, therefore, does not provide information on *urine* uric acid excretion. For example, an individual with high uric acid generation and concurrent high fractional excretion of uric acid will have high urine uric acid excretion with a normal (or even low) serum uric acid level. If alkalinization of the urine alone is not successful and if dietary modifications do not reduce urine uric acid sufficiently, then the addition of a xanthine oxidase inhibitor, such as allopurinol or febuxostat, can reduce urine uric acid excretion by 40–50%.

Cystine Cystine excretion is not easily modified. Long-term dietary cystine restriction is not feasible and is unlikely to be successful; thus, the focus for cystine stone prevention is on increasing cystine solubility. This goal may be achieved by treatment with medication that covalently binds to cystine (tiopronin or penicillamine) and a medication that raises urine pH. Tiopronin is the preferred choice owing to its better adverse event profile. The preferred alkalinizing agent to achieve a urine pH of 7.5 is potassium citrate or bicarbonate as sodium salts may increase cystine excretion. As with all stone types, and especially in patients with cystinuria, maintaining a high urine volume is an essential component of the preventive regimen.

Struvite Struvite stones, also known as *infection stones* or *triple-phosphate stones*, form only when the upper urinary tract is infected with urease-producing bacteria such as *Proteus mirabilis, Klebsiella pneumoniae*, or *Providencia* species. Urease produced by these bacteria hydrolyzes urea and may elevate the urine pH to a supraphysiologic level (>8.0). Struvite stones may grow quickly and fill the renal pelvis (*staghorn calculi*).

Struvite stones require complete removal by a urologist. New stone formation can be avoided by the prevention of UTIs. In patients with recurrent upper UTIs (e.g., some individuals with surgically altered urinary drainage or spinal cord injury), the urease inhibitor acetohydroxamic acid can be considered; however, this agent should be used with caution because of potential side effects.

LONG-TERM FOLLOW-UP

In general, the preventive regimens described above do not cure the underlying pathophysiologic process. Thus, these recommendations typically need to be followed for the patient's lifetime, and it is essential to tailor recommendations in a way that is acceptable to the patient. Because the memory of the acute stone event fades and patients often return to old habits (e.g., insufficient fluid intake), long-term follow-up, including repeat 24-h urine collections typically annually, is important to ensure that the preventive regimen has been implemented and has resulted in the desired reduction in the risk of new stone formation.

Follow-up imaging should be planned thoughtfully. Many patients with recurrent episodes of renal colic that lead to emergency room visits often undergo repeat CT studies. While CT does provide the best information, the radiation dose is higher than that with plain abdominal radiography (KUB). Small stones may be missed by KUB, and ultrasound has a limited ability to determine the size and number of stones. Minimizing radiation exposure should be a goal of the long-term follow-up plan and must be balanced against the gain in diagnostic information.

331 Urinary Tract Obstruction

Julian L. Seifter

Obstruction to the flow of urine, with attendant stasis and elevation in urinary tract pressure, impairs renal and urinary conduit functions and is a common cause of acute and chronic kidney disease (obstructive nephropathy). Early recognition and prompt treatment of urinary tract obstruction (UTO) can prevent or reverse devastating effects on kidney structure and function, and decrease susceptibility to hypertension, infection, and stone formation. Chronic obstruction may lead to permanent loss of renal mass (renal atrophy) and excretory capability. Because obstructive disease may be secondary to serious underlying inflammatory, vascular, or malignant disease, familiarity with clinical findings, appropriate diagnostic testing, and the therapeutic approach is of great importance to the clinician.

Recent developments have advanced our knowledge of fetal and genetic causes of lower urinary tract obstruction (LUTO) and chronic anomalies of the kidneys and urinary tracts (CAKUT), the rubric for a cluster of developmental uropathies associated with cysts and obstruction. In the last few years, studies in mice, zebrafish, and pluripotent stem cells (kidney organoids) have identified possible genetic mutations implicated in cases of CAKUT producing low nephron number, including duplications and deletions (copy number variants) and familial candidate genes (*HFN1β*, *PAX2*, *SIX1*, *GATA3*, and

many others). Given that there is no nephrogenesis in humans after birth, obstructive disease manifesting in early or middle adulthood may in fact have origins in a decreased number of nephrons during fetal development. Fetal LUTO, if untreated, often results in pulmonary hypoplasia and death in infancy; kidney failure may be a more long-term outcome. Since amniotic fluid is produced by fetal ingestion of urine, LUTO should be suspected when the mother develops oligohydramnios or anhydramnios. Improvements in second-trimester diagnosis and treatment with vesicoamniotic shunting have improved neonatal survival.

One of the most significant concerns in renal medicine is progression to a chronically fibrotic failing kidney. To date, there has been no demonstration of reversal of scarring, but many investigations are underway to find antifibrosis drugs, including those that address fibrosis in genetic diseases that lead to obstructive nephropathy. Many mechanisms contribute to this progression, including inflammatory responses, hemodynamic consequences of the declining number of healthy nephrons, and compression of normal nephrons by cysts in genetic diseases such as autosomal dominant polycystic kidney disease (ADPKD), where a gene mutation in polycystin causes proliferation of cystic masses. In ADPKD, primary cilia of tubule epithelial cells have been implicated in the development of cysts, resulting in inflammatory processes and cell death. Polycystic disease is one of several such ciliopathies that ultimately lead to fibrosis.

ETIOLOGY

Obstruction to urine flow can result from *intrinsic* or *extrinsic mechanical blockade* as well as from *functional defects* not associated with fixed occlusion of the urinary drainage system. Mechanical obstruction can occur at any level of the urinary tract, from within the renal tubules or the renal calyces to the external urethral meatus (obstructive uropathy). Normal points of narrowing, such as the ureteropelvic and ureterovesical junctions, bladder neck, and urethral meatus, are common sites of obstruction. When lower UTO is above the level of the bladder, unilateral dilatation of the ureter (*hydroureter*) and renal pyelocalyceal system (*hydronephrosis*) occurs; lesions at or below the level of the bladder cause bilateral involvement.

Common forms of obstruction are listed in Table 331-1. Childhood causes include *congenital malformations*, such as narrowing of the ureteropelvic junction (UPJ) and abnormal insertion of the ureter into the bladder, the most common cause. Vesicoureteral reflux in the absence of urinary tract infection or bladder neck obstruction often resolves with age. Reinsertion of the ureter into the bladder is indicated if reflux is severe and unlikely to improve spontaneously, if renal function deteriorates, or if urinary tract infections recur despite chronic antimicrobial therapy. Vesicoureteral reflux may cause prenatal hydronephrosis and, if severe, can lead to recurrent urinary infections, hypertension, and renal scarring in childhood. Posterior urethral valves are the most common cause of bilateral hydronephrosis in boys. In adults, UTO has usually been attributed to *acquired defects*. Pelvic tumors, calculi, and urethral stricture predominate. Ligation of, or injury to, the ureter during pelvic or colonic surgery can lead to hydronephrosis, which, if unilateral, may remain undetected. Obstructive uropathy may also result from extrinsic neoplastic (carcinoma of cervix or colon) or inflammatory disorders. Lymphomas, particularly follicular, and pelvic or colonic neoplasms with retroperitoneal involvement are causes of ureteral obstruction. As many as 50% of men aged >40 years may have lower urinary tract symptoms associated with benign prostatic hypertrophy, but these symptoms may occur without bladder outlet obstruction. Regardless of the primary cause, the chronic kidney disease that results may be exacerbated by a secondary contributor like diabetes mellitus, hypertension, kidney stones, infection, and metabolic disturbances.

Functional impairment of urine flow occurs when voiding is altered by abnormal pontine or sacral centers of micturition control. It may be asymptomatic or associated with lower urinary tract symptoms such as frequency, urgency, and postmicturition incontinence, nocturia, straining to void, slow stream, hesitancy, or a feeling of incomplete emptying. A history should be sought for trauma, back injury, surgery, diabetes mellitus, neurologic or psychiatric conditions, and medications. Causes include neurogenic bladder, often with adynamic ureter, and vesicoureteral reflux. Reflux in children may result in severe unilateral or bilateral hydroureter and hydronephrosis. Overflow urinary incontinence combined with sudden-onset fecal incontinence, severe lower back pain, and saddle anesthesia, requires emergency evaluation for possible cauda equina syndrome. Urinary retention may be the consequence of α-adrenergic and anticholinergic agents, as well as opiates. Hydronephrosis in pregnancy is due to relaxational effects of progesterone on smooth muscle of the renal pelvis, as well as ureteral compression by the enlarged uterus, more often on the right side.

TABLE 331-1 Common Mechanical Causes of Urinary Tract Obstruction

URETER	BLADDER OUTLET	URETHRA
Congenital		
Ureteropelvic junction narrowing or obstruction Ureterovesical junction narrowing or obstruction and reflux Ureterocele Retrocaval ureter	Bladder neck obstruction Ureterocele	Posterior urethral valves Anterior urethral valves Stricture Meatal stenosis Phimosis
Acquired Intrinsic Defects		
Calculi Inflammation Infection Trauma Sloughed papillae Tumor Blood clots	Benign prostatic hyperplasia Cancer of prostate Cancer of bladder Calculi Diabetic neuropathy Spinal cord disease Anticholinergic drugs and α-adrenergic agonists	Stricture Tumor Calculi Trauma Phimosis
Acquired Extrinsic Defects		
Pregnant uterus Retroperitoneal fibrosis Aortic aneurysm Uterine leiomyomata Carcinoma of uterus, prostate, bladder, colon, rectum Lymphoma Pelvic inflammatory disease, endometriosis Accidental surgical ligation	Carcinoma of cervix, colon Trauma	Trauma

Diagnostic tools to identify anatomic obstruction include urinary flow measurements and a postvoid residual measurement. Bladder volume may be readily assessed by bedside ultrasound. Cystourethroscopy and urodynamic studies may be reserved for the symptomatic patient to assess the filling phase (cystometry), pressure-volume relationship of the bladder, bladder compliance, and capacity. Pressure-flow analysis evaluates bladder contractility and bladder outlet resistance during voiding. Bladder obstruction is characterized by high pressures in women, whereas in men, a diagnosis of bladder outlet obstruction is based on flow rate and voiding pressures. A voiding cystourethrogram may be useful in evaluating incomplete emptying and bladder neck and urethral pathology.

CLINICAL FEATURES AND PATHOPHYSIOLOGY

The pathophysiology and clinical features of UTO are summarized in Table 331-2. Flank pain, the symptom that most commonly leads to medical attention, is due to distention of the collecting system or renal capsule. Pain severity is influenced more by the rate at which distention develops than by the degree of distention. Acute supravesical

TABLE 331-2 Pathophysiology of Bilateral Ureteral Obstruction

HEMODYNAMIC EFFECTS	TUBULE EFFECTS	CLINICAL FEATURES
Acute		
↑ Renal blood flow ↓ GFR ↓ Medullary blood flow ↑ Vasodilator prostaglandins, nitric oxide	↑ Ureteral and tubule pressures ↑ Reabsorption of Na^+, urea, water	Pain (capsule distention) Azotemia, oliguria, or anuria
Chronic		
↓ Renal blood flow ↓↓ GFR ↑ Vasoconstrictor prostaglandins ↑ Renin-angiotensin production	↓ Medullary osmolarity ↓ Concentrating ability Structural damage; parenchymal atrophy ↓ Transport functions for Na^+, K^+, H^+	Azotemia Hypertension AVP-insensitive polyuria Natriuresis Hyperkalemic, hyperchloremic acidosis
Release of Obstruction		
Slow ↑ in GFR (variable)	↓ Tubule pressure ↑ Solute load per nephron (urea, NaCl) Natriuretic factors present	Postobstructive diuresis Potential for volume depletion and electrolyte imbalance due to losses of Na^+, K^+, PO_4^{2-}, Mg^{2+}, and water

Abbreviations: AVP, arginine vasopressin; GFR, glomerular filtration rate.

obstruction, as from a stone lodged in a ureter **(Chap. 330)**, is associated with excruciating, sometimes intermittent, pain, known as *renal colic*. This pain often radiates to the lower abdomen, testes, or labia. By contrast, more insidious causes of obstruction, such as chronic narrowing of the UPJ, may produce little or no pain and yet result in total destruction of the affected kidney. Flank pain that occurs only with micturition is pathognomonic of vesicoureteral reflux.

Obstruction of urine flow results in an increase in hydrostatic pressures proximal to the site of obstruction. It is this buildup of pressure that leads to the accompanying pain, the distention of the collecting system in the kidney, and elevated intratubular pressures that initiate tubular dysfunction. In the first days of obstruction, the dilatation of the poorly compliant collecting system may be minimal. As the increased hydrostatic pressure is expressed in the urinary space of the glomeruli, further filtration decreases or stops completely.

Azotemia develops when overall excretory function is impaired, often in the setting of bladder outlet obstruction, bilateral renal pelvic or ureteric obstruction, or unilateral disease in a patient with a solitary functioning kidney. Complete bilateral obstruction should be suspected when acute renal failure is accompanied by anuria. Any patient with renal failure otherwise unexplained, or with a history of nephrolithiasis, hematuria, diabetes mellitus, prostatic enlargement, pelvic surgery, trauma, or tumor should be evaluated for UTO.

In the acute setting, partial, bilateral obstruction may mimic prerenal azotemia with a high blood urea nitrogen–to–creatinine ratio, concentrated urine, and sodium retention. Renal vascular resistance may be increased. However, with more prolonged obstruction, symptoms of *polyuria* and *nocturia* commonly accompany partial UTO and result from loss of medullary hypertonicity with diminished renal concentrating ability. Failure to produce urine free of salt (natriuresis) is due to downregulation of salt reabsorption in the proximal tubule and of transport proteins including the Na^+, K^+ adenosine triphosphatase (ATPase), Na:K:2Cl cotransporter (NKCC2) in the thick ascending limb, and the epithelial Na^+ channel (ENaC) in collecting duct cells. In addition to direct effects on renal transport mechanisms, increased prostaglandin E_2 (PGE_2) (due to induction of cyclooxygenase-2 [COX-2]), angiotensin II (with its downregulation of Na^+ transporters), and atrial or B-type natriuretic peptides (ANP or BNP) due to volume expansion in the azotemic patient contribute to decreased salt reabsorption along the nephron. Nitric oxide synthases (NOS) in ureteral smooth muscle and urothelial tissues have been found to oppose the high ureteral pressure in unilateral obstruction.

Dysregulation of aquaporin-2 water channels in the collecting duct contributes to the polyuria. The defect usually does not improve with administration of vasopressin and is, therefore, a form of acquired nephrogenic diabetes insipidus.

Wide fluctuations in urine output in a patient with azotemia should always raise the possibility of intermittent or partial UTO. If fluid intake is inadequate, severe dehydration and hypernatremia may develop. However, as with other causes of poor renal function, excesses of salt and water intake may result in edema and hyponatremia.

Partial bilateral UTO often results in *acquired distal renal tubular acidosis, hyperkalemia*, and *renal salt wasting*. The H^+-ATPase, situated on the apical membrane of the α-intercalated cells of the collecting duct, is critical for distal H^+ secretion. The trafficking of intracellular H^+ pumps from the cytoplasm to the cell membrane is disrupted in UTO. The decreased function of the ENaC, in the apical membrane of neighboring collecting duct principal cells, contributes to decreased Na^+ reabsorption (salt wasting) and, therefore, decreased K^+ secretion via K^+ channels. Ammonium (NH^+) excretion important to the elimination of H^+ is impaired. These defects in tubule function are often accompanied by renal tubulointerstitial damage. Azotemia with hyperkalemia and metabolic acidosis should prompt consideration of UTO.

The renal interstitium becomes edematous and infiltrated with mononuclear inflammatory cells early in UTO. Later, interstitial fibrosis and atrophy of the papillae and medulla occur and precede these processes in the cortex. The increase in angiotensin II noted in UTO contributes to the inflammatory response and fibroblast accumulation through mechanisms involving profibrotic cytokines. With time, this process leads to chronic kidney damage.

UTO must always be considered in patients with urinary tract infections or urolithiasis. Urinary stasis encourages the growth of organisms. Urea-splitting bacteria are associated with magnesium ammonium phosphate (struvite) calculi that may take on a staghorn appearance. *Hypertension* is frequent in acute and subacute unilateral obstruction and is usually a consequence of increased release of renin by the involved kidney. Chronic kidney disease from bilateral UTO, often associated with extracellular volume expansion, may result in significant hypertension. *Erythrocytosis*, an infrequent complication of obstructive uropathy, is secondary to increased erythropoietin production.

DIAGNOSIS

A history of difficulty in voiding, pain, infection, or change in urinary volume is common. Evidence for distention of the kidney or urinary bladder can often be obtained by palpation and percussion of the abdomen. A careful rectal and genital examination may reveal enlargement or nodularity of the prostate, abnormal rectal sphincter tone, or a rectal or pelvic mass.

Urinalysis may reveal hematuria, pyuria, and bacteriuria. The urine sediment is often normal, even when obstruction leads to marked azotemia and extensive structural damage. An abdominal scout film, although insensitive, may detect nephrocalcinosis or a radiopaque stone. As indicated in **Fig. 331-1**, if UTO is suspected, a bladder catheter should be inserted. Abdominal ultrasonography should be performed to evaluate renal and bladder size, as well as pyelocalyceal contour. Ultrasonography is ~90% specific and sensitive for detection of hydronephrosis. False-positive results are associated with diuresis, renal cysts, or the presence of an extrarenal pelvis, a normal congenital variant. Congenital UPJ obstruction may be mistaken for renal cystic disease. Hydronephrosis may be absent on ultrasound when obstruction is <48 h in duration or associated with volume contraction, staghorn calculi, retroperitoneal fibrosis, or infiltrative renal disease. Duplex Doppler ultrasonography may detect an increased resistive index in urinary obstruction. The radiodensity of renal stones is measured in Hounsfield units (HUs). Calcium oxalate and calcium phosphate stones may be distinguished from uric acid calculi by their HU radiodensities on noncontrast computed tomography (CT) scan, the test of choice for acute flank pain.

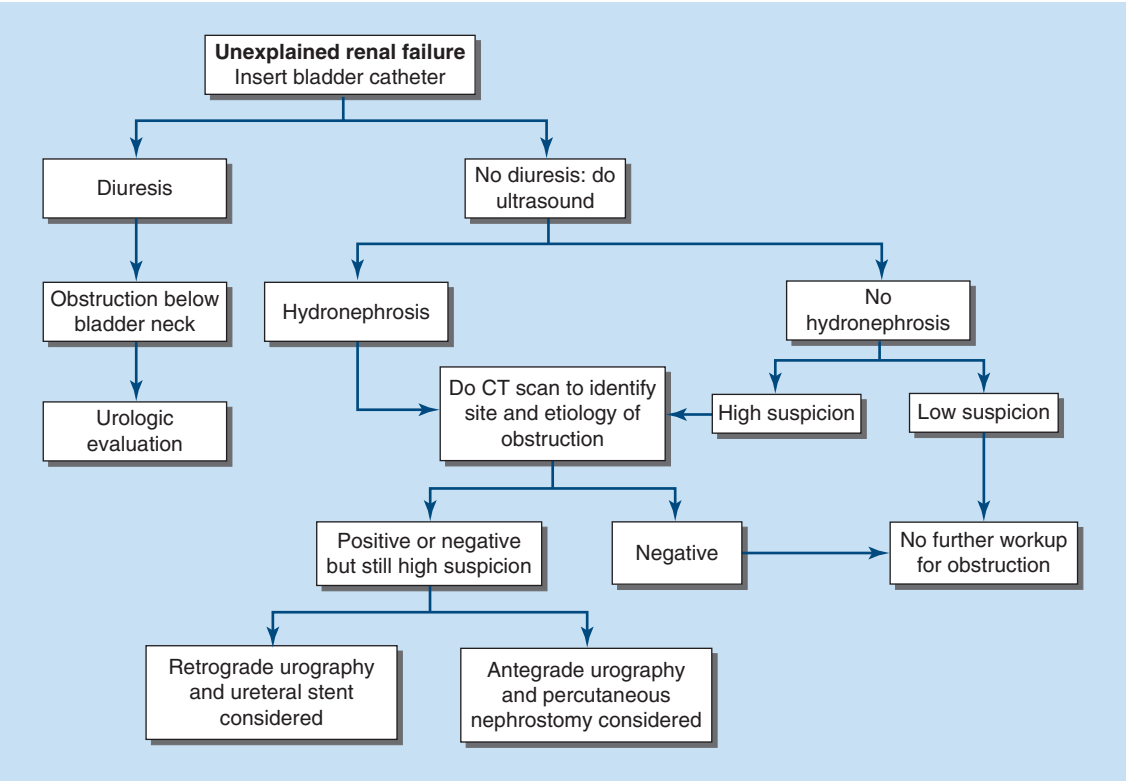

FIGURE 331-1 Diagnostic approach for urinary tract obstruction in unexplained renal failure. CT, computed tomography.

Recent advances in technology have led to alternatives and have replaced the once standard intravenous urogram in the further evaluation of UTO. The high-resolution multidetector row CT scan, in particular, has the advantages of visualizing the retroperitoneum, as well as identifying both intrinsic and extrinsic sites of obstruction. Noncontrast CT scans improve visualization of the urinary tract in the patient with renal impairment and are safer for patients at risk for contrast nephropathy. Magnetic resonance urography is not at this time superior to the CT scan, and certain gadolinium agents carry a risk of systemic sclerosis in patients with renal insufficiency. Recently, promising alternatives to gadolinium have emerged, including iron-based contrast and inhalation of xenon gas, although thus far, gadolinium produces the clearest images and most-established safety. CT scanning may define the site of obstruction, identify and characterize kidney stones, and demonstrate dilatation of the calyces, renal pelvis, and ureter above the obstruction. The ureter may be tortuous in chronic obstruction. Though radionuclide scans give less anatomic detail than CT scans, they are able to give differential renal function. In the case of asymmetric renal function, the clinician may decide on a preferable kidney to decompress in the case of bilateral obstruction. Furosemide is sometimes given to increase detection with imaging and to distinguish functional from anatomic obstruction. The increase in urinary flow may bring out the pain of an acute obstructive process.

To facilitate visualization of a suspected lesion in a ureter or renal pelvis, *retrograde* or *antegrade urography* should be attempted. These procedures do not carry risk of contrast-induced acute kidney injury in patients with renal insufficiency. The retrograde approach involves catheterization of the involved ureter under cystoscopic control, whereas the antegrade technique necessitates percutaneous placement of a catheter into the renal pelvis. Although the antegrade approach may provide immediate decompression of a unilateral obstructing lesion, many urologists initially attempt the retrograde approach unless the catheterization is unsuccessful.

Voiding cystourethrography is of value in the diagnosis of vesicoureteral reflux and bladder neck and urethral obstructions. Postvoiding films reveal residual urine. Endoscopic visualization by the urologist often permits precise identification of lesions involving the urethra, prostate, bladder, and ureteral orifices.

TREATMENT

Urinary Tract Obstruction

UTO complicated by infection requires immediate relief of obstruction to prevent development of generalized sepsis and progressive renal damage. Sepsis necessitates prompt urologic intervention. Drainage may be achieved by nephrostomy, ureterostomy, or ureteral, urethral, or suprapubic catheterization. Prolonged antibiotic treatment may be necessary. Chronic or recurrent infections in a poorly functioning obstructed kidney may necessitate nephrectomy. When infection is not present, surgery is often delayed until acid-base, fluid, and electrolyte status is restored. Nevertheless, the site of obstruction should be ascertained as soon as feasible. Elective relief of obstruction is usually recommended in patients with urinary retention, recurrent urinary tract infections, persistent pain, or progressive loss of renal function. Benign prostatic hypertrophy may be treated medically with α-adrenergic blockers and 5α-reductase inhibitors. Renal colic may be treated with anti-inflammatory medication as edema often contributes to an obstructing ureteral stone, and α-adrenergic blockers may also be of benefit. The clinician should be aware of the risk of intraoperative floppy iris syndrome associated with cataract surgery in patients taking α-adrenergic blockers. Use of nonsteroidal anti-inflammatory medication must take into account the potential for renal harm, and opiates in patients with decreased renal function may be dangerous and should be used with caution. Functional obstruction secondary to neurogenic bladder may be decreased with the combination of frequent voiding and cholinergic drugs.

PROGNOSIS

With relief of obstruction, the prognosis regarding return of renal function depends largely on whether irreversible renal damage has occurred. When obstruction is not relieved, the course will depend mainly on whether the obstruction is complete or incomplete and bilateral or unilateral, as well as whether or not urinary tract infection is also present. Complete obstruction with infection can lead to total destruction of the kidney within days. Partial return of glomerular filtration rate may

follow relief of complete obstruction of 1 and 2 weeks' duration, but after 8 weeks of obstruction, recovery is unlikely. In the absence of definitive evidence of irreversibility, every effort should be made to decompress the obstruction in the hope of restoring renal function at least partially. A renal radionuclide scan, performed after a prolonged period of decompression, may be used to predict the reversibility of renal dysfunction.

POSTOBSTRUCTIVE DIURESIS

Relief of bilateral, but not unilateral, complete obstruction commonly results in polyuria, which may be massive. The urine is usually hypotonic and may contain large amounts of sodium chloride, potassium, phosphate, and magnesium. The natriuresis is due in part to the correction of extracellular volume expansion, the increase in natriuretic factors accumulated during the period of renal failure, and depressed salt and water reabsorption when urine flow is reestablished. The retained urea is excreted with improved glomerular filtration rate, resulting in an osmotic diuresis that increases the urine volume of electrolyte-free water. Electrolyte-free water excretion (hypotonic urine) is recognized as being present when the sum of the urinary concentrations of sodium and potassium is lower than the serum sodium concentration. Precipitating factors include suppression of antidiuretic hormone at arterial baroreceptor sites, elevation of natriuretic peptides, or nephrogenic diabetes insipidus due to obstructive tubular injury. In the majority of patients, this diuresis results in the *appropriate* excretion of the excesses of retained salt and water. When extracellular volume and composition return to normal, the diuresis usually abates spontaneously. Occasionally, iatrogenic expansion of extracellular volume is responsible for, or sustains, the diuresis observed in the postobstructive period. Replacement with intravenous fluids in amounts less than urinary losses usually prevents this complication. More aggressive fluid management is required in the setting of hypovolemia, hypotension, or disturbances in serum electrolyte concentrations.

The loss of electrolyte-free water with urea may result in hypernatremia. Measured urinary output and serum and urine sodium, potassium, and osmolal concentrations should guide the use of appropriate intravenous replacement. Often replacement with 0.45% saline is required because of the likelihood of appropriately matching urine electrolyte concentrations. Relief of obstruction may be followed by urinary salt and water losses severe enough to provoke profound dehydration and vascular collapse. In these patients, decreased tubule reabsorptive capacity is probably responsible for the marked diuresis. Appropriate therapy in such patients includes intravenous administration of salt-containing solutions to replace sodium and volume deficits.

Section 1 Disorders of the Alimentary Tract

332 Approach to the Patient with Gastrointestinal Disease

William L. Hasler, Chung Owyang

ANATOMIC CONSIDERATIONS

The gastrointestinal (GI) tract extends from the mouth to the anus and is composed of organs with distinct functions. Sphincters assist in gut compartmentalization to separate the organs. Distinct gut wall layers contribute to regional activities. The mucosa regulates fluid and nutrient transfer but is also a barrier to prevent entry of some luminal contents. Smooth muscle and enteric nerves mediate propulsion. Many organs possess a serosal layer to provide a supportive foundation and permit external input. The gut interacts with many other systems. Pancreaticobiliary conduits deliver bile and enzymes into the duodenum. Lymphatic channels assist in gut immune activities. Intrinsic nerves control propulsion and fluid regulation. Extrinsic neural input provides volitional or involuntary control specific for each gut region.

FUNCTIONS OF THE GI TRACT

The GI tract serves two main functions—assimilating nutrients and eliminating waste. In the mouth, food is processed, mixed with salivary amylase, and delivered to the pharynx. Aborally propagating esophageal contractions propel the ingested bolus into the stomach in coordination with relaxation of the upper and lower esophageal sphincters. Basal tone in the lower esophageal sphincter prevents gastroesophageal reflux.

The stomach triturates and mixes food with pepsin and acid. The proximal stomach serves a storage function by relaxing to accommodate the meal. Phasic contractions in the distal stomach propel food residue against the pylorus, where it is ground and thrust proximally for further mixing prior to emptying into the duodenum.

Most nutrient absorption occurs in the small intestine. Mucosal villi provide maximal surface area and possess specialized enzymes and transporters. Triturated food from the stomach mixes with pancreatic secretions and bile in the duodenum. Pancreatic juice contains both enzymes for digestion and bicarbonate to optimize luminal pH for enzyme activation. Bile secreted by the liver and stored in the gallbladder is needed for lipid digestion. Most nutrients and minerals are rapidly absorbed in the proximal intestine, while bile acids and vitamin B_{12} are absorbed in the ileum. Bile contains byproducts of erythrocyte degradation, toxins, medications, and cholesterol that are emptied into the colon along with indigestible residue. The ileocecal junction is a sphincter that limits coloileal reflux of colonic microbes.

The colon prepares waste for evacuation by to-and-fro contractions that dehydrate the stool. As a consequence, daily luminal volumes decrease from 1000–1500 mL in the ileum to 100–200 mL that are expelled from the rectum. Esophageal transit takes seconds, stomach and small intestine emptying times range from minutes to a few hours, but colon propagation requires >1 day in most individuals. A dense colonic microbiome ferments undigested carbohydrates and short-chain fatty acids and modulates immune activity. The colon terminates in the anus, which possesses volitional and involuntary controls to retain stool in the rectum until it can be released in a convenient setting.

EXTRINSIC MODULATION OF GUT FUNCTION

GI function is modified by influences outside the gut. Unlike other systems, the gut is in continuity with the outside environment. Several mechanisms protect against injury from foods, medications, toxins, and microbes. Mucosal immune pathways include epithelial and lamina propria lymphocytes and plasma cells and lymph node chains to prevent noxious agents from entering the circulation. Antimicrobial peptides secreted by Paneth cells defend against pathogens. Drugs and toxins absorbed into the portal venous circulation are filtered and detoxified in the liver. Many GI reflexes involve extrinsic vagus or splanchnic nerve pathways. The brain-gut axis alters function in gut regions not under volitional regulation. Stress disrupts normal gut motor, secretory, and sensory activities.

OVERVIEW OF GI DISEASES

GI diseases range in severity from conditions that produce mild symptoms and no long-term morbidity to those with intractable symptoms or adverse outcomes. Diseases may be localized to one gut organ or exhibit diffuse involvement at many sites.

CLASSIFICATION OF GI DISEASES

GI diseases are manifestations of alterations in nutrient and fluid assimilation, transit and sensation, immune function, and vascular supply. Neoplastic degeneration may affect any GI site. Genetic factors underlie some disorders.

Impaired Digestion and Absorption Diseases of the stomach, small intestine, biliary tree, and pancreas can disrupt digestion and absorption. The most common maldigestion syndrome, lactase deficiency, produces gas and diarrhea after ingesting dairy products but has no adverse outcomes. Intestinal sucrase-isomaltase deficiency produces similar symptoms after consuming sucrose. Disorders that affect digestion and/or absorption more diffusely, including celiac disease, bacterial overgrowth, infectious enteritis, Crohn's ileitis, and radiation enteritis produce anemia, dehydration, electrolyte disorders, or malnutrition. Gastric acid hypersecretory conditions impair digestion by damaging the intestinal mucosa, impairing pancreatic enzyme activation, and accelerating transit. Benign or neoplastic biliary obstruction impairs fat digestion. Impaired pancreatic enzyme release in chronic pancreatitis or pancreatic cancer impairs digestion and leads to malnutrition.

Altered Secretion Some GI diseases result from alteration of gut secretion. Gastric acid hypersecretion occurs in gastrinoma, G-cell hyperplasia, retained antrum, and some patients with duodenal ulcers. Gastric acid is reduced in atrophic gastritis and pernicious anemia. Intestinal or colonic hypersecretion and/or impaired absorption causes diarrhea with acute bacterial or viral infection, chronic *Giardia* or cryptosporidia infections, small-intestinal bacterial overgrowth, bile salt diarrhea, microscopic colitis, diabetic diarrhea, and endocrine neoplasias with tumor overproduction of secretagogue transmitters such as vasoactive intestinal polypeptide.

Altered Gut Transit Mechanical obstruction can block transit of gut contents. Esophageal occlusion most often is due to stricture (from acid exposure or eosinophilic esophagitis) or neoplasm. Gastric obstruction develops from ulcer disease or cancer. Small-intestinal obstruction commonly results from adhesions but also occurs with Crohn's disease, radiation- or drug-induced strictures, and malignancy. The most common cause of colonic obstruction is colon cancer, although inflammatory strictures develop with inflammatory bowel disease (IBD), after diverticulitis, or with some medications.

Delayed propulsion can develop in any gut region. Achalasia is characterized by impaired esophageal body peristalsis and incomplete lower esophageal sphincter relaxation. Gastroparesis is the delay in gastric emptying resulting from impaired antral motility or spastic

pyloric contraction. Intestinal pseudoobstruction is the disruption of small-bowel contractility due to enteric nerve or smooth-muscle injury. Slow-transit constipation results from diffusely impaired colon propulsion. Constipation also occurs with anorectal outlet abnormalities such as rectal prolapse, intussusception, or dyssynergia—a failure of anal or puborectalis relaxation with defecation.

Disorders of rapid propulsion are less common. Rapid gastric emptying occurs with postvagotomy dumping syndrome and some cases of functional dyspepsia and cyclic vomiting syndrome. Exaggerated intestinal or colonic motor patterns may contribute to diarrhea in irritable bowel syndrome (IBS). Accelerated transit with hyperdefecation is noted in hyperthyroidism.

Immune Dysregulation Many inflammatory GI conditions are consequences of altered immune function. Mucosal inflammation in celiac disease results from dietary ingestion of gluten-containing grains. Eosinophilic esophagitis and eosinophilic gastroenteritis exhibit prominent mucosal eosinophil infiltration. Ulcerative colitis and Crohn's disease are types of IBD that produce mucosal injury primarily in the lower gut. The microscopic colitides, lymphocytic and collagenous colitis, exhibit subepithelial infiltrates without visible mucosal damage. Abnormal mast cell function underlies mastocytosis and may play a role in some IBS cases. Bacterial, viral, and protozoal organisms produce ileitis or colitis in selected patients. GI manifestations of COVID-19 include nausea, vomiting, diarrhea, abdominal pain, and hepatic abnormalities. Gut microbiome alterations (termed dysbiosis) may trigger IBD, celiac disease, and IBS flares and may be factors in oncogenesis in some cases of pancreatic cancer.

Impaired Gut Blood Flow Ischemic damage occurs as a consequence of impaired blood flow. Rare cases of gastroparesis result from celiac artery blockage. Intestinal and colonic ischemia are more common and can be consequences of arterial embolus or thrombosis, venous thrombosis, or hypoperfusion from dehydration, sepsis, hemorrhage, or reduced cardiac output. These conditions produce mucosal injury, hemorrhage, perforation, or stricturing with chronic ischemia. Radiation enterocolitis may lead to reduced mucosal blood flow without large vessel occlusion.

Neoplastic Degeneration All GI regions are susceptible to malignant degeneration. In the United States, colorectal cancer is most common and usually presents after age 45. Gastric cancer is prevalent, especially in certain Asian populations, and may be a consequence of *Helicobacter pylori* infection. Esophageal cancer develops with chronic acid reflux or after excessive alcohol or tobacco use. Small-intestinal neoplasms are rare but occur with underlying inflammatory diseases. Most GI cancers exhibit carcinomatous histology, but lymphomas and other cell types can be seen. Anal cancers arise after prior anal infection or inflammation. Pancreatic and biliary cancers elicit severe pain, weight loss, and jaundice and have poor prognoses. Hepatocellular carcinoma usually arises in the setting of chronic viral hepatitis or cirrhosis secondary to other causes.

Disorders without Obvious Organic Abnormalities The most prevalent GI disorders show no abnormalities on biochemical or structural testing and include IBS, functional dyspepsia, and functional heartburn. These disorders have been given a new nomenclature and are termed disorders of gut-brain interaction (DGBI). DGBIs exhibit complex pathophysiology including altered gut motor function, exaggerated visceral sensory response to noxious stimulation, abnormal central nervous system processing of visceral pain sensation, and mucosal immune defects. Many patients with DGBIs have significant emotional disturbances on psychometric testing.

Genetic Influences Some GI diseases exhibit hereditary components. Family members of IBD patients show genetic predisposition to disease development. Colonic, esophageal, and pancreatic malignancies arise in certain inherited disorders. Lynch syndrome is an autosomal dominant condition with increased risk for developing colon and gynecologic cancers. Genetic dysmotility syndromes are described. Familial clustering is observed in DGBIs, although this may be secondary learned familial illness behavior rather than a true genetic factor.

SYMPTOMS OF GI DISEASE

Symptoms of GI disease include abdominal pain, heartburn, nausea and vomiting, altered bowel habits, GI bleeding, jaundice, and other manifestations (Table 332-1).

Abdominal Pain Abdominal pain results from GI disease and extraintestinal conditions of the genitourinary tract, abdominal wall, thorax, or spine. Visceral pain generally is midline in location and vague in character. Parietal pain is localized and precisely described. Painful inflammatory diseases include peptic ulcer, appendicitis, diverticulitis, IBD, pancreatitis, cholecystitis, and infectious enterocolitis. Noninflammatory sources include biliary colic, mesenteric ischemia, and neoplasia. The most common causes of abdominal pain are IBS and functional dyspepsia.

Heartburn Heartburn, a burning substernal sensation, is experienced by 40% of the population. Heartburn usually results from excess gastroesophageal acid reflux, but some cases exhibit normal acid exposure and are caused by nonacidic reflux or heightened esophageal nerve sensitivity.

Nausea and Vomiting Nausea and vomiting are caused by GI diseases, medications, toxins, infection, endocrine disorders, labyrinthine conditions, and central nervous system disease. Mechanical obstruction should be excluded as a cause of chronic nausea and vomiting. Disorders of propulsion including gastroparesis and intestinal pseudoobstruction elicit similar symptoms. Nausea and vomiting also are reported with IBS or gastroduodenal DGBIs (chronic nausea vomiting syndrome, cyclic vomiting syndrome, cannabinoid hyperemesis syndrome).

Altered Bowel Habits Altered bowel habits are common complaints. Constipation may be reported as infrequent defecation,

TABLE 332-1 Common Causes of Common Gastrointestinal (GI) Symptoms

ABDOMINAL PAIN	NAUSEA AND VOMITING	DIARRHEA	GI BLEEDING	OBSTRUCTIVE JAUNDICE
Appendicitis	Medications	Infection	Ulcer disease	Bile duct stones
Gallstone disease	GI obstruction	Poorly absorbed sugars	Esophagitis	Cholangiocarcinoma
Pancreatitis	Motor disorders	Inflammatory bowel disease	Varices	Cholangitis
Diverticulitis	Functional bowel disorder	Microscopic colitis	Vascular lesions	Sclerosing cholangitis
Ulcer disease	Cyclic vomiting syndrome	Functional bowel disorder	Neoplasm	Ampullary stenosis
Esophagitis	Cannabinoid hyperemesis syndrome	Celiac disease	Diverticula	Ampullary carcinoma
GI obstruction	Enteric infection	Pancreatic insufficiency	Hemorrhoids	Pancreatitis
Inflammatory bowel disease	Pregnancy	Hyperthyroidism	Fissures	Pancreatic tumor
Functional bowel disorder	Endocrine disease	Ischemia	Inflammatory bowel disease	
Vascular disease	Motion sickness	Endocrine tumor	Infectious colitis	
Gynecologic causes	Central nervous system disease			
Renal stone				

straining with defecation, passage of hard stools, or a sense of incomplete fecal evacuation and is caused by obstruction, motor disorders, medications, and endocrine diseases (hypothyroidism, hyperparathyroidism). Diarrhea may be reported as frequent defecation, passage of loose/watery stools, fecal urgency, or a similar sense of incomplete evacuation and can result from infections, inflammatory causes, malabsorption, and medications. IBS produces constipation, diarrhea, or an alternating bowel pattern. Fecal mucus is common in IBS, whereas pus and blood characterize IBD. Malabsorption can cause steatorrhea. A history of contaminated water exposure raises concern for protozoal causes (*Giardia, Cryptosporidium*).

GI Bleeding Upper GI bleeding presents with melena or hematemesis, whereas lower GI bleeding produces bright red or maroon stools. However, briskly bleeding upper sites can elicit red rectal bleeding, while slowly bleeding ascending colon sites may cause melena. Chronic occult GI bleeding may present with iron deficiency anemia. Causes of upper GI bleeding include ulcers, gastroduodenitis, esophagitis, portal hypertensive etiologies, malignancy, gastroesophageal junction tears, and vascular lesions. Lower GI sources include hemorrhoids, anal fissures, diverticula, ischemic colitis, neoplasm, IBD, infectious colitis, drug-induced colitis, arteriovenous malformations, and other vascular lesions.

Jaundice Jaundice results from prehepatic, intrahepatic, or posthepatic disease. Posthepatic causes of jaundice include biliary (choledocholithiasis, acute cholangitis, primary sclerosing cholangitis, strictures, neoplasm) and pancreatic (pancreatitis, stricture, malignancy) disorders.

Other Symptoms Dysphagia, odynophagia, and unexplained chest pain suggest esophageal disease. Globus sensation is reported with acid reflux but also occurs with upper esophageal sphincter dysfunction, hypersensitivity, or affective disorders. Weight loss, anorexia, and fatigue are reported with neoplastic, inflammatory, motility, pancreatic, and psychiatric conditions. IBD is associated with hepatobiliary dysfunction, skin and eye lesions, and arthritis. Celiac disease may present with dermatitis herpetiformis. Jaundice produces pruritus. Conversely, systemic diseases have GI consequences. Systemic lupus may cause gut ischemia, presenting with pain or bleeding.

EVALUATION OF THE PATIENT WITH GI DISEASE

Evaluation of suspected GI disease begins with a careful history and examination and may be followed by investigation with tools to test gut structure or function and luminal contents in selected cases. In patients with normal diagnostic assessment, validated symptom profiles can be characterized to confidently define the presence of a DGBI.

HISTORY

The history in suspected GI disease has several components. Symptom timing, profiles, and duration suggest specific etiologies. Short-duration symptoms commonly result from acute infection or inflammation, toxin exposure, or ischemia. Long-standing symptoms point to chronic inflammation, neoplasia, or DGBIs. Luminal obstruction presents with dysphagia, nausea and vomiting, bloating and distention, or constipation depending on the site of blockage. Symptoms from obstruction, ischemia, IBD, and DGBIs are worsened by meals, while ulcer symptoms may be relieved by eating. Ulcer pain occurs intermittently over weeks to months, whereas biliary colic has sudden onset and lasts up to several hours. Acute pancreatitis pain is severe and persists for days to weeks. Meals elicit diarrhea while defecation relieves discomfort in some IBD and IBS cases. DGBIs are exacerbated by stress. Sudden awakening by pain suggests organic rather than functional causes. Diarrhea from malabsorption usually improves with fasting, whereas secretory diarrhea persists without oral intake.

Symptom relation to other factors offers insight into underlying diagnostic possibilities. Obstructive symptoms with a history of abdominal surgery raise concern for adhesions. Loose stools after gastrectomy or cholecystectomy suggest dumping syndrome or postcholecystectomy diarrhea. Symptom onset after travel prompts consideration of infection. Medications produce pain, altered bowel habits, or GI bleeding. Celiac disease is prevalent in people of northern European descent, whereas IBD is more common in Jewish populations. A sexual history may raise concern for infection or immunodeficiency.

Symptom criteria devised by working groups improve diagnosis of DGIBs and reduce unnecessary diagnostic testing. The best accepted symptom-based criteria are the Rome criteria, which exhibit sensitivities and specificities of 55–75% when tested against structural findings in IBS and functional dyspepsia, indicating the need for careful test selection in patients with high risk of organic disease.

PHYSICAL EXAMINATION

The physical examination complements information from the history. Fever suggests inflammation or neoplasm. Orthostasis is produced by significant blood loss, dehydration, sepsis, or autonomic neuropathy. Skin, eye, or joint findings may point to specific diagnoses such as IBD. Neck examination with swallowing assessment evaluates dysphagia. Lung and cardiac examinations can suggest cardiopulmonary disease as causes of abdominal pain or nausea, while pelvic examination tests for gynecologic sources of pain. Rectal examination may detect blood from mucosal injury or neoplasm or a palpable inflammatory mass in appendicitis. Metabolic conditions and gut motor disorders can have associated peripheral neuropathy.

Abdominal inspection may reveal distention from obstruction, neoplasm, or ascites or vascular abnormalities with liver disease. Auscultation detects bruits or friction rubs from vascular disease or hepatic tumors. Loss of bowel sounds signifies ileus, whereas high-pitched, hyperactive sounds characterize intestinal obstruction. Percussion assesses liver size and detects shifting dullness from ascites. Palpation assesses for hepatosplenomegaly and neoplastic or inflammatory masses. Intestinal ischemia elicits severe pain but little tenderness. Patients with visceral pain may exhibit generalized discomfort, whereas those with parietal pain or peritonitis have localized pain with involuntary guarding, rigidity, or rebound. Patients with musculoskeletal abdominal wall pain may note tenderness exacerbated by Valsalva or leg lift maneuvers.

TOOLS FOR PATIENT EVALUATION

Laboratory, radiographic, and functional tests help to diagnose suspected GI disease. The GI tract is amenable to internal evaluation using endoscopy and to examination of luminal contents. Histopathologic examination of GI tissues complements this testing.

Laboratory Laboratory tests can provide useful information. Iron-deficiency anemia suggests mucosal blood loss, whereas vitamin B_{12} deficiency results from intestinal, gastric, or pancreatic disease. Both conditions also result from inadequate oral intake. Leukocytosis and increased sedimentation rates and C-reactive proteins are found in inflammation, whereas leukopenia is seen in viral illness. Severe vomiting or diarrhea elicits electrolyte disturbances, acid-base abnormalities, and elevated blood urea nitrogen. Pancreaticobiliary or liver disease produces elevated pancreatic or liver chemistries. Thyroid chemistries, cortisol, and calcium levels evaluate for endocrinologic causes of symptoms. Pregnancy testing is considered for women with unexplained nausea. Serologic tests screen for atrophic gastritis, celiac disease, connective tissue diseases, and paraneoplastic dysmotility syndromes. Hormone and neurotransmitter levels are obtained for suspected endocrine neoplasia. Measurement of serum gastrin after secretin administration can facilitate gastrinoma diagnosis. Intraabdominal malignancies produce tumor markers including carcinoembryonic antigen, CA 19-9, CA 125, and α-fetoprotein. Blood testing monitors thiopurine metabolites in IBD patients on immunosuppressant agents. Research into novel biomarkers is being conducted to predict longitudinal course and treatment response in IBD and other conditions. Ascitic fluid is analyzed for infection, malignancy, or findings of portal hypertension. Urine samples screen for carcinoid, porphyria, and heavy metal intoxication. Genetic testing is indicated in some patients with hereditary predisposition to selected GI diseases. Pharmacogenetic methods can determine which therapies should not be given to specific patients.

Luminal Contents Luminal contents are analyzed in selected settings. Fecal *Helicobacter pylori* antigen testing can detect active infection with this agent in ulcer disease or dyspepsia. Stool samples are cultured for bacterial pathogens, examined for leukocytes and parasites, or tested for *Giardia* antigen. Fecal fat is increased with malabsorption. Fecal elastase is decreased with exocrine pancreatic insufficiency. Inflammatory conditions such as IBD produce fecal calprotectin or lactoferrin elevations. Stool electrolytes can be measured in diarrheal conditions. Laxative screens are performed for suspected laxative abuse. Fecal immunochemical and multitarget fecal DNA tests can be used for colon cancer screening in low-risk populations. Gastric acid is quantified to exclude gastrinoma. Esophageal pH/impedance testing is done for refractory gastroesophageal reflux and can characterize mechanisms underlying unexplained belching.

Endoscopy Indications for endoscopic procedures are listed in Table 332-2, which can diagnose causes of bleeding, pain, nausea and vomiting, weight loss, altered bowel function, and fever. Upper endoscopy evaluates the esophagus, stomach, and duodenum and is advocated as the initial test for suspected ulcer disease, esophagitis, neoplasm, malabsorption, and Barrett's metaplasia and dysplasia because of its abilities to visualize and biopsy abnormalities. Endoscopically obtained duodenal aspirates can be examined for parasites or cultured for bacterial overgrowth. It should be recognized that upper endoscopy is normal in 85% of patients with unexplained dyspepsia. Colonoscopy is the preferred procedure for colon cancer screening and surveillance with possible excision of noncancerous polyps. Colonoscopy also can obtain biopsies for colitis or ileitis secondary to IBD, microscopic colitis, immune checkpoint inhibitor use, infection, ischemia, and radiation. Sigmoidoscopy examines the colon to the splenic flexure and excludes distal causes of bleeding, inflammation, or obstruction in young patients not at significant risk for colon cancer. For elusive GI bleeding from arteriovenous malformations or superficial ulcers, small-intestinal examination is performed with push enteroscopy, capsule endoscopy, or double-balloon enteroscopy. Capsule endoscopy also visualizes small-intestinal Crohn's disease in individuals with negative radiography. Endoscopic ultrasound (EUS) diagnoses and stages GI malignancy, excludes choledocholithiasis, evaluates pancreatitis, and assesses anal sphincter integrity. Endoscopic retrograde cholangiopancreatography (ERCP) provides diagnoses and affords therapy of pancreatic and biliary disease.

Radiography/Nuclear Medicine Radiographic tests evaluate visceral and extraluminal structures. Esophagography is the initial procedure to exclude subtle rings, strictures, or achalasia as causes of dysphagia, whereas fluoroscopic triple-phase swallow testing evaluates oropharyngeal dysphagia. Small-bowel contrast radiology detects intestinal tumors, strictures, and fistulae and can estimate intestinal transit. Contrast enemas are performed when colonoscopy is unsuccessful or contraindicated. Defecography characterizes anorectal dysfunction as a cause of constipation. Ultrasound and computed tomography (CT) evaluate regions not accessible by endoscopy or contrast studies, including the liver, pancreas, gallbladder, kidneys, and retroperitoneum, and can diagnose appendicitis, mass lesions, fluid collections, organ enlargement, and (in the case of ultrasound) gallstones. CT and magnetic resonance (MR) colonography are alternatives to colonoscopy for colon cancer screening. MR methods image pancreaticobiliary ducts to exclude neoplasm, stones, and sclerosing cholangitis and the liver to characterize benign and malignant tumors. CT or MR enterography assesses small-bowel thickening, stricturing, masses, and fistulae in IBD and other inflammatory or neoplastic conditions. Percutaneous transhepatic cholangiography accesses the biliary tree in obstructive jaundice. CT and MR angiographic techniques can define mesenteric occlusion and detect acute intraluminal hemorrhage. Ultrasound or MR elastography quantifies fibrosis in chronic liver disease. Positron emission tomography (PET) distinguishes malignant from benign disease in several organ systems. Imaging with combined PET-CT techniques using DOTA-octreotate and related agents has improved detection of neuroendocrine tumors.

Scintigraphy evaluates structural abnormalities and quantifies luminal transit. Radionuclide scans localize bleeding sites in patients with brisk hemorrhage to direct therapy with endoscopy, angiography, or surgery. Radiolabeled leukocyte scans search for intraabdominal abscesses not visualized on CT. Biliary scintigraphy complements ultrasound in assessing cholecystitis. Scintigraphy to quantify esophageal and gastric emptying is well established. Scintigraphic measures of small-intestinal or colonic transit are less widely used.

TABLE 332-2 Common Indications for Endoscopy

UPPER ENDOSCOPY	COLONOSCOPY	ENDOSCOPIC RETROGRADE CHOLANGIOPANCREATOGRAPHY	ENDOSCOPIC ULTRASOUND	CAPSULE ENDOSCOPY	DOUBLE-BALLOON ENDOSCOPY
Dyspepsia despite treatment	Cancer screening	Jaundice	Staging of malignancy	Obscure bleeding	Ablation of small-intestinal bleeding sources
Dyspepsia with signs of organic disease	Lower gastrointestinal (GI) bleeding	Postbiliary surgery complaints	Characterize and biopsy submucosal mass	Suspected Crohn's disease of the small intestine	Biopsy of suspicious small-intestinal masses/ulcers
Refractory vomiting	Anemia	Cholangitis	Bile duct stones		
Dysphagia	Diarrhea	Gallstone pancreatitis	Chronic pancreatitis		
Upper GI bleeding	Polypectomy	Pancreatic/biliary/ampullary tumor	Drain pseudocyst		
Anemia	Obstruction	Unexplained pancreatitis	Anal continuity		
Weight loss	Biopsy radiologic abnormality	Pancreatitis with unrelenting pain	Direct stent placement		
Malabsorption	Cancer surveillance: family history prior polyp/cancer, colitis	Fistulas			
Biopsy radiologic abnormality	Palliate neoplasm	Biopsy radiologic abnormality			
Polypectomy	Remove foreign body	Pancreaticobiliary drainage			
Place gastrostomy	Place stent across stenosis	Sample bile			
Barrett's surveillance		Sphincter of Oddi manometry			
Palliate neoplasm					
Sample duodenal tissue/fluid					
Remove foreign body					
Endoscopic mucosal resection or endoscopic submucosal dissection for dysplasia or early cancer					
Place stent across stenosis					
Endoscopic myotomy for achalasia or gastroparesis					
Endoscopic bariatric procedures					

Histopathologic Assessment Endoscopic mucosal biopsies evaluate for inflammatory (including celiac disease, IBD, microscopic colitis), infectious, dysplastic, and neoplastic disease. Gastric biopsies can detect *H. pylori* on immunohistochemical staining and determine antibiotic sensitivity from biopsy cultures. Deep rectal biopsies facilitate diagnosis of Hirschsprung's disease or amyloid. Liver biopsy is performed for abnormal liver chemistries, unexplained jaundice, some cases of viral hepatitis, and following liver transplants to exclude rejection. Biopsies obtained during CT or ultrasound evaluate for intraabdominal conditions not accessible by endoscopy.

Methods to visually scrutinize histologic features and detect dysplasia during endoscopy prior to targeted biopsy in colitis, Barrett's esophagus, and gastric malignancy include narrow-band imaging, chromoendoscopy, confocal laser endomicroscopy, and optical coherence tomography. Artificial intelligence techniques using machine learning are in development for detecting dysplasia and early cancer in images from biopsies.

Functional Testing Tests of gut function provide important data when structural testing is nondiagnostic. High-resolution esophageal manometry defines esophageal motility disorders including achalasia. Small-intestinal manometry tests for pseudoobstruction and colon manometry evaluate for colonic inertia. Anorectal manometry with balloon expulsion testing characterizes unexplained incontinence or constipation from outlet dysfunction. The functional lumen imaging probe measures reduced distensibility in the lower esophageal sphincter in achalasia, the upper esophageal sphincter with Zenker's diverticula, and the pylorus in gastroparesis. Measurement of breath hydrogen and methane while fasting and after oral mono- or oligosaccharide challenge screen for carbohydrate intolerance and small-intestinal bacterial overgrowth. Urea breath testing assesses for persistent *H. pylori* infection. Gastric emptying breath testing is an alternative to scintigraphy for gastroparesis diagnosis.

TREATMENT

Gastrointestinal Disease

Management of GI diseases depends on the cause of symptoms. Treatment options include dietary modifications, medications, treatment of gut dysbiosis, therapeutic endoscopy, interventional radiology, surgery, psychological approaches, and physical therapy. Smartphone applications have been developed for diverse purposes ranging from providing instructions for endoscopy preparation to educating and promoting adherence to diet restrictions.

NUTRITIONAL MODIFICATION

Nutritional modifications for GI disease can reduce symptoms, correct pathologic defects, or replace normal food intake with enteral or parenteral formulations. Changes that improve symptoms but do not reverse organic abnormalities include lactose restriction for lactase deficiency, liquid meals in gastroparesis, carbohydrate restrictions with dumping syndrome, avoidance of selected meats with alpha gal syndrome, and low-FODMAP (fermentable oligo-, di-, monosaccharides and polyols) diets in IBS. The gluten-free diet for celiac disease exemplifies a primary therapy to reduce mucosal inflammation. Likewise, elimination diets may improve histology and symptoms in eosinophilic esophagitis. Medium-chain triglycerides replace normal fats in short-gut syndrome or severe ileal disease. Perfusing liquid meals through a gastrostomy is performed in patients who cannot swallow safely. Enteral jejunostomy feedings are considered for gastric dysmotility syndromes that preclude feeding into the stomach. Total parenteral hyperalimentation is used for generalized gut failure in patients for whom enteral nutrition cannot be sustained.

PHARMACOTHERAPY

Medications in several categories treat GI diseases. Considerable resources are expended on over-the-counter remedies. Prescription drugs are offered as short-term or continuous therapy to reduce GI symptoms. Other prescription agents modify disease activity with the intent to alter longitudinal disease course. Alternative treatments are popular in conditions for which traditional therapies provide incomplete relief.

Over-the-Counter Agents Over-the-counter agents are reserved for mild GI symptoms. Antacids, histamine H_2 antagonists, alginates, and proton pump inhibitors (PPIs) decrease symptoms in gastroesophageal reflux disease (GERD) and dyspepsia. Fiber supplements, stool softeners, enemas, and laxatives are used for constipation. Laxatives are categorized as stimulants, osmotic agents (including isotonic preparations containing polyethylene glycol), and poorly absorbed sugars. Nonprescription antidiarrheal agents include bismuth subsalicylate, kaolin-pectin combinations, and loperamide. Lactase pills are used for lactose intolerance. Gaseous symptoms may be reduced by bacterial α-galactosidase, antiflatulents, and adsorbents. Using nonprescription preparations for chronic persistent symptoms should be supervised by a health care provider to ensure that an underlying severe medical illness is not missed.

Prescription Drugs for Symptom Control Prescription drugs are approved to treat symptoms in many GI diseases. Higher-dose PPIs are advocated for GERD when over-the-counter preparations are inadequate. Given acutely, PPIs slow acute upper GI bleeding, reducing requirements for endoscopic therapy. PPIs slow progression of Barrett's metaplasia and can manage eosinophilic esophagitis. Vonoprazan is the first drug in a newer acid suppressant class of potassium-competitive acid blockers for severe acid-related disorders and as an adjunct to *H. pylori* eradication. Baclofen reduces gastroesophageal reflux by increasing lower esophageal sphincter barrier function. Other therapies of eosinophilic esophagitis include swallowed fluticasone and budesonide. Cytoprotective agents like sucralfate are available for upper gut ulcers. Prokinetic drugs stimulate GI propulsion in gastroparesis, chronic intestinal pseudoobstruction, acute colonic pseudoobstruction, and slow-transit constipation. Secretagogue drugs are prescribed for refractory constipation, whereas peripheral opioid antagonists are offered for opioid-induced constipation. Prescription antidiarrheals include opioid drugs, anticholinergic antispasmodics, tricyclics, bile acid binders, and serotonin antagonists. Opioids may be needed for pain control in disseminated malignancy and chronic pancreatitis. Antiemetics reduce nausea and vomiting. Pancreatic enzymes decrease malabsorption and pain from pancreatic disease. The antisecretory somatostatin analogue octreotide treats hypersecretory states. Some DGBIs require neuromodulators, including tricyclic agents, for control of pain, diarrhea, or nausea. Nonselective beta blockers can reduce the risk of variceal hemorrhage with portal hypertension.

Prescription Drugs for Disease Modification Other prescription medication classes modify disease activity by actions to reduce inflammation, modulate immune function, and target neoplasm. Immunomodulatory drugs are used in IBD, microscopic colitis, immune checkpoint inhibitor colitis, refractory celiac disease, autoimmune pancreatitis, and gut vasculitis. Biologic agents that inhibit tumor necrosis activity and antibodies targeting integrins, proinflammatory cytokines, Janus kinase inhibitors, and cell adhesion molecules have benefits in IBD. Agents effective for acute severe ulcerative colitis requiring hospitalization include corticosteroids, infliximab, and cyclosporine. Biologics that deplete eosinophils or inhibit mast cells show promise in eosinophilic disorders. *H. pylori* eradication treats some gastric malignancies. Most GI carcinomas respond poorly to chemotherapy with or without radiotherapy, whereas lymphomas may be cured with these interventions. Cancer treatment programs including immunotherapies, immune checkpoint inhibitors, and tumor vaccines are in development.

Complementary and Alternative Medicines Several alternative treatments are available to manage GI symptoms. Ginger, acupressure, and acustimulation are used for nausea. Pyridoxine is given

for nausea in first-trimester pregnancy. Peppermint oil and caraway seed oil products and herbal preparations such as STW 5 (a nine-herb mixture) are useful for functional dyspepsia and IBS. Low-potency pancreatic enzyme preparations are sold as digestive aids but have little evidence to support their efficacy.

THERAPIES TARGETING GUT DYSBIOSIS

Antibiotics are prescribed to treat *H. pylori*–induced ulcers, infectious diarrhea, complicated diverticulitis, and small intestinal bacterial overgrowth. Some cases of diarrhea-predominant IBS respond to the nonabsorbable antibiotic rifaximin. Probiotics containing bacterial cultures and prebiotics that selectively nourish nonnoxious commensal bacteria have been given as adjunctive therapy for infectious diarrhea and IBS, with limited evidence of efficacy. Postbiotics are metabolites made by probiotic organisms that inhibit pathogenic luminal bacteria. Transplanting donor feces into the colon by colonoscopy or enema is effective treatment for recurrent *Clostridioides difficile* colitis. Commercial oral and rectal microbiota-based products have been approved or are in development for this indication.

THERAPEUTIC ENDOSCOPY

In addition to its diagnostic role, endoscopy has numerous therapeutic capabilities. Cautery techniques and injection of vasoconstrictor substances can stop hemorrhage from ulcers and vascular malformations. Endoscopically placed clips can occlude arterial bleeding sites, while hemostatic powder sprays can stop brisk persistent GI bleeding. Endoscopic encirclement of esophageal varices and hemorrhoids with constricting bands stops hemorrhage from these sites. Bleeding gastric varices can be injected with thrombin or cyanoacrylate. Endoscopy can remove polyps in the stomach, small bowel, or colon. Decompressive colonoscopy withdraws excess gas in some cases of acute colonic pseudoobstruction. Endoscopic mucosal resection, submucosal dissection, and radiofrequency techniques ablate some cases of Barrett's esophagus with dysplasia and resect superficial cancers or subepithelial tumors elsewhere in the gut. Obstructions of the GI lumen and pancreaticobiliary tree are relieved by endoscopic dilation or placing plastic or expandable metal stents. Endoscopic sphincterotomy of the ampulla of Vater treats choledocholithiasis. Cholangioscopy can facilitate stone lithotripsy in the common bile duct, ablation of small ductal tumors, and placement of gallbladder stents to facilitate drainage in nonoperative candidates. Interventional EUS is used for pancreatic cyst gastrostomy using lumen-apposing metal stents, pancreatic necrosectomy, and placement of fiducial markers to direct pancreatic and rectal radiotherapy. EUS also can facilitate endoscopic access to the excluded distal stomach in patients who have undergone bariatric gastric bypass surgery using similar stents so that ERCP can be done for pancreaticobiliary conditions. EUS-directed stent placement can manage postsurgical stenoses after pancreatic resection. Endoscopy is used to insert gastric feeding tubes. Peroral endoscopic myotomy is performed on the lower esophageal sphincter in achalasia, the pylorus in gastroparesis, and the upper esophageal sphincter for Zenker's diverticulum. Endoscopic treatments for acid reflux including transoral incisionless fundoplication have been developed as potential alternatives to surgery. Endoscopic bariatric methods, including intragastric balloons, sleeve gastroplasty, and duodenal resurfacing and diversion, have been devised.

INTERVENTIONAL RADIOLOGY

Interventional radiology techniques offer benefits in selected settings. Angiographic embolization or vasoconstriction decreases bleeding from gut sites not amenable to endoscopic intervention. Angiographic embolectomy, stent placement, and thrombolysis also manage mesenteric ischemia. Dilatation or stenting under fluoroscopic guidance relieves luminal strictures. Contrast enemas can reduce colon volvulus. CT- and ultrasound-directed drainage of abdominal fluid collections can obviate the need for surgery. Percutaneous transhepatic cholangiography relieves biliary obstruction when ERCP is contraindicated. Percutaneous cholecystostomy treats acute cholecystitis in patients unable to undergo cholecystectomy. Transjugular intrahepatic portosystemic shunts are performed for variceal hemorrhage not amenable to endoscopic therapy. Lithotripsy is rarely performed to fragment gallstones in patients who are not surgical candidates. Radiologic approaches are often chosen over endoscopy for gastroenterostomy placement. Radiographic assistance is sometimes needed for placement of central venous catheters for parenteral nutrition.

SURGERY

Roles of surgery in GI conditions include disease cure, symptom control, maintenance of nutrition, and palliation of unresectable neoplasm. Surgery cures medication-unresponsive ulcerative colitis, diverticulitis, cholecystitis, appendicitis, and intraabdominal abscess, but only reduces symptoms and treats complications in Crohn's disease. Surgery is performed for ulcer complications like bleeding, obstruction, or perforation and intestinal obstructions that persist after conservative care. Gastroesophageal fundoplication is performed for refractory acid reflux. Acid exposure time on pH testing helps select candidates for fundoplication. Achalasia responds to operations to reduce lower esophageal sphincter tone. Operations for motor disorders include implanted electrical stimulators for gastroparesis and electrical devices and artificial sphincters for fecal incontinence. Surgery can place a jejunostomy for long-term enteral feedings. Other common indications for surgery include hernias, hemorrhoids, and nonhealing anal fissures.

PSYCHOLOGICAL APPROACHES AND PHYSICAL THERAPY

Psychological therapies, including psychotherapy, cognitive behavioral therapy, and hypnosis, show efficacy in DGBIs and are most beneficial for patients with significant psychological dysfunction. Behavioral therapists provide instruction in diaphragmatic breathing for belching or rumination. Biofeedback methods administered by physical therapists can treat refractory fecal incontinence or constipation secondary to dyssynergia.

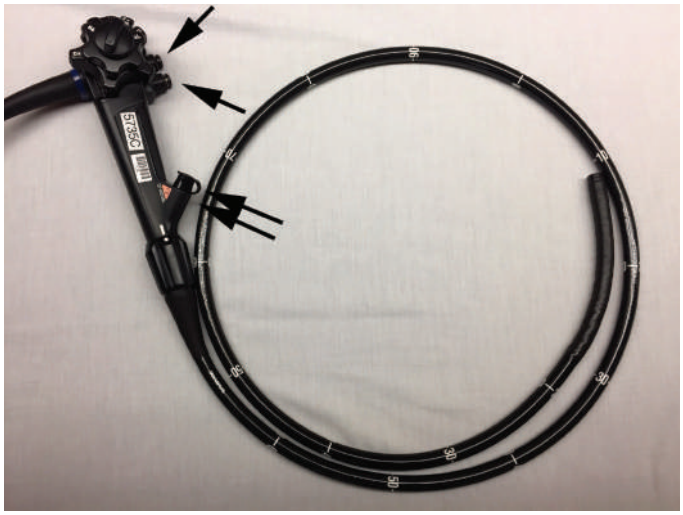
333 Gastrointestinal Endoscopy

Louis Michel Wong Kee Song, Vinay Chandrasekhara, Mark Topazian

Gastrointestinal endoscopy has been attempted for over 200 years, but the introduction of semirigid and flexible gastroscopes in the mid-twentieth century marked the dawn of the modern endoscopic era. Since then, rapid advances in endoscopic technology have led to



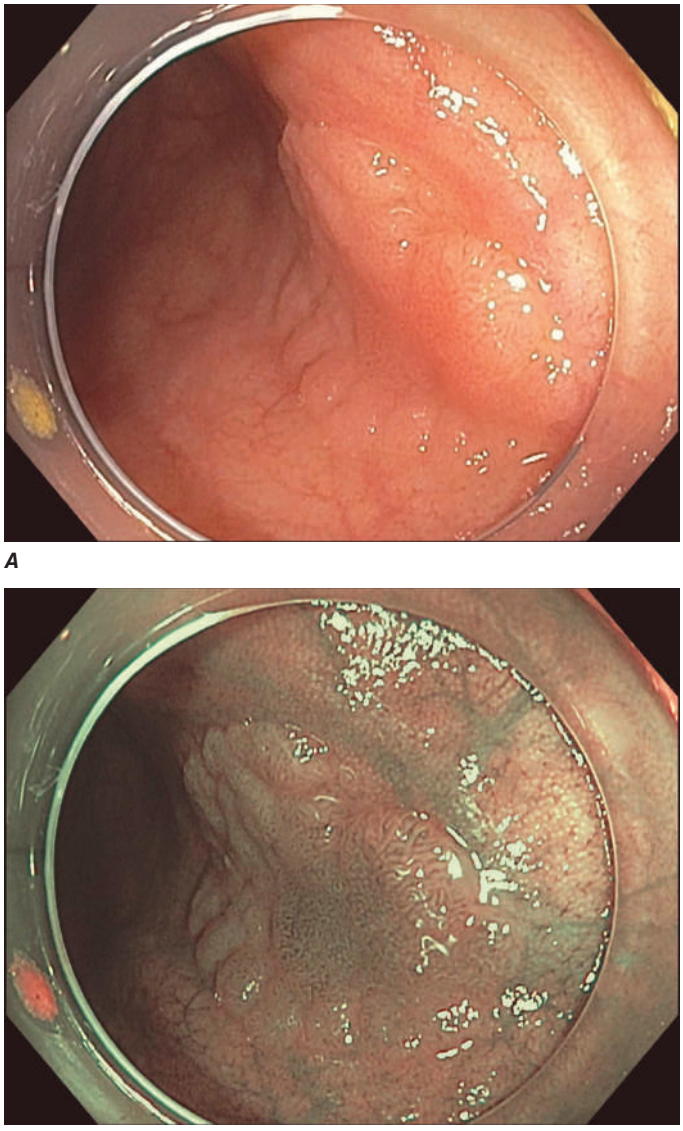


FIGURE 333-1 Gastrointestinal endoscope. Shown here is a conventional colonoscope with control knobs for tip deflection, push buttons for suction and air insufflation (*single arrows*), and a working channel for passage of accessories (*double arrows*).

dramatic changes in the diagnosis and treatment of many digestive diseases. Innovative endoscopic devices and new endoscopic treatment modalities continue to expand the use of endoscopy in patient care.

Flexible endoscopes provide an electronic video image generated by a charge-coupled device (CCD) or a complementary metal oxide semiconductor (CMOS) chip in the tip of the endoscope. Operator controls permit deflection of the endoscope tip; fiberoptic bundles or light-emitting diodes provide light at the tip of the endoscope; and working channels allow washing, suctioning, and the passage of instruments **(Fig. 333-1)**. Progressive changes in the diameter and stiffness of endoscopes have improved the ease and patient tolerance of endoscopy. High-resolution and high-definition endoscopes equipped with electronic and optical magnification capabilities enable acquisition of images with a high level of detail. Advanced imaging techniques, including narrow-band imaging **(Fig. 333-2)** and real-time image-processing enhancement algorithms, aid in tissue characterization or differentiation.

ENDOSCOPIC PROCEDURES

UPPER ENDOSCOPY

Upper gastrointestinal endoscopy, also referred to as esophagogastroduodenoscopy (EGD), is performed by passing a flexible endoscope through the mouth into the esophagus, stomach, and duodenum. The procedure is the best method for examining the upper gastrointestinal mucosa **(Fig. 333-3)**. While the upper gastrointestinal radiographic series has similar accuracy for diagnosis of duodenal ulcer **(Fig. 333-4)**, EGD is superior for detection of gastric ulcers **(Fig. 333-5)** and flat mucosal lesions, such as Barrett's esophagus **(Fig. 333-6)**, and it permits directed biopsy and endoscopic therapy. Intravenous sedation is given to most patients in the United States to ease the anxiety and discomfort of the procedure, although in many countries, EGD is routinely performed with topical pharyngeal anesthesia only. Patient tolerance of unsedated EGD is improved by the use of an ultrathin, 5-mm diameter endoscope that can be passed transorally or transnasally.

COLONOSCOPY

Colonoscopy is performed by passing a flexible colonoscope through the anal canal into the rectum and colon. The cecum is reached in >95% of cases, and the terminal ileum **(Fig. 333-7)** can usually be examined. Colonoscopy is the gold standard for imaging the colonic mucosa **(Fig. 333-8)**. Colonoscopy has greater sensitivity than barium enema for the detection of colitis **(Fig. 333-9)**, colon polyps **(Fig. 333-10)**, and colorectal cancer **(Fig. 333-11)**. Computed tomography (CT) colonography rivals the accuracy of colonoscopy for the detection of some polyps and cancer, although it is not as sensitive for the detection of flat lesions, such as serrated polyps **(Fig. 333-12)**. Intravenous sedation is usually given before colonoscopy in the United States, although a willing patient and a skilled examiner can complete the procedure without sedation in many cases.

FLEXIBLE SIGMOIDOSCOPY

Flexible sigmoidoscopy is akin to colonoscopy, but it visualizes only the rectum and a variable portion of the left colon, typically to 60 cm from the anal verge. This procedure may result in abdominal cramping and discomfort, but it is brief and thus can be performed without sedation. Flexible sigmoidoscopy is primarily used for evaluation of diarrhea and rectal outlet bleeding.

SMALL-BOWEL ENDOSCOPY

Three endoscopic techniques are currently used to evaluate the small intestine, most often in patients presenting with presumed small-bowel bleeding. For *capsule endoscopy*, the patient swallows a disposable capsule that contains a CMOS chip camera. Color still images **(Fig. 333-13)** are transmitted wirelessly to an external receiver at several frames per second until the capsule's battery is exhausted or it is passed into the toilet. Capsule endoscopy enables visualization of the small-bowel mucosa beyond the reach of a conventional endoscope,

and at present, it is solely a diagnostic procedure. Patients with a history of prior intestinal surgery or Crohn's disease are at risk for capsule retention at the site of a clinically unsuspected small-bowel stricture, and ingestion of a "patency capsule" composed of radiologically opaque biodegradable material may be indicated before capsule endoscopy in such patients.

Push enteroscopy is generally performed using a variable-stiffness pediatric or adult colonoscope, or a dedicated enteroscope with or without the assistance of a stiffening overtube that extends from the mouth to the small intestine. The proximal to mid-jejunum is usually reached, and the instrument channel of the endoscope allows for biopsy or endoscopic therapy.

Deeper intubation of the small bowel can be accomplished by *single- or double-balloon enteroscopy*, which enables pleating of the small intestine onto an overtube **(Fig. 333-14, Video V5-1)**. With balloon-assisted enteroscopy, the entire small intestine can be visualized in some patients when both the oral and anal routes of insertion are used. Biopsies and endoscopic therapy, such as thermal ablation of vascular ectasias and polypectomy, can be performed throughout the visualized small bowel **(Fig. 333-15)**.

ENDOSCOPIC RETROGRADE CHOLANGIOPANCREATOGRAPHY

During endoscopic retrograde cholangiopancreatography (ERCP), a side-viewing endoscope is passed through the mouth to the duodenum,

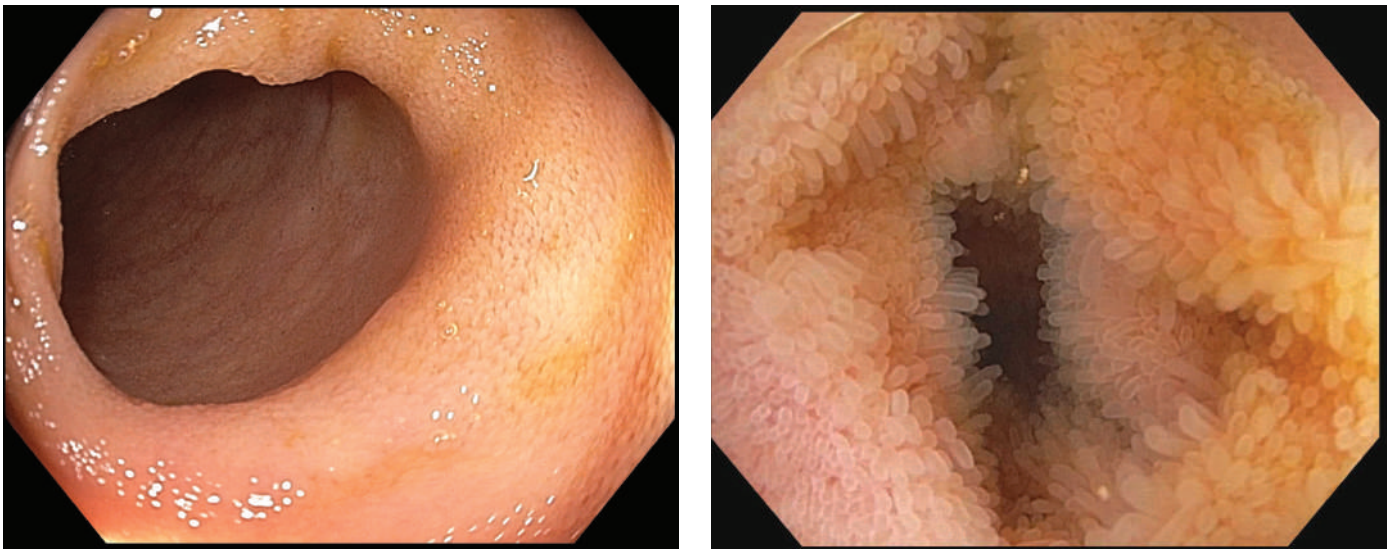

FIGURE 333-7 Colonoscopic view of terminal ileum. ***A.*** Normal-appearing terminal ileum (TI). ***B.*** View of normal villi of TI enhanced by examination under water immersion.

the bile duct and/or pancreatic duct is cannulated with a thin plastic catheter, and radiographic contrast material is injected under fluoroscopic guidance (Fig. 333-16). When indicated, the major papilla can be incised using the technique of endoscopic sphincterotomy (Fig. 333-17). Stones can be retrieved from the ducts, biopsies can be performed, strictures can be dilated and/or stented (Fig. 333-18), and ductal leaks can be treated (Fig. 333-19). ERCP is usually performed for therapy but is also important diagnostically as it facilitates tissue sampling of biliary or pancreatic ductal strictures.

ENDOSCOPIC ULTRASOUND

Endoscopic ultrasound (EUS) utilizes ultrasound transducers incorporated into the tip of a flexible endoscope. Ultrasound images are obtained of the gut wall and adjacent organs, vessels, lymph nodes, and other structures. High-resolution images are obtained by bringing a high-frequency ultrasound transducer close to the area of interest via endoscopy. EUS provides the most accurate preoperative local staging of esophageal, pancreatic, and rectal malignancies (Fig. 333-20), but it does not detect distant metastases that are beyond its imaging range. EUS is also useful for diagnosis of bile duct stones, gallbladder disease, subepithelial gastrointestinal lesions, and chronic pancreatitis. Fine-needle aspirates and core biopsies of organs, masses, and lymph nodes in the posterior mediastinum, abdomen, retroperitoneum, and pelvis can be obtained under EUS guidance (Fig. 333-21). EUS-guided therapeutic procedures are increasingly performed, including drainage of abscesses, pseudocysts, and pancreatic necrosis into the gut lumen (Video V5-2); celiac plexus neurolysis for treatment of pancreatic pain; ethanol ablation of pancreatic neuroendocrine tumors; treatment of gastric and intestinal varices; biliary or pancreatic drainage; and endoscopic gastrojejunostomy for palliation of malignant gastric outlet obstruction (Video V5-3).

NATURAL ORIFICE TRANSLUMINAL ENDOSCOPIC SURGERY

Natural orifice transluminal endoscopic surgery (NOTES) represents a collection of endoscopic methods that entail passage of an endoscope or its accessories into or through the wall of the gastrointestinal tract to perform diagnostic or therapeutic interventions. Some NOTES procedures, such as percutaneous endoscopic gastrostomy (PEG) or endoscopic necrosectomy of pancreatic necrosis, are well-established clinical procedures (Video V5-2); others such as peroral endoscopic myotomy (POEM) for achalasia (Fig. 333-22) and gastroparesis, peroral endoscopic tumorectomy (POET) (Fig. 333-23), and endoscopic full-thickness resection (EFTR) of gastrointestinal mural lesions (Fig. 333-24, Video V5-4), are newer minimally invasive therapeutic options.

ENDOSCOPIC RESECTION AND CLOSURE TECHNIQUES

Endoscopic mucosal resection (EMR) **(Fig. 333-25, Video V5-5)** and endoscopic submucosal dissection (ESD) **(Fig. 333-26, Video V5-6)** are the two commonly used techniques for the resection of benign and early-stage malignant gastrointestinal neoplasms. In addition to providing larger specimens for more accurate histopathologic assessment and diagnosis, these techniques may be curative for some dysplastic lesions and superficial carcinomas involving the esophagus, stomach, and colon.

Several devices are available for closure of mucosal defects created by EMR and ESD, as well as gastrointestinal fistulas and perforations. Endoscopic clips deployed through the working channel of an

endoscope have been used for many years to treat bleeding lesions, and the development of larger over-the-scope clips has facilitated endoscopic closure of gastrointestinal fistulas and perforations not previously amenable to endoscopic therapy **(Video V5-7)**. Endoscopic suturing can be used to close some perforations and large defects **(Fig. 333-27)**, anastomotic leaks, and fistulas. Endoscopic suturing may also be used to prevent stent migration **(Fig. 333-28, Video V5-8)** and to perform endoscopic bariatric procedures. These technologies are playing an expanding role in patient care.

RISKS OF ENDOSCOPY

Medications used during sedation may cause respiratory depression or allergic reactions. All endoscopic procedures carry some risk of bleeding and gastrointestinal perforation. The risk is small with diagnostic upper endoscopy, flexible sigmoidoscopy, and colonoscopy (<1:1000 procedures), but it ranges from 0.5 to 5% when therapeutic maneuvers such as polypectomy, EMR, ESD, control of hemorrhage, or stricture dilation are performed. The risk of adverse events for diagnostic EUS (without needle aspiration) is similar to that for diagnostic upper endoscopy.

Infectious complications are uncommon with most endoscopic procedures. Some procedures carry a higher incidence of postprocedural bacteremia, and prophylactic antibiotics may be indicated **(Table 333-1)**. Management of antithrombotic agents before endoscopic procedures should take into account the procedural risk of hemorrhage, the agent, and the patient condition, as summarized in **Table 333-2**.

ERCP carries additional risks. Pancreatitis occurs in ~5% of patients undergoing the procedure, and young, anicteric patients with normal

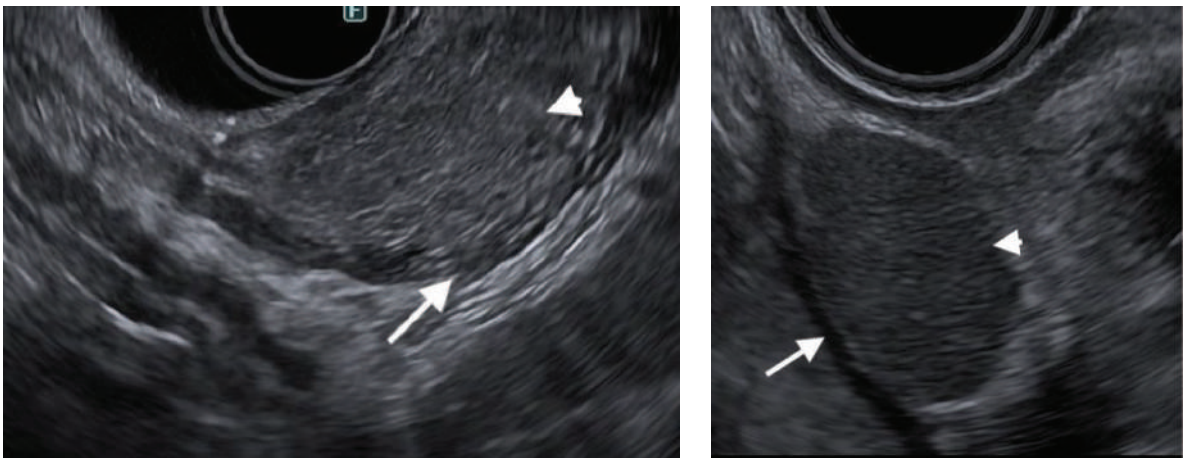
ducts are at increased risk (up to 25%). Post-ERCP pancreatitis is usually mild and self-limited, but it may result in prolonged hospitalization, surgery, diabetes, or death when severe. Significant bleeding occurs after endoscopic sphincterotomy in ~1% of cases. Ascending cholangitis, pseudocyst infection, duodenal perforation, and abscess formation may occur as a result of ERCP.

PEG tube placement during EGD is associated with a 10–15% incidence of adverse events, most often wound infections. Fasciitis, pneumonia, bleeding **(Fig. 333-29)**, buried bumper syndrome **(Fig. 333-30)**, and colonic injury may result from PEG tube placement.

URGENT ENDOSCOPY



■ ACUTE GASTROINTESTINAL HEMORRHAGE

Endoscopy is the primary diagnostic and therapeutic procedure for patients with acute gastrointestinal hemorrhage. Although gastrointestinal bleeding stops spontaneously in most cases, some patients will have persistent or recurrent hemorrhage that may be life-threatening. Clinical predictors of rebleeding help identify patients most likely to benefit from urgent endoscopy and endoscopic, angiographic, or surgical hemostasis.

Initial Evaluation The initial evaluation of the bleeding patient focuses on the severity of hemorrhage as reflected by the presence of supine hypotension or tachycardia, postural vital sign changes, and the frequency of hematemesis or melena. Decreases in hematocrit and hemoglobin lag behind the clinical course and are not reliable gauges of the magnitude of acute bleeding. Nasogastric tube aspiration and lavage can also be used to judge the severity of bleeding, but these are no longer routinely performed for this purpose. The bedside initial evaluation, completed well before the bleeding source is confidently identified, guides immediate supportive care of the patient; triage to outpatient follow-up, a hospital ward, or an intensive care unit; and timing of endoscopy. The severity of the initial hemorrhage is the most important indication for urgent endoscopy, since a large initial bleed increases the likelihood of ongoing or recurrent bleeding. Patients with resting hypotension or orthostatic change in vital signs, repeated hematemesis, bloody nasogastric aspirate that does not clear with large-volume lavage, or those requiring blood transfusions should be considered for urgent endoscopy within 12–24 h of presentation. In addition, patients with cirrhosis, coagulopathy, or respiratory or renal failure and those >70 years old are more likely to have significant rebleeding and to benefit from prompt evaluation and treatment.

Bedside evaluation also suggests an upper or lower gastrointestinal source of bleeding in most patients. Over 90% of patients with melena are bleeding proximal to the ligament of Treitz, and ~85% of patients with hematochezia are bleeding from the colon. Melena can result from bleeding in the small bowel or right colon, especially in older patients with slow colonic transit. Conversely, some patients with massive hematochezia may be bleeding from an upper gastrointestinal source, with rapid intestinal transit. An urgent upper endoscopy should be considered in such patients.

Endoscopy should be performed after the patient has been resuscitated with intravenous fluids and transfusions, as necessary. Marked coagulopathy or thrombocytopenia is usually treated before endoscopy, since correction of these abnormalities may lead to resolution of bleeding, and techniques for endoscopic hemostasis are limited in such patients. Metabolic derangements should also be addressed. Tracheal intubation for airway protection should be considered before upper endoscopy in patients with repeated recent hematemesis, particularly in those with suspected variceal hemorrhage. A single dose of erythromycin (3–4 mg/kg or 250 mg) administered intravenously 30–90 min before upper endoscopy increases gastric emptying and may clear blood and clots from the stomach to improve endoscopic visualization.

Most patients with hematochezia who are otherwise stable can undergo semi-elective colonoscopy. Controlled trials have not shown a benefit to urgent colonoscopy (within 24 h of presentation) in patients hospitalized with hematochezia, although selected patients with massive or recurrent large-volume episodes of hematochezia should probably undergo urgent colonoscopy after both upper endoscopy and a rapid colonic purge with an oral polyethylene glycol solution. Colonoscopy has a higher diagnostic yield than radionuclide bleeding scans or catheter-based angiography in lower gastrointestinal bleeding, and endoscopic therapy can be applied in some cases. Urgent colonoscopy can be hindered by poor visualization due to persistent vigorous bleeding with recurrent hemodynamic instability, and other techniques (e.g., angiography or even emergent subtotal colectomy) must be employed. The anal and rectal mucosa should also be visualized endoscopically early in the course of massive rectal bleeding, as bleeding lesions in or close to the anal canal may be identified that are amenable to endoscopic or surgical transanal hemostatic techniques.

Peptic Ulcer The endoscopic appearance of peptic ulcers provides useful prognostic information and guides the need for endoscopic

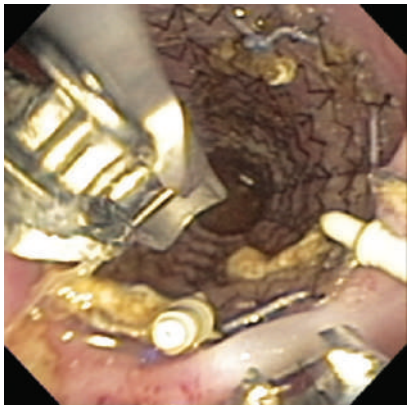
therapy in patients with acute hemorrhage **(Fig. 333-31)**. A clean-based ulcer is associated with a low risk (3–5%) of rebleeding; patients with melena and a clean-based ulcer may be discharged home from the emergency room or endoscopy suite if they are young, reliable, otherwise healthy, and able to return as needed. Flat pigmented spots and adherent clots covering the ulcer base have a 10% and 20% risk of rebleeding, respectively. Flat pigmented spots do not require treatment, but endoscopic therapy is often applied to an ulcer with an adherent clot. When a fibrin plug is seen protruding from a vessel wall in the base of an ulcer (so-called sentinel clot or visible vessel), the risk of rebleeding from the ulcer approximates 40%. This finding typically leads to endoscopic therapy to decrease the rebleeding rate. When active spurting from an ulcer is seen, there is a 90% risk of ongoing bleeding without endoscopic or surgical therapy.



Endoscopic therapy of ulcers with high-risk stigmata typically lowers the rebleeding rate to 5–10%. Several hemostatic techniques are available, including injection of epinephrine or a sclerosant into and around the vessel **(Fig. 333-32)**, "coaptive coagulation" of the vessel in the base of the ulcer using a thermal probe that is pressed against the site of bleeding **(Fig. 333-33)**, placement of through-the-scope clips **(Fig. 333-34)** or an over-the-scope clip **(Fig. 333-35)**, application of a hemostatic powder or gel, or a combination of these modalities **(Video V5-9)**. Epinephrine injection can slow or stop active bleeding, but it is not a stand-alone technique for definitive

TABLE 333-1 Antibiotic Prophylaxis for Endoscopic Procedures

PATIENT CONDITION	PROCEDURE CONTEMPLATED	GOAL OF PROPHYLAXIS	PERIPROCEDURAL ANTIBIOTIC PROPHYLAXIS
All cardiac conditions	Any endoscopic procedure	Prevention of infective endocarditis	Not recommended
Bile duct obstruction in the absence of cholangitis	ERCP with complete drainage	Prevention of cholangitis	Not recommended
Bile duct obstruction in the absence of cholangitis	ERCP with anticipated incomplete drainage (e.g., sclerosing cholangitis, hilar strictures)	Prevention of cholangitis	Recommended; continue antibiotics after the procedure
Sterile pancreatic fluid collection (e.g., pseudocyst, necrosis), which communicates with pancreatic duct	ERCP	Prevention of cyst infection	Recommended; continue antibiotics after the procedure
Sterile pancreatic fluid collection	Transmural drainage	Prevention of cyst infection	Recommended
Solid lesion along upper GI tract	EUS-FNA or FNB	Prevention of local infection	Not recommended[a]
Solid lesion along lower GI tract	EUS-FNA or FNB	Prevention of local infection	Not recommended[a]
Cystic lesions along GI tract (including mediastinum and pancreas)	EUS-FNA or FNB	Prevention of cyst infection	Recommended
All patients	Percutaneous endoscopic feeding tube placement	Prevention of peristomal infection	Recommended[b]
Cirrhosis with acute GI bleeding	Recommended for all such patients, regardless of endoscopic procedures	Prevention of infectious complications and reduction of mortality	Recommended, upon admission[c]
Continuous peritoneal dialysis	Lower GI tract endoscopy	Prevention of bacterial peritonitis	Recommended
Synthetic vascular graft and other nonvalvular cardiovascular devices	Any endoscopic procedure	Prevention of graft and device infection	Not recommended[d]
Prosthetic joints	Any endoscopic procedure	Prevention of septic arthritis	Not recommended[d]

[a]Low rates of bacteremia and local infection. [b]Cefazolin or an antibiotic with equivalent coverage of oral and skin flora. [c]Risk for bacterial infection associated with cirrhosis and GI bleeding is well established; ceftriaxone or a quinolone antibiotic recommended. [d]Very low risk of infection.

Abbreviations: ERCP, endoscopic retrograde cholangiopancreatography; EUS-FNA, endoscopic ultrasound–fine-needle aspiration; EUS-FNB, endoscopic ultrasound–fine needle biopsy; GI, gastrointestinal.

hemostasis. In conjunction with endoscopic therapy, the administration of a proton pump inhibitor decreases the risk of rebleeding and improves patient outcome.

Varices Two complementary strategies guide therapy of bleeding varices: local treatment of the bleeding varices and treatment of the underlying portal hypertension. Local therapies, including endoscopic variceal band ligation, endoscopic variceal sclerotherapy, stent placement, and tamponade with a stent or Sengstaken-Blakemore tube, effectively control acute hemorrhage in most patients, although therapies that decrease portal pressure (pharmacologic treatment, surgical shunts, or radiologically placed transjugular intrahepatic portosystemic shunts) also play an important role.

Endoscopic variceal ligation (EVL) is indicated for the prevention of a first bleed (primary prophylaxis) from large esophageal varices **(Fig. 333-36)**, particularly in patients in whom nonselective beta blockers are contraindicated or not tolerated. EVL is also the preferred endoscopic therapy for control of active esophageal variceal bleeding and for subsequent eradication of esophageal varices (secondary prophylaxis). During EVL, a varix is suctioned into a cap fitted at the tip of the endoscope, and a rubber band is released from the cap, ligating the varix **(Fig. 333-37, Video V5-10)**. EVL controls acute hemorrhage in up to 90% of patients. Complications of EVL, such as postligation ulcer bleeding and esophageal stenosis, are uncommon. Endoscopic variceal sclerotherapy (EVS) involves the injection of a sclerosing, thrombogenic solution into or next to esophageal varices. EVS also controls acute hemorrhage in most patients, but due to its higher complication rate, it is generally used as salvage therapy when band ligation fails. Bleeding from large gastric fundal varices **(Fig. 333-38)** is best treated with endoscopic cyanoacrylate ("glue") injection **(Video V5-11)** or EUS-guided coil placement and cyanoacrylate injection, since EVL or EVS of these varices is associated with a high rebleeding rate. Complications of cyanoacrylate injection include infection and glue embolization to other organs, such as the lungs, brain, and spleen.

After treatment of the acute hemorrhage, an elective course of endoscopic therapy can be undertaken with the goal of eradicating esophageal varices and preventing rebleeding months to years later. However, this chronic therapy is less successful, preventing long-term rebleeding in ~50% of patients. Pharmacologic therapies that decrease portal pressure have similar efficacy. The preferred strategy, however, for secondary prophylaxis of variceal bleeding is the combination of EVL with a nonselective beta blocker.

Dieulafoy's Lesion This lesion, also called persistent caliber artery, is a large-caliber arteriole that runs immediately beneath the gastrointestinal epithelium and bleeds through a focal mucosal erosion **(Fig. 333-39)**. Dieulafoy's lesion commonly involves the lesser curvature of the proximal stomach, causes impressive arterial hemorrhage, and may be difficult to diagnose when not actively bleeding; it is often recognized only after repeated endoscopy for recurrent bleeding. Endoscopic therapy, such as thermal coagulation, band ligation, clip placement, or endoscopic suturing, is typically effective for control of bleeding and sealing of the underlying vessel once the lesion has been identified **(Video V5-12)**. Rescue therapies, such as angiographic embolization or surgical oversewing, are considered in situations where endoscopic therapy has failed.

Mallory-Weiss Tear A Mallory-Weiss tear is a linear mucosal rent near or across the gastroesophageal junction that is often associated with retching or vomiting **(Fig. 333-40)**. When the tear disrupts a submucosal arteriole, brisk hemorrhage may result. Endoscopy is the best method for diagnosis, and an actively bleeding tear can be treated endoscopically with coaptive coagulation, band ligation, or clip placement, with or without epinephrine injection **(Video V5-13)**. Unlike peptic ulcer, a Mallory-Weiss tear with a nonbleeding sentinel clot in its base rarely rebleeds and thus does not necessitate endoscopic therapy.

Vascular Ectasias Vascular ectasias are flat mucosal vascular anomalies that are best diagnosed by endoscopy. They usually cause slow intestinal blood loss and occur either in a sporadic fashion or in a well-defined pattern of distribution (e.g., gastric antral vascular ectasia [GAVE] or "watermelon stomach") **(Fig. 333-41)**. Cecal vascular ectasias, GAVE, and radiation-induced rectal ectasias are often responsive

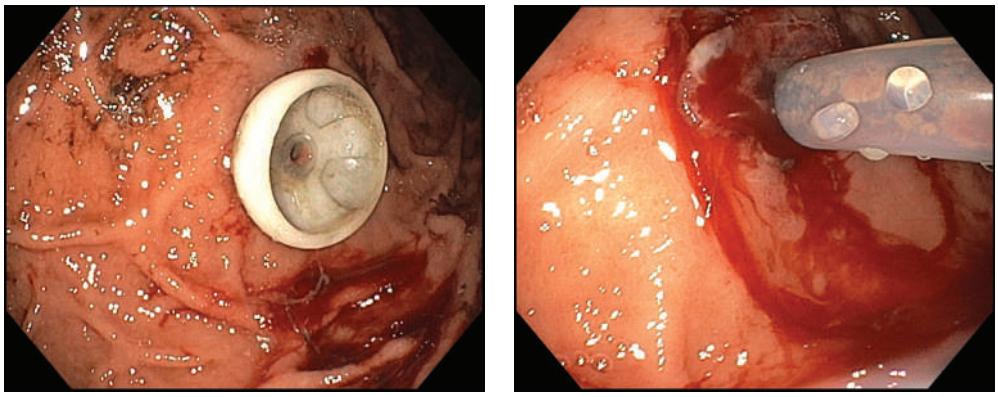

TABLE 333-2 Management of Antithrombotic Drugs Prior to Endoscopic Procedures

DRUG	BLEEDING RISK OF PROCEDURE	MANAGEMENT	INTERVAL BETWEEN LAST DOSE AND PROCEDURE	COMMENTS
Warfarin	Low[a] High[b]	Continue Discontinue	N/A 3–7 days (usually 5), INR should be ≤1.5 for procedure	Ensure that INR is not supratherapeutic Consider bridging therapy with low-molecular-weight heparin for patients at high risk of thrombosis[c]; usually safe to resume warfarin on the same or next day For life-threatening GI hemorrhage, consider reversal with unactivated prothrombin complex concentrate
Dabigatran, rivaroxaban, apixaban, edoxaban	Low[a]	Hold morning dose on day of procedure	N/A	
Dabigatran	High[b]	Discontinue	2–3 days if GFR is ≥50 mL/min, 4–5 days if GFR is 30–49 mL/min	Bridging therapy not recommended; resume drug when bleeding risk is low For life-threatening GI hemorrhage, consider use of a reversal agent
Rivaroxaban, apixaban, edoxaban	High[a]	Discontinue	2 days if GFR is ≥60 mL/min, 3 days if GFR is 30–59 mL/min, 4 days if GFR is <30 mL/min	Bridging therapy not recommended; resume drug when bleeding risk is low For life-threatening GI hemorrhage, consider use of a reversal agent
Heparin	Low[a] High[b]	Continue Discontinue	N/A 4–6 h for unfractionated heparin	Skip one dose if using low-molecular-weight heparin
Aspirin	Any	Continue	N/A	Low-dose aspirin does not substantially increase the risk of endoscopic procedures
Aspirin with dipyridamole	Low[a] High[b]	Continue Discontinue	N/A 2–7 days	Consider continuing aspirin monotherapy
$P2Y_{12}$ receptor antagonists (clopidogrel, prasugrel, ticlopidine, ticagrelor, cangrelor)	Low[a] High[b]	Continue Coronary stent in place: discuss with cardiologist No coronary stent: discontinue, consider substituting aspirin	N/A 5 days (clopidogrel or ticagrelor), 7 days (prasugrel), 10–14 days (ticlopidine)	Risk of stent thrombosis for at least 12 months after insertion of drug-eluting coronary stent or 1 month after insertion of bare metal coronary stent

[a]Low-risk endoscopic procedures include esophagogastroduodenoscopy (EGD) or colonoscopy with or without biopsy, endoscopic ultrasound (EUS) without fine-needle aspiration (FNA), and endoscopic retrograde cholangiopancreatography (ERCP) with stent exchange. [b]High-risk endoscopic procedures include EGD or colonoscopy with dilation, polypectomy, or thermal ablation; percutaneous endoscopic gastrostomy (PEG); EUS with FNA; and ERCP with sphincterotomy or pseudocyst drainage. [c]Bridging therapy with low-molecular-weight heparin should be considered for patients discontinuing warfarin who are at high risk for thromboembolism, including those with (1) prosthetic metal heart valve, (2) atrial fibrillation with a CHA_2DS_2-VASc score ≥3, mitral stenosis, prosthetic valve or history of stroke or transient ischemic attack; (3) mechanical mitral valve; (4) mechanical aortic valve with other thromboembolic risk factors or older-generation mechanical aortic valve; or (5) venous thromboembolism (VTE) within the past 3 months.

Abbreviations: GFR, glomerular filtration rate; GI, gastrointestinal; INR, international normalized ratio; N/A, not applicable.

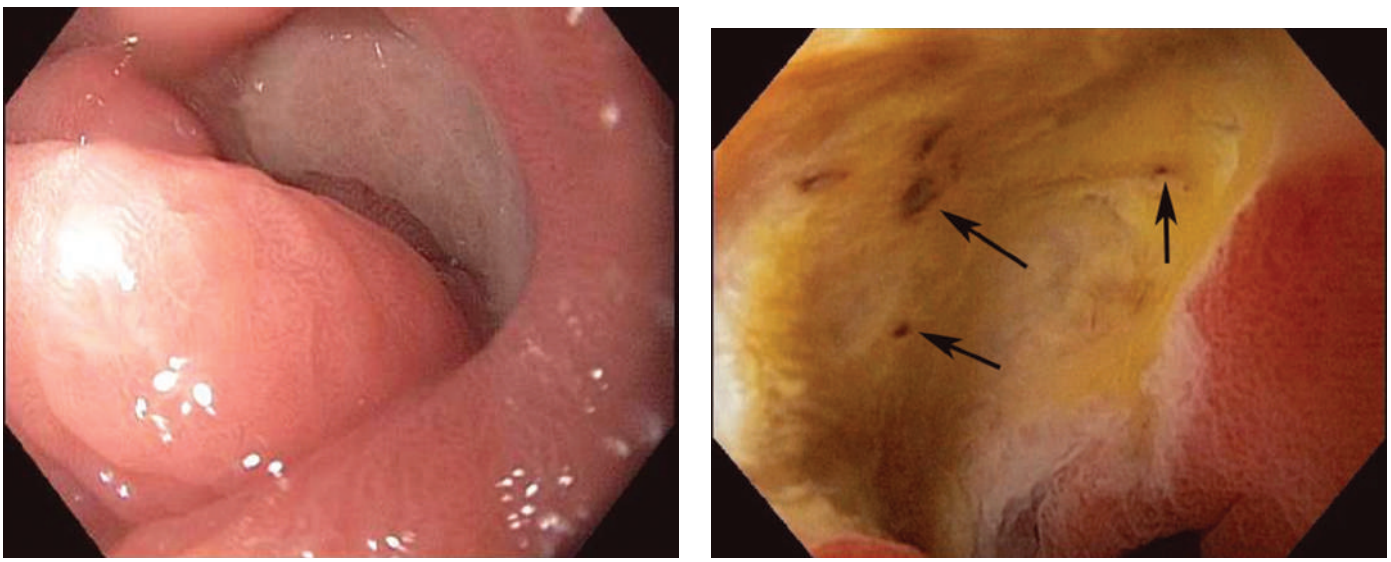
to local endoscopic ablative therapy, such as argon plasma coagulation (Video V5-14). Patients with diffuse small-bowel vascular ectasias (associated with chronic renal failure and with hereditary hemorrhagic telangiectasia) may continue to bleed despite endoscopic treatment of easily accessible lesions by conventional endoscopy. These patients may benefit from deep enteroscopy with endoscopic hemostasis, or pharmacologic therapy, such as octreotide or low-dose thalidomide, in those who continue to bleed despite endoscopic therapy.

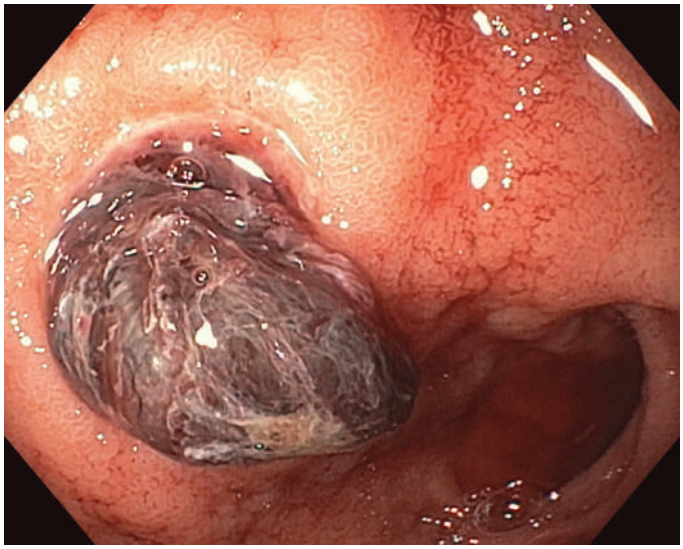
Colonic Diverticula Diverticula form where nutrient arteries penetrate the muscular wall of the colon en route to the colonic mucosa (Fig. 333-42). The artery found in the base of a diverticulum may bleed, causing painless and impressive hematochezia. Colonoscopy is indicated in patients with hematochezia and suspected diverticular hemorrhage, since other causes of bleeding (e.g., vascular ectasias, colitis, and colon cancer) must be excluded. In addition, an actively bleeding diverticulum may be seen and treated during colonoscopy (Fig. 333-43, Video V5-15).

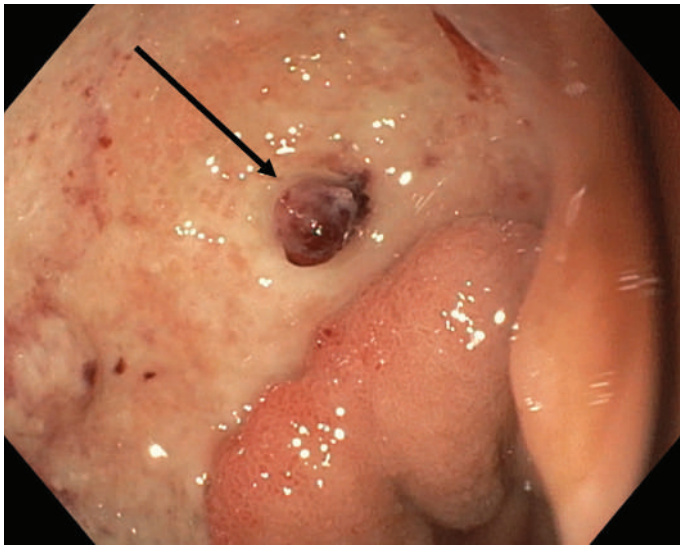
GASTROINTESTINAL OBSTRUCTION AND PSEUDOOBSTRUCTION

Endoscopy is useful for evaluation and treatment of some forms of gastrointestinal obstruction. An important exception is small-bowel obstruction due to surgical adhesions, which is generally not diagnosed or treated endoscopically. Esophageal, gastroduodenal, and colonic obstruction or pseudoobstruction can all be diagnosed and often managed endoscopically.

Acute Esophageal Obstruction Esophageal obstruction by impacted food (Fig. 333-44) or an ingested foreign body (Fig. 333-45) is a potentially life-threatening event and represents an endoscopic emergency. Left untreated, the patient may develop esophageal ulceration,







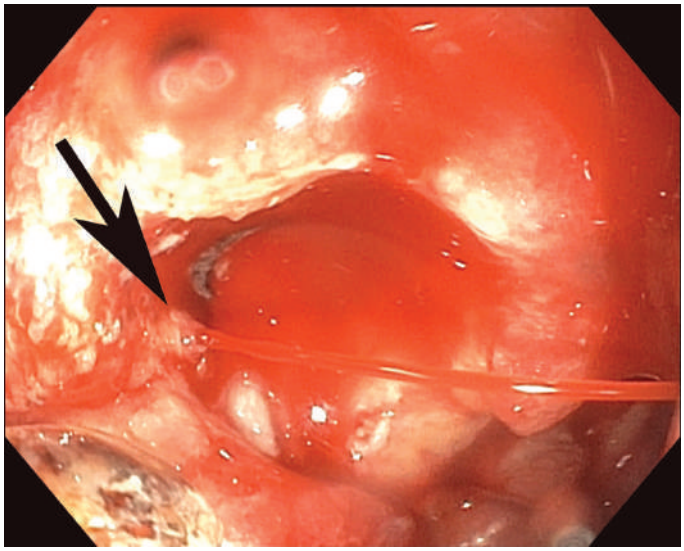


FIGURE 333-31 Stigmata of hemorrhage in peptic ulcers. ***A.*** Gastric antral ulcer with a clean base. ***B.*** Duodenal ulcer with flat pigmented spots (*arrows*). ***C.*** Duodenal ulcer with a dense adherent clot. ***D.*** Duodenal ulcer with a pigmented protuberance/visible vessel (*arrow*). ***E.*** Duodenal ulcer with active spurting (*arrow*).

ischemia, and perforation. Patients with persistent esophageal obstruction often have hypersalivation and are usually unable to swallow water. Sips of a carbonated beverage, sublingual nifedipine or nitrates, or intravenous glucagon may resolve an esophageal food impaction, but in many patients, an underlying web, ring, or stricture is present, and endoscopic removal of the obstructing food bolus is necessary. Endoscopy is generally the best initial test in such patients since endoscopic removal of the obstructing material is usually possible, and the presence of an underlying esophageal pathology can often be determined. Radiographs of the chest and neck should be considered before endoscopy in patients with fever, obstruction for ≥24 h, or ingestion of a sharp object, such as a fishbone. Radiographic contrast studies interfere with subsequent endoscopy and are not advisable in most patients with a clinical picture of esophageal obstruction.

Gastric Outlet Obstruction Obstruction of the gastric outlet is commonly caused by gastric, duodenal, or pancreatic malignancy or chronic peptic ulceration with stenosis of the pylorus **(Fig. 333-46)**. Patients vomit partially digested food many hours after eating. Gastric decompression with a nasogastric tube and subsequent lavage for removal of retained material is the first step in treatment. Endoscopy is useful for diagnosis and treatment. Patients with benign pyloric stenosis may be treated with endoscopic balloon dilation of the pylorus, and a course of endoscopic dilation results in long-term relief of symptoms

in ~50% of patients. Removable, fully covered lumen-apposing metal stents (LAMS) may also be used to treat benign pyloric stenosis **(Video V5-16)**. Malignant gastric outlet obstruction can be relieved with endoscopically placed expandable stents across the obstruction in patients with inoperable malignancy **(Video V5-17)** or by EUS-guided gastroenterostomy to bypass the obstruction **(Video V5-3)**.

Colonic Obstruction and Pseudoobstruction These conditions both present with abdominal distention and discomfort, tympany, and a dilated colon on plain abdominal radiography. The radiographic appearance may be characteristic of a particular condition, such as sigmoid volvulus **(Fig. 333-47)**. Both obstruction and pseudoobstruction may lead to colonic perforation if left untreated. Acute colonic pseudoobstruction is a form of colonic ileus that is usually attributable to electrolyte disorders, narcotic and anticholinergic medications, immobility (as after surgery), or retroperitoneal hemorrhage or mass. Multiple causative factors are often present. Colonoscopy, water-soluble contrast enema, or CT may be used to assess for an obstructing lesion and differentiate obstruction from pseudoobstruction. One of these diagnostic studies should be strongly considered if the patient does not have clear risk factors for pseudoobstruction, if radiographs do not show air in the rectum, or if the patient fails to improve when underlying causes of pseudoobstruction have been addressed. The risk of cecal perforation in pseudoobstruction rises when the cecal diameter exceeds 12 cm, and decompression of the colon may be achieved using intravenous neostigmine or via colonoscopic decompression **(Fig. 333-48)**. Most patients should receive a trial of conservative therapy (with correction of electrolyte disorders, discontinuation of offending medications, and increased mobilization) before undergoing an invasive decompressive procedure for colonic pseudoobstruction.

Acute colonic obstruction is an indication for urgent intervention. In the past, emergent diverting colostomy was usually performed with a subsequent second operation after bowel preparation to treat the underlying cause of obstruction. Colonoscopic placement of an

FIGURE 333-39 (*Continued*)

expandable stent is an alternative treatment option that can relieve malignant colonic obstruction without emergency surgery and permit bowel preparation for an elective one-stage operation **(Fig. 333-49, Video V5-18)**.

ACUTE BILIARY OBSTRUCTION

The steady, severe pain that occurs when a gallstone acutely obstructs the common bile duct often brings patients to seek medical attention. The diagnosis of a ductal stone is suspected when the patient is jaundiced or when serum liver tests or pancreatic enzyme levels are elevated; it is confirmed by transabdominal ultrasound, EUS, magnetic resonance cholangiopancreatography (MRCP), or direct cholangiography (performed endoscopically, percutaneously, or during surgery). ERCP is the primary means of treating common bile duct stones (Figs. 333-16 and 333-17), although they can also be removed by bile duct exploration at the time of cholecystectomy. Radiologic percutaneous biliary drainage may be required in some cases.

Bile Duct Imaging While transabdominal ultrasound diagnoses only a minority of bile duct stones, MRCP and EUS are >90% accurate and have an important role in diagnosis. Examples of these modalities are shown in **Fig. 333-50**.

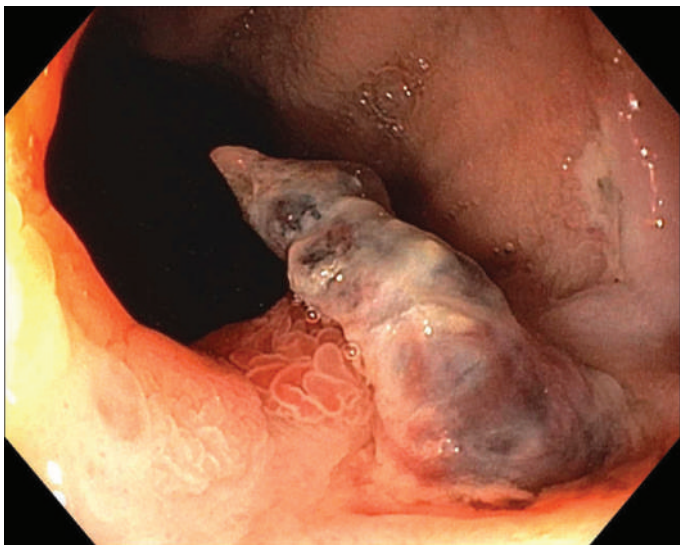

FIGURE 333-40 Mallory-Weiss tear with an adherent clot at the gastroesophageal junction following forceful retching and vomiting.

If the suspicion for a bile duct stone is high and urgent treatment is required (as in a patient with obstructive jaundice and biliary sepsis), ERCP is the procedure of choice since it remains the gold standard for diagnosis and allows for immediate treatment **(Video V5-19)**. If a persistent bile duct stone is relatively unlikely (as in a patient with gallstone pancreatitis), ERCP may be supplanted by less invasive imaging techniques, such as EUS, MRCP, or intraoperative cholangiography performed during cholecystectomy, sparing some patients the risk and discomfort of ERCP.

Ascending Cholangitis Charcot's triad of jaundice, abdominal pain, and fever is present in ~70% of patients with ascending cholangitis and biliary sepsis. These patients are managed initially with fluid resuscitation and intravenous antibiotics. Abdominal ultrasound is often performed to assess for gallbladder stones and bile duct dilation. However, the bile duct may not be dilated early in the course of acute biliary obstruction. Medical management usually improves the patient's clinical status, providing a window of ~24 h during which biliary drainage should be established, typically by ERCP. Undue delay can result in recrudescence of overt sepsis and increased morbidity and mortality rates. In addition to Charcot's triad, the presence of shock and confusion (Reynolds's pentad) is associated with a high mortality rate and should prompt urgent intervention to restore biliary drainage.

Gallstone Pancreatitis Gallstones may cause acute pancreatitis as they pass through the ampulla of Vater. The occurrence of gallstone pancreatitis usually implies passage of a stone into the duodenum, and only ~20% of patients harbor a persistent stone in the ampulla or the common bile duct. Retained stones are more common in patients with jaundice, rising serum liver tests following hospitalization, severe pancreatitis, or superimposed ascending cholangitis.

Urgent ERCP decreases the morbidity rate of gallstone pancreatitis in a subset of patients with retained bile duct stones. It is unclear whether the benefit of ERCP is mainly attributable to treatment and prevention of ascending cholangitis or to relief of pancreatic ductal obstruction. ERCP is warranted early in the course of gallstone pancreatitis if ascending cholangitis is suspected, especially in a jaundiced patient. Urgent ERCP may also benefit patients predicted to have severe pancreatitis using a clinical index of severity, such as the Glasgow or Ranson score. Since the benefit of ERCP is limited to patients with a retained bile duct stone, a strategy of initial MRCP or EUS for diagnosis decreases the utilization of ERCP in gallstone pancreatitis and improves clinical outcomes by limiting the occurrence of ERCP-related adverse events.

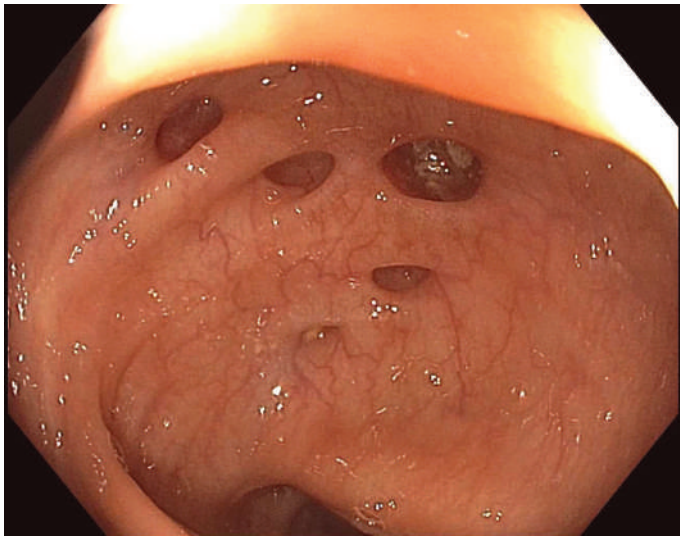
ELECTIVE ENDOSCOPY

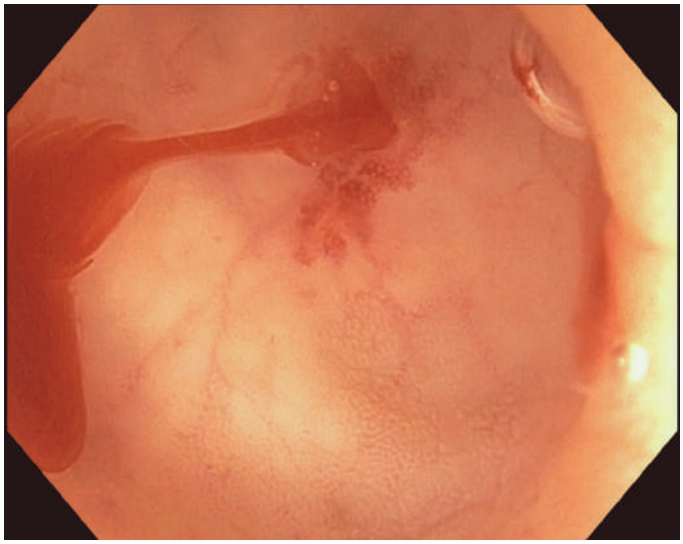
DYSPEPSIA

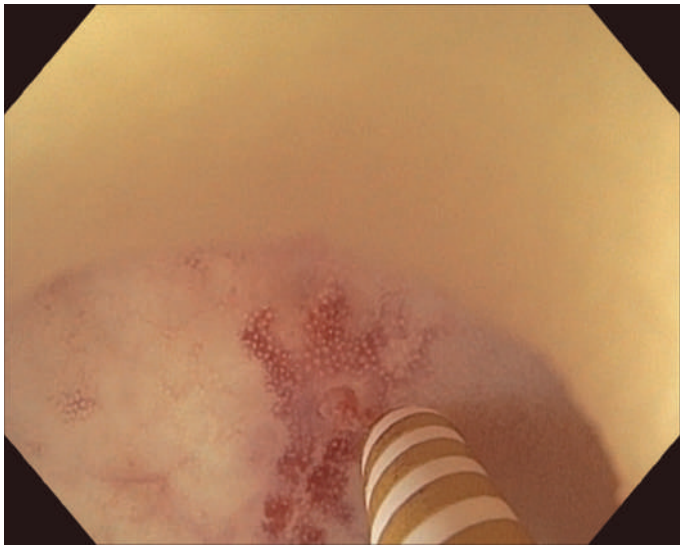
Dyspepsia is a chronic or recurrent burning discomfort or pain in the upper abdomen that may be caused by diverse processes, such as gastroesophageal reflux, peptic ulcer disease, and "nonulcer dyspepsia," a heterogeneous category that includes disorders of motility, sensation, and somatization. Gastric and esophageal malignancies are less common causes of dyspepsia. Careful history-taking allows accurate differential diagnosis of dyspepsia in only about half of patients. In the remainder, endoscopy can be a useful diagnostic tool, especially in patients whose symptoms are not resolved by *Helicobacter pylori* treatment or an empirical trial of acid-reducing therapy. Endoscopy should be performed at the outset in patients with dyspepsia and alarm features, such as weight loss, obstructive symptoms, or iron-deficiency anemia.

GASTROESOPHAGEAL REFLUX DISEASE

When classic symptoms of gastroesophageal reflux are present, such as water brash and substernal heartburn, presumptive diagnosis and empirical treatment are often sufficient. Endoscopy is a sensitive test for diagnosis of esophagitis **(Fig. 333-51)**, but it will miss nonerosive reflux disease (NERD) since some patients have symptomatic reflux without esophagitis. The most sensitive test for diagnosis of gastroesophageal reflux disease (GERD) is 24-h ambulatory pH and impedance monitoring. Endoscopy is indicated in patients with reflux symptoms refractory to antisecretory therapy; in those with alarm symptoms, such as dysphagia, weight loss, or gastrointestinal bleeding; and in those with recurrent dyspepsia after treatment that is not clearly due to reflux on clinical grounds alone. Endoscopy should be considered in patients with long-standing GERD, as they have a sixfold increased risk of harboring Barrett's esophagus compared to patients with <1 year of reflux symptoms.







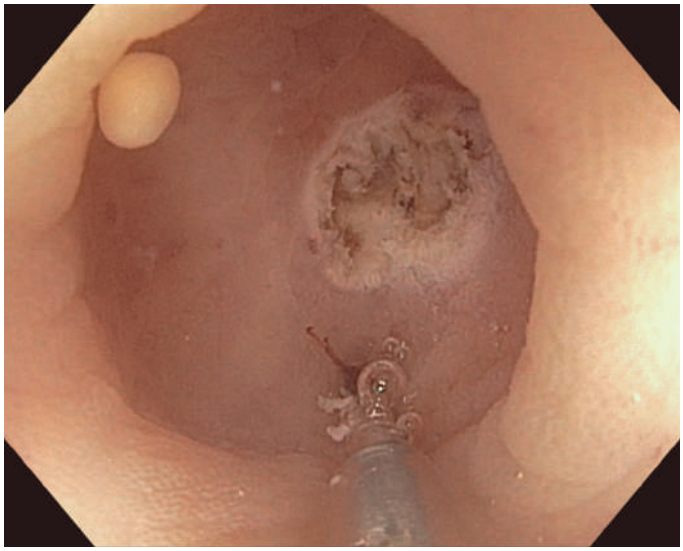


FIGURE 333-42 Colonic diverticula.

FIGURE 333-43 Diverticular hemorrhage. *A.* Actively bleeding sigmoid diverticulum. *B.* Treatment of the bleeding vessel at the dome of the diverticulum with a contact thermal probe. *C.* Hemostasis secured following contact coagulation with tattoo injection to aid future localization.

Barrett's Esophagus and Esophageal Squamous Dysplasia

Barrett's esophagus is specialized columnar metaplasia that replaces the normal squamous mucosa of the distal esophagus in some persons with GERD. Barrett's epithelium is a major risk factor for adenocarcinoma of the esophagus and is readily detected endoscopically, due to proximal displacement of the squamocolumnar junction (Fig. 333-6). A screening EGD for Barrett's esophagus should be considered in patients with a chronic (≥10 year) history of GERD symptoms, even if their symptoms have been mild. Endoscopic biopsy is the gold standard for confirmation of Barrett's esophagus and for dysplasia or cancer arising in Barrett's mucosa.

Periodic EGD with biopsies is recommended for surveillance of patients with Barrett's esophagus. Endoscopic resection (EMR or ESD) and/or ablation are treatment options when high-grade dysplasia or intramucosal cancer are found in the Barrett's mucosa. Both endoscopic therapy and periodic surveillance are acceptable options in patients with Barrett's esophagus and low-grade dysplasia. Radiofrequency ablation (RFA) is the most common ablative modality used for endoscopic treatment of Barrett's esophagus, and other modalities, such as cryotherapy, are also available.

Esophageal squamous dysplasia is the precursor lesion of esophageal squamous cell cancer (ESCC), the most common type of esophageal malignancy worldwide. Endoscopic detection of esophageal squamous dysplasia often requires specialized imaging methods, such as chromoendoscopy with Lugol's iodine solution. Once detected, it can be treated endoscopically with EMR, ESD, or RFA **(Fig. 333-52)**. Population-based screening for esophageal squamous dysplasia has been shown to decrease the occurrence of ESCC in high-incidence regions.

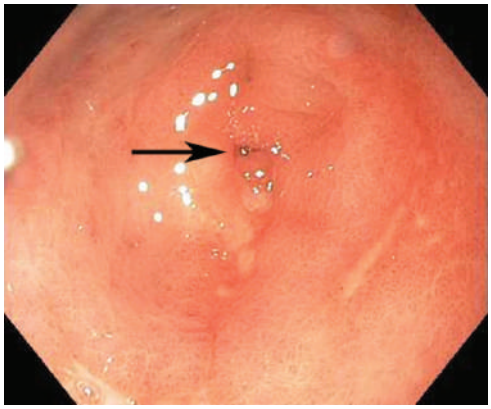
PEPTIC ULCER

Peptic ulcer classically causes epigastric gnawing or burning, often occurring nocturnally and promptly relieved by food or antacids. Although endoscopy is the most sensitive diagnostic test for peptic ulcer, it is not a cost-effective strategy in young patients with ulcer-like dyspeptic symptoms unless endoscopy is available at low cost. Patients with suspected peptic ulcer should be evaluated for *H. pylori* infection. Serology (which diagnoses past or current infection), urea breath testing (current infection), and stool tests (current infection) are noninvasive and less costly than endoscopy with biopsy. Patients aged >50 and those with alarm symptoms or persistent symptoms despite treatment should undergo endoscopy to exclude malignancy.

NONULCER DYSPEPSIA

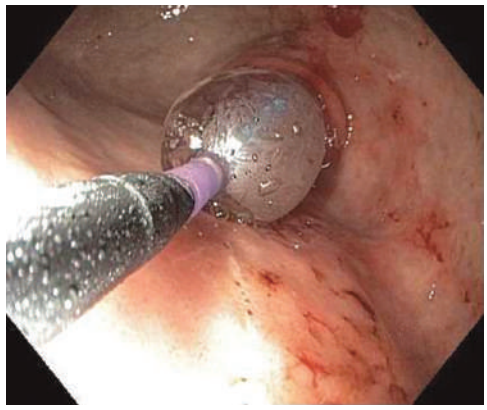
Nonulcer dyspepsia may be associated with bloating and, unlike peptic ulcer, tends not to remit and recur. Most patients describe persistent symptoms despite acid-reducing, prokinetic, or anti-*Helicobacter*

FIGURE 333-44 Esophageal food impaction. Meat bolus impacted in the distal esophagus.



therapy and are referred for endoscopy to exclude a refractory ulcer and assess for other causes. Although endoscopy is useful for excluding other diagnoses, its impact on the treatment of patients with nonulcer dyspepsia is limited.

DYSPHAGIA



About 50% of patients presenting with difficulty swallowing have a mechanical obstruction; the remainder have a motility disorder, such as achalasia or diffuse esophageal spasm, or an inflammatory disorder, such as eosinophilic esophagitis. Careful history-taking often points to a presumptive diagnosis and leads to the appropriate use of diagnostic tests. Esophageal strictures **(Fig. 333-53)** typically cause progressive dysphagia, first for solids, then for liquids; motility disorders often cause intermittent dysphagia for both solids and liquids. Some underlying disorders have characteristic historic features: Schatzki's ring **(Fig. 333-54)** causes episodic dysphagia for solids, typically at the beginning of a meal; oropharyngeal motor disorders typically present with difficulty initiating deglutition (*transfer dysphagia*) and nasal reflux or coughing with swallowing; and achalasia may cause nocturnal regurgitation of undigested food from the esophagus.

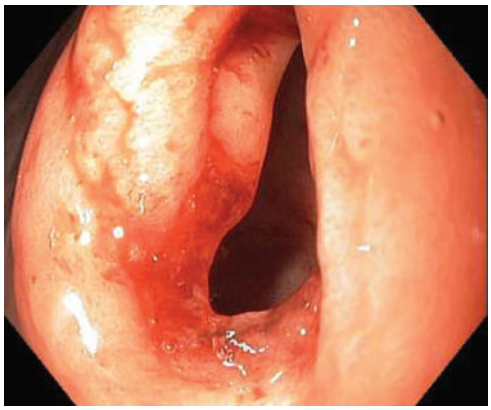


FIGURE 333-45 Esophageal foreign body. Intentionally ingested toothbrush impacted in the esophageal lumen.

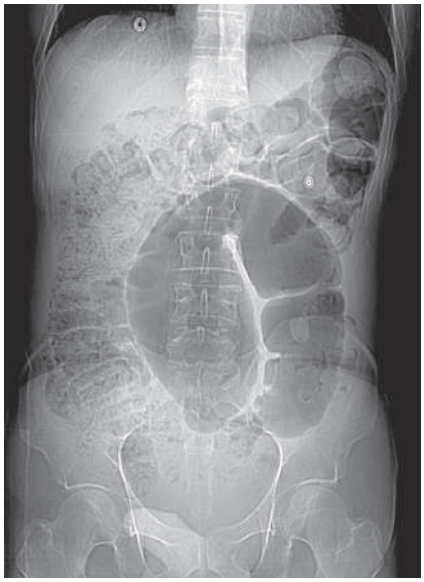
A

B



C

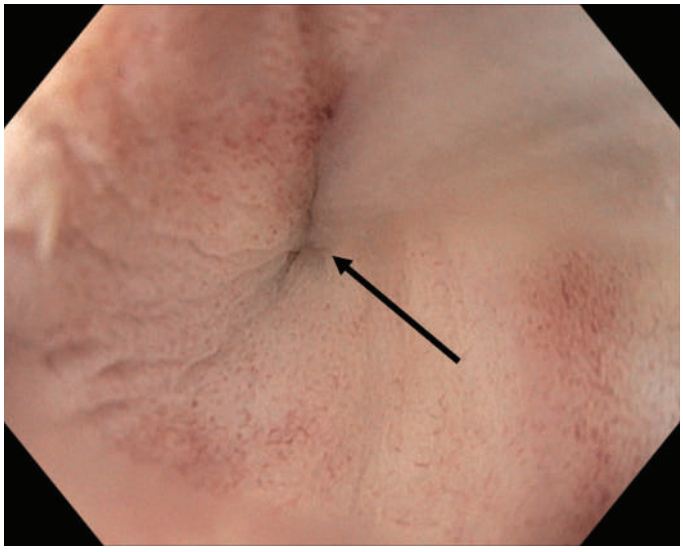


FIGURE 333-46 Gastric outlet obstruction due to pyloric stenosis. ***A.*** Nonsteroidal anti-inflammatory agent–induced ulcer disease with severe stenosis of the pylorus (*arrow*). ***B.*** Balloon dilation of the stenosis. ***C.*** Appearance of pyloric ring after dilation.

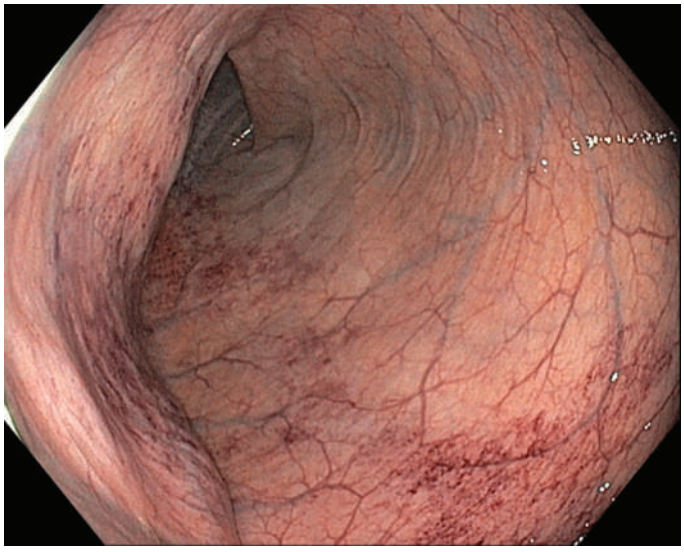
When mechanical obstruction is suspected, endoscopy is a useful initial diagnostic test, since it permits immediate biopsy and/or dilation of strictures, masses, or rings. The presence of linear furrows and multiple corrugated rings throughout a narrowed esophagus should raise suspicion for eosinophilic esophagitis, an increasingly recognized cause of recurrent dysphagia and food impaction **(Fig. 333-55)**. Blind or forceful passage of an endoscope may lead to perforation in a patient with stenosis of the cervical esophagus or a Zenker's diverticulum **(Fig. 333-56)**, but gentle passage of an endoscope under direct visual guidance is reasonably safe. Endoscopy can miss a subtle stricture or ring in some patients.



When transfer dysphagia is evident or an esophageal motility disorder is suspected, esophageal radiography and/or a video-swallow study are the best initial diagnostic tests. The oropharyngeal swallowing mechanism, esophageal peristalsis, and the lower esophageal sphincter

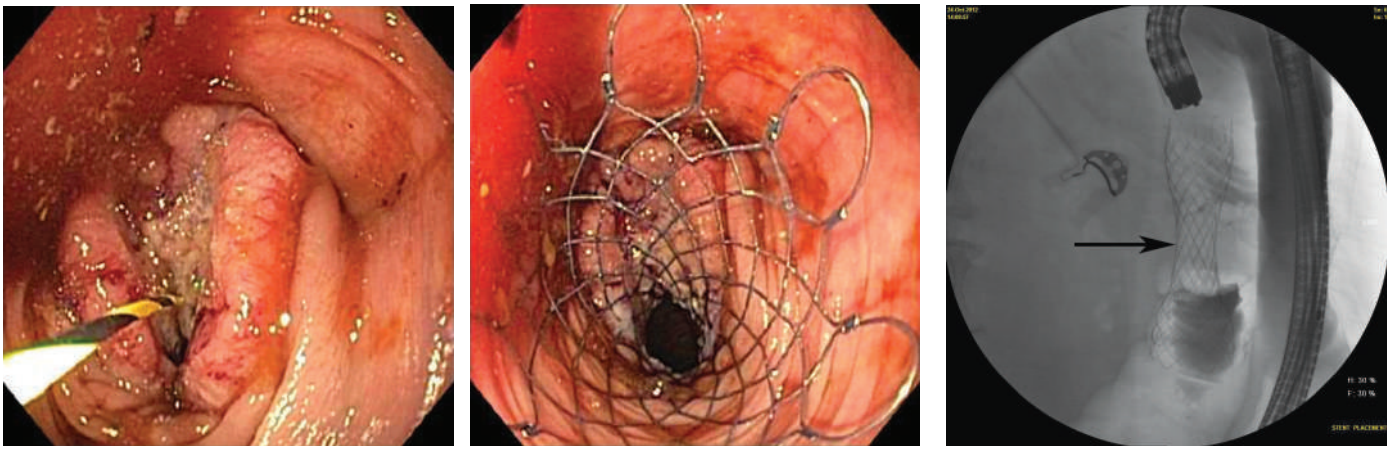
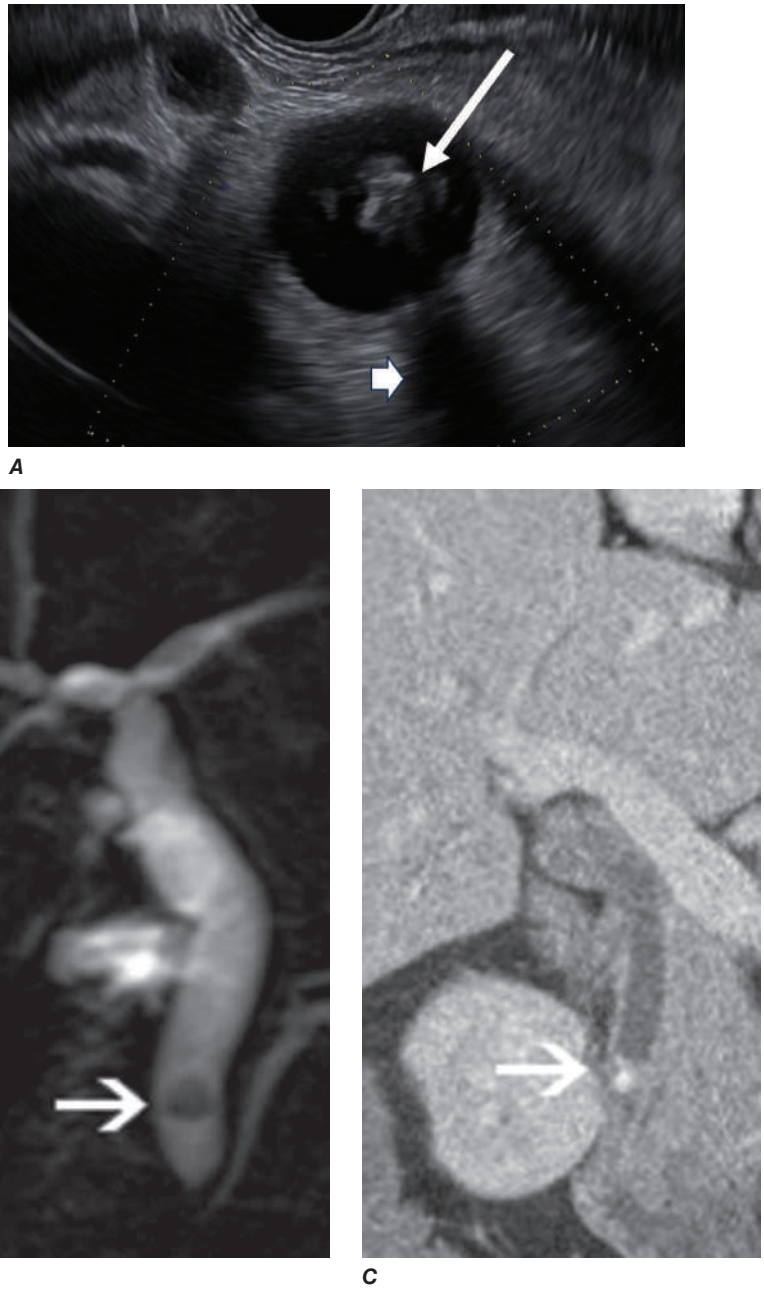
can all be assessed. In some disorders, subsequent esophageal manometry is required for diagnosis.



Various causes of dysphagia are amenable to endoscopic therapy. Benign strictures, rings, and webs can be dilated using a through-the-scope balloon **(Fig. 333-57)** or a tapered polyvinyl dilator passed over a guide wire. In some instances, fibrotic strictures may respond to needle-knife electroincision **(Fig. 333-58)** when they prove refractory to dilation. Self-expanding esophageal stents can be used to palliate dysphagia from malignant obstruction **(Fig. 333-59)**, and flexible endoscopic cricopharyngeal myotomy is an option for Zenker's diverticulum **(Video V5-20)**. Recent advances in third-space (submucosal) endoscopy have enabled the development of procedures, such as POEM **(Video V5-21)** and POET **(Video V5-22)**, for the management of achalasia and select subepithelial esophageal tumors, respectively.

ENDOSCOPIC TREATMENT OF OBESITY

A significant proportion of Americans are overweight or obese, and obesity-associated diabetes has become a major public health problem. Bariatric surgery is the most effective weight-loss intervention, decreasing long-term mortality in obese persons, but many patients choose not to undergo surgery. Endoscopic treatments for obesity have been developed and include insertion of an intragastric balloon or duodenojejunal bypass liner, placement of a percutaneous gastric tube for aspiration of gastric contents after meals, duodenal mucosal electroporation, or endoscopic sleeve gastroplasty, which utilizes endoscopic suturing to narrow the lumen of the gastric body **(Video V5-23)**. Prospective trials show that these treatments induce total-body weight loss of 7–20% and provide varying degrees of glycemic control and improvement in other diseases linked to obesity, such as metabolic-associated fatty liver disease (MAFLD). Additional endoscopic modalities are undergoing clinical trials. The efficacy of bariatric endoscopy may approach that of bariatric surgery in the short term. Long-term outcomes are still under evaluation.



TREATMENT OF MALIGNANCIES

Endoscopy plays an important role in the treatment of gastrointestinal malignancies. Early-stage malignancies limited to the mucosal and superficial submucosal layers may be resected using the techniques

A B C

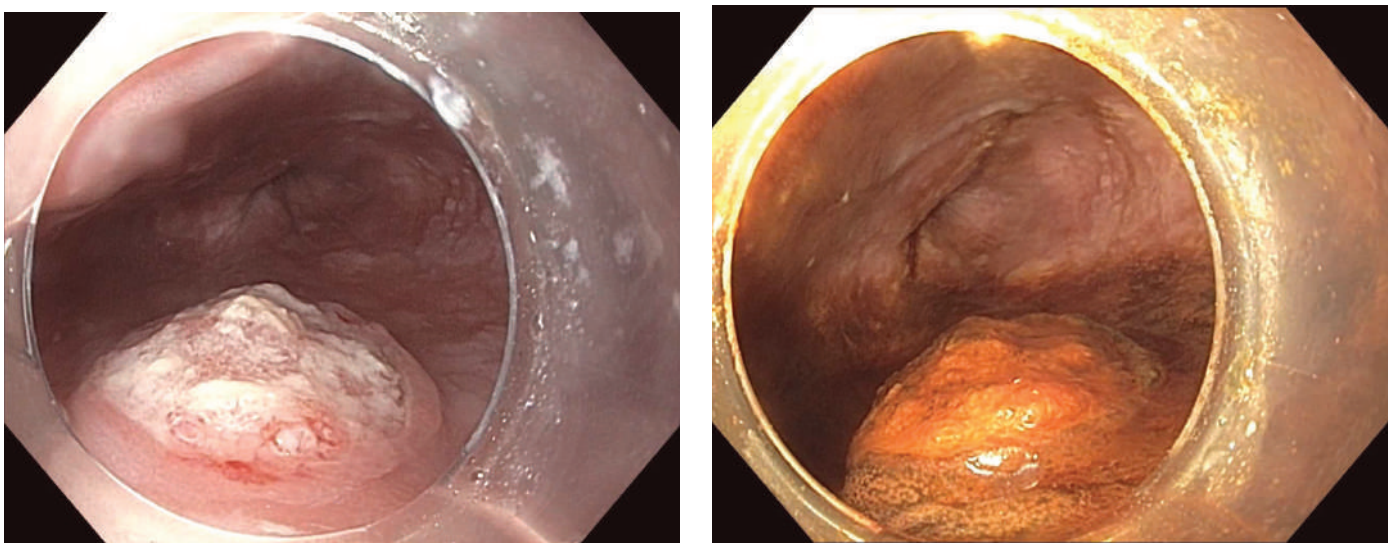
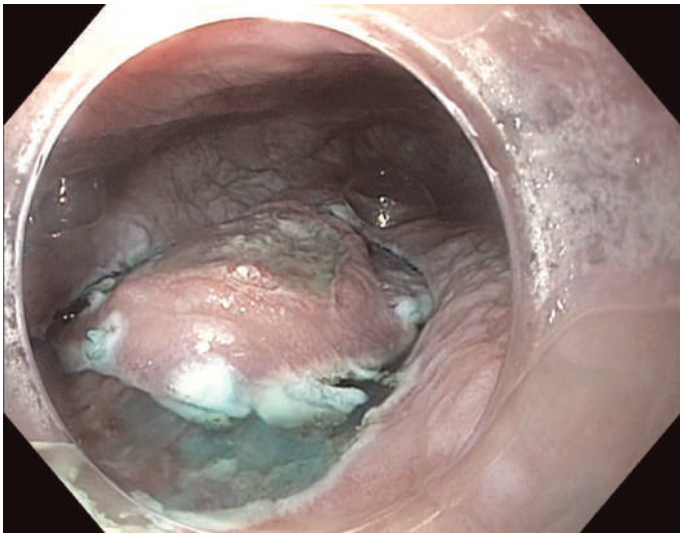
of EMR (Video V5-5) or ESD (Video V5-6). RFA and cryotherapy are effective modalities for ablative treatment of high-grade dysplasia and intramucosal cancer in Barrett's esophagus **(Video V5-24)**. Gastrointestinal stromal tumors can be removed en bloc by endoscopic full-thickness resection (Video V5-4). In general, endoscopic techniques offer the advantage of a minimally invasive approach to treatment but rely on other imaging techniques (such as CT, magnetic resonance imaging [MRI], positron emission tomography [PET], and EUS) to exclude distant metastases or locally advanced disease better treated by surgery or other modalities. The decision to treat an early-stage gastrointestinal malignancy endoscopically is often made in collaboration with a surgeon and/or oncologist.

Endoscopic palliation of gastrointestinal malignancies relieves symptoms and, in many cases, prolongs survival. Malignant obstruction can be relieved by endoscopic stent placement (Figs. 333-18, 333-49, 333-59, and **333-60**; Videos V5-17 and V5-18), and malignant gastrointestinal bleeding can be palliated endoscopically as well. EUS-guided celiac plexus neurolysis may relieve pancreatic cancer pain.

ANEMIA AND OCCULT BLOOD IN THE STOOL

Iron-deficiency anemia may be attributed to poor iron absorption (as in celiac sprue) or, more commonly, chronic blood loss. Intestinal bleeding should be strongly suspected in men and postmenopausal women with iron-deficiency anemia, and colonoscopy is indicated in





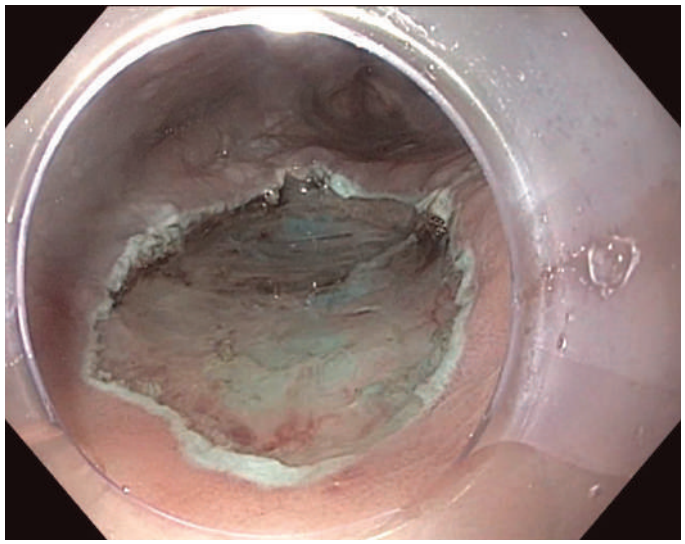


FIGURE 333-52 Early squamous cell cancer. ***A.*** Nodularity in the distal esophagus due to T1 esophageal squamous cell cancer. ***B.*** The nodular lesion remains unstained following chromoendoscopy with Lugol's solution without additional unstained areas. ***C.*** Circumferential mucosal incision around the lesion. ***D.*** Resection defect following en bloc removal of the lesion via endoscopic submucosal dissection.

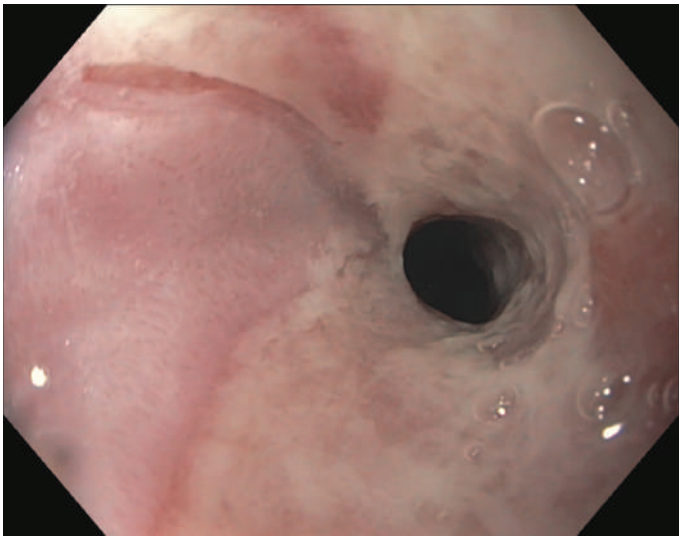
C

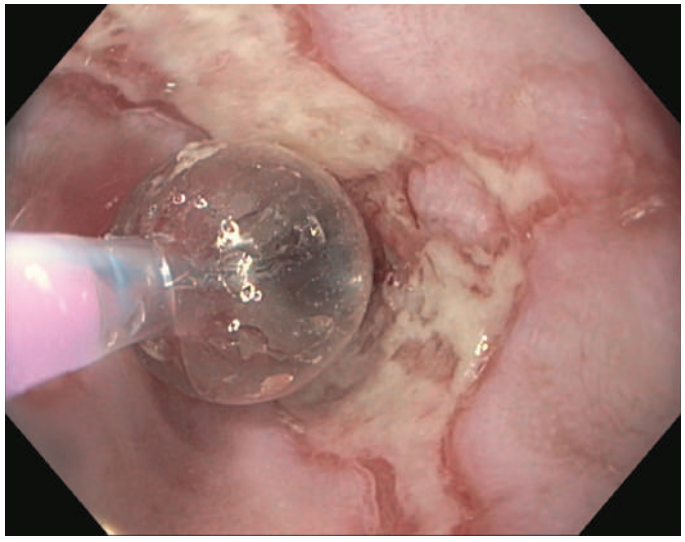
D

FIGURE 333-52 (*Continued*)



such patients, even in the absence of detectable occult blood in the stool. Approximately 30% will have large colonic polyps or colorectal cancer, and a few patients will have colonic vascular lesions. When a convincing source of blood loss is not found in the colon, upper gastrointestinal endoscopy should be considered; if no lesion is found, duodenal biopsies should be obtained to exclude sprue **(Fig. 333-61)**. Small-bowel evaluation with capsule endoscopy **(Fig. 333-62)**, CT or magnetic resonance (MR) enterography, or deep enteroscopy may be appropriate if both EGD and colonoscopy are unrevealing.

Tests for occult blood in the stool detect hemoglobin or the heme moiety and are most sensitive for colonic blood loss, although they will also detect larger amounts of upper gastrointestinal bleeding. Patients with occult blood in the stool should undergo colonoscopy to diagnose or exclude colorectal neoplasia, especially if they are >50 years old or have a family history of colonic neoplasia. Whether upper endoscopy is also indicated depends on the patient's symptoms.



The small intestine may be the source of chronic intestinal bleeding, especially if colonoscopy and upper endoscopy are not diagnostic. The utility of small-bowel evaluation varies with the clinical setting and is most important in patients in whom bleeding causes chronic or recurrent anemia. In contrast to the low diagnostic yield of small-bowel radiography, positive findings on capsule endoscopy are seen in 50–70% of patients with suspected small intestinal bleeding. The most common finding is mucosal vascular ectasia. CT and MR enterography accurately detect small-bowel masses and Crohn's disease and are also useful for initial small-bowel evaluation. Deep enteroscopy may follow capsule endoscopy for biopsy of lesions or to provide specific therapy, such as argon plasma coagulation of vascular ectasias **(Fig. 333-63)**.

COLORECTAL CANCER SCREENING

The majority of colon cancers develop from preexisting colonic adenomas, and colorectal cancer can be largely prevented by the detection and removal of adenomatous polyps **(Video V5-25)**. The choice of screening strategy for an asymptomatic person depends on personal and family history. Individuals with inflammatory bowel disease, a history of colorectal polyps or cancer, family members with adenomatous polyps or cancer, or certain familial cancer syndromes **(Fig. 333-64)** are at increased risk for colorectal cancer. An individual without these factors is generally considered at average risk.

A

B

FIGURE 333-53 Esophageal stricture. ***A.*** Peptic stricture associated with esophagitis. ***B.*** Balloon dilation of peptic stricture.

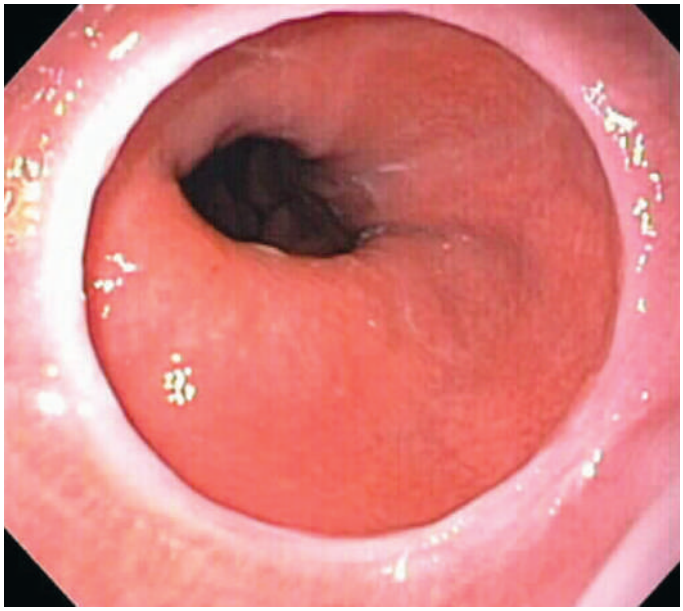


FIGURE 333-54 Schatzki's ring at the gastroesophageal junction.

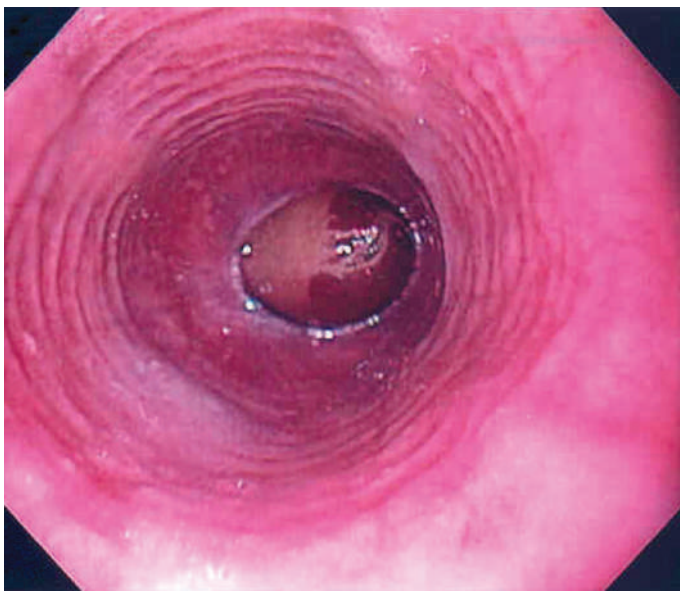
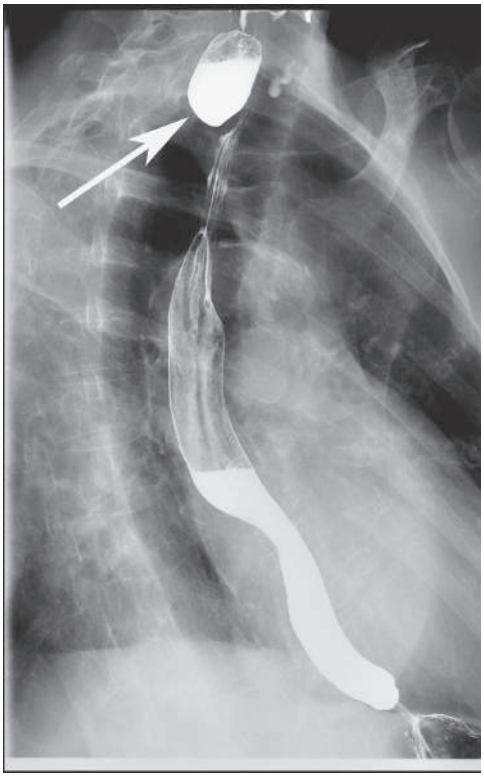
Screening strategies are summarized in **Table 333-3**. While fecal immunochemical tests (FITs) for heme or stool tests for occult blood have been shown to decrease the mortality rate from colorectal cancer, they do not detect some cancers and many polyps. FIT-DNA multitargeted stool DNA tests appear to be more sensitive, but direct visualization of the colon is the gold standard method for detection of polyps and cancers and remains a preferred screening strategy. Sigmoidoscopy is also used for colorectal cancer screening. However, the distribution of colon cancers has changed in the United States over time, with proportionally fewer rectal and left-sided cancers than in the past. Large American studies of colonoscopy for screening of average-risk individuals show that cancers are roughly equally distributed between the left and right colon and half of patients with right-sided lesions have no polyps in the left colon. Visualization of the entire colon thus appears to be the optimal strategy for colorectal cancer screening and prevention.

Computed tomography colonography (CTC) is a radiologic technique that images the colon with CT following rectal insufflation of the colonic lumen. Computer rendering of CT images generates an electronic display of a virtual "flight" along the colonic lumen, simulating colonoscopy **(Fig. 333-65)**. Findings detected during CTC often require subsequent conventional colonoscopy for confirmation and treatment.





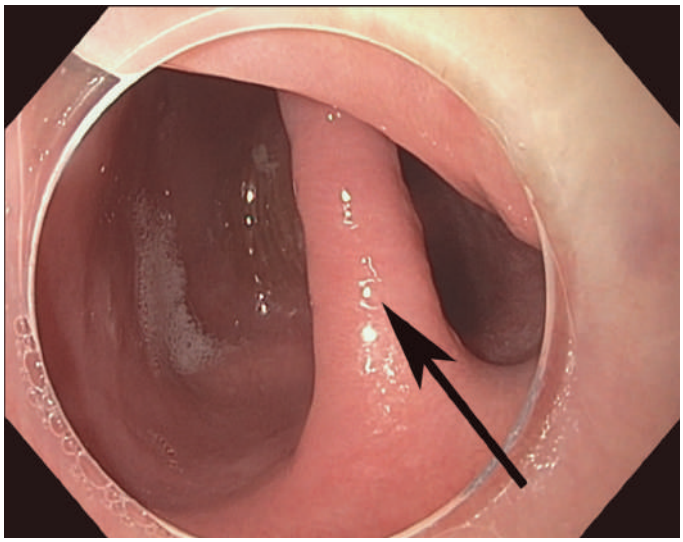


FIGURE 333-55 Eosinophilic esophagitis. Multiple circular rings of the esophagus creating a corrugated appearance and an impacted grape at the narrowed esophagogastric junction. The diagnosis requires biopsy with histologic finding of ≥15 eosinophils/high-power field.

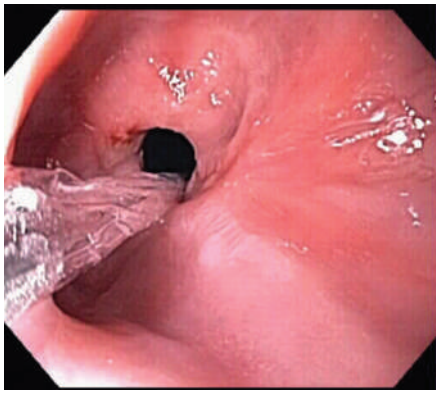
DIARRHEA

Most cases of diarrhea are acute, self-limited, and due to infections or medication. Chronic diarrhea (lasting >4–6 weeks) is more often due to a primary inflammatory, malabsorptive, or motility disorder; is less likely to resolve spontaneously; and generally, requires diagnostic evaluation. Patients with chronic diarrhea or severe, unexplained acute diarrhea often undergo endoscopy if stool tests for pathogens are



C

D

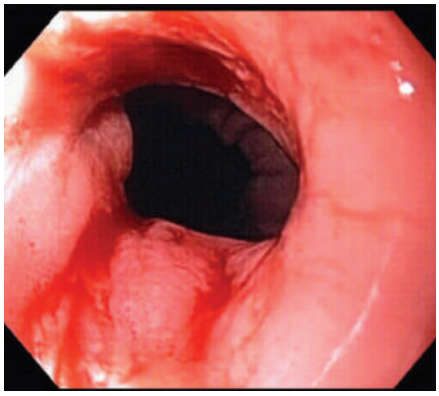


FIGURE 333-56 (*Continued*)

A

B

C

FIGURE 333-57 Endoscopic management of peptic stricture. ***A.*** Peptic stricture. ***B.*** Through-the-scope balloon dilation of stricture. ***C.*** Improvement in luminal diameter after dilation.

unrevealing. The choice of endoscopic testing depends on the clinical setting.

Patients with colonic symptoms and findings such as bloody diarrhea, tenesmus, fever, or leukocytes in stool generally undergo sigmoidoscopy or colonoscopy to assess for colitis (Fig. 333-9). Sigmoidoscopy is an appropriate initial test in most patients. Conversely, patients with symptoms and findings suggesting small-bowel disease, such as large-volume watery stools, substantial weight loss, and malabsorption of iron, calcium, or fat, may undergo upper endoscopy with duodenal aspirates for assessment of bacterial overgrowth and biopsies for assessment of mucosal diseases, such as celiac sprue.

Many patients with chronic diarrhea do not fit either of these patterns. In the setting of a long-standing history of altered bowel habits dating to early adulthood, without findings such as blood in the stool or anemia, a diagnosis of irritable bowel syndrome may be made without direct visualization of the bowel and by relying on appropriate blood tests (including complete blood count, C-reactive protein and antibody tests for celiac disease) to screen for other diagnoses. Steatorrhea and upper abdominal pain may prompt evaluation of the pancreas rather than the gut. Patients whose chronic diarrhea is not easily categorized often undergo initial colonoscopy to examine the entire colon and terminal ileum for inflammatory or neoplastic disease **(Fig. 333-66)**.

MINOR HEMATOCHEZIA

Bright red blood passed with or on formed brown stool usually has an anal, rectal, or sigmoid source **(Fig. 333-67)**. Even trivial amounts of hematochezia should be investigated with colonoscopy and/or flexible sigmoidoscopy together with anoscopy to exclude polyps or cancers, especially in patients >40 years old and those with a personal or family history of colorectal polyps or cancer. Patients reporting red blood on the toilet tissue only, without blood in the toilet or on the stool, are generally bleeding from a lesion in the anal canal; careful external inspection, digital examination, and sigmoidoscopy with anoscopy may be sufficient for diagnosis in such cases.

PANCREATITIS

About 20% of patients with pancreatitis have no identified cause after routine clinical investigation (including a review of medication and alcohol use; measurement of serum triglyceride, calcium, and immunoglobulin G subclass 4 [IgG4] levels; abdominal ultrasonography; and CT or MRI). Endoscopic assessment leads to a specific diagnosis

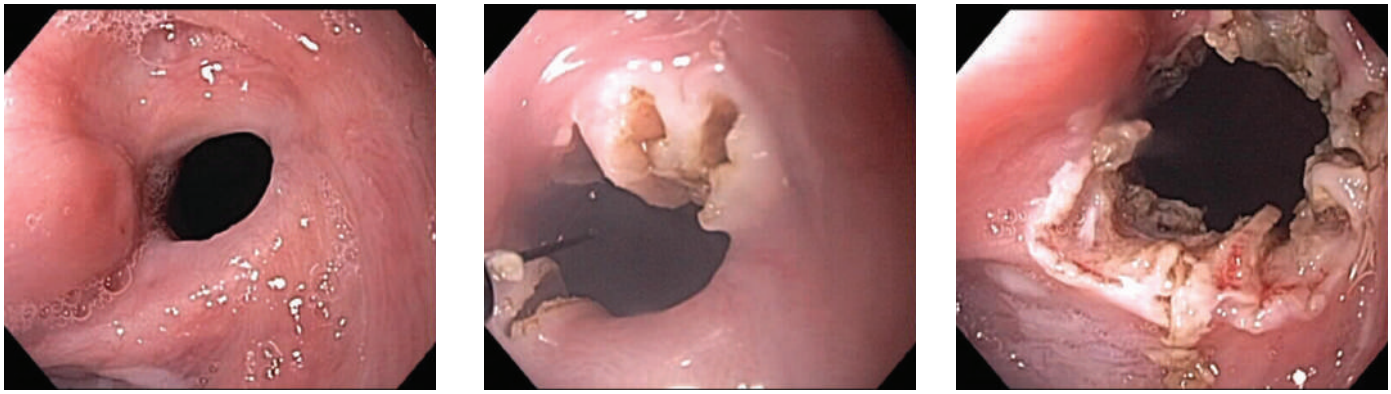

FIGURE 333-58 Endoscopic management of an esophagogastric anastomotic stricture. ***A.*** Recurrent anastomotic stricture despite periodic balloon dilation. ***B.*** Needle-knife electroincision of stricture. ***C.*** Improvement in luminal opening after therapy.

in the majority of such patients, often altering clinical management. Endoscopic investigation is particularly appropriate if the patient has had more than one episode of pancreatitis.

Microlithiasis, or the presence of microscopic crystals in bile, is a leading cause of previously unexplained acute pancreatitis and is sometimes seen during abdominal ultrasonography as layering sludge or flecks of floating, echogenic material in the gallbladder. EUS may identify microlithiasis or gallstones not seen on transabdominal ultrasound.

Previously undetected chronic pancreatitis, pancreatic malignancy, or pancreas divisum may be diagnosed by either ERCP or EUS. Autoimmune pancreatitis is often suspected based on CT, MRI, or serologic findings, but it may first become apparent during EUS and may require EUS-guided pancreatic biopsy for histologic diagnosis.

Severe pancreatitis often results in pancreatic fluid collections. Symptomatic pseudocysts and areas of walled-off pancreatic necrosis can be drained into the stomach or duodenum endoscopically, using transpapillary and transmural endoscopic techniques. Pancreatic necrosis can be debrided by direct endoscopic necrosectomy (Video V5-2) via an endoscopically created transmural drainage site.

CANCER STAGING

Local staging of esophageal, gastric, pancreatic, bile duct, and rectal cancers can be obtained with EUS (Fig. 333-20). EUS with fine-needle aspiration (Fig. 333-21) or biopsy currently provides the most accurate preoperative assessment of local tumor and nodal staging, but it does not detect many distant metastases. Details of the local tumor stage can guide treatment decisions, including resectability and need for neoadjuvant therapy. EUS with transesophageal needle biopsy may also be used to assess the presence of non-small-cell lung cancer in mediastinal nodes.

OPEN-ACCESS ENDOSCOPY

Direct scheduling of endoscopic procedures by providers without preceding gastroenterology consultation, or *open-access endoscopy*, is common. When the indications for endoscopy are clear-cut and appropriate, the procedural risks are low, and the patient understands what to expect, open-access endoscopy streamlines patient care and decreases costs.

Patients referred for open-access endoscopy should have a recent history, physical examination, and medication list that are available for review when the patient comes to the endoscopy suite. Patients with unstable or symptomatic cardiovascular or respiratory conditions should not be referred directly for open-access endoscopy. Those with particular conditions who are undergoing certain procedures should be prescribed prophylactic antibiotics before endoscopy (Table 333-1). In addition, patients taking anticoagulants and/or antiplatelet drugs may require adjustment of these agents before endoscopy based on the procedural risk for bleeding and their underlying risk for a thromboembolic event (Table 333-2).

Common indications for open-access EGD include dyspepsia resistant to a trial of appropriate therapy, dysphagia, gastrointestinal bleeding, and persistent anorexia or early satiety. Open-access colonoscopy is often requested in men or postmenopausal women with iron-deficiency anemia, in patients with hematochezia or occult blood in the stool, in patients with a previous history of colorectal adenomatous polyps or cancer, and for colorectal cancer screening. Flexible sigmoidoscopy is commonly performed as an open-access procedure.

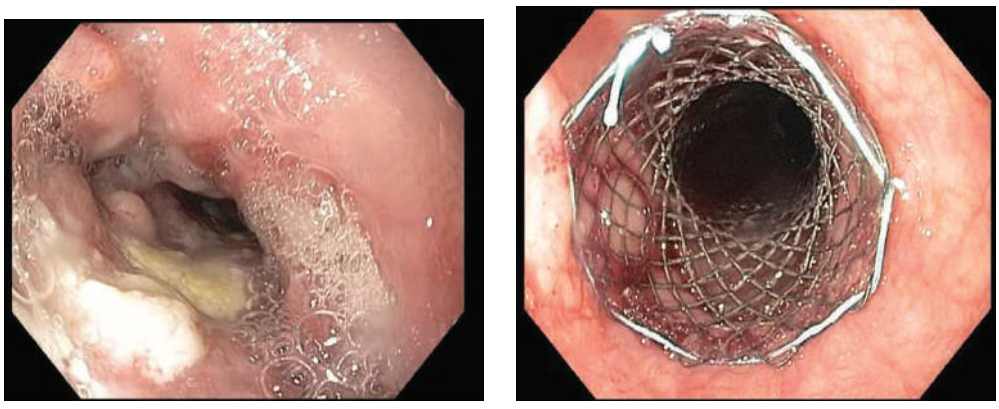

FIGURE 333-59 Palliation of malignant dysphagia. ***A.*** Obstructing distal esophageal cancer. ***B.*** Palliative stent placement.

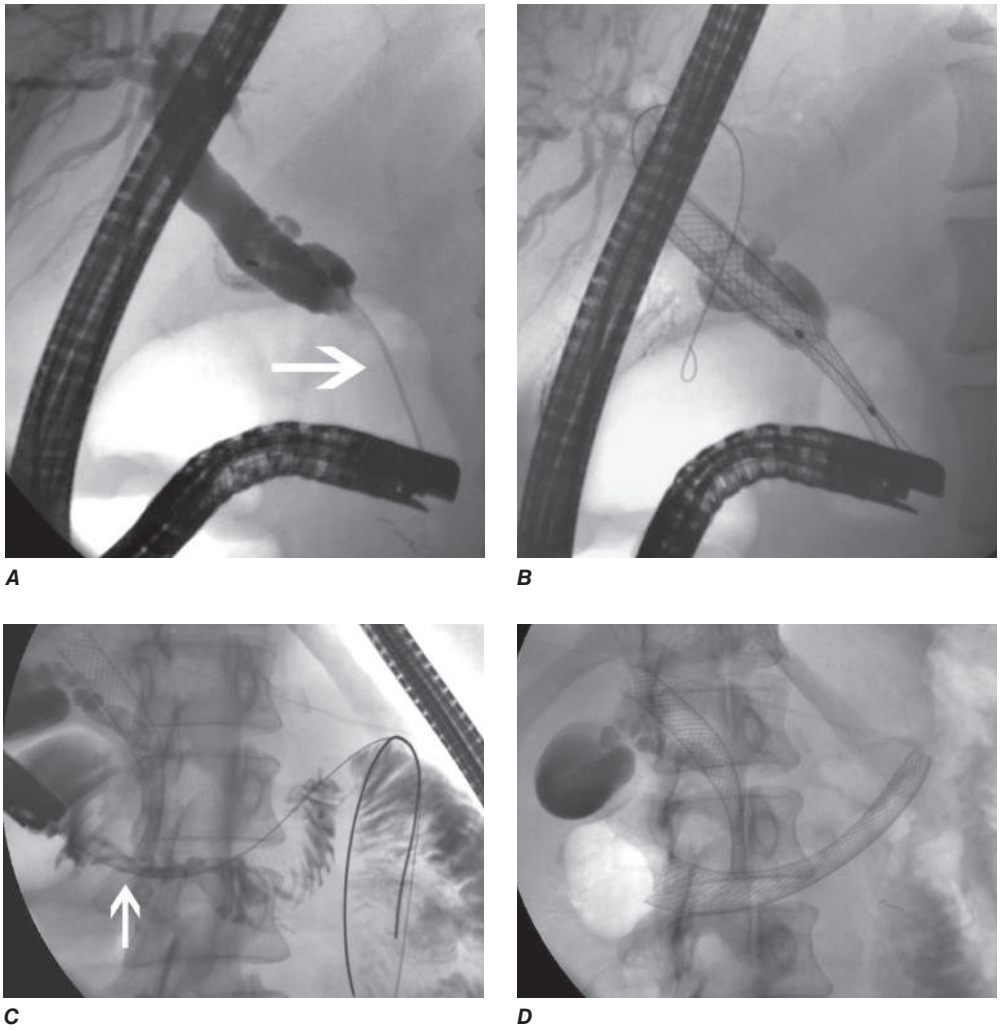

FIGURE 333-60 Placement of biliary and duodenal self-expanding metal stents (SEMS) for obstruction caused by pancreatic cancer. ***A.*** Endoscopic retrograde cholangiopancreatography (ERCP) demonstrates a distal bile duct stricture (*arrow*). ***B.*** A biliary SEMS is placed. ***C.*** Contrast injection demonstrates a duodenal stricture (*arrow*). ***D.*** Biliary and duodenal SEMS in place.

When patients are referred for open-access colonoscopy, the primary care provider may need to choose a colonic preparation. Commonly used oral preparations include polyethylene glycol lavage solution, with or without citric acid. A "split-dose" regimen improves the quality of colonic preparation. Osmotic purgative preparations (such as sodium phosphate or magnesium citrate) are also effective but may cause fluid and electrolyte abnormalities and renal toxicity, especially in patients with renal failure or congestive heart failure and those >70 years of age.

TABLE 333-3 Colorectal Cancer Screening Strategies

	CHOICES/RECOMMENDATIONS	COMMENTS
Average-Risk Patients		
Asymptomatic individuals between 45 and 75 years of age	Colonoscopy every 10 years[a]	Gold standard cancer prevention strategy
	Multitargeted stool DNA test every 1–3 years	Less sensitive than colonoscopy; colonoscopy if results are positive
	FIT or HSgFOBT every year, with or without flexible sigmoidoscopy every 10 years	Less sensitive than colonoscopy; colonoscopy if results are positive
	CT colonography every 5 years	Colonoscopy if results are positive
	Flexible sigmoidoscopy every 5 years	Does not detect proximal colon polyps and cancers; colonoscopy if an adenomatous polyp is found
Asymptomatic individuals > 75 years of age	Selective screening	Consider patient's overall health, results of previous screening exams, and preferences
Personal History of Polyps or CRC		
1–2 small (<10 mm) tubular adenomas	Repeat colonoscopy in 7–10 years[a]	Assuming complete polyp resection. Interval may vary based on prior personal history and family history
3–4 tubular adenomas <10 mm	Repeat colonoscopy in 3–5 years[a]; subsequent colonoscopy based on findings	Assuming complete polyp resection
5–10 tubular adenomas <10 mm	Repeat colonoscopy in 3 years[a]	Assuming complete polyp resection
>10 adenomas on a single exam	Repeat colonoscopy in 1 year[a]	Consider evaluation for FAP or HNPCC; see recommendations below
Adenoma ≥10 mm, or adenoma with tubulovillous or villous histology, or high-grade dysplasia	Repeat colonoscopy in 3 years[a]	Assuming complete polyp resection
Piecemeal removal of any sessile polyp	Exam in 6 months to verify complete removal	
Small (<1 cm) hyperplastic polyps of sigmoid and rectum	Repeat colonoscopy in 10 years[a]	Those with hyperplastic polyposis syndrome merit more frequent follow-up
Hyperplastic polyp ≥10 mm	Repeat colonoscopy in 3–5 years[a]	
1–2 SSPs <10 mm	Repeat colonoscopy in 5–10 years[a]	Assuming complete polyp resection
3–4 SSPs <10 mm	Repeat colonoscopy in 3–5 years[a]	Assuming complete polyp resection
5–10 SSPs <10 mm, or any single SSP ≥10 mm, or any SSP with dysplasia	Repeat colonoscopy in 3 years[a]	Assuming complete polyp resection. Serrated polyposis syndrome merits more frequent follow-up
Piecemeal removal of serrated polyp ≥1 cm	Exam in 2–6 months to verify complete removal	
Colon cancer	Evaluate entire colon around the time of resection, then repeat colonoscopy in 1 year[a]	Subsequent colonoscopy in 3 years if the 1-year examination is normal
Inflammatory Bowel Disease		
Long-standing (>8 years) ulcerative pancolitis or Crohn's colitis, or left-sided ulcerative colitis of >15 years' duration	Colonoscopy with biopsies every 1–2 years	Consider chromoendoscopy or other advanced imaging techniques for detection of flat dysplasia during colonoscopy
Family History of Polyps or CRC		
First-degree relatives with only small tubular adenomas	Same as average risk	
One first-degree relative with CRC or advanced adenoma at age ≥60 years	Begin screening starting at age 40, tests and intervals per average-risk recommendations	
One first-degree relative with CRC or advanced adenoma at age <60 years, *or* two first-degree relatives with CRC or advanced adenomas at any age	Colonoscopy every 5 years beginning at age 40 years or 10 years before the age at diagnosis of the youngest affected relative, whichever is earlier	
Familial adenomatous polyposis (FAP)	Sigmoidoscopy or colonoscopy annually, beginning at age 10–12 years	Consider genetic counseling and testing; consider screening family members
Hereditary nonpolyposis colorectal cancer (HNPCC; Lynch syndrome)	Colonoscopy every 2 years beginning at age 20–25 years (or 10 years younger than the youngest first-degree relative was when diagnosed with CRC) until age 40, then annually thereafter	Consider histologic evaluation for microsatellite instability in tumor specimens of patients who meet modified Bethesda criteria; consider genetic counseling and testing, consider screening family members
Serrated polyposis syndrome (SPS)	Colonoscopy at age 40 (or the same age at which the youngest first-degree relative was when diagnosed with SPS, or 10 years younger than the youngest first-degree relative was when diagnosed with CRC), then every 1–2 years thereafter	Consider screening family members, even of patients with multiple serrated polyps who do not meet SPS criteria
Family colon cancer syndrome X	Colonoscopy every 3–5 years beginning 10 years before the age at diagnosis of the youngest affected relative	

[a]Assumes good colonic preparation and complete examination to cecum. [b]High-risk adenoma: any adenoma ≥1 cm in size or containing high-grade dysplasia or villous features.

Abbreviations: CRC, colorectal cancer; CT, computed tomography; FIT, fecal immunochemical test; HSgFOBT, high-sensitivity guaiac fecal occult blood test; SSP, sessile serrated polyp.

334 Diseases of the Esophagus

Peter J. Kahrilas, Ikuo Hirano*

ESOPHAGEAL STRUCTURE AND FUNCTION

The esophagus is a hollow, muscular tube coursing through the posterior mediastinum joining the hypopharynx to the stomach with a sphincter at each end. It functions to transport food and fluid between these ends, otherwise remaining empty. The physiology of swallowing, esophageal motility, and oral and pharyngeal dysphagia are described in **Chap. 47**. Esophageal diseases can be manifested by impaired function or pain. Key functional impairments are swallowing disorders and excessive gastroesophageal reflux. Pain, sometimes indistinguishable from cardiac chest pain, can result from inflammation, infection, dysmotility, or neoplasm.

SYMPTOMS OF ESOPHAGEAL DISEASE

The clinical history remains central to the evaluation of esophageal symptoms. A thoughtfully obtained history will often expedite management. Important details include weight gain or loss, gastrointestinal bleeding, dietary habits including the timing of meals, smoking, and alcohol consumption. The major esophageal symptoms are heartburn, regurgitation, chest pain, dysphagia, odynophagia, and globus sensation.

Heartburn (pyrosis), the most common esophageal symptom, is characterized by a discomfort or burning sensation behind the sternum that arises from the epigastrium and may radiate toward the neck. Heartburn is usually an intermittent symptom, most commonly experienced after eating, during exercise, and while lying recumbent. The discomfort is relieved with drinking water or taking an antacid but can occur frequently, interfering with normal activities including sleep. The association between heartburn and gastroesophageal reflux disease (GERD) is so strong that empirical therapy for GERD has become accepted management. However, the term *heartburn* is often misused and/or referred to using other terms such as *indigestion* or *repeating*, making it important to clarify the intended meaning.

*Deceased.

Regurgitation is the effortless return of food or fluid into the pharynx without nausea or retching. Patients report a sour or burning fluid in the throat or mouth that may also contain undigested food particles. Bending, belching, or maneuvers that increase intraabdominal pressure can provoke regurgitation. A clinician needs to discriminate among regurgitation, vomiting, and rumination. *Vomiting* is preceded by nausea and accompanied by retching. *Rumination* is a behavior in which recently swallowed food is regurgitated and then reswallowed repetitively for up to an hour. Although there is some linkage between rumination and cognitive deficiency, the behavior is also exhibited by unimpaired individuals.

Chest pain is a common esophageal symptom with characteristics similar to cardiac pain, sometimes making this distinction difficult. Esophageal pain is usually experienced as a pressure-type sensation in the mid chest, radiating to the mid back, arms, or jaws. The similarity to cardiac pain is likely because the two organs share a nerve plexus and the nerve endings in the esophageal wall have poor discriminative ability among stimuli. Esophageal distention or even chemostimulation (e.g., with acid) will often be perceived as chest pain. Gastroesophageal reflux is the most common cause of esophageal chest pain.

Esophageal *dysphagia* **(Chap. 47)** is often described as a feeling of food "sticking" or even lodging in the chest. Important distinctions are between uniquely solid food dysphagia as opposed to liquid and solid, episodic versus constant dysphagia, and progressive versus static dysphagia. If the dysphagia is for liquids as well as solid food, it suggests a motility disorder such as achalasia. Conversely, uniquely solid food dysphagia is suggestive of a stricture, web, ring, or tumor. Of note, a patient's localization of food hang-up in the esophagus is notoriously imprecise. Approximately 30% of distal esophageal obstructions are perceived as cervical dysphagia. In such instances, the absence of concomitant symptoms generally associated with oropharyngeal dysphagia such as aspiration, nasopharyngeal regurgitation, cough, drooling, or obvious neuromuscular compromise should suggest an esophageal etiology.

Odynophagia is pain either caused by or exacerbated by swallowing. Although typically considered distinct from dysphagia, odynophagia may manifest concurrently with dysphagia. Odynophagia is more common with pill or infectious esophagitis than with reflux esophagitis and should prompt a search for these entities. When odynophagia does occur in GERD, it is likely related to an esophageal ulcer or extensive erosions.

Globus sensation, also known as globus pharyngeus, is the perception of a lump or fullness in the throat that is felt irrespective of swallowing. Although such patients are frequently referred for an evaluation of dysphagia, globus sensation is often relieved by the act of swallowing. As implied by its alternative name, "globus hystericus," globus sensation often occurs in the setting of anxiety or obsessive-compulsive disorders. Clinical experience teaches that it is often attributable to GERD.

Water brash is excessive salivation resulting from a vagal reflex triggered by acidification of the esophageal mucosa. This is not a common symptom. Afflicted individuals will describe the unpleasant sensation of the mouth rapidly filling with salty thin fluid, often in the setting of concomitant heartburn.

DIAGNOSTIC STUDIES

ENDOSCOPY

Endoscopy, also known as esophagogastroduodenoscopy (EGD), is the most useful test for the evaluation of the proximal gastrointestinal tract. Modern instruments produce high-quality, color images of the esophageal, gastric, and duodenal lumen. Endoscopes also have an instrumentation channel through which biopsy forceps, injection catheters for focal delivery of therapeutic agents, balloon dilators, or devices for hemostasis or removal of mucosal lesions can be used. The key advantages of endoscopy over barium radiography are as follows: (1) increased sensitivity for the detection of mucosal lesions; (2) vastly increased sensitivity for the detection of abnormalities mainly identifiable by color, such as Barrett's metaplasia or vascular lesions; (3) the ability to obtain biopsy specimens for histologic examination of suspected abnormalities; and (4) the ability to dilate strictures during the examination. Submucosal ("third space") endoscopy has emerged as a diagnostic modality for assessment of subepithelial lesions, resection of superficial dysplastic areas, and therapy of esophageal motility disorders. The main disadvantages of endoscopy are low sensitivity for detection of very proximal esophageal strictures or narrow caliber esophagus without focal stricturing, cost, and the need for sedatives or anesthetics.

RADIOGRAPHY

Contrast radiography of the esophagus, stomach, and duodenum can demonstrate reflux of the contrast media, hiatal hernia, mucosal granularity, erosions, ulcerations, and strictures. The sensitivity of radiography compared with endoscopy for detecting reflux esophagitis reportedly ranges from 22 to 95%, with higher grades of esophagitis (i.e., ulceration or stricture) exhibiting greater detection rates. Conversely, the sensitivity of barium radiography for detecting esophageal strictures is greater than that of endoscopy, especially when the study is done in conjunction with a 13-mm barium tablet. Barium studies also provide an assessment of esophageal function and morphology that may be undetected on endoscopy. Tracheoesophageal fistula, altered postsurgical anatomy, and extrinsic esophageal compression are conditions where radiographic imaging complements endoscopic assessment. Hypopharyngeal pathology and disorders of the cricopharyngeus muscle are better appreciated on radiographic examination than with endoscopy, particularly with rapid sequence or video fluoroscopic recording. The major shortcoming of barium radiography is that it rarely obviates the need for endoscopy. Either a positive or a negative study is usually followed by an endoscopic evaluation to obtain biopsies, provide therapy, clarify findings in the case of a positive examination, or add a level of certainty in the case of a negative examination.

ENDOSCOPIC ULTRASOUND

Endoscopic ultrasound (EUS) instruments combine an endoscope with an ultrasound transducer to create a transmural image of the tissue surrounding the endoscope tip. The key advantage of EUS over alternative radiologic imaging techniques is much greater resolution attributable to the proximity of the ultrasound transducer to the area being examined. Available devices can provide either radial imaging (360-degree, cross-sectional) or a curved linear image that can guide fine-needle aspiration of imaged structures such as lymph nodes or tumors. Major esophageal applications of EUS are to stage esophageal cancer, to evaluate dysplasia in Barrett's esophagus, and to assess submucosal lesions.

ESOPHAGEAL MANOMETRY

Esophageal manometry, or motility testing, entails positioning a catheter with multiple pressure sensors within the esophagus and then observing the contractility following test swallows. The upper esophageal sphincter and lower esophageal sphincter (LES) appear as zones of high pressure that relax on swallowing, whereas the intersphincteric esophagus exhibits peristaltic contractions. Manometry is used to diagnose motility disorders (achalasia, diffuse esophageal spasm [DES]) and to assess peristaltic integrity prior to the surgery for reflux disease. Technologic advances have enhanced esophageal manometry as high-resolution esophageal pressure topography **(Fig. 334-1)**. Manometry can also be combined with intraluminal impedance monitoring. Impedance recordings use a series of paired electrodes added to the manometry catheter. Esophageal luminal contents in contact with the electrodes decrease (liquid) or increase (air) the impedance signal, allowing detection of anterograde or retrograde esophageal bolus transit.

FUNCTIONAL LUMEN IMAGING PROBE

The functional lumen imaging probe (FLIP) is a catheter-based technology that utilizes high-resolution impedance planimetry during volume-controlled esophageal distension to measure esophageal cross-sectional area and distensibility (i.e., cross-sectional area in relation to distension pressure) along a 16-cm length of the esophagus. These data

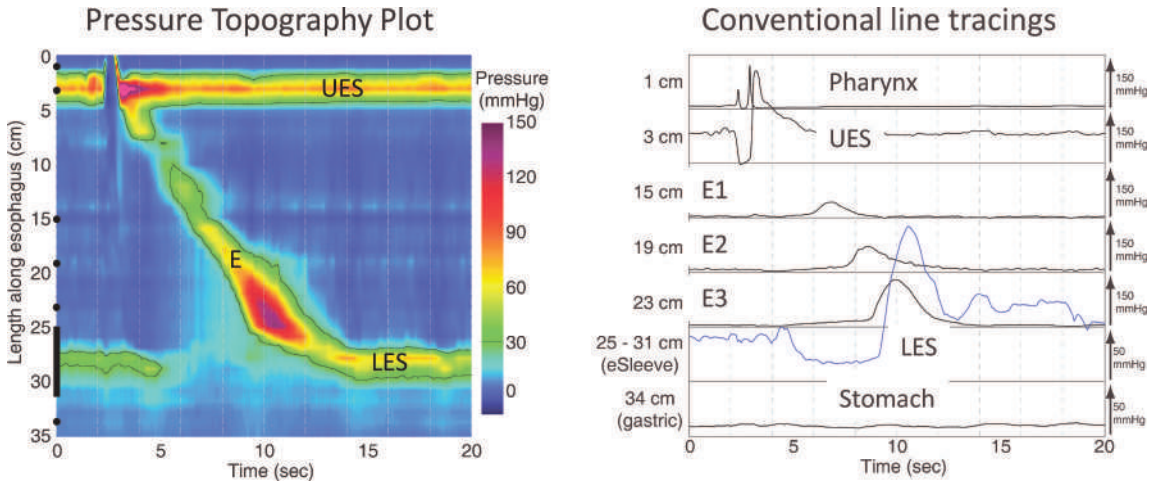

FIGURE 334-1 High-resolution esophageal pressure topography (*left*) and conventional manometry (*right*) of a normal swallow. E, esophageal body; LES, lower esophageal sphincter; UES, upper esophageal sphincter.

are displayed in real time on a computer monitor both as a cylinder of varied diameter along the 16-cm length of the probe or as real-time diameter topography akin to high-resolution manometry. FLIP studies are performed with sedation in conjunction with upper endoscopy or intraoperatively; the probe is passed transorally. Assessing esophageal motility with FLIP is based on quantifying esophagogastric junction opening during volumetric distention and characterizing distension-induced esophageal contractility, which is, in essence, secondary peristalsis. These findings are classified according to a scheme known as FLIP panometry. There is excellent correlation between FLIP panometry and high-resolution manometry in the detection of both achalasia and normal contractility, the two most important potential findings. Hence, FLIP can be used to evaluate patients with esophageal dysphagia, often in lieu of manometry.

REFLUX TESTING

GERD is often diagnosed in the absence of endoscopic signs of esophagitis, which would otherwise define the disease. This occurs in the settings of partially treated disease, an abnormally sensitive esophageal mucosa, or, most commonly, in nonerosive reflux disease. In such instances, reflux testing can demonstrate excessive esophageal exposure to refluxed gastric fluid, the physiologic abnormality of GERD. This can be done by ambulatory 24- to 96-h esophageal pH recording using either a wireless pH-sensitive transmitter that is affixed to the esophageal mucosa or a transnasally positioned wire electrode with the tip stationed in the distal esophagus. Either way, the outcome is expressed as the percentage of the day that the pH was <4 (indicative of recent acid reflux), with values exceeding 6% indicative of GERD. Reflux testing is useful in the evaluation of patients presenting with atypical symptoms or an inexplicably poor response to therapy. Intraluminal impedance monitoring can be added to pH monitoring to detect reflux events irrespective of whether or not they are acidic, potentially increasing the sensitivity of the study.

STRUCTURAL DISORDERS

HIATAL HERNIA

Hiatal hernia is a herniation of viscera, most commonly the stomach, into the mediastinum through the esophageal hiatus of the diaphragm. Four types of hiatal hernia are distinguished, with type I, or sliding hiatal hernia, comprising about 95% of the overall total. A sliding hiatal hernia is one in which the gastroesophageal junction and gastric cardia translocate cephalad as a result of weakening of the phrenoesophageal ligament attaching the gastroesophageal junction to the diaphragm at the hiatus and dilatation of the diaphragmatic hiatus. The incidence of sliding hernia increases with age. True to its name, sliding hernias enlarge with increased intraabdominal pressure, swallowing, and respiration. Conceptually, sliding hernias are the result of wear and tear: increased intraabdominal pressure from abdominal obesity, pregnancy, etc., along with hereditary factors predisposing to the condition. The main significance of sliding hernias is the propensity of affected individuals to develop GERD.

Type II, III, and IV hiatal hernias are all subtypes of paraesophageal hernia in which there is herniation into the mediastinum of viscera above the gastric cardia. With type II and III paraesophageal hernias, the gastric fundus herniates, with the distinction being that in type II, the gastroesophageal junction remains fixed at the hiatus, whereas type III is a combined sliding and paraesophageal hernia. With type IV hiatal hernias, viscera other than the stomach herniate into the mediastinum, most commonly the colon. With type II and III paraesophageal hernias, the stomach progressively inverts as it herniates, and large paraesophageal hernias can lead to an "upside down stomach," gastric volvulus, and even strangulation of the stomach. Because of this risk, surgical repair is often advocated for large paraesophageal hernias, particularly when they are symptomatic.

RINGS AND WEBS

A lower esophageal mucosal ring, also called a *B ring*, is a thin membranous narrowing at the squamocolumnar mucosal junction **(Fig. 334-2)**.

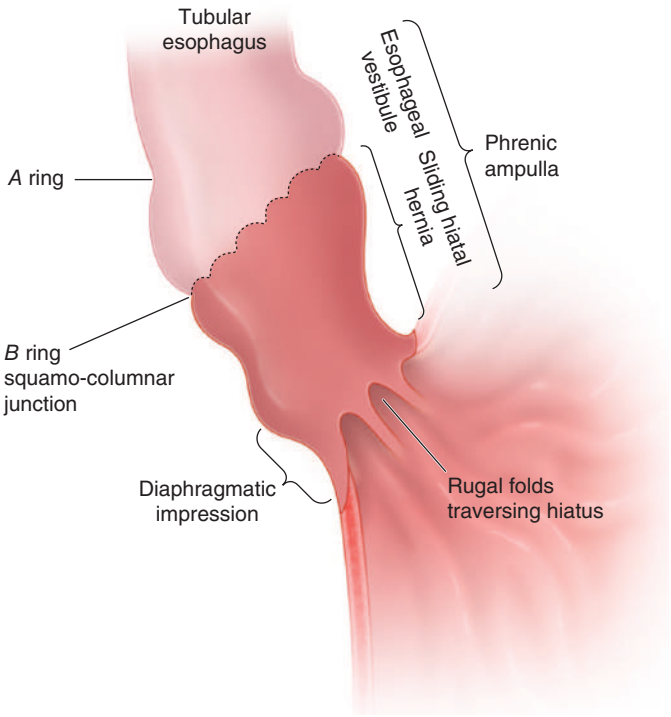

FIGURE 334-2 Radiographic anatomy of the gastroesophageal junction.

Its origin is unknown, but B rings are demonstrable in ~10–15% of the general population and are usually asymptomatic. When the lumen diameter is <13 mm, distal rings are usually associated with episodic solid food dysphagia and are called *Schatzki rings*. Patients typically present older than 40 years, consistent with an acquired rather than congenital origin. Schatzki ring is a common cause of intermittent food impaction, also known as "steakhouse syndrome" because meat is a typical instigator. Symptomatic rings are readily treated by dilation.

Web-like constrictions higher in the esophagus can be of congenital or inflammatory origin. Asymptomatic cervical esophageal webs are demonstrated in ~10% of people and typically originate along the anterior aspect of the esophagus. Depending on the degree of impingement, they can cause intermittent dysphagia to solids similar to Schatzki rings and are similarly treated with dilation. The combination of symptomatic proximal esophageal webs and iron-deficiency anemia in middle-aged women constitutes Plummer-Vinson or Paterson-Kelly syndrome.

DIVERTICULA

Esophageal diverticula are categorized by location, with the most common being epiphrenic, hypopharyngeal (Zenker's), and midesophageal. Epiphrenic and Zenker's diverticula are false diverticula involving herniation of the mucosa and submucosa through the muscular layer of the esophagus. These lesions result from increased intraluminal pressure associated with distal obstruction. In the case of Zenker's, the obstruction is a stenotic cricopharyngeus muscle (upper esophageal sphincter), and the hypopharyngeal herniation occurs in an area of natural weakness proximal to the cricopharyngeus known as *Killian's triangle* **(Fig. 334-3)**. Small Zenker's diverticula are usually asymptomatic, but when they enlarge sufficiently to retain food and saliva, they can be associated with dysphagia, halitosis, and aspiration. Treatment is by surgical diverticulectomy and cricopharyngeal myotomy or transoral, endoscopic myotomy.

Epiphrenic diverticula are often associated with achalasia or esophageal hypercontractile disorders. Midesophageal diverticula may be caused by traction from adjacent inflammation (tuberculosis, histoplasmosis), in which case they are true diverticula involving all layers of the esophageal wall, or by pulsion associated with esophageal motility disorders. Midesophageal and epiphrenic diverticula are often asymptomatic; symptoms tend to correlate more with the underlying esophageal disorder. Large epiphrenic diverticula can be removed surgically, usually in conjunction with a myotomy. Diffuse intramural esophageal pseudodiverticulosis is a rare entity resulting from dilatation of the excretory ducts of submucosal esophageal glands **(Fig. 334-4)**.

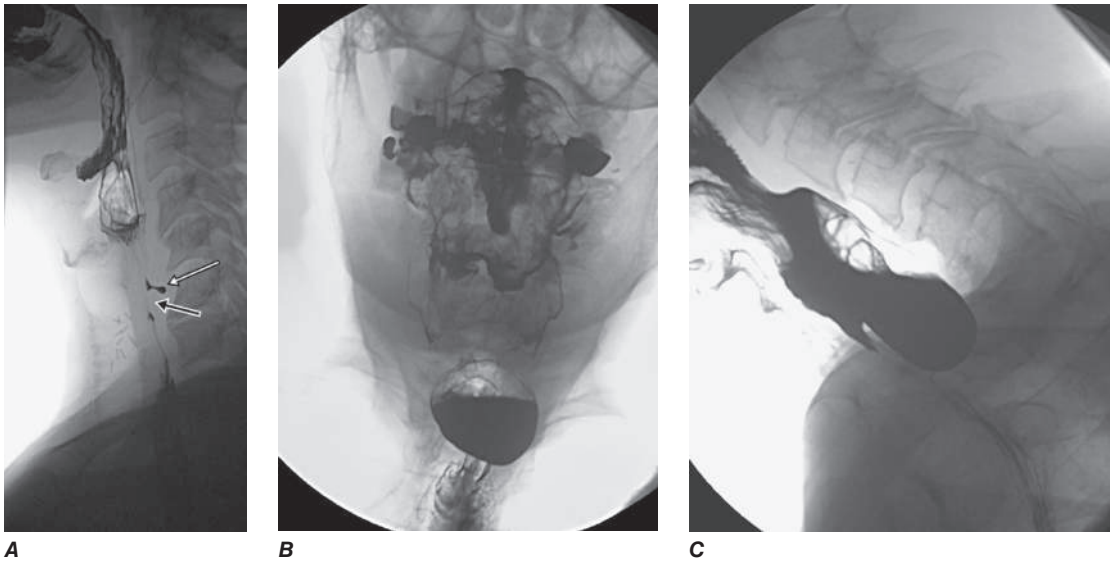

FIGURE 334-4 Intramural esophageal pseudodiverticulosis associated with chronic obstruction. Invaginations of contrast into the esophageal wall outline deep esophageal glands.

Esophageal candidiasis or strictures are commonly found in association with pseudodiverticulosis.

TUMORS

The American Cancer Society's 2023 estimates for esophageal cancer in the United States are about 21,560 new cases (79% men) and

A ***B*** ***C***

FIGURE 334-3 Examples of small (*A*) and large (*B, C*) Zenker's diverticula arising from Killian's triangle in the distal hypopharynx. Smaller diverticula are evident only during the swallow, whereas larger ones retain food and fluid.

16,120 deaths. It is ~7 times less common than colorectal cancer but kills about a third as many patients, emphasizing both the rarity and lethality of esophageal cancer. One notable trend is the shift of dominant esophageal cancer type from squamous cell to adenocarcinoma, strongly linked to reflux disease and Barrett's metaplasia. Other distinctions between cell types are the predilection for adenocarcinoma to affect the distal esophagus in white males and for squamous cell carcinoma to affect the more proximal esophagus in black males with the added risk factors of smoking, alcohol consumption, caustic injury, and human papillomavirus infection **(Chap. 85)**.

The typical presentation of esophageal cancer is of progressive solid food dysphagia and weight loss. Associated symptoms may include odynophagia, iron deficiency, cough from tracheoesophageal fistula, and hoarseness from left recurrent laryngeal nerve injury. Generally, respiratory symptoms are manifestations of locally invasive or even metastatic disease. Even when detected as a small lesion, esophageal cancer has poor survival because of the abundant esophageal lymphatics leading to early regional lymph node metastases.

Benign esophageal tumors are uncommon and usually discovered incidentally. They include gastrointestinal stromal tumors, leiomyoma, fibrovascular polyps, squamous papilloma, granular cell tumors, lipomas, mesenchymal neoplasms, and inflammatory fibroid polyps.

CONGENITAL ANOMALIES

The most common congenital esophageal anomaly is esophageal atresia, occurring in ~2.5 per 10,000 live births. Atresia can occur in several permutations, the common denominator being developmental failure of fusion between the proximal and distal esophagus associated with a tracheoesophageal fistula, most commonly with the distal segment excluded. Alternatively, there can be an H-type configuration in which esophageal fusion has occurred, but with a tracheoesophageal fistula. Esophageal atresia is usually recognized and corrected surgically within the first few days of life. Later life complications include dysphagia from anastomotic strictures or absent peristalsis and reflux, which can be severe. Less common developmental anomalies include congenital esophageal stenosis, webs, and duplications.

Dysphagia can also result from vascular congenital abnormalities that cause extrinsic compression of the esophagus, a condition called dysphagia lusoria. Most commonly, the esophagus is compressed by an aberrant right subclavian artery arising from the descending aorta and passing behind the esophagus. Alternatively, vascular rings may surround and constrict the esophagus.

Heterotopic gastric mucosa, also known as an esophageal inlet patch, is a focus of gastric-type epithelium in the proximal cervical esophagus; the estimated prevalence is 4–5%. The inlet patch is thought to result from incomplete replacement of embryonic columnar epithelium with squamous epithelium. The majority of inlet patches are asymptomatic, but acid production along with associated symptoms and even ulceration can occur as most contain fundic-type gastric epithelium with parietal cells.

ESOPHAGEAL MOTILITY DISORDERS

Esophageal motility disorders are diseases attributable to abnormal esophageal neuromuscular dysfunction commonly associated with dysphagia, chest pain, or heartburn. The major entities are achalasia, distal esophageal spasm (DES), and GERD. Motility disorders can also be secondary to systemic disease processes, as is the case with pseudoachalasia, Chagas' disease, and scleroderma. Not included in this discussion are diseases affecting the pharynx and proximal esophagus, the impairment of which is almost always part of a more global neuromuscular disease process.

ACHALASIA

Achalasia is a rare disease with a population incidence estimated to be 1–3 per 100,000 and presentation usually occurring between age 25 and 60 years. Although there is some degree of heterogeneity in its pathogenesis, the classic cases are caused by autoimmune-mediated death of ganglion cells within the esophageal myenteric plexus; with long-standing disease, aganglionosis is noted. The disease involves both excitatory (cholinergic) and inhibitory (nitric oxide) ganglionic neurons, which mediate deglutitive LES relaxation and the sequential propagation of peristalsis. Their absence leads to impaired deglutitive LES relaxation and absent peristalsis. Increasing evidence suggests that the ultimate cause of ganglion cell degeneration in achalasia is an autoimmune process attributable to a latent infection with human herpes simplex virus 1 combined with genetic susceptibility.

Long-standing achalasia is characterized by progressive dilatation and sigmoid deformity of the esophagus, sometimes associated with hypertrophy of the LES. Clinical manifestations may include dysphagia, regurgitation, chest pain, and weight loss. Most patients report solid and liquid food dysphagia. Regurgitation occurs when food, fluid, and secretions are retained in the dilated esophagus. Patients with advanced achalasia are at risk for bronchitis, pneumonia, or lung abscess from chronic regurgitation and aspiration. Chest pain may manifest early in the course of achalasia. Patients describe a squeezing, pressure-like retrosternal pain, sometimes radiating to the neck, arms, jaw, and back. Paradoxically, some patients complain of heartburn that may be a chest pain equivalent. Treatment of achalasia is less effective at alleviating chest pain than it is in relieving dysphagia or regurgitation.

The differential diagnosis of achalasia includes DES, Chagas' disease, opioid-induced esophageal dysmotility, and pseudoachalasia. Chagas' disease is endemic in areas of central Brazil, Venezuela, and northern Argentina and spread by the bite of the reduviid (kissing) bug that transmits the protozoan *Trypanosoma cruzi*. The chronic phase of the disease develops years after infection and results from destruction of autonomic ganglion cells throughout the body, including the heart, gut, urinary tract, and respiratory tract. Manometric features of achalasia have been described in patients on chronic opioids and may be confused with primary achalasia. Tumor infiltration, most commonly seen with carcinoma in the gastric cardia or distal esophagus, can also mimic primary achalasia. The resultant "pseudoachalasia" accounts for up to 5% of suspected cases and is more likely with advanced age, abrupt onset of symptoms (<1 year), and weight loss. Hence, endoscopy is a necessary part of the evaluation of achalasia. When the clinical suspicion for pseudoachalasia is high and endoscopy is nondiagnostic, computed tomography (CT) scanning or EUS may be of value. Rarely, pseudoachalasia can result from a paraneoplastic syndrome with circulating antineuronal antibodies.

Achalasia is diagnosed by barium swallow x-ray and/or esophageal manometry. Endoscopy excludes tumors or benign mechanical strictures of the esophagogastric junction. The barium swallow x-ray appearance is of a dilated esophagus with poor emptying, an air-fluid level, and tapering at the LES giving it a beak-like appearance **(Fig. 334-5)**. Occasionally, an epiphrenic diverticulum is observed. In long-standing achalasia, the esophagus may assume a sigmoid configuration. The diagnostic criteria for achalasia with esophageal manometry

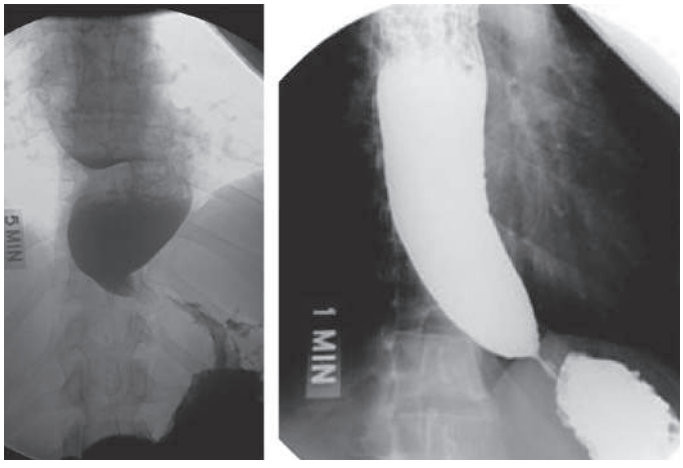

FIGURE 334-5 Achalasia with esophageal dilatation, tapering at the gastroesophageal junction, and an air-fluid level within the esophagus. The example on the *left* shows sigmoid deformity with very advanced disease.

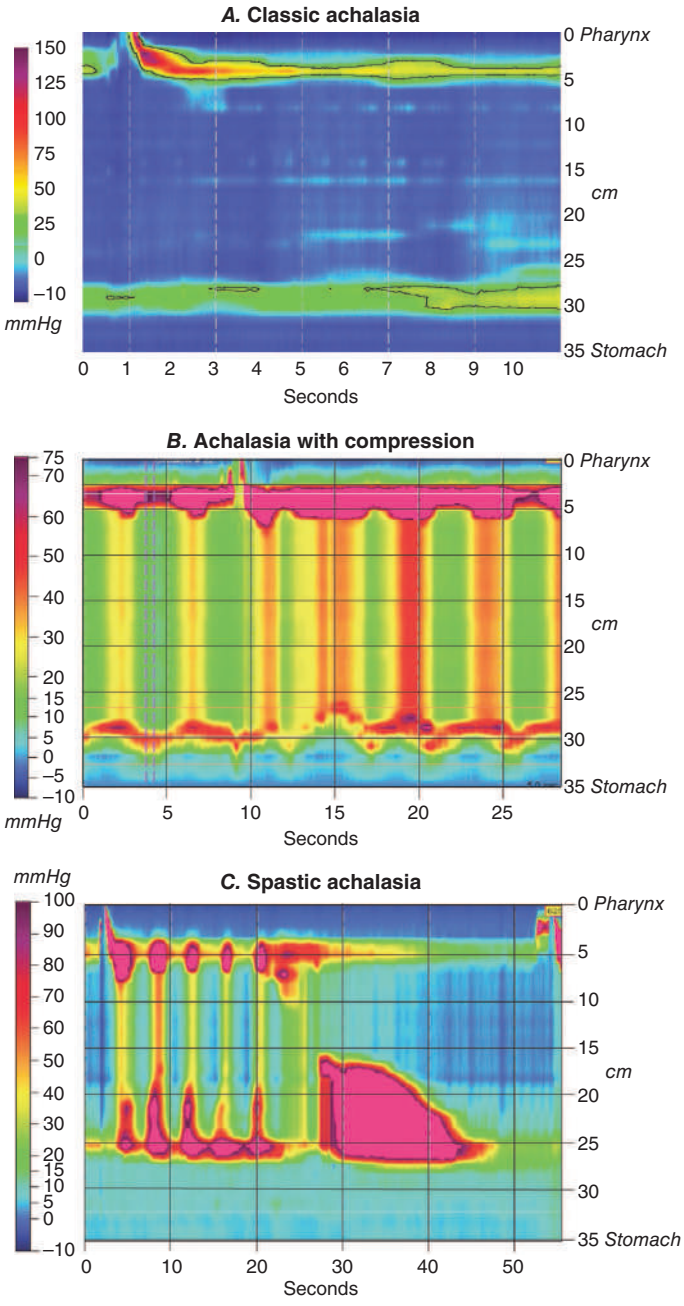

FIGURE 334-6 Three subtypes of achalasia: classic (*A*), with esophageal compression (*B*), and spastic achalasia (*C*) imaged with high-resolution manometry. All are characterized by impaired lower esophageal sphincter (LES) relaxation and absent peristalsis. However, classic achalasia has minimal pressurization of the esophageal body, whereas substantial fluid pressurization is observed in achalasia with esophageal compression, and spastic esophageal contractions are observed with spastic achalasia.

are impaired LES relaxation and absent peristalsis. High-resolution manometry has somewhat advanced this diagnosis; three subtypes of achalasia are differentiated based on the pattern of pressurization in the nonperistaltic esophagus **(Fig. 334-6)**. Because manometry identifies early disease before esophageal dilatation and food retention, it is the most sensitive diagnostic test.

No method of preventing or "curing" achalasia is known. Therapy is thus directed at reducing LES pressure so that gravity and esophageal pressurization permit esophageal emptying. While peristalsis does not recover, remnants of peristalsis masked by esophageal pressurization and dilatation prior to therapy may be demonstrable following effective treatment. LES pressure can be reduced by pharmacologic therapy, pneumatic balloon dilation, or LES myotomy by means of submucosal (third space) endoscopy or laparoscopic surgery. Pharmacologic therapies are relatively ineffective but can be offered as temporizing therapies. Nitrates or calcium channel blockers are administered before eating but should be used with caution because of their effects on blood pressure. Botulinum toxin, injected into the LES under endoscopic guidance, inhibits acetylcholine release from nerve endings and improves dysphagia in about two-thirds of cases for at least 6 months. Sildenafil and alternative phosphodiesterase inhibitors effectively decrease LES pressure, but practicalities limit their clinical use in achalasia.

The only durable therapies for achalasia are pneumatic dilation and LES myotomy. Pneumatic dilation, with a reported efficacy ranging widely from 60 to 90%, is an endoscopic technique using a noncompliant, cylindrical balloon dilator positioned across the LES and inflated to a diameter of 3–4 cm. The major complication is perforation, with a reported incidence of 0.5–5%. The most common surgical procedure for achalasia is laparoscopic Heller myotomy, usually performed in conjunction with an antireflux procedure (partial fundoplication); good to excellent results are reported in 62–90% of cases. A European randomized controlled trial demonstrated an equivalent response rate of ~90% for both pneumatic dilation and laparoscopic Heller myotomy at 5-year follow-up. Occasionally, patients with advanced disease fail to respond to pneumatic dilation or Heller myotomy or relapse years after response to primary therapy. In such refractory cases, esophageal resection with gastric pull-up or interposition of a segment of transverse colon may be the only option other than gastrostomy feeding.

An endoscopic approach to LES myotomy is increasingly available, referred to as peroral endoscopic (or esophageal) myotomy (POEM). This technique involves endoscopically incising the esophageal mucosa and creating a tunnel in the submucosa of the esophageal wall through which the circular muscle of the LES and a calibrated length of distal esophagus are transected with electrocautery. GERD is common after POEM but managed effectively with medications. Potential advantages over the conventional laparoscopic approach include avoidance of surgical disruption of the diaphragmatic hiatus and more rapid recovery. An international, multicenter, randomized trial of POEM and pneumatic dilation demonstrated greater symptom relief with POEM compared to dilation at 2 and 5 years. A European, multicenter, randomized trial of POEM and Heller myotomy reported similar efficacy for symptom relief, exceeding 80% with either.

In untreated or inadequately treated achalasia, esophageal dilatation predisposes to stasis esophagitis. Prolonged stasis esophagitis is the likely explanation for the association between achalasia and esophageal squamous cell cancer. Tumors develop after years of achalasia, usually in the setting of extreme esophageal dilatation, with the overall squamous cell cancer risk increased 17-fold compared to controls.

DISTAL ESOPHAGEAL SPASM

DES is manifest by episodes of dysphagia and chest pain attributable to abnormal esophageal contractions with normal deglutitive LES relaxation. The pathophysiology and natural history of DES are poorly defined. Radiographically, DES has been characterized by tertiary contractions or a "corkscrew esophagus" **(Fig. 334-7)**, but in many instances, these abnormalities are indicative of achalasia. Manometrically, a variety of defining features have been proposed including uncoordinated ("spastic") activity in the distal esophagus, spontaneous and repetitive contractions, or high-amplitude and prolonged contractions. High-resolution manometry has defined DES by the occurrence of contractions in the distal esophagus with short latency relative to the time of the pharyngeal contraction, a dysfunction indicative of impairment of inhibitory myenteric plexus neurons. When defined with this restrictive criterion **(Fig. 334-8)**, DES is substantially less common than achalasia.

Esophageal chest pain closely mimics angina pectoris. Features suggesting esophageal pain include pain that is nonexertional, prolonged, meal-related, relieved with antacids, accompanied by heartburn, dysphagia, or regurgitation, and interrupts sleep. However, all of these features exhibit overlap with cardiac pain, which still must be the primary consideration. Furthermore, even within the spectrum of esophageal diseases, both chest pain and dysphagia are also characteristic of peptic

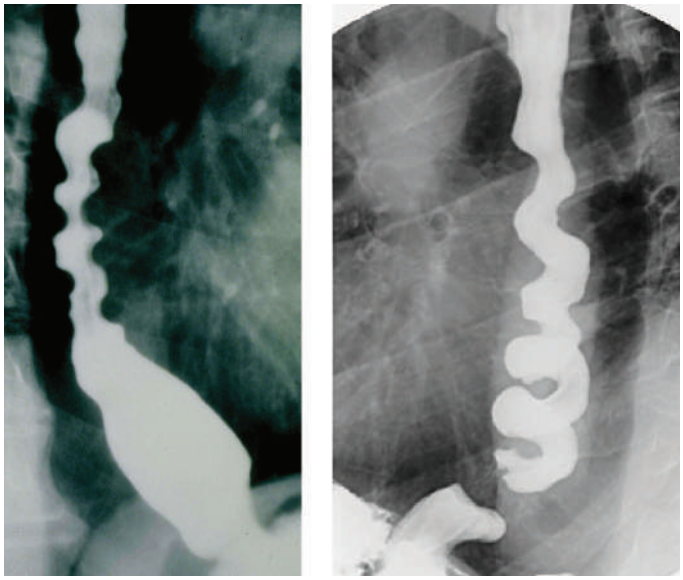

FIGURE 334-7 Distal esophageal spasm. The characteristic "corkscrew" esophagus results from spastic contraction of the circular muscle in the esophageal wall; more precisely, this is actually a helical array of muscle. These findings are also seen with spastic achalasia.

or infectious esophagitis. Only after these more common entities have been excluded by evaluation and/or treatment should a diagnosis of DES be pursued.

Although DES is diagnosed by manometry, endoscopy is useful to identify alternative structural and inflammatory lesions that may cause chest pain. Radiographically, a "corkscrew esophagus," "rosary bead esophagus," pseudodiverticula, or curling can be indicative of DES, but these are also found with spastic achalasia. Given these vagaries of defining DES and the resultant heterogeneity of patients identified for inclusion in therapeutic trials, it is not surprising that trial results have been disappointing. Only small, uncontrolled trials exist, reporting response to nitrates, calcium channel blockers, hydralazine, botulinum toxin, and anxiolytics. POEM with distal esophageal myotomy or surgical myotomy should be considered only with severe weight loss or intractable pain. These indications are extremely rare.

NONSPECIFIC MANOMETRIC FINDINGS

Manometric studies done to evaluate chest pain and/or dysphagia often report minor abnormalities (e.g., hypertensive or hypotensive peristalsis, hypertensive LES) that are insufficient to diagnose either achalasia or DES. These findings are of unclear significance. Reflux and psychiatric diagnoses, particularly anxiety and depression, are common among such individuals. A lower visceral pain threshold and symptoms of irritable bowel syndrome are noted in more than half of such patients. Consequently, therapy for these individuals should target either the most common esophageal disorder, GERD, or cognitive disorders that may be present.

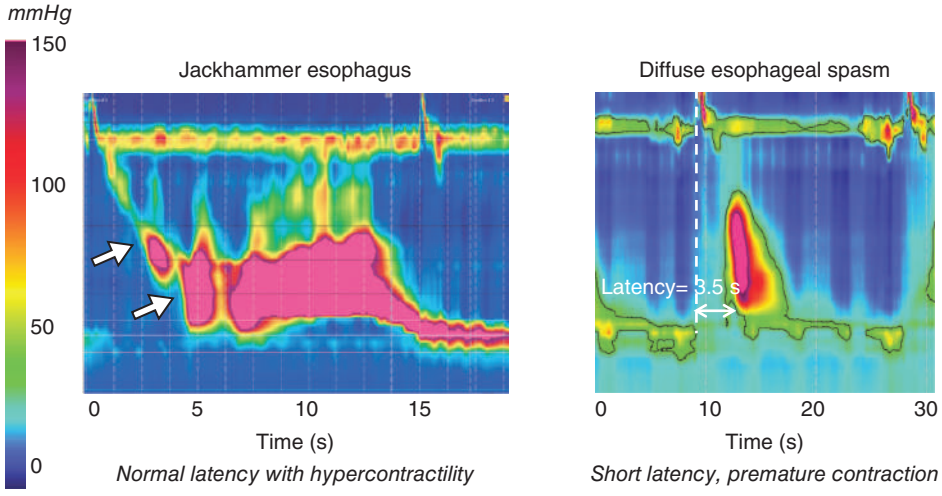
GASTROESOPHAGEAL REFLUX DISEASE

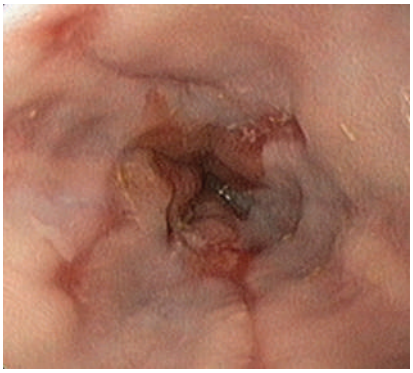
The current concept of GERD is that it encompasses a family of conditions with the commonality that they are caused by gastroesophageal reflux resulting in either troublesome symptoms or an array of potential esophageal and extraesophageal manifestations. It is estimated that 10–15% of adults in the United States are affected by GERD, although such estimates are based on population studies of self-reported chronic heartburn. With respect to the esophagus, the spectrum of injury includes esophagitis, stricture, Barrett's esophagus, and adenocarcinoma **(Fig. 334-9)**. Of particular concern is the rising incidence of esophageal adenocarcinoma, an epidemiologic trend that parallels the increasing incidence of GERD. About 9200 incident cases of esophageal adenocarcinoma were noted in the United States in 2020 (estimated as half of all esophageal cancers); this disease burden has increased sixfold in the past 20 years.

PATHOPHYSIOLOGY

The best-defined subset of GERD patients, albeit a minority overall, have esophagitis. Esophagitis occurs when refluxed gastric acid and pepsin induce inflammation of the esophageal mucosa that leads to microscopic injury and macroscopic erosions or ulcers. Experimental evidence supports a cytokine-mediated inflammatory pathway rather than direct caustic injury to the esophageal epithelium. Note that some degree of gastroesophageal reflux is normal, physiologically intertwined with the mechanism of belching (transient LES relaxation), but esophagitis results from excessive reflux, often accompanied by impaired clearance/neutralization of the refluxed gastric juice. Restricting reflux to that which is physiological levels depends on the anatomic and physiologic integrity of the esophagogastric junction, a complex valvular mechanism functionally dependent on the LES, the surrounding crural diaphragm, and the native subdiaphragmatic end-to-side architecture of the gastroesophageal junction. Pathologic reflux is a consequence of the interplay between progressive anatomic distortion of the native architecture of the gastroesophageal junction and physiology. Relevant factors include (1) widening of the diaphragmatic hiatus and diminished crural diaphragm sphincteric function; (2) loss of an intraabdominal esophageal segment with complete disabling of the native flap valve architecture; (3) axial hiatus hernia, which causes LES hypotension and loss of the ability to prevent reflux during swallow-induced LES relaxation, inspiration, or straining; and (4) increased compliance of gastroesophageal junction leading to wider sphincter opening during transient LES relaxations (the belch reflex) with loss of the ability to prevent liquid escaping along with the gas. Factors tending to exacerbate reflux regardless of mechanism are abdominal obesity, pregnancy, gastric hypersecretory states, delayed gastric emptying, disruption of esophageal peristalsis, and gluttony.

After acid reflux, peristalsis returns the refluxed fluid to the stomach, and acid clearance is completed by titration of the residual acid by bicarbonate contained in swallowed saliva. Consequently, two causes of prolonged acid clearance are impaired peristalsis and reduced salivation. Impaired peristaltic emptying can be attributable to disrupted peristalsis or superimposed reflux associated with a hiatal hernia. With





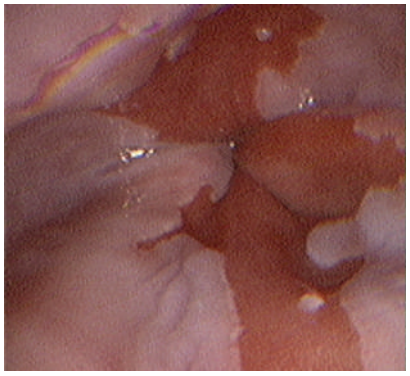


FIGURE 334-8 Esophageal pressure topography of the two major variants of esophageal spasm: hypercontractile esophagus (*left*) and distal esophageal spasm (*right*). Hypercontractile esophagus is defined by the extraordinarily vigorous, sometimes repetitive contractions with normal peristaltic onset and normal latency of the contraction. Distal esophageal spasm is similar but primarily defined by a short latency (premature) contraction.

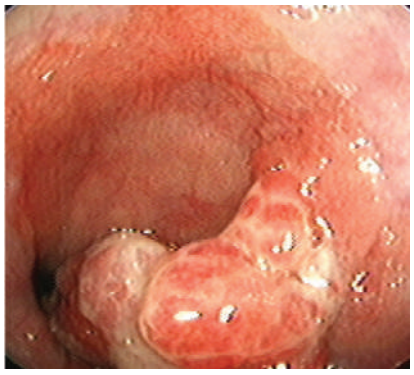

A Erosive esophagitis

B Esophageal stricture with chronic erosive esophagitis

C Barrett's esophagus

D Esophageal adenocarcinoma with Barrett's esophagus

FIGURE 334-9 Endoscopic appearance of (*A*) peptic esophagitis, **(*B*)** a peptic stricture, **(*C*)** Barrett's metaplasia, and **(*D*)** adenocarcinoma developing within an area of Barrett's esophagus.

superimposed reflux, fluid retained within a sliding hiatal hernia refluxes back into the esophagus during swallow-related LES relaxation, a phenomenon that does not normally occur.

Inherent in the pathophysiologic model of GERD is that gastric juice is harmful to the esophageal epithelium. However, gastric acid hypersecretion is usually not a dominant factor in the development of esophagitis. An obvious exception is with Zollinger-Ellison syndrome, which is associated with severe esophagitis in ~50% of patients. Another caveat is with chronic *Helicobacter pylori* gastritis, which may have a protective effect by inducing atrophic gastritis with concomitant hypoacidity. Pepsin, bile, and pancreatic enzymes within gastric secretions can also injure the esophageal epithelium, but their noxious properties are either lessened without an acidic environment or dependent on acidity for activation. Bile warrants attention because it persists in refluxate despite acid-suppressing medications. Bile can traverse the cell membrane, imparting severe cellular injury in a weakly acidic environment, and has also been invoked as a cofactor in the pathogenesis of Barrett's metaplasia and adenocarcinoma. Hence, the causticity of gastric refluxate extends beyond hydrochloric acid.

SYMPTOMS

Heartburn and regurgitation are the typical symptoms of GERD. Somewhat less common are dysphagia and chest pain. In each case, multiple potential mechanisms for symptom genesis operate that extend beyond the basic concepts of mucosal erosion and activation of afferent sensory nerves. Specifically, visceral hypersensitivity is increasingly recognized as a cofactor. Nonetheless, the dominant clinical strategy is empirical treatment with acid inhibitors, reserving further evaluation for those who fail to respond. Important exceptions to this are patients with chest pain or persistent dysphagia, each of which may be indicative of GERD or alternative diagnoses. With chest pain, cardiac disease must be considered. With dysphagia, eosinophilic esophagitis (EoE) should be considered as an alternative diagnosis along with peptic stricture, motility disorders, or esophageal cancer.

Extraesophageal syndromes associated with GERD include chronic cough, laryngitis, asthma, and dental erosions. Other conditions including pharyngitis, chronic bronchitis, pulmonary fibrosis, chronic sinusitis, cardiac arrhythmias, sleep apnea, and recurrent aspiration pneumonia have proposed associations with GERD. However, in both cases, it is important to emphasize the word *association* as opposed to *causation*. In many instances, the disorders likely coexist without causality. Potential mechanisms for extraesophageal GERD manifestations are either regurgitation with direct contact between the refluxate and supraesophageal structures or via a vagovagal reflex wherein reflux activation of esophageal afferent nerves triggers efferent vagal reflexes such as bronchospasm, cough, or arrhythmias.

DIFFERENTIAL DIAGNOSIS

Although generally quite characteristic, symptoms from GERD need to be distinguished from symptoms related to infectious or pill esophagitis, EoE, peptic ulcer disease, dyspepsia, biliary colic, coronary artery disease, and esophageal motility disorders. It is especially important that coronary artery disease be given early consideration because of its potentially lethal implications. The remaining elements of the differential diagnosis can be addressed by endoscopy, upper gastrointestinal series, or esophageal manometry as appropriate. Erosive esophagitis at the esophagogastric junction is the endoscopic hallmark of GERD, but it is identified in only about one-third of GERD patients. The distinction among etiologies of esophagitis is readily made by endoscopic appearance, but mucosal biopsies are necessary to evaluate for infectious or eosinophilic inflammation. In terms of endoscopic appearance, the ulcerations seen in peptic esophagitis are usually few and distal, whereas infectious ulcerations are numerous, punctate, and diffuse. EoE characteristically exhibits multiple esophageal edema, rings, linear furrows, white punctate exudate, and strictures. Esophageal ulcerations from pill esophagitis are usually singular and deep at points of luminal narrowing, especially near the carina, with sparing of the distal esophagus.

COMPLICATIONS

The complications of GERD are related to chronic esophagitis (bleeding and stricture) and the relationship between GERD and esophageal adenocarcinoma. However, both erosive esophagitis and peptic strictures have become increasingly rare in the era of potent antisecretory medications. Conversely, the most severe histologic consequence of GERD is Barrett's metaplasia with the associated risk of esophageal adenocarcinoma, and the incidence of these lesions has increased, not decreased, in the era of potent acid suppression. Barrett's metaplasia, recognized endoscopically by salmon-colored mucosa extending proximally from the gastroesophageal junction (Fig. 334-9) or histopathologically by the finding of intestinal metaplasia, is associated with a significantly increased risk for development of esophageal adenocarcinoma.

Barrett's metaplasia can progress to adenocarcinoma through the intermediate stages of low- and high-grade dysplasia **(Fig. 334-10)**. Owing to this risk, areas of Barrett's metaplasia and especially any included areas of mucosal irregularity should be carefully inspected and extensively biopsied. The rate of cancer development is estimated at 0.1–0.3% per year, but vagaries in definitional criteria and of the extent of Barrett's metaplasia requisite to establish the diagnosis have contributed to variability and inconsistency in this risk assessment. The group at greatest risk is obese white males in their sixth decade of life. However, despite common practice, the utility of endoscopic screening and surveillance programs intended to control the adenocarcinoma risk remains an open question. Also of note, although in a large

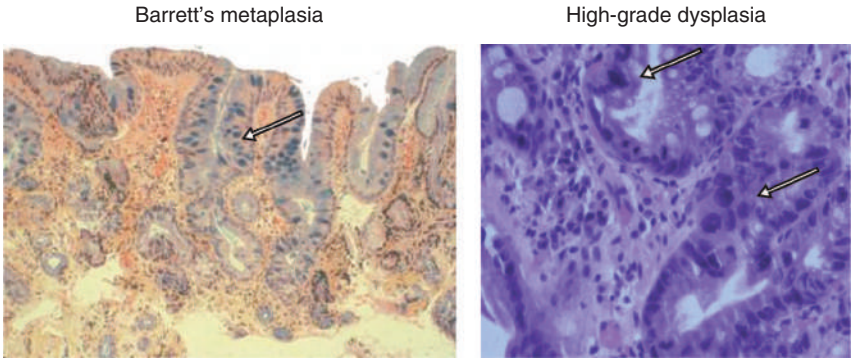

FIGURE 334-10 Histopathology of Barrett's metaplasia and Barrett's metaplasia with high-grade dysplasia (arrows). H&E, hematoxylin and eosin.

randomized, controlled trial of chemoprevention in Barrett's patients, high-dose proton pump inhibitor therapy along with aspirin did significantly better at achieving the composite endpoint of delaying all-cause mortality or Barrett's progression, the effect was driven mainly by improved overall survival rather than reduced Barrett's dysplasia or adenocarcinoma development.

Although the management of Barrett's esophagus remains controversial, the finding of dysplasia in Barrett's, particularly high-grade dysplasia, mandates further intervention. In addition to the high rate of progression to adenocarcinoma, there is also a high prevalence of unrecognized coexisting cancer with high-grade dysplasia. Treatment recommendations for Barrett's esophagus with high-grade dysplasia have evolved over the past several years. Historically, esophagectomy was the gold standard treatment for high-grade dysplasia. However, esophagectomy has a mortality ranging from 3 to 10%, along with substantial morbidity. Prospective studies have demonstrated the efficacy of endoscopic mucosal ablation therapy with substantially less morbidity and essentially no mortality. Consequently, current societal guidelines endorse endoscopic mucosal ablation therapies for the management of high-grade dysplasia.

TREATMENT

Gastroesophageal Reflux Disease

Lifestyle modifications are routinely advocated as GERD therapy. Broadly speaking, these fall into three categories: (1) avoidance of foods that reduce LES pressure, making them "refluxogenic" (these commonly include fatty foods, alcohol, spearmint, peppermint, and possibly coffee and tea); (2) avoidance of acidic foods that are inherently irritating (citrus fruits, tomato-based foods); and (3) adoption of behaviors to minimize reflux and/or heartburn. In general, minimal evidence supports the efficacy of these measures. However, clinical experience dictates that subsets of patients benefit from specific recommendations based on their individual history and symptom profile. A patient with sleep disturbance from nighttime heartburn is more likely to benefit from elevation of the head of the bed and avoidance of eating before retiring. The most broadly applicable recommendation is for weight reduction. Even though the benefit with respect to reflux cannot be assured, the strong epidemiologic relationship between body mass index and GERD and the secondary health gains of weight reduction is beyond dispute.

The dominant pharmacologic approach to GERD management is with inhibitors of gastric acid secretion, and abundant data support the effectiveness of this approach. Pharmacologically reducing the acidity of gastric juice does not prevent reflux, but it ameliorates reflux symptoms and allows esophagitis to heal. The hierarchy of effectiveness among pharmaceuticals for healing esophagitis parallels their antisecretory potency. Potassium competitive acid blockers (PCABs) are more efficacious than proton pump inhibitors (PPIs), which are more efficacious than histamine-2 receptor antagonists (H_2RAs). The differences are most evident with severe esophagitis, much less so with mild disease.

Paradoxically, the perceived frequency and severity of heartburn correlate poorly with the presence or severity of esophagitis. When GERD treatments are assessed in terms of resolving heartburn, both efficacy and differences among pharmaceuticals are less clear-cut than with the objective of healing esophagitis. Although the same overall hierarchy of effectiveness exists between PPIs and H_2RAs (minimal data are available for PCABs), observed efficacy rates are lower and vary widely, likely reflecting patient heterogeneity.

Reflux symptoms tend to be chronic, irrespective of esophagitis. Thus, a common management strategy is indefinite treatment with PPIs or H_2RAs as necessary for symptom control. The side effects of PPI therapy are generally minimal. Rare cases of interstitial nephritis and severe, reversible hypomagnesemia have been reported. Vitamin B_{12} and iron absorption may be compromised and susceptibility to enteric infections, particularly *Clostridioides difficile* colitis, increased with treatment. Observational data have also noted an association between PPI exposure and renal disease, dementia, and cardiovascular disease, but the hazard ratios reported in these studies were small, and the potential for unrecognized residual confounding bias was substantial. Population studies have also suggested a slight increased risk of bone fracture with chronic PPI use suggesting an impairment of calcium absorption, but prospective studies have failed to corroborate this. Nonetheless, as with any medication, PPI dosage should be minimized to that necessary for the clinical indication.

Laparoscopic fundoplication, wherein the proximal stomach is wrapped around the distal esophagus to create an antireflux barrier, is a surgical alternative to the management of chronic GERD. Just as with PPI therapy, evidence on the utility of fundoplication is strongest for treating esophagitis, and controlled trials suggest similar efficacy to PPI therapy. However, the benefits of fundoplication must be weighed against potential deleterious effects, including surgical morbidity and mortality, postoperative dysphagia, failure or breakdown requiring reoperation, an inability to belch, and increased bloating, flatulence, and bowel symptoms after surgery.

EOSINOPHILIC ESOPHAGITIS

EoE is increasingly recognized in adults and children around the world. Current prevalence estimates in the United States identified 4–8 cases per 10,000 with a predilection for white males between 30 and 40 years of age. The increasing prevalence of EoE is attributable to a combination of an increasing incidence and a growing recognition of the condition. There is also an incompletely understood, but important, interaction between EoE and GERD that may confound the diagnosis of the disease. Genome-wide analysis studies demonstrated susceptibility elements at 5q22 (thymic stromal lymphopoietin) and 2p23 (CAPN14) in EoE.

EoE is diagnosed by the combination of esophageal symptoms and esophageal mucosal biopsies demonstrating eosinophil-predominant

inflammation. Alternative etiologies of esophageal eosinophilia include GERD, drug hypersensitivity, connective tissue disorders, hypereosinophilic syndrome, Crohn's disease, eosinophilic gastroenteritis, and infection. EoE is an immunologic disorder induced by antigen sensitization in susceptible individuals. Food allergens are the dominant triggers, although aeroallergens may also contribute. The natural history of EoE is incompletely understood, but an increased risk of esophageal stricture development paralleling the duration of untreated disease has been noted.

EoE should be strongly considered in children and adults with dysphagia and esophageal food impactions. In preadolescent children, symptom presentations of EoE include chest or abdominal pain, nausea, vomiting, and food aversion. Other symptoms in adults may include atypical chest pain and heartburn. An atopic history of IgE-mediated food allergy, asthma, eczema, and/or allergic rhinitis is present in the majority of patients. Peripheral blood eosinophilia is demonstrable in 25–50% of patients, but the specificity of this finding is problematic in the setting of concomitant atopy. The characteristic endoscopic esophageal findings include loss of vascular markings (edema), multiple esophageal rings, longitudinally oriented furrows, whitish exudate, and strictures **(Fig. 334-11)**. Histologic confirmation is made with the demonstration of esophageal mucosal eosinophilia (peak density ≥15 eosinophils per high-power field) **(Fig. 334-12)**. Complications of EoE in adolescents and adults include food impaction, esophageal stricture, narrow-caliber esophagus, and (rarely) esophageal perforation. In children, complications include feeding difficulties and weight loss.

Since the complications of EoE are a consequence of ongoing eosinophilic inflammation, preventing them is dependent on follow up endoscopy with biopsies to verify a selected therapy's effectiveness in controlling eosinophilic inflammation. Primary therapy often starts with a PPI, which is effective at improving eosinophilic inflammation in 30–50% of patients. Additional first-line therapies include elimination diets or swallowed topical glucocorticoids. Elemental formula diets devoid of allergenic protein are a highly effective therapy but are limited by palatability. Notably, allergy testing by means of either serum IgE or skin prick testing has demonstrated poor sensitivity and specificity in the identification of foods responsible for EoE in an individual patient. Empiric elimination of common food allergies (milk, wheat, egg, soy, nuts, and seafood) followed by systematic reintroduction has been an effective diet therapy in both children and adults. The intent of the elimination diet approach is the identification and long-term avoidance of specific food trigger(s). Swallowed, topical glucocorticoids (e.g., fluticasone propionate or budesonide) are effective in 50–80% of patients. Systemic glucocorticoids are not generally recommended due to side effects and lack of proven benefit beyond that achieved with topical glucocorticoids. The first U.S. Food and Drug Administration–approved treatment for EoE is the interleukin 4 and 13–blocking biologic dupilumab, injected subcutaneously once a week. Additional therapies targeting other immune pathways and allergic cytokine mediators have also shown promise in initial clinical trials. Esophageal dilation is highly effective at relieving dysphagia in patients with fibrostenosis but does not address the underlying inflammatory process. Dilation should be approached cautiously because of the risk of deep, esophageal mural laceration or perforation in the characteristic stiff-walled esophagus. Once an effective therapy is identified, maintenance therapy is advocated due to the chronicity of EoE and nearly universal disease recurrence upon cessation of therapy.

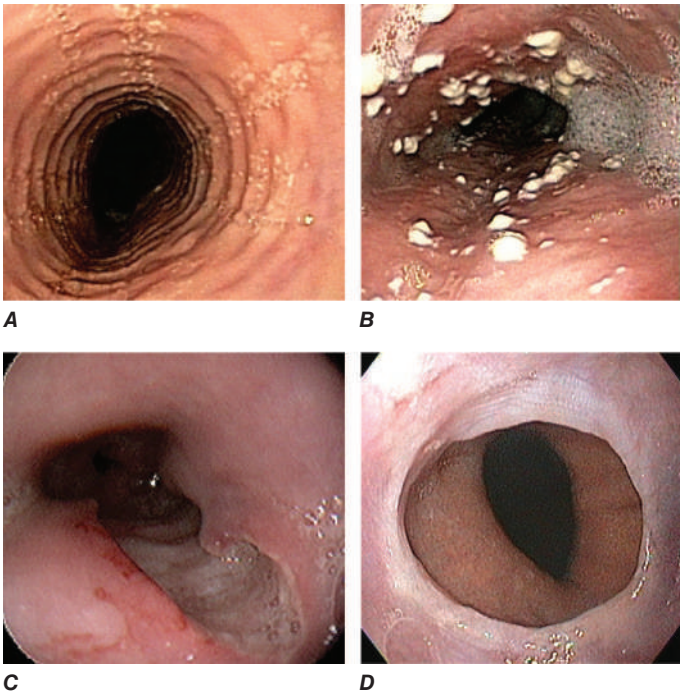

FIGURE 334-11 Endoscopic features of (*A*) eosinophilic esophagitis (EoE), **(*B*)** *Candida* esophagitis, **(*C*)** giant ulcer associated with HIV, and **(*D*)** a Schatzki ring.

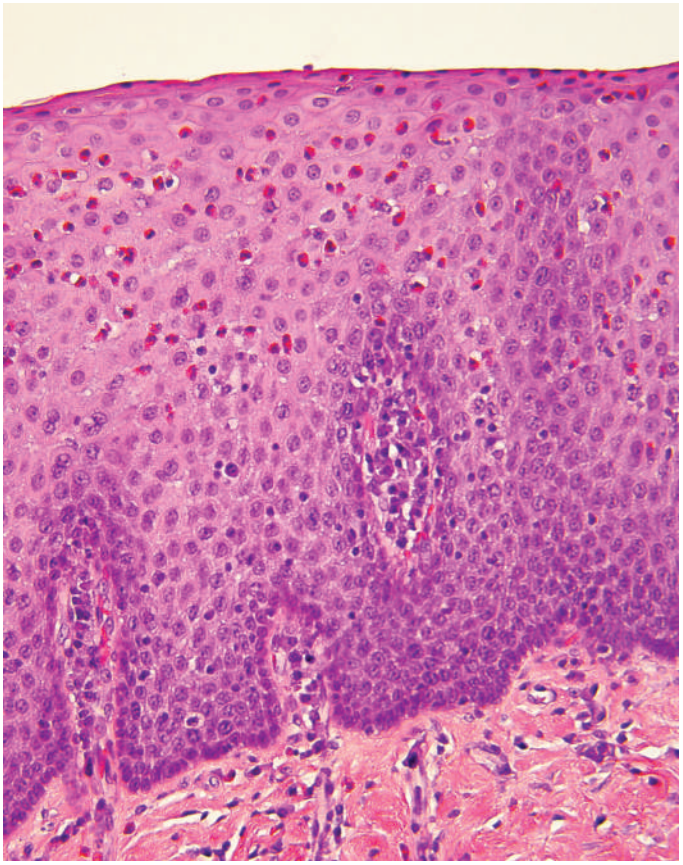

FIGURE 334-12 Histopathology of eosinophilic esophagitis (EoE) showing infiltration of the esophageal squamous epithelium with eosinophils. Additional features of basal cell hyperplasia and lamina propria fibrosis are present. Eosinophilic inflammation can also be seen with gastroesophageal reflux disease.

INFECTIOUS ESOPHAGITIS

With the increased use of immunosuppression for organ transplantation and chronic inflammatory diseases, use of chemotherapy, and the AIDS epidemic, infections with *Candida* species, herpesvirus, and cytomegalovirus (CMV) have become relatively common. Although rare, infectious esophagitis also occurs among the non-immunocompromised, with herpes simplex and *Candida albicans* being the most common pathogens. Among AIDS patients, infectious esophagitis becomes more common as the CD4 count declines; cases are rare with a CD4 count >200 and common when <100. HIV itself may also be associated with a self-limited syndrome of acute esophageal ulceration with oral ulcers and a maculopapular skin rash at the time of seroconversion. Additionally, some patients with advanced disease have deep, persistent esophageal ulcers treated with oral glucocorticoids or

thalidomide. However, with the widespread use of highly effective antiviral therapies, these HIV complications have become less common.

Regardless of the infectious agent, odynophagia is a characteristic symptom of infectious esophagitis; dysphagia, chest pain, and hemorrhage are also common. Odynophagia is uncommon with reflux esophagitis, so its presence should always raise suspicion of an alternative etiology.

CANDIDA ESOPHAGITIS

Candida is normally found in the throat but can become pathogenic and produce esophagitis in a compromised host; *C. albicans* is most common. *Candida* esophagitis also occurs with esophageal stasis secondary to esophageal motor disorders and diverticula. Patients complain of odynophagia and dysphagia. If oral thrush is present, empirical therapy is appropriate, but co-infection is common, and persistent symptoms should lead to prompt endoscopy with biopsy, which is the most useful diagnostic evaluation. *Candida* esophagitis has a characteristic appearance of white plaques or exudate with friability. Oral fluconazole (400 mg on the first day, followed by 200 mg daily) for 7–14 days is the preferred initial treatment. Patients refractory to that may respond to higher dose fluconazole, voriconazole, itraconazole, or posaconazole. Alternatively, poorly responsive patients or those who cannot swallow medications can be treated with an intravenous echinocandin or amphotericin B.

HERPETIC ESOPHAGITIS

Herpes simplex virus type 1 or 2 may cause esophagitis. Vesicles on the nose and lips may coexist and are suggestive of a herpetic etiology. Varicella-zoster virus can also cause esophagitis in children with chickenpox or adults with zoster. The characteristic endoscopic findings are vesicles and small, superficial ulcerations. Because herpes simplex infections are limited to squamous epithelium, biopsies from the ulcer margins are most likely to reveal the characteristic ground-glass nuclei, eosinophilic Cowdry's type A inclusion bodies, and giant cells. Culture or polymerase chain reaction (PCR) assays are helpful to identify acyclovir-resistant strains. Acyclovir (200 mg orally five times a day for 7–10 days) can be used for immunocompetent hosts, although the disease is typically self-limited after a 1- to 2-week period in such patients. Immunocompromised patients are treated with acyclovir (400 mg orally five times a day for 14–21 days), famciclovir (500 mg orally three times a day), or valacyclovir (1 g orally three times a day). In patients with severe odynophagia, intravenous acyclovir, 5 mg/kg every 8 h for 7–14 days, reduces this morbidity.

CYTOMEGALOVIRUS

CMV esophagitis occurs primarily in immunocompromised patients, particularly those with HIV, malignancy, and recipients of bone marrow or organ transplants. CMV is usually reactivated from a latent infection. Endoscopically, CMV lesions appear as large serpiginous ulcers in an otherwise normal mucosa, particularly in the distal esophagus. Biopsies from the ulcer bases have the greatest diagnostic yield for finding the pathognomonic large nuclear or cytoplasmic inclusion bodies. Immunohistology with monoclonal antibodies to CMV and in situ hybridization tests are useful for early diagnosis. Data on therapy for CMV esophagitis are limited. Treatment studies of CMV gastrointestinal disease have demonstrated effectiveness of both ganciclovir (5 mg/kg every 12 h IV) and valganciclovir (900 mg orally every 12 h). Therapy is continued until healing, which may take 3–6 weeks. Maintenance therapy may be needed for patients with relapsing disease.

MECHANICAL TRAUMA AND IATROGENIC INJURY

ESOPHAGEAL PERFORATION

Most cases of esophageal perforation are from instrumentation of the esophagus or trauma. Alternatively, forceful vomiting or retching can lead to spontaneous rupture at the gastroesophageal junction (Boerhaave's syndrome). More rarely, corrosive esophagitis or neoplasms lead to perforation. Instrument perforation from endoscopy or nasogastric tube placement typically occurs in the hypopharynx or at the gastroesophageal junction. Perforation may also occur at the site of a stricture in the setting of endoscopic food disimpaction or therapeutic esophageal dilation. Esophageal perforation causes pleuritic retrosternal pain often associated with pneumomediastinum and subcutaneous emphysema. Mediastinitis is a major complication of esophageal perforation, and prompt recognition is key to optimizing outcome. CT of the chest is most sensitive in detecting mediastinal air. Esophageal perforation is confirmed by a contrast swallow, usually Gastrografin followed by thin barium. Treatment includes nasogastric suction and parenteral broad-spectrum antibiotics with prompt surgical drainage and repair in noncontained leaks. Conservative therapy with nasogastric suction, NPO status, and antibiotics without surgery may be appropriate in cases of contained perforation that are detected early. Endoscopic clipping or stent placement may be indicated in nonoperated iatrogenic perforations or nonoperable cases such as perforated tumors.

MALLORY-WEISS TEAR

Vomiting, retching, or vigorous coughing can cause a nontransmural tear at the gastroesophageal junction that is a common cause of upper gastrointestinal bleeding. Most patients present with hematemesis. Antecedent vomiting is the norm but not always evident. Bleeding usually abates spontaneously, but protracted bleeding may respond to local epinephrine or cauterization therapy, endoscopic clipping, or angiographic embolization. Surgery is rarely needed.

RADIATION ESOPHAGITIS

Radiation esophagitis can complicate treatment for thoracic cancers, especially breast and lung cancers, with the risk proportional to radiation dosage. Radiosensitizing drugs such as doxorubicin, bleomycin, cyclophosphamide, and cisplatin increase the risk. Dysphagia and odynophagia may last weeks to months after therapy. The esophageal mucosa becomes erythematous, edematous, and friable. Submucosal fibrosis and degenerative tissue changes and stricturing may occur years after the radiation exposure. Radiation exposure in excess of 5000 cGy has been associated with increased risk of esophageal stricture. Treatment for acute radiation esophagitis is supportive. Chronic strictures are managed with esophageal dilation.

CORROSIVE ESOPHAGITIS

Caustic esophageal injury from ingestion of alkali or, less commonly, acid can be accidental or from attempted suicide. Absence of oral injury does not exclude possible esophageal involvement. Thus, early endoscopic evaluation is recommended to assess and grade injury to the esophageal mucosa. Severe corrosive injury may lead to esophageal perforation, bleeding, stricture, and death. Glucocorticoids have not been shown to improve the clinical outcome of acute corrosive esophagitis and are not recommended. Healing of more severe grades of caustic injury is commonly associated with severe stricture formation and often requires life-long repeated dilation.

PILL ESOPHAGITIS

Pill-induced esophagitis occurs when a swallowed pill fails to traverse the entire esophagus and lodges within the lumen. Generally, this is attributed to poor "pill-taking habits": inadequate liquid with the pill or lying down immediately after taking a pill. The most common location for the pill to lodge is in the mid-esophagus near the crossing of the aorta or carina. Extrinsic compression from these structures halts the movement of the pill or capsule. Since initially reported in 1970, thousands of cases of pill esophagitis have been reported, suggesting that this is not an unusual occurrence. A wide variety of medications are implicated, with the most common being doxycycline, tetracycline, quinidine, phenytoin, potassium chloride, ferrous sulfate, nonsteroidal anti-inflammatory drugs (NSAIDs), and bisphosphonates.

Typical symptoms of pill esophagitis are the sudden onset of chest pain and odynophagia. Characteristically, the pain will develop over a period of hours or will awaken the individual from sleep. A classic history in the setting of ingestion of a recognized pill offender obviates

the need for diagnostic testing in most patients. When endoscopy is performed, localized ulceration or inflammation is evident. Histologically, acute inflammation is typical. Chest CT imaging will sometimes reveal esophageal thickening consistent with transmural inflammation. Although the condition usually resolves within days to weeks, symptoms may persist for months and stricture can develop in severe cases. No specific therapy is known to hasten the healing process, but antisecretory medications are frequently prescribed to remove concomitant reflux as an aggravating factor. When healing results in stricture formation, dilation is indicated.

FOREIGN BODIES AND FOOD IMPACTION

Food or foreign bodies may lodge in the esophagus, causing complete obstruction, which in turn can cause an inability to handle secretions (foaming at the mouth) and severe chest pain. Food impaction may occur due to peptic stricture, carcinoma, Schatzki ring, EoE, achalasia, or simply inattentive eating. If it does not resolve spontaneously, impacted food should be removed endoscopically. Use of meat tenderizer enzymes to facilitate passage of a meat bolus is discouraged because of potential esophageal injury. Glucagon (1 mg IV) is sometimes tried before endoscopic dislodgement. After emergent treatment, patients should be evaluated for potential causes of the impaction with treatment rendered as indicated.

ESOPHAGEAL MANIFESTATIONS OF SYSTEMIC DISEASE

SCLERODERMA AND CONNECTIVE TISSUE DISORDERS

Scleroderma esophagus (hypotensive LES and absent esophageal contractility) was initially described as a manifestation of scleroderma or other collagen vascular diseases and thought to be specific for these disorders. However, this nomenclature subsequently has been discarded because an estimated half of qualifying patients do not have an identifiable rheumatologic disease, and reflux disease is often the only identifiable association. When scleroderma esophagus occurs as a manifestation of a connective tissue disorder, the histopathologic findings are of infiltration and destruction of the esophageal muscularis propria with collagen deposition and fibrosis and reduction in the number of interstitial cells of Cajal. The pathogenesis of absent peristalsis and LES hypotension in the absence of a connective tissue disorder is unknown. Regardless of the underlying cause, the manometric abnormalities predispose patients to severe GERD due to inadequate LES barrier function combined with poor esophageal clearance of refluxed acid. Dysphagia may also be manifest but is generally mild and alleviated by eating in an upright position and using liquids to facilitate solid transit.

DERMATOLOGIC DISEASES

A host of dermatologic disorders (lichen planus, pemphigus vulgaris, bullous pemphigoid, cicatricial pemphigoid, Behçet's syndrome, and epidermolysis bullosa) can affect the oropharynx and esophagus, particularly the proximal esophagus, with blisters, bullae, ulceration, webs, and strictures. Topical or systemic anti-inflammatory therapy is effective for mucosal healing. Stevens-Johnson syndrome and graft-versus-host disease can also involve the esophagus. Esophageal dilation may be necessary to treat strictures.

335 Peptic Ulcer Disease and Related Disorders

John Del Valle

PEPTIC ULCER DISEASE

A *peptic ulcer* is defined as disruption of the mucosal integrity of the stomach and/or duodenum leading to a local defect or excavation due to active inflammation. Although burning epigastric pain exacerbated by fasting and improved with meals is a symptom complex associated with peptic ulcer disease (PUD), it is now clear that >90% patients with this symptom complex (dyspepsia) do not have ulcers and that the majority of patients with peptic ulcers may be asymptomatic. Ulcers occur within the stomach and/or duodenum and are often chronic in nature. Acid peptic disorders are very common in the United States, with 4 million individuals (new cases and recurrences) affected per year. Lifetime overall prevalence of PUD in the United States is ~8.4% with a slightly higher prevalence in men. PUD significantly affects quality of life by impairing overall patient well-being and contributing substantially to work absenteeism. Moreover, an estimated 15,000 deaths per year occur as a consequence of complicated PUD. The financial impact of these common disorders has been substantial, with an estimated burden on direct and indirect health care costs of ~$6 billion per year in the United States, with $3 billion spent on hospitalizations, $2 billion on physician office visits, and $1 billion in decreased productivity and days lost from work.

GASTRIC PHYSIOLOGY

Gastric Anatomy The gastric epithelial lining consists of rugae that contain microscopic gastric pits, each branching into four or five gastric glands made up of highly specialized epithelial cells. The makeup of gastric glands varies with their anatomic location. Glands within the gastric cardia comprise <5% of the gastric gland area and contain mucous and endocrine cells. The 75% of gastric glands are found within the oxyntic mucosa and contain mucous neck, parietal, chief, endocrine, enterochromaffin, and enterochromaffin-like (ECL) cells **(Fig. 335-1)**. Highly specialized tuft cells are located in the neck region of the gastric gland. These specialized cells are thought to sample luminal contents, which in turn may be important in regulating gastric acid secretion. Pyloric glands contain mucous and endocrine cells (including gastrin cells) and are found in the antrum.

The parietal cell, also known as the oxyntic cell, is usually found in the neck or isthmus or in the oxyntic gland. The resting, or unstimulated, parietal cell has prominent cytoplasmic tubulovesicles and intracellular canaliculi containing short microvilli along its apical surface **(Fig. 335-2)**. H^+,K^+-adenosine triphosphatase (ATPase) is expressed in the tubulovesicle membrane; upon cell stimulation, this membrane, along with apical membranes, transforms into a dense network of apical intracellular canaliculi containing long microvilli. Acid secretion, a process requiring high energy, occurs at the apical canalicular surface. Numerous mitochondria (30–40% of total cell volume) generate the energy required for secretion.

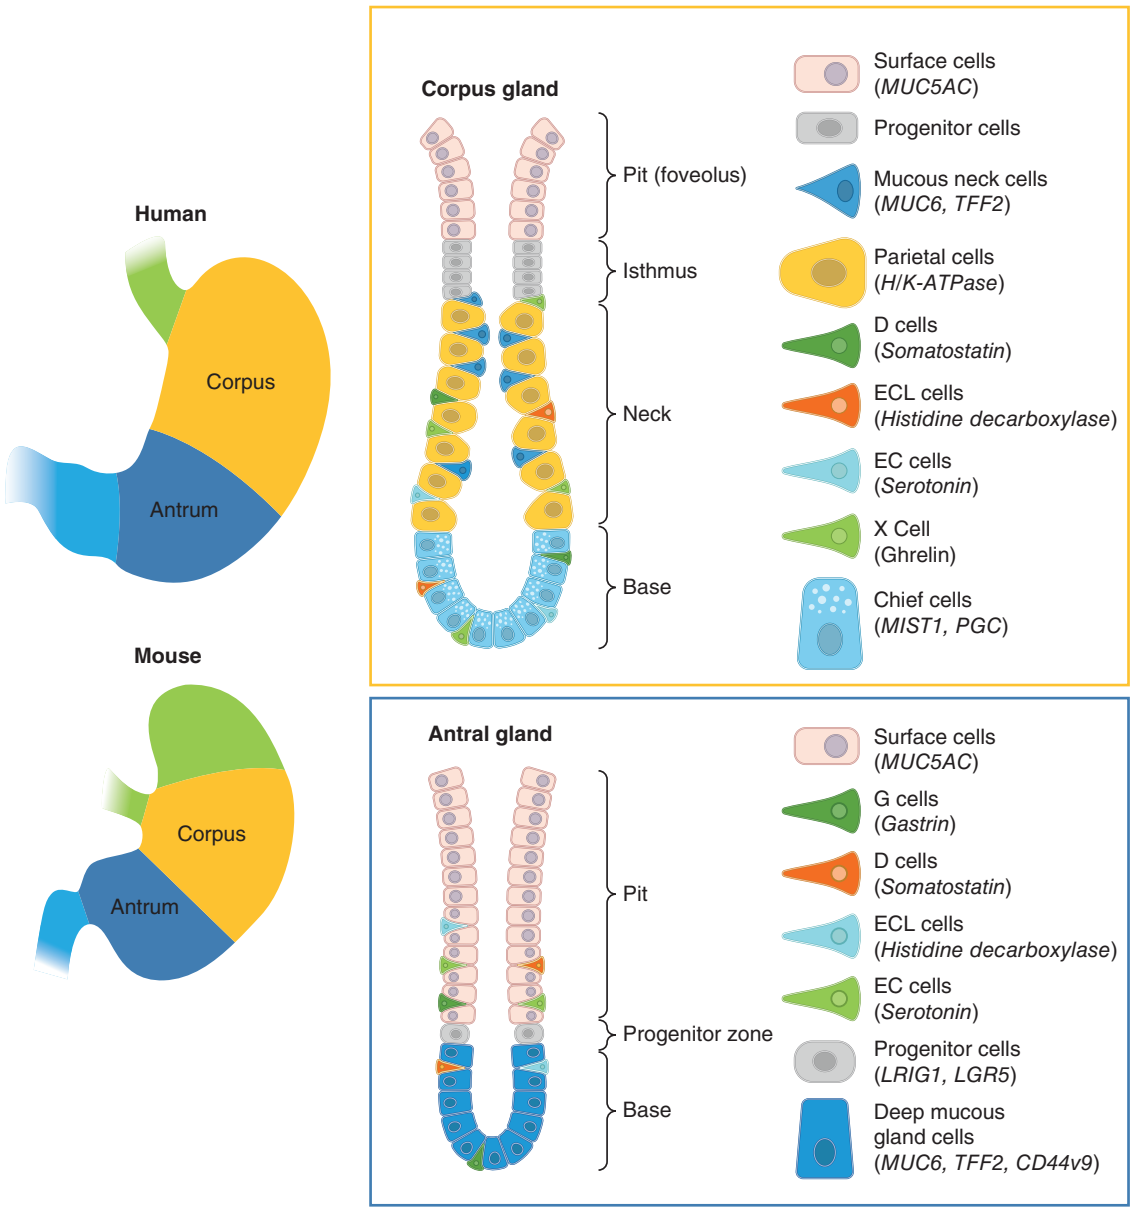

FIGURE 335-1 Diagrammatic representation of the oxyntic gastric gland. Cellular constituents of the stomach. The human stomach is divided into three components the cardia, the corpus and the antrum. The oxyntic gland which contains the majority of the acid producing cells are located in the corpus. Glands located in the antrum secrete predominantly mucus and also contain the important gastrin producing cells. It is also important to note that key progenitor cells are located within both the gastric corpus and antral glands. *(Reproduced with permission from AC Engevik et al: The physiology of the gastric parietal cell. Physiol Rev 100:573, 2020, Figure 1.)*

Gastroduodenal Mucosal Defense The gastric epithelium is under constant assault by a series of endogenous noxious factors, including hydrochloric acid (HCl), pepsinogen/pepsin, and bile salts. In addition, a steady flow of exogenous substances such as medications, alcohol, and bacteria encounter the gastric mucosa. A highly intricate biologic system is in place to provide defense from mucosal injury and to repair any injury that may occur.

The mucosal defense system can be envisioned as a three-level barrier, composed of preepithelial, epithelial, and subepithelial elements (Fig. 335-3). The first line of defense is a mucus-bicarbonate-phospholipid layer, which serves as a physicochemical barrier to multiple molecules, including hydrogen ions. Mucus is secreted in a regulated fashion by gastroduodenal surface epithelial cells. It consists primarily of water (95%) and a mixture of phospholipids and glycoproteins (mucin). The mucous gel functions as a nonstirred water layer impeding diffusion of ions and molecules such as pepsin. Bicarbonate, secreted in a regulated manner by surface epithelial cells of the gastroduodenal mucosa into the mucous gel, forms a pH gradient ranging

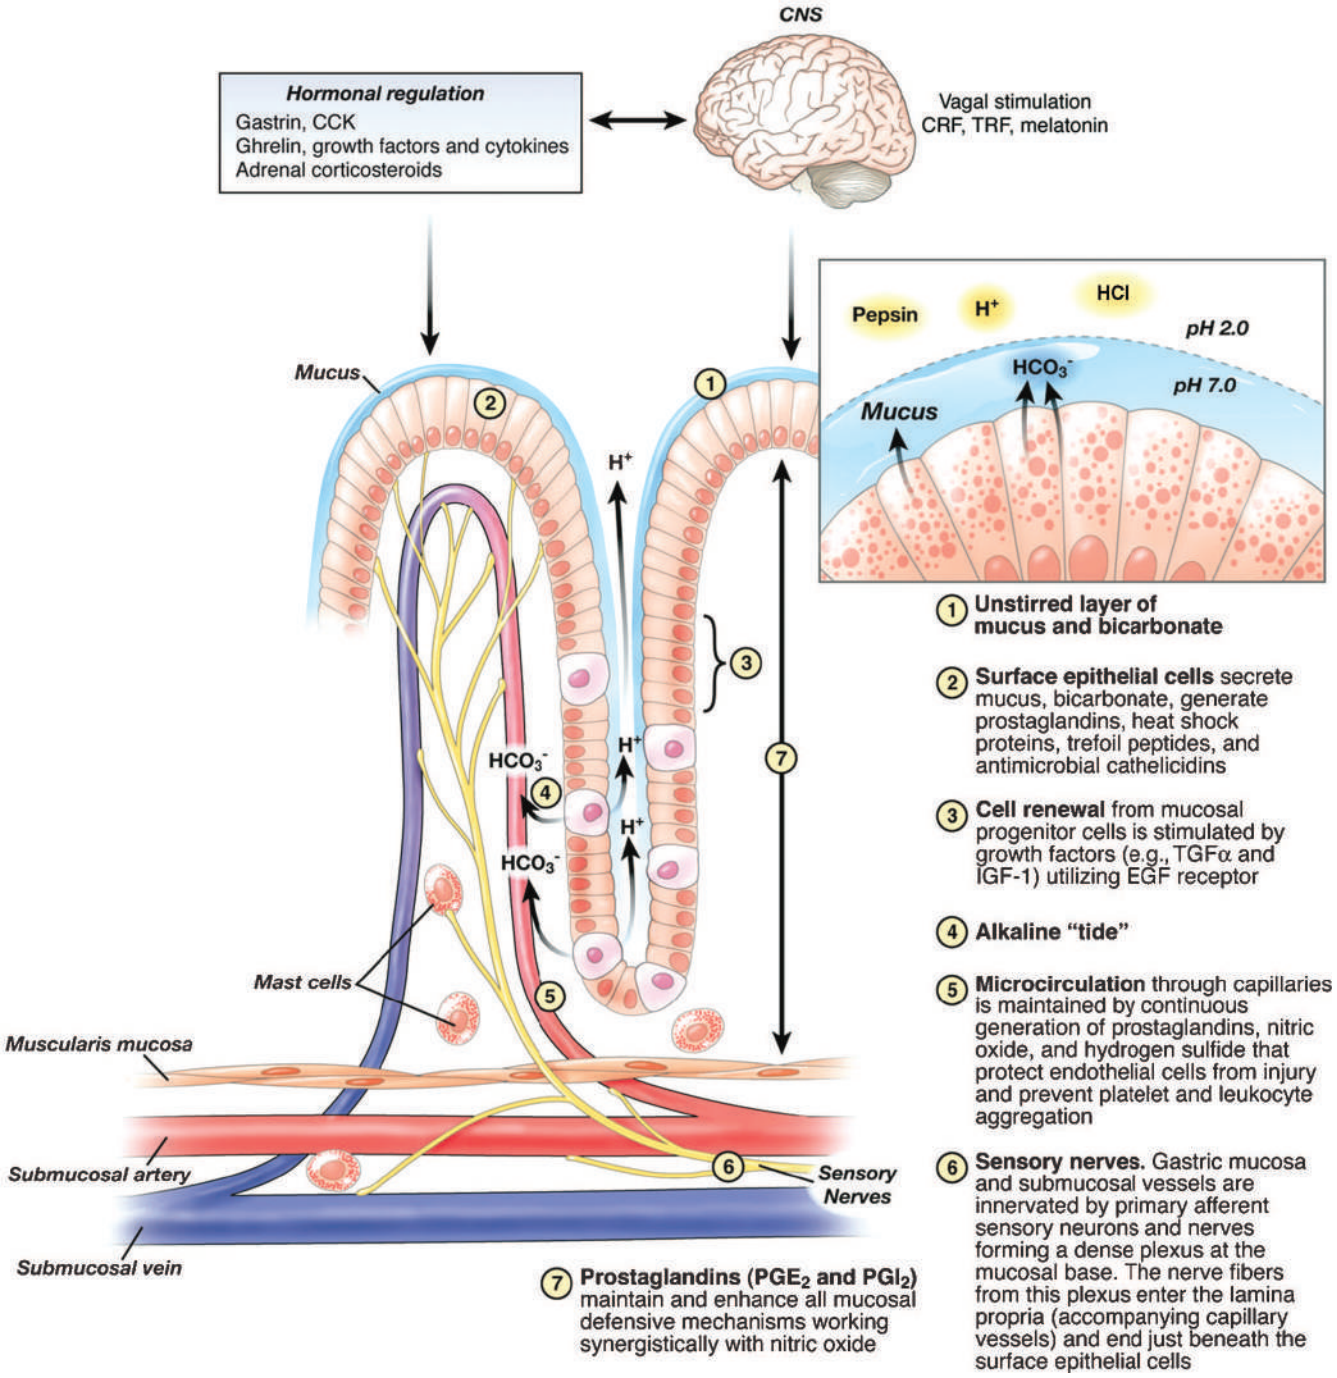

FIGURE 335-3 Components involved in providing gastroduodenal mucosal defense and repair. CCK, cholecystokinin; CRF, corticotropin-releasing factor; EGF, epidermal growth factor; HCl, hydrochloride; IGF, insulin-like growth factor; TGFα, transforming growth factor α; TRF, thyrotropin releasing factor. *(Republished with permission of John Wiley and Son's Inc, from Bioregulation and Its Disorders in the Gastrointestinal Tract, T Yoshikawa, T Arakawa [eds]: 1998; permission conveyed through Copyright Clearance Center, Inc.)*

from 1 to 2 at the gastric luminal surface and reaching 6–7 along the epithelial cell surface.

Surface epithelial cells provide the next line of defense through several factors, including mucus production, epithelial cell ionic transporters that maintain intracellular pH and bicarbonate production, and intracellular tight junctions. Surface epithelial cells generate heat shock proteins that prevent protein denaturation and protect cells from certain factors such as increased temperature, cytotoxic agents, or oxidative stress. Epithelial cells also generate trefoil factor family peptides and cathelicidins, which also play a role in surface cell protection and regeneration. If the preepithelial barrier is breached, gastric epithelial cells bordering a site of injury can migrate to restore a damaged region (*restitution*). This process occurs independent of cell division and requires uninterrupted blood flow and an alkaline pH in the surrounding environment. Several growth factors, including epidermal growth factor (EGF), transforming growth factor (TGF) α, and basic fibroblast growth factor (FGF), modulate the process of restitution. Larger defects that are not effectively repaired by restitution require cell proliferation. Epithelial cell regeneration is regulated by prostaglandins and growth factors such as EGF and TGF-α. In tandem with epithelial cell renewal, formation of new vessels (*angiogenesis*) within the injured microvascular bed occurs. Both FGF and vascular endothelial growth factor (VEGF) are important in regulating angiogenesis in the gastric mucosa. In addition, the gastric peptide gastrin (see below) has been found to stimulate cell proliferation, migration, invasion, angiogenesis, and autophagy. Finally, gastric parietal cells (see below) express sonic hedgehog, a family of proteins important in regulating cell lineage in multiple organs. This latter finding suggests that parietal cells may also have the ability to regulate gastric stem cells.

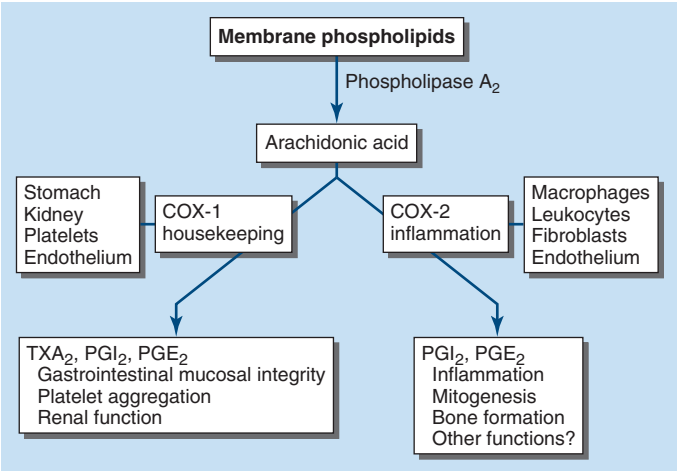

FIGURE 335-4 Schematic representation of the steps involved in synthesis of prostaglandin E_2 (PGE_2) and prostacyclin (PGI_2). Characteristics and distribution of the cyclooxygenase (COX) enzymes 1 and 2 are also shown. TXA_2, thromboxane A_2.

An elaborate microvascular system within the gastric submucosal layer is the key component of the subepithelial defense/repair system, providing HCO_3^-, which neutralizes the acid generated by the parietal cell. Moreover, this microcirculatory bed provides an adequate supply of micronutrients and oxygen while removing toxic metabolic by-products. Several locally produced factors including nitric oxide (NO) (see below), hydrogen sulfide, and prostacyclin contribute to the vascular protective pathway through vasodilation of the microcirculation.

Prostaglandins play a central role in gastric epithelial defense/repair **(Fig. 335-4)**. The gastric mucosa contains abundant levels of prostaglandins that regulate the release of mucosal bicarbonate and mucus, inhibit parietal cell secretion, and are important in maintaining mucosal blood flow and epithelial cell restitution. Prostaglandins are derived from esterified arachidonic acid, which is formed from phospholipids (cell membrane) by the action of phospholipase A_2. A key enzyme that controls the rate-limiting step in prostaglandin synthesis is cyclooxygenase (COX), which is present in two isoforms (COX-1, COX-2), each having distinct characteristics regarding structure, tissue distribution, and expression. COX-1 is expressed in a host of tissues, including the stomach, platelets, kidneys, and endothelial cells. This isoform is expressed in a constitutive manner and plays an important role in maintaining the integrity of renal function, platelet aggregation, and gastrointestinal (GI) mucosal integrity. In contrast, the expression of COX-2 is inducible by inflammatory stimuli, and it is expressed in macrophages, leukocytes, fibroblasts, and synovial cells. The beneficial effects of nonsteroidal anti-inflammatory drugs (NSAIDs) on tissue inflammation are due to inhibition of COX-2; the toxicity of these drugs (e.g., GI mucosal ulceration and renal dysfunction) is related to inhibition of the COX-1 isoform. The highly COX-2–selective NSAIDs have the potential to provide the beneficial effect of decreasing tissue inflammation while minimizing toxicity in the GI tract. Selective COX-2 inhibitors have had adverse effects on the cardiovascular (CV) system, leading to increased risk of myocardial infarction. Therefore, the U.S. Food and Drug Administration (FDA) has removed two of these agents (valdecoxib and rofecoxib) from the market (see below).

NO is important in the maintenance of gastric mucosal integrity. The key enzyme NO synthase is constitutively expressed in the mucosa and contributes to cytoprotection by stimulating gastric mucus, increasing mucosal blood flow, and maintaining epithelial cell barrier function. The central nervous system (CNS) and hormonal factors also play a role in regulating mucosal defense through multiple pathways (Fig. 335-3).

Since the discovery of *Helicobacter pylori* and its impact on gastric pathology, it has become clear that the stomach has an elaborate and complex inherent immunologic system in place. Although a detailed description of the gastric immune system is beyond the scope of this chapter, several features are worth highlighting. The gastric immune response to certain pathogens such as *H. pylori* (see below) involves extensive interplay between innate (dendritic cells, epithelial cells, neutrophils, and macrophages) and adaptive (B and T cells) components. Helper T cells (T_H and T_H regulatory cells) have been extensively studied and appear to play an important role in a broad array of gastric physiology extending from gastric secretion to epithelial cell turnover via production of a number of cytokines.

The discovery of *H. pylori* has also led to the understanding that the stomach, once thought to be devoid of microorganisms due to its highly adverse environment (acid and pepsin), can serve as host for bacterial communities consisting of hundreds of phylotypes, otherwise known as its microbiota. The conceptual framework of the microbiome has been receiving extensive attention in light of its importance in human health and disease. The overall relevance of the gastric microbiome and its impact on gastric pathology remain to be established, but it is likely that alteration of microorganism homeostasis will play a role in aspects of certain disorders such as PUD, gastritis, and gastric cancer.

Physiology of Gastric Secretion Understanding of the physiology of gastric secretion is important when considering the pathophysiology of PUD and the therapeutic options available. A detailed review of the many components of gastric acid secretion is beyond the scope of this chapter, and the reader is referred to Engevik et al (see Further Reading) for a comprehensive discussion on this very important topic. For the purposes of this chapter, a brief review of acid secretion will follow. HCl and pepsinogen are the two principal gastric secretory products capable of inducing mucosal injury. Gastric acid and pepsinogen play a physiologic role in protein digestion; absorption of iron, calcium, magnesium, and vitamin B_{12}; and killing ingested bacteria. Acid secretion should be viewed as occurring under basal and stimulated conditions. Basal acid production occurs in a circadian pattern, with the highest levels occurring during the night and lowest levels during the morning hours. Cholinergic input via the vagus nerve and histaminergic input from local gastric sources are the principal contributors to basal acid secretion. Stimulated gastric acid secretion occurs primarily in three phases based on the site where the signal originates (cephalic, gastric, and intestinal). Sight, smell, and taste of food are the components of the cephalic phase, which stimulates gastric secretion via the vagus nerve. The gastric phase is activated once food enters the stomach. This component of secretion is driven by nutrients (amino acids and amines) that directly (via peptone and amino acid receptors) and indirectly (via stimulation of intramural gastrin-releasing peptide neurons) stimulate the G cell to release gastrin, which in turn activates the parietal cell via direct and indirect mechanisms. Distention of the stomach wall also leads to gastrin release and acid production. The last phase of gastric acid secretion is initiated as food enters the intestine and is mediated by luminal distention and nutrient assimilation. A series of pathways that inhibit gastric acid production are also set into motion during these phases. The GI hormone somatostatin is released from endocrine cells found in the gastric mucosa (D cells) in response to HCl. Somatostatin can inhibit acid production by both direct (parietal cell) and indirect mechanisms (decreased histamine release from ECL cells, ghrelin release from Gr cells, and gastrin release from G cells). Additional neural (central and peripheral) and humoral (amylin, atrial natriuretic peptide [ANP], cholecystokinin, ghrelin, interleukin 11 [IL-11], obestatin, secretin, and serotonin) factors play a role in counterbalancing acid secretion. Under physiologic circumstances, these phases occur simultaneously. Ghrelin, the appetite-regulating hormone expressed in Gr cells in the stomach, and its related peptide motilin (released from the duodenum) may increase gastric acid secretion through stimulation of histamine release from ECL cells, but this remains to be confirmed.

The acid-secreting parietal cell is located in the oxyntic gland, adjacent to other cellular elements (ECL cell, D cell) important in the gastric secretory process **(Fig. 335-5)**. This unique cell also secretes intrinsic factor (IF) and IL-11. The parietal cell expresses receptors for several stimulants of acid secretion, including histamine (H_2), gastrin (cholecystokinin 2/gastrin receptor), and acetylcholine (muscarinic, M_3). Binding of histamine to the H_2 receptor and activation of the

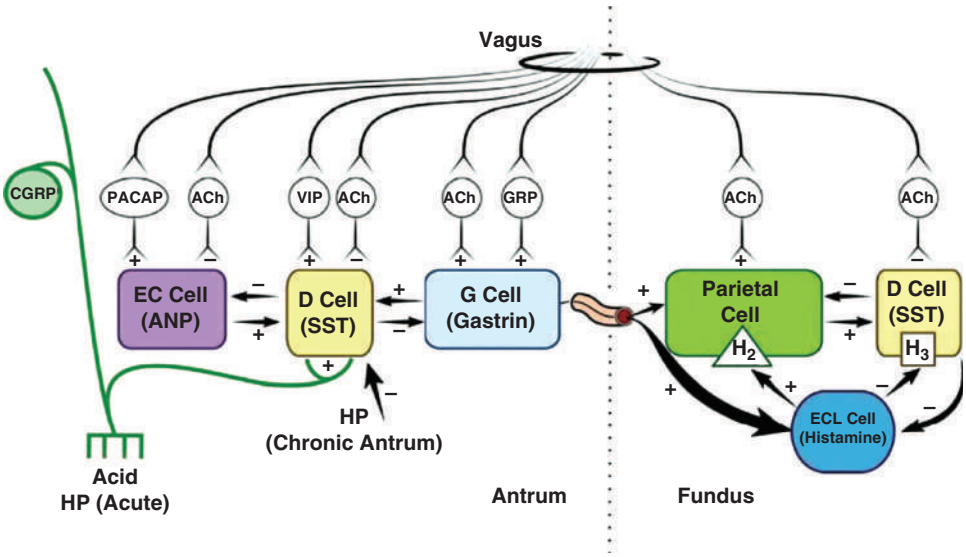

FIGURE 335-5 Regulation of gastric acid secretion at the cellular level. ACh, acetylcholine; ANP, atrial natriuretic peptide; CGRP, calcitonin gene-related peptide; EC, enterochromaffin; ECL, enterochromaffin-like; GRP, gastrin-releasing peptide; PACAP, pituitary adenylate-cyclase activating peptide; SST, somatostatin; VIP, vasoactive intestinal peptide.

gastrin and muscarinic receptors result in stimulation of downstream signaling pathways, which in turn regulates the acid-secreting pump, H^+,K^+-ATPase. Parietal cells also express receptors for ligands that inhibit acid production (glucagon-like peptide 1, prostaglandins, somatostatin, EGF, neurotensin, and urocortin). Histamine also stimulates gastric acid secretion indirectly by activating the histamine H_3 receptor on D cells, which inhibits somatostatin release.

The enzyme H^+,K^+-ATPase is responsible for generating the large concentration of H^+ ions. This enzyme uses the chemical energy of adenosine triphosphate (ATP) to transfer H^+ ions from parietal cell cytoplasm to the secretory canaliculi in exchange for K^+. The H^+,K^+-ATPase is located within the secretory canaliculus and in nonsecretory cytoplasmic tubulovesicles. The tubulovesicles are impermeable to K^+, which leads to an inactive pump in this location. The distribution of pumps between the nonsecretory vesicles and the secretory canaliculus varies according to parietal cell activity (Fig. 335-2). Proton pumps are recycled back to the inactive state in cytoplasmic vesicles once parietal cell activation ceases. In addition, acid secretion requires a number of apical and basolateral parietal cell membrane chloride and potassium channels. Parietal cells also express members of the sonic hedgehog (Shh) family proteins, which play an important role in regulating cell types in multiple organs. This family of proteins may also regulate cell differentiation as well as restitution of mucosal defense in the gastric epithelium.

The chief cell, found primarily in the gastric fundus, synthesizes and secretes pepsinogen, the inactive precursor of the proteolytic enzyme pepsin. The acid environment within the stomach leads to cleavage of the inactive precursor to pepsin and provides the low pH (<2) required for pepsin activity. Pepsin activity is significantly diminished at a pH of 4 and irreversibly inactivated and denatured at a pH of ≥7. Many of the secretagogues that stimulate acid secretion also stimulate pepsinogen release. The precise role of pepsin in the pathogenesis of PUD remains to be established.

PATHOPHYSIOLOGIC BASIS OF PUD

PUD encompasses both gastric ulcers (GUs) and duodenal ulcers (DUs). *Ulcers* are defined as breaks in the mucosal surface >5 mm in size, with depth to the submucosa. DUs and GUs share many common features in terms of pathogenesis, diagnosis, and treatment, but several factors distinguish them from one another. *H. pylori* and NSAIDs are the most common risk factors for PUD, with estimated odds ratios in the United States of 3.7 and 3.3, respectively. Additional risk factors (odds ratio) include chronic obstructive lung disease (2.34), chronic renal insufficiency (2.29), current tobacco use (1.99), former tobacco use (1.55), older age (1.67), three or more doctor visits in a year (1.49), coronary heart disease (1.46), former alcohol use (1.29), African-American race (1.20), obesity (1.18), and diabetes (1.13). Selective serotonin reuptake inhibitors (SSRIs) and gastric bypass surgery are also associated with an increased incidence of PUD. A rise in idiopathic PUD has also been noted. The mechanisms by which some of these risk factors lead to ulcer disease are highlighted below.

Epidemiology • **DUODENAL ULCERS** DUs are estimated to occur in 6–15% of the Western population. The incidence of DUs declined steadily from 1960 to 1980 and has remained stable since then. The death rates, need for surgery, and physician visits have decreased by >50% over the past 30 years. The reason for the reduction in the frequency of DUs is likely related to the decreasing frequency of *H. pylori* in turn associated with overall improved sanitary conditions across the world. Before the discovery of *H. pylori*, the natural history of DUs was typified by frequent recurrences after initial therapy. Eradication of *H. pylori* has reduced these recurrence rates by >80%.

GASTRIC ULCERS GUs tend to occur later in life than duodenal lesions, with a peak incidence reported in the sixth decade. More than one-half of GUs occur in males and are less common than DUs, perhaps due to the higher likelihood of GUs being silent and presenting only after a complication develops. Autopsy studies suggest a similar incidence of DUs and GUs.

Pathology • **DUODENAL ULCERS** DUs occur most often in the first portion of the duodenum (>95%), with ~90% located within 3 cm of the pylorus. They are usually ≤1 cm in diameter but can occasionally reach 3–6 cm (giant ulcer). Ulcers are sharply demarcated, with depth at times reaching the muscularis propria. The base of the ulcer often consists of a zone of eosinophilic necrosis with surrounding fibrosis. Malignant DUs are extremely rare.

GASTRIC ULCERS In contrast to DUs, GUs can represent a malignancy and should be biopsied upon discovery. Benign GUs are most often found distal to the junction between the antrum and the acid secretory mucosa. Benign GUs are quite rare in the gastric fundus and are histologically similar to DUs. Benign GUs associated with *H. pylori* are also associated with antral gastritis. In contrast, NSAID-related GUs are not accompanied by chronic active gastritis but may instead have evidence of a chemical gastropathy, typified by foveolar hyperplasia, edema of the lamina propria, and epithelial regeneration in the absence of *H. pylori*. Extension of smooth-muscle fibers into the upper portions of the mucosa, where they are not typically found, may also occur.

Pathophysiology • **DUODENAL ULCERS** *H. pylori* and NSAID-induced injuries account for the majority of DUs. Many acid secretory

abnormalities have been described in DU patients. Of these, average basal and nocturnal gastric acid secretion appears to be increased in DU patients as compared to controls; however, the level of overlap between DU patients and control subjects is substantial. The reason for this altered secretory process is unclear, but *H. pylori* infection may contribute. Bicarbonate secretion is significantly decreased in the duodenal bulb of patients with an active DU as compared to control subjects. *H. pylori* infection may also play a role in this process (see below).

GASTRIC ULCERS As in DUs, the majority of GUs can be attributed to either *H. pylori* or NSAID-induced mucosal damage. Prepyloric GUs or those in the body associated with a DU or a duodenal scar are similar in pathogenesis to DUs. Gastric acid output (basal and stimulated) tends to be normal or decreased in GU patients. When GUs develop in the presence of minimal acid levels, impairment of mucosal defense factors may be present.

***H. PYLORI* AND ACID PEPTIC DISORDERS** Although gastric infection with the bacterium *H. pylori* was once thought to account for the majority of PUD **(Chap. 168)**, more recent studies suggest that only one-fourth of DUs and one-sixth of GUs were associated with *H. pylori* infection. These changes are likely due to successful rates of eradication of the organism coupled with improved sanitary conditions. It appears that NSAIDs have become the most common cause of PUD (see below). This organism also plays a role in the development of gastric mucosa-associated lymphoid tissue (MALT) lymphoma and gastric adenocarcinoma. Although the entire genome of *H. pylori* has been sequenced, it is still not clear how this organism, which resides in the stomach, causes ulceration in the duodenum. *H. pylori* eradication efforts may lead to a decrease in gastric cancer in high-risk populations, particularly in individuals who have not developed chronic atrophic gastritis and gastric metaplasia.

The Bacterium The bacterium, initially named *Campylobacter pylori-dis*, is a gram-negative microaerophilic rod found most commonly in the deeper portions of the mucous gel coating the gastric mucosa or between the mucous layer and the gastric epithelium. It may attach to gastric epithelium but under normal circumstances does not appear to invade cells. It is strategically designed to live within the aggressive environment of the stomach. It is S-shaped (~0.5–3 μm in size) and contains multiple sheathed flagella. Initially, *H. pylori* resides in the antrum but, over time, migrates toward the more proximal segments of the stomach. The organism is capable of transforming into a coccoid form, which represents a dormant state that may facilitate survival in adverse conditions. The genome of *H. pylori* (1.65 million base pairs) encodes ~1500 proteins. Among this multitude of proteins, some factors are essential determinants of *H. pylori*–mediated pathogenesis and colonization such as the outer membrane protein (Hop proteins), urease, and the vacuolating cytotoxin (Vac A). Moreover, the majority of *H. pylori* strains contain a genomic fragment that encodes the cag pathogenicity island (cag-PAI). Several of the genes that make up cag-PAI encode components of a type IV secretion island that translocates Cag A into host cells. Once in the cell, Cag A activates a series of cellular events important in cell growth and cytokine production. *H. pylori* also has extensive genetic diversity that in turn enhances its ability to promote disease. The first step in infection by *H. pylori* is dependent on the bacteria's motility and its ability to produce urease. Urease produces ammonia from urea, an essential step in alkalinizing the surrounding pH. Additional bacterial factors include but are not limited to, catalase, lipase, adhesins, platelet-activating factor, and pic B (induces cytokines). Multiple strains of *H. pylori* exist and are characterized by their ability to express several of these factors (Cag A, Vac A, etc.). It is possible that the different diseases related to *H. pylori* infection can be attributed to different strains of the organism with distinct pathogenic features.

Epidemiology The prevalence of *H. pylori* varies throughout the world and depends largely on the overall standard of living in the region, with overall global prevalence decreasing. The global prevalence of *H. pylori* infection in adults has declined from 50–55% to 43% during 2014 to 2020. Contributing factors to these changes likely include improvement of socioeconomic status and living standards as well as enhanced hygiene conditions. It is also possible that the increased use of antibiotics specifically with eradication therapies in individuals with infection could be a contributing factor to the overall decrease in global prevalence with a high variability in *H. pylori* infection throughout the world. In developing parts of the world, 80% of the population may be infected by the age of 20, whereas the prevalence is 20–50% in industrialized countries. In contrast, in the United States, this organism is rare in childhood. The overall prevalence of *H. pylori* in the United States is ~30%, with individuals born before 1950 having a higher rate of infection than those born later. About 10% of Americans <30 years of age are colonized with the bacteria. The rate of infection with *H. pylori* in industrialized countries has decreased substantially in recent decades. The steady increase in the prevalence of *H. pylori* noted with increasing age is due primarily to a cohort effect, reflecting higher transmission during a period in which the earlier cohorts were children. It has been calculated through mathematical models that improved sanitation during the latter half of the nineteenth century dramatically decreased transmission of *H. pylori.* Moreover, with the present rate of intervention, the organism ultimately will be eliminated from the United States. Two factors that predispose to higher colonization rates include poor socioeconomic status and less education about the organism. These factors, not race, are responsible for the rate of *H. pylori* infection in blacks and Hispanic Americans being double the rate seen in whites of comparable age. Other risk factors for *H. pylori* infection are (1) birth or residence in a developing country, (2) domestic crowding, (3) unsanitary living conditions, (4) unclean food or water, and (5) exposure to gastric contents of an infected individual.

Transmission of *H. pylori* occurs from person to person, following an oral-oral or fecal-oral route. The risk of *H. pylori* infection is declining in developing countries. The rate of infection in the United States has fallen by >50% when compared to 30 years ago.

Pathophysiology *H. pylori* infection is virtually always associated with a chronic active gastritis, but only 10–15% of infected individuals develop frank peptic ulceration. The basis for this difference is unknown but is likely due to a combination of host and bacterial factors, some of which are outlined below. Initial studies suggested that >90% of all DUs were associated with *H. pylori*, but *H. pylori* is present in only one-sixth of individuals with GUs and one-fourth of patients with DUs. The pathophysiology of ulcers not associated with *H. pylori* or NSAID ingestion (or the rare Zollinger-Ellison syndrome [ZES]) is becoming more relevant as the incidence of *H. pylori* is dropping, particularly in the Western world (see below).

The particular end result of *H. pylori* infection (gastritis, PUD, gastric MALT lymphoma, gastric cancer) is determined by a complex interplay between bacterial and host factors **(Fig. 335-6)**.

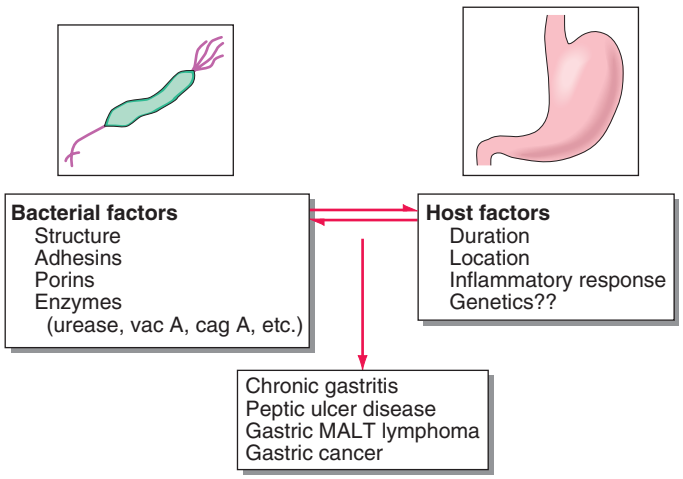

FIGURE 335-6 Outline of the bacterial and host factors important in determining *H. pylori*–induced gastrointestinal disease. MALT, mucosal-associated lymphoid tissue.

Bacterial factors: H. pylori is able to facilitate gastric residence, induce mucosal injury, and avoid host defense. Different strains of *H. pylori* produce different virulence factors including γ-glutamyl transpeptidase (GGT), cytotoxin-associated gene A (Cag A) product, and virulence components vacuolating toxin (Vac A), in addition to pathogen-associated molecular patterns (PAMPs) such as flagella and lipopolysaccharide (LPS). A specific region of the bacterial genome, the pathogenicity island (cag-PAI), encodes the virulence factors Cag A and pic B. Vac A also contributes to pathogenicity, although it is not encoded within the pathogenicity island. These virulence factors, in conjunction with additional bacterial constituents, can cause mucosal damage, in part through their ability to target the host immune cells. For example, Vac A targets human CD4 T cells, inhibiting their proliferation, and in addition can disrupt normal function of B cells, CD8 T cells, macrophages, and mast cells. Multiple studies have demonstrated that *H. pylori* strains that are cag-PAI positive are associated with a higher risk of PUD, premalignant gastric lesions, and gastric cancer than are strains that lack the cag-PAI. In addition, *H. pylori* may directly inhibit parietal cell H^+,K^+-ATPase activity through a Cag A–dependent mechanism, leading in part to the low acid production observed after acute infection with the organism. Urease, which allows the bacteria to reside in the acidic stomach, generates NH_3, which can damage epithelial cells. The bacteria produce surface factors that are chemotactic for neutrophils and monocytes, which in turn contribute to epithelial cell injury (see below). *H. pylori* makes proteases and phospholipases that break down the glycoprotein lipid complex of the mucous gel, thus reducing the efficacy of this first line of mucosal defense. *H. pylori* expresses adhesins (outer membrane proteins like BabA), which facilitate attachment of the bacteria to gastric epithelial cells. Although LPS of gram-negative bacteria often plays an important role in the infection, *H. pylori* LPS has low immunologic activity compared to that of other organisms. It may promote a smoldering chronic inflammation.

Host factors: Studies in twins suggest that there may be genetic predisposition to acquire *H. pylori.* The inflammatory response to *H. pylori* includes recruitment of neutrophils, lymphocytes (T and B), macrophages, and plasma cells. The pathogen leads to local injury by binding to class II major histocompatibility complex (MHC) molecules expressed on gastric epithelial cells, leading to cell death (*apoptosis*). Moreover, bacterial strains that encode cag-PAI can introduce Cag A into the host cells, leading to further cell injury and activation of cellular pathways involved in cytokine production and repression of tumor-suppressor genes. Elevated concentrations of multiple cytokines are found in the gastric epithelium of *H. pylori*–infected individuals, including interleukin (IL) 1α/β, IL-2, IL-6, IL-8, tumor necrosis factor (TNF) α, and interferon (IFN) γ. *H. pylori* infection also leads to both a mucosal and a systemic humoral response, which does not lead to eradication of the bacteria but further compounds epithelial cell injury. Additional mechanisms by which *H. pylori* may cause epithelial cell injury include (1) activated neutrophil-mediated production of reactive oxygen or nitrogen species and enhanced epithelial cell turnover and (2) apoptosis related to interaction with T cells (T helper 1 [T_H1] cells) and IFN-γ. Finally, the human stomach is colonized by a host of commensal organisms that may affect the likelihood of *H. pylori* infection and subsequent mucosal injury. Moreover, colonization of the stomach with *H. pylori* likely alters the composition of the gastric microbiota. The impact of the latter on gastric pathophysiology remains unknown but some studies suggest a potential increase in the development of gastric cancer. *H. pylori* also appears to regulate NO formation via different mechanisms that in turn may contribute to the organism's cytotoxic effects. Specifically, *H. pylori*–derived factors, such as urease, or the bacterium itself, stimulate NO synthase (NOS2) expression in macrophages and in gastric epithelial cells leading to NO release and subsequent cytotoxic effect on surrounding cells. *H. pylori* also leads to the formation of 8-nitroguanine (8-NO2-Gua), which in conjunction with oncoprotein Cag A, may contribute to the development of gastric cancer.

The basis for *H. pylori*–mediated duodenal ulceration remains unclear. Studies suggest that *H. pylori* associated with duodenal ulceration may be more virulent. In addition, certain specific bacterial factors such as the DU-promoting gene A (*dupA*) may be associated with the development of DUs. Another potential contributing factor is that gastric metaplasia in the duodenum of DU patients, which may be due to high acid exposure (see below), permits *H. pylori* to bind to it and produce local injury secondary to the host response. Another hypothesis is that *H. pylori* antral infection could lead to increased acid production, increased duodenal acid, and mucosal injury. Basal and stimulated (meal, gastrin-releasing peptide [GRP]) gastrin release is increased in *H. pylori*–infected individuals, and somatostatin-secreting D cells may be decreased. *H. pylori* infection might induce increased acid secretion through both direct and indirect actions of *H. pylori* and proinflammatory cytokines (IL-8, TNF, and IL-1) on G, D, and parietal cells **(Fig. 335-7)**. GUs, in contrast, are associated with *H. pylori*–induced pangastritis and normal or low gastric acid secretion. The *H. pylori*–mediated decrease in gastric acid secretion after long-term infection may be due to the bacterium's ability to inhibit H^+,K^+-ATPase expression. *H. pylori* infection has also been associated with decreased duodenal mucosal bicarbonate production. Data supporting and contradicting each of these interesting theories have been demonstrated. Thus, the mechanism by which *H. pylori* infection of the stomach leads to duodenal ulceration remains to be established. The development of in vitro organoids, a unique tool that replicates in part the multicellular structure of the intact organ, provides a more physiologic model for experimentation in an in vitro system. Moreover, the development of advanced microscopic optical imaging techniques will lead to increased understanding of parietal cell adaptation to *H. pylori* infection.

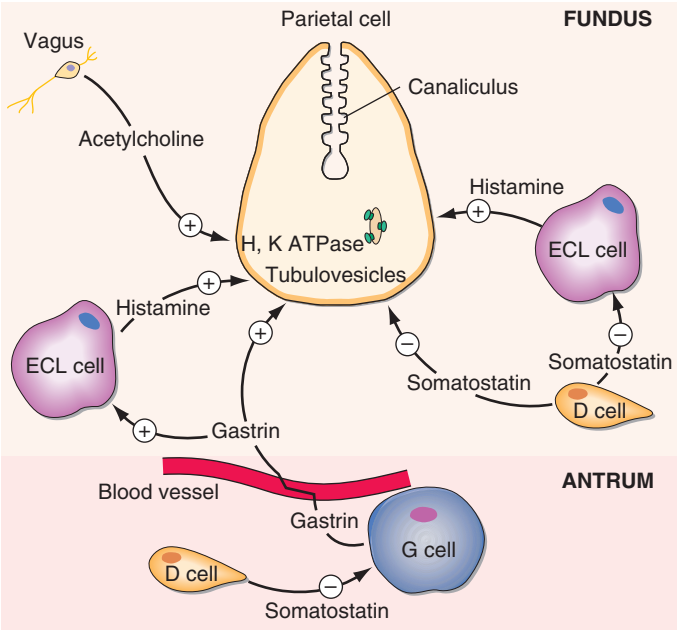

FIGURE 335-7 Summary of potential mechanisms by which *H. pylori* may lead to gastric secretory abnormalities. D, somatostatin cell; ECL, enterochromaffin-like cell; G, G cell. *(Reproduced with permission from J Calam et al: How does Helicobacter pylori cause mucosal damage? Its effect on acid and gastrin physiology. Gastroenterology 113:543, 1997.)*

In summary, the final effect of *H. pylori* on the GI tract is variable and determined by microbial and host factors. The type and distribution of gastritis correlate with the ultimate gastric and duodenal pathology observed. Specifically, the presence of antral-predominant gastritis is associated with DU formation; gastritis involving primarily the corpus predisposes to the development of GUs, gastric atrophy, and ultimately gastric carcinoma **(Fig. 335-8)**.

NSAID-INDUCED DISEASE

Epidemiology NSAIDs represent a group of the most commonly used medications in the world and the United States. It is estimated that 7 billion dollars per year are spent on NSAIDs worldwide, with >30 billion over-the-counter tablets sold. More than 30 million individuals take NSAIDs, with >100 million prescriptions sold yearly in the United States

FIGURE 335-9 Effect of nonsteroidal anti-inflammatory drugs (NSAIDs) on different target organs. The action of NSAIDs on major organs including stomach, small intestine, heart, liver, kidney, respiratory tract, and brain is mainly mediated through prostaglandin endoperoxide synthase (PGHS)–dependent prostanoid modulation and alteration of mitochondrial functional integrity leading to mitochondrial oxidative stress (MOS) generation, depolarization of mitochondrial transmembrane potential ($\Delta\Psi m$), and consequent cell death. However, in heart, low-dose aspirin actually offers cardioprotection through antithrombotic effect. *Upward arrows* indicate upregulation/elevation; *downward arrows* indicate downregulation/depletion. *(From S Bindu et al: Non-steroidal anti-inflammatory drugs (NSAIDs) and organ damage: A current perspective. Biochem Pharmacol 180:114147, 2020.)*

alone. In fact, after the introduction of COX-2 inhibitors in the year 2000, the number of prescriptions written for NSAIDs was >111 million at a cost of $4.8 billion. Side effects and complications due to NSAIDs are considered the most common drug-related toxicities in the United States. The spectrum of NSAID-induced morbidity ranges from nausea and dyspepsia (prevalence reported as high as 50–60%) to a serious GI complication such as endoscopy-documented peptic ulceration (15–30% of individuals taking NSAIDs regularly), which is complicated by bleeding or perforation in as many as 1.5% of users per year. It is estimated that NSAID-induced GI bleeding accounts for 60,000–120,000 hospital admissions per year, and deaths related to NSAID-induced toxicity may be as high as 16,000 per year in the United States. Approximately 4–5% of patients develop symptomatic ulcers within 1 year. Unfortunately, dyspeptic symptoms do not correlate with NSAID-induced pathology. Over 80% of patients with serious NSAID-related complications did not have preceding dyspepsia. In view of the lack of warning signs, it is important to identify patients who are at increased risk for morbidity and mortality related to NSAID usage. Even 75 mg/d of aspirin may lead to serious GI ulceration; thus, no dose of NSAID is completely safe. In fact, the incidence of mucosal injury (ulcers and erosions) in patients taking low-dose aspirin (75–325 mg) has been estimated to range from as low as 8 to as high as 60%. It appears that *H. pylori* infection increases the risk of PUD-associated GI bleeding in chronic users of low-dose aspirin. Established risk factors include advanced age, history of ulcer, concomitant use of glucocorticoids, high-dose NSAIDs, multiple NSAIDs, concomitant use of anticoagulants or clopidogrel, and serious or multisystem disease. Possible risk factors include concomitant infection with *H. pylori*, cigarette smoking, and alcohol consumption. SSRIs have a synergistic effect on the induction of GI bleeding believed to be due in part to this agent's ability to decrease platelet aggregation by decreasing serotonin content in platelets.

Pathophysiology Prostaglandins play a critical role in maintaining gastroduodenal mucosal integrity and repair. It therefore follows that interruption of prostaglandin synthesis can impair mucosal defense and repair, thus facilitating mucosal injury via a systemic mechanism. Animal studies have demonstrated that neutrophil adherence to the gastric microcirculation plays an essential role in the initiation of NSAID-induced mucosal injury. A summary of the pathogenetic pathways by which systemically administered NSAIDs may lead to mucosal injury is shown in **Fig. 335-9**. Single nucleotide polymorphisms (SNPs) have been found in several genes, including those encoding certain subtypes of cytochrome P450 (see below), IL-1β (*IL-1β*), angiotensinogen (*AGT*), and an organic ion transporting polypeptide (*SLCO1B1*), but these findings need confirmation in larger-scale studies.

Injury to the mucosa also occurs as a result of the topical use of NSAIDs, leading to increased epithelial surface permeability. Aspirin and many NSAIDs are weak acids that remain in a nonionized lipophilic form when found within the acid environment of the stomach. Under these conditions, NSAIDs migrate across lipid membranes of epithelial cells, leading to cell injury once trapped intracellularly in an ionized form. Topical NSAIDs can also alter the surface mucous layer, permitting back diffusion of H^+ and pepsin, leading to further epithelial cell damage. Moreover, enteric-coated or buffered preparations are also associated with risk of peptic ulceration. NSAIDs can also lead to mucosal injury via production of additional proinflammatory mediators such as TNF and leukotrienes through simultaneous activation of the lipoxygenase pathway.

The interplay between *H. pylori* and NSAIDs in the pathogenesis of PUD is complex. Meta-analysis supports the conclusion that each of these aggressive factors is an independent and synergistic risk factor for PUD and its complications such as GI bleeding. For example, eradication of *H. pylori* reduces the likelihood of GI complications in high-risk individuals to levels observed in individuals with average risk of NSAID-induced complications.

In summary, NSAID-induced mucosal injury is a multifaceted process involving the interaction of multiple, often synergistic pathophysiologic processes at the epithelium and surrounding interfaces.

PATHOGENETIC FACTORS UNRELATED TO *H. PYLORI* AND NSAIDS IN ACID PEPTIC DISEASE Cigarette smoking has been implicated in the pathogenesis of PUD. Not only have smokers been found to have ulcers more frequently than do nonsmokers, but smoking appears to decrease healing rates, impair response to therapy, and increase ulcer-related complications such as perforation. The mechanism responsible for increased ulcer diathesis in smokers is unknown. Theories have included altered gastric emptying, decreased proximal duodenal bicarbonate production, increased risk for *H. pylori* infection, and cigarette-induced generation of noxious mucosal free radicals. Genetic predisposition may play a role in ulcer development. First-degree relatives of DU patients are three times as likely to develop an ulcer; however, the potential role of *H. pylori* infection in contacts is a major consideration. Increased frequencies of blood group O and of the nonsecretor status have also been implicated as genetic risk factors for peptic diathesis. However, *H. pylori* preferentially binds to group O antigens. Additional genetic factors have been postulated to predispose certain

individuals to developing PUD and/or upper GI bleeding. Specifically, genes encoding the NSAID-metabolizing enzymes cytochrome P450 2C9 and 2C8 (CYP2C9 and CYP2C8) are potential susceptibility genes for NSAID-induced PUD, but unfortunately, the studies have not been consistent in demonstrating this association. In a United Kingdom study, the *CYP2C19*17* gain-of-function polymorphism was associated with PUD in a Caucasian cohort, irrespective of ulcer etiology. These findings need to be confirmed in broader studies. Psychological stress has been thought to contribute to PUD, but studies examining the role of psychological factors in its pathogenesis have generated conflicting results. Although PUD is associated with certain personality traits (neuroticism), these same traits are also present in individuals with nonulcer dyspepsia (NUD) and other functional and organic disorders.

Diet has also been thought to play a role in peptic diseases. Certain foods and beverages can cause dyspepsia, but no convincing studies indicate an association between ulcer formation and a specific diet. Specific chronic disorders have been shown to have a strong association with PUD: (1) advanced age, (2) chronic pulmonary disease, (3) chronic renal failure, (4) cirrhosis, (5) nephrolithiasis, (6) α_1-antitrypsin deficiency, and (7) systemic mastocytosis. Disorders with a possible association are (1) hyperparathyroidism, (2) coronary artery disease, (3) polycythemia vera, (4) chronic pancreatitis, (5) former alcohol use, (6) obesity, (7) African-American race, and (8) three or more doctor visits in a year.

Multiple factors play a role in the pathogenesis of PUD. The two predominant causes are *H. pylori* infection and NSAID ingestion. PUD not related to *H. pylori* or NSAIDs is increasing. Other less common causes of PUD are shown in **Table 335-1**. These etiologic agents should be considered as the incidence of *H. pylori* is decreasing. Independent of the inciting or injurious agent, peptic ulcers develop as a result of an imbalance between mucosal protection/repair and aggressive factors. Gastric acid plays an important role in mucosal injury.

CLINICAL FEATURES

History Abdominal pain is common to many GI disorders, including DU and GU, but it has a poor predictive value for the presence of either DU or GU. Approximately two-thirds of patients with PUD do not have abdominal pain, and up to 87% of patients with NSAID-induced mucosal disease can present with a complication (bleeding, perforation, and obstruction) without antecedent symptoms. Despite this poor correlation, a careful history and physical examination are essential components of the approach to a patient suspected of having peptic ulcers.

Duodenal obstruction (e.g., annular pancreas)
Infiltrating disease
Ischemia
Radiation therapy
Eosinophilic infiltration
Sarcoidosis
Crohn's disease
Idiopathic hypersecretory state

Abbreviations: Hp, *H. pylori*; NSAIDs, nonsteroidal anti-inflammatory drugs.

Epigastric pain described as a burning or gnawing discomfort can be present in both DU and GU. The discomfort is also described as an ill-defined, aching sensation or as hunger pain. The typical pain pattern in DU occurs 90 min to 3 h after a meal and is frequently relieved by antacids or food. Pain that awakes the patient from sleep (between midnight and 3 A.M.) is the most discriminating symptom, with two-thirds of DU patients describing this complaint. Unfortunately, this symptom is also present in one-third of patients with NUD (see below). Elderly patients are less likely to have abdominal pain as a manifestation of PUD and may instead present with a complication such as ulcer bleeding or perforation. The pain pattern in GU patients may be different from that in DU patients, where discomfort may actually be precipitated by food. Nausea and weight loss occur more commonly in GU patients. Endoscopy detects ulcers in <30% of patients who have dyspepsia.

The mechanism for development of abdominal pain in ulcer patients is unknown. Several possible explanations include acid-induced activation of chemical receptors in the duodenum, enhanced duodenal sensitivity to bile acids and pepsin, and altered gastroduodenal motility.

Variation in the intensity or distribution of the abdominal pain, as well as the onset of associated symptoms such as nausea and/or vomiting, may be indicative of an ulcer complication. Dyspepsia that becomes constant, is no longer relieved by food or antacids, or radiates to the back may indicate a penetrating ulcer (pancreas). Sudden onset of severe, generalized abdominal pain may indicate perforation. Pain worsening with meals, nausea, and vomiting of undigested food suggest gastric outlet obstruction. Tarry stools or coffee-ground emesis indicate bleeding.

Physical Examination Epigastric tenderness is the most frequent finding in patients with GU or DU. Pain may be found to the right of the midline in 20% of patients. Unfortunately, the predictive value of this finding is low. Physical examination is critically important for discovering evidence of ulcer complication. Tachycardia and orthostasis suggest dehydration secondary to vomiting or active GI blood loss. A severely tender, board-like abdomen suggests a perforation. Presence of a succussion splash indicates retained fluid in the stomach, suggesting gastric outlet obstruction.

PUD-Related Complications • **GASTROINTESTINAL BLEEDING** GI bleeding is the most common complication observed in PUD. Bleeding is estimated to occur in 19.4–57 per 100,000 individuals in a general population or in ~15% of patients. Bleeding and complications of ulcer disease occur more often in individuals >60 years of age. The 30-day mortality rate is as high as 2.5–10%. The higher incidence in the elderly is likely due to the increased use of NSAIDs in this group. In addition, up to 80% of the mortality in PUD-related bleeding is due to nonbleeding causes such as multiorgan failure (24%), pulmonary complications (24%), and malignancy (34%).

Greater than 50% of patients with ulcer-related hemorrhage bleed without any preceding warning signs or symptoms.

PERFORATION The second most common ulcer-related complication is perforation, being reported in as many as 6–7% of PUD patients with an estimated 30-day mortality of >20%. Acute abdominal pain, tachycardia, and abdominal rigidity compose the classic triad associated with this complication. It is essential to remember that elderly patients or individuals who are immunosuppressed may not have this classic presentation. As in the case of bleeding, the incidence of perforation in the elderly appears to be increasing secondary to increased use of NSAIDs. Perforation of DUs has become less common in light of the increased rates of *H. pylori* eradication, with NSAID-induced GUs leading to perforation occurring more commonly. *Penetration* is

a form of perforation in which the ulcer bed tunnels into an adjacent organ. DUs tend to penetrate posteriorly into the pancreas, leading to pancreatitis, whereas GUs tend to penetrate into the left hepatic lobe. Gastrocolic fistulas associated with GUs have also been described. Mortality for this complication can be >20% within 30 days.

GASTRIC OUTLET OBSTRUCTION Gastric outlet obstruction is the least common ulcer-related complication, occurring in 1–2% of patients. A patient may have relative obstruction secondary to ulcer-related inflammation and edema in the peripyloric and duodenal region. This process often resolves with ulcer healing. A fixed, mechanical obstruction secondary to scar formation in the peripyloric areas is also possible. The latter requires endoscopic (balloon dilation with or without placement of a biodegradable stent) or surgical intervention with a stricturoplasty or gastrojejunostomy. Signs and symptoms relative to mechanical obstruction may develop insidiously. New onset of early satiety, nausea, vomiting, increase of postprandial abdominal pain, and weight loss should make gastric outlet obstruction a possible diagnosis.

Differential Diagnosis The list of GI and non-GI disorders that can mimic ulceration of the stomach or duodenum is quite extensive. The most commonly encountered diagnosis among patients seen for upper abdominal discomfort is functional dyspepsia (FD) or *essential dyspepsia*, which refers to a group of heterogeneous disorders typified by upper abdominal pain without the presence of an ulcer. The symptoms can range from postprandial fullness and early satiety to epigastric burning pain. The dichotomy of this symptom complex has led to the identification of two subcategories of FD including postprandial distress syndrome (PDS) and epigastric pain syndrome (EPS). Dyspepsia has been reported to occur in up to 30% of the U.S. population. Up to 80% of patients seeking medical care for dyspepsia have a negative diagnostic evaluation. The etiology of FD is not established, but postinfectious states, certain foods, and *H. pylori* infection may contribute to the pathogenesis of this common disorder.

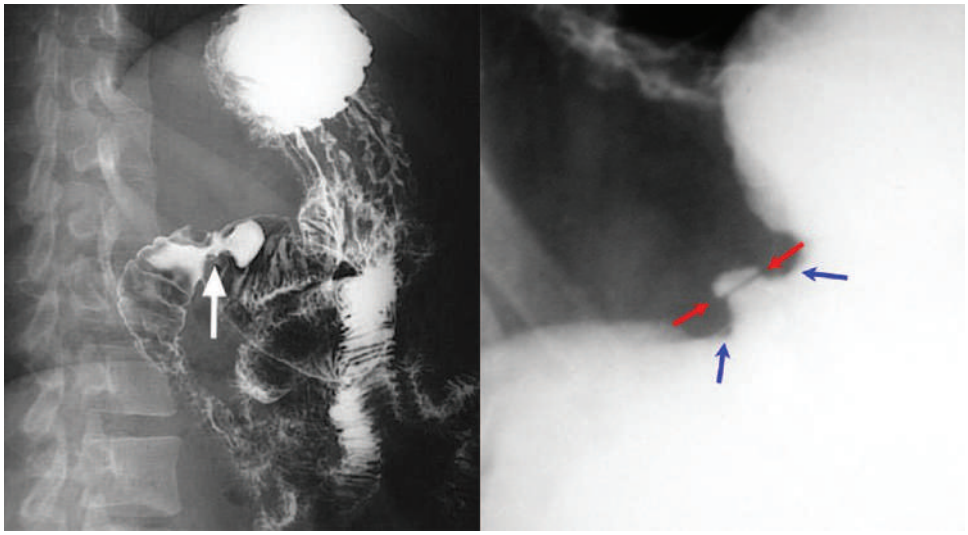
Several additional disease processes that may present with "ulcer-like" symptoms include proximal GI tumors, gastroesophageal reflux, vascular disease, pancreaticobiliary disease (biliary colic, chronic pancreatitis), and gastroduodenal Crohn's disease.

Diagnostic Evaluation In view of the poor predictive value of abdominal pain for the presence of a gastroduodenal ulcer and the multiple disease processes that can mimic this disease, the clinician is often confronted with having to establish the presence of an ulcer. Documentation of an ulcer requires either a radiographic (barium study, rarely done in today's environment) or an endoscopic procedure. However, a large percentage of patients with symptoms suggestive of an ulcer have NUD; testing for *H. pylori* and antibiotic therapy (see below) are appropriate for individuals who are otherwise healthy, without red flag signs such as nausea, vomiting, weight loss, or evidence of GI bleeding and <60 years of age, before embarking on a diagnostic evaluation **(Chap. 48)**.

Barium studies of the proximal GI tract are rarely used as a first test for documenting an ulcer **(Fig. 335-10)**. Endoscopy provides the most sensitive and specific approach for examining the upper GI tract **(Fig. 335-11)**. In addition to permitting direct visualization of the mucosa, endoscopy facilitates photographic documentation of a mucosal defect and tissue biopsy to rule out malignancy (GU) or *H. pylori*. Endoscopic examination is particularly helpful in identifying lesions too small to detect by radiographic examination, for evaluation of atypical radiographic abnormalities, or to determine if an ulcer is a source of blood loss.

Although the methods for diagnosing *H. pylori* are outlined in **Chap. 168**, a brief summary will be included here **(Table 335-2)**. Several biopsy urease tests have been developed (PyloriTek, CLOtest, Hpfast, Pronto Dry) that have a sensitivity and specificity of >90–95%. Several noninvasive methods for detecting this organism have been developed. Three types of studies routinely used include serologic testing, the ^{13}C-urea breath test, and the fecal *H. pylori* (Hp) antigen test (monoclonal antibody test). A urinary Hp antigen test and a home breath test appear promising.

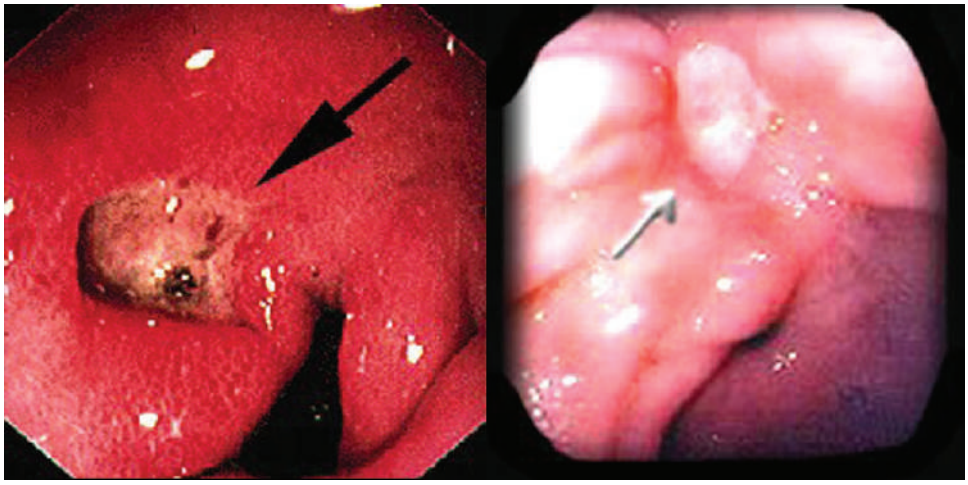
Occasionally, specialized testing such as serum gastrin and gastric acid analysis may be needed in individuals with complicated or refractory PUD (see "Zollinger-Ellison Syndrome," below). Screening for aspirin or NSAIDs (blood or urine) may also be necessary in refractory *H. pylori*–negative PUD patients.



TREATMENT

Peptic Ulcer Disease

Before the discovery of *H. pylori*, the therapy of PUD was centered on the old dictum by Schwartz of "no acid, no ulcer." Although acid secretion is still important in the pathogenesis of PUD, eradication of *H. pylori* and therapy/prevention of NSAID-induced disease is the mainstay of treatment. A summary of commonly used drugs for treatment of acid peptic disorders is shown in **Table 335-3**.



ACID-NEUTRALIZING/INHIBITORY DRUGS

Antacids Before we understood the important role of histamine in stimulating parietal cell activity, neutralization of secreted acid with antacids constituted the main form of therapy for peptic ulcers. They are now rarely, if ever, used as the primary therapeutic agent

A **B**

A *B*

FIGURE 335-11 Endoscopy demonstrating (*A*) a benign duodenal ulcer and (*B*) a benign gastric ulcer.

but instead are often used by patients for symptomatic relief of dyspepsia. The most commonly used agents are mixtures of aluminum hydroxide and magnesium hydroxide. Aluminum hydroxide can produce constipation and phosphate depletion; magnesium hydroxide may cause loose stools. Many of the commonly used antacids (e.g., Maalox, Mylanta) have a combination of both aluminum and magnesium hydroxide in order to avoid these side effects. The magnesium-containing preparation should not be used in chronic renal failure patients because of possible hypermagnesemia, and aluminum may cause chronic neurotoxicity in these patients.

Calcium carbonate and sodium bicarbonate are potent antacids with varying levels of potential problems. The long-term use of calcium carbonate (converts to calcium chloride in the stomach) can lead to milk-alkali syndrome (hypercalcemia and hyperphosphatemia with possible renal calcinosis and progression to renal insufficiency). Sodium bicarbonate may induce systemic alkalosis.

H_2 Receptor Antagonists Four of these agents are presently available (cimetidine, ranitidine, famotidine, and nizatidine), and their structures share homology with histamine. Although each has different potency, all will significantly inhibit basal and stimulated acid secretion to comparable levels when used at therapeutic doses. Moreover, similar ulcer-healing rates are achieved with each drug when used at the correct dosage. Presently, this class of drug is often used for treatment of active ulcers (4–6 weeks) in combination with antibiotics directed at eradicating *H. pylori* (see below).

Cimetidine was the first H_2 receptor antagonist used for the treatment of acid peptic disorders. Cimetidine may have weak antiandrogenic side effects resulting in reversible gynecomastia and impotence, primarily in patients receiving high doses for prolonged periods of time (months to years). In view of cimetidine's ability to inhibit cytochrome P450, careful monitoring of drugs such as warfarin, phenytoin, and theophylline is indicated with long-term usage. Other rare reversible adverse effects reported with cimetidine include confusion and elevated levels of serum aminotransferases, creatinine, and serum prolactin. Famotidine is a more potent H_2 receptor antagonists than cimetidine. It can be used once a day at bedtime for ulcer prevention, which was commonly done before the discovery of *H. pylori* and the development of proton pump inhibitors (PPIs). Patients may develop tolerance to H_2 blockers, a rare event with PPIs (see below). Comparable nighttime dosing regimens are cimetidine 800 mg and famotidine 40 mg.

Additional rare, reversible systemic toxicities reported with H_2 receptor antagonists include pancytopenia, neutropenia, anemia, and thrombocytopenia, with a prevalence rate varying from 0.01 to 0.2%. Cimetidine can bind to hepatic cytochrome P450; famotidine does not.

Proton Pump (H^+,K^+-ATPase) Inhibitors Omeprazole, esomeprazole, lansoprazole, rabeprazole, and pantoprazole are substituted

TABLE 335-2 Tests for Detection of *Helicobacter pylori*

TEST	SENSITIVITY/ SPECIFICITY, %	COMMENTS
Invasive (Endoscopy/Biopsy Required)		
Rapid urease	80–95/95–100	Simple, false negative with recent use of PPIs, antibiotics, or bismuth compounds
Histology	60–90/>95	Requires pathology processing and staining; provides histologic information
Culture	76-90/100	Time-consuming, expensive, dependent on experience; allows determination of antibiotic susceptibility
Noninvasive		
Serology	74.4/59	Inexpensive, convenient; not useful for early follow-up; cannot distinguish active and prior infection
Urea breath test	>95/>95	Simple, rapid; useful for early follow-up; false negatives with recent therapy (see rapid urease test)
Stool antigen	>95/>95	Inexpensive, convenient

Abbreviation: PPIs, proton pump inhibitors.

TABLE 335-3 Drugs Used in the Treatment of Peptic Ulcer Disease

DRUG TYPE/ MECHANISM	EXAMPLES	DOSE
Acid-Suppressing Drugs		
Antacids	Mylanta, Maalox, Tums, Gaviscon	100–140 meq/L 1 and 3 h after meals and hs
H_2 receptor antagonists	Cimetidine	400 mg bid
	Famotidine	40 mg hs
Proton pump inhibitors	Omeprazole	20 mg/d
	Lansoprazole	30 mg/d
	Rabeprazole	20 mg/d
	Pantoprazole	40 mg/d
	Esomeprazole	20 mg/d
	Dexlansoprazole	30 mg/d
Mucosal Protective Agents		
Sucralfate	Sucralfate	1 g qid
Prostaglandin analogue	Misoprostol	200 μg qid
Bismuth-containing compounds	Bismuth subsalicylate (BSS)	See anti–*H. pylori* regimens (Table 335-4)

Abbreviation: hs, at bedtime (*hora somni*).

benzimidazole derivatives that covalently bind and irreversibly inhibit H^+,K^+-ATPase. Esomeprazole is the S-enantiomer of omeprazole, which is a racemic mixture of both S- and R-optical isomers. The R-isomer of lansoprazole, dexlansoprazole, is the most recent PPI approved for clinical use. Its reported advantage is a dual delayed-release system aimed at improving treatment of gastroesophageal reflux disease (GERD). These are the most potent acid inhibitory agents available. Omeprazole and lansoprazole are the PPIs that have been used for the longest time. Both are acid-labile and are administered as enteric-coated granules in a sustained-release capsule that dissolves within the small intestine at a pH of 6. Lansoprazole is available in an orally disintegrating tablet that can be taken with or without water, an advantage for individuals who have significant dysphagia. Absorption kinetics are similar to the capsule. In addition, a lansoprazole-naproxen combination preparation that has been made available is targeted at decreasing NSAID-related GI injury (see below). Omeprazole is available as non–enteric-coated granules mixed with sodium bicarbonate in a powder form that can be administered orally or via gastric tube. The sodium bicarbonate has two purposes: to protect the omeprazole from acid degradation and to promote rapid gastric alkalinization and subsequent proton pump activation, which facilitates rapid action of the PPI. Pantoprazole and rabeprazole are available as enteric-coated tablets. Pantoprazole is also available as a parenteral formulation for intravenous use. These agents are lipophilic compounds; upon entering the parietal cell, they are protonated and trapped within the acid environment of the tubulovesicular and canalicular system. These agents potently inhibit all phases of gastric acid secretion. Onset of action is rapid, with a maximum acid inhibitory effect between 2 and 6 h after administration and duration of inhibition lasting up to 72–96 h. With repeated daily dosing, progressive acid inhibitory effects are observed, with basal and secretagogue-stimulated acid production being inhibited by >95% after 1 week of therapy. The half-life of PPIs is ~18 h; thus, it can take between 2 and 5 days for gastric acid secretion to return to normal levels once these drugs have been discontinued. Because the pumps need to be activated for these agents to be effective, their efficacy is maximized if they are administered before a meal (except for the immediate-release formulation of omeprazole) (e.g., in the morning before breakfast). Mild to moderate hypergastrinemia has been observed in patients taking these drugs. Carcinoid tumors developed in some animals given the drugs chronically; however, extensive experience has failed to demonstrate gastric carcinoid tumor development in humans. Serum gastrin levels return to normal levels within 1–2 weeks after drug cessation. Rebound gastric acid hypersecretion has been described in *H. pylori*–negative individuals after discontinuation of PPIs. It occurs even after relatively short-term usage (2 months) and may last for up to 2 months after the PPI has been discontinued. The mechanism involves gastrin-induced hyperplasia and hypertrophy of histamine-secreting ECL cells. The clinical relevance of this observation is that individuals may have worsening symptoms of GERD or dyspepsia upon stopping the PPI. Gradual tapering of the PPI and switching to an H_2 receptor antagonist may prevent this from occurring. *H. pylori*–induced inflammation and concomitant decrease in acid production may explain why this does not occur in *H. pylori*–positive patients. IF production is also inhibited, but vitamin B_{12} deficiency anemia is uncommon, probably because of the large stores of the vitamin. As with any agent that leads to significant hypochlorhydria, PPIs may interfere with absorption of drugs such as ketoconazole, ampicillin, iron, and digoxin. Hepatic cytochrome P450 can be inhibited by the earlier PPIs (omeprazole, lansoprazole). Rabeprazole, pantoprazole, and esomeprazole do not appear to interact significantly with drugs metabolized by the cytochrome P450 system. The overall clinical significance of this observation is not definitely established. Caution should be taken when using theophylline, warfarin, diazepam, atazanavir, and phenytoin concomitantly with PPIs.

The list of potential side effects with long-term PPI use has steadily grown over the years. These agents are commonly used since several formulations have become available as over-the-counter medications. Moreover, up to 70% of current prescriptions for long-term PPIs may be unwarranted and between 35 and 60% of in-hospital use of PPIs may be inappropriate. Interpretation of the multiple studies should take into consideration that the vast majority were retrospective observational studies in which confounding factors could not be accounted for entirely.

Long-term acid suppression, especially with PPIs, has been associated with a higher incidence of community-acquired pneumonia as well as community- and hospital-acquired *Clostridioides difficile*–associated disease. A meta-analysis showed a 74% increased risk of *C. difficile* infection and a 2.5-fold higher risk of reinfection as compared to nonusers. In light of these concerns, the FDA published a safety alert regarding the association between *C. difficile* infection and PPI use. Although the risk of spontaneous bacterial peritonitis in cirrhotics was thought to be increased, the data here are less supportive. The impact of PPI-induced changes in the host microbiome is postulated to play a role in the increased risk of infection, but this theory needs to be confirmed. These observations require confirmation but should alert the practitioner to take caution when recommending these agents for long-term use, especially in elderly patients at risk for developing pneumonia or *C. difficile* infection.

Diarrhea is also associated with PPI use, which in some cases has been associated with the development of collagenous colitis (hazard ratio of 4.5), particularly with lansoprazole. The mechanism for PPI-induced collagenous colitis is unclear, but in vitro studies demonstrate that PPIs may induce collagen gene expression. The colitis usually resolves with cessation of the PPI.

A population-based study revealed that long-term use of PPIs was associated with the development of hip fractures in older women. The absolute risk of fracture remained low and may be zero despite an observed increase associated with the dose and duration of acid suppression. The mechanism for this observation is not clear, and this finding must be confirmed before making broad recommendations regarding the discontinuation of these agents in patients who benefit from them. Long-term use of PPIs has also been implicated in the development of iron, vitamin B_{12}, and magnesium deficiency. A meta-analysis of nine observational studies found a 40% increase in hypomagnesemia in PPI users as compared to nonusers. One approach to consider in patients needing to take PPIs long term is to check a complete blood count looking for evidence of anemia due to iron or vitamin B_{12} deficiency, vitamin B_{12} level, and a magnesium level after 1–2 years of PPI use, but these recommendations are not evidence based or recommended by expert opinion. PPIs may exert a negative effect on the antiplatelet effect of clopidogrel. Although the evidence is mixed and inconclusive, a small increase in mortality and readmission rate for coronary events was seen in patients receiving a PPI while on clopidogrel in earlier studies. Subsequently, three meta-analyses reported an inverse correlation between clopidogrel and PPI use; therefore, the influence of this drug interaction on mortality is not clearly established. The mechanism involves the competition of the PPI and clopidogrel with the same cytochrome P450 (CYP2C19). Whether this is a class effect of PPIs is unclear; there appears to be at least a theoretical advantage of pantoprazole over the other PPIs, but this has not been confirmed. This drug interaction is particularly relevant in light of the common use of aspirin and clopidogrel for prevention of coronary events and the efficacy of PPIs in preventing GI bleeding in these patients. The FDA has made several recommendations while awaiting further evidence to clarify the impact of PPI therapy on clopidogrel use. Health care providers should continue to prescribe clopidogrel to patients who require it and should reevaluate the need for starting or continuing treatment with a PPI. From a practical standpoint, additional recommendations to consider include the following: Patients taking clopidogrel with aspirin, especially with other GI risk factors for bleeding, should receive GI protective therapy. Although high-dose H_2 blockers have been considered an option, these do not appear to be as effective as PPIs. If PPIs are to be given, some have recommended that there be a 12-h separation between

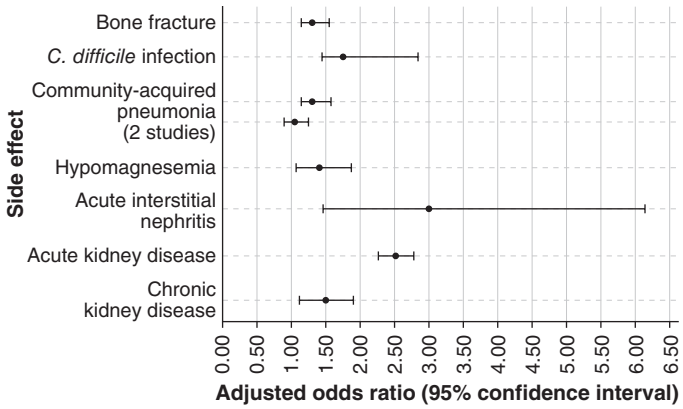

FIGURE 335-12. Evidence supporting the potential adverse effects of proton pump inhibitor drugs. *(Adapted from AJ Schoenfeld, D Grady: Adverse effects associated with proton pump inhibitors. JAMA Intern Med 176:172, 2016.)*

administration of the PPI and clopidogrel to minimize competition of the two agents with the involved cytochrome P450. One option is to give the PPI 30 min before breakfast and the clopidogrel at bedtime. Insufficient data are available to firmly recommend one PPI over another. Additional concerning side effects with long-term PPI use include increased cardiac risks independent of clopidogrel use, dementia, and acute and chronic kidney injury. Again, the data are often retrospective and confounding variables were not consistently eliminated, thus making it difficult to establish a definitive association between PPIs and the toxicities outlined. A summary of the side effects with the corresponding relative risks is shown in **Fig. 335-12**. Ultimately, heightened awareness of inappropriate long-term use of PPIs is paramount. Patients aged ≥65 years of age have a higher risk for some of the long-term side effects of PPIs highlighted above, in part due to the higher prevalence of concomitant chronic diseases. It is therefore essential to carefully select individuals, especially among the elderly, who need long-term PPI therapy and discontinue it in those individuals who do not need it. Abrupt withdrawal of a PPI in a long-term user may result in a component of rebound hyperacidity; thus, this agent should be tapered gradually over the course of 1–2 weeks with possible transition to an H_2 blocker for a short period of time.

Development of novel acid inhibitory agents continues in an attempt to primarily address the need for better agents to treat GERD. For example, modified H_2 blockers with greater potency and duration as well as novel PPIs with longer half-life and potency are under study. For example, tenatoprazole is a PPI containing an imidazopyridine ring instead of a benzimidazole ring, which promotes irreversible proton pump inhibition. This agent has a longer half-life than the other PPIs and may be beneficial for inhibiting nocturnal acid secretion, which has significant relevance in GERD. Additional PPIs with longer half-life and combined with other agents are being studied, but the details are beyond the scope of this chapter. A second new class of agents is the potassium-competitive acid pump antagonists (P-CAPs). These compounds inhibit gastric acid secretion via potassium competitive binding of the H^+,K^+-ATPase. Revaprazan, vonoprazan and tegoprazan are agents approved for use in Korea and Japan, and vonoprazan has been approved by the FDA for use in the United States. Vonoprazan may be superior to PPIs when combined with antibiotics for the treatment of *H. pylori*, and this novel agent was awarded Fast Track status by the FDA for the treatment of *H. pylori* in combination with both amoxicillin and clarithromycin and with amoxicillin alone.

CYTOPROTECTIVE AGENTS

Sucralfate Sucralfate is a complex sucrose salt in which the hydroxyl groups have been substituted by aluminum hydroxide and sulfate. This compound is insoluble in water and becomes a viscous paste within the stomach and duodenum, binding primarily to sites of active ulceration. Sucralfate may act by several mechanisms: serving as a physicochemical barrier, promoting a trophic action by binding growth factors such as EGF, enhancing prostaglandin synthesis, stimulating mucus and bicarbonate secretion, and enhancing mucosal defense and repair. Toxicity from this drug is rare, with constipation being most common (2–3%). It should be avoided in patients with chronic renal insufficiency to prevent aluminum-induced neurotoxicity. Hypophosphatemia and gastric bezoar formation have also been reported rarely. Standard dosing of sucralfate is 1 g qid.

Bismuth-Containing Preparations Sir William Osler considered bismuth-containing compounds the drug of choice for treating PUD. The resurgence in the use of these agents is due to their effect against *H. pylori*. Colloidal bismuth subcitrate (CBS) and bismuth subsalicylate (BSS; Pepto-Bismol) are the most widely used preparations. The mechanism by which these agents induce ulcer healing is unclear. Adverse effects with short-term use include black stools, constipation, and darkening of the tongue. Long-term use with high doses, especially with the avidly absorbed CBS, may lead to neurotoxicity. These compounds are commonly used as one of the agents in an anti–*H. pylori* regimen (see below).

Prostaglandin Analogues In view of their central role in maintaining mucosal integrity and repair, stable prostaglandin analogues were developed for the treatment of PUD. The mechanism by which this rapidly absorbed drug provides its therapeutic effect is through enhancement of mucosal defense and repair. The most common toxicity noted with this drug is diarrhea (10–30% incidence). Other major toxicities include uterine bleeding and contractions; misoprostol is contraindicated in women who may be pregnant, and women of childbearing age must be made clearly aware of this potential drug toxicity. The standard therapeutic dose is 200 μg qid.

Miscellaneous Drugs A number of drugs including anticholinergic agents and tricyclic antidepressants were used for treating acid peptic disorders, but in light of their toxicity and the development of potent antisecretory agents, these are rarely, if ever, used today. Newer agents such as teprenone, an acyclic polyisoprenoid compound used as a gastric mucosal protector that is employed to treat gastritis and GUs outside of the United States; plant-based therapies; and CCK2 receptor antagonists are intriguing therapies but require further evaluation.

THERAPY OF *H. PYLORI*

The physician's goal in treating PUD is to provide relief of symptoms (pain or dyspepsia), promote ulcer healing, and ultimately prevent ulcer recurrence and complications. The greatest influence of understanding the role of *H. pylori* in peptic disease has been the ability to prevent recurrence. Documented eradication of *H. pylori* in patients with PUD is associated with a dramatic decrease in ulcer recurrence to <10–20% as compared to 59% in GU patients and 67% in DU patients when the organism is not eliminated. Eradication of the organism may lead to diminished recurrent ulcer bleeding. The effect of its eradication on ulcer perforation is unclear.

Extensive effort has been made in determining who of the many individuals with *H. pylori* infection should be treated. The common conclusion arrived at by multiple consensus conferences around the world is that *H. pylori* should be eradicated in patients with documented PUD. This holds true independent of time of presentation (first episode or not), severity of symptoms, presence of confounding factors such as ingestion of NSAIDs, or whether the ulcer is in remission. Some have advocated treating patients with a history of documented PUD who are found to be *H. pylori* positive by stool antigen or breath testing. Between 60 and 90% of patients with gastric MALT lymphoma experience complete remission of the tumor in response to *H. pylori* eradication. The Maastricht VI/Florence Consensus Report recommends a test-and-treat approach for patients with uninvestigated dyspepsia if the local incidence of *H. pylori* is >20%. The American College of Gastroenterology (ACG) clinical guidelines (developed for North America) recommend that individuals aged <60 years with uninvestigated dyspepsia should

be tested and treated for *H. pylori*. In addition, recommendations from this consensus report and the ACG clinical guidelines include testing and offering eradication of *H. pylori* in patients who will be using NSAIDs (including low-dose aspirin) on a long-term basis, especially if there is a prior history of PUD. These individuals will require continued PPI treatment as well as eradication treatment, because eradication of the organism alone does not eliminate the risk of gastroduodenal ulcers in patients already receiving long-term NSAIDs. Moreover, it appears that eradication of *H pylori* decreases NSAID-induced GI bleeding. Treating patients with NUD to prevent gastric cancer or patients with GERD requiring long-term acid suppression remains controversial. Guidelines from the ACG suggest eradication of *H. pylori* in patients who have undergone resection of early gastric cancer. The Maastricht VI/Florence Consensus Report also evaluated *H. pylori* treatment in gastric cancer prevention and recommends that eradication should be considered in the following situations: first-degree relatives of family members with gastric cancer; patients with previous gastric neoplasm treated by endoscopic or subtotal resection; individuals with a risk of gastritis (severe pangastritis or body-predominant gastritis) or severe atrophy; patients with gastric acid inhibition for >1 year; individuals with strong environmental risk factors for gastric cancer (heavy smoking; high exposure to dust, coal, quartz, or cement; and/or work in quarries); and *H. pylori*–positive patients with a fear of gastric cancer. Finally, the ACG clinical guidelines recommend testing and offering *H. pylori* eradication to patients with unexplained iron-deficiency anemia and idiopathic thrombocytopenic purpura. The Maastricht VI/Florence Consensus Report concurs with the ACG with the aforementioned recommendations and in addition recommends eradicating *H. pylori* in patients with unexplained vitamin B_{12} deficiency. Despite this, concerns have been raised about the widespread use of antibiotics for the therapy of all cases of *H. pylori* positivity, including the potential for increased bacterial resistance rates, reported weight gain, and alteration of the microbiome. In fact, the increasing incidence of bacterial resistance to antibiotics coupled with variability in general prevalence of the organism worldwide and limitations in developing personalized *H. pylori*–driven sensitivity therapies have led to increasing challenges in effectively treating this organism.

Multiple drugs have been evaluated in the therapy of *H. pylori.* No single agent is effective in eradicating the organism. Combination therapy for 14 days provides the greatest efficacy, although regimens based on sequential administration of antibiotics also appear promising (see below). A shorter administration course (7–10 days), although attractive, has not proved as successful as the 14-day regimens. The agents used with the greatest frequency include amoxicillin, metronidazole, tetracycline, clarithromycin, and bismuth compounds. Moreover, the steady increase in *H pylori* resistance to antibiotics, in particular clarithromycin and metronidazole, has significantly impacted the approach to eradication of this organism (see below). In addition, increasing resistance to antibiotics has led to a higher incidence of *H. pylori* infections that are refractory to first-line therapies.

Suggested treatment regimens for *H. pylori* are outlined in **Table 335-4**. Choice of a particular regimen will be influenced by several factors, including efficacy, patient tolerance, existing antibiotic resistance, prior antibiotic use, and cost of the drugs. The aim for initial eradication rates should be 85–90%. The combination of bismuth, metronidazole, and tetracycline was the first triple regimen found effective against *H. pylori.* The combination of two

TABLE 335-4 Recommended First-Line Therapies for *H. pylori* Infection

REGIMEN	DRUGS (DOSES)	DOSING FREQUENCY	DURATION (DAYS)	FDA APPROVAL
Clarithromycin triple (Only in patients without prior exposure to macrolides, incidence of clarithromycin <15%, or either of the above unknown)	PPI (standard or double dose)	bid	14	Yes[a]
	Clarithromycin (500 mg)			
	Amoxicillin (1 g) or metronidazole (500 mg tid)			
Bismuth quadruple (Now often recommended as first-line therapy)	PPI (standard dose)	bid	10–14	No[b]
	Bismuth subcitrate (120–300 mg) or subsalicylate (300 mg)	qid		
	Tetracycline (500 mg)	qid		
	Metronidazole (250–500 mg)	qid (250 mg) tid to qid (500 mg)		
Concomitant	PPI (standard dose)	bid	10–14	No
	Clarithromycin (500 mg)			
	Amoxicillin (1 g)			
	Nitroimidazole (500 mg)[c]			
Sequential	PPI (standard dose)	bid	5–7	No
	PPI, clarithromycin (500 mg) + nitroimidazole (500 mg)[c]	bid	5–7	
Hybrid	PPI (standard dose) + amoxicillin (1 g)	bid	7	No
	PPI, amoxicillin, clarithromycin (500 mg), nitroimidazole (500 mg)[c]	bid	7	
Levofloxacin triple	PPI (standard or double dose) + amoxicillin (1 g)	bid	5–7	No
	Levofloxacin (500 mg)	qd		
	Amoxicillin (1 g)	bid		
Levofloxacin sequential	PPI (standard or double dose) + amoxicillin (1 g)	bid	5–7	No
	PPI, amoxicillin, levofloxacin (500 mg qd), nitroimidazole (500 mg)[c]	bid	5–7	
LOAD	Levofloxacin (250 mg)	qd	7–10	No
	PPI (double dose)	qd		
	Nitazoxanide (500 mg)	bid		
	Doxycycline (100 mg)	qd		

[a]Several PPI, clarithromycin, and amoxicillin combinations have achieved FDA approval. The regimen of a PPI, clarithromycin, and metronidazole is not an FDA-approved treatment regimen. [b]The regimen of a PPI, bismuth, tetracycline, and metronidazole combined with a PPI for 10 days is an FDA-approved treatment regimen. [c]Metronidazole or tinidazole.

Abbreviations: bid, twice daily; FDA, Food and Drug Administration; PPI, proton pump inhibitor; tid, three times daily; qd, once daily; qid, four times daily.

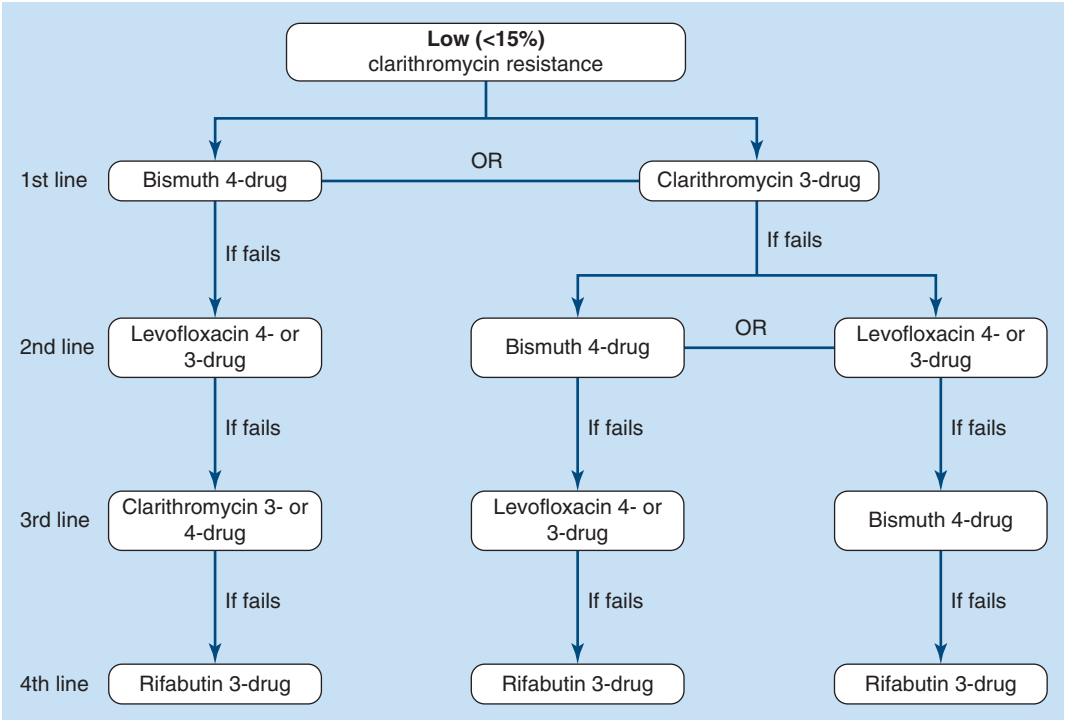
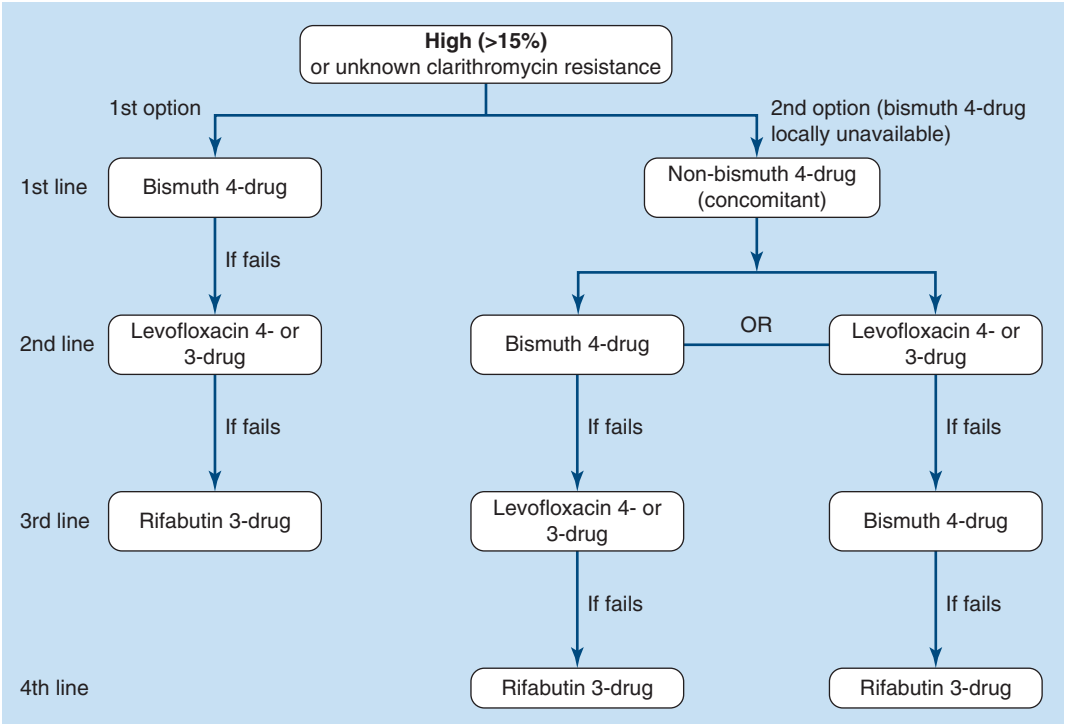
antibiotics plus either a PPI, H_2 blocker, or bismuth compound has comparable success rates. Addition of acid suppression assists in providing early symptom relief and enhances bacterial eradication.

Triple therapy, although effective, has several drawbacks, including the potential for poor patient compliance and drug-induced side effects. Compliance is being addressed by simplifying the regimens so that patients can take the medications twice a day. Simpler (dual therapy) and shorter regimens (7 and 10 days) are not as effective as triple therapy for 14 days. One anti–*H. pylori* regimen is available in prepackaged formulation: Prevpac (lansoprazole, clarithromycin, and amoxicillin).The contents of the Prevpac are to be taken twice per day for 14 days, understanding that clarithromycin-based triple therapy should be avoided in settings where *H. pylori* resistance to this agent exceeds 15% or the patient has been recently exposed to macrolide antibiotics or if neither of these factors is known (see below).



Side effects have been reported in up to 20–30% of patients on triple therapy. Bismuth may cause black stools, constipation, or darkening of the tongue. The most feared complication with amoxicillin is pseudomembranous colitis, but this occurs in <1–2% of patients. Amoxicillin can also lead to antibiotic-associated diarrhea, nausea, vomiting, skin rash, and allergic reaction. Concomitant use of probiotics may ameliorate some of the antibiotic side effects (see below). Tetracycline has been reported to cause rashes and, very rarely, hepatotoxicity and anaphylaxis.

One important concern with treating patients who may not need therapy is the potential for development of antibiotic-resistant strains. The incidence and type of antibiotic-resistant *H. pylori* strains vary worldwide. Strains resistant to metronidazole, clarithromycin, amoxicillin, and tetracycline have been described, with the latter two being uncommon. Antibiotic-resistant strains are the most common cause for treatment failure in compliant patients. Unfortunately, in vitro resistance does not predict outcome in patients. Culture and sensitivity testing of *H. pylori* is not performed routinely. In light of this, culture-independent methods are needed to determine antibiotic resistance. Detection of resistance toward several antibiotics can be achieved by detecting different *H. pylori* mutations or other genetic changes, but the accuracy of the molecular tools available vary widely between different antibiotics. Therefore, a standardized approach to determine antibiotic resistance that is easy to use is still not readily available. In addition, the standard method of obtaining tissue through endoscopy is cost prohibitive when considering the widespread presence of this organism in certain parts of the world; thus, new efforts are aimed at developing techniques that capitalize on DNA extraction and performing polymerase chain reaction (PCR) on stool samples from patients infected with *H. pylori*. These diagnostic modalities are still in early phases of development. In light of this, most recommendations for treatment of *H. pylori* outline that if individual susceptibility testing is not available, first-line therapy in areas of a high incidence of clarithromycin resistance (>15%) or in situations where resistance to clarithromycin is not known that bismuth quadruple therapy should be the first line of treatment. If not available, non-bismuth concomitant quadruple therapy may be a consideration. An algorithmic approach to the therapy of *H. pylori* as outlined in the Maastricht VI/Florence Consensus Report is provided in **Fig. 335-13**. Although resistance to metronidazole has been found in as many as 30% of isolates in North America and 80% in developing countries, triple therapy is effective in eradicating the organism in >50% of patients infected with a resistant strain. Clarithromycin resistance is seen in 13–16% of individuals in the United States, with resistance to amoxicillin being <1% and resistance to both metronidazole and clarithromycin in the 5% range. Resistance to tetracycline and rifabutin (see below) is reported to be <2% in the United States. In light of the paucity of *H. pylori* antibiotic real-time resistance data, asking the patient about prior antibiotic exposure should be included in the decision-making and used as a surrogate for potential antibiotic resistance, especially when it comes to prior macrolide use. Clarithromycin use should be excluded in patients with prior macrolide usage.



Failure of *H. pylori* eradication with triple therapy in a compliant patient is usually due to infection with a resistant organism. Additional important factors in treatment failure include inadequate acid suppression and inadequate adherence to the recommended regimen. Addressing both of these latter issues is critical before embarking on selecting alternative antibiotics for eradication of *H. pylori*. An in-depth review of the approach to patients with refractory *H. pylori* is beyond the scope of this chapter, and readers are referred to the American Gastroenterological Association 2021 guidelines (see Further Reading) for in-depth discussion of this important topic. A series of salvage therapies for *H. pylori* are shown in **Table 335-5**. The combination of PPI, amoxicillin, and rifabutin for 10 days has also been used successfully (86% cure rate) in patients infected with resistant strains. Additional regimens considered for second-line therapy include levofloxacin-based triple therapy (levofloxacin, amoxicillin, PPI) for 10 days and furazolidone-based triple therapy (furazolidone, amoxicillin, PPI) for 14 days. Unfortunately, no treatment regimen is universally accepted for patients in whom two courses of antibiotics have failed. If eradication is still not achieved in a compliant patient, then culture and sensitivity of the organism should be considered. One challenge with this approach is that culture and sensitivity testing is cumbersome and not widely available; thus, *H. pylori* resistance data within specific communities are often not available. Non-culture-based approaches using molecular markers to determine potential resistance through stool testing are being developed but are not widely available. Additional factors that may lower eradication rates include the patient's country of origin (higher in Northeast Asia than other parts of Asia or Europe) and cigarette smoking. In addition, meta-analysis suggests that even the most effective regimens (quadruple therapy including PPI, bismuth, tetracycline, and metronidazole and triple therapy including PPI, clarithromycin, and amoxicillin) may have suboptimal eradication rates (<80%), thus demonstrating the need for the development of more efficacious treatments.

In view of the observation that 15–25% of patients treated with first-line therapy may still remain infected with the organism, new approaches to treatment have been explored. One promising approach is sequential therapy. Regimens examined consist of 5 days of amoxicillin and a PPI, followed by an additional 5 days of PPI plus tinidazole and clarithromycin or levofloxacin. One promising regimen that has the benefit of being shorter in duration, easier to take, and less expensive is 5 days of concomitant therapy (PPI twice daily, amoxicillin 1 g twice daily, levofloxacin 500 mg twice daily, and tinidazole 500 mg twice daily). Initial studies have demonstrated eradication rates of >90% with good patient tolerance. Confirmation of these findings and applicability of this approach in the United States are needed, although some experts are recommending abandoning clarithromycin-based triple therapy in the United States for the concomitant therapy or the alternative sequential therapies highlighted above.

Innovative non-antibiotic-mediated approaches have been explored in an effort to improve eradication rates of *H. pylori*. Pretreatment of patients with *N*-acetylcysteine as a mucolytic agent to destroy the *H. pylori* biofilm and therefore impair antibiotic resistance has been examined, but more studies are needed to confirm the applicability of this approach. In vitro studies suggest that certain probiotics like *Lactobacillus* or its metabolites can inhibit *H. pylori.* Administration of probiotics has been attempted in several clinical studies in an effort to maximize antibiotic-mediated eradication with varying results. Overall, it appears that the use of certain probiotics, such as *Lactobacillus* spp., *Saccharomyces* spp., *Bifidobacterium* spp., and *Bacillus clausii*, did not alter eradication rates but importantly decreased antibiotic-associated side effects including nausea, dysgeusia, diarrhea, and abdominal discomfort/pain, resulting in enhanced tolerability of *H. pylori* therapies. Additional studies are needed to confirm the potential benefits of probiotics in this setting. Statins, specifically atorvastatin, have been used with some success as an adjunct to quadruple therapy in patients with NUD. Additional nonpharmacologic therapies are

FIGURE 335-13 Empirical approach to *Helicobacter pylori* eradication if individual antibiotic susceptibility testing is not avaliable. A. Low <15% clarithromycin resistance; B. High >15% or unknown clarithromycin resistance. Treatment regimens: Bismuth 4-drug—proton pump inhibitor (PPI), bismuth, tetracycline, metronidazole; Clarithromycin 3-drug—PPI, clarithromycin, amoxicillin (use only if clarithromycin sensitivity is known); Nonbismuth 4-drug—PPI, clarithromycin, amoxicillin, metronidazole; Levofloxacin 4-drug—PPI, levofloxacin, amoxicillin, bismuth; Levofloxacin 3-drug—same as levofloxacin 4-drug omitting bismuth; Rifabutin 3-drug in the setting of high fluoroquinolone resistance—rifabutin, high dose PPI, amoxicillin. (modified from Malfetheiner P, et al: Gut 71:9, 2022). *(Adapted from permission from P Malfertheiner et al: Management of Helicobacter pylori infection-the Maastricht V/Florence Consensus Report. Gut 71:9, 2022.)*

also being explored including oxygen-enriched environment or hyperbaric oxygen therapy, antimicrobial photodynamic therapy, nanomaterials, antimicrobial peptides, phase therapy, and modified lysins. Readers are referred to a recent comprehensive review on this topic (Luo et al in Further Reading).

Reinfection after successful eradication of *H. pylori* is rare in the United States (<1% per year). If recurrent infection occurs within the first 6 months after completing therapy, the most likely explanation is recrudescence as opposed to reinfection.

THERAPY OF NSAID-RELATED GASTRIC OR DUODENAL INJURY

Medical intervention for NSAID-related mucosal injury includes treatment of an active ulcer and primary prevention of future

TABLE 335-5 Salvage Therapies for *H. pylori* Infection

REGIMEN	DRUGS (DOSES)	DOSING FREQUENCY	DURATION (DAYS)	FDA APPROVAL
Bismuth quadruple	PPI (standard dose) Bismuth subcitrate (120–300 mg) or subsalicylate (300 mg) Tetracycline (500 mg) Metronidazole (500 mg)	bid qid qid tid or qid	14	No[a]
Levofloxacin triple	PPI (standard dose) Levofloxacin (500 mg) Amoxicillin (1 g)	bid qd bid	14	No
Concomitant	PPI (standard dose) Clarithromycin (500 mg) Amoxicillin (1 g) Nitroimidazole (500 mg)	bid bid bid bid or tid	10–14	No

injury. Recommendations for the treatment and primary prevention of NSAID-related mucosal injury are listed in Table 335-6. Ideally, the injurious agent should be stopped as the first step in the therapy of an active NSAID-induced ulcer. If that is possible, then treatment with one of the acid inhibitory agents (H_2 blockers, PPIs) is indicated. Cessation of NSAIDs is not always possible because of the patient's severe underlying disease. Only PPIs can heal GUs or DUs, independent of whether NSAIDs are discontinued.

The widespread use of NSAIDs has created some concern due to the increasing likelihood of GI and CV side effects associated with these agents. The approach to primary prevention has included avoiding the agent, using the lowest possible dose of the agent for the shortest period of time possible, using NSAIDs that are theoretically less injurious, using newer topical NSAID preparations, and/or using concomitant medical therapy to prevent NSAID-induced injury. Several nonselective NSAIDs that are associated with a lower likelihood of GI and CV toxicity include naproxen and ibuprofen, although the beneficial effect may be eliminated if higher dosages of the agents are used. Primary prevention of NSAID-induced ulceration can be accomplished by a PPI and, if not tolerated, misoprostol (200 μg qid). High-dose H_2 blockers (famotidine 40 mg bid) have also shown some promise in preventing endoscopically documented ulcers, although PPIs are superior. The highly selective COX-2 inhibitors, celecoxib and rofecoxib, are 100 times more selective inhibitors of COX-2 than standard NSAIDs, leading to gastric or duodenal mucosal injury that is comparable to placebo. Their utilization led to an increase in CV events initially leading to both celecoxib and rofecoxib being withdrawn from the market. After continued analysis of available data, the FDA concluded that celecoxib is no less safe than several nonopioid pain killers and has been allowed to remain on the market with a warning label that it was associated with increased risk of heart attacks and strokes. Additional caution was engendered when the CLASS study demonstrated that the advantage of celecoxib in preventing GI complications was offset when low-dose aspirin was used simultaneously. Therefore, gastric protection therapy is required in individuals taking COX-2 inhibitors and aspirin prophylaxis. Finally, much of the work demonstrating the benefit of COX-2 inhibitors and PPIs on GI injury has been performed in individuals of average risk; it is unclear if the same level of benefit will be achieved in high-risk patients. For example, concomitant use of warfarin and a COX-2 inhibitor was associated with rates of GI bleeding similar to those observed in patients taking nonselective NSAIDs. A combination of factors, including withdrawal of the majority of COX-2 inhibitors from the market, the observation that low-dose aspirin appears to diminish the beneficial effect of COX-2–selective inhibitors, and the growing use of aspirin for prophylaxis of CV events, has significantly altered the approach to gastric protective therapy during the use of NSAIDs. A set of guidelines for the approach to the use of NSAIDs was published by the ACG and is shown in Table 335-7.

TABLE 335-6 Recommendations for Treatment of NSAID-Related Mucosal Injury

CLINICAL SETTING	RECOMMENDATION
Active ulcer	
NSAID discontinued	H_2 receptor antagonist or PPI
NSAID continued	PPI
Prophylactic therapy	Misoprostol PPI Selective COX-2 inhibitor
H. pylori infection	Eradication if tests positive for *H. pylori*

Abbreviations: COX-2, isoenzyme of cyclooxygenase; NSAID, nonsteroidal anti-inflammatory drug; PPI, proton pump inhibitor.

TABLE 335-7 Guide to NSAID Therapy

	NO/LOW NSAID GI RISK	NSAID GI RISK
No CV risk (no aspirin)	Traditional NSAID	Coxib *or* Traditional NSAID + PPI *or* misoprostol Consider non-NSAID therapy
CV risk (consider aspirin)	Traditional NSAID + PPI *or* misoprostol if GI risk warrants gastroprotection Consider non-NSAID therapy	A gastroprotective agent must be added if a traditional NSAID is prescribed Consider non-NSAID therapy

Abbreviations: CV, cardiovascular; GI, gastrointestinal; NSAID, nonsteroidal anti-inflammatory drug; PPI, proton pump inhibitor.

Individuals who are not at risk for CV events, do not use aspirin, and are without risk for GI complications can receive nonselective NSAIDs without gastric protection. In those without CV risk factors but with a high potential risk (prior GI bleeding or multiple GI risk factors) for NSAID-induced GI toxicity, cautious use of a selective COX-2 inhibitor and co-therapy with high-dose PPI or misoprostol are recommended. Individuals at moderate GI risk without cardiac risk factors can be treated with a COX-2 inhibitor alone or with a nonselective NSAID with PPI or misoprostol. Individuals with CV risk factors, who require low-dose aspirin and have low potential for NSAID-induced toxicity, should be considered for a non-NSAID agent or use of a traditional NSAID such as naproxen (lower CV side effects) in combination with gastric protection, if warranted. Finally, individuals with CV and GI risks who require aspirin must be considered for non-NSAID therapy, but if that is not an option, then gastric protection with any type of NSAID must be considered. Any patient, regardless of risk status, who is being considered for long-term traditional NSAID therapy should also be considered for *H. pylori* testing and treatment if positive. Assuring the use of GI protective agents with NSAIDs is difficult, even in high-risk patients. This is in part due to underprescribing of the appropriate protective agent; other times, the difficulty is related to patient compliance. The latter may be due to patients forgetting to take multiple pills or preferring not to take the extra pill, especially if they have no GI symptoms. Several NSAID gastroprotective-containing combination pills are now commercially available, including double-dose famotidine with ibuprofen, diclofenac with misoprostol, and naproxen with esomeprazole. Although initial studies suggested improved compliance and a cost advantage when taking these combination drugs, their clinical benefit over the use of separate pills has not been established. One additional concern with NSAID-induced GI complications is the relatively low rate of primary care provider compliance with established guidelines outlining preventative measures. An intervention including professional education, informatics to facilitate review, and financial incentives for practices to review patients' charts to assess appropriateness showed a reduced rate of high-risk prescribing of antiplatelet medications and NSAIDs with a tendency toward improved clinical outcomes. Efforts continue toward developing safer NSAIDs, including topical NSAIDs, NSAID formulations that are rapidly absorbed (diclofenac potassium powder mixed with a buffering agent, Prosorb and SoluMatrix technology), NO-releasing NSAIDs, hydrogen sulfide–releasing NSAIDs, dual COX/5-LOX inhibitors, NSAID prodrugs, and agents that can effectively sequester unbound NSAIDs without interfering with their efficacy.

APPROACH AND THERAPY: SUMMARY

Controversy continues regarding the best approach to the patient who presents with dyspepsia **(Chap. 48)**. The discovery of *H. pylori* and its role in pathogenesis of ulcers has added a new variable to the equation. Previously, if a patient <60 years of age presented with dyspepsia and without alarming signs or symptoms suggestive of an ulcer complication or malignancy, an empirical therapeutic trial with acid suppression was commonly recommended; today, however, a test-and-treat approach with a noninvasive diagnostic tool for *H. pylori* and eradication of the organism, if positive, is recommended **(Fig. 335-14)**.

Once an ulcer (GU or DU) is documented, the main issue to consider is whether *H. pylori* or an NSAID is involved. With *H. pylori* present, independent of the NSAID status, triple or quadruple therapy is recommended for 14 days, followed by continued acid-suppressing drugs (H_2 receptor antagonist or PPIs) for a total of 4–6 weeks. *H. pylori* eradication should be documented 4 weeks after completing antibiotics. The test of choice for documenting eradication is the laboratory-based validated monoclonal stool antigen test or a urea breath test (UBT). The patient must be off antisecretory agents for at least 7 days when being tested for eradication of *H. pylori* with UBT or stool antigen. Serologic testing is not useful for the purpose of documenting eradication because

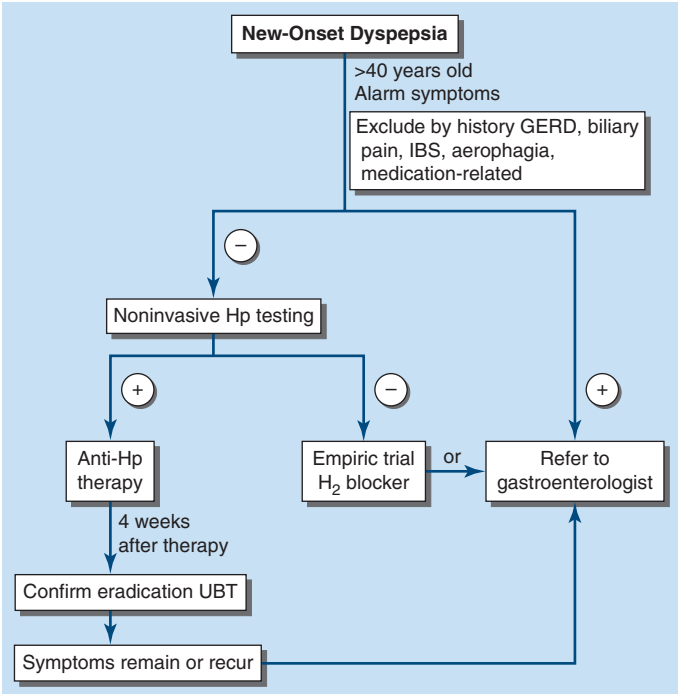

FIGURE 335-14 Overview of new-onset dyspepsia. GERD, gastroesophageal reflux disease; Hp, *Helicobacter pylori*; IBS, irritable bowel syndrome; UBT, urea breath test. *(Reproduced with permission from BS Anand, DY Graham: State-of-the-Art: Ulcer and Gastritis, Endoscopy 31:215, 1999. © Georg Thieme Verlag KG.)*

antibody titers fall slowly and often do not become undetectable. Some recommend that patients with complicated ulcer disease or who are frail should be treated with long-term acid suppression, thus making documentation of *H. pylori* eradication a moot point. In view of this discrepancy in practice, it would be best to discuss with the patient the different options available.

Several issues differentiate the approach to a GU versus a DU. GUs, especially of the body and fundus, have the potential of being malignant. Multiple biopsies of a GU should be taken initially; even if these are negative for neoplasm, repeat endoscopy to document healing at 8–12 weeks should be performed, with biopsy if the ulcer is still present. About 70% of GUs eventually found to be malignant undergo significant (usually incomplete) healing. Repeat endoscopy is warranted in patients with DU if symptoms persist despite medical therapy or a complication is suspected.

The majority (>90%) of GUs and DUs heal with the conventional therapy outlined above. A GU that fails to heal after 12 weeks and a DU that does not heal after 8 weeks of therapy should be considered refractory. Once poor compliance and persistent *H. pylori* infection have been excluded, NSAID use, either inadvertent or surreptitious, must be excluded. In addition, cigarette smoking must be eliminated. For a GU, malignancy must be meticulously excluded. Next, consideration should be given to a gastric acid hypersecretory state such as ZES (see "Zollinger-Ellison Syndrome," below) or the idiopathic form, which can be excluded with gastric acid analysis. Although a subset of patients has gastric acid hypersecretion of unclear etiology as a contributing factor to refractory ulcers, ZES should be excluded with a fasting gastrin or secretin stimulation test (see below). More than 90% of refractory ulcers (either DUs or GUs) heal after 8 weeks of treatment with higher doses of PPI (omeprazole 40 mg/d; lansoprazole 30–60 mg/d). This higher dose is also effective in maintaining remission. Surgical intervention may be a consideration at this point; however, other rare causes of refractory ulcers must be excluded before recommending surgery. Rare etiologies of refractory ulcers that may be diagnosed by gastric or duodenal biopsies include ischemia, Crohn's disease, amyloidosis, sarcoidosis, lymphoma, eosinophilic gastroenteritis, smoking crack cocaine, or infection (cytomegalovirus [CMV], tuberculosis, or syphilis).

SURGICAL THERAPY

Surgical intervention in PUD can be viewed as being either elective, for treatment of medically refractory disease, or as urgent/emergent, for the treatment of an ulcer-related complication. The development of pharmacologic and endoscopic approaches for the treatment of peptic disease and its complications has led to a substantial decrease in the number of operations needed for this disorder with a drop of >90% for elective ulcer surgery over the past four decades. Refractory ulcers are an exceedingly rare occurrence. Surgery is more often required for treatment of an ulcer-related complication.

Hemorrhage is the most common ulcer-related complication, occurring in ~15–25% of patients. Bleeding may occur in any age group but is most often seen in older patients (sixth decade or beyond). The majority of patients stop bleeding spontaneously, but endoscopic therapy **(Chap. 333)** is necessary in some. Parenterally and orally administered PPIs also decrease ulcer rebleeding in patients who have undergone endoscopic therapy. Patients unresponsive or refractory to endoscopic intervention will require angiographic intervention or surgery (~5% of transfusion-requiring patients).

Free peritoneal perforation occurs in ~2–3% of DU patients, with NSAID-induced GU perforations occurring more commonly. Sudden onset of severe abdominal pain with peritoneal signs and evidence of pneumoperitoneum on abdominal imaging is the classic presentation of a perforated viscous, but this presentation occurs in only two-thirds of patients. The latter is especially true in elderly patients (>70 years old), obese individuals, and immunocompromised patients. It is important to keep in mind that, as in the case of bleeding, up to 10% of these patients will not have antecedent ulcer symptoms. Delay in diagnosis clearly leads to higher mortality; thus, early suspicion and intervention with nasogastric suction, intravenous PPI, antibiotics, and surgical consultation are essential. Concomitant bleeding may occur in up to 10% of patients with perforation, with mortality being increased substantially. Peptic ulcer can also penetrate into adjacent organs, especially with a posterior DU, which can penetrate into the pancreas, colon, liver, or biliary tree.

Pyloric channel ulcers or DUs can lead to gastric outlet obstruction in ~2–3% of patients. This can result from chronic scarring or from impaired motility due to inflammation and/or edema with pylorospasm. Patients may present with early satiety, nausea, vomiting of undigested food, and weight loss. Conservative management with nasogastric suction, intravenous hydration/nutrition, and antisecretory agents is indicated for 7–10 days with the hope that a functional obstruction will reverse. If a mechanical obstruction persists, endoscopic intervention with balloon dilation may be effective. Surgery should be considered if all else fails.

Specific Operations for Duodenal Ulcers Surgical treatment was originally designed to decrease gastric acid secretion. Operations most commonly performed include (1) vagotomy and drainage (by pyloroplasty, gastroduodenostomy, or gastrojejunostomy), (2) highly selective vagotomy (which does not require a drainage procedure), and (3) vagotomy with antrectomy. The specific procedure performed is dictated by the underlying circumstances: elective versus emergency, the degree and extent of duodenal ulceration, the etiology of the ulcer (*H. pylori*, NSAIDs, malignancy), and the expertise of the surgeon. Moreover, the trend has been toward a dramatic decrease in the need for surgery for treatment of refractory PUD, and when needed, minimally invasive and anatomy-preserving operations are preferred.

Vagotomy is a component of each of these procedures and is aimed at decreasing acid secretion through ablating cholinergic input to the stomach. Unfortunately, both truncal and selective vagotomy (preserves the celiac and hepatic branches) result in gastric atony despite successful reduction of both basal acid output (BAO; decreased by 85%) and maximal acid output (MAO; decreased by 50%). Drainage through pyloroplasty or gastroduodenostomy is required in an effort to compensate for the vagotomy-induced gastric motility disorder. This procedure has an intermediate complication rate and a 10% ulcer recurrence rate. To minimize gastric dysmotility, highly selective vagotomy (also known as parietal cell, super-selective, or proximal vagotomy) was developed. Only the vagal fibers innervating the portion of the stomach that contains parietal cells are transected, thus leaving fibers important for regulating gastric motility intact. Although this procedure leads to an immediate decrease in both BAO and stimulated acid output, acid secretion recovers over time. By the end of the first postoperative year, basal and stimulated acid output are ~30 and 50%, respectively, of preoperative levels. Ulcer recurrence rates are higher with highly selective vagotomy (≥10%), although the overall complication rates are the lowest of the three procedures.

The procedure that provides the lowest rates of ulcer recurrence (1%) but has the highest complication rate is vagotomy (truncal or selective) in combination with antrectomy. Antrectomy is aimed at eliminating an additional stimulant of gastric acid secretion, gastrin. Two principal types of reanastomoses are used after antrectomy: gastroduodenostomy (Billroth I) or gastrojejunostomy (Billroth II) **(Fig. 335-15)**. Although Billroth I is often preferred over II, severe duodenal inflammation or scarring may preclude its performance. Prospective, randomized studies confirm that partial gastrectomy followed by Roux-en-Y reconstruction leads to a significantly better clinical, endoscopic, and histologic outcome than Billroth II reconstruction.

Of these procedures, highly selective vagotomy may be the procedure of choice in the elective setting, except in situations where ulcer recurrence rates are high (prepyloric ulcers and those refractory to medical therapy). Selection of vagotomy and antrectomy may be more appropriate in these circumstances.

These procedures have been traditionally performed by standard laparotomy. The advent of laparoscopic surgery has led several surgical teams to successfully perform highly selective vagotomy, truncal vagotomy/pyloroplasty, and truncal vagotomy/antrectomy

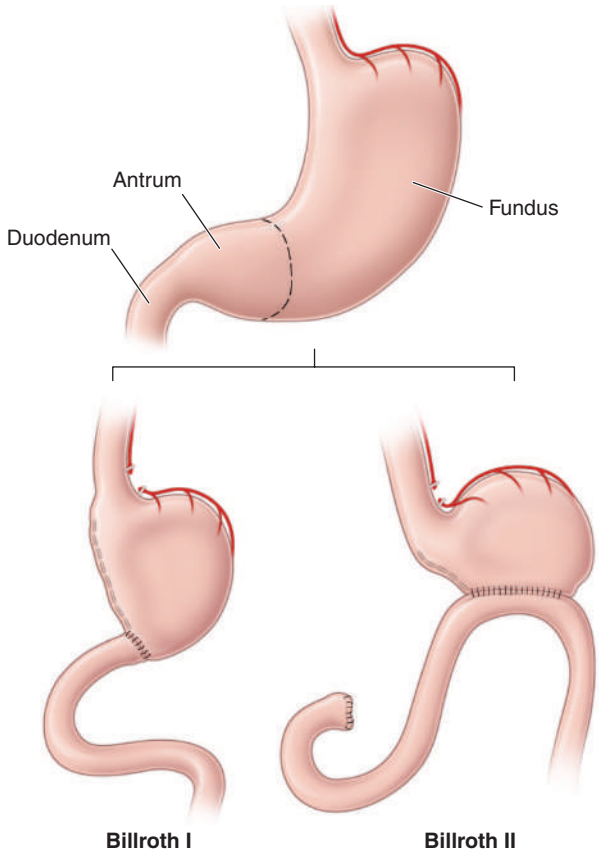

FIGURE 335-15 Schematic representation of Billroth I and II procedures.

through this approach. An increase in the number of laparoscopic procedures for treatment of PUD has occurred. Laparoscopic repair of perforated peptic ulcers is safe, feasible for the experienced surgeon, and associated with decreased postoperative pain, although it does take longer than an open approach. Moreover, no difference between the two approaches is noted in postoperative complications or length of hospital stay.

Specific Operations for GUs The location and presence of a concomitant DU dictate the operative procedure performed for a GU. Antrectomy (including the ulcer) with a Billroth I anastomosis is the treatment of choice for an antral ulcer. Vagotomy is performed only if a DU is present. Although ulcer excision with vagotomy and drainage procedure has been proposed, the higher incidence of ulcer recurrence makes this a less desirable approach. Ulcers located near the esophagogastric junction may require a more radical approach, a subtotal gastrectomy with a Roux-en-Y esophagogastrojejunostomy (Csendes' procedure). A less aggressive approach, including antrectomy, intraoperative ulcer biopsy, and vagotomy (Kelling-Madlener procedure), may be indicated in fragile patients with a high GU. Ulcer recurrence approaches 30% with this procedure.

Surgery-Related Complications Complications seen after surgery for PUD are related primarily to the extent of the anatomic modification performed. Minimal alteration (highly selective vagotomy) is associated with higher rates of ulcer recurrence and less GI disturbance. More aggressive surgical procedures have a lower rate of ulcer recurrence but a greater incidence of GI dysfunction. Overall, morbidity and mortality related to these procedures are quite low. Morbidity associated with vagotomy and antrectomy or pyloroplasty is ≤5%, with mortality ~1%. Highly selective vagotomy has lower morbidity and mortality rates of 1 and 0.3%, respectively.

In addition to the potential early consequences of any intraabdominal procedure (bleeding, infection, thromboembolism), gastroparesis, duodenal stump leak, and efferent loop obstruction can be observed.

Recurrent Ulceration The risk of ulcer recurrence is directly related to the procedure performed. Ulcers that recur after partial gastric resection tend to develop at the anastomosis (stomal or marginal ulcer). Epigastric abdominal pain is the most frequent presenting complaint (>90%). Severity and duration of pain tend to be more progressive than observed with DUs before surgery.

Ulcers may recur for several reasons, including incomplete vagotomy, inadequate drainage, retained antrum, and, less likely, persistent or recurrent *H. pylori* infection. ZES should have been excluded preoperatively. Surreptitious use of NSAIDs is an important reason for recurrent ulcers after surgery, especially if the initial procedure was done for an NSAID-induced ulcer. Once *H. pylori* and NSAIDs have been excluded as etiologic factors, the question of incomplete vagotomy or retained gastric antrum should be explored. For the latter, fasting plasma gastrin levels should be determined. If elevated, retained antrum or ZES (see below) should be considered. Incomplete vagotomy can be ruled out by gastric acid analysis coupled with sham feeding. In this test, gastric acid output is measured while the patient sees, smells, and chews a meal (without swallowing). The cephalic phase of gastric secretion, which is mediated by the vagus, is being assessed with this study. An increase in gastric acid output in response to sham feeding is evidence that the vagus nerve is intact. A rise in serum pancreatic polypeptide >50% within 30 min of sham feeding is also suggestive of an intact vagus nerve.

Medical therapy with H_2 blockers will heal postoperative ulceration in 70–90% of patients. The efficacy of PPIs has not been fully assessed in this group, but one may anticipate greater rates of ulcer healing compared to those obtained with H_2 blockers. Repeat operation (complete vagotomy, partial gastrectomy) may be required in a small subgroup of patients who have not responded to aggressive medical management.

Afferent Loop Syndromes Although rarely seen today as a result of the decrease in the performance of Billroth II anastomosis, two types of afferent loop syndrome can occur in patients who have undergone this type of partial gastric resection. The more common of the two is bacterial overgrowth in the afferent limb secondary to stasis. Patients may experience postprandial abdominal pain, bloating, and diarrhea with concomitant malabsorption of fats and vitamin B_{12}. Cases refractory to antibiotics may require surgical revision of the loop. The less common afferent loop syndrome can present with severe abdominal pain and bloating that occur 20–60 min after meals. Pain is often followed by nausea and vomiting of bile-containing material. The pain and bloating may improve after emesis. The cause of this clinical picture is theorized to be incomplete drainage of bile and pancreatic secretions from an afferent loop that is partially obstructed. Cases refractory to dietary measures may need surgical revision or conversion of the Billroth II anastomosis to a Roux-en-Y gastrojejunostomy.

Dumping Syndrome Dumping syndrome consists of a series of vasomotor and GI signs and symptoms and occurs in patients who have undergone vagotomy and drainage (especially Billroth procedures). Two phases of dumping, early and late, can occur. Early dumping takes place 15–30 min after meals and consists of crampy abdominal discomfort, nausea, diarrhea, belching, tachycardia, palpitations, diaphoresis, light-headedness, and, rarely, syncope. These signs and symptoms arise from the rapid emptying of hyperosmolar gastric contents into the small intestine, resulting in a fluid shift into the gut lumen with plasma volume contraction and acute intestinal distention. Release of vasoactive GI hormones (vasoactive intestinal polypeptide, neurotensin, motilin) is also theorized to play a role in early dumping.

The late phase of dumping typically occurs 90 min to 3 h after meals. Vasomotor symptoms (light-headedness, diaphoresis, palpitations, tachycardia, and syncope) predominate during this phase. This component of dumping is thought to be secondary to hypoglycemia from excessive insulin release.

Dumping syndrome is most noticeable after meals rich in simple carbohydrates (especially sucrose) and high osmolarity. Ingestion of large amounts of fluids may also contribute. After vagotomy and drainage, up to 50% of patients will experience dumping syndrome to some degree early on. Signs and symptoms often improve with time, but a severe protracted picture can occur in up to 1% of patients.

Dietary modification is the cornerstone of therapy for patients with dumping syndrome. Small, multiple (six) meals devoid of simple carbohydrates coupled with elimination of liquids during meals is important. Antidiarrheals and anticholinergic agents are complementary to diet. Guar and pectin, which increase the viscosity of intraluminal contents, may be beneficial in more symptomatic individuals. Acarbose, an α-glucosidase inhibitor that delays digestion of ingested carbohydrates, has also been shown to be beneficial in the treatment of the late phases of dumping. The somatostatin analogue octreotide has been successful in diet-refractory cases. This drug is administered subcutaneously (50 μg tid), titrated according to clinical response. A long-acting depot formulation of octreotide can be administered once every 28 days and provides symptom relief comparable to the short-acting agent. In addition, patient weight gain and quality of life appear to be superior with the long-acting form.

Postvagotomy Diarrhea Up to 10% of patients may seek medical attention for the treatment of postvagotomy diarrhea. This complication is most commonly observed after truncal vagotomy, which is rarely performed today. Patients may complain of intermittent diarrhea that occurs typically 1–2 h after meals. Occasionally, the symptoms may be severe and relentless. This is due to a motility disorder from interruption of the vagal fibers supplying the luminal gut. Other contributing factors may include decreased absorption of nutrients (see below), increased excretion of bile acids, and release of luminal factors that promote secretion. Diphenoxylate or

loperamide is often useful in symptom control. The bile salt–binding agent cholestyramine may be helpful in severe cases. Surgical reversal of a 10-cm segment of jejunum may yield a substantial improvement in bowel frequency in a subset of patients.

Bile Reflux Gastropathy A subset of post–partial gastrectomy patients who present with abdominal pain, early satiety, nausea, and vomiting will have mucosal erythema of the gastric remnant as the only finding. Histologic examination of the gastric mucosa reveals minimal inflammation but the presence of epithelial cell injury. This clinical picture is categorized as bile or alkaline reflux gastropathy/gastritis. Although reflux of bile is implicated as the reason for this disorder, the mechanism is unknown. Prokinetic agents, cholestyramine, and sucralfate have been somewhat effective treatments. Severe refractory symptoms may require using either nuclear scanning with ^{99m}Tc-HIDA to document reflux. Surgical diversion of pancreaticobiliary secretions away from the gastric remnant with a Roux-en-Y gastrojejunostomy consisting of a long (50–60 cm) Roux limb has been used in severe cases. Bilious vomiting improves, but early satiety and bloating may persist in up to 50% of patients.

Maldigestion and Malabsorption Weight loss can be observed in up to 60% of patients after partial gastric resection. Patients can experience a 10% loss of body weight, which stabilizes 3 months postoperatively. A significant component of this weight reduction is due to decreased oral intake. However, mild steatorrhea can also develop. Reasons for maldigestion/malabsorption include decreased gastric acid production, rapid gastric emptying, decreased food dispersion in the stomach, reduced luminal bile concentration, reduced pancreatic secretory response to feeding, and rapid intestinal transit.

Decreased serum vitamin B_{12} levels can be observed after partial gastrectomy. This is usually not due to deficiency of IF, since a minimal amount of parietal cells (source of IF) is removed during antrectomy. Reduced vitamin B_{12} may be due to competition for the vitamin by bacterial overgrowth or inability to split the vitamin from its protein-bound source due to hypochlorhydria.

Iron-deficiency anemia may be a consequence of impaired absorption of dietary iron in patients with a Billroth II gastrojejunostomy. Absorption of iron salts is normal in these individuals; thus, a favorable response to oral iron supplementation can be anticipated. Folate deficiency with concomitant anemia can also develop in these patients. This deficiency may be secondary to decreased absorption or diminished oral intake.

Malabsorption of vitamin D and calcium resulting in osteoporosis and osteomalacia is common after partial gastrectomy and gastrojejunostomy (Billroth II). Osteomalacia can occur as a late complication in up to 25% of post–partial gastrectomy patients. Bone fractures occur twice as commonly in men after gastric surgery as in a control population. It may take years before x-ray findings demonstrate diminished bone density. Elevated alkaline phosphatase, reduced serum calcium, bone pain, and pathologic fractures may be seen in patients with osteomalacia. The high incidence of these abnormalities in this subgroup of patients justifies treating them with vitamin D and calcium supplementation indefinitely. Therapy is especially important in females. Copper deficiency has also been reported in patients undergoing surgeries that bypass the duodenum, where copper is primarily absorbed. Patients may present with a rare syndrome that includes ataxia, myelopathy, and peripheral neuropathy.

Gastric Adenocarcinoma The incidence of adenocarcinoma in the gastric stump is increased 15 years after resection. Some have reported a four- to fivefold increase in gastric cancer 20–25 years after resection. The pathogenesis is unclear but may involve alkaline reflux, bacterial proliferation, or hypochlorhydria. The role of endoscopic screening is not clear, and most guidelines do not support its use.

Additional Complications Reflux esophagitis and a higher incidence of gallstones and cholecystitis have been reported in patients undergoing subtotal gastrectomy. The latter is thought to be due to decreased gallbladder contractility associated with vagotomy and bypass of the duodenum, leading to decreased postprandial release of cholecystokinin.

RELATED CONDITIONS

ZOLLINGER-ELLISON SYNDROME

Severe peptic ulcer diathesis secondary to gastric acid hypersecretion due to unregulated gastrin release from a non–β-cell, often well-differentiated neuroendocrine tumor (NET; gastrinoma) defines the components of ZES. Initially, ZES was typified by aggressive and refractory ulceration in which total gastrectomy provided the only chance for enhancing survival. Today, it can be cured by surgical resection in up to 40% of patients with the sporadic form of the disease (see below).

Epidemiology The true incidence of ZES is unknown, but estimates suggest that it varies from 0.1 to 1% of individuals presenting with PUD, with 0.1–3 individuals per year having this rare diagnosis. Others have estimated an incidence of 0.5–3 per million population. Females are slightly more commonly affected than males, and the majority of patients are diagnosed between ages 30 and 65. In addition, the time of diagnosis is estimated to be between 4 and 7 years after the onset of symptoms. Gastrinomas are classified into sporadic tumors (80%) and those associated with multiple endocrine neoplasia (MEN) type 1 (see below). The widespread availability and use of PPIs have led to a decreased patient referral for gastrinoma evaluation, delay in diagnosis, and an increase in false-positive diagnoses of ZES. In fact, diagnosis may be delayed for ≥6 years after symptoms consistent with ZES are displayed.

Pathophysiology Hypergastrinemia originating from an autonomous neoplasm is the driving force responsible for the clinical manifestations in ZES. Gastrin stimulates acid secretion through gastrin receptors on parietal cells and by inducing histamine release from ECL cells. Gastrin also has a trophic action on gastric epithelial cells. Longstanding hypergastrinemia leads to markedly increased gastric acid secretion through both parietal cell stimulation and increased parietal cell mass. The increased gastric acid output leads to peptic ulcer diathesis, erosive esophagitis, and diarrhea.

Tumor Distribution Although early studies suggested that the vast majority of gastrinomas occurred within the pancreas, a significant number of these lesions are extrapancreatic. Between 60 and 90% of these tumors are found within the hypothetical gastrinoma triangle (confluence of the cystic and common bile ducts superiorly, junction of the second and third portions of the duodenum inferiorly, and junction of the neck and body of the pancreas medially). Duodenal tumors constitute the most common nonpancreatic lesion; between 60 and 100% of gastrinomas are found here. Duodenal tumors are smaller, slower growing, and less likely to metastasize than pancreatic lesions and occur primarily in the first and second portion of the duodenum (90%). Less common extrapancreatic sites include stomach, bones, ovaries, heart, liver, and lymph nodes. More than 60% of tumors are considered malignant (determined by local invasion and/or evidence of metastasis), with up to 30–50% of patients having multiple lesions or metastatic disease at presentation. Histologically, gastrin-producing cells appear well-differentiated (grade 1 or 2 histologically), expressing markers typically found in endocrine neoplasms (chromogranin, neuron-specific enolase). Although not clearly established in gastrinomas, histologic grade in pancreatic NETs generally is an important predictor of survival in these rare neoplasms (Chap. 89).

Clinical Manifestations Gastric acid hypersecretion is responsible for the signs and symptoms observed in patients with ZES. The most common clinical presentation for gastrinoma patients is abdominal pain in the presence of acid peptic disorders. Peptic ulcer is the most common clinical manifestation, occurring in >90% of gastrinoma patients. Initial presentation and ulcer location (duodenal

bulb) may be indistinguishable from common PUD. Clinical situations that should create suspicion of gastrinoma are ulcers in unusual locations (second part of the duodenum and beyond), ulcers refractory to standard medical therapy, ulcer recurrence after acid-reducing surgery, ulcers presenting with frank complications (bleeding, obstruction, and perforation), or ulcers in the absence of *H. pylori* or NSAID ingestion. Symptoms of esophageal origin are present in up to two-thirds of patients with ZES, with a spectrum ranging from mild esophagitis to frank ulceration with stricture and Barrett's mucosa.

Diarrhea, the next most common clinical manifestation, is found in up to 70% of patients. Although diarrhea often occurs concomitantly with acid peptic disease, it may also occur independent of an ulcer and classically will abate with PPI therapy. Etiology of the diarrhea is multifactorial, resulting from marked volume overload to the small bowel, pancreatic enzyme inactivation by acid, and damage of the intestinal epithelial surface by acid. The epithelial damage can lead to a mild degree of maldigestion and malabsorption of nutrients. The diarrhea may also have a secretory component due to the direct stimulatory effect of gastrin on enterocytes or the co-secretion of additional hormones from the tumor such as vasoactive intestinal peptide.

Gastrinomas can develop in the presence of MEN 1 syndrome **(Chaps. 89 and 400)** in ~25% of patients. This autosomal dominant disorder involves primarily three organ sites: the parathyroid glands (80–90%), pancreas (40–80%), and pituitary gland (30–60%). The syndrome is caused by inactivating mutations of the *MEN1* tumor-suppressor gene found on the long arm of chromosome 11q13. The gene encodes for menin, which has an important role in DNA replication and transcriptional regulation. A genetic diagnosis is obtained by sequencing of the *MEN1* gene, which can reveal mutations in 70–90% of typical MEN 1 cases. A family may have an unknown mutation, making a genetic diagnosis impossible, and therefore, certain individuals will require a clinical diagnosis, which is determined by whether a patient has tumors in two of the three endocrine organs (parathyroid, pancreas/duodenum, or pituitary) or has a family history of MEN 1 and one of the endocrine organ tumors. In view of the stimulatory effect of calcium on gastric secretion, the hyperparathyroidism and hypercalcemia seen in MEN 1 patients may have a direct effect on ulcer disease. Resolution of hypercalcemia by parathyroidectomy reduces gastrin and gastric acid output in gastrinoma patients. An additional distinguishing feature in ZES patients with MEN 1 is the higher incidence of gastric carcinoid tumor development (as compared to patients with sporadic gastrinomas). ZES presents and is diagnosed earlier in MEN 1 patients, and they have a more indolent course as compared to patients with sporadic gastrinoma. Gastrinomas tend to be smaller, multiple, and located in the duodenal wall more often than is seen in patients with sporadic ZES. Establishing the diagnosis of MEN 1 is critical in order to provide genetic counseling to the patient and their family and also to determine the recommended surgical approach. Therefore, gastrinoma patients should be screened for MEN 1 by performing a detailed family history and obtaining several serum markers including calcium, parathyroid, prolactin, and pancreatic polypeptide levels.

Diagnosis Establishing an early diagnosis is important in order to minimize the long-term sequelae of gastric acid hypersecretion, prevent metastatic disease, and counsel family members if a diagnosis of MEN 1 is established. Biochemical measurements of gastrin and acid secretion in patients suspected of having ZES play an important role is establishing this rare diagnosis. Often, patients suspected of having ZES will be treated with a PPI in an effort to ameliorate symptoms and decrease the likelihood of possible acid-related complications. The presence of the PPI, which will lower acid secretion and potentially elevate fasting gastrin levels in normal individuals, will make the diagnostic approach in these individuals somewhat difficult. Significant morbidity related to peptic diathesis has been described when stopping PPIs in gastrinoma patients; therefore, a systematic approach in stopping these agents is warranted (see below). The first step in the evaluation of a patient suspected of having ZES is to obtain a fasting gastrin level. A list of clinical scenarios that should arouse suspicion regarding this diagnosis is shown in **Table 335-8**. Fasting gastrin levels obtained using a dependable assay are usually <150 pg/mL. A normal fasting gastrin, on two separate occasions, especially if the patient is on a PPI, virtually excludes this diagnosis. Virtually all gastrinoma patients will have a gastrin level >150–200 pg/mL. Measurement of fasting gastrin should be repeated to confirm the clinical suspicion. Some of the commercial biochemical assays used for measuring serum gastrin may be inaccurate. Variable specificity of the antibodies used have led to both false-positive and false-negative fasting gastrin levels, placing in jeopardy the ability to make an accurate diagnosis of ZES.

TABLE 335-8 When to Obtain a Fasting Serum Gastrin Level

Multiple ulcers
Ulcers in unusual locations; associated with severe esophagitis; resistant to therapy with frequent recurrences; in the absence of nonsteroidal anti-inflammatory drug ingestion or *H*elicobacter *pylori* infection
Ulcer patients awaiting surgery
Severe or refractory GERD
GERD associated with diarrhea
Extensive family history for peptic ulcer disease
Postoperative ulcer recurrence
Basal hyperchlorhydria
Unexplained diarrhea or steatorrhea
Diarrhea improved with PPI
Hypercalcemia
Family history of pancreatic islet, pituitary, or parathyroid tumor
Prominent gastric or duodenal folds

Multiple processes can lead to an elevated fasting gastrin level, the most frequent of which are gastric hypochlorhydria and achlorhydria, with or without pernicious anemia. Gastric acid induces feedback inhibition of gastrin release. A decrease in acid production will subsequently lead to failure of the feedback inhibitory pathway, resulting in net hypergastrinemia. Gastrin levels will thus be high in patients using antisecretory agents for the treatment of acid peptic disorders and dyspepsia. *H. pylori* infection can also cause hypergastrinemia. Additional causes of elevated gastrin include retained gastric antrum; G-cell hyperplasia; gastric outlet obstruction; renal insufficiency; massive small-bowel obstruction; and conditions such as rheumatoid arthritis, vitiligo, diabetes mellitus, and pheochromocytoma. Although a fasting gastrin >10 times normal is highly suggestive of ZES, two-thirds of patients will have fasting gastrin levels that overlap with levels found in the more common disorders outlined above, especially if a PPI is being taken by the patient. The effect of the PPI on gastrin levels and acid secretion will linger several days after stopping the PPI; therefore, it should be stopped for a minimum of 7 days before testing. During this period, the patient should be placed on a histamine H_2 antagonist, such as famotidine, twice to three times per day. Although this type of agent has a short-term effect on gastrin and acid secretion, it needs to be stopped 24 h before repeating fasting gastrin levels or performing some of the tests highlighted below. The patient may take antacids for the final day, stopping them ~12 h before testing is performed. Heightened awareness of complications related to gastric acid hypersecretion during the period of PPI cessation is critical.

Historically the next study typically recommended for establishing a biochemical diagnosis of gastrinoma is to assess acid secretion. Unfortunately, few centers perform this type of testing; thus, only a brief summary will be provided here. Typically, nothing further needs to be done if decreased acid output in the absence of a PPI is observed. A pH can be measured on gastric fluid obtained either during endoscopy or through nasogastric aspiration; a pH <3 is suggestive of a gastrinoma, but a pH >3 is not helpful in excluding the diagnosis. In those situations where the pH is >3, formal gastric acid analysis should be performed if available. Normal BAO in nongastric surgery patients is typically <5 meq/h. A BAO >15 meq/h in the presence of

hypergastrinemia is considered pathognomonic of ZES, but up to 12% of patients with common PUD may have elevated BAO to a lesser degree that can overlap with levels seen in ZES patients. In an effort to improve the sensitivity and specificity of gastric secretory studies, a BAO/MAO ratio was established using pentagastrin infusion as a way to maximally stimulate acid production, with a BAO/MAO ratio >0.6 being highly suggestive of ZES. Pentagastrin is no longer available in the United States, making measurement of MAO virtually impossible. An endoscopic method for measuring gastric acid output has been developed but requires further validation.

Gastrin provocative tests have been developed in an effort to differentiate between the causes of hypergastrinemia and are especially helpful in patients with indeterminate acid secretory studies. The tests are the secretin stimulation test and the calcium infusion study; the latter is rarely, if ever, utilized in our current environment due to the cumbersome nature of the test and its lower sensitivity and specificity than secretin stimulation. The most sensitive and specific gastrin provocative test for the diagnosis of gastrinoma is the secretin study. An increase in gastrin of ≥120 pg within 15 min of secretin injection has a sensitivity and specificity of >90% for ZES. PPI-induced hypochlorhydria or achlorhydria may lead to a false-positive secretin test; thus, this agent must be stopped for 1 week before testing.

In light of the limited availability of the biochemical studies outlined above, more studies make a diagnosis of gastrinoma based on the presence of elevated gastrin and low gastric pH in the right clinical setting coupled with tumor localization tests outlined below and positive histology by biopsy (difficult to obtain). Revised guidelines for the best approach to establishing a diagnosis of gastrinoma taking into consideration the above outlined limitations are being considered, but none have replaced the established guidelines outlined earlier in this section (see Jensen et al in Further Reading).

Tumor Localization Once the biochemical diagnosis of gastrinoma has been confirmed (if possible), the tumor must be located. Multiple imaging studies have been used in an effort to enhance tumor localization **(Table 335-9)**. The broad range of sensitivity is due to the variable success rates achieved by the different investigative groups. Endoscopic ultrasound (EUS) permits imaging of the pancreas with a high degree of resolution (<5 mm). This modality is particularly helpful in excluding small neoplasms within the pancreas and in assessing the presence of surrounding lymph nodes and vascular involvement, but it is not very sensitive (43%) for finding duodenal lesions. This latter observation has led some to not include EUS in the routine preoperative evaluation of a patient suspected of having a gastrinoma. Several types of endocrine tumors express cell-surface receptors for somatostatin, in particular the subtype 2 (SSTR2). This permits the localization, staging, and prediction of therapeutic response to somatostatin analogues (see below) by gastrinomas. The original functional scinitigraphic tool developed measuring the uptake of the stable somatostatin analogue ^{111}In-pentetreotide (OctreoScan) has demonstrated sensitivity and specificity rates of >80%. Positron emission tomography (PET)–computed tomography (CT) with ^{68}Ga-DOTATATE has been developed and is superior than OctreoScan for assessing tumor presence in patients with well-differentiated NETs such as gastrinomas, with sensitivity and specificity of >90%, making it the functional imaging study of choice when available. ^{18}F-Fluordeoxyglucose (^{18}F-FDG) PET imaging has been found to be useful in pancreatic NETs, including gastrinomas, particularly as a prognostic marker.

Up to 50% of patients have metastatic disease at diagnosis. Success in controlling gastric acid hypersecretion has shifted the emphasis of therapy toward providing a surgical cure. Detecting the primary tumor and excluding metastatic disease are critical in view of this paradigm shift. Once a biochemical diagnosis has been confirmed, the patient should first undergo an abdominal CT scan, magnetic resonance imaging (MRI), or OctreoScan/PET-CT with ^{68}Ga-DOTATATE (depending on availability) to exclude metastatic disease. Once metastatic disease has been excluded, an experienced endocrine surgeon may opt for exploratory laparotomy with intraoperative ultrasound or transillumination. In other centers, careful examination of the peripancreatic area with EUS, accompanied by endoscopic exploration of the duodenum for primary tumors, will be performed before surgery. Selective arterial secretin injection may be a useful adjuvant for localizing tumors in a subset of patients. The extent of the diagnostic and surgical approach must be carefully balanced with the patient's overall physiologic condition and the natural history of a slow-growing gastrinoma.

TABLE 335-9 Sensitivity of Imaging Studies in Zollinger-Ellison Syndrome

STUDY	SENSITIVITY, %	
	PRIMARY GASTRINOMA	HEPATIC METASTATIC GASTRINOMA
Ultrasound	0–28	15–77
CT scan	0–59	99–100
Selective angiography	35–68	96–100
Portal venous sampling	70–90	N/A
SASI	55–78	N/A
MRI	20–25	88–100
OctreoScan	55–77	90–100
EUS	28–86	N/A

Abbreviations: CT, computed tomography; EUS, endoscopic ultrasonography; MRI, magnetic resonance imaging; N/A, not applicable; OctreoScan, imaging with ^{111}In-pentetreotide; SASI, selective arterial secretin injection.

TREATMENT

Zollinger-Ellison Syndrome

Treatment of functional endocrine tumors is directed at ameliorating the signs and symptoms related to hormone overproduction, curative resection of the neoplasm, and attempts to control tumor growth in metastatic disease.

PPIs are the treatment of choice and have decreased the need for total gastrectomy. Initial PPI doses tend to be higher than those used for treatment of GERD or PUD. The initial dose of omeprazole, lansoprazole, rabeprazole, or esomeprazole should be in the range of 60 mg in divided doses in a 24-h period. When gastric acid analysis was more widely available, dosing was adjusted to achieve a BAO <10 meq/h (at the drug trough) in surgery-naive patients and to <5 meq/h in individuals who have previously undergone an acid-reducing operation. Close monitoring of clinical symptoms when starting PPIs and increasing the dose accordingly are paramount. Although the somatostatin analogue has inhibitory effects on gastrin release from receptor-bearing tumors and inhibits gastric acid secretion to some extent, PPIs have the advantage of reducing parietal cell activity to a greater degree. Despite this, octreotide or lanreotide may be considered as adjunctive therapy to the PPI in patients with tumors that express somatostatin receptors and have peptic symptoms that are difficult to control with high-dose PPI.

The ultimate goal of surgery would be to provide a definitive cure. Improved understanding of tumor distribution has led to immediate cure rates as high as 33% with 10-year disease-free intervals as high as 95% in sporadic gastrinoma patients undergoing surgery. A positive outcome is highly dependent on the experience of the surgical team treating these rare tumors. Surgical therapy of gastrinoma patients with MEN 1 remains controversial because of the difficulty in rendering these patients disease-free with surgery. In contrast to the encouraging postoperative results observed in patients with sporadic disease, <5% of MEN 1 patients are disease-free 5 years after an operation. Moreover, in contrast to patients with sporadic ZES, the clinical course of MEN 1 patients tends to be benign and rarely leads to disease-related mortality, recommending that early surgery be deferred. Some groups suggest surgery only if a clearly identifiable, nonmetastatic lesion is documented by structural studies. Others advocate a more aggressive approach, where

all patients free of hepatic metastasis are explored and all detected tumors in the duodenum are resected; this is followed by enucleation of lesions in the pancreatic head, with a distal pancreatectomy to follow. The outcome of the two approaches has not been clearly defined. Laparoscopic surgical interventions may provide attractive approaches in the future but currently seem to be of some limited benefit in patients with gastrinoma because a significant percentage of the tumors may be extrapancreatic and difficult to localize with a laparoscopic approach. Finally, patients selected for surgery should be individuals whose health status would lead them to tolerate a more aggressive operation and obtain the long-term benefits from such aggressive surgery, which are often witnessed after 10 years.

Therapy of metastatic endocrine tumors in general remains suboptimal; gastrinomas are no exception. In light of the observation that in many instances tumor growth is indolent and that many individuals with metastatic disease remain relatively stable for significant periods of time, many advocate not instituting systemic tumor-targeted therapy until evidence of tumor progression or refractory symptoms not controlled with PPIs are noted. Medical approaches, including biologic therapy (IFN-α, long-acting somatostatin analogues, and peptide receptor radionuclides), systemic chemotherapy (streptozotocin, 5-fluorouracil, and doxorubicin), and hepatic artery embolization, may lead to significant toxicity without a substantial improvement in overall survival. Use of temozolomide with capecitabine has demonstrated radiographic regression and progression-free survival in patients with well-differentiated NETs in the range of 70% and 18 months, respectively. Systemic therapy with radiolabeled somatostatin analogues (peptide receptor radiotherapy [PRRT]) has been used in the therapy of metastatic NETs and appears to be very promising in terms of radiographic regression, symptoms, and progression-free survival, but additional studies are warranted. Several promising therapies are being explored, including radiofrequency ablation or cryoablation of liver lesions and use of agents that block the VEGF receptor pathway (sunitinib, surufatinib), the mammalian target of rapamycin, and immune checkpoint inhibitors **(Chap. 89)**.

Surgical approaches, including debulking surgery and liver transplantation for hepatic metastasis, have also produced limited benefit.

The overall 5- and 10-year survival rates for gastrinoma patients are 62–75% and 47–53%, respectively. Individuals with the entire tumor resected or those with a negative laparotomy have 5- and 10-year survival rates >90%. Patients with incompletely resected tumors have 5- and 10-year survival rates of 43 and 25%, respectively. Patients with hepatic metastasis have <20% survival at 5 years. Favorable prognostic indicators include primary duodenal wall tumors, isolated lymph node tumor, the presence of MEN 1, and undetectable tumor upon surgical exploration. Poor outcome is seen in patients with shorter disease duration; female sex; older age at diagnosis; higher gastrin levels (>10,000 pg/mL); poor histologic differentiation; high proliferative index; certain tumor molecular changes including chromosome 1qLOH and chromosome XLOH; large pancreatic primary tumors (>2–3 cm); metastatic disease to lymph nodes, liver, and bone; and Cushing's syndrome. Rapid growth of hepatic metastases is also predictive of poor outcome.

STRESS-RELATED MUCOSAL INJURY

Patients suffering from shock, sepsis, massive burns, severe trauma, or head injury can develop acute erosive gastric mucosal changes or frank ulceration with bleeding. Classified as stress-induced gastritis or ulcers, injury is most commonly observed in the acid-producing (fundus and body) portions of the stomach. The most common presentation is GI bleeding, which is usually minimal but can occasionally be life-threatening. Respiratory failure requiring mechanical ventilation and underlying coagulopathy are risk factors for bleeding, which tends to occur 48–72 h after the acute injury or insult.

Histologically, stress injury does not contain inflammation or *H. pylori*; thus, "gastritis" is a misnomer. Although elevated gastric acid secretion may be noted in patients with stress ulceration after head trauma (Cushing's ulcer) and severe burns (Curling's ulcer), mucosal ischemia, breakdown of the normal protective barriers of the stomach, systemic release of cytokines, poor GI motility, and oxidative stress also play an important role in the pathogenesis. Acid must contribute to injury in view of the significant drop in bleeding noted when acid inhibitors are used as prophylaxis for stress gastritis.

Improvement in the general management of intensive care unit patients has led to a significant decrease in the incidence of GI bleeding due to stress ulceration. The estimated decrease in bleeding is from 20–30% to <5%. This improvement has led to some debate regarding the need for prophylactic therapy. The high mortality associated with stress-induced clinically important GI bleeding (>40%) and the limited benefit of medical (endoscopic, angiographic) and surgical therapy in a patient with hemodynamically compromising bleeding associated with stress ulcer/gastritis support the use of preventive measures in high-risk patients (mechanically ventilated, coagulopathy, multiorgan failure, or severe burns). Meta-analysis comparing H_2 blockers with PPIs for the prevention of stress-associated clinically important and overt GI bleeding demonstrates superiority of the latter without increasing the risk of nosocomial infections, increasing mortality, or prolonging intensive care unit length of stay. Therefore, PPIs are the treatment of choice for stress prophylaxis. Oral PPI is the best option if the patient can tolerate enteral administration. Pantoprazole is available as an intravenous formulation for individuals in whom enteral administration is not possible. If bleeding occurs despite these measures, endoscopy, intra-arterial vasopressin, and embolization are options. If all else fails, then surgery should be considered. Although vagotomy and antrectomy may be used, the better approach would be a total gastrectomy, which has an exceedingly high mortality rate in this setting. Concerns with the effect of PPIs on the immune system coupled with the high cost of this agent have led to several comparative studies of PPIs and H_2 receptor antagonists for stress prophylaxis in patients requiring mechanical ventilation. Although the PEPTIC trial demonstrated comparative efficacy between the two agents regarding mortality, technical aspects of the study led to some limitation in the final interpretation of the results. A meta-analysis performed in neurocritical patients did not reach strong clinical recommendations about the utility of ulcer prophylaxis. Reasons for this conclusion included the overall high or unclear risk of bias of individual trials, the low event rates, and the modest sample size examined. Currently, a trial to determine safety and efficacy of pantoprazole compared to placebo for preventing stress-induced erosions is ongoing in mechanically ventilated patients.

GASTRITIS

The term *gastritis* should be reserved for histologically documented inflammation of the gastric mucosa. Gastritis is not the mucosal erythema seen during endoscopy and is not interchangeable with "dyspepsia." The etiologic factors leading to gastritis are broad and heterogeneous. Gastritis has been classified based on time course (acute vs chronic), histologic features, and anatomic distribution or proposed pathogenic mechanism **(Table 335-10)**.

The correlation between the histologic findings of gastritis, the clinical picture of abdominal pain or dyspepsia, and endoscopic findings noted on gross inspection of the gastric mucosa is poor. Therefore, there is no typical clinical manifestation of gastritis.

Acute Gastritis The most common causes of acute gastritis are infectious. Acute infection with *H. pylori* induces gastritis. However, *H. pylori* acute gastritis has not been extensively studied. It is reported as presenting with sudden onset of epigastric pain, nausea, and vomiting, and limited mucosal histologic studies demonstrate a marked infiltrate of neutrophils with edema and hyperemia. If not treated, this picture will evolve into one of chronic gastritis. Hypochlorhydria lasting for up to 1 year may follow acute *H. pylori* infection.

Bacterial infection of the stomach or phlegmonous gastritis is a rare, potentially life-threatening disorder characterized by marked and diffuse acute inflammatory infiltrates of the entire gastric wall, at times accompanied by necrosis. Elderly individuals, alcoholics, and AIDS

TABLE 335-10 Classification of Gastritis

I. Acute gastritis
  A. Acute *Helicobacter pylori* infection
  B. Other acute infectious gastritides
    1. Bacterial (other than *H. pylori*)
    2. *Helicobacter heilmannii*
    3. Phlegmonous
    4. Mycobacterial
    5. Syphilitic
    6. Viral
    7. Parasitic
    8. Fungal
II. Chronic atrophic gastritis
  A. Type A: Autoimmune, body-predominant
  B. Type B: *H. pylori*–related, antral-predominant
  C. Indeterminate
III. Uncommon forms of gastritis
  A. Lymphocytic
  B. Eosinophilic
  C. Crohn's disease
  D. Sarcoidosis
  E. Isolated granulomatous gastritis
  F. Russell body gastritis

patients may be affected. Potential iatrogenic causes include polypectomy and mucosal injection with India ink. Organisms associated with this entity include streptococci, staphylococci, *Escherichia coli*, *Proteus*, and *Haemophilus* species. Failure of supportive measures and antibiotics may result in gastrectomy.

Other types of infectious gastritis may occur in immunocompromised individuals such as AIDS patients. Examples include herpetic (herpes simplex) or CMV gastritis. The histologic finding of intranuclear inclusions would be observed in the latter.

Chronic Gastritis Chronic gastritis is identified histologically by an inflammatory cell infiltrate consisting primarily of lymphocytes and plasma cells, with very scant neutrophil involvement. Distribution of the inflammation may be patchy, initially involving superficial and glandular portions of the gastric mucosa. This picture may progress to more severe glandular destruction, with atrophy and metaplasia. Chronic gastritis has been classified according to histologic characteristics. These include superficial atrophic changes and gastric atrophy. The association of atrophic gastritis with the development of gastric cancer has led to the development of endoscopic and serologic markers of severity. Some of these include gross inspection and classification of mucosal abnormalities during standard endoscopy, magnification endoscopy, endoscopy with narrow band imaging and/or autofluorescence imaging, and measurement of several serum biomarkers including pepsinogen I and II levels, gastrin-17, and anti–*H. pylori* serologies. The clinical utility of these tools is currently being explored.

The early phase of chronic gastritis is *superficial gastritis.* The inflammatory changes are limited to the lamina propria of the surface mucosa, with edema and cellular infiltrates separating intact gastric glands. The next stage is *atrophic gastritis.* The inflammatory infiltrate extends deeper into the mucosa, with progressive distortion and destruction of the glands. The final stage of chronic gastritis is *gastric atrophy.* Glandular structures are lost, and there is a paucity of inflammatory infiltrates. Endoscopically, the mucosa may be substantially thin, permitting clear visualization of the underlying blood vessels.

Gastric glands may undergo morphologic transformation in chronic gastritis. Intestinal metaplasia denotes the conversion of gastric glands to a small intestinal phenotype with small-bowel mucosal glands containing goblet cells. The metaplastic changes may vary in distribution from patchy to fairly extensive gastric involvement. Intestinal metaplasia is an important predisposing factor for gastric cancer **(Chap. 85)**.

Chronic gastritis has also been classified according to the predominant site of involvement. Type A refers to the body-predominant form (autoimmune), and type B is the antral-predominant form (*H. pylori*–related). This classification is artificial in view of the difficulty in distinguishing between these two entities. The term *AB gastritis* has been used to refer to a mixed antral/body picture. Histologic classification is the most accurate way to approach chronic gastritis.

TYPE A GASTRITIS The less common of the two forms involves primarily the fundus and body, with antral sparing. Traditionally, this form of gastritis has been associated with pernicious anemia **(Chap. 104)** in the presence of circulating antibodies against parietal cells and IF; thus, it is also called *autoimmune gastritis. H. pylori* infection can lead to a similar distribution of gastritis.

Antibodies to parietal cells have been detected in >90% of patients with pernicious anemia and in up to 50% of patients with type A gastritis. The parietal cell antibody is directed against H^+,K^+-ATPase. T cells are also implicated in the injury pattern of this form of gastritis. A subset of patients infected with *H. pylori* develop antibodies against H^+,K^+-ATPase, potentially leading to the atrophic gastritis pattern seen in some patients infected with this organism. The mechanism is thought to involve molecular mimicry between *H. pylori* LPS and H^+,K^+-ATPase.

Parietal cell antibodies and atrophic gastritis are observed in family members of patients with pernicious anemia. These antibodies are observed in up to 20% of individuals aged >60 and in ~20% of patients with vitiligo and Addison's disease. About one-half of patients with pernicious anemia have antibodies to thyroid antigens, and ~30% of patients with thyroid disease have circulating anti–parietal cell antibodies. Anti-IF antibodies are more specific than parietal cell antibodies for type A gastritis, being present in ~40% of patients with pernicious anemia. Another parameter consistent with this form of gastritis being autoimmune in origin is the higher incidence of specific familial histocompatibility haplotypes such as HLA-B8 and HLA-DR3. Low pepsinogen levels have also been observed; thus, this marker has been used as an additional diagnostic tool in autoimmune gastritis.

The parietal cell–containing gastric gland is preferentially targeted in this form of gastritis, and achlorhydria results. Parietal cells are the source of IF, the lack of which will lead to vitamin B_{12} deficiency and its sequelae (megaloblastic anemia, neurologic dysfunction).

Gastric acid plays an important role in feedback inhibition of gastrin release from G cells. Achlorhydria, coupled with relative sparing of the antral mucosa (site of G cells), leads to hypergastrinemia. Gastrin levels can be markedly elevated (>500 pg/mL) in patients with pernicious anemia. ECL cell hyperplasia with frank development of gastric carcinoid tumors may result from gastrin trophic effects. Hypergastrinemia and achlorhydria may also be seen in nonpernicious anemia–associated type A gastritis.

TYPE B GASTRITIS Type B, or antral-predominant, gastritis is the more common form of chronic gastritis. *H. pylori* infection is the cause of this entity. Although described as "antral-predominant," this is likely a misnomer in view of studies documenting the progression of the inflammatory process toward the body and fundus of infected individuals. The conversion to a pangastritis is time dependent and estimated to require 15–20 years. This form of gastritis increases with age, being present in up to 100% of persons aged >70. Histology improves after *H. pylori* eradication. The number of *H. pylori* organisms decreases dramatically with progression to gastric atrophy, and the degree of inflammation correlates with the level of these organisms. Early on, with antral-predominant findings, the quantity of *H. pylori* is highest and a dense chronic inflammatory infiltrate of the lamina propria is noted, accompanied by epithelial cell infiltration with polymorphonuclear leukocytes **(Fig. 335-16)**.

Multifocal atrophic gastritis, gastric atrophy with subsequent metaplasia, has been observed in chronic *H. pylori*–induced gastritis. This may ultimately lead to development of gastric adenocarcinoma (Fig. 335-8; **Chap. 85**). *H. pylori* infection is now considered an independent risk factor for gastric cancer. Worldwide epidemiologic studies have documented a higher incidence of *H. pylori* infection in

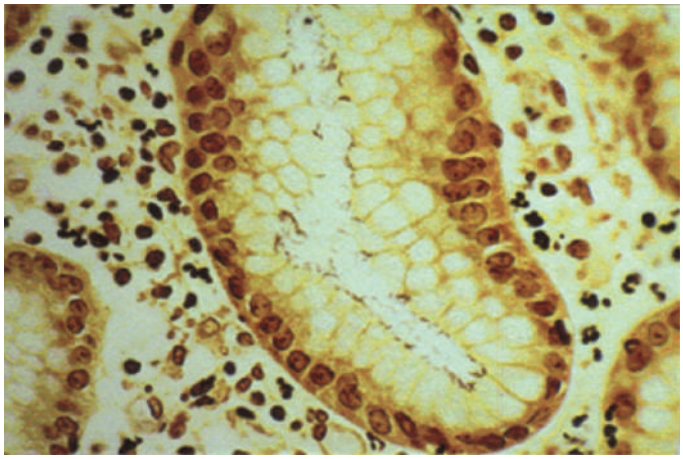

FIGURE 335-16 Chronic gastritis and *H. pylori* organisms. Steiner silver stain of superficial gastric mucosa showing abundant darkly stained microorganisms layered over the apical portion of the surface epithelium. Note that there is no tissue invasion.

patients with adenocarcinoma of the stomach as compared to control subjects. Seropositivity for *H. pylori* is associated with a three- to sixfold increased risk of gastric cancer. This risk may be as high as ninefold after adjusting for the inaccuracy of serologic testing in the elderly. The mechanism by which *H. pylori* infection leads to cancer is unknown, but it appears to be related to the chronic inflammation induced by the organism. Eradication of *H. pylori* as a general preventative measure for gastric cancer is being evaluated but is not yet recommended.

Infection with *H. pylori* is also associated with development of a low-grade B-cell lymphoma, gastric MALT lymphoma **(Chap. 113)**. The chronic T-cell stimulation caused by the infection leads to production of cytokines that promote the B-cell tumor. The tumor should be initially staged with a CT scan of the abdomen and EUS. Tumor growth remains dependent on the presence of *H. pylori*, and its eradication is often associated with complete regression of the tumor. The tumor may take more than a year to regress after treating the infection. Such patients should be followed by EUS every 2–3 months. If the tumor is stable or decreasing in size, no other therapy is necessary. If the tumor grows, it may have become a high-grade B-cell lymphoma. When the tumor becomes a high-grade aggressive lymphoma histologically, it loses responsiveness to *H. pylori* eradication.

TREATMENT

Chronic Gastritis

Treatment in chronic gastritis is aimed at the sequelae and not the underlying inflammation. Patients with pernicious anemia will require parenteral vitamin B_{12} supplementation on a long-term basis. Eradication of *H. pylori* is often recommended even if PUD or a low-grade MALT lymphoma is not present. Expert opinion suggests that patients with atrophic gastritis complicated by intestinal metaplasia without dysplasia should undergo surveillance endoscopy every 3 years.

Miscellaneous Forms of Gastritis *Lymphocytic gastritis* is characterized histologically by intense infiltration of the surface epithelium with lymphocytes. The infiltrative process is primarily in the body of the stomach and consists of mature T cells and plasmacytes. The etiology of this form of chronic gastritis is unknown. It has been described in patients with celiac sprue, but whether there is a common factor associating these two entities is unknown. No specific symptoms suggest lymphocytic gastritis. A subgroup of patients has thickened folds noted on endoscopy. These folds are often capped by small nodules that contain a central depression or erosion; this form of the disease is called *varioliform gastritis. H. pylori* probably plays no significant role in lymphocytic gastritis. Therapy with glucocorticoids or sodium cromoglycate has obtained unclear results.

Marked eosinophilic infiltration involving any layer of the stomach (mucosa, muscularis propria, and serosa) is characteristic of *eosinophilic gastritis.* Affected individuals will often have circulating eosinophilia with clinical manifestation of systemic allergy. Involvement may range from isolated gastric disease to diffuse eosinophilic gastroenteritis. Antral involvement predominates, with prominent edematous folds being observed on endoscopy. These prominent antral folds can lead to outlet obstruction. Patients can present with epigastric discomfort, nausea, and vomiting. Treatment with glucocorticoids has been successful.

Several systemic disorders may be associated with *granulomatous gastritis.* Gastric involvement has been observed in Crohn's disease. Involvement may range from granulomatous infiltrates noted only on gastric biopsies to frank ulceration and stricture formation. Gastric Crohn's disease usually occurs in the presence of small-intestinal disease. Several rare infectious processes can lead to granulomatous gastritis, including histoplasmosis, candidiasis, syphilis, and tuberculosis. Other unusual causes of this form of gastritis include sarcoidosis, idiopathic granulomatous gastritis, and eosinophilic granulomas involving the stomach. Establishing the specific etiologic agent in this form of gastritis can be difficult, at times requiring repeat endoscopy with biopsy and cytology. Occasionally, a surgically obtained full-thickness biopsy of the stomach may be required to exclude malignancy.

Russell body gastritis (RBG) is a mucosal lesion of unknown etiology that has a pseudotumoral endoscopic appearance. Histologically, it is defined by the presence of numerous plasma cells containing Russell bodies (RBs) that express kappa and lambda light chains. Only 10 cases have been reported, and 7 of these have been associated with *H. pylori* infection. The lesion can be confused with a neoplastic process, but it is benign in nature, and the natural history of the lesion is not known. There have been cases of resolution of the lesion when *H. pylori* was eradicated.

Immune checkpoint inhibitor–induced enterocolitis and gastritis are recognized sequelae of these oncologic therapies. The gastritis typically occurs later in the course of therapy. The diagnosis is made by the histologic findings on gastric mucosal biopsies obtained endoscopically. This is an important diagnosis to make since therapy with glucocorticoids and potentially IL-6 receptor blockers will be required. Moreover, this side effect will have an effect on the oncologic therapy prescribed.

MÉNÉTRIER'S DISEASE

Ménétrier's disease (MD) is a very rare gastropathy characterized by large, tortuous mucosal folds. MD has an average age of onset of 40–60 years with a male predominance. The differential diagnosis of large gastric folds includes ZES, malignancy (lymphoma, infiltrating carcinoma), infectious etiologies (CMV, histoplasmosis, syphilis, tuberculosis), gastritis polyposa profunda, and infiltrative disorders such as sarcoidosis. MD is most commonly confused with large or multiple gastric polyps (prolonged PPI use) or familial polyposis syndromes. The mucosal folds in MD are often most prominent in the body and fundus, sparing the antrum. Histologically, massive foveolar hyperplasia (hyperplasia of surface and glandular mucous cells) and a marked reduction in oxyntic glands and parietal cells and chief cells are noted. This hyperplasia produces the prominent folds observed. The pits of the gastric glands elongate and may become extremely dilated and tortuous. Although the lamina propria may contain a mild chronic inflammatory infiltrate including eosinophils and plasma cells, MD is not considered a form of gastritis. The etiology of this unusual clinical picture in children is often CMV, but the etiology in adults is unknown. Overexpression of the growth factor TGF-α has been demonstrated in patients with MD. The overexpression of TGF-α in turn results in overstimulation of the epidermal growth factor receptor (EGFR) pathway and increased proliferation of mucus cells, resulting in the observed foveolar hyperplasia.

The clinical presentation in adults is usually insidious and progressive. Epigastric pain, nausea, vomiting, anorexia, peripheral edema,

and weight loss are signs and symptoms in patients with MD. Occult GI bleeding may occur, but overt bleeding is unusual and, when present, is due to superficial mucosal erosions. In fact, bleeding is more often seen in one of the common mimics of MD, gastric polyposis. Twenty to 100% of patients (depending on time of presentation) develop a protein-losing gastropathy due to hypersecretion of gastric mucus accompanied by hypoalbuminemia and edema. Gastric acid secretion is usually reduced or absent because of the decreased parietal cells. Large gastric folds are readily detectable by either radiographic (barium meal) or endoscopic methods. Endoscopy with deep mucosal biopsy, preferably full thickness with a snare technique, is required to establish the diagnosis and exclude other entities that may present similarly. A nondiagnostic biopsy may lead to a surgically obtained full-thickness biopsy to exclude malignancy. Although MD is considered premalignant by some, the risk of neoplastic progression is not defined. Complete blood count, serum gastrin, serum albumin, CMV and *H. pylori* serology, and pH testing of gastric aspirate during endoscopy should be included as part of the initial evaluation of patients with large gastric folds. A retrospective case-control study suggested an increased risk of developing gastric adenocarcinoma and decreased 5- and 10-year survival compared to a control cohort. Additional studies will be required to confirm these initial findings, but this may be difficult to achieve in light of the rarity of this unusual diagnosis.

TREATMENT

Ménétrier's Disease

Medical therapy with anticholinergic agents, prostaglandins, PPIs, prednisone, somatostatin analogues (octreotide), and H_2 receptor antagonists yields varying results. Ulcers should be treated with a standard approach. The discovery that MD is associated with overstimulation of the EGFR pathway has led to the successful use of the EGF inhibitory antibody, cetuximab, in these patients. Specifically, four of seven patients who completed a 1-month trial with this agent demonstrated near-complete histologic remission and improvement in symptoms. Cetuximab is now considered the first-line treatment for MD, leaving partial or total gastrectomy for severe disease with persistent and substantial protein loss despite therapy with this agent.

336 Disorders of Absorption

Deborah C. Rubin

A wide range of diseases affect gastrointestinal (GI) absorptive function and may result in malabsorption syndromes. These disorders affect one or more of the three phases of enteral nutrient processing. *Luminal digestion* is initiated by lingual and gastric lipase and gastric pepsin and continues in the small bowel by the actions of pancreatic enzymes and bile salts. *Small-intestinal mucosal digestion and absorption* are mediated by enterocyte brush border enzymes including disaccharidases, enterokinases, and peptidases, which digest nutrients upon contact, and by mixed micelles containing lipids and bile salts. Protein and carbohydrate digestive products are transported into the enterocyte by carriers and transporters, and lipids enter by diffusion mediated by micelles. Once in the enterocyte, nutrients may be reprocessed for *postmucosal absorption* and entry into lymphatics (long-chain triglycerides as part of chylomicrons) or are transported into the bloodstream. Malabsorptive diseases or syndromes can be classified by their effects on one or more of these three phases of absorption **(Table 336-1)**.

Disorders of absorption also have diverse clinical presentations. For example, the deficiency of a single brush border membrane protein such as lactase causes symptoms of diarrhea by affecting the absorption of one nutrient, lactose. Celiac sprue may be localized to the duodenum and present with isolated iron deficiency or may cause diffuse intestinal mucosal disease, affecting the absorption of multiple nutrients and causing a constellation of symptoms and clinical presentations.

Definition of Diarrhea Diarrhea is the most common symptom associated with disorders of absorption. For most patients, diarrhea as a symptom is defined as an increase in stool number or frequency or a change in consistency. Because normal bowel patterns may vary from as many as two to four bowel movements per day to one stool per week, it is critical to use an objective measure of diarrhea to help direct evaluation. In health, stool volume or weight is <200 mL or <200 g, respectively, in 24 h. Collection of stool for weight/volume determination is one of the most useful tools for an evaluation of diarrhea. In particular, a 72-h collection for weight/volume and fecal fat determination is the gold standard for documenting the presence of steatorrhea, or fatty stool. Steatorrhea, defined as increased stool fat excretion to >7% of dietary fat, is a common manifestation of malabsorption. Steatorrhea often results in large, bulky, and malodorous stools. Malabsorption of single nutrients like lactose may result in an osmotic diarrhea, in which the osmotically active unabsorbed nutrient causes fluid to be drawn into the GI tract lumen. Malabsorptive diarrhea frequently is precipitated by eating and resolves or significantly decreases at night,

TABLE 336-1 Classification of Malabsorption Syndromes

- Inadequate digestion
  - Postgastrectomy[a]
  - Deficiency or inactivation of pancreatic lipase
    - Exocrine pancreatic insufficiency
      - Chronic pancreatitis
      - Pancreatic carcinoma
      - Cystic fibrosis
      - Pancreatic insufficiency—congenital or acquired
  - Gastrinoma—acid inactivation of lipase
  - Drugs—orlistat
- Reduced intraduodenal bile-acid concentration/impaired micelle formation
  - Liver disease
    - Parenchymal liver disease
    - Cholestatic liver disease
  - Bacterial overgrowth in small intestine:
    - Anatomic stasis
      - Afferent loop
      - Stasis/blind
      - Loop/strictures/fistulae
    - Functional stasis
      - Diabetes[a]
      - Scleroderma[a]
      - Intestinal pseudo-obstruction
  - Interrupted enterohepatic circulation of bile salts
    - Ileal resection
    - Crohn's disease
  - Drugs (binding or precipitating bile salts)—neomycin, cholestyramine, calcium carbonate
  - Impaired mucosal absorption/mucosal loss or defect
    - Intestinal resection or bypass[a]
    - Inflammation, infiltration, or infection:
      - Crohn's disease[a]
      - Amyloidosis
      - Scleroderma[a]
      - Lymphoma[a]

- Endocrine and metabolic disorders
  - Diabetes[a]
  - Hypoparathyroidism
  - Adrenal insufficiency
  - Hyperthyroidism
  - Carcinoid syndrome

[a]Malabsorption caused by more than one mechanism.

with fasting, and thus can frequently be distinguished from secretory diarrheas, for example from infectious causes such as bacterial enterotoxigenic *Escherichia coli*. In this circumstance, intestinal fluid and electrolyte secretion is stimulated by enterotoxin and will continue even during fasting.

OVERVIEW: NUTRIENT DIGESTION AND ABSORPTION

Luminal digestive processes begin in the mouth and proceed throughout the GI tract, mediated by salivary amylase, lingual and gastric lipases, gastric acid, pancreatic enzymes, and bile salts. As nutrients are digested in the lumen of the proximal GI tract, they are further processed by enterocyte brush border enzymes including disaccharidases such as lactase and sucrase-isomaltase, which produce monosaccharides, and peptidases, which hydrolyze polypeptides into tripeptides and dipeptides and amino acids. Lipids in mixed micelles are then absorbed into enterocytes.

The surface area of the small bowel, which is normally 600 cm long, is further enhanced by circular folds, villi, and microvilli. Following uptake into enterocytes, nutrients are further processed and transported into the lymphatics or into the portal circulation for use by other cells throughout the body. The intestine is also presented with 7–9 L of fluid daily, a volume comprising dietary fluid intake (1–2 L/day) and salivary, gastric, pancreatic, biliary, and intestinal fluid (6–7 L/day). In health, almost all of this fluid is reabsorbed by the small bowel and colon, resulting in a normal stool volume of <200 mL or stool weight of <200 g.

SPECIFIC NUTRIENTS

Lipids Lipid absorption is a complex process that requires hydrolysis by pancreatic enzymes and bile salts for physiochemical dispersion of fats, followed by absorption of processed lipid nutrients dispersed in bile salt–mixed micelles across the intestinal epithelium. Bile acids are synthesized in the liver, secreted into the intestinal lumen, and constantly recirculated by absorption in the ileum. The ileum expresses fibroblast growth factor 19 (FGF19), which is a physiologic bile acid sensor. FGF19 is secreted from the ileum into the bloodstream in response to bile acid flux and negatively regulates hepatic bile acid synthesis by affecting the transcription of hepatic CYP7A1.

Thus, assimilation of dietary lipid requires three integrated processes: an intraluminal or digestive phase, a mucosal or absorptive phase, and a delivery or postabsorptive phase (Table 336-2).

Gastric lipases begin the lipolytic process. Following entry into the small bowel, long-chain triglycerides, with carbon lengths >12 and that are the major component of dietary lipid, are hydrolyzed by pancreatic lipases into fatty acids and monoglyceride during a process called *lipolysis* (Fig. 336-1). Long-chain free fatty acids are dispersed by bile salts into mixed micelles, which contact the brush border and permit fatty acid absorption into enterocytes across this specialized apical membrane. The other two types of fatty acids that compose fats, medium-chain and short-chain fatty acids, are soluble in the unstirred water layer. Medium-chain triglycerides with carbon chain lengths of 8–12 are found in coconut oil. Long-chain fatty acids are re-esterified to triglycerides in enterocytes, packaged into chylomicrons that contain apolipoproteins on the surface, which are subsequently secreted into the extracellular space, and because of their size, are excluded

TABLE 336-2 Defects in Lipid Digestion and Absorption in Steatorrhea

PHASE, PROCESS	PATHOPHYSIOLOGIC DEFECT	DISEASE EXAMPLE
Digestive		
Lipolysis formation	Decreased lipase secretion	Chronic pancreatitis
Micelle formation	Decreased intraduodenal bile acids	
Absorptive		
Mucosal uptake and re-esterification	Mucosal dysfunction	Celiac disease
Postabsorptive		
Chylomicron formation	Absent β-lipoproteins	Abetalipoproteinemia
Delivery from intestine	Abnormal lymphatics	Intestinal lymphangiectasia

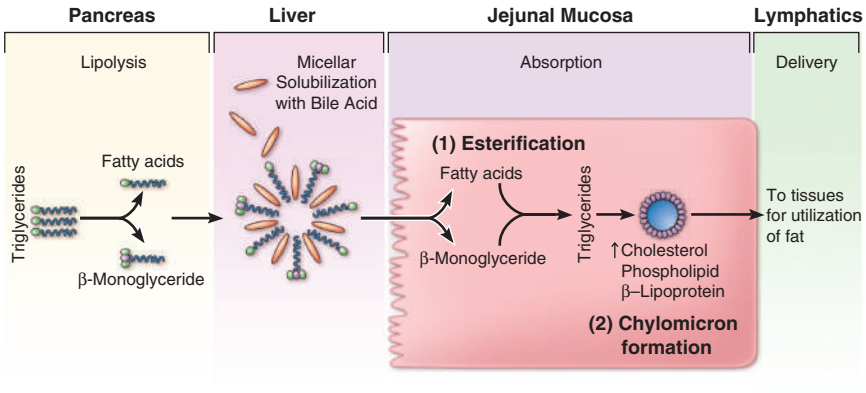

FIGURE 336-1 Schematic representation of lipid digestion and absorption. Dietary lipid is in the form of long-chain triglycerides. The overall process can be divided into (1) a digestive phase that includes both lipolysis and micelle formation requiring pancreatic lipase and conjugated bile acids, respectively, in the duodenum; (2) an absorptive phase for mucosal uptake and re-esterification; and (3) a postabsorptive phase that includes chylomicron formation and exit from the intestinal epithelial cell via lymphatics. *(Courtesy of John M. Dietschy, MD; with permission.)*

from capillaries and enter the lymphatics. Medium-chain triglycerides do not require micelle formation or pancreatic lipolysis as they are directly absorbed intact from the small bowel into the bloodstream, and short-chain fatty acids (carbon length <8) are produced by and absorbed in the colon.

Carbohydrates Dietary carbohydrate consists of starch, sucrose, lactose, maltose, and monosaccharides such as glucose and fructose. Starch is digested by salivary α-amylase in the mouth, followed by pancreatic amylase. The main products include maltotriose, maltose, and α-dextrins. These are further digested on the brush border membrane by disaccharidases such as glucoamylase and sucrase-isomaltase. Dietary lactose is digested by brush border lactase, sucrose by sucrase, and trehalose by trehalase. The final digested products are glucose, fructose, and galactose, which are transported into the enterocyte by transporters such as SLCA5 (formerly SGLT-1), which transports glucose or galactose in a sodium-dependent manner, and GLUT-5, which transports fructose by facilitated diffusion. Glucose, galactose, and fructose exit the cell via GLUT-2.

Proteins Dietary protein digestion begins in the stomach by pepsin. Pancreatic proteases including endopeptidases, exopeptidases, and trypsin are activated in the small-bowel lumen. Trypsinogen is activated by brush border enterokinase to generate active trypsin. Trypsin in turn activates chymotrypsinogen to chymotrypsin, proelastase to elastase, and procarboxypeptidases to carboxypeptidases A and B. These enzymes digest protein into dipeptides, tripeptides, larger polypeptides, or free amino acids. At the brush border, peptidases digest larger peptides into dipeptides and tripeptides or free amino acids, which enter the enterocyte via specialized carriers. Most dipeptides and tripeptides are further metabolized intracellularly by cytoplasmic peptidase into amino acids, which directly enter the bloodstream via carriers in the basolateral membrane. Small amounts of dipeptides and tripeptides may also enter the bloodstream.

LUMINAL PHASE OF DIGESTION

The luminal phase of digestion begins in the mouth, starting with mastication and lipase secretion by the tongue and salivary glands. The stomach continues the luminal digestive process, via gastric acid, gastric lipase, and pepsin secretion as well as mechanical trituration of contents. In the small-bowel lumen, pancreatic enzymes (amylase, lipases, carboxypeptidase, trypsin, and other endopeptidases) contribute to carbohydrate, lipid, and protein digestion, respectively. Bile salts produced by the liver are secreted into the intestinal lumen (and reabsorbed in the ileum via the enterohepatic circulation) and are required for efficient lipid absorption.

Disorders That Affect the Luminal Phase of Digestion The luminal phase may be disrupted by *disorders of gastric and intestinal motility* including the sequelae of gastric surgery, systemic diseases such as scleroderma, or endocrine disorders such as diabetes mellitus; *pancreatic diseases* leading to pancreatic insufficiency with reduced pancreatic enzyme secretion; or *luminal bile salt deficiency* caused by hepatobiliary disease, ileal disease, or small-bowel bacterial overgrowth.

Gastric Resection Surgical procedures that remove or bypass part of the stomach and duodenal bulb such as Roux-en-Y gastric bypass for weight loss, or resection of the gastric antrum and duodenal bulb with creation of a Billroth II anastomosis for treatment of peptic ulcer disease, result in rapid gastric emptying into the jejunum, which leads to diarrhea and weight loss due to inadequate mixing of luminal nutrients with bile and pancreatic secretions.

Disordered Intestinal Motility Hyperthyroidism may cause diarrhea and malabsorption due to increased intestinal motility with rapid transit, also resulting in inadequate nutrient mixing with pancreaticobiliary secretions. Long-standing diabetes mellitus may result in damage to the enteric nervous system resulting in increased motility and diarrhea, or reduced motility and constipation. Disorders that affect the intestinal smooth muscle such as connective tissue disorders including scleroderma may have profound effects on GI motility.

Pancreatic Disorders Chronic pancreatitis **(see Chap. 359)** may result in a marked reduction in pancreatic enzyme secretion and pancreatic insufficiency, with subsequent fat, protein, and carbohydrate malabsorption. Patients with chronic pancreatitis present with *steatorrhea*, or fatty stools, which are often voluminous, bulky, and malodorous. Patients with steatorrhea also develop deficiency of fat-soluble vitamins including vitamins A, E, and most commonly, vitamins D and K, which depend on the same lipid absorption mechanisms and thus are malabsorbed along with dietary fat. Weight loss is common. **For a discussion of causes of acute and chronic pancreatitis, please see Chap. 359.**

Disorders That Result in Luminal Bile Salt Deficiency Bile acid synthesis and the enterohepatic circulation are shown in **Fig. 336-2**.

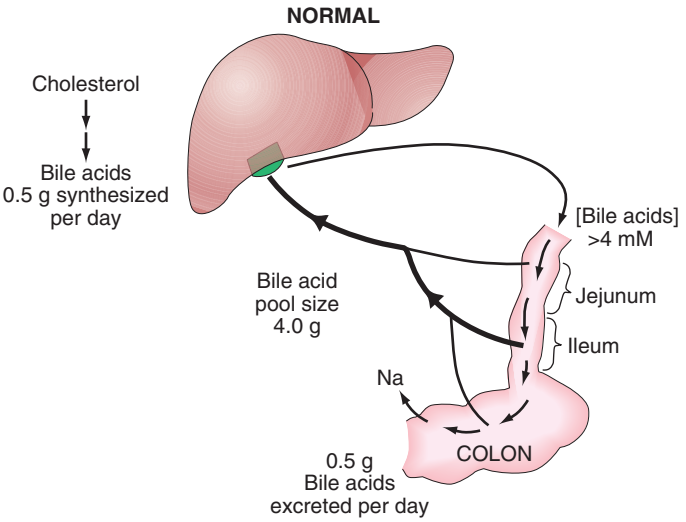

FIGURE 336-2 Schematic representation of the enterohepatic circulation of bile acids. Bile-acid synthesis is cholesterol catabolism and occurs in the liver. Bile acids are secreted in bile and are stored in the gallbladder between meals and at night. Food in the duodenum induces the release of cholecystokinin, a potent stimulus for gallbladder contraction resulting in bile-acid entry into the duodenum. Bile acids are primarily absorbed via an Na-dependent transport process that is located only in the ileum. A relatively small quantity of bile acids (~500 mg) is not absorbed in a 24-h period and is lost in stool. Fecal bile acid losses are matched by bile-acid synthesis. The bile acid pool (the total amount of bile acids in the body) is ~4 g and is circulated twice during each meal or six to eight times in a 24-h period.

TABLE 336-3 Defects in Enterohepatic Circulation of Bile Acids

PROCESS	PATHOPHYSIOLOGIC DEFECT	DISEASE EXAMPLE
Synthesis	Decreased hepatic function	Cirrhosis
Biliary secretion	Altered canalicular function	Primary biliary cholangitis
Maintenance of conjugated bile acids	Bacterial overgrowth	Jejunal diverticulosis
Reabsorption	Abnormal ileal function	Crohn's disease

Bile acids are synthesized from cholesterol in the liver. The two primary bile acids are cholic acid and chenodeoxycholic acid. These are conjugated in the liver to taurine and glycine and are secreted into bile ducts, stored in the gallbladder, and then delivered to the intestinal lumen. Conjugation prevents bile acids from passive diffusion in the small-bowel lumen, retaining bile acid concentrations required for lipid absorption. Bile acids emulsify fats and fat-soluble vitamins to facilitate their absorption. Bile acids are efficiently reabsorbed in the ileum into the portal circulation and are extracted by the liver in a process called *enterohepatic circulation* (Fig. 336-2). Small amounts are deconjugated in the ileum by bacteria or pass into the colon and are deconjugated and metabolized by colonic bacteria to become secondary bile acids. The two major secondary bile acids are lithocholic acid and deoxycholic acid.

Processes that affect any of the above pathways may result in luminal bile salt deficiency and malabsorption. Thus, hepatobiliary diseases, intestinal ileal resection, extensive disease such as Crohn's disease, and small-bowel bacterial overgrowth may result in luminal bile salt deficiency and malabsorption **(Table 336-3)**.

Hepatobiliary Disease Hepatic disorders that result in decreased bile acid synthesis due to hepatocyte dysfunction or reduced secretion of bile into the gut lumen caused by diseases of the bile ducts such as primary sclerosing cholangitis or primary biliary cholangitis may result in luminal bile salt deficiency and fat malabsorption. These are discussed in **Chap. 357**.

Ileal Resection or Ileal Disease Diseases that involve the ileal mucosa or that result in ileal resection may lead to reduced recycling of bile acids by the enterohepatic circulation and increased entry into and concentration of bile acids in the colon, which produces a secretory diarrhea, or may result in malabsorption due to inadequate bile acid concentrations in the small-bowel lumen. In general, resection or disease involving <100 cm of ileum results in bile acid spillage into the colon; resections of >100 cm result in loss of bile acids that exceed liver synthetic capacity, and malabsorption becomes the dominant pathophysiologic mechanism for diarrhea, due to bile acid deficiency **(Table 336-4)**. The most common disorder of the GI tract that targets the ileum is Crohn's disease **(Chap. 337)**, which is a chronic inflammatory disorder that may involve the entire GI tract, but most commonly the ileum and colon. If severe or refractory to treatment, Crohn's disease may lead to chronic inflammation, marked epithelial dysfunction, and stricturing and fibrosis, and surgical resection may be required to treat small-bowel obstruction or refractory disease.

TABLE 336-4 Comparison of Bile Acid and Fatty Acid Diarrhea

	BILE-ACID DIARRHEA	FATTY ACID DIARRHEA
Extent of ileal disease	Limited	Extensive
Ileal bile acid absorption	Reduced	Reduced
Fecal bile acid excretion	Increased	Increased
Fecal bile acid loss compensated by hepatic synthesis	Yes	No
Bile acid pool size	Normal	Reduced
Intraduodenal (bile acid)	Normal	Reduced
Steatorrhea	None or mild	>20 g
Response to cholestyramine	Yes	No
Response to low fat diet	No	Yes

Primary Bile Acid Diarrhea A subset of patients with functional diarrhea or irritable bowel syndrome with diarrhea have been shown to have bile acid malabsorption. Although the mechanisms are still being elucidated, reduced FGF19 secretion by ileal enterocytes has been observed. FGF19 regulates serum 7-alpha-hydroxy-4-cholesten-3-one (C4) levels; reductions in circulating FGF19 lead to increased hepatic bile acid synthesis via increased C4 expression. Chronic diarrhea results from increased bile acid spillage into the colon, which induces a secretory diarrhea and exerts prokinetic effects via TGR5.

Treatment Bile acid sequestrants are effective in reducing diarrhea by binding bile acids to prevent spillage into the colon. Hepatic synthesis of bile acids is sufficient to maintain intraluminal concentrations that are adequate for fat absorption.

Small-Intestinal Bacterial Overgrowth The intestine contains a rich microbiome. Bacterial titers increase along the horizontal axis of the gut from duodenum to ileum. However, intestinal disorders affecting motility or causing stasis of bowel contents may lead to small-intestinal bacterial overgrowth. These include scleroderma bowel, chronic intestinal pseudo-obstruction, the creation of blind surgical loops such as Roux-en-Y gastric bypass, Billroth II anastomosis, small-bowel strictures, or fibrosis from inflammatory disorders such as Crohn's disease and diffuse diverticulosis **(Fig. 336-3)**. Surgical resection of the ileocecal valve increases ileal bacterial counts from the colon. Hypochlorhydria from chronic proton pump inhibitor use also increases the risk of small-intestinal bacterial overgrowth. Bacterial overgrowth causes deconjugation of bile acids, which facilitates their absorption in the proximal bowel and results in luminal bile acid deficiency, which in turn causes malabsorptive diarrhea with steatorrhea. Bacterial overgrowth may also damage the brush border and result in carbohydrate maldigestion and short-chain fatty acid production in the colon, with diarrhea and gas. These patients are also at risk for B_{12} deficiency due to bacterial metabolism of B_{12} resulting in macrocytic anemia and peripheral neuropathy. In contrast, elevated serum folate levels may also be observed, derived from bacterial synthesis of folate.

Small-intestinal bacterial overgrowth has also been observed in patients with diarrhea-predominant irritable bowel syndrome. The underlying mechanisms are unclear, but treatment of bacterial overgrowth leads to resolution of symptoms in a subset of irritable bowel syndrome patients.

Diagnosis Duodenal aspirate for bacterial titers is the gold standard but is not generally available to most practitioners. Breath hydrogen testing with administration of lactulose, a nondigestible disaccharide, or glucose is widely available but must be interpreted carefully to avoid false-positive results. Many clinicians choose to treat empirically with antibiotics (see "Treatment") and observe for resolution of symptoms.

Treatment When possible, surgical correction of blind loops, endoscopic or surgical treatment of strictures, and removal of large diverticula can be pursued for definitive therapy, in addition to treatment of underlying disorders such as Crohn's disease to avoid recurrent stricture formation or fibrosis. Other disorders such as scleroderma or other diffuse motility disorders may not be easily treated. In these circumstances, treatment with the nonabsorbable antibiotic, rifaximin, or with other antibiotics such as metronidazole, doxycycline, amoxicillin-clavulanic acid, or cephalosporins for several weeks is often pursued. Patients may require retreatment or even chronic therapy with rotating antibiotics depending on the severity of symptoms.

MUCOSAL PHASE OF DIGESTION AND ABSORPTION

The intestinal epithelium (also known as the mucosa) plays a critical role in continued digestion of nutrients and absorption from the intestinal lumen into the bloodstream and lymphatics.

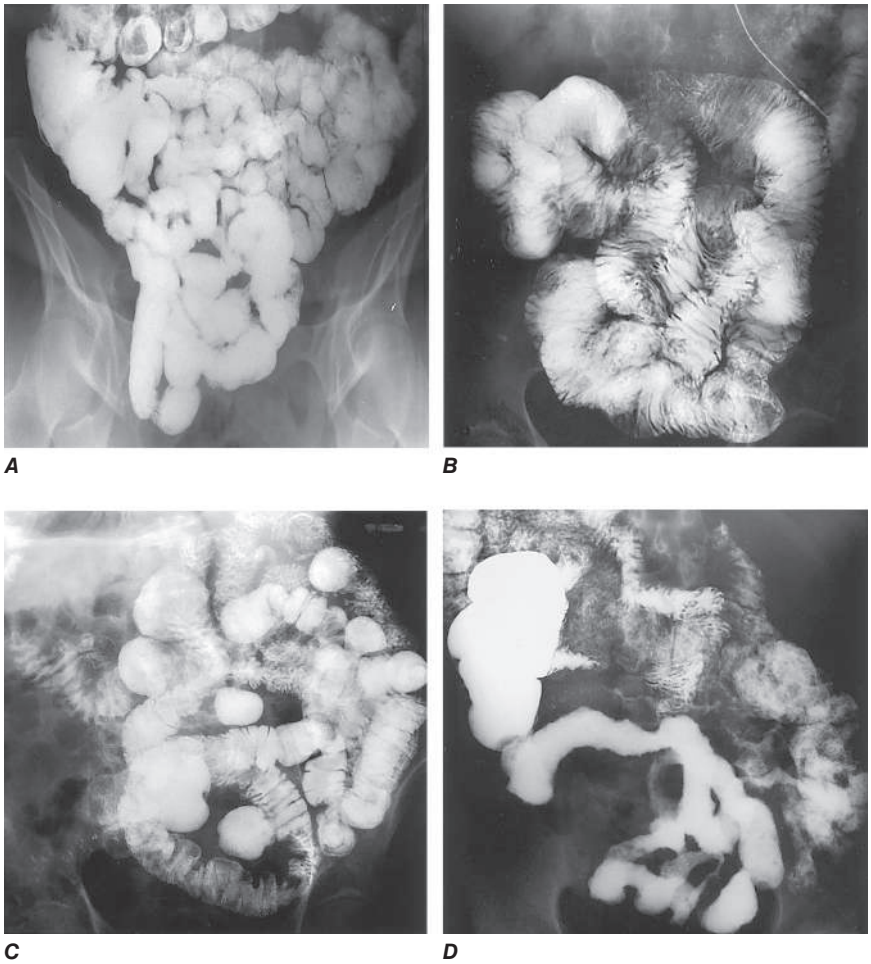

FIGURE 336-3 Barium contrast small-intestinal radiologic examinations. ***A.*** Normal individual. ***B.*** Celiac disease. ***C.*** Jejunal diverticulosis. ***D.*** Crohn's disease. *(Courtesy of Morton Burrell, MD, Yale University; with permission.)*

The small-bowel epithelial or mucosal digestive and absorptive phase is mediated by enterocytic brush border enzymes, including peptidases and hydrolases. Brush border enterokinase is required for the conversion of pancreatic trypsinogen to trypsin, which further activates trypsinogen and other pancreatic protease proenzymes. The brush border membrane of the small-bowel epithelium expresses a wide variety of disaccharidases, peptidases, and other hydrolases that continue the digestive process for carbohydrates and proteins, with enzymatic digestion of disaccharides to monosaccharides and dipeptidases to amino acids, which are then absorbed by specific transporters. Long-chain fatty acids are re-esterified to triglycerides in enterocytes, packaged into chylomicrons with apolipoproteins on the surface, which are subsequently secreted into the extracellular space, and because of their size, are excluded from capillaries and enter the lymphatics.

INTESTINAL MUCOSAL DISORDERS

DISORDERS OF ENTEROCYTE CARBOHYDRATE TRANSPORTERS AND ENZYME DEFICIENCIES

Lactose Intolerance Due to Lactase Deficiency This is the most common brush border disaccharidase deficiency and is a frequent cause of diarrhea, abdominal pain, gassiness, and bloating. Lactose is present in many dairy products but is also a "hidden" component of a vast number of processed foods.

Lactose malabsorption can result from lactase deficiency, which is regulated by primary genetic mechanisms (adult-type hypolactasia) or secondary due to damage to the epithelial (mucosal) lining of the gut, from infections (viral, bacterial, or parasitic) or from intestinal mucosal diseases. Congenital lactase deficiency is very rare and is an autosomal recessive disorder. Hypolactasia in adulthood is very common throughout the world and is considered to be the genetic wild-type; lactase persistence results from a C to T mutation (LACTASE LCT-13910CT and LCT-13910TT), and adults with hypolactasia have absence of this "persistence" allele. Lactose is metabolized by lactase into glucose and galactose, which are both absorbed by transporters at the enterocyte surface. Patients who are lactase deficient have elevated luminal lactose levels upon ingestion of lactose. The mechanism for diarrhea in lactase deficiency is complex. Undigested lactose acts as an osmotic substance to draw fluid into the small-bowel lumen. In addition, when unabsorbed lactose enters the colon, luminal bacteria ferment lactose, producing intestinal gas (hydrogen, carbon dioxide, and methane), bloating, and abdominal pain. Luminal lactose is metabolized by bacteria into short-chain fatty acids that can be absorbed by the colon, but watery diarrhea may occur when a large lactose load exceeds the colon's absorptive capacity.

Diagnosis When lactose intolerance is suspected, a common initial approach is to institute a lactose-exclusion diet and assess for resolution of symptoms. This is a rapid and generally effective diagnostic and therapeutic method. Patients are provided with a list of lactose-containing foods and lactose-free alternatives. Patients are also counseled on alternative calcium sources, because dairy-containing foods are a major source of dietary calcium, which is important for osteoporosis prevention.

Should the results of dietary exclusion be ambiguous, a lactose-tolerance test or breath hydrogen test may prove useful. For the lactose-tolerance test, patients ingest a standardized liquid lactose solution (usually 50 g of lactose) followed by timed measurements of serum glucose for 90 min. If lactose digestion is normal, glucose levels should rise by >20 mg/L. Serum glucose rise <20 mg/L plus the presence of symptoms of lactose intolerance (abdominal discomfort, gassiness, and diarrhea) is considered a positive test. A breath hydrogen test is performed by measuring breath hydrogen levels following ingestion

of a standardized lactose load. Breath hydrogen levels should not exceed >20 ppm above the fasting baseline. Generally, the peak occurs between 2 and 4 h. Both methods may be inaccurate if the patient has abnormal gastric emptying or abnormal intestinal transit. Breath hydrogen measurements may be abnormal in the setting of bacterial overgrowth, which may cause very similar symptoms.

Treatment Patients may elect to completely eliminate lactose from their diets. It is very important to consider calcium and vitamin D supplementation because elimination of milk and soft cheeses removes important dietary sources. They also may need to consult a dietitian for guidance about hidden lactose in prepared or other foods. An alternative is to consider using lactase supplementation, which is available over the counter but which may need to be titrated to avoid symptoms.

Glucose-Galactose Malabsorption This rare congenital disorder is an autosomal recessive disease in which mutations occur in the *SLC5A1* gene (also known as *SGLT1*). SLC5A1 is a brush border protein and member of the sodium-dependent glucose transporter family; mutations in this gene result in malabsorption of glucose and galactose. Gene sequencing has shown that most patients have loss-of-function single-nucleotide variations. SLC5A1 actively transports glucose or galactose coupled to sodium cotransport; patients who are homozygous for these loss-of-function variants have severe congenital diarrhea and death if unrecognized. Treatment focuses on eliminating glucose- and galactose-containing foods and substituting fructose-containing foods. Fructose is absorbed by the brush border transporter GLUT5 by facilitated diffusion and is not dependent on SLC5A1.

Sucrase-Isomaltase Deficiency This is another rare congenital autosomal recessive disorder, caused by mutations in the sucrase-isomaltase gene. Infants present with diarrhea that begins with ingestion of sucrose coincident with the introduction of table foods. Sucrase-isomaltase gene variants have been identified that cause symptoms later in life and may be associated with increased risk of irritable bowel syndrome.

Abetalipoproteinemia Abetalipoproteinemia is a rare disorder of lipid metabolism associated with abnormal erythrocytes (acanthocytes), neurologic symptoms, and steatorrhea **(see Chap. 419)**. Lipolysis, micelle formation, and lipid uptake are all normal in patients with abetalipoproteinemia, but the re-esterified triglyceride cannot exit the epithelial cell because of the failure to produce chylomicrons. This disorder results from mutation of microsomal triglyceride transfer protein (MTP), which catalyzes the transfer of triglyceride onto nascent apolipoprotein B–containing particles. Mutations in MTP decrease this transfer and decrease formation of chylomicrons. Small-intestinal biopsy samples obtained from these rare patients in the postprandial state reveal lipid-laden small-intestinal epithelial cells that become normal in appearance after a 72- to 96-h fast.

INTESTINAL MUCOSAL DISORDERS THAT RESULT IN MALABSORPTION OF MULTIPLE NUTRIENTS

CELIAC DISEASE

Celiac disease, also known as celiac sprue or gluten-sensitive enteropathy, is a small-intestinal enteropathy that results from an immune response to gluten ingestion and is characterized by autoantibodies to tissue transglutaminase. Gluten is found in foods produced from wheat, rye, barley, and some varieties of oats, and it is a common additive to prepared foods and pharmaceuticals. Tissue transglutaminase is involved in the pathogenesis of this disorder, as it deamidates glutamine residues of gluten-derived peptides, facilitating their presentation by antigen-presenting cells.

Epidemiology and Genetics The incidence and prevalence of celiac disease have been increasing worldwide. Increased awareness among clinicians and patients has led to increases in detection, but there is evidence that the true incidence appears to be increasing as well. Global prevalence has been measured at 1.4%. In the United States, data from the National Health and Nutrition Examination survey showed seroprevalence of 0.2% in non-Hispanic black populations, 0.3% in Hispanic individuals, and 1.0% in white populations.

The prevalence of celiac disease is 10–15% in first-degree relatives. Host genetic factors include histocompatibility locus antigens HLADQ2 and DQ8; the presence of one of the two haplotypes is necessary but not sufficient for developing celiac disease. HLADQ2 and DQ8 are found in 25–35% of the general population; because most carriers never develop celiac disease, detection of these alleles is not useful for diagnosis. However, a negative test is very useful for ruling out celiac disease, with a negative predictive value of >99%. This is particularly helpful in patients who self-discontinued gluten ingestion prior to serologic or endoscopic testing.

Presentation Patients with celiac disease have a wide variety of disease manifestations, ranging from being asymptomatic, to having isolated iron-deficiency anemia due to duodenal disease, to severe diarrhea, weight loss, and malabsorption of multiple nutrients with more diffuse disease. Celiac disease primarily affects the proximal small intestine; it may involve the duodenum only or may cause widespread jejunal disease resulting in severe symptoms.

Diarrhea, weight loss, and growth failure in children are common presenting complaints, but additional signs and symptoms have become increasingly recognized to be associated with celiac disease, including bloating and irregular bowel habits, migraine headaches, and ataxia. In addition, patients may be identified after presenting with osteoporosis, iron-deficiency anemia, or detection of abnormal liver enzymes.

Mechanism of Diarrhea Patients with celiac disease have villus atrophy in the proximal small intestine and thus develop steatorrhea from mucosal malabsorption and may have lactase deficiency. However, they also develop a secretory component due to crypt hyperplasia and fluid hypersecretion from the crypt epithelium.

Associated Diseases Patients with celiac disease have a higher incidence of other autoimmune disorders such as type 1 diabetes mellitus and autoimmune thyroid disease. Dermatitis herpetiformis is a skin disorder that is highly associated with celiac disease, characterized by a vesicular rash mediated by IgA deposits in the skin. Down syndrome and Turner syndrome patients also have an increased risk of celiac disease.

Diagnosis Patients are screened for celiac disease first by testing for serum antibodies, including the screening test of choice, which is tissue transglutaminase IgA (TTG-IgA). Serum IgA levels should also be measured to detect false-negative results from IgA deficiency. If a patient is IgA deficient, IgG-based testing including TTG-IgG or anti- deamidated gliadin peptide (DGP-IgG) antibody testing can be performed. The diagnosis in adults with positive antibody levels is confirmed by endoscopy with small-intestinal biopsy; biopsy is required in most patients to confirm the diagnosis. Biopsies typically show characteristic villus blunting, crypt hyperplasia, and inflammation, including increased intraepithelial lymphocytes. The Marsh classification categorizes different types of celiac disease–related lesions and is currently used to quantify severity of disease involvement.

Family members of patients with celiac disease are screened if symptomatic; recommendations regarding screening asymptomatic family members are still controversial.

Complications Complications of celiac disease include refractory celiac disease, enteropathy-associated T-cell lymphoma, hyposplenism, and small-bowel adenocarcinoma.

Refractory Celiac Disease This complication is most common in patients with ongoing active celiac disease, found in about 10% of patients with persistent active disease. Patients have ongoing diarrhea and weight loss with persistent villus atrophy on biopsy after 1 year of following a strict gluten-free diet. These patients also have negative celiac serology, confirming their adherence to the gluten-free diet. Type 1 refractory celiac disease has a normal intraepithelial lymphocyte population, whereas type 2 disease has clonal expansion of CD3+ intraepithelial lymphocytes that also contain a monoclonal rearrangement of the gamma chain of the T-cell receptor. Type 2 refractory

celiac disease has a worse prognosis due to its association with T-cell lymphoma, which occurs in 33–50% of cases after 5 years. The therapy for celiac disease–related lymphoma is intense and includes high-dose chemotherapy and sometimes stem cell transplantation.

Small-bowel adenocarcinoma is a very rare cancer in the general population but is increased in celiac disease patients.

Therapy and Follow-Up The mainstay of celiac disease treatment is institution of a strict gluten-free diet. This is challenging for patients because of the widespread presence of gluten in both raw and prepared foods, inaccurate food labeling, and cross-contamination during food preparation. Patients must receive rigorous dietary instruction from a dietitian and adhere lifelong to a gluten-free diet.

For patients whose symptoms resolve, serologic follow-up is generally recommended to confirm compliance with a gluten-free diet. A follow-up biopsy to document complete healing of villus atrophy is also generally recommended. However, subsequent biopsies are not recommended unless symptoms recur. For patients without symptom resolution, a biopsy is required to determine the degree of disease activity and to rule out other causes of persistent diarrhea and complications such as refractory celiac disease or T-cell lymphoma. The most common cause of residual disease activity is dietary nonadherence or inadvertent gluten exposure. These patients pursue repeat consultation with a dietitian and efforts to reduce restaurant or other out-of-the-home exposure or cross-contamination at home. If biopsies are negative but symptoms persist, other causes of abdominal pain and diarrhea that are associated with celiac disease are considered, including irritable bowel syndrome, microscopic colitis, small-bowel bacterial overgrowth, and lactose or fructose intolerance.

Nonceliac Gluten Sensitivity These patients have symptoms consistent with celiac disease but have negative serology and negative biopsies and no evidence for wheat allergy. Upon discontinuation of gluten, they have relief of abdominal pain, diarrhea, headaches/migraines, and other celiac disease–type symptoms. The etiology of this disorder remains unknown.

WHIPPLE'S DISEASE

Whipple's disease is a chronic, multiorgan disease caused by *Tropheryma whipplei*, a gram-positive non-acid-fast, periodic acid–Schiff (PAS)–positive rod, which is ubiquitous in the environment. Whipple's disease most commonly occurs in middle-aged men. Classic Whipple's disease is defined by the presence of arthralgias, weight loss, diarrhea, and abdominal pain. Other manifestations including central nervous system (CNS) and cardiac involvement are common and occur later in the disease. *T. whipplei* can be detected by polymerase chain reaction on involved tissue and is difficult to detect in the bloodstream. The intestinal lesion is also characterized by PAS-positive macrophages.

Clinical Presentation Arthralgias and arthritis are present for an average of 6 years before the GI symptoms begin, consistent with a persistent and substantial lag in diagnosis, which is still a problem today. Joint disease is present in >80% of patients. GI manifestations include diarrhea, abdominal pain, and weight loss from malabsorption. CNS involvement is common and may include symptoms such as psychiatric manifestations or memory problems. Dementia and encephalitis may occur in later stages. Cardiac involvement may include endocarditis, pericarditis, and myocarditis.

Diagnosis For patients with GI manifestations, endoscopy with biopsies is performed and tissue is tested for *T. whipplei* by polymerase chain reaction. Tissue is also stained for PAS-positive macrophages, and immunohistochemistry may also be performed to detect *T. whipplei.*

Treatment Prolonged antibiotics are recommended, although the optimal regimen is still uncertain. Relapses are common and often associated with the first manifestations of CNS involvement.

TROPICAL SPRUE

Tropical sprue is a poorly understood syndrome that is manifested by chronic diarrhea, steatorrhea, weight loss, and nutritional deficiencies, including both folate and vitamin B_{12}. Malabsorption of two unrelated substances is required for diagnosis. This disease occurs in 8–20% of people who have had an attack of infectious gastroenteritis in India and is considered by some to be a postinfectious complication. It is prevalent in some but not all tropical areas, including southern India, Pakistan, the Philippines, Puerto Rico, Haiti, and Cuba. It occurs in residents of as well as visitors to these areas.

Chronic diarrhea in a tropical environment is most often caused by infectious agents, including *Giardia lamblia*, *Yersinia enterocolitica*, *Entamoeba histolytica, Clostridioides difficile*, *Cryptosporidium parvum*, *Isospora belli*, *Strongyloides stercoralis*, and *Cyclospora cayetanensis*. Tropical sprue should not be entertained as a possible diagnosis until the presence of cysts and trophozoites has been excluded in three stool samples. **Infections of the GI tract and diarrhea are discussed in Chaps. 49, 138, 139, 169–173, and 230.**

Etiology Because tropical sprue responds to antibiotics, the consensus is that it may be caused by one or more infectious agents. Nonetheless, the etiology and pathogenesis of tropical sprue are uncertain. Its occurrence is not evenly distributed in all tropical areas; it is rarely observed in Africa, Jamaica, or Southeast Asia. The incidence of tropical sprue appears to have decreased substantially during the past two or three decades, perhaps in relation to improved sanitation in many tropical countries during this time. Some have speculated that the reduced occurrence is attributable to the wider use of antibiotics in acute diarrhea, especially in travelers to tropical areas from temperate countries. Folic acid is absorbed exclusively in the duodenum and proximal jejunum, and most patients with tropical sprue have evidence of folate malabsorption and depletion.

The clinical pattern of tropical sprue varies in different areas of the world (e.g., India vs Puerto Rico). Not infrequently, individuals in southern India initially report the occurrence of acute enteritis before the development of steatorrhea and malabsorption. In contrast, in Puerto Rico, a more insidious onset of symptoms and a more dramatic response to antibiotics are seen compared with some other locations. Tropical sprue in different areas of the world may not be the same disease, and similar clinical entities may have different etiologies.

Diagnosis The diagnosis of tropical sprue is based on an abnormal small-intestinal mucosal biopsy in an individual with chronic diarrhea and evidence of malabsorption who is either residing or has recently lived in a tropical country. The small-intestinal biopsy in tropical sprue does not reveal pathognomonic features but resembles, and can often be indistinguishable from, that seen in celiac disease **(Fig. 336-4)**. The biopsy sample in tropical sprue has less villous architectural alteration and more mononuclear cell infiltrate in the lamina propria. In contrast to those of celiac disease, the histologic features of tropical sprue manifest with a similar degree of severity throughout the small intestine, and a gluten-free diet does not result in either clinical or histologic improvement in tropical sprue.

Treatment Broad-spectrum antibiotics and folic acid are most often curative, especially if the patient leaves the tropical area and does not return. Tetracycline should be used for up to 6 months and may be associated with improvement within 1–2 weeks. Folic acid alone induces hematologic remission as well as improvement in appetite, weight gain, and some morphologic changes in small-intestinal biopsy. Because of marked folate deficiency, folic acid is most often given together with antibiotics.

ENVIRONMENTAL ENTERIC DYSFUNCTION

Environmental enteric dysfunction (EED; formerly known as tropical enteropathy) occurs in low- and middle-income countries and is characterized by altered crypt villus morphology with crypt atrophy and mucosal inflammation and barrier dysfunction, resulting in chronic low-grade malabsorption. It is associated with childhood stunting, a major worldwide health problem. Gut microbiota and adverse environmental and economic conditions contribute to its pathogenesis. Although the gold standard for diagnosis is small-bowel biopsy, this is often limited by lack of resources. Therapies for EED are the subject of intense investigation.

SHORT-BOWEL SYNDROME

OVERVIEW

Short-bowel syndrome results from intestinal resection to treat a multitude of disorders including Crohn's disease, vascular diseases such as mesenteric arterial or venous thrombosis resulting in intestinal ischemia, volvulus, trauma, internal herniation, radiation enteritis, and diffuse carcinoma, among others. In children, the most common causes of short-bowel syndrome are necrotizing enterocolitis, intestinal atresias, volvulus, and malrotation. Short-bowel syndrome is defined as extensive removal of small intestine resulting in <200 cm of remaining small bowel. Intestinal failure is functionally defined as persistent parenteral nutrition dependence, generally found in patients who have <100 cm of remaining small bowel and no residual colon in continuity.

Clinical Features Loss of small-bowel surface area in short-bowel syndrome results in severe diarrhea, weight loss, and malabsorption of multiple nutrients, including fat, protein, and carbohydrate. The severity of symptoms and ultimate dependence on parenteral nutrition are generally related to the extent of resection, presence or absence of residual colon in continuity, retention of the ileocecal valve, and severity of the underlying disease. The intestine has a remarkable capacity to adapt to loss of small-bowel surface area, but this adaptive process is variable from patient to patient. Following resection, the adapting residual intestine exhibits an increase in crypt cell proliferation resulting in epithelial hyperplasia. The adaptive process generally continues for up to 2 years after resection, but improvements in nutrient, fluid, and electrolyte absorptive capacity have been reported even as late as 3–5 years after surgery. Massive diarrhea generally occurs in the first three postoperative months, associated with increased gastric acid secretion and malabsorption. Gradually, patients show enhanced functional capacity and reduced diarrhea. Specific nutrient deficiencies are dependent upon which segment of gut has been removed. For example, resection of the ileum results in loss of B_{12} absorptive and bile salt reabsorptive capacity. Malabsorbed bile salts reach the colon and cause a secretory diarrhea. In addition, resection of >100 cm of ileum results in such severe bile salt malabsorption that the liver cannot compensate by increased synthesis, thus precipitating fat malabsorption due to bile salt insufficiency/deficiency. Substantial resection of the colon

also results in fluid and electrolyte loss and imbalance. The colon also plays a role in nutrient absorption because it metabolizes malabsorbed carbohydrate into short-chain fatty acids that can be absorbed by the colon and can contribute several hundred additional calories per day.

Long-Term Complications Because massive resection often leads to severe fat malabsorption, fat-soluble vitamin deficiency is common, and vitamin D deficiency can be very difficult to treat even with high-dose oral vitamin D supplementation, resulting in an increased risk of osteoporosis. Patients with a history of multiple surgeries often have extensive adhesive disease, and the residual intestine may have markedly abnormal motility or areas of stricturing and narrowing, resulting in recurrent bacterial overgrowth. The frequency of renal calcium oxalate stones increases in patients with a shortened small bowel with an intact colon in continuity; calcium is saponified in the intestinal luminal contents that contain fatty acids, freeing oxalate to be absorbed in the colon resulting in hyperoxaluria.

Treatment The major focus of treatment for short-bowel syndrome is to control diarrhea and normalize nutrient, fluid, and electrolyte absorption so that patients can maintain their weight and have a healthy nutritional status without the support of parenteral nutrition. Medications include opiates and derivatives including loperamide and diphenoxylate-atropine, which slow intestinal motility to allow for more contact time between luminal nutrients and the small-bowel mucosal surface. In the first year following resection, acid-blocking medications are used to treat gastric hypersecretion, including proton pump inhibitors or histamine 2 antagonists. Small-bowel bacterial overgrowth is common and is treated with antibiotics if suspected. The only medication that is specific for short-bowel syndrome but limited for use in parenteral nutrition or intravenous fluid–dependent patients is teduglutide, a glucagon-like peptide 2 (GLP-2) analogue that enhances crypt cell proliferation and villus hyperplasia and increases nutrient and fluid and electrolyte absorption. Patients treated with teduglutide have an average reduction of 20% of their parenteral nutrition requirements. Greater efficacy has been noted for patients without a residual colon, likely due to lower circulating endogenous GLP-2 levels compared to those with a colon in continuity.

Dietary Therapy Patients with short-bowel syndrome must consume three to four times their normal caloric intake to maintain their weight. The presence of luminal nutrients is required for the adaptive process to occur, so early feeding is recommended, even if parenteral nutrition is also required. These effects are most likely mediated by direct contact with the mucosa as well as stimulation of secretion of gut hormones such as GLP-2.

If the patient has all or part of their colon remaining in continuity, a low-fat diet is instituted to reduce the concentration of malabsorbed fatty acids that induce a secretory diarrhea. High complex carbohydrates are encouraged because when malabsorbed and present in the colon, they are converted to short-chain fatty acids and are absorbed, contributing several hundred additional kilocalories per day. All patients are asked to take a high-potency multivitamin on a daily basis. Patients in whom oral nutrition fails are fed with parenteral nutrition.

Monitoring Patients with short-bowel syndrome are at high risk for osteoporosis due to dietary calcium and vitamin D malabsorption, so they are periodically monitored for vitamin D deficiency and calcium levels and with dual x-ray absorptiometry (DEXA) studies to assess bone density. Malabsorption of vitamins and minerals is common; therefore, fat-soluble vitamins, vitamin B_{12}, folic acid, iron, magnesium, and zinc are monitored periodically. More unusual deficiencies include copper, selenium, and chromium, but these are usually seen in parenteral nutrition–dependent patients and can be corrected by adjusting daily intravenous dosages. Signs and symptoms of vitamin and mineral deficiency are also carefully monitored (e.g., hair loss, skin and nail changes, neurologic symptoms such as peripheral neuropathy).

DISORDERS OF POSTMUCOSAL ABSORPTION

Following uptake into enterocytes, nutrients are further processed and transported into the lymphatics or into the portal circulation for use by other cells throughout the body. Primary or secondary disorders of the lymphatics may result in significant diarrhea and malabsorption. Primary disorders of the intestinal lymphatics include intestinal lymphangiectasia, which may be congenital or acquired. Secondary causes of intestinal lymphatic damage or blockage include retroperitoneal fibrosis, fibrosing mesenteritis, and lymphoma. Circulatory causes of impaired delivery of nutrients from the intestine include Fontan physiology, congestive heart failure, and constrictive pericarditis. The end result of damage to lymphatic channels is malabsorption and diarrhea with concomitant protein-losing enteropathy.

PROTEIN-LOSING ENTEROPATHY

Protein-losing enteropathy refers to a large group of GI and non-GI disorders characterized by hypoproteinemia and edema in the absence of liver disease with reduced protein synthesis, or kidney disease with proteinuria. These diseases are characterized by excess protein loss in the GI tract. Diseases that may result in increased protein loss into the GI tract can be classified into three groups: (1) mucosal ulceration, such that the protein loss primarily represents exudation across damaged mucosa (e.g., ulcerative colitis, GI carcinomas); (2) nonulcerated mucosa, but with evidence of mucosal damage so that the protein loss represents loss across epithelia with altered permeability (e.g., celiac disease and Ménétrier's disease [hypertrophic gastropathy] in the small intestine and stomach, respectively); and (3) lymphatic dysfunction, representing either primary lymphatic disease or lymphatic disease secondary to partial lymphatic obstruction that may occur as a result of enlarged lymph nodes or cardiac disease. These result in increased lymphatic pressure, causing exudation of protein into the GI tract lumen.

Diagnosis The diagnosis of protein-losing enteropathy is suggested by diarrhea, peripheral edema, and low serum albumin and globulin levels in the absence of renal and hepatic disease. An individual with protein-losing enteropathy rarely has selective loss of *only* albumin or *only* globulins. Therefore, marked reduction of serum albumin with normal serum globulins should suggest renal and/or hepatic disease. Likewise, reduced serum globulins with normal serum albumin levels are more likely a result of reduced globulin synthesis rather than enhanced globulin loss into the intestine. Alpha-1 antitrypsin, a protein that accounts for ~4% of total serum proteins and is resistant to proteolysis, can be used to detect enhanced rates of serum protein loss into the intestinal tract but cannot be used to assess gastric protein loss because of its degradation in an acid milieu. Alpha-1 antitrypsin can be measured in a spot or 24-h stool collection and, if elevated, is diagnostic. A more accurate determination is alpha-1 antitrypsin clearance, measured by determining stool volume as well as both stool and plasma alpha-1 antitrypsin concentrations. In addition to the loss of protein via abnormal and distended lymphatics, peripheral lymphocytes may be lost via lymphatics, with consequent relative lymphopenia and specifically loss of CD3+ T cells. Thus, lymphopenia in a patient with hypoproteinemia indicates increased loss of protein into the GI tract.

Patients with increased protein loss into the GI tract from lymphatic obstruction often have steatorrhea and diarrhea. The steatorrhea is a result of altered lymphatic flow as lipid-containing chylomicrons exit from intestinal epithelial cells via intestinal lymphatics (Table 336-2; Fig. 336-4). In the absence of mechanical or anatomic lymphatic obstruction, intrinsic intestinal lymphatic dysfunction—with or without lymphatic dysfunction in the peripheral extremities—has been designated *intestinal lymphangiectasia.* Similarly, ~50% of individuals with intrinsic peripheral lymphatic disease (Milroy's disease) also have intestinal lymphangiectasia and hypoproteinemia. Other than steatorrhea and enhanced protein loss into the GI tract, all other aspects of intestinal absorptive function are normal in intestinal lymphangiectasia.

Endoscopy and Imaging Endoscopy (including double-balloon enteroscopy) with biopsy and video capsule endoscopy may be performed to rule out mucosal disease. Magnetic resonance enterography or computed axial tomography may provide additional insight into the

underlying cause and can detect specific lesions, and lymphangiography can be used for diagnosis and potential therapeutic intervention.

Other Causes Ménétrier's disease (also called *hypertrophic gastropathy*) is an uncommon entity that involves the body and fundus of the stomach and is characterized by large gastric folds, reduced gastric acid secretion, and, at times, enhanced protein loss into the stomach.

Patients who have idiopathic protein-losing enteropathy without evidence of GI disease should be examined for cardiac disease. As more patients with congenital heart disease reach adulthood, Fontan physiology has become a more common cause of protein-losing enteropathy. Other cardiac causes include right-sided valvular disease and chronic pericarditis **(Chaps. 277, 278, 279 and 281)**.

Treatment As excess protein loss into the GI tract is most often secondary to a specific disease, treatment should be directed primarily to the underlying disease process and not to the hypoproteinemia. When enhanced protein loss is secondary to lymphatic obstruction, it is critical to establish the nature of this obstruction. Identification of mesenteric nodes or lymphoma may be possible by imaging studies. Similarly, it is important to exclude cardiac disease as a cause of protein-losing enteropathy. Patients with congenital heart disease may be examined by intranodal lymphangiography or noncontrast magnetic resonance lymphangiography and may undergo embolization of the site of lymphatic leakage or surgical lymphatic interventions to decompress the lymphatic system or target exclusion of abnormal lymphatic channels.

The increased protein loss that occurs in intestinal lymphangiectasia is a result of distended lymphatics associated with lipid malabsorption. The hypoproteinemia is treated with a low-fat, high-protein diet and the administration of medium-chain triglycerides, which do not exit from the intestinal epithelial cells via lymphatics but are delivered to the body via the portal vein. Other medical therapies including octreotide, a somatostatin analogue, intravenous heparin, budesonide and other glucocorticoids, and sirolimus have been studied but have generally been ineffective. Supportive care includes repletion of nutritional deficiencies and support stockings for leg edema control.

APPROACH TO THE PATIENT

Evaluation of the Patient with Suspected Malabsorption

The evaluation of patients with malabsorption is often challenging due to the large number of underlying disorders and the wide array of available tests. Thus, an extensive history and careful physical examination are essential to develop a more limited differential diagnosis and thereby avoid extensive and unnecessary testing.

HISTORY

A careful history should include questions about symptoms including abdominal pain, diarrhea, weight loss, bloating, symptoms or signs of selective nutrient deficiency including iron-deficiency anemia, bone fracture, or osteoporosis suggesting vitamin D and/or calcium deficiency, peripheral neuropathy resulting from vitamin B_{12} deficiency, hair loss that may result from generalized protein deficiency, predisposing disorders such as chronic pancreatitis or liver disease particularly involving the bile ducts such as primary biliary cholangitis or primary sclerosing cholangitis, history of small-bowel resection (due to Crohn's disease, trauma, ischemic bowel disease, etc.), and travel history. A multitude of nonspecific symptoms such as fatigue and weakness may also be reported. The protean manifestations of malabsorption and the underlying pathophysiology of clinical manifestations are summarized in **Table 336-5**.

PHYSICAL EXAMINATION

A careful physical examination may provide clues to underlying nutrient deficiencies and help assess severity of the malabsorptive process. For example, evidence of significant weight loss may be detected by bitemporal wasting and reduced arm circumference, iron deficiency may cause nail spooning, and vitamin B_{12} deficiency may result in significant peripheral neuropathy resulting in sensory reduction with tingling or numbness.

TABLE 336-5 Pathophysiology of Clinical Manifestations of Malabsorption Disorders

SYMPTOM OR SIGN	MECHANISM
Weight loss/malnutrition	Anorexia, malabsorption of nutrients
Diarrhea	Impaired absorption or secretion of water and electrolytes; colonic fluid secretion secondary to unabsorbed dihydroxy bile acids and fatty acids
Flatus	Bacterial fermentation of unabsorbed carbohydrate
Glossitis, cheilosis, stomatitis	Deficiency of iron, vitamin B_{12}, folate, and vitamin A
Abdominal pain	Bowel distention or inflammation, pancreatitis
Bone pain	Calcium, vitamin D malabsorption, protein deficiency, osteoporosis
Tetany, paresthesia	Calcium and magnesium malabsorption
Weakness	Anemia, electrolyte depletion (particularly K^+)
Azotemia, hypotension	Fluid and electrolyte depletion
Amenorrhea, decreased libido	Protein depletion, decreased calories, secondary hypopituitarism
Anemia	Impaired absorption of iron, folate, vitamin B_{12}
Bleeding	Vitamin K malabsorption, hypoprothrombinemia
Night blindness/ xerophthalmia	Vitamin A malabsorption
Peripheral neuropathy	Vitamin B_{12},thiamine, vitamin E, pyridoxine, and niacin deficiency
Dermatitis	Deficiency of vitamin A, zinc, and essential fatty acid

LABORATORY EXAMINATION

Diseases that exclusively affect the proximal small intestine (e.g., celiac disease limited to the duodenum) may result in iron-deficiency anemia. Resection or disease of the terminal ileum frequently results in B_{12} deficiency since B_{12} absorption occurs exclusively in the ileum, causing a macrocytic anemia. Disorders that cause steatorrhea are almost invariably associated with fat-soluble vitamin deficiency, specifically vitamin D (very common), vitamin E, vitamin A, and vitamin K. The functional result of vitamin K deficiency is an elevated prothrombin time/international normalized ratio (INR), so this blood test is frequently measured instead of vitamin K levels. Serum carotene levels can suggest fat malabsorption but may decrease simply due to poor dietary consumption of leafy vegetables.

To diagnose steatorrhea, a spot stool can be submitted for Sudan III staining, which is specific for fecal fat. This is a useful qualitative but not quantitative test. Stool for elastase is helpful for diagnosing pancreatic insufficiency. A 24-h assessment of stool volume/weight is useful to establish the presence of clinically significant absorptive or secretory diarrhea versus diarrhea from other causes such as proctitis, which causes frequent, small, low-volume stools. The gold standard for documenting steatorrhea is the 72-h fecal fat collection, which is performed in concert with the patient's consumption of a 100-g fat diet. This test is highly accurate but difficult to obtain due to patient reluctance to collect stool. Also patients with fat malabsorption may poorly tolerate a 100-g fat diet. A diet with strictly quantified albeit reduced fat calories may be substituted. Finally, the calculation of the stool osmotic gap is a very useful and easy way to diagnose an osmotic diarrhea. A spot stool sample is sent to the lab for quantitation of fecal sodium and potassium concentration. Although stool osmolality can also be measured in the lab, measurements are often inaccurate due to bacterial degradation of nonabsorbed carbohydrate as the stool sits prior to examination.

Because normal stool osmolality reflects serum osmolality at 290 mOsm/kg H_2O, the osmotic gap may be calculated as follows:

$$290 - 2\,(\text{stool [Na+]} + \text{stool [K+]}).$$

If >50–100, a stool osmotic gap is present indicating the presence of unmeasured osmoles (e.g., malabsorbed lactose), and osmotic diarrhea can be diagnosed. If <50, one can presume a secretory component. Of note, malabsorbed fatty acids may also cause a secretory diarrhea by inducing secretion in the colon, so a malabsorptive diarrhea may have both an osmotic and secretory component. Extensive celiac disease may cause both osmotic diarrhea due to malabsorbed carbohydrate and also secretory diarrhea due to crypt hyperplasia.

Urinary D-xylose Test The urinary D-xylose test for carbohydrate absorption provides a measure of proximal small-bowel absorptive function. D-Xylose, a pentose, is absorbed almost exclusively in the proximal small intestine and is excreted in the urine. The D-xylose test is usually performed by administering 25 g of D-xylose and collecting urine for 5 h. An abnormal test (excretion of <4.5 g) primarily reflects duodenal/jejunal mucosal disease. The ease of obtaining a mucosal biopsy of the small intestine by endoscopy and the false-negative rate of the D-xylose test have led to its diminished use. When small-intestinal mucosal disease is suspected, a small-intestinal mucosal biopsy should be performed. The D-xylose test can also be abnormal in patients with delayed gastric emptying, impaired renal function, and sequestration in patients with large collections of fluid in a third space (i.e., ascites, pleural fluid).

Radiologic Examination A small-bowel follow-through barium examination may be very useful for detecting evidence of small-bowel diseases such as celiac disease, jejunal diverticulosis that predisposes to small-bowel bacterial overgrowth, or Crohn's disease (Fig. 336-3). Magnetic resonance enterography and computed tomography enterography are commonly used for diagnosis and management of inflammatory, stricturing disorders such as Crohn's disease and as an initial assessment of malabsorption, providing a means to visualize the entire luminal GI tract as well as the hepatobiliary tree and pancreas.

Endoscopic Evaluation and Small-Bowel Biopsies Endoscopy with small-bowel biopsy is essential in the evaluation of patients with documented steatorrhea or chronic diarrhea, as well as to evaluate abnormalities detected by radiologic imaging or by capsule endoscopy. In patients with documented steatorrhea and no evidence of pancreatic or hepatobiliary disease, an upper endoscopy and possible small-bowel enteroscopy are required to examine the small-bowel mucosa and to take biopsies for analysis. An upper endoscopy will visualize the stomach and duodenum; the maximum reach of the typical upper endoscopy scope is the ligament of Treitz. Small-bowel enteroscopy using a longer scope such as a pediatric colonoscope can be used to visualize the jejunum. Single- and double-balloon enteroscopy provide a means for examining much more of the jejunum and, if successful, will reach the ileum. Capsule endoscopy provides another means for visualizing the entire small bowel. Colonoscopy can be used for a retrograde view and biopsy of the terminal ileum.

Biopsy Analysis Small-bowel pathology may be divided into the three groups (Table 336-6) described below.

1. *Diffuse histopathologic findings* involving the entire or majority of the mucosa that are specific for a particular disease entity; these include agammaglobulinemia (e.g., combined variable immunodeficiency) and abetalipoproteinemia. Immune globulin deficiency is associated with a variety of histopathologic findings on small-intestinal mucosal biopsy. The characteristic feature is the absence of or substantial reduction in the number of plasma cells in the lamina propria; the mucosal architecture may be either perfectly normal or flat (i.e., villous atrophy). Abetalipoproteinemia is characterized by a normal mucosal appearance except for the presence of mucosal absorptive cells that contain lipid postprandially and disappear after a prolonged period of either fat-free intake or fasting.
2. *Patchy lesions that are specific for a disease entity* include, for example, intestinal lymphoma or intestinal lymphangiectasia. Several diseases feature an abnormal small-intestinal mucosa with a patchy distribution. As a result, biopsy samples obtained randomly or in the absence of endoscopically visualized abnormalities may not reveal diagnostic features. Intestinal lymphoma can at times be diagnosed on mucosal biopsy by the identification of malignant lymphoma cells in the lamina propria and submucosa (Chap. 113). Dilated lymphatics in the submucosa and sometimes in the lamina propria indicate lymphangiectasia associated with hypoproteinemia secondary to protein loss into the intestine. Eosinophilic gastroenteritis comprises a heterogeneous group of disorders with a spectrum of presentations and symptoms, with an eosinophilic infiltrate of the lamina propria, and with or without peripheral eosinophilia. The patchy nature of the infiltrate and its presence in the submucosa often lead to an absence of histopathologic findings on mucosal biopsy. Amyloid deposition can be identified by Congo red staining in some patients with amyloidosis involving the duodenum (Chap. 117). Whipple's disease exhibits PAS-positive macrophages, and immunohistochemical analysis can detect the pathogenic organism. Although in severe cases the lesions are diffuse, patchy disease may also occur, requiring enteroscopy and sampling of multiple mucosal sites.
3. *Diffuse nonspecific lesions* may be found in more than one disorder. For example, villus atrophy/absence may be found in celiac disease, tropical sprue, or bacterial overgrowth, among other disorders. Several microorganisms can be identified in small-intestinal biopsy samples, establishing a correct diagnosis. At times, the biopsy is

TABLE 336-6 Diseases That Can Be Diagnosed by Small-Intestinal Mucosal Biopsies

LESIONS	PATHOLOGIC FINDINGS
Diffuse, Specific	
Agammaglobulinemia	No plasma cells; either normal or absent villi ("flat mucosa")
Abetalipoproteinemia	Normal villi; epithelial cells vacuolated with fat postprandially
Patchy, Specific	
Intestinal lymphoma	Malignant cells in lamina propria and submucosa
Intestinal lymphangiectasia	Dilated lymphatics; clubbed villi
Eosinophilic gastroenteritis	Eosinophil infiltration of lamina propria and mucosa
Amyloidosis	Amyloid deposits
Crohn's disease	Noncaseating granulomas
Infection by one or more microorganisms (see text)	Specific organisms
Mastocytosis	Mast cell infiltration of lamina propria
Whipple's disease	Lamina propria includes macrophages containing material positive on periodic acid–Schiff staining; can be diffuse or patchy.
Diffuse, Nonspecific	
Celiac disease	Short or absent villi; mononuclear infiltrate; epithelial cell damage; hypertrophy of crypts
Tropical sprue	Similar to celiac disease
Bacterial overgrowth	Patchy damage to villi; lymphocyte infiltration
Folate deficiency	Short villi; decreased mitosis in crypts; megalocytosis
Vitamin B_{12} deficiency	Similar to folate deficiency
Radiation enteritis	Similar to folate deficiency
Zollinger-Ellison syndrome	Mucosal ulceration and erosion from acid
Protein-calorie malnutrition	Villous atrophy; secondary bacterial overgrowth
Drug-induced enteritis	Variable histology

performed specifically to diagnose infection (e.g., Whipple's disease or giardiasis). In most other instances, the infection is detected incidentally during the workup for diarrhea or other abdominal symptoms. Many of these infections occur in immunocompromised patients with diarrhea; the etiologic agents include *Cryptosporidium*, *Isospora belli*, microsporidia, *Cyclospora*, *Toxoplasma*, cytomegalovirus, adenovirus, *Mycobacterium avium-intracellulare*, and *G. lamblia*. In immunocompromised patients, when *Candida, Aspergillus, Cryptococcus*, or *Histoplasma* organisms are seen on duodenal biopsy, their presence generally reflects systemic infection. Apart from Whipple's disease and infections in the immunocompromised host, small-bowel biopsy is seldom used as the primary mode of diagnosis of infection. Even giardiasis is more easily diagnosed by stool antigen studies and/or duodenal aspiration than by duodenal biopsy.

SUMMARY

The evaluation and management of patients with disorders of absorption are challenging due to the complexity of the underlying pathophysiology and the large number of associated diseases. A diagnostic approach based on the information summarized in Tables 336-1 and 336-5 should prove useful for guiding the care of these challenging patients.

337 Inflammatory Bowel Disease

Sonia Friedman, Richard S. Blumberg

Inflammatory bowel disease (IBD) is a chronic idiopathic inflammatory disease of the gastrointestinal tract. Ulcerative colitis (UC) and Crohn's disease (CD) are the two major types of IBD.

GLOBAL CONSIDERATIONS: EPIDEMIOLOGY

UC and CD have emerged as global diseases in the twenty-first century. The disease burden is high, with a prevalence of >0.3% in North America, Oceania, and most countries in Europe. In newly industrialized countries in Africa, Asia, and South America where there is increased urbanization and Westernization, the incidence of IBD has been rising and mirrors the prior increase of IBD in the Western world in the twentieth century. For example, in Brazil, the annual percent change is +11.1% (95% confidence interval [CI], 4.8–17.8%) for CD and +14.9% (95% CI, 10.4–19.6%) for UC, whereas in Taiwan, the annual percent change is +4.0% (95% CI, 1.0–7.1%) for CD and +4.8% (95% CI, 1.8–8.0%) for UC. In a study of newly diagnosed IBD cases between 2011 and 2013 from 13 countries or regions in the Asia Pacific, the mean annual IBD incidence per 100,000 was 1.50 (95% CI, 1.43–1.57). India (9.31; 95% CI, 8.38–10.31) and China (3.64; 95% CI, 2.97–4.42) had the highest IBD incidences in Asia. The highest reported prevalence values were in Europe (UC, 505 per 100,000 in Norway; CD, 322 per 100,000 in Germany) and North America (UC, 286 per 100,000 in the United States; CD, 319 per 100,000 in Canada). The most recent U.S. study showed that 2.39 million Americans are diagnosed with IBD. The most likely factors that explain the geographic variability of IBD rates, especially the rising incidence in developing countries and urban areas, are environmental variables including changes in diet (with downstream effects on the intestinal microbiota), exposure to sunlight or temperature differences, and socioeconomic status and hygiene **(Table 337-1)**.

Peak incidence of UC and CD is in the second to fourth decades, with 78% of CD studies and 51% of UC studies reporting the highest incidence among those aged 20–29 years old. A second modest rise in incidence occurs between the seventh and ninth decades of life. The female-to-male ratio ranges from 0.51 to 1.58 for UC studies and 0.34 to 1.65 for CD studies, suggesting that the diagnosis of IBD is not gender-specific. Pediatric IBD (patients <17 years old) composes ~20–25% of all IBD patients, and ~5% of all IBD patients are <10 years old. Children with IBD are also grouped as those with early-onset (EO) IBD (patients <10 years old), very-early-onset (VEO) IBD (patients <6 years old), and infantile IBD (patients <2 years old). VEOIBD and infantile IBD mainly affect the colon and are resistant to standard medications, and patients often have a strong family history of IBD, with at least one first-degree relative affected. In infantile IBD or VEOIBD, a number of rare, single genetic mutations have been identified as the basis for this susceptibility in up to 10% of patients, suggesting a simple Mendelian origin of the disease in these cases.

Although the greatest prevalence of IBD is among Whites, the prevalence of IBD in Latinx, Black, and Asian people is increasing. Urban areas have a higher prevalence of IBD than rural areas, and high socioeconomic classes have a higher prevalence than lower socioeconomic classes.

Epidemiologic studies have identified a number of potential environmental factors that are associated with disease risk **(Fig. 337-1)**.

TABLE 337-1 Epidemiology of IBD

	ULCERATIVE COLITIS	CROHN'S DISEASE
Age of onset	Second to fourth decades and seventh to ninth decades	Second to fourth decades and seventh to ninth decades
Ethnicity	White > Black > Latinx > Asian	
Female-to-male ratio	0.51–1.58	0.34–1.65
Smoking	May prevent disease (odds ratio 0.58)	May cause disease (odds ratio 1.76)
Oral contraceptives	No increased risk	Hazard ratio 2.82
Appendectomy	Protective (risk reduction 13–26%)	Not protective
Monozygotic twins	6–18% concordance	38–58% concordance
Dizygotic twins	0–2% concordance	4% concordance
Infections in the first year of life	1.6 and 3 times the risk of developing IBD by age 10 and 20 years	

Abbreviation: IBD, inflammatory bowel disease.

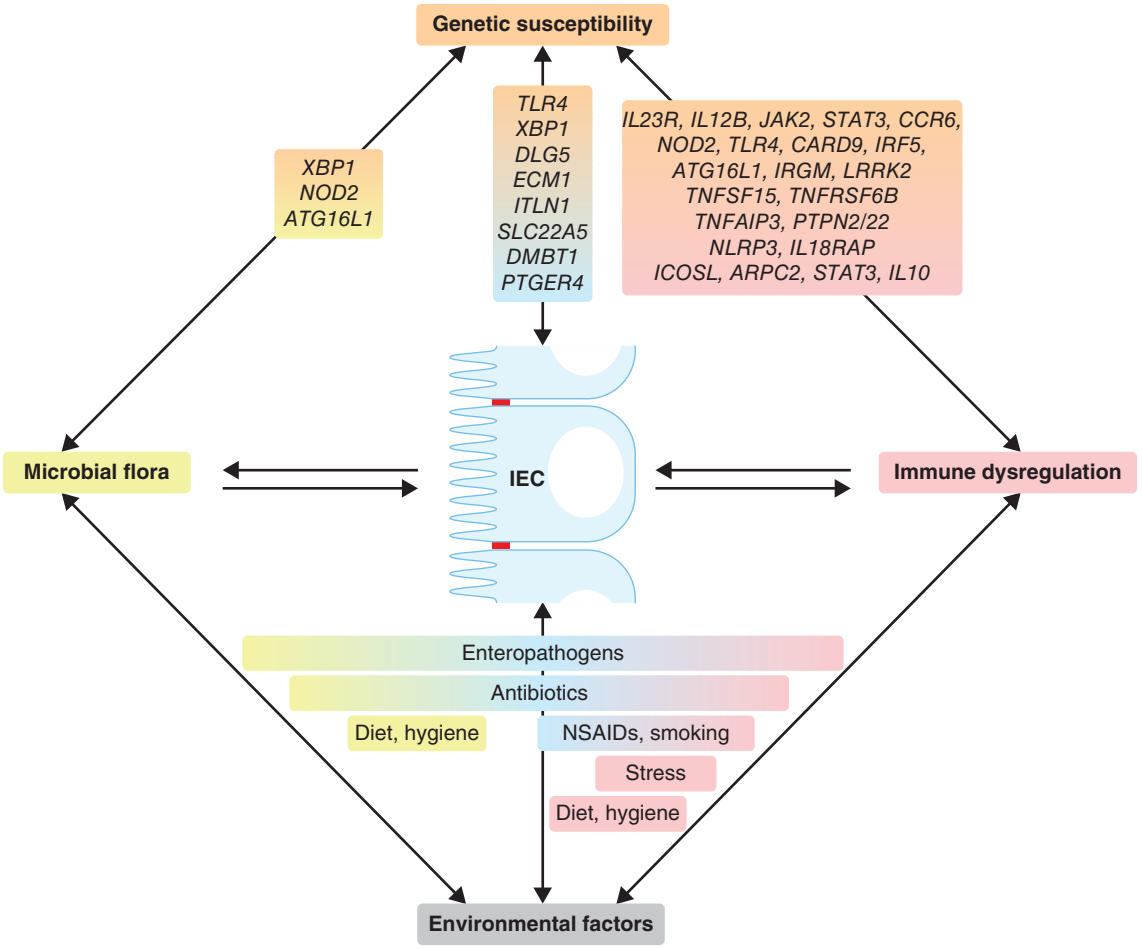

FIGURE 337-1 Pathogenesis of inflammatory bowel disease (IBD). In IBD, the tridirectional relationship between the commensal flora (microbiota), intestinal epithelial cells (IECs), and mucosal immune system is dysregulated, leading to chronic inflammation. Each of these three factors is affected by genetic and environmental factors that determine risk for the disease. NSAIDs, nonsteroidal anti-inflammatory drugs. (*Republished with permission Annual Review of Immunology from Inflammatory Bowel Disease, A Kaser et al: 28:573, 2010. Permission conveyed through Copyright Clearance Center, Inc.*)

Smoking is an important risk factor in IBD with opposite effects on UC (odds ratio [OR] 0.58) and CD (OR 1.76) that may be influenced by genetic risk factors and ethnic origin. Previous appendectomy with confirmed appendicitis (risk reduction of 13–26%), particularly at a young age, has a protective effect on the development of UC across different geographical regions and populations. Appendectomy is modestly associated with the development of CD, but this may be due to diagnostic bias. Oral contraceptive use is associated with an increased risk of CD, with a reported hazard ratio as high as 2.82 among current users and 1.39 among past users. The association between oral contraceptive use and UC is limited to women with a history of smoking. Breast-feeding may protect against the development of IBD, which supports the potential importance of early-life exposures to later IBD development. Infections in the first year of life are associated with development of IBD, especially before the ages of 10 and 20 years. Infectious gastroenteritis with pathogens (e.g., *Salmonella*, *Shigella*, *Campylobacter* spp., *Clostridioides difficile*) increases IBD risk by two- to threefold. Diets high in animal protein, sugars, sweets, oils, fish and shellfish, and dietary fat, especially ω-6 fatty acids, and low in ω-3 fatty acids have been implicated in increasing the risk of IBD. A protective effect of vitamin D on the risk of CD has been reported.

IBD is a familial disease in 5–10% of patients (Fig. 337-2), and the strongest risk factor for the development of IBD is a first-degree relative with the disease. The children of mothers and fathers with UC have an approximately fourfold increased risk of UC, and the children of mothers and fathers with CD have an almost eightfold increased risk of CD. Some of these patients may exhibit early-onset disease during the first decade of life and, in CD, a concordance of anatomic site and clinical type within families. In twin studies, 38–58% of monozygotic twins are concordant for CD, and 6–18% are concordant for UC, whereas 4% of dizygotic twins are concordant for CD, and 0–2% are concordant for UC in Swedish and Danish cohorts. In the remainder of patients, IBD is observed in the absence of a family history (i.e., sporadic disease).

GLOBAL CONSIDERATIONS: IBD PHENOTYPES

IBD location and behavior show racial differences that may reflect underlying genetic variations and have important implications for diagnosis and management of disease. Blacks and Latinxs tend to have an ileocolonic CD distribution. Data from East Asia show that

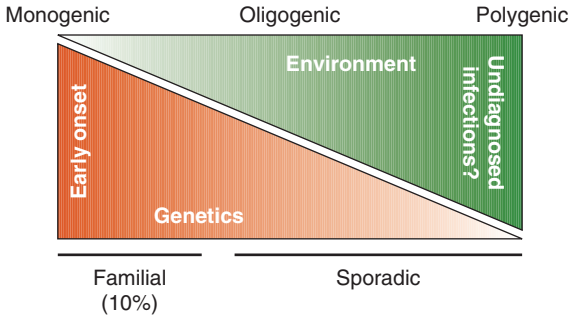

FIGURE 337-2 A model for the syndromic nature of inflammatory bowel disease (IBD). Genetic and environmental factors variably influence the development and phenotypic manifestations of IBD. At the one extreme, IBD is exemplified as a simple Mendelian disorder as observed in early-onset IBD due to single-gene defects such as *IL10*, *IL10RA*, and *IL10RB*; and at the other extreme, it may be exemplified by as yet to be described emerging infectious diseases. (*Reproduced with permission from A Kaser et al: Genes and environment: How will our concepts on the pathophysiology of IBD develop in the future? Dig Dis 28:395, 2010.*)

ileocolonic CD is the most common CD phenotype (50.5–71%) and perianal disease is more common in East Asian patients (30.3–58.8%) than Whites (25.1–29.6%). Pancolonic disease is more common than left-sided colitis or proctitis among Black, Latinx, and Asian patients with UC. Older Asian patients with UC (age >60) tend to have a more aggressive disease course. Among Blacks, joint involvement is the predominant extraintestinal manifestation (EIM) reported and ranges from 15.7 to 29.6%. Ocular involvement is also common in African Americans and ranges from 7.1 to 13%. Dermatologic manifestations are the most common EIMs reported in Latinxs (10–13%). These ethnic variations indicate the importance of different genetic and/or environmental factors in the pathogenesis of this disorder.

ETIOLOGY AND PATHOGENESIS

Under physiologic conditions, homeostasis normally exists between the commensal microbiota, epithelial cells that line the interior of the intestines (intestinal epithelial cells [IECs]), and immune cells within the tissues (Fig. 337-1). A consensus hypothesis is that each of these three major host compartments that function together as an integrated "supraorganism" (microbiota, IECs, and immune cells) are affected by specific environmental (e.g., smoking, antibiotics, enteropathogens) and genetic factors that, in a susceptible host, cumulatively and interactively disrupt homeostasis during the course of one's life and, in so doing, culminate in a chronic state of dysregulated inflammation; i.e., IBD. Although chronic activation of the mucosal immune system may represent an appropriate response to an infectious agent, a search for such an agent has thus far been unrewarding in IBD. As such, IBD is currently considered an inappropriate immune response to the endogenous (autochthonous) commensal microbiota within the intestines, with or without some component of autoimmunity. Importantly, the normal, uninflamed intestines contain a large number of immune cells that are in a unique state of activation, in which the gut is restrained from full immunologic responses to the commensal microbiota and dietary antigens by very powerful regulatory pathways that function within the immune system (e.g., T regulatory cells that express the FoxP3 transcription factor and suppress inflammation). Maintenance of homeostasis also involves oversight from local parenchymal cells including nerve, endothelial, and stromal cells, as well as the commensal microbiota that provide essential remedial factors necessary for health and serve as a target of the immune response. During the course of infections or other environmental stimuli in the normal host, full activation of the lymphoid tissues in the intestines occurs but is rapidly superseded by dampening of the immune response and tissue repair. In IBD, such processes may not be regulated normally.

GENETIC CONSIDERATIONS

The genetic underpinning of IBD is known from its concordance in identical twins, its occurrence in the context of several genetic syndromes, and the development of severe, refractory IBD in early life in association with single-gene defects that affect the immune system **(Table 337-2)**. More than 60 different gene defects have been identified in patients with VEOIBD and infantile IBD by whole-exome sequencing (WES), in whom most of the monogenic mutations have been discovered. These include mutations in genes encoding, for example, interleukin (IL) 10, the IL-10 receptor (IL-10R), cytotoxic T-lymphocyte-associated protein-4 (*CTLA4*), neutrophil cytosolic factor 2 protein (*NCF2*), X-linked inhibitor of apoptosis protein (*XIAP*), lipopolysaccharide responsive and beige-like anchor protein (*LRBA*), and tetratricopeptide repeat domain 7A protein (*TTC7*), among many other genes that are involved in host-commensal interactions. A monogenic etiology may also be possible in a small subset of adult patients with IBD. In addition, IBD has a familial origin in at least 10% of afflicted adults, consistent with an inherited basis for this disease (Fig. 337-2). However, the majority of pediatric and adult IBD cases are multigenic (or polygenic) in origin, suggesting a syndromic nature of this disease that gives rise to multiple clinical subgroups beyond the simple classification as UC and CD. The polygenic nature of the disease has been elucidated through a variety of genetic approaches, including candidate gene studies, linkage analysis, and genome-wide association studies (GWAS) that focus on the identification of disease-associated single nucleotide polymorphisms (SNPs) within the human genome and WES and whole-genome sequencing to elucidate the specific mutations potentially involved. GWAS have identified ~240 genetic loci with multiple potential candidate genes; two-thirds of these loci are associated with both disease phenotypes, with the remainder being specific for either CD or UC **(Table 337-3)**. These genetic similarities account for the overlapping immunopathogenesis and consequently epidemiologic observations of both diseases in the same families and similarities in response to therapies. Because the specific causal variants for each identified gene or locus are mostly unknown as most risk loci are contained within regulatory (noncoding) regions of the associated genes, it is not clear whether the similarities in the genetic risk factors associated with CD and UC are shared at a structural or functional level. The risk conferred by each identified gene or locus is unequal and generally small, such that only ~20% of the disease risk is considered to be explained by the current genetic information. Further, many of the genetic risk factors identified are also observed to be associated with risk for other immune-mediated diseases, suggesting that related immunogenetic pathways are involved in the pathogenesis of multiple different disorders, accounting for the common responsiveness to similar types of biologic therapies (e.g., anti–tumor necrosis factor [TNF] therapies) and possibly the simultaneous occurrence of these disorders. The diseases and the genetic risk factors that are shared with IBD include, for example, rheumatoid arthritis (*TNFAIP3*), psoriasis (*IL23R*, *IL12B*), ankylosing spondylitis (*IL23R*), type 1 diabetes mellitus (*IL10*, *PTPN2*), asthma (*ORMDL3*), and systemic lupus erythematosus (*TNFAIP3*, *IL10*), among others.

The genetic factors that are recognized to mediate risk for IBD have highlighted the importance of shared mechanisms of disease that variably affect CD and/or UC (Table 337-3). These include the following: those genes that are associated with fundamental cell biologic processes such as the unfolded protein response due to endoplasmic reticulum stress, autophagy, and metabolism that regulate the ability of cells to manage the physiologic needs of the intestinal environment; those associated with innate immunity associated with nonlymphoid cells that function in responses to and control of microbes; those associated with the regulation of adaptive immunity that control the balance between inflammatory and anti-inflammatory cellular pathways associated with lymphocytes; and, finally, those that are involved in the development and resolution of inflammation associated with

TABLE 337-2 Primary Genetic Disorders Associated with IBD

NAME	GENETIC ASSOCIATION	PHENOTYPE
Turner's syndrome	Loss of part or all of X chromosome	Associated with UC and colonic CD
Hermansky-Pudlak syndrome	Autosomal recessive disorder genes involved in the biogenesis of lysosome-related organelles or adaptor protein-3 complex	Granulomatous colitis, oculocutaneous albinism, platelet dysfunction, and pulmonary fibrosis
Wiskott-Aldrich syndrome (WAS)	X-linked recessive disorder, loss of WAS protein function	Colitis, immunodeficiency, severely dysfunctional platelets, and thrombocytopenia
Glycogen storage disease type 1b	Autosomal recessive disorder of *SLC37A4* resulting in deficiency of the glucose-6-phosphate translocase	Granulomatous colitis, presents in infancy with hypoglycemia, growth failure, hepatomegaly, and neutropenia
Immune dysregulation polyendocrinopathy, enteropathy X-linked (IPEX)	Loss of FoxP3 transcription factor and T regulatory cell function	UC-like autoimmune enteropathy, with endocrinopathy (neonatal type 1 diabetes or thyroiditis), dermatitis
Early-onset IBD	Deficient IL-10 and IL-10 receptor function	Severe, refractory IBD in early life

Abbreviations: CD, Crohn's disease; IBD, inflammatory bowel disease; IL, interleukin; UC, ulcerative colitis.

TABLE 337-3 Some Genetic Loci Associated with Crohn's Disease and/or Ulcerative Colitis

CHROMOSOME	PUTATIVE GENE	GENE NAME	PROTEIN FUNCTION	CD	UC
Unfolded Protein Response, Autophagy, and Metabolism					
2q37	*ATG16L1*	ATG16 autophagy related 16-like 1	Autophagy	+	
5q31	*SLC22A5*	Solute carrier family 22, member 5	β-Carnitine transporter	+	
5q33	*IRGM*	Immunity-related GTPase family, M	Autophagy	+	
7p21	*AGR2*	Anterior gradient 2	Unfolded protein response	+	+
12q12	*LRRK2*	Leucine-rich repeat kinase 2	Autophagy	+	
13q14	*LACC1*	Laccase domain containing 1 (FAMIN)	Immunometabolic regulator	+	
17q21	*ORMDL3*	Orosomucoid related member 1-like 3	Unfolded protein response and lipid synthesis	+	+
22q12	*XBP1*	X-box binding protein 1	Unfolded protein response	+	+
Innate Immunity					
1q23	*ITLN1*	Intelectin 1	Bacterial binding	+	
16q12	*NOD2*	Nucleotide-binding oligomerization domain containing 2	Bacterial sensing and autophagy activation	+	
Adaptive Immunity					
1p31	*IL23R*	Interleukin 23 receptor	T_H17 cell stimulation	+	+
1q32	*IL10*	Interleukin 10	Treg-associated cytokine		+
5q33	*IL12B*	Interleukin 12 subunit beta	IL-12 p40 chain of IL-12/IL-23	+	+
18p11	*PTPN2*	Protein tyrosine phosphatase, nonreceptor type 2	T-cell regulation	+	
Inflammation and Healing					
3p21	*MST1*	Macrophage Stimulating 1	Macrophage activation	+	+
5p13	*PTGER4*	Prostaglandin E receptor 4	PGE_2 receptor	+	+
6q23	*TNFAIP3*	Tumor necrosis factor, alpha-induced protein 3 (A20)	Toll-like receptor regulation	+	
6q27	*CCR6*	Chemokine (C-C motif) receptor 6	Dendritic cell migration	+	
9p24	*JAK2*	Janus kinase 2	IL-6R and IL-23R signaling	+	+
9q32	*TNFSF15*	Tumor necrosis factor–like cytokine 1A (TL1A)	Promotes inflammation and fibrosis	+	+
17q21	*STAT3*	Signal transducer and activator of transcription 3	IL-6R, IL-23R, and IL-10R signaling	+	+

Abbreviations: CD, Crohn's disease; GTPase, guanosine triphosphatase; IL, interleukin; PGE_2, prostaglandin E_2; Treg, T regulatory cell; UC, ulcerative colitis.

healing that control leukocyte recruitment and inflammatory mediator production or the development of fibrosis. Each of these genetic susceptibilities contributes in an incremental manner to IBD risk, variably affects the activities of virtually all subtypes of immune and nonimmune cells within the intestines, and encodes mutations (polymorphisms) that promote or protect from IBD. Some of these loci are associated with specific subtypes of disease such as the association between *NOD2* polymorphisms and fibrostenosing CD or *ATG16L1* and fistulizing disease, especially within the ileum. However, the clinical utility of these genetic risk factors for the diagnosis or determination of prognosis and therapeutic responses remains to be defined.

COMMENSAL MICROBIOTA AND IBD

The endogenous commensal microbiota within the intestines plays a central role in the pathogenesis of IBD. Humans are born with sterile guts and acquire their commensal microbiota initially from the mother during egress through the birth canal and subsequently from environmental sources. A stable configuration of up to 1000 species of bacteria that achieves a biomass of ~10^{12} colony-forming units per gram of feces is achieved by 3 years of age, which likely persists into adult life, with each individual human possessing a unique combination of species. In addition, the intestines contain other microbial life forms including fungi, archaea, viruses, and protists. The microbiota is thus considered as a critical and sustaining component of the human organism. The establishment and maintenance of the intestinal microbiota composition and function are under the control of host (e.g., immune and epithelial responses), environmental (e.g., diet and antibiotics), and likely genetic (e.g., *NOD2*) factors (Fig. 337-1). In turn, the microbiota, through its structural components and metabolic activity, has major influences on the epithelial and immune function of the host, which, through epigenetic effects, may have durable consequences. During early life when the commensal microbiota is being established, these microbial effects on the host may be particularly important in determining later life risk for IBD. Specific components of the microbiota can promote or protect from disease. The commensal microbiota in patients with both UC and CD is demonstrably different from that of nonafflicted individuals, a state of dysbiosis suggesting the presence of microorganisms that drive disease (e.g., Proteobacteria such as enteroinvasive and adherent *Escherichia coli*) and to which the immune response is directed and/or the loss of microorganisms that hinder inflammation (e.g., Firmicutes such as *Faecalibacterium prausnitzii*). Many of the changes in the commensal microbiota occur as a consequence of the inflammation and are thus potential secondary drivers of disease. In addition, agents that alter the intestinal microbiota such as metronidazole, ciprofloxacin, and elemental diets, may improve CD. CD may also respond to fecal diversion, demonstrating the ability of luminal contents to exacerbate disease.

DEFECTIVE IMMUNE REGULATION IN IBD

The mucosal immune system does not normally elicit an inflammatory immune response to luminal contents due to oral (mucosal) tolerance. Administration of soluble antigens orally, rather than subcutaneously or intramuscularly, leads to antigen-specific control of the response and the host's ability to tolerate the antigen. Multiple mechanisms are involved in the induction of oral tolerance and include deletion or anergy (nonresponsiveness) of antigen-reactive T cells or induction of CD4+ T cells that suppress gut inflammation (e.g., T regulatory cells expressing the FoxP3 transcription factor) and that secrete anti-inflammatory cytokines such as IL-10, IL-35, and transforming growth factor β (TGF-β). Oral tolerance may be responsible for the lack of immune responsiveness to dietary antigens and the commensal microbiota in the intestinal lumen. In IBD, this suppression of inflammation is altered, leading to uncontrolled inflammation. The mechanisms of this regulated immune suppression are incompletely known.

Gene knockout ($^{-/-}$) or transgenic (Tg) mouse models of IBD, including those that are directed at genes associated with risk for the human disease, have revealed that deleting specific cytokines (e.g., IL-2, IL-10, TGF-β) or their receptors, deleting molecules associated with T-cell antigen recognition (e.g., T-cell antigen receptors), or interfering with IEC barrier function and the regulation of responses to commensal bacteria (e.g., mucus glycoproteins or nuclear factor-κB [NF-κB]) leads to spontaneous colitis or enteritis. In the majority of circumstances, intestinal inflammation in these animal models requires the presence of the commensal microbiota. However, in some cases, activation of certain elements of the intestinal immune system may be exacerbated by the absence of bacteria, resulting in severe colitis and emphasizing the presence of protective properties of the commensal microbiota. Thus, a variety of specific alterations in either the microbiota or host can lead to uncontrolled immune activation and inflammation directed at the intestines in mice. How these relate to human IBD remains to be defined, but they are consistent with inappropriate responses of the genetically susceptible host to the commensal microbiota.

THE INFLAMMATORY CASCADE IN IBD

In both UC and CD, inflammation likely emerges from the genetic predisposition of the host in the context of yet-to-be-defined environmental factors. Once initiated in IBD by abnormal innate immune sensing of bacteria by parenchymal cells (e.g., IECs) and hematopoietic cells (e.g., macrophages, dendritic cells), the immune inflammatory response is perpetuated by T-cell and B-cell activation when coupled together with inadequate regulatory pathways. A sequential cascade of inflammatory mediators extends the response, making each step a potential target for therapy. Inflammatory cytokines from innate immune cells such as IL-1, IL-6, IL-12, IL-23, and TNF have diverse effects on tissues. They promote fibrogenesis, collagen production, activation of tissue metalloproteinases, and/or the production of other inflammatory mediators; they also activate the coagulation cascade in local blood vessels (e.g., increased production of von Willebrand factor). These cytokines are normally produced in response to infection but are usually turned off or inhibited by cytokines such as IL-10 and TGF-β at the appropriate time to limit tissue damage. In IBD, their activity is not regulated, resulting in an imbalance between the proinflammatory and anti-inflammatory mediators. Some of these cytokines activate other inflammatory cells (macrophages and B cells), and others such as chemokines act indirectly to recruit other lymphocytes, inflammatory leukocytes, and mononuclear cells from the bloodstream into the gut through interactions between homing receptors on leukocytes (e.g., α4β7 integrin) and addressins on vascular endothelium (e.g., MadCAM1). Lymphocytes such as CD4+ T helper (T_H) cells emerge from the lymph nodes under the influence of sphingosine-1-phosphate (S1P) gradients that act on S1P receptors (S1PR) expressed on the lymphocyte and endothelium. CD4+ T_H cells that promote inflammation are of four major types, all of which may be associated with colitis in animal models and perhaps humans: T_H1 cells (secrete IL-2, interferon [IFN] γ), T_H2 cells (secrete IL-4, IL-5, IL-13), T_H9 cells (secrete IL-9), and T_H17 cells (secrete IL-17, IL-21, IL-22). T_H17 cells may also provide protective functions. Innate immune-like cells (ILCs) that lack T-cell receptors are also present in intestines, polarize to the same functional fates, and may similarly participate in IBD. T_H1 cells induce transmural granulomatous inflammation that resembles CD; T_H2 cells and related natural killer T cells that secrete IL-4, IL-5, and IL-13 induce superficial mucosal inflammation resembling UC in animal models; T_H9 cells promote allergic-like inflammation; and T_H17 cells may be responsible for neutrophilic recruitment. Each of these T-cell subsets cross-regulates each other. The T_H1 cytokine pathway is initiated by IL-12, a key cytokine in the pathogenesis of experimental models of mucosal inflammation. IL-4 and IL-23, together with IL-6 and TGF-β, induce T_H2 and T_H17 cells, respectively, and IL-23 inhibits the suppressive function of regulatory T cells. Activated macrophages secrete TNF and IL-6. Cytokines produced by innate immune cells and lymphocytes exert their effects on target cells through cytokine-specific receptors, which precisely engage intracellular Janus kinases (JAK) 1, 2, and/or 3 for transmission of intracellular activating signals.

These characteristics of the immune response in IBD explain the beneficial therapeutic effects of antibodies to block proinflammatory cytokines or the signaling by their receptors (e.g., anti-TNF, anti-IL-12, anti-IL-23, JAK inhibitors), molecules that antagonize the activity of S1PR-induced emigration of lymphocytes from the lymph nodes (ozanimod), or antibodies that impede leukocyte recruitment into the intestines (e.g., anti-α4β7). They also highlight the potential usefulness of cytokines that inhibit inflammation and promote regulatory T cells or promote intestinal barrier function (e.g., IL-10) in the treatment of IBD. Therapies such as the 5-aminosalicylic acid (5-ASA) compounds and glucocorticoids are also potent inhibitors of these inflammatory mediators through inhibition of transcription factors such as NF-κB that regulate their expression.

PATHOLOGY

ULCERATIVE COLITIS: MACROSCOPIC FEATURES

UC is a mucosal disease that usually involves the rectum and extends proximally to involve all or part of the colon. About 40–50% of patients have disease limited to the rectum and rectosigmoid, 30–40% have disease extending beyond the sigmoid but not involving the whole colon, and 20% have a pancolitis. Proximal spread occurs in continuity without areas of uninvolved mucosa. When the whole colon is involved, the inflammation extends 2–3 cm into the terminal ileum in 10–20% of patients. The endoscopic changes of *backwash ileitis* are superficial and mild and are of little clinical significance. Although variations in macroscopic activity may suggest skip areas, biopsies from normal-appearing mucosa are usually abnormal. Thus, it is important to obtain multiple biopsies from apparently uninvolved mucosa, whether proximal or distal, during endoscopy. One caveat is that effective medical therapy can change the appearance of the mucosa such that either skip areas or the entire colon can be microscopically normal.

With mild inflammation, the mucosa is erythematous and has a fine granular surface that resembles sandpaper. In more severe disease, the mucosa is hemorrhagic, edematous, and ulcerated **(Fig. 337-3)**. In long-standing disease, inflammatory polyps (pseudopolyps) may be present as a result of epithelial regeneration. The mucosa may appear normal in remission, but in patients with many years of disease, it appears atrophic and featureless, and the entire colon becomes narrowed and shortened. Patients with fulminant disease can develop a toxic colitis or megacolon where the bowel wall becomes thin and the mucosa is severely ulcerated; this may lead to perforation.

ULCERATIVE COLITIS: MICROSCOPIC FEATURES

Histologic findings correlate well with the endoscopic appearance and clinical course of UC. The process is limited to the mucosa and

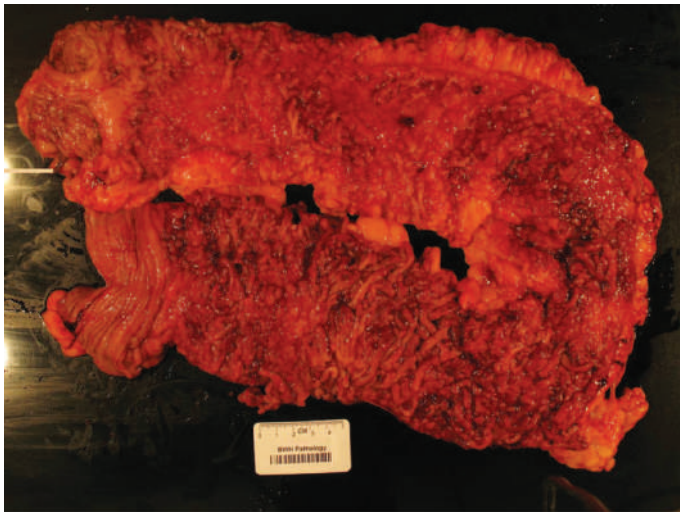

FIGURE 337-3 Ulcerative colitis. Diffuse (nonsegmental) mucosal disease, with broad areas of ulceration. The bowel wall is not thickened, and there is no cobblestoning. (*Courtesy of Dr. R. Odze, Division of Gastrointestinal Pathology, Department of Pathology, Brigham and Women's Hospital, Boston, Massachusetts; with permission.*)

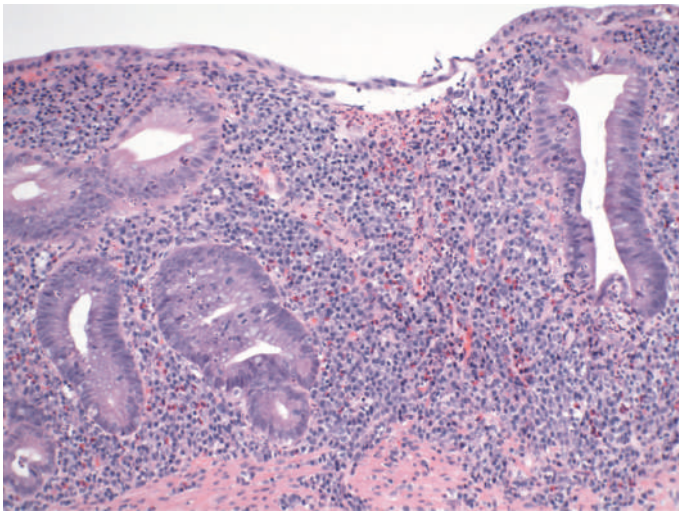

FIGURE 337-4 Medium-power view of colonic mucosa in ulcerative colitis showing diffuse mixed inflammation, basal lymphoplasmacytosis, crypt atrophy and irregularity, and superficial erosion. These features are typical of chronic active ulcerative colitis. (*Courtesy of Dr. R. Odze, Division of Gastrointestinal Pathology, Department of Pathology, Brigham and Women's Hospital, Boston, Massachusetts; with permission.*)

FIGURE 337-5 Crohn's disease of the colon showing thickening of the wall, with stenosis, linear serpiginous ulcers, and cobblestoning of the mucosa. (*Courtesy of Dr. R. Odze, Division of Gastrointestinal Pathology, Department of Pathology, Brigham and Women's Hospital, Boston, Massachusetts; with permission.*)

superficial submucosa, with deeper layers unaffected except in fulminant disease. In UC, two major histologic features suggest chronicity and help distinguish it from infectious or acute self-limited colitis. First, the crypt architecture of the colon is distorted; crypts may be bifid and reduced in number, often with a gap between the crypt bases and the muscularis mucosae. Second, some patients have basal plasma cells and multiple basal lymphoid aggregates. Mucosal vascular congestion, with edema and focal hemorrhage, and an inflammatory cell infiltrate of neutrophils, lymphocytes, plasma cells, and macrophages may be present. The neutrophils invade the epithelium, usually in the crypts, giving rise to cryptitis and, ultimately, to crypt abscesses **(Fig. 337-4)**. Ileal changes in patients with backwash ileitis include villous atrophy and crypt regeneration with increased inflammation, increased neutrophil and mononuclear inflammation in the lamina propria, and patchy cryptitis and crypt abscesses.

CROHN'S DISEASE: MACROSCOPIC FEATURES

CD can affect any part of the gastrointestinal (GI) tract from the mouth to the anus. Some 30–40% of patients have small-bowel disease alone, 40–55% have disease involving both the small and large intestines, and 15–25% have colitis alone. In the 75% of patients with small-intestinal disease, the terminal ileum is involved in 90%. Unlike UC, which almost always involves the rectum, the rectum is often spared in CD. CD is often segmental with skip areas throughout the diseased intestine **(Fig. 337-5)**. Perianal disease, manifesting as perirectal fistulas, fissures, abscesses, and anal stenosis, is present in one-third of patients with CD, particularly those with colonic involvement. Rarely, CD may also involve the liver and the pancreas.

Unlike UC, CD is a transmural process. Endoscopically, aphthous or small superficial ulcerations characterize mild disease; in more active disease, stellate ulcerations fuse longitudinally and transversely to demarcate islands of mucosa that frequently are histologically normal. This "cobblestone" appearance is characteristic of CD, both endoscopically and by barium radiography. As in UC, pseudopolyps can form in CD.

Active CD is characterized by focal inflammation and formation of fistula tracts, which resolve by fibrosis and stricturing of the bowel. The bowel wall thickens and becomes narrowed and fibrotic, leading to chronic, recurrent bowel obstructions. Projections of thickened mesentery known as "creeping fat" encase the bowel, and serosal and mesenteric inflammation promotes adhesions and fistula formation.

CROHN'S DISEASE: MICROSCOPIC FEATURES

The earliest lesions are aphthoid ulcerations and focal crypt abscesses with loose aggregations of macrophages, which form noncaseating granulomas in all layers of the bowel wall **(Fig. 337-6)**. Granulomas are a characteristic feature of CD and are less commonly found on mucosal biopsies than on surgical resection specimens. Other histologic features of CD include submucosal or subserosal lymphoid aggregates, particularly away from areas of ulceration, gross and microscopic skip areas, and transmural inflammation that is accompanied by fissures that penetrate deeply into the bowel wall and sometimes form fistulous tracts or local abscesses.

CLINICAL PRESENTATION

ULCERATIVE COLITIS

Signs and Symptoms The major symptoms of UC are diarrhea, rectal bleeding, tenesmus, passage of mucus, and crampy abdominal pain. The severity of symptoms correlates with the extent of disease. Although UC can present acutely, symptoms usually have been present for weeks to months.

Patients with proctitis usually pass fresh blood or blood-stained mucus, either mixed with stool or streaked onto the surface of a normal or hard stool. They also have tenesmus, or urgency with a feeling of incomplete evacuation, but rarely have abdominal pain. With proctitis

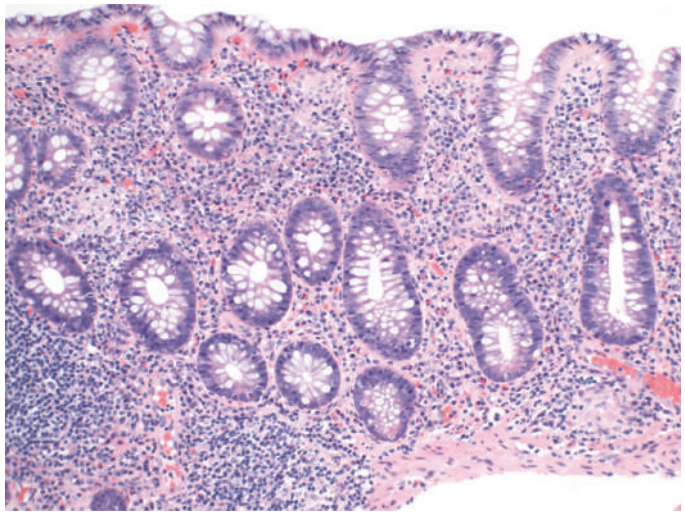

FIGURE 337-6 Medium-power view of Crohn's colitis showing mixed acute and chronic inflammation, crypt atrophy, and multiple small epithelioid granulomas in the mucosa. (*Courtesy of Dr. R. Odze, Division of Gastrointestinal Pathology, Department of Pathology, Brigham and Women's Hospital, Boston, Massachusetts; with permission.*)

TABLE 337-4 Montreal Classification of Extent and Severity of Ulcerative Colitis (UC)

EXTENT	ANATOMY
E1: Ulcerative proctitis	Involvement limited to the rectum
E2: Left-sided UC (distal UC)	Involvement limited to the colorectum distal to the splenic flexure
E3: Extensive UC (pancolitis)	Involvement extends proximal to the splenic flexure
SEVERITY	**DEFINITION**
S0: Clinical remission	Absence of symptoms
S1: Mild disease activity	≤4 stools/d (with or without blood), absence of systemic illness, normal inflammatory markers (ESR)
S2: Moderate disease activity	≥4 stools/d but minimal signs of systemic toxicity
S3: Severe disease activity	≥6 bloody stools/d, pulse ≥90 beats/min, temperature ≥37.5°C, hemoglobin <10.5 g/100 mL, and ESR ≥30 mm/h

Abbreviation: ESR, erythrocyte sedimentation rate.

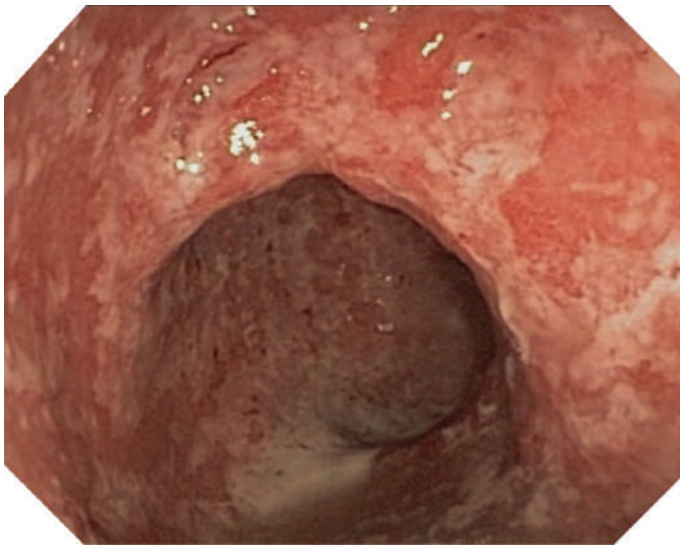

FIGURE 337-7 Colonoscopy with acute ulcerative colitis: severe colon inflammation with erythema, friability, and exudates. (*Courtesy of Dr. M. Hamilton, Gastroenterology Division, Department of Medicine, Brigham and Women's Hospital, Boston, Massachusetts; with permission.*)

or proctosigmoiditis, proximal transit slows, which may account for the constipation commonly seen in patients with distal disease.

When the disease extends beyond the rectum, blood is usually mixed with stool or grossly bloody diarrhea may be noted. Colonic motility is altered by inflammation with rapid transit through the inflamed intestine. When the disease is severe, patients pass a liquid stool containing blood, pus, and fecal matter. Diarrhea is often nocturnal and/or postprandial. Although severe pain is not a prominent symptom, some patients with active disease may experience lower abdominal discomfort or mild central abdominal cramping. Severe cramping and abdominal pain can occur with severe attacks of the disease. Other symptoms in moderate to severe disease include anorexia, nausea, vomiting, fever, and weight loss.

Physical signs of proctitis include a tender anal canal and blood on rectal examination. With more extensive disease, patients have tenderness to palpation directly over the colon. Patients with a toxic colitis have severe pain and bleeding, and those with megacolon have hepatic tympany. Both may have signs of peritonitis if a perforation has occurred. The classification of disease activity is shown in **Table 337-4**.

Laboratory, Endoscopic, and Radiographic Features Active disease can be associated with a rise in acute-phase reactants (C-reactive protein [CRP]), platelet count, and erythrocyte sedimentation rate (ESR) and a decrease in hemoglobin. Fecal lactoferrin, a glycoprotein present in activated neutrophils, is a highly sensitive and specific marker for detecting intestinal inflammation. Fecal calprotectin is present in neutrophils and monocytes, and the levels correlate well with histologic inflammation, predict relapses, and detect pouchitis. Both fecal lactoferrin and calprotectin are an integral part of IBD management and are used frequently to rule out active inflammation versus symptoms of irritable bowel or bacterial overgrowth. In severely ill patients, the serum albumin level will fall rather quickly. Leukocytosis may be present but is not a specific indicator of disease activity. Diagnosis relies on the patient's history, clinical symptoms, negative stool and/or tissue examination for bacteria, *C. difficile* toxin, ova and parasites, and viruses depending on epidemiologic considerations and clinical presentation; sigmoidoscopic appearance **(see Fig. 333-4*A*)**; and histology of rectal or colonic biopsy specimens.

Sigmoidoscopy is used to assess disease activity and is usually performed before treatment. If the patient is not having an acute flare, colonoscopy is used to assess disease extent and activity **(Fig. 337-7)**. Endoscopically mild disease is characterized by erythema, decreased vascular pattern, and mild friability. Moderate disease is characterized by marked erythema, absent vascular pattern, friability, and erosions, and severe disease is characterized by spontaneous bleeding and ulcerations. Histologic features change more slowly than clinical features but can also be used to grade disease activity. Intestinal ultrasound is a newer tool to assess UC activity and mucosal healing and correlates well with endoscopy and inflammatory markers.

Complications Only 15% of patients with UC present initially with severe disease. Massive hemorrhage occurs in 1% of patients, and treatment for the disease usually stops the bleeding. *Toxic megacolon* is defined as a transverse or right colon with a diameter of >6 cm, with loss of haustration in patients with severe attacks of UC. It occurs rarely and can be triggered by electrolyte abnormalities and narcotics. About 50% of acute dilations will resolve with conservative management alone, but urgent colectomy is required for those who do not improve. Perforation is the most dangerous of the local complications, and the physical signs of peritonitis may not be obvious, especially if the patient is receiving glucocorticoids. Although perforation is rare, the mortality rate for perforation complicating a toxic megacolon is ~15%. In addition, patients can develop a toxic colitis and such severe ulcerations that the bowel may perforate without first dilating.

Strictures occur in ~5% of patients and are always a concern in UC because of the possibility of underlying neoplasia. Although benign strictures can form from the inflammation and fibrosis of UC, strictures that are impassable with the colonoscope should be presumed malignant until proven otherwise. A stricture that prevents passage of the colonoscope is an indication for surgery. UC patients occasionally develop anal fissures, perianal abscesses, or hemorrhoids, but the occurrence of extensive perianal lesions should suggest CD.

CROHN'S DISEASE

Signs and Symptoms Although CD usually presents as acute or chronic bowel inflammation, the inflammatory process evolves toward one of two patterns of disease: a fibrostenotic obstructing pattern or a penetrating fistulous pattern, each with different treatments and prognoses. The site of disease influences the clinical manifestations **(Table 337-5)**.

ILEOCOLITIS Because the most common site of inflammation is the terminal ileum, the usual presentation of ileocolitis is a chronic history of recurrent episodes of right lower quadrant pain and diarrhea. Sometimes the initial presentation mimics acute appendicitis with pronounced right lower quadrant pain, a palpable mass, fever, and leukocytosis. Pain is usually colicky; it precedes and is relieved by defecation. A low-grade fever is usually noted. High-spiking fever suggests intraabdominal abscess formation. Weight loss is common—typically

TABLE 337-5 Vienna and Montreal Classifications of Crohn's Disease

	VIENNA	MONTREAL
Age at diagnosis	A1: <40 years A2: >40 years	A1: <16 years A2: Between 17 and 40 years A3: >40 years
Location	L1: Ileal L2: Colonic L3: Ileocolonic L4: Upper	L1: Ileal L2: Colonic L3: Ileocolonic L4: Isolated upper disease[a]
Behavior	B1: Nonstricturing, nonpenetrating B2: Stricturing B3: Penetrating	B1: Nonstricturing, nonpenetrating B2: Stricturing B3: Penetrating p: Perianal disease modifier[b]

[a]L4 is a modifier and can be added to L1–L3 when there is concomitant foregut disease. [b]p is added to B1–B3 when there is concomitant perianal disease.

10–20% of body weight—and develops as a consequence of diarrhea, anorexia, and fear of eating.

An inflammatory mass may be palpated in the right lower quadrant of the abdomen. The mass is composed of inflamed bowel, induration of the mesentery, and enlarged abdominal lymph nodes. The "string sign" on radiographic studies results from a severely narrowed loop of bowel, which makes the lumen resemble a frayed cotton string. It is caused by incomplete filling of the lumen as the result of edema, irritability, and spasms associated with inflammation and ulcerations. The sign may be seen in both nonstenotic and stenotic phases of the disease.

Bowel obstruction may take several forms. In the early stages of disease, bowel wall edema and spasm produce intermittent obstructive manifestations and increasing symptoms of postprandial pain. Over several years, persistent inflammation gradually progresses to fibrostenotic narrowing and stricture. Diarrhea will decrease and be replaced by chronic bowel obstruction. Acute episodes of obstruction occur as well, precipitated by bowel inflammation and spasm or sometimes by impaction of undigested food or medication. These episodes usually resolve with intravenous fluids and gastric decompression.

Severe inflammation of the ileocecal region may lead to localized wall thinning, with microperforation and fistula formation to the adjacent bowel, the skin, or the urinary bladder, or to an abscess cavity in the mesentery. Enterovesical fistulas typically present as dysuria or recurrent bladder infections or, less commonly, as pneumaturia or fecaluria. Enterocutaneous fistulas follow tissue planes of least resistance, usually draining through abdominal surgical scars. Enterovaginal fistulas are rare and present as dyspareunia or as a feculent or foul-smelling, often painful vaginal discharge. They are unlikely to develop without a prior hysterectomy.

JEJUNOILEITIS Extensive inflammatory disease is associated with a loss of digestive and absorptive surface, resulting in malabsorption and steatorrhea. Nutritional deficiencies can also result from poor intake and enteric losses of protein and other nutrients. Intestinal malabsorption can cause anemia, hypoalbuminemia, hypocalcemia, hypomagnesemia, coagulopathy, and hyperoxaluria with nephrolithiasis in patients with an intact colon. Many patients need to take intravenous iron since oral iron is poorly tolerated and often ineffective. Vertebral fractures are caused by a combination of vitamin D deficiency, hypocalcemia, and prolonged glucocorticoid use. Pellagra from niacin deficiency can occur in extensive small-bowel disease, and malabsorption of vitamin B_{12} can lead to megaloblastic anemia and neurologic symptoms. Other important nutrients to measure and replete if low are folate and vitamins A, E, and K. Levels of minerals such as zinc, selenium, copper, and magnesium are often low in patients with extensive small-bowel inflammation or resections, and these should be repleted as well. Most patients should take daily multivitamin, calcium, and vitamin D supplements.

Diarrhea is characteristic of active disease; its causes include (1) bacterial overgrowth in obstructive stasis or fistulization, (2) bile acid malabsorption due to a diseased or resected terminal ileum, (3) intestinal inflammation with decreased water absorption and increased secretion of electrolytes, and (4) enteroenteric fistula(e).

COLITIS AND PERIANAL DISEASE Patients with colitis present with low-grade fevers, malaise, diarrhea, crampy abdominal pain, and sometimes hematochezia. Gross bleeding is not as common as in UC and appears in about one-half of patients with exclusively colonic disease. Only 1–2% exhibit massive bleeding. Pain is caused by passage of fecal material through narrowed and inflamed segments of the large bowel. Decreased rectal compliance is another cause for diarrhea in Crohn's colitis patients.

Stricturing can occur in the colon in 4–16% of patients and produce symptoms of bowel obstruction. If the endoscopist is unable to traverse a stricture in Crohn's colitis, surgical resection should be considered, especially if the patient has symptoms of chronic obstruction. Colonic disease may fistulize into the stomach or duodenum, causing feculent vomiting, or to the proximal or mid-small bowel, causing malabsorption by "short circuiting" the absorptive surface and bacterial overgrowth. Ten percent of women with Crohn's colitis will develop a rectovaginal fistula.

Perianal disease affects about one-third of patients with Crohn's colitis and is manifested by incontinence, large hemorrhoidal tags, anal strictures, anorectal fistulas, and perirectal abscesses. Not all patients with perianal fistula will have endoscopic evidence of colonic inflammation.

GASTRODUODENAL DISEASE Symptoms and signs of upper GI tract disease include nausea, vomiting, and epigastric pain. Patients usually have a *Helicobacter pylori*–negative gastritis. The second portion of the duodenum is more commonly involved than the bulb. Fistulas involving the stomach or duodenum arise from the small or large bowel and do not necessarily signify the presence of upper GI tract involvement. Patients with advanced gastroduodenal CD may develop a chronic gastric outlet obstruction. About 30% of children diagnosed with CD have esophagogastroduodenal involvement. The classification of disease activity is shown in Table 337-5.

Laboratory, Endoscopic, and Radiographic Features Laboratory abnormalities include elevated ESR and CRP. In more severe disease, findings include hypoalbuminemia, anemia, and leukocytosis. Fecal calprotectin and lactoferrin levels have been used to distinguish IBD from irritable bowel syndrome (IBS), to assess whether CD is active, and to detect postoperative recurrence of CD. Fecal calprotectin is a more sensitive marker of ileocolonic or colonic inflammation rather than isolated ileal inflammation.

Endoscopic features of CD include rectal sparing, aphthous ulcerations, fistulas, and skip lesions. Colonoscopy allows examination and biopsy of mass lesions or strictures and biopsy of the terminal ileum. Upper endoscopy is useful in diagnosing gastroduodenal involvement in patients with upper tract symptoms. An ileal or colonic stricture may be dilated with a balloon introduced through the colonoscope. Strictures ≤4 cm in length and those at anastomotic sites respond better to endoscopic dilation. The perforation rate is as high as 10%. Most endoscopists dilate only fibrotic strictures and not those associated with active inflammation. Wireless capsule endoscopy (WCE) allows direct visualization of the entire small-bowel mucosa **(Fig. 337-8)**. The diagnostic yield of detecting lesions suggestive of active CD is higher with WCE than computed tomography (CT) or magnetic resonance (MR) enterography. WCE should not be used in the setting of a small-bowel stricture. Capsule retention occurs in <1% of patients with suspected CD, but retention rates of 4–6% are seen in patients with established CD. It is helpful to give the patient with CD a patency capsule, which is made of barium and starts to dissolve 30 h after ingestion. An abdominal x-ray can be taken at around 30 h after ingestion to see if the capsule is still present in the small bowel, which would indicate a stricture.

In CD, early radiographic findings in the small bowel include thickened folds and aphthous ulcerations. "Cobblestoning" from longitudinal and transverse ulcerations most frequently involves the small bowel. In more advanced disease, strictures, fistulas, inflammatory masses, and abscesses may be detected. The earliest macroscopic findings of colonic CD are aphthous ulcers. These small ulcers are often

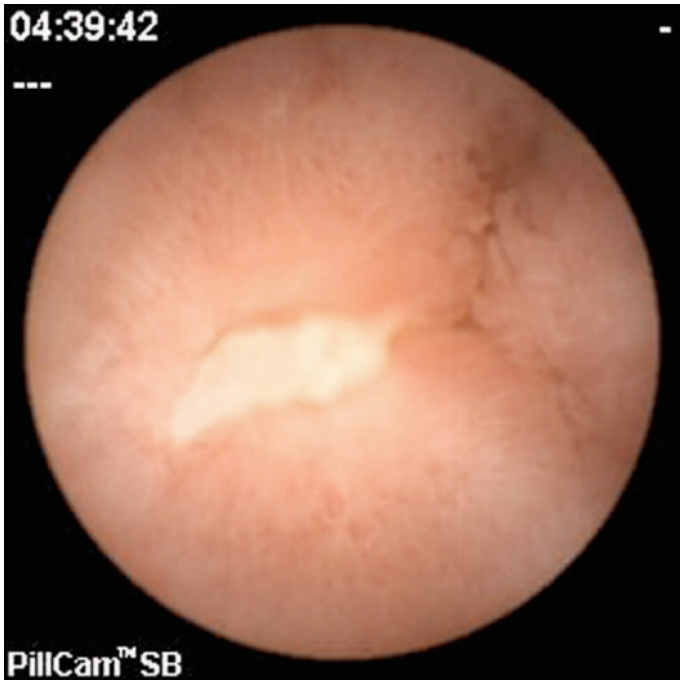

FIGURE 337-8 Wireless capsule endoscopy image in a patient with Crohn's disease of the ileum shows ulcerations and narrowing of the intestinal lumen. (*Courtesy of Dr. S. Reddy, Gastroenterology Division, Department of Medicine, Brigham and Women's Hospital, Boston, Massachusetts; with permission.*)

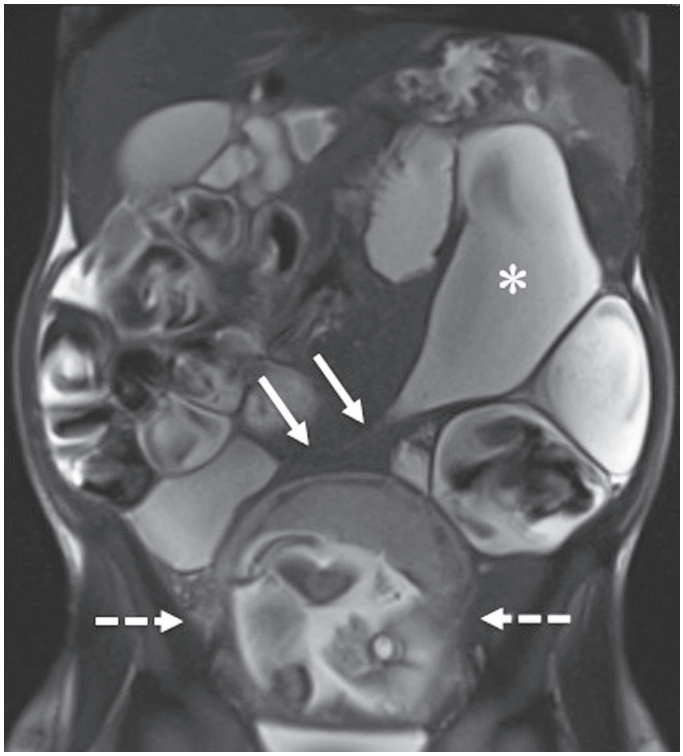

FIGURE 337-9 A coronal magnetic resonance image was obtained using a half Fourier single-shot T2-weighted acquisition with fat saturation in a 27-year-old pregnant (23 weeks' gestation) woman. The patient had Crohn's disease and was maintained on mercaptopurine and prednisone. She presented with abdominal pain, distension, vomiting, and small-bowel obstruction. The image reveals a 7- to 10-cm long stricture at the terminal ileum (*white arrows*) causing obstruction and significant dilatation of the proximal small bowel (*white asterisk*). A fetus is seen in the uterus (*dashed white arrows*). (*Courtesy of Drs. J. F. B. Chick and P. B. Shyn, Abdominal Imaging and Intervention, Department of Radiology, Brigham and Women's Hospital, Harvard Medical School, Boston, Massachusetts; with permission.*)

multiple and separated by normal intervening mucosa. As the disease progresses, aphthous ulcers become enlarged, deeper, and occasionally connected to one another, forming longitudinal stellate, serpiginous, and linear ulcers **(see Fig. 333-4*B*)**.

The transmural inflammation of CD leads to decreased luminal diameter and limited distensibility. As ulcers progress deeper, they can lead to fistula formation. The segmental nature of CD results in wide gaps of normal or dilated bowel between involved segments.

CT enterography and MR enterography have been shown to be equally accurate in the identification of active small-bowel inflammation. MRI is thought to offer superior soft tissue contrast and has the added advantage of avoiding radiation exposure changes **(Figs. 337-9** and **337-10)**. The lack of ionizing radiation is particularly appealing in younger patients and when monitoring response to therapy where serial images will be obtained. Pelvic MRI is superior to pelvic CT for demonstrating pelvic lesions such as ischiorectal abscesses and perianal fistulas **(Fig. 337-11)**. An underutilized resource for assessing small-bowel CD is small-bowel ultrasound (SBUS). SBUS is at least as sensitive as MR enterography and CT enterography for detecting small-bowel CD, with a sensitivity of 94%, specificity of 97%, positive predictive value of 97%, and negative predictive value of 94%. Use of oral contrast medium can increase the sensitivity and specificity to detect small-bowel lesions to 100%. SBUS is best suited for distal small-bowel assessment, as the sensitivity of detecting lesions within the duodenum and proximal jejunum may be lower due to anatomic position. The limitations of SBUS include availability and operator dependence.

Complications Because CD is a transmural process, serosal adhesions develop that provide direct pathways for fistula formation and reduce the incidence of free perforation. Perforation occurs in 1–2% of patients, usually in the ileum but occasionally in the jejunum or as a complication of toxic megacolon. The peritonitis of free perforation, especially colonic, may be fatal. Intraabdominal and pelvic abscesses occur in 10–30% of patients with CD at some time in the course of their illness. CT-guided percutaneous drainage of the abscess is standard therapy. Despite adequate drainage, most patients need resection of the offending bowel segment. Percutaneous drainage has an especially high failure rate in abdominal wall abscesses. Systemic glucocorticoid therapy increases the risk of intraabdominal and pelvic abscesses in CD patients who have never had an operation. Other complications include intestinal obstruction in 40%, massive hemorrhage, malabsorption, and severe perianal disease.

Serologic Markers Clinical factors described at diagnosis are more helpful than serologies at predicting the natural history of IBD. The positive and negative predictive values of serologic tests such as anti-*Saccharomyces cerevisiae* antibody (ASCA) and perinuclear antineutrophil cytoplasmic antibody (pANCA) vary depending on the prevalence of IBD in different populations, such that their clinical usefulness is unclear.

DIFFERENTIAL DIAGNOSIS OF UC AND CD

Once a diagnosis of IBD is made, distinguishing between UC and CD is impossible initially in up to 15% of cases. These are termed *indeterminate colitis*. Fortunately, in most cases, the true nature of the underlying colitis becomes evident later in the course of the patient's disease. Approximately 5% of colon resection specimens are difficult to classify as either UC or CD because they exhibit overlapping histologic features.

INFECTIOUS DISEASES

Infections of the small intestines and colon can mimic CD or UC. They may be bacterial, fungal, viral, or protozoal in origin **(Table 337-6)**. *Campylobacter* colitis can mimic the endoscopic appearance of severe UC and can cause a relapse of established UC. *Salmonella* can cause watery or bloody diarrhea, nausea, and vomiting. Shigellosis causes watery diarrhea, abdominal pain, and fever followed by rectal tenesmus and by the passage of blood and mucus per rectum. All three are usually self-limited, but 1% of patients infected with *Salmonella* become asymptomatic carriers. *Yersinia enterocolitica* infection occurs mainly in the terminal ileum and causes mucosal ulceration, neutrophil

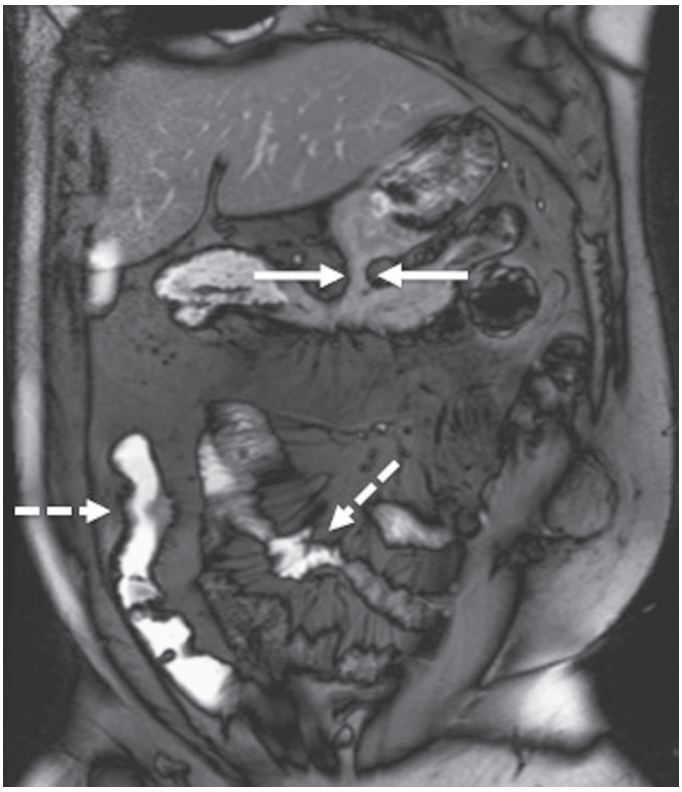

FIGURE 337-10 A coronal balanced, steady-state, free precession, T2-weighted image with fat saturation was obtained in a 32-year-old man with Crohn's disease and prior episodes of bowel obstruction, fistulas, and abscesses. He was being treated with mercaptopurine and presented with abdominal distention and diarrhea. The image demonstrates a new gastrocolic fistula (*solid white arrows*). Multifocal involvement of the small bowel and terminal ileum is also present (*dashed white arrows*). (*Courtesy of Drs. J. F. B. Chick and P. B. Shyn, Abdominal Imaging and Intervention, Department of Radiology, Brigham and Women's Hospital, Harvard Medical School, Boston, Massachusetts; with permission.*)

FIGURE 337-11 Axial T2-weighted fat-saturated image obtained in a 39-year-old male with Crohn's disease shows a defect in the internal sphincter at the 6 o'clock position of the mid anal canal (*open white arrow*) communicating with a 1.1-cm intersphincteric collection (*black arrow*). Wide defect in the external sphincter at the 7 o'clock position (*solid white arrow*) leads to a moderate-sized perianal abscess in the ischioanal fossa (*asterisk*). (*Courtesy of Drs. J.S. Quon and P.B. Shyn, Abdominal Imaging and Intervention, Department of Radiology, Brigham and Women's Hospital, Harvard Medical School, Boston, Massachusetts; with permission.*)

TABLE 337-6 Diseases That Mimic IBD

Infectious Etiologies		
Bacterial	**Mycobacterial**	**Viral**
Salmonella	Tuberculosis	Cytomegalovirus
Shigella	*Mycobacterium avium*	Herpes simplex
Toxigenic	**Parasitic**	HIV
Escherichia coli	Amebiasis	**Fungal**
Campylobacter	*Isospora*	Histoplasmosis
Yersinia	*Trichuris trichiura*	*Candida*
Clostridioides *difficile*	Hookworm	*Aspergillus*
Gonorrhea	*Strongyloides*	
Chlamydia trachomatis		

Noninfectious Etiologies		
Inflammatory	**Neoplastic**	**Drugs and Chemicals**
Appendicitis	Lymphoma	NSAIDs
Diverticulitis	Metastatic	Phosphosoda
Diversion colitis	Carcinoma	Cathartic colon
Collagenous/lymphocytic colitis	Carcinoma of the ileum	Gold
Ischemic colitis	Carcinoid	Oral contraceptives
Radiation colitis/enteritis	Familial polyposis	Cocaine
Solitary rectal ulcer syndrome		Immune checkpoint inhibitor colitis
Eosinophilic gastroenteritis		Mycophenolate mofetil
Neutropenic colitis		
Behçet's syndrome		
Graft-versus-host disease		

Abbreviations: IBD, inflammatory bowel disease; NSAIDs, nonsteroidal anti-inflammatory drugs.

invasion, and thickening of the ileal wall. Other bacterial infections that may mimic IBD include *C. difficile*, which presents with watery diarrhea, tenesmus, nausea, and vomiting; and *E. coli*, three categories of which can cause colitis. These are enterohemorrhagic, enteroinvasive, and enteroadherent *E. coli*, all of which can cause bloody diarrhea and abdominal tenderness. Gonorrhea, *Chlamydia*, and syphilis can also cause proctitis.

GI involvement with mycobacterial infection occurs primarily in the immunosuppressed patient but may occur in patients with normal immunity. Distal ileal and cecal involvement predominates, and patients present with symptoms of small-bowel obstruction and a tender abdominal mass. The diagnosis is made most directly by colonoscopy with biopsy and culture. Although most of the patients with viral colitis are immunosuppressed, cytomegalovirus (CMV) and herpes simplex proctitis may occur in immunocompetent individuals. CMV occurs most commonly in the esophagus, colon, and rectum but may also involve the small intestine. Symptoms include abdominal pain, bloody diarrhea, fever, and weight loss. With severe disease, necrosis and perforation can occur. Diagnosis is made by identification of characteristic intranuclear inclusions in mucosal cells on biopsy. Herpes simplex infection of the GI tract is limited to the oropharynx, anorectum, and perianal areas. Symptoms include anorectal pain, tenesmus, constipation, inguinal adenopathy, difficulty with urinary voiding, and sacral paresthesias. Diagnosis is made by rectal biopsy with identification of characteristic cellular inclusions and viral culture. HIV itself can cause diarrhea, nausea, vomiting, and anorexia. Small-intestinal biopsies show partial villous atrophy; small-bowel bacterial overgrowth and fat malabsorption may also be noted.

Protozoan parasites include *Isospora belli*, which can cause a self-limited infection in healthy hosts but causes a chronic profuse, watery diarrhea and weight loss in AIDS patients. *Entamoeba histolytica* or related species infect ~10% of the world's population; symptoms include abdominal pain, tenesmus, frequent loose stools containing

blood and mucus, and abdominal tenderness. Colonoscopy reveals focal punctate ulcers with normal intervening mucosa; diagnosis is made by biopsy or serum amebic antibodies. Fulminant amebic colitis is rare but has a mortality rate of >50%.

Other parasitic infections that may mimic IBD include hookworm (*Necator americanus*), whipworm (*Trichuris trichiura*), and *Strongyloides stercoralis.* In severely immunocompromised patients, *Candida* or *Aspergillus* can be identified in the submucosa. Disseminated histoplasmosis can involve the ileocecal area.

NONINFECTIOUS DISEASES

Diverticulitis can be confused with CD clinically and radiographically. Both diseases cause fever, abdominal pain, tender abdominal mass, leukocytosis, elevated ESR, partial obstruction, and fistulas. Perianal disease or ileitis on small-bowel series favors the diagnosis of CD. Significant endoscopic mucosal abnormalities are more likely in CD than in diverticulitis. Endoscopic or clinical recurrence following segmental resection favors CD. Diverticular-associated colitis is similar to CD, but mucosal abnormalities are limited to the sigmoid and descending colon.

Ischemic colitis is commonly confused with IBD. The ischemic process can be chronic and diffuse, as in UC, or segmental, as in CD. Colonic inflammation due to ischemia may resolve quickly or may persist and result in transmural scarring and stricture formation. Ischemic bowel disease should be considered in the elderly following abdominal aortic aneurysm repair or when a patient has a hypercoagulable state or a severe cardiac or peripheral vascular disorder. Patients usually present with sudden onset of left lower quadrant pain, urgency to defecate, and the passage of bright red blood per rectum. Endoscopic examination often demonstrates a normal-appearing rectum and a sharp transition to an area of inflammation in the descending colon and splenic flexure.

The effects of radiotherapy on the GI tract can be difficult to distinguish from IBD. Acute symptoms can occur within 1–2 weeks of starting radiotherapy. When the rectum and sigmoid are irradiated, patients develop bloody, mucoid diarrhea and tenesmus, as in distal UC. With small-bowel involvement, diarrhea is common. Late symptoms include malabsorption and weight loss. Stricturing with obstruction and bacterial overgrowth may occur. Fistulas can penetrate the bladder, vagina, or abdominal wall. Flexible sigmoidoscopy reveals mucosal granularity, friability, numerous telangiectasias, and occasionally discrete ulcerations. Biopsy can be diagnostic.

Solitary rectal ulcer syndrome is uncommon and can be confused with IBD. It occurs in persons of all ages and may be caused by impaired evacuation and failure of relaxation of the puborectalis muscle. Single or multiple ulcerations may arise from anal sphincter overactivity, higher intrarectal pressures during defecation, and digital removal of stool. Patients complain of constipation with straining and pass blood and mucus per rectum. Other symptoms include abdominal pain, diarrhea, tenesmus, and perineal pain. Ulceration, which may be as large as 5 cm in diameter, is usually observed anteriorly or anterolaterally 3–15 cm from the anal verge. Biopsies can be diagnostic.

Several types of colitis are associated with nonsteroidal anti-inflammatory drugs (NSAIDs), including de novo colitis, reactivation of IBD, and proctitis caused by use of suppositories. Most patients with NSAID-related colitis present with diarrhea and abdominal pain, and complications include stricture, bleeding, obstruction, perforation, and fistulization. Withdrawal of these agents is crucial, and in cases of reactivated IBD, standard therapies are indicated.

Colitis secondary to immune checkpoint inhibitors (ICIs), termed ICI-related colitis, has emerged as these agents have found use in a wide variety of cancers. Immune checkpoint proteins such as CTLA-4 and programmed cell death protein 1 (PD-1) are receptors expressed on the surface of effector T cells that interact with their ligands CD80/CD86 (CTLA-4) and programmed death ligand 1 (PD-L1) on antigen-presenting cells and normally function as inhibitors of immune responses. ICIs block these inhibitory pathways and promote the activation and proliferation of the native adaptive T-cell response against malignant cells as their mechanism of antitumor activity. While very effective at enhancing antitumor T-cell activity, ICIs also activate global T-cell responses that induce several autoimmune-related adverse events. Although immune-related adverse events of ICIs occur in multiple organ systems, the GI tract is affected in 21–44% of patients. The most common clinical presentation is self-limited diarrhea that can be associated with frank colitis and can lead to significant morbidity and mortality if not managed appropriately. Treatment is generally based on symptom severity. Moderate to severe symptoms usually require glucocorticoids, whereas biologics such as anti-TNF agents and integrin inhibitors are used in steroid-refractory cases.

THE ATYPICAL COLITIDES

Two atypical colitides—collagenous colitis and lymphocytic colitis—have normal endoscopic appearances. Collagenous colitis has two main histologic components: increased subepithelial collagen deposition and colitis with increased intraepithelial lymphocytes. The female-to-male ratio is 9:1, and most patients present in the sixth or seventh decade of life. The main symptom is chronic watery diarrhea. Risk factors include smoking; use of NSAIDs, proton pump inhibitors, or beta blockers; and a history of autoimmune disease.

Lymphocytic colitis has features similar to collagenous colitis, including age at onset and clinical presentation, but it has almost equal incidence in men and women and no subepithelial collagen deposition on pathologic section. However, intraepithelial lymphocytes are increased. Use of sertraline (but not beta blockers) is an additional risk factor. The frequency of celiac disease is increased in lymphocytic colitis and ranges from 9 to 27%. Celiac disease should be excluded in all patients with lymphocytic colitis, particularly if diarrhea does not respond to conventional therapy. Treatments for both microscopic colitides vary depending on symptom severity and include, antidiarrheals (e.g., loperamide and diphenoxylate), bismuth, aminosalicylates, budesonide, systemic glucocorticoids, and biologics for refractory disease.

Diversion colitis is an inflammatory process that arises in segments of the large intestine that are not continuous with the fecal stream. It usually occurs in patients with ileostomy or colostomy when a mucus fistula or a Hartmann's pouch has been created. Clinically, patients have mucus or bloody discharge from the rectum. Erythema, granularity, friability, and, in more severe cases, ulceration can be seen on endoscopy. Histopathology shows areas of active inflammation with foci of cryptitis and crypt abscesses. Crypt architecture is normal, which differentiates it from UC but not necessarily CD. Short-chain fatty acid enemas may help in diversion colitis, but the definitive therapy is surgical reanastomosis.

EXTRAINTESTINAL MANIFESTATIONS

Up to one-third of IBD patients have at least one extraintestinal disease manifestation. Please see **Table 337-7** for a summary of IBD EIMs.

DERMATOLOGIC

Erythema nodosum (EN) occurs in up to 15% of CD patients and 10% of UC patients. Attacks usually correlate with bowel activity; skin lesions develop after the onset of bowel symptoms, and patients frequently have concomitant active peripheral arthritis. The lesions of EN are hot, red, tender nodules measuring 1–5 cm in diameter and are found on the anterior surface of the lower legs, ankles, calves, thighs, and arms. Therapy is directed toward the underlying bowel disease.

Pyoderma gangrenosum (PG) is seen in 1–12% of UC patients and less commonly in Crohn's colitis. Although it usually presents after the diagnosis of IBD, PG may occur years before the onset of bowel symptoms, run a course independent of the bowel disease, respond poorly to colectomy, and even develop years after proctocolectomy. It is usually associated with severe disease. Lesions are commonly found on the dorsal surface of the feet and legs but may occur on the arms, chest, stoma, and even the face. PG usually begins as a pustule and then spreads concentrically to rapidly undermine healthy skin. Lesions then ulcerate, with violaceous edges surrounded by a margin of erythema. Centrally, they contain necrotic tissue with blood and exudates. Lesions may be single or multiple and grow as large as 30 cm. They are sometimes very difficult to treat and often require IV antibiotics, IV glucocorticoids, dapsone, azathioprine, thalidomide, IV cyclosporine (CSA), infliximab, or adalimumab.

TABLE 337-7 Extraintestinal Manifestations

CATEGORY	CLINICAL COURSE	TREATMENT
Rheumatologic Disorders (5–20%)		
Peripheral arthritis	Asymmetric, migratory Parallels bowel activity	Reduce bowel inflammation
Sacroiliitis	Symmetric: spine and hip joints Independent of bowel activity	Steroids, injections, methotrexate, anti-TNF
Ankylosing spondylitis	Gradual fusion of spine Independent of bowel activity Two-thirds have HLA-B27 antigen	Physical therapy, steroids, injections, methotrexate, anti-TNF, IL-17 inhibitors, JAK inhibitors
Metabolic Bone Disorders (up to 40% of patients)		
Osteoporosis	Risk increased by glucocorticoids, cyclosporine, methotrexate, total parenteral nutrition, malabsorption, and inflammation Fracture rates highest in the elderly (age >60)	Screening with DEXA scan, check vitamin D levels, treat if osteoporosis or osteopenia on long-term corticosteroids
Osteonecrosis	Death of osteocytes and adipocytes and eventual bone collapse; affects hips more than knees or shoulders; risk factor is steroid use	Pain control, injections, joint replacement
Dermatologic Disorders (10–20%)		
Erythema nodosum	Hot, red, tender, nodules/extremities Parallels bowel activity	Reduce bowel inflammation
Pyoderma gangrenosum	Ulcerating, necrotic lesions on extremities, trunk, face, stoma Independent of bowel activity	Antibiotics, steroids, cyclosporine, infliximab, dapsone, azathioprine, intralesional steroids; not debridement or colectomy
Psoriasis	Unrelated to bowel activity	Topical steroids, light therapy, methotrexate, infliximab, adalimumab, ustekinumab, risankizumab, JAK inhibitors
Pyoderma vegetans	Intertriginous areas Parallels bowel activity	Evanescent; resolves without progression
Pyostomatitis vegetans	Mucous membranes Parallels bowel activity	Evanescent; resolves without progression
Metastatic Crohn's disease (CD)	CD of the skin Parallels bowel activity	Reduce bowel inflammation
Sweet syndrome	Neutrophilic dermatosis Parallels bowel activity	Reduce bowel inflammation
Aphthous stomatitis	Oral ulcerations Parallels bowel activity	Reduce bowel inflammation/topical therapy
Ocular Disorders (1–11%)		
Uveitis	Ocular pain, photophobia, blurred vision, headache Independent of bowel activity	Topical or systemic steroids
Episcleritis	Mild ocular burning Parallels bowel activity	Topical corticosteroids
Hepatobiliary Disorders (10–35%)		
Fatty liver	Secondary to chronic illness, malnutrition, steroid therapy	Improve nutrition, reduce steroids
Cholelithiasis	Patients with ileitis or ileal resection Malabsorption of bile acids, depletion of bile salt pool, secretion of lithogenic bile	Reduce bowel inflammation; cholecystectomy in symptomatic patients
Primary sclerosing cholangitis (PSC)	Intrahepatic and extrahepatic Inflammation and fibrosis leading to biliary cirrhosis and hepatic failure 7–10% cholangiocarcinoma Small-duct PSC involves small-caliber bile ducts and has a better prognosis	Cholecystectomy in patients with gallbladder polyps due to the high incidence of malignancy
Urologic		
Nephrolithiasis (10–20%)	CD patients following small-bowel resection; calcium oxalate stones most common	Low-oxalate diet; control of bowel inflammation; surgical intervention
Less Common Extraintestinal Manifestations		
Thromboembolic disorders	Increased risk of venous and arterial thrombosis; factors responsible include abnormalities of the platelet-endothelial interaction, hyperhomocysteinemia, alterations in the coagulation cascade, impaired fibrinolysis, involvement of tissue factor–bearing microvesicles, disruption of the normal coagulation system by autoantibodies, and a genetic predisposition	Anticoagulation; control of inflammation
Cardiopulmonary	Endocarditis, myocarditis, pleuropericarditis, interstitial lung disease	Treatment is varied; stop 5-ASA agents as they can rarely cause interstitial lung disease
Systemic amyloidosis	Secondary (reactive) in long-standing IBD, especially CD	Colchicine and referral to specialty center
Pancreatitis	Duodenal fistulas, ampullary CD, gallstones, PSC, drugs (MP, azathioprine, 5-ASAs), autoimmune, primary CD of the pancreas	Treatment is varied; stop offending medication; diagnose and treat with ERCP and/or cholecystectomy

Abbreviations: 5-ASA, 5-aminosalicylic acid; DEXA, dual-energy x-ray absorptiometry; ERCP, endoscopic retrograde cholangiopancreatography; IBD, inflammatory bowel disease; IL, interleukin; MP, mercaptopurine; TNF, tumor necrosis factor.

Other dermatologic manifestations include pyoderma vegetans, which occurs in intertriginous areas; pyostomatitis vegetans, which involves the mucous membranes; Sweet syndrome, a neutrophilic dermatosis; and metastatic CD, a rare disorder defined by cutaneous granuloma formation. Psoriasis affects 5–10% of patients with IBD and is unrelated to bowel activity, consistent with the potential shared immunogenetic basis of these diseases. Perianal skin tags are found in 75–80% of patients with CD, especially those with colon involvement. Oral mucosal lesions, seen often in CD and rarely in UC, include aphthous stomatitis and "cobblestone" lesions of the buccal mucosa.

RHEUMATOLOGIC

Peripheral arthritis develops in 15–20% of IBD patients, is more common in CD, and worsens with exacerbations of bowel activity. It is asymmetric, polyarticular, and migratory and most often affects large joints of the upper and lower extremities. Treatment is directed at reducing bowel inflammation. In severe UC, colectomy frequently cures the arthritis.

Ankylosing spondylitis (AS) occurs in ~10% of IBD patients and is more common in CD than UC. About two-thirds of IBD patients with AS express the HLA-B27 antigen. The AS activity is not related to bowel activity and does not remit with glucocorticoids or colectomy. It most often affects the spine and pelvis, producing symptoms of diffuse low-back pain, buttock pain, and morning stiffness. The course is continuous and progressive, leading to permanent skeletal damage and deformity. Anti-TNF therapy reduces spinal inflammation and improves functional status and quality of life.

Sacroiliitis is symmetric, occurs equally in UC and CD, is often asymptomatic, does not correlate with bowel activity, and does not always progress to AS. Other rheumatic manifestations include hypertrophic osteoarthropathy, pelvic/femoral osteomyelitis, and relapsing polychondritis.

OCULAR

The incidence of ocular complications in IBD patients is 1–10%. The most common are conjunctivitis, anterior uveitis/iritis, and episcleritis. Uveitis is associated with both UC and Crohn's colitis, may be found during periods of remission, and may develop in patients following bowel resection. Symptoms include ocular pain, photophobia, blurred vision, and headache. Prompt intervention, sometimes with systemic glucocorticoids, is required to prevent scarring and visual impairment. Episcleritis is a benign disorder that presents with symptoms of mild ocular burning. It occurs in 3–4% of IBD patients, more commonly in Crohn's colitis, and is treated with topical glucocorticoids.

HEPATOBILIARY

Hepatic steatosis is detectable in about one-half of the abnormal liver biopsies from patients with CD and UC; patients usually present with hepatomegaly. Fatty liver usually results from a combination of chronic debilitating illness, malnutrition, and glucocorticoid therapy. Cholelithiasis occurs in 10–35% of CD patients with ileitis or ileal resection. Gallstone formation is caused by malabsorption of bile acids, resulting in depletion of the bile salt pool and the secretion of lithogenic bile.

Primary sclerosing cholangitis (PSC) is a disorder characterized by both intrahepatic and extrahepatic bile duct inflammation and fibrosis, frequently leading to biliary cirrhosis and hepatic failure; ~5% of patients with UC have PSC, but 50–75% of patients with PSC have IBD. PSC occurs less often in patients with CD. Although it can be recognized after the diagnosis of IBD, PSC can be detected earlier or even years after proctocolectomy. Consistent with this, the immunogenetic basis for PSC appears to be overlapping but distinct from UC based on GWAS, although both IBD and PSC are commonly pANCA positive. Most patients have no symptoms at the time of diagnosis; when symptoms are present, they consist of fatigue, jaundice, abdominal pain, fever, anorexia, and malaise. The traditional gold standard diagnostic test is endoscopic retrograde cholangiopancreatography (ERCP), but magnetic resonance cholangiopancreatography (MRCP) is sensitive, specific, and safer. MRCP is reasonable as an initial diagnostic test in children and adults and can visualize irregularities, multifocal strictures, and dilatations of all levels of the biliary tree. In patients with PSC, both ERCP and MRCP demonstrate multiple bile duct strictures alternating with relatively normal segments.

Gallbladder polyps in patients with PSC have a high incidence of malignancy, and cholecystectomy is recommended, even if a mass lesion is <1 cm in diameter. Gallbladder surveillance with ultrasound should be performed annually. Endoscopic stenting may be palliative for cholestasis secondary to bile duct obstruction. Patients with symptomatic disease develop cirrhosis and liver failure over 5–10 years and eventually require liver transplantation. PSC patients have a 10–15% lifetime risk of developing cholangiocarcinoma and then cannot be transplanted. Patients with IBD and PSC are at increased risk of colon cancer and should be surveyed yearly by colonoscopy and biopsy.

In addition, cholangiography is normal in a small percentage of patients who have a variant of PSC known as *small duct primary sclerosing cholangitis*. This variant (sometimes referred to as "pericholangitis") is probably a form of PSC involving small-caliber bile ducts. It has similar biochemical and histologic features to classic PSC. It has a significantly better prognosis than classic PSC, although it may evolve into classic PSC. Granulomatous hepatitis and hepatic amyloidosis are much rarer EIMs of IBD.

UROLOGIC

The most frequent genitourinary complications are calculi, ureteral obstruction, and ileal bladder fistulas. The highest frequency of nephrolithiasis (10–20%) occurs in patients with CD following small-bowel resection. Calcium oxalate stones develop secondary to hyperoxaluria, which results from increased absorption of dietary oxalate. Normally, dietary calcium combines with luminal oxalate to form insoluble calcium oxalate, which is eliminated in the stool. In patients with ileal dysfunction, however, nonabsorbed fatty acids bind calcium and leave oxalate unbound. The unbound oxalate is then delivered to the colon, where it is readily absorbed, especially in the presence of inflammation.

METABOLIC BONE DISORDERS

Low bone mass occurs in 14–42% of IBD patients. The risk is increased by glucocorticoids, CSA, methotrexate (MTX), and total parenteral nutrition (TPN). Malabsorption and inflammation mediated by IL-1, IL-6, TNF, and other inflammatory mediators also contribute to low bone density. An increased incidence of hip, spine, wrist, and rib fractures has been noted: 36% in CD and 45% in UC. The absolute risk of an osteoporotic fracture is ~1% per person per year. Fracture rates, particularly in the spine and hip, are highest among the elderly (age >60). One study noted an OR of 1.72 for vertebral fracture and an OR of 1.59 for hip fracture. The disease severity predicted the risk of a fracture. Only 13% of IBD patients who had a fracture were on any kind of antifracture treatment. Up to 20% of bone mass can be lost per year with chronic glucocorticoid use. The effect is dose-dependent. Budesonide may also suppress the pituitary-adrenal axis and thus carries a risk of causing osteoporosis.

Osteonecrosis is characterized by death of osteocytes and adipocytes and eventual bone collapse. The pain is aggravated by motion and swelling of the joints. It affects the hips more often than knees and shoulders, and in one series, 4.3% of patients developed osteonecrosis within 6 months of starting glucocorticoids. Diagnosis is made by bone scan or magnetic resonance imaging (MRI), and treatment consists of pain control, cord decompression, osteotomy, and joint replacement.

THROMBOEMBOLIC DISORDERS

Patients with IBD have an increased risk of both venous and arterial thrombosis even if the disease is not active. Factors responsible for the hypercoagulable state have included abnormalities of the platelet-endothelial interaction, hyperhomocysteinemia, alterations in the coagulation cascade, impaired fibrinolysis, involvement of tissue factor–bearing microvesicles, disruption of the normal coagulation system by autoantibodies, and a genetic predisposition. A spectrum of vasculitides involving small, medium, and large vessels has also been observed.

More common cardiopulmonary manifestations include endocarditis, myocarditis, pleuropericarditis, and interstitial lung disease. A secondary or reactive amyloidosis can occur in patients with long-standing IBD, especially in patients with CD. Amyloid material is deposited systemically and can cause diarrhea, constipation, and renal failure. The renal disease can be successfully treated with colchicine. Pancreatitis is a rare EIM of IBD and results from duodenal fistulas; ampullary CD; gallstones; PSC; drugs such as mercaptopurine, azathioprine, or, very rarely, 5-ASA agents; autoimmune pancreatitis; and primary CD of the pancreas.

TREATMENT

Inflammatory Bowel Disease

5-ASA AGENTS

These agents are effective at inducing and maintaining remission in UC. Peroxisome proliferator–activated receptor γ (PPAR-γ) may mediate 5-ASA therapeutic action by decreasing nuclear localization of NF-κB. Sulfa-free aminosalicylate formulations include alternative azo-bonded carriers, 5-ASA dimers, and delayed-release and controlled-release preparations. Each has the same efficacy as sulfasalazine when equimolar concentrations are used.

Sulfasalazine is effective treatment for mild to moderate UC, but its high rate of side effects limits its use. Although sulfasalazine is more effective at higher doses, at 6 or 8 g/d, up to 30% of patients experience allergic reactions or intolerable side effects such as headache, anorexia, nausea, and vomiting that are attributable to the sulfapyridine moiety that is attached to 5-ASA. Hypersensitivity reactions, independent of sulfapyridine levels, include rash, fever, hepatitis, agranulocytosis, hypersensitivity pneumonitis, pancreatitis, worsening of colitis, and reversible sperm abnormalities. Sulfasalazine can also impair folate absorption, and patients should be given folic acid supplements.

Balsalazide contains an azo bond binding mesalamine to the carrier molecule 4-aminobenzoyl-β-alanine; it is effective in the colon.

Delzicol and Asacol HD (high dose) are enteric-coated forms of mesalamine with the 5-ASA being released at pH >7. They disintegrate with complete breakup of the tablet occurring in many different parts of the gut ranging from the small intestine to the splenic flexure; they have increased gastric residence when taken with a meal. *Lialda* is a once-a-day formulation of mesalamine (Multi-Matrix System [MMX]) designed to release mesalamine in the colon. The MMX technology incorporates mesalamine into a lipophilic matrix within a hydrophilic matrix encapsulated in a polymer resistant to degradation at a low pH (<7) to delay release throughout the colon. The safety profile appears to be comparable to other 5-ASA formulations.

Apriso is a formulation containing encapsulated mesalamine granules that delivers mesalamine to the terminal ileum and colon via a proprietary extended-release mechanism (Intellicor). The outer coating of this agent (Eudragit L) dissolves at a pH >6. In addition, there is a polymer matrix core that aids in sustained release throughout the colon. Because Lialda and Apriso are given once daily, an anticipated benefit is improved compliance compared with two to four daily doses required for other mesalamine preparations.

Pentasa is another mesalamine formulation that uses an ethylcellulose coating to allow water absorption into small beads containing the mesalamine. Water dissolves the 5-ASA, which then diffuses out of the bead into the lumen. Disintegration of the capsule occurs in the stomach. The microspheres then disperse throughout the entire GI tract from the small intestine through the distal colon in both fasted and fed conditions.

Salofalk Granu-Stix, an unencapsulated version of mesalamine, has been in use in Europe for induction and maintenance of remission for several years.

Appropriate doses of the 5-ASA compounds are shown in **Table 337-8**. Some 50–75% of patients with mild to moderate UC improve when treated with 5-ASA doses equivalent to 2 g/d of mesalamine; the dose response continues up to at least 4.8 g/d.

More common side effects of the 5-ASA medications include headaches, nausea, hair loss, and abdominal pain. Rare side effects of the 5-ASA medications include renal impairment, hematuria, pancreatitis, and paradoxical worsening of colitis. Renal function tests and urinalysis should be checked yearly.

Topical *Rowasa* enemas are composed of mesalamine and are effective in mild-to-moderate distal UC. Combination therapy with mesalamine in both oral and enema form is more effective than either treatment alone for both distal and extensive UC.

Canasa suppositories composed of mesalamine are effective in treating proctitis.

GLUCOCORTICOIDS

The majority of patients with moderate to severe UC benefit from oral or parenteral glucocorticoids. Prednisone is usually started at doses of 40–60 mg/d for active UC that is unresponsive to 5-ASA therapy. Parenteral glucocorticoids may be administered as hydrocortisone, 300 mg/d, or methylprednisolone, 40–60 mg/d. A newer glucocorticoid for UC, budesonide (Uceris), is released entirely in the colon and has minimal to no glucocorticoid side effects. The dose is 9 mg/d for 8 weeks, and no taper is required. Topically applied glucocorticoids (hydrocortisone enemas or budesonide foam) are also beneficial for distal colitis and may serve as an adjunct in those who have rectal involvement plus more proximal

TABLE 337-8 Oral 5-Aminosalicylic Acid (5-ASA) Preparations

PREPARATION	FORMULATION	DELIVERY	DOSING PER DAY
Azo-Bond			
Sulfasalazine (500 mg) (Azulfidine)	Sulfapyridine-5-ASA	Colon	3–6 g (acute) 2–4 g (maintenance)
Balsalazide (750 mg) (Colazal)	Aminobenzoyl-alanine–5-ASA	Colon	6.75–9 g
Delayed-Release			
Mesalamine (400, 800 mg) (Delzicol, Asacol HD)	Eudragit S (pH 7)	Distal ileum-colon	2.4–4.8 g (acute) 1.6–4.8 g (maintenance)
Mesalamine (1.2 g) (Lialda)	MMX mesalamine (SPD476)	Ileum-colon	2.4–4.8 g
Controlled-Release			
Mesalamine (250, 500, 1000 mg) (Pentasa)	Ethylcellulose microgranules	Stomach-colon	2–4 g (acute) 1.5–4 g (maintenance)
Delayed- and Extended-Release			
Mesalamine (0.375 g) (Apriso)	Intellicor extended-release mechanism	Ileum-colon	1.5 g (maintenance)

Abbreviation: MMX, Multi-Matrix System.

disease. Hydrocortisone enemas are significantly absorbed from the rectum and can lead to adrenal suppression with prolonged administration. Topical 5-ASA therapy is more effective than topical steroid therapy in the treatment of distal UC.

Glucocorticoids are also effective for treatment of moderate to severe CD. Controlled-ileal-release budesonide has been nearly equal to prednisone for ileocolonic CD with fewer glucocorticoid side effects. Budesonide is used for 2–3 months at a dose of 9 mg/d and then tapered. Glucocorticoids play no role in maintenance therapy in either UC or CD. Once clinical remission has been induced, they should be tapered according to the clinical activity, normally at a rate of no more than 5–10 mg/week. The side effects are numerous, including fluid retention, abdominal striae, fat redistribution, hyperglycemia, subcapsular cataracts, osteonecrosis, osteoporosis, myopathy, emotional disturbances, and withdrawal symptoms. Most of these side effects, aside from osteonecrosis, are related to the dose and duration of therapy.

ANTIBIOTICS

Antibiotics have no role in the treatment of active or quiescent UC. However, pouchitis, which occurs in ~30–50% of UC patients after colectomy and ileal pouch anal anastomosis (IPAA), usually responds to treatment with a variety of antibiotics including metronidazole and ciprofloxacin. Some patients require long-term treatment with antibiotics for chronic pouchitis.

AZATHIOPRINE AND MERCAPTOPURINE

Azathioprine and mercaptopurine (MP) are purine analogues used concomitantly with biologic therapy or, much less often, as the sole immunosuppressants. Azathioprine is rapidly absorbed and converted to MP, which is then metabolized to the active end product, thioinosinic acid, an inhibitor of purine ribonucleotide synthesis and cell proliferation. Efficacy can be seen as early as 3–4 weeks but can take up to 4–6 months. Adherence can be monitored by measuring the levels of 6-thioguanine and 6-methylmercaptopurine, end products of MP metabolism. The doses used range from 2 to 3 mg/kg per day for azathioprine and 1 to 1.5 mg/kg per day for MP.

Although azathioprine and MP are usually safe, pancreatitis occurs in 3–4% of patients, typically presents within the first few weeks of therapy, and is completely reversible when the drug is stopped. Other side effects include nausea, fever, rash, and hepatitis. Bone marrow suppression (particularly leukopenia) is dose-related and often delayed, necessitating regular monitoring of the complete blood cell count (CBC). Additionally, 1 in 300 individuals lacks thiopurine methyltransferase, the enzyme responsible for drug metabolism to inactive end products (6-methylmercaptopurine); an additional 11% of the population are heterozygotes with intermediate enzyme activity. Both are at increased risk of toxicity because of increased accumulation of active 6-thioguanine metabolites. Although 6-thioguanine and 6-methylmercaptopurine levels can be followed to determine correct drug dosing and reduce toxicity, weight-based dosing is an acceptable alternative. CBCs and liver function tests should be monitored frequently regardless of dosing strategy.

One meta-analysis demonstrated a fourfold risk of lymphoma in IBD patients on azathioprine and MP. The highest risk for thiopurine-associated lymphoma is in patients >65 years old actively using thiopurines (yearly incidence rate per 1000 patient-years of 5.41), with a moderate risk in those between the ages of 50 and 65 (incidence rate of 2.58 compared to an incidence rate of 0.37 in patients <50 years old). Patients using thiopurines also have a two- to threefold increased risk of nonmelanoma skin cancers.

METHOTREXATE

MTX inhibits dihydrofolate reductase, resulting in impaired DNA synthesis. Additional anti-inflammatory properties may be related to decreases in the production of IL-1. It is used most often concomitantly with biologic therapy to decrease antibody formation and improve disease response. Intramuscular (IM) or subcutaneous (SC) doses range from 15 to 25 mg/week. Potential toxicities include leukopenia and hepatic fibrosis, necessitating periodic evaluation of CBCs and liver enzymes. The role of liver biopsy in patients on long-term MTX is uncertain but is probably limited to those with increased liver enzymes. Hypersensitivity pneumonitis is a rare but serious complication of therapy.

CYCLOSPORINE

CSA is a lipophilic peptide with inhibitory effects on both the cellular and humoral immune systems. CSA blocks the production of IL-2 by T helper lymphocytes. CSA binds to cyclophilin, and this complex inhibits calcineurin, a cytoplasmic phosphatase enzyme involved in the activation of T cells. CSA also indirectly inhibits B-cell function by blocking helper T cells. CSA has a more rapid onset of action than MP and azathioprine.

CSA is most effective when given at 2–4 mg/kg per day IV in severe UC that is refractory to IV glucocorticoids, with 82% of patients responding. CSA can be an alternative to infliximab for steroid-refractory UC before colectomy. Levels as measured by monoclonal radioimmunoassay or by the high-performance liquid chromatography assay should be maintained between 150 and 350 ng/mL.

CSA may cause significant toxicity; renal function should be monitored frequently. Hypertension, gingival hyperplasia, hypertrichosis, paresthesias, tremors, headaches, and electrolyte abnormalities are common side effects. Creatinine elevation calls for dose reduction or discontinuation. Seizures may also complicate therapy, especially if the patient is hypomagnesemic or if serum cholesterol levels are <3.1 mmol/L (<120 mg/dL). Opportunistic infections, most notably *Pneumocystis jirovecii* pneumonia, may occur with combination immunosuppressive treatment; antibiotic prophylaxis with trimethoprim-sulfamethoxazole should be given.

TACROLIMUS

Tacrolimus is a macrolide antibiotic with immunomodulatory properties similar to CSA but 100 times as potent and not dependent on bile or mucosal integrity for absorption. Thus, tacrolimus has good oral absorption despite proximal small-bowel Crohn's involvement. Tacrolimus is effective in children with refractory IBD and in adults with extensive involvement of the small bowel. Tacrolimus use is decreasing due to side effects and the expanding choice of biologic and small-molecule therapies.

BIOLOGIC THERAPIES

Biologic therapy is now commonly given as an initial therapy for patients with moderate to severe CD and UC to prevent future complications of IBD. High-risk patients with UC who are more likely to require biologics include those with moderate to severe disease, steroid-dependent or steroid-refractory disease, and refractory pouchitis. High-risk patients with CD who are more likely to require biologics include those who are <30 years old, with extensive disease, perianal or severe rectal disease and/or deep ulcerations in the colon, and stricturing or penetrating disease behavior. The current goal of IBD treatment with biologics is to treat early in the disease course, treat aggressively with appropriate therapies, check drug and drug metabolite levels, administer dual therapy with immunomodulators and biologics in appropriate patients, and aim for deep remission (endoscopic and histologic remission). Patients who respond to biologic therapies enjoy an improvement in clinical symptoms; a better quality of life; less disability, fatigue, and depression; and fewer surgeries and hospitalizations.

Anti-TNF Therapies TNF is a proinflammatory cytokine that regulates immune cells to coordinate a systemic immune response. Dysregulation of TNF production has been associated with immune-mediated disorders including IBD, and inhibition of TNF signaling is used in the treatment of IBD. Four TNF inhibitors are currently approved for the treatment of IBD: infliximab, adalimumab, certolizumab pegol, and golimumab. Infliximab, a chimeric IgG1 antibody against TNF-α, was the first biologic therapy approved for moderately to severely active inflammatory and fistulizing CD and UC.

Randomized trials support combination therapy with infliximab and azathioprine for moderate to severe CD and UC. For moderate to severe CD, combination therapy has been shown to be more effective than either infliximab or azathioprine alone. Similarly, combination therapy has been shown to be more effective for moderate to severe UC than either infliximab or azathioprine alone.

Hospitalized patients with acute severe glucocorticoid-refractory UC have a high inflammatory burden and may develop a protein-losing enteropathy, leading to an accelerated consumption, excessive fecal wasting, and low serum concentrations of infliximab. Given a clear exposure–response relationship for infliximab in patients with IBD, intensive infliximab dosing regimens have been used in these patients.

Adalimumab (ADA) is a recombinant human monoclonal IgG1 antibody containing only human peptide sequences and is injected subcutaneously. ADA binds TNF and neutralizes its function by blocking the interaction between TNF and its cell-surface receptor. Therefore, it seems to have a similar mechanism of action to infliximab but with less immunogenicity. ADA is approved for treatment of moderate to severe CD and UC. For CD and UC, results with ADA are better in patients who are naïve to anti-TNF than in patients who have previously been treated with infliximab. In clinical practice, the remission rate in both CD and UC patients taking ADA increases with a dose increase to 40 mg weekly instead of every other week.

Certolizumab pegol is a pegylated form of an anti-TNF Fab portion of an antibody administered SC once monthly. SC certolizumab pegol is effective for induction of clinical response in patients with active inflammatory CD.

Golimumab is another fully human IgG1 antibody against TNF-α and is currently approved for the treatment of moderately to severely active UC. Like ADA and certolizumab, golimumab is injected SC.

Side Effects of Anti-TNF Therapies

Development of Antibodies and Drug Levels The development of antibodies to infliximab is associated with an increased risk of infusion reactions and a decreased response to treatment. Current practice does not include giving on-demand or episodic infusions in contrast to scheduled periodic infusions because patients are most likely to develop antibodies. Anti-infliximab antibodies are generally present when the quality of response or the response duration to infliximab infusion decreases. Commercial assays can detect both infliximab and ADA antibodies and measure trough levels to determine optimal dosing. If a patient has high anti-infliximab antibodies and a low trough level of infliximab, it is best to switch to another anti-TNF therapy. If a patient has a therapeutic anti-TNF level and active inflammatory symptoms, the drug should be switched to a different class of biologic. Most acute infusion reactions and serum sickness can be managed with glucocorticoids and antihistamines. Some reactions can be serious and would necessitate a change in therapy, especially if a patient has anti-infliximab antibodies. It is now common practice to add an immunomodulator such as azathioprine, MP, or MTX to anti-TNF therapy to help prevent antibody formation.

Non-Hodgkin's Lymphoma (NHL) The baseline risk of NHL in CD patients is 2 in 10,000, slightly higher than in the general population. Azathioprine and/or MP therapy increases the risk to ~4 in 10,000. It is difficult to assess whether anti-TNF medications are associated with lymphoma because many patients are also receiving thiopurines. After adjustment for co-treatments, no excess risk of lymphoma was found in a Danish study of a cohort of IBD patients exposed to anti-TNF medications.

Hepatosplenic T-Cell Lymphoma (HSTCL) HSTCL is a nearly universally fatal lymphoma in patients with or without CD. In patients with CD, a total of 37 unique cases have been reported. Eighty-six percent of the patients were male, and the median age was 26 years. Patients had CD for a mean of 10 years before the diagnosis of HSTCL. Thirty-six patients had used either MP or azathioprine, and 28 patients had used infliximab.

Skin Lesions New-onset psoriasiform skin lesions develop in nearly 5% of IBD patients treated with anti-TNF therapy. Most often, these can be treated topically, and occasionally, anti-TNF therapy must be decreased, switched, or stopped. Patients with IBD may have a slight, unexplained, intrinsic higher risk of developing melanoma. The risk of melanoma is increased almost twofold with anti-TNF and not thiopurine use. The risk of nonmelanoma skin cancer is increased with thiopurines and biologics, especially with ≥1 year of follow-up. Patients on these medications should have a skin check at least once a year.

Infections All of the anti-TNF drugs are associated with an increased risk of infections, particularly reactivation of latent tuberculosis and opportunistic fungal infections including disseminated histoplasmosis and coccidioidomycosis. Patients should have a purified protein derivative (PPD) or a QuantiFERON-TB Gold test before initiation of anti-TNF therapy. Patients >65 years old have a higher rate of infections and death on infliximab or ADA than those <65 years old.

Other Acute liver injury due to reactivation of hepatitis B virus and to autoimmune effects and cholestasis has been reported. Rarely, infliximab and the other anti-TNF drugs have been associated with optic neuritis, seizures, new onset or exacerbation of clinical symptoms, and radiographic evidence of central nervous system demyelinating disorders, including multiple sclerosis. They may exacerbate symptoms in patients with New York Heart Association functional class III/IV heart failure.

ANTI-INTEGRINS

Integrins are expressed on the cell surface of leukocytes and serve as mediators of leukocyte adhesion to vascular endothelium and entry into the intestines. α4-Integrin along with its β1 or β7 subunit interact with endothelial ligands termed adhesion molecules. Interaction between α4β7 and mucosal addressin cellular adhesion molecule (MAdCAM-1) is important in lymphocyte trafficking to gut mucosa.

Natalizumab is a recombinant humanized IgG4 antibody against α4-integrin and is effective in induction and maintenance of patients with CD. However, natalizumab is no longer used for CD due to the risk of progressive multifocal leukoencephalopathy (PML) and the development of alternative biologic and small-molecule therapies.

Vedolizumab (VDZ), another leukocyte trafficking inhibitor, is a monoclonal antibody directed against α4β7-integrin specifically and has the ability to convey gut-selective immunosuppression. Unlike natalizumab, it inhibits adhesion of a discrete gut-homing subset of T lymphocytes to MAdCAM-1, but not to vascular adhesion molecule 1. VDZ decreases GI inflammation without inhibiting systemic immune responses or affecting T-cell trafficking to the central nervous system. It may be prescribed as a first-line biologic or after failure of a TNF antagonist in patients with CD or UC. Vedolizumab is more effective than adalimumab for first-line biologic therapy in moderate to severe UC.

Ustekinumab, a fully human IgG1 monoclonal antibody, blocks the biologic activity of IL-12 and IL-23 through their common p40 subunit by inhibiting the interaction of these cytokines with their receptors on T cells, natural killer cells, and antigen-presenting cells. It is as equally effective as adalimumab for first-line biologic therapy for moderate to severe CD and is another option for treatment of moderate to severe UC. It is particularly appealing for use in patients with concomitant psoriatic arthritis.

Risankizumab is a monoclonal antibody that selectively binds to the IL-23 p19 subunit, inhibiting its interaction with the IL-23R complex It is the first selective IL-23 inhibitor approved for moderate to severe CD and provides an additional therapeutic option for patients, particularly those who have been previously treated with other advanced IBD therapies.

SMALL MOLECULES

Small molecules (drugs with molecular weight <1 kDa) are a new class of orally administered medications developed for IBD that lack the immunogenicity associated with monoclonal antibodies. The

advantage of small molecules is their ability to diffuse through cell membranes into the intracellular space and inhibit cytokine signaling pathways. This mechanism of action may be more efficacious compared to monoclonal antibodies that inhibit specific targets because several cytokine pathways are involved in IBD pathogenesis and inhibiting numerous cytokines may be synergistic. A key regulatory pathway of many cytokines associated with IBD is the JAK/STAT pathway that activates transcription and translation of proteins that mediate the immune response. Janus kinase (JAK) is a family of intracellular, nonreceptor tyrosine kinases that regulate cytokine signaling via the JAK/STAT pathway, ultimately suppressing the immune response and inflammation. The JAK family members include JAK1, JAK2, JAK3, and tyrosine kinase 2 (TYK2).

Tofacitinib is a reversible and competitive JAK inhibitor used for the treatment of moderate to severe UC refractory to conventional therapy. It competes with ATP to bind to the ATP-docking site of the kinase domain of JAK. By competing with ATP, tofacitinib inhibits phosphorylation and activation of JAK, leading to downstream reduction of cytokine production and alteration of the immune response. Although tofacitinib is a pan-JAK inhibitor, it has higher specificity for JAK1 and JAK3 than for JAK2 and TYK2. The pan-JAK inhibition is concerning for adverse events and overall safety.

Upadacitinib is an oral, selective, and reversible JAK inhibitor that is approved for both UC and CD. It potently inhibits JAK1 and is less potent against the other isoforms, JAK2, JAK3, and TYK2. Upadacitinib demonstrates rapid clinical and endoscopic improvement at the end of induction, which is sustained to the end of maintenance, with a positive benefit/risk profile.

The FDA review concluded that there is an increased risk of serious adverse events including heart attack, stroke, cancer, blood clots, and death in patients who are prescribed JAK inhibitors. Patients who are at risk for cardiovascular disease, have a history of blood clots, are current or past smokers, and/or are over the age of 50 should consider alternative therapies. The risk of herpes zoster is higher with JAK inhibitors, and patients should receive the shingles vaccine (Shingrix). Tofacitinib and upadacitinib are FDA approved for use as second-line agents after failure of anti-TNF therapy.

Ozanimod is a potent sphingosine-1-phosphate (S1P1) receptor modulator that binds selectively with high affinity to the S1P receptor subtypes S1P1 and S1P5, both of which are involved in immune regulation. By preventing trafficking of disease-exacerbating lymphocytes from the lymph nodes to the gut, ozanimod may provide immunomodulatory effects and moderate disease processes.

Ozanimod is approved for the treatment of moderate to severe ulcerative colitis. It is administered as a daily capsule.

The biologic and small-molecule therapies used in daily practice are detailed in **Table 337-9**.

NUTRITIONAL THERAPIES

Diet has long been thought to contribute to the pathogenesis of IBD and may also be an avenue for managing disease activity. Diet plays a significant role in shaping the gut microbiome, and dietary components may interact with the microbiome and stimulate a mucosal immune response. In fact, active CD responds to exclusive enteral nutrition (EEN) or bowel rest with TPN, interventions as effective as glucocorticoids in inducing remission but not as effective for maintenance therapy. In contrast to CD, active UC is not effectively treated by elemental diets or TPN.

Dietary approaches to maintenance therapy in CD have largely been adapted from epidemiologic studies; however, significant heterogeneity is noted among research study outcomes. In general, low fiber, refined carbohydrates (especially sweetened beverages), animal fats, red meat, and processed meat have been associated with onset of IBD. Therefore, the overall dietary approach is to maximize fiber intake, particularly from fruits and vegetables, and to limit consumption of higher-risk foods. Several defined diets adhere to these principles with some variation, including the Mediterranean diet pattern, specific carbohydrate diet, semi-vegetarian diet, and IBD anti-inflammatory diet (IBD-AID). However, it remains unclear whether diet studies will eventually lead to evidence-based nutrition guidelines.

Standard medical management of UC and CD is shown in **Fig. 337-12**.

SURGICAL THERAPY

Ulcerative Colitis Nearly one-half of patients with extensive chronic UC undergo surgery within the first 10 years of their illness. The indications for surgery are listed in **Table 337-10**. Morbidity is ~20% for elective, 30% for urgent, and 40% for emergency proctocolectomy. The risks are primarily hemorrhage, contamination and sepsis, and neural injury. The operation of choice is an IPAA.

Because UC is a mucosal disease, the rectal mucosa can be dissected and removed down to the dentate line of the anus or ~2 cm proximal to this landmark. The ileum is fashioned into a pouch that serves as a neorectum. This ileal pouch is then sutured circumferentially to the anus in an end-to-end fashion. If performed carefully, this operation preserves the anal sphincter and maintains continence. The overall operative morbidity is 10%, with the major complication being bowel obstruction. Pouch failure necessitating conversion to permanent ileostomy occurs in 5–10% of patients. Some inflamed rectal mucosa is usually left behind, and thus, endoscopic surveillance is necessary. Primary dysplasia of the ileal mucosa of the pouch has occurred rarely.

Patients with IPAA usually have ~6–10 bowel movements a day. On validated quality-of-life indices, they report better performance in sports and sexual activities than ileostomy patients. The most frequent complication of IPAA is pouchitis in ~30–50% of patients with UC. This syndrome consists of increased stool frequency, watery stools, cramping, urgency, nocturnal leakage of stool, arthralgias, malaise, and fever. Pouch biopsies may distinguish true pouchitis from underlying CD. Although pouchitis usually responds to antibiotics, 3–5% of patients remain refractory and may require chronic antibiotic therapy, biologics, or even pouch removal.

Crohn's Disease The majority of patients with CD will require at least one operation in their lifetime. The need for surgery is related to duration of disease and the site of involvement. Patients with small-bowel disease have an 80% chance of requiring surgery. Those with colitis alone have a 50% chance. Surgery is an option only when medical treatment has failed or complications dictate its necessity. The indications for surgery are shown in Table 337-10.

Small-Intestinal Disease Because CD is chronic and recurrent, with no clear surgical cure, as little intestine as possible is resected. Current surgical alternatives for treatment of obstructing CD include resection of the diseased segment and strictureplasty. Surgical resection of the diseased segment is the most frequently performed operation, and in most cases, primary anastomosis can be done to restore continuity. An end-to-end anastomosis may provide the best opportunity for an optimal functional outcome, compared to an antiperistaltic side-to-side anastomosis, which creates a functional block to motility leading to distention and pain at the anastomotic site in a subgroup of patients. If much of the small bowel has already been resected and the strictures are short, with intervening areas of normal mucosa, strictureplasties should be done to avoid a functionally insufficient length of bowel. The strictured area of intestine is incised longitudinally and the incision sutured transversely, thus widening the narrowed area. Complications of strictureplasty include prolonged ileus, hemorrhage, fistula, abscess, leak, and restricture.

Risk factors for early recurrence of disease include cigarette smoking, penetrating disease (internal fistulas, abscesses, or other evidence of penetration through the wall of the bowel), early recurrence since a previous surgery, multiple surgeries, and a young age at the time of the first surgery. Aggressive postoperative treatment with biologics should be considered for this group of patients. It is also recommended to evaluate for endoscopic recurrence of CD via a colonoscopy, if possible, 3–6 months after surgery.

TABLE 337-9 Biologic and Small-Molecule Agents in the Treatment of Inflammatory Bowel Disease

MEDICATION	DOSAGE	INDICATION	SERIOUS TOXICITIES	OTHER COMMON SIDE EFFECTS	TESTING
Infliximab	5 mg/kg at 0, 2, and 6 weeks, then every 8 weeks; may increase dose to 10 mg/kg every 4 weeks depending on trough levels Intensive dosing for hospitalized corticosteroid-refractory patients	Moderate to severe Crohn's disease and ulcerative colitis Fistulizing Crohn's disease	Increased risk of infections (bacterial and fungal), tuberculosis (TB) reactivation, hepatitis B reactivation, lymphoma (controversial), psoriasis, melanoma and nonmelanoma skin cancers, drug-induced lupus Contraindicated in multiple sclerosis, class III/IV congestive heart failure	Infusion reactions	Prior to infusion: TB testing Hepatitis B testing (HBsAb, HBsAg, HBcAb) Maintenance: Skin check yearly Influenza, pneumococcal vaccinations Hepatitis B vaccine if not immune
Adalimumab	160 mg day 0, 80 mg day 14 and then 40 mg every 14 days; may increase to 40 mg every 7 days depending on trough levels	Moderate to severe Crohn's disease and ulcerative colitis Fistulizing Crohn's disease	As above	Injection site reactions (better with citrate-free preparation)	As above
Certolizumab	400 mg on days 0 and 14, then 400 mg every 28 days	Moderate to severe Crohn's disease	As above	As above	As above
Golimumab	200 mg on day 0, 100 mg on day 14, then 100 mg every 28 days	Moderate to severe ulcerative colitis	As above	As above	As above
Vedolizumab	300 mg at 0, 2, and 6 weeks, then every 8 weeks; may increase dose to 300 mg every 4 weeks	Moderate to severe ulcerative colitis (more effective than adalimumab as first-line therapy in one study) Moderate to severe Crohn's disease.	No increased risk of serious systemic or opportunistic infections No increased risk of malignancy	Nasopharyngitis, headache, arthralgias, nausea	Prior to infusion: TB testing Hepatitis B testing (HBsAb, HBsAg, HBcAb) Maintenance: Influenza, pneumococcal vaccinations Hepatitis B vaccine if not immune
Ustekinumab	6 mg/kg IV, then 90 mg every 8 weeks; may increase dose to 90 mg every 4 weeks	Moderate to severe Crohn's disease and ulcerative colitis	Reversible posterior leukoencephalopathy syndrome (presents with headaches, seizures, confusion, and visual disturbances), anaphylaxis, and angioedema	Nasopharyngitis, upper respiratory tract infection, fatigue, headache	Prior to infusion: TB testing Hepatitis B testing (HBsAb, HBsAg, HBcAb) Maintenance: Influenza, pneumococcal vaccinations Hepatitis B vaccine if not immune
Risankizumab	600 mg IV every 4 weeks × 3 doses then 180 mg or 360 mg SC every 8 weeks	Moderate to severe Crohn's disease	Reversible posterior leukoencephalopathy syndrome (presents with headaches, seizures, confusion, and visual disturbances), anaphylaxis, and angioedema	Nasopharyngitis, upper respiratory tract infection, fatigue, headache	TB testing Hepatitis B testing (HBsAb, HBsAg, HBcAb) Maintenance: Influenza, pneumococcal vaccinations Hepatitis B vaccine if not immune
Tofacitinib	10 mg bid; can decrease to 5 mg bid when patient in remission	Moderate to severe ulcerative colitis	Increased risk of heart attack, stroke, cancer, blood clots, and death. Patients who are at risk for cardiovascular disease, are current or past smokers, and/or are over the age of 50 should consider alternative therapies. Increased risk of viral infections, including herpes zoster, and bacterial and invasive fungal infections	Elevated lipids, neutropenia, anemia, elevated liver enzymes	Prior to infusion: First dose of Shingrix recommended, TB testing Hepatitis B testing (HBsAb, HBsAg, HBcAb) Maintenance: Influenza, pneumococcal vaccinations Hepatitis B vaccine if not immune
Upadacitinib	45 mg PO qd × 8 weeks for ulcerative colitis; 45 mg PO qd × 12 weeks for Crohn's disease, then 15 or 30 mg qd	Moderate to severe ulcerative colitis or Crohn's disease	Increased risk of heart attack, stroke, cancer, blood clots, and death. Patients who are at risk for cardiovascular disease, are current or past smokers, and/or are over the age of 50 should consider alternative therapies. Increased risk of viral infections, including herpes zoster, and bacterial and invasive fungal infections	Elevated lipids, neutropenia, anemia, elevated liver enzymes	Prior to infusion: First dose of Shingrix recommended, TB testing Hepatitis B testing (HBsAb, HBsAg, HBcAb) Maintenance: Influenza, pneumococcal vaccinations Hepatitis B vaccine if not immune
Ozanimod	0.23 mg PO days 1–4, 0.46 mg PO days 5–7, 0.92 mg PO thereafter	Moderate to severe UC	Bradycardia, atrioventricular conduction delay, increased blood pressure, macular edema, posterior reversible encephalopathy syndrome	Infections, elevated liver enzymes	Prior to infusion: First dose of Shingrix recommended, TB testing Hepatitis B testing (HBsAb, HBsAg, HBcAb) Maintenance: Influenza, pneumococcal vaccinations Hepatitis B vaccine if not immune

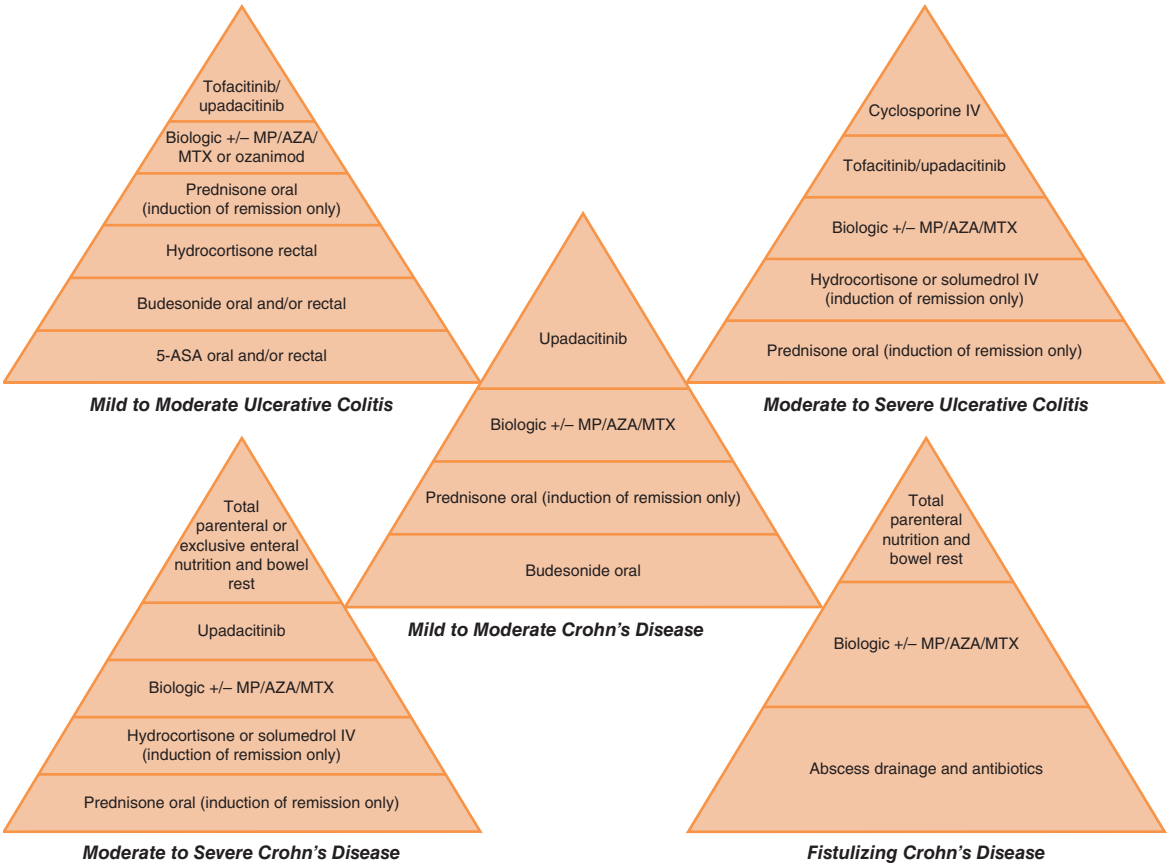

FIGURE 337-12 Medical management of inflammatory bowel disease. 5-ASA, 5-aminosalicylic acid; AZA, azathioprine; MP, mercaptopurine; MTX, methotrexate.

Colorectal Disease A greater percentage of patients with Crohn's colitis require surgery for intractability, fulminant disease, and anorectal disease. Several alternatives are available, ranging from the use of a temporary loop ileostomy to resection of segments of diseased colon or even the entire colon and rectum. For patients with segmental involvement, segmental colon resection with primary anastomosis can be performed. In 20–25% of patients with extensive colitis, the rectum is spared sufficiently to consider rectal preservation. Most surgeons believe that an IPAA is contraindicated in CD due to the high incidence of pouch failure. A diverting colostomy may help heal severe perianal disease or rectovaginal fistulas, but disease almost always recurs with reanastomosis. These patients often require a total proctocolectomy and ileostomy.

TABLE 337-10 Indications for Surgery

ULCERATIVE COLITIS	CROHN'S DISEASE
Intractable disease	Small Intestine
Fulminant disease	Stricture and obstruction
Toxic megacolon	unresponsive to medical therapy
Colonic perforation	Massive hemorrhage
Massive colonic hemorrhage	Refractory fistula
Extracolonic disease	Abscess
Colonic obstruction	Colon and rectum
Colon cancer prophylaxis	Intractable disease
Colon dysplasia or cancer	Fulminant disease
	Perianal disease unresponsive to medical therapy
	Refractory fistula
	Colonic obstruction
	Cancer prophylaxis
	Colon dysplasia or cancer

IBD AND PREGNANCY

Patients with quiescent UC and CD have normal fertility rates; the fallopian tubes can be scarred by the inflammatory process of CD, especially on the right side because of the proximity of the terminal ileum. In addition, perirectal, perineal, and rectovaginal abscesses and fistulas as well as pelvic surgery can result in dyspareunia. Infertility in men can be caused by sulfasalazine but reverses when treatment is stopped. Women with an IPAA have decreased fertility due to scarring or occlusion of the fallopian tubes secondary to pelvic inflammation and adhesions, although studies have shown that fertility is improved with laparoscopic versus open IPAA.

Mild or quiescent UC or CD has no effect on birth outcomes. The courses of CD and UC during pregnancy mostly correlate with disease activity at the time of conception. Patients should be in remission for 3–6 months before conceiving. Most CD patients can deliver vaginally, but cesarean delivery may be the preferred route of delivery for patients with anorectal and perirectal abscesses and fistulas to reduce the likelihood of fistulas developing or extending into the episiotomy scar. Unless they desire multiple children, UC patients with an IPAA may consider a cesarean delivery due to an increased risk of future fecal incontinence.

Sulfasalazine and all mesalamines are safe for use in pregnancy and nursing with the caveat that additional folate supplementation must be given with sulfasalazine. Topical 5-ASA agents are safe during pregnancy and nursing. Glucocorticoids are generally safe for use during pregnancy and are indicated for patients with moderate to severe disease activity. The amount of glucocorticoids received by the nursing infant is minimal. The safest antibiotics to use for CD in pregnancy for short periods of time (weeks, not months) are ampicillin and cephalosporins. Metronidazole can be used in the second or third trimester. Ciprofloxacin causes cartilage lesions in immature animals and should be avoided because of the absence of data on its effects on growth and development in humans.

MP and azathioprine pose minimal or no risk during pregnancy. Breast milk has been shown to contain negligible levels of MP/azathioprine when measured in a limited number of patients.

MTX is teratogenic and should be discontinued at least 3 months before conception.

In a large prospective and multiple retrospective studies, no increased risk of stillbirths, miscarriages, or spontaneous abortions was seen with infliximab, ADA, certolizumab, vedolizumab, or ustekinumab. These biologics, with the exception of certolizumab, are IgG1 antibodies and are actively transported across the placenta in the late second and third trimesters. Infants can have serum levels of infliximab, ADA, vedolizumab, and ustekinumab well into the first year of life, and live vaccines should be avoided until 12 months of age. Certolizumab crosses the placenta by passive diffusion, and infant serum and cord blood levels are minimal. The biologics are safe in nursing. Miniscule levels of infliximab, ADA, certolizumab, vedolizumab, and ustekinumab have been reported in breast milk. These levels are of no clinical significance. It is recommended that drugs should not be switched during pregnancy unless necessitated by the medical condition of the IBD. Tofacitinib and upadacitinib should not be used during pregnancy. Animal studies show teratogenic effects with both of these drugs, and data in humans are limited. A washout period of at least 4 weeks is recommended before conception. Surgery in UC should be performed only for emergency indications, including severe hemorrhage, perforation, and megacolon refractory to medical therapy. Total colectomy and ileostomy carry a 50% risk of postoperative spontaneous abortion. The best time to perform surgery is in the second trimester if necessary. Patients with IPAAs have increased nighttime stool frequency during pregnancy that resolves postpartum. Transient small-bowel obstruction or ileus has been noted in up to 8% of patients with ileostomies.

CANCER IN IBD

ULCERATIVE COLITIS

Patients with long-standing UC are at increased risk for developing colonic epithelial dysplasia and carcinoma **(Fig. 337-13)**.

The risk of neoplasia in chronic UC increases with duration and extent of disease. In contrast to the relatively high risk in one large meta-analysis (2% after 10 years, 8% after 20 years, and 18% after 30 years of disease), a decrease in the risk of colorectal cancer has been noted over time potentially due to better control of inflammation and better colonoscopic surveillance. The rates of colon cancer are still about 1.5–2 times higher than in the general population, and colonoscopic surveillance is the standard of care.

Annual or biennial colonoscopy with multiple biopsies is recommended for patients with >8–10 years of extensive colitis (greater than one-third of the colon involved) or 12–15 years of proctosigmoiditis (less than one-third but more than just the rectum) and has been widely used to screen and survey for subsequent dysplasia and carcinoma. International guideline societies have recommended chromoendoscopy for dysplasia surveillance in IBD. Chromoendoscopy enhances the visualization of the surface and pit pattern of the mucosa, as well as borders of lesions, in order to better define areas of dysplasia compared to standard-definition white light endoscopy. In real-life settings, the practice has been to use standard-definition white light endoscopy with surveillance biopsies in patients with chronic colitis at average risk and chromoendoscopy in higher-risk patients including those with a history of dysplasia, PSC, or family history of colorectal cancer.

Risk factors for cancer in UC include long-duration disease, extensive disease, family history of colon cancer, PSC, a colon stricture, and the presence of postinflammatory pseudopolyps on colonoscopy.

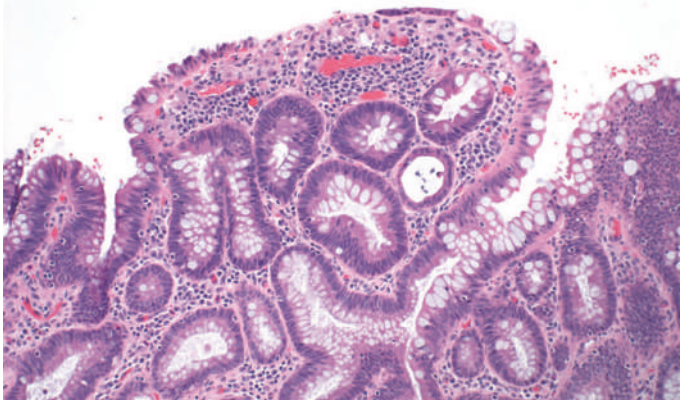

FIGURE 337-13 Medium-power view of low-grade dysplasia in a patient with chronic ulcerative colitis. Low-grade dysplastic crypts are interspersed among regenerating crypts. (*Courtesy of Dr. R. Odze, Division of Gastrointestinal Pathology, Department of Pathology, Brigham and Women's Hospital, Boston, Massachusetts; with permission.*)

CROHN'S DISEASE

Risk factors for developing cancer in Crohn's colitis are long-duration and extensive disease, bypassed colon segments, colon strictures, PSC, and family history of colon cancer. The cancer risks in CD and UC are probably equivalent for similar extent and duration of disease. In the CESAME study, a prospective observational cohort of IBD patients in France, the standardized incidence ratios of colorectal cancer were 2.2 for all IBD patients (95% CI, 1.5–3.0; $p < .001$) and 7.0 for patients with long-standing extensive colitis (both Crohn's and UC) (95% CI, 4.4–10.5; $p < .001$). Thus, the same endoscopic surveillance strategy used for UC is recommended for patients with chronic Crohn's colitis. A pediatric colonoscope can be used to pass narrow strictures in CD patients, but surgery should be considered in symptomatic patients with impassable strictures.

MANAGEMENT OF DYSPLASIA AND CANCER

Dysplasia can be flat or polypoid. If flat high-grade dysplasia is encountered on colonoscopic surveillance, the usual treatment is colectomy for UC and either colectomy or segmental resection for CD. If flat low-grade dysplasia is found (Fig. 337-13), most investigators recommend immediate colectomy. Adenomas may occur coincidently in UC and CD patients with chronic colitis and can be removed endoscopically provided that biopsies of the surrounding mucosa are free of dysplasia.

IBD patients are also at greater risk for other malignancies. Patients with CD may have an increased risk of NHL, leukemia, and myelodysplastic syndromes. Severe, chronic, complicated perianal disease in CD patients may be associated with an increased risk of cancer in the lower rectum and anal canal (squamous cell cancers). Although the absolute risk of small-bowel adenocarcinoma in CD is low (2.2% at 25 years in one study), patients with long-standing, extensive, small-bowel disease should be considered for screening.

COVID-19 AND IBD

COVID-19, caused by SARS-CoV-2, was first reported in December 2019 and has rapidly spread throughout the world, leading to an international pandemic. Glucocorticoids, immunomodulators (thiopurines, MTX), biologics, and JAK inhibitors, commonly used to treat IBD, are associated with higher rates of serious viral and bacterial infections, and patients with IBD using these medications are potentially at increased risk of a serious COVID-19 infection. Yet, it is also possible that some forms of immune suppression may blunt the excessive immune response/cytokine storm characteristic of severe COVID-19 infection and consequently reduce mortality. Using data from the Surveillance Epidemiology of Coronavirus Under Research Exclusion for Inflammatory Bowel Disease, it was found that increasing age (adjusted OR 1.04; 95% CI, 1.01–1.02), two or more comorbidities (adjusted OR 2.9; 95% CI, 1.1–7.8), and systemic glucocorticoids (adjusted OR 6.9; 95% CI, 2.3–20.5) are associated with severe COVID-19 in IBD patients. Anti-TNF treatment was not associated with severe COVID-19 (adjusted OR 0.9; 95% CI, 0.4–2.2).

338 Irritable Bowel Syndrome

Chung Owyang, Prashant Singh

Irritable bowel syndrome (IBS) is a functional bowel disorder characterized by abdominal pain or discomfort and altered bowel habits in the absence of detectable structural abnormalities. No clear diagnostic markers exist for IBS; thus, the diagnosis of the disorder is based on clinical presentation. In 2016, the Rome III criteria for the diagnosis of IBS were updated to Rome IV **(Table 338-1)**. Throughout the world, ~10% of adults and adolescents have symptoms consistent with IBS. IBS symptoms fluctuate over time and often overlap with other functional disorders such as fibromyalgia, headache, backache, and genitourinary symptoms. Severity of symptoms varies and can significantly impair quality of life, resulting in high direct and indirect health care costs. Altered gastrointestinal (GI) motility, visceral hyperalgesia, disturbance of brain–gut interaction, abnormal central processing, autonomic and hormonal events, microbial dysbiosis, genetic and environmental factors, and psychosocial disturbances are variably involved, depending on the individual.

TABLE 338-1 Rome IV Diagnostic Criteria for Irritable Bowel Syndrome[a]

Recurrent abdominal pain, on average, at least 1 day per week in the last 3 months, associated with ≥2 of the following criteria:

1. Related to defecation
2. Associated with a change in frequency of stool
3. Associated with a change in form (appearance) of stool

[a]Criteria fulfilled for the last 3 months with symptom onset at least 6 months prior to diagnosis.

CLINICAL FEATURES

IBS is a disorder that affects all ages, although most patients have their first symptoms before age 45. Women are diagnosed with IBS two to three times as often as men and make up 80% of the population with severe IBS. As indicated in Table 338-1, abdominal pain is essential for diagnosing IBS. This should be associated with defecation and/or have its onset associated with a change in frequency or form of stool. In comparison to Rome III, the Rome IV criteria are more stringent, requiring abdominal pain to occur at a minimum of once a week and eliminating "discomfort" as one of the criteria. Painless diarrhea or constipation does not fulfill the diagnostic criteria to be classified as IBS. Supportive symptoms that are not part of the diagnostic criteria include straining, urgency or a feeling of incomplete defecation, passing mucus, and bloating.

Abdominal Pain According to the current IBS diagnostic criteria, abdominal pain is a prerequisite clinical feature of IBS. Abdominal pain in IBS is highly variable in intensity and location and can occur anywhere in the abdomen. It is frequently episodic and crampy, but it may be superimposed on a background of constant ache. Pain may be mild enough to be ignored, or it may interfere with daily activities. Despite this, malnutrition due to inadequate caloric intake is exceedingly rare with IBS. Sleep deprivation is also unusual because abdominal pain is almost uniformly present only during waking hours. Pain is often exacerbated by eating or emotional stress and improved by the passage of flatus or stools. In addition, female patients with IBS commonly report worsening symptoms during the premenstrual and menstrual phases.

Altered Bowel Habits Alteration in bowel habits is the most consistent clinical feature in IBS. Based on the predominant bowel type, IBS can be classified into IBS with predominant constipation (IBS-C), IBS with predominant diarrhea (IBS-D), and IBS with both mixed constipation and diarrhea (IBS-M). However, bowel pattern subtypes are highly unstable. In a patient population with ~33% prevalence rates of IBS-D, IBS-C, and IBS-M forms, 75% of patients change subtypes and 29% switch between IBS-C and IBS-D over 1 year.

Patients with IBS-C have symptoms of hard stools (often with narrow caliber), infrequent stools (less than three bowel movements per week), incomplete evacuation, straining, sensation of anal blockage, and digitalization. On the other hand, those with IBS-D usually have small volumes of loose stools (generally <200 mL). This is often associated with fecal urgency, the passage of mucus, and in some cases incontinence. Diarrhea may be aggravated by emotional stress or eating. Weight loss, nocturnal symptoms, and bleeding per rectum are not common in patients with IBS and, when present, should warrant evaluation for other causes.

Gas and Flatulence Patients with IBS frequently complain of bloating, abdominal distention and increased belching or flatulence, all of which they attribute to increased gas. Although some patients with these symptoms actually may have a larger amount of gas, quantitative measurements reveal that most patients who complain of increased gas generate no more than a normal amount of intestinal gas. Most patients with IBS have impaired transit and intolerance of intestinal gas loads. In addition, patients with IBS tend to reflux gas from the distal to the more proximal intestine, which may explain the belching. Some patients with bloating may also experience visible distention with increase in abdominal girth.

Upper GI Symptoms Between 25 and 50% of patients with IBS complain of dyspepsia, heartburn, nausea, and vomiting. This suggests that other areas of the gut apart from the colon may be involved. Prolonged ambulant recordings of small-bowel motility in patients with IBS show a high incidence of abnormalities in the small bowel during the diurnal (waking) period; nocturnal motor patterns are not different from those of healthy controls. The overlap between dyspepsia and IBS is high. The prevalence of IBS is higher among patients with dyspepsia (31.7%) than among those who reported no symptoms of dyspepsia (7.9%). Conversely, among patients with IBS, 55.6% reported symptoms of dyspepsia. In addition, the functional abdominal symptoms can change over time. Those with predominant dyspepsia or IBS can

flux between the two. Thus, it is conceivable that functional dyspepsia and IBS are two manifestations of a single, more extensive digestive system disorder. Furthermore, IBS symptoms are prevalent in other functional GI disorders such as noncardiac chest pain patients and esophageal hypersensitivity.

PATHOPHYSIOLOGY

The pathogenesis of IBS is poorly understood, although roles of abnormal gut motor and sensory activity, central neural dysfunction, psychological disturbances, mucosal inflammation, stress, and luminal factors such as bile acid malabsorption and gut dysbiosis have been proposed (Fig. 338-1).

GI Motor Abnormalities Studies of colonic myoelectrical and motor activity under unstimulated conditions have not shown consistent abnormalities in IBS. In contrast, colonic motor abnormalities are more prominent under stimulated conditions in IBS. IBS patients may exhibit increased rectosigmoid motor activity for up to 3 h after eating. Similarly, inflation of rectal balloons both in IBS-D and IBS-C patients leads to marked and prolonged distention-evoked contractile activity. Recordings from the transverse, descending, and sigmoid colon showed that the motility index and peak amplitude of high-amplitude propagating contractions (HAPCs) in IBS-D patients were greatly increased compared to those in healthy subjects and were associated with rapid colonic transit and accompanied by abdominal pain.

Visceral Hypersensitivity IBS patients frequently exhibit exaggerated sensory responses to visceral stimulation. The frequency of perceptions of food intolerance is at least twofold more common than in the general population. On the other hand, prolonged fasting in IBS patients is often associated with significant improvement in symptoms. Rectal balloon inflation produces nonpainful and painful sensations at lower volumes in IBS patients than in healthy controls without altering rectal tension, suggestive of visceral afferent dysfunction in IBS. Similar studies show gastric and esophageal hypersensitivity in patients with nonulcer dyspepsia and noncardiac chest pain, raising the possibility that these conditions have a similar pathophysiologic basis. Lipids lower the thresholds for the first sensation of gas, discomfort, and pain in IBS patients. Hence, postprandial symptoms in IBS patients may be explained in part by a nutrient-dependent exaggerated sensory component of the gastrocolonic response. In contrast to enhanced gut sensitivity, IBS patients do not exhibit heightened sensitivity elsewhere in the body. Thus, the afferent pathway disturbances in IBS appear to be selective for visceral innervation with sparing of somatic pathways. The mechanisms responsible for visceral hypersensitivity are still under investigation.

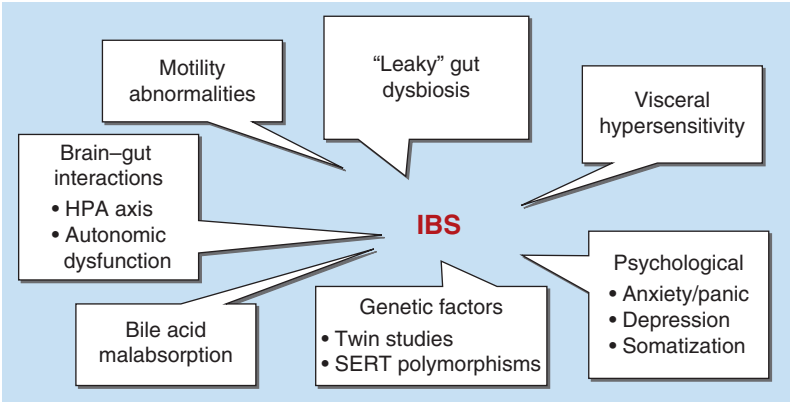

FIGURE 338-1 Pathophysiology of irritable bowel syndrome (IBS). The cause of IBS is likely to be multifactorial. Patients often show evidence of visceral hypersensitivity and motility abnormalities. Many IBS patients have increased anxiety and/or depression, and their symptoms are often exacerbated by mental or physical stress, suggesting abnormal brain–gut interaction. Genetic studies suggest a few IBS patients may have genetic abnormalities affecting the serotonin transport system in the enteric nerves. Up to 30% of IBS patients may have bile acid malabsorption. Gut dysbiosis and impaired mucosa permeability also have been reported in many IBS patients. This may lead to subclinical mucosa inflammation. HPA, hypothalamic-pituitary-adrenal; SERT, serotonin reuptake transporter.

Central Neural Dysregulation The role of central nervous system (CNS) factors in the pathogenesis of IBS is strongly suggested by the clinical association of emotional disorders and stress with symptom exacerbation and the therapeutic response to therapies that act on cerebral cortical sites. Functional brain imaging studies such as magnetic resonance imaging (MRI) have shown that in response to distal colonic stimulation, the mid-cingulate cortex—a brain region concerned with attention processes and response selection—shows greater activation in IBS patients. Modulation of this region is associated with changes in the subjective unpleasantness of pain. In addition, IBS patients also show preferential activation of the prefrontal lobe, which contains a vigilance network within the brain that increases alertness. These may represent a form of cerebral dysfunction, leading to hypervigilance of visceral pain.

Abnormal Psychological Features Abnormal psychiatric features are recorded in up to 80% of IBS patients, especially in referral centers; however, no single psychiatric diagnosis predominates. Most of these patients demonstrated exaggerated symptoms in response to visceral distention, and this abnormality persists even after exclusion of psychological factors.

Psychological factors influence pain thresholds in IBS patients, as stress alters sensory thresholds. An association between prior sexual or physical abuse and development of IBS has been reported. Clinical studies suggest that IBS has a strong developmental component that involves interactions of genetic and epigenetic factors early in life. These may modulate brain networks related to emotional arousal and/or central autonomic control, salience, and somatosensory integration. Abuse is associated with greater pain reporting, psychological distress, and poor health outcome. Brain functional MRI studies show greater activation of the posterior and middle dorsal cingulate cortex, which is implicated in affect processing in IBS patients with a past history of sexual abuse.

Postinfectious IBS A systematic review found that >10% of patients with infectious enteritis develop IBS later and the risk was four-fold higher compared to individuals without infectious enteritis. Conversely, about a third of IBS patients experienced an acute "gastroenteritis-like" illness at the onset of their chronic IBS symptomatology. This group of "postinfective" IBS occurs more commonly in females and affects younger rather than older patients. Other risk factors include clinical severity of infection (e.g., prolonged duration, requiring antibiotics), type of infection (risk is higher for parasitic and bacterial infection compared to viral), and presence of psychological comorbidities. Increased rectal mucosal enteroendocrine cells and T lymphocytes following *Campylobacter* enteritis may contribute to postinfective IBS. Persistent bacterial dysbiosis following an infection causing abnormal suppression of host proteolytic activity leading to altered intestinal barrier has also been implicated in a subset of these patients.

Immune Activation and Mucosal Inflammation Some patients with IBS display persistent signs of low-grade mucosal inflammation with activated lymphocytes, mast cells, and enhanced expression of proinflammatory cytokines. Other studies also indicate that peripheral blood mononuclear cells (PBMCs) from IBS patients show abnormal release of proinflammatory cytokines such as interleukin (IL) 6, IL-1β, and tumor necrosis factor (TNF). These abnormalities may contribute to abnormal epithelial secretion, increased permeability, and visceral hypersensitivity. Located at the host-environment interface, mast cells are in close proximity to sensory nerves. Electromicroscopic evidence of mast cell activation is commonly observed in the colonic mucosa of IBS patients. The proximity of activated mast cells to submucosal nerve fibers correlates with the frequency and severity of abdominal pain in patients with IBS. Other studies report that the colonic mucosa of IBS patients releases increased amounts of mast cell mediators, including histamine, proteases, and prostaglandin E_2.

These findings, together with the observation that marked excitation of visceral sensory nerves innervating the colon occurs after exposure to IBS mucosal supernatant, support a prominent role for mast cells in the pathogenesis of visceral hypersensitivity. Increasing evidence suggests that some members of the superfamily of transient receptor potential (TRP) cation channels such as TRPV1 (vanilloid) channels are central to the initiation and persistence of visceral hypersensitivity. Mucosal inflammation can lead to increased expression and/or sensitization of TRPV1. Enhanced expression of TRPV1 channels in the sensory neurons of the gut has been observed in IBS, and such expression appears to correlate with visceral hypersensitivity and abdominal pain.

Altered Intestinal Permeability The gut epithelial lining represents a semipermeable barrier that allows nutrient and water absorption while being restrictive against pathogenic molecules, toxins, and bacteria. The intestinal barrier is impaired in a subset of patients with IBS. This is primarily described in patients with IBS-D and postinfectious IBS. It is unclear whether or not those with IBS-C and IBS-M also have increased intestinal permeability. There appears to be a correlation between altered intestinal permeability and symptom severity in IBS. Studies have not only shown structural changes in barrier function, such as a decrease in gene and protein expression of tight junction proteins, but also functional consequences, such as the increased passage of macromolecules including bacteria across the epithelial barrier in Ussing chamber studies. Although the exact etiology of the altered mucosal barrier is not well understood, several factors such as stress, diet, and microbial dysbiosis appear to play a key role. Several studies have shown a key role of mast cell activation in mediating barrier dysfunction due to stress and diet-related dysbiosis.

Altered Gut Flora IBS patients have fourfold increased odds of having small-intestinal bacterial overgrowth compared to healthy controls based on positive lactulose or glucose hydrogen breath test. This finding, however, has been challenged by a number of other studies that found no increased incidence of bacterial overgrowth based on jejunal aspirate culture. An abnormal H_2 breath test can occur because of rapid small-bowel transit and may lead to erroneous interpretation. It is unclear if an abnormal breath test can predict the response to available treatment options such as nonselective antibiotics, and therefore, the role of testing for small-intestinal bacterial overgrowth in IBS patients remains unclear.

Many, but not all, studies using culture-independent approaches such as 16S rRNA gene-based analysis found significant differences between the molecular profile of the fecal microbiota of IBS patients and that of healthy subjects. Although an IBS-specific microbial signature has not yet been identified, but overall, the diversity of fecal microbiome appears to be significantly lower in IBS patients compared to healthy controls. However, the functional significance of this finding is not well understood. Despite a lack of consensus on the exact microbial difference between IBS patients and controls, IBS patients generally had decreased proportions of the genera *Bifidobacterium* and *Faecalibacterium* and increased abundance of family Enterobacteriaceae (phylum Proteobacteria), family Lactobacillaceae, and genus *Bacteroides* (phylum Bacteroidetes) **(Fig. 338-2)**. Experiments with animal models have shown that colonization of germ-free animals with microbiota from patients with IBS can induce visceral hypersensitivity, alter gut-brain axis, impair intestinal permeability, and alter GI transit time, indicating the importance and possible etiologic role of the microbiota in IBS. Gut dysbiosis acting in concert with genetic susceptibility and environmental insults may alter mucosal permeability and increase antigen presentation to the immune cells in the lamina propria. This may result in mast cell activation and altered enteric neuronal and smooth-muscle function causing IBS symptoms. In addition, release of cytokines and chemokines from mucosal inflammation may generate extra-GI symptoms such as chronic fatigue, muscle pain, and anxiety **(Fig. 338-3)**.

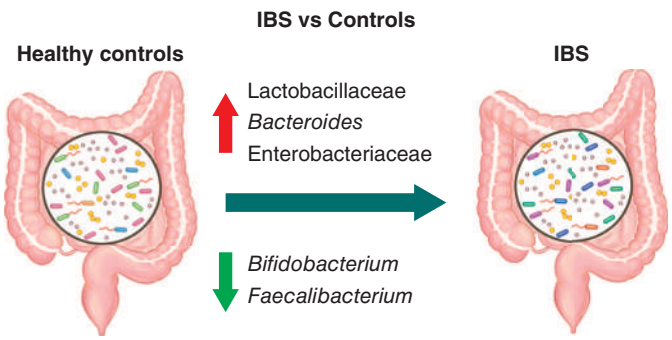

FIGURE 338-2 Changes in gut microbiota among patients with irritable bowel syndrome (IBS). (*Adapted from R Pittayanon et al: Gastroenterology 157:97, 2019.*)

Abnormal Serotonin Pathways The serotonin-containing enterochromaffin cells in the colon are increased in a subset of IBS-D patients compared to healthy individuals. Furthermore, postprandial plasma serotonin levels were significantly higher in this group of patients compared to healthy controls. Tryptophan hydroxylase 1 (TPH1) is the rate-limiting enzyme in enterochromaffin cell serotonin biosynthesis, and functional TPH1 polymorphism has been shown to be associated with IBS subtypes. In addition, gut microbes promote colonic serotonin production through an effect of short-chain fatty acids on enterochromaffin cells. In IBS patients, the expression of mucosal serotonin reuptake transporter (SERT) is downregulated due to gram-negative gut dysbiosis, leading to abnormal mucosal serotonin levels in IBS. Because serotonin plays an important role in the regulation of GI motility and visceral perception, the increased release of serotonin may contribute to the postprandial symptoms of these patients.

Bile Acids Up to 25% of patients with IBS-D are found to have evidence of idiopathic bile acid diarrhea. Mechanisms leading to increased hepatic synthesis and colonic bile acid levels in idiopathic bile acid diarrhea include reduced synthesis of fibroblast growth factor 19 (FGF-19) by the ileal mucosa or genetic variation in proteins involved in negative feedback of bile acid synthesis. Increased colonic bile acid levels in turn influence bowel habit by accelerating colonic transit, intestinal permeability, and visceral hypersensitivity.

APPROACH TO THE PATIENT

Irritable Bowel Syndrome

Because IBS is a disorder for which no pathognomonic abnormalities have been identified, its diagnosis relies on recognition of positive clinical features and elimination of other organic diseases. Symptom-based criteria have been developed for the purpose of differentiating patients with IBS from those with organic diseases. These include the Manning, Rome I, Rome II, Rome III, and Rome IV criteria. Rome IV criteria for the diagnosis of IBS were published in 2016 (Table 338-1) and defined IBS on the basis of abdominal pain and altered bowel habits that occur with sufficient frequency in affected patients. A careful history and physical examination are frequently helpful in establishing the diagnosis. Clinical features suggestive of IBS include recurrence of lower abdominal pain with altered bowel habits over a period of time without progressive deterioration, onset of symptoms during periods of stress or emotional upset, absence of other systemic symptoms such as fever and weight loss, and small-volume stool without any evidence of blood.

On the other hand, the appearance of the disorder for the first time in old age, progressive course from time of onset, rectal bleeding, significant weight loss persistent diarrhea after a 48-h fast, and presence of nocturnal diarrhea or steatorrheal stools argue against the diagnosis of IBS.

Because the major symptoms of IBS—abdominal pain, abdominal bloating, and alteration in bowel habits—are common complaints of many GI organic disorders, the list of differential diagnoses is a long one. The quality, location, and timing of pain may be

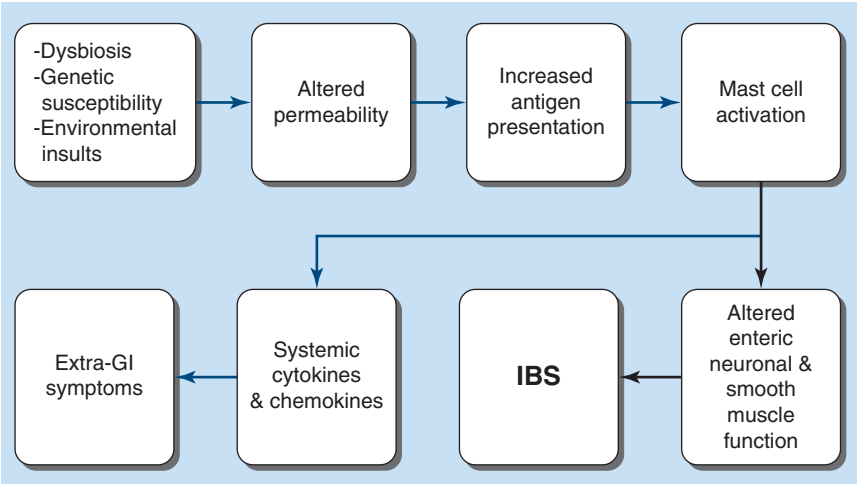

FIGURE 338-3 Gut dysbiosis and irritable bowel syndrome (IBS). Gut dysbiosis acting in concert with genetic and environmental factors may alter intestinal permeability and increase antigen presentation, resulting in mast cell activation. Products of mast cell degranulation may alter neuronal and smooth-muscle function causing IBS symptoms. The cytokines and chemokines generated from mucosal inflammation may cause symptoms such as fibromyalgia, chronic fatigue, and mood changes. GI, gastrointestinal. (*Adapted from NJ Talley, AA Fodor: Gastroenterology 141:1555, 2011.*)

helpful to suggest specific disorders. Pain due to IBS that occurs in the epigastric or periumbilical area must be differentiated from biliary tract disease, peptic ulcer disorders, intestinal ischemia, and carcinoma of the stomach and pancreas. If pain occurs mainly in the lower abdomen, the possibility of diverticular disease of the colon, inflammatory bowel disease (including ulcerative colitis and Crohn's disease), and carcinoma of the colon must be considered. Postprandial pain accompanied by bloating, nausea, and vomiting suggests gastroparesis or partial intestinal obstruction. Patients with small intestinal bacteria overgrowth can present with abdominal pain, nausea, and bloating. Intestinal infestation with *Giardia lamblia* or other parasites may cause similar symptoms. When diarrhea is the major complaint, the possibility of lactase deficiency, laxative abuse, malabsorption, celiac sprue, hyperthyroidism, inflammatory bowel disease (IBD), and infectious diarrhea must be ruled out. On the other hand, constipation may be a side effect of many different drugs, such as anticholinergic, antihypertensive, and antidepressant medications. Endocrinopathies such as hypothyroidism and hypoparathyroidism must also be considered in the differential diagnosis of constipation. In addition, acute intermittent porphyria and lead poisoning may present in a fashion similar to IBS, with painful constipation as the major complaint. These possibilities are suspected on the basis of their clinical presentations and are confirmed by appropriate serum and urine tests.

Few tests are required for patients who have typical IBS symptoms and no alarm features. Unnecessary investigations may be costly and even harmful. The American Gastroenterological Association has delineated factors to be considered when determining the aggressiveness of the diagnostic evaluation. These include the duration of symptoms, the change in symptoms over time, the age and sex of the patient, the referral status of the patient, prior diagnostic studies, a family history of colorectal malignancy, and the degree of psychosocial dysfunction. Thus, a younger individual with mild symptoms requires a minimal diagnostic evaluation, while an older person or an individual with rapidly progressive symptoms should undergo a more thorough exclusion of organic disease. Most patients should have a complete blood count and fecal calprotectin (or fecal lactoferrin), and/or C-reactive protein should be checked in patients with IBS-D even in the absence of alarm features to rule out IBD. Serologic testing for celiac disease should be performed in patients with symptoms of IBS-D if the prevalence of celiac disease in the general population is 1% or higher. Stool examination for ova and parasites is not necessary for all patients with IBS-D but could be helpful in regions where parasitic infections are endemic/common or if history suggests a possibility of parasitic infection (e.g., drinking untreated water). In the presence of alarm features or symptom onset after age 40, or in the absence of response to traditional therapies such as antidiarrheals, colonoscopy is warranted. Random biopsies to rule out microscopic colitis should be performed if the patient has persistent or chronic diarrhea. If the main symptoms are diarrhea and increased gas, the possibility of lactase deficiency should be ruled out with a hydrogen breath test or with evaluation after a 3-week lactose-free diet. Excessive gas with bloating also raises the possibility of small-bowel bacteria overgrowth, and this should be ruled out with a glucose hydrogen breath test. In patients with concurrent symptoms of dyspepsia, upper GI radiographs or esophagogastroduodenoscopy may be advisable. In patients with postprandial right upper quadrant pain, an ultrasonogram of the gallbladder should be obtained. Laboratory features that argue against IBS include evidence of anemia, elevated sedimentation rate, presence of leukocytes or blood in stool, and stool volume >200–300 mL/d. These findings would necessitate other diagnostic considerations.

TREATMENT

Irritable Bowel Syndrome

PATIENT COUNSELING AND DIETARY ALTERATIONS

Reassurance and careful explanation of the functional nature of the disorder are of primary importance, along with counseling on how to identify triggers for the patient's IBS symptoms. Stress management may be helpful if stress is a trigger, and identifying obvious food precipitants is an important first step in patient counseling and dietary change. As a therapeutic trial, patients should be encouraged to eliminate any foodstuffs that appear to produce symptoms. However, patients should avoid nutritionally depleted diets. It is unclear if exercise improves overall IBS symptoms, but given its low risk and overall health benefits, it should be encouraged in all IBS patients.

STOOL-BULKING AGENTS

High-fiber diets and fiber supplementation are frequently used in treating IBS. The water-holding action of fibers may contribute to increased stool bulk, and fiber also speeds up colonic transit in most people. Furthermore, because of its hydrophilic properties, soluble fiber binds water by soaking up extra water in the colon and therefore can be helpful with diarrhea in some IBS patients. Furthermore, fiber supplementation with psyllium has been shown to reduce perception of rectal distention, indicating that fiber may have a positive effect on visceral afferent function.

Controlled trials of dietary fiber in IBS patients have produced variable results. This is not surprising since IBS is a heterogeneous disorder, with some patients being constipated and other having predominant diarrhea. Most investigations report increases in stool weight, decreases in colonic transit times, and improvement in constipation. Others have noted benefits in patients with alternating diarrhea and constipation, pain, and bloating. However, most studies observe no response in patients with diarrhea- or pain-predominant IBS. While studies do not support the use of insoluble dietary fiber such as wheat bran in IBS, soluble fibers such as psyllium preparations are often found to be effective in managing IBS symptoms. Fiber should be started at a nominal dose and slowly titrated up as tolerated over the course of several weeks to a targeted dose of 20–30 g of total dietary and supplementary fiber per day. Even when used judiciously, fiber can exacerbate bloating, flatulence, constipation, and diarrhea.

ANTISPASMODICS

Clinicians have observed that anticholinergic drugs may provide temporary relief for symptoms such as painful cramps related to intestinal spasm. Although controlled clinical trials have produced mixed results, evidence generally supports the beneficial effects of anticholinergic drugs for pain. Physiologic studies demonstrate that anticholinergic drugs inhibit the gastrocolic reflex; hence, postprandial pain is best managed by giving antispasmodics 30 min before meals so that effective blood levels are achieved shortly before the anticipated onset of pain. Most anticholinergics contain natural belladonna alkaloids, which may cause xerostomia, urinary hesitancy and retention, blurred vision, and drowsiness. They should be used in the elderly with caution. Some physicians prefer to use synthetic anticholinergics such as dicyclomine that have less effect on mucous membrane secretion and produce fewer undesirable side effects. Peppermint oil appears to reduce abdominal cramps by some undefined mechanism. In a meta-analysis of 10 double-blind, randomized controlled trials evaluating 1030 IBS patients, peppermint oil was found to be significantly superior to placebo for global improvement of IBS symptoms and reduction in abdominal pain. The most commonly reported adverse event was heartburn, which was mild and transient.

ANTIDIARRHEAL AGENTS

Peripherally acting opiate-based agents are the initial therapy of choice for IBS-D. Physiologic studies demonstrate increases in segmenting colonic contractions, delays in fecal transit, increases in anal pressures, and reductions in rectal perception with these drugs. When diarrhea is severe or the predominant symptom, small doses of loperamide, 2–4 mg every 4–6 h up to a maximum of 12 mg/d, can be prescribed. These agents are less addictive than paregoric, codeine, or tincture of opium. In general, the intestines do not become tolerant of the antidiarrheal effect of opiates, and increasing doses are not required to maintain antidiarrheal potency. These agents are most useful if taken before anticipated stressful events that are known to cause diarrhea. However, not infrequently, a high dose of loperamide may cause cramping because of increases in colonic contractions. Eluxadoline, a locally acting, mixed μ-opioid receptor agonist, κ-opioid receptor agonist, and δ-opioid receptor antagonist with minimal systemic bioavailability, has been approved for treating abdominal pain and diarrhea by the U.S. Food and Drug administration (FDA) for patients with IBS-D. Given a small risk of pancreatitis associated with eluxadoline, it should not be prescribed for patients with prior cholecystectomy or significant alcohol use or prior history of pancreatitis. Other antidiarrheal agents that may be used in IBS patients are the bile acid binders cholestyramine or colesevelam because up to 30% of IBS-D patients may have bile acid malabsorption.

OSMOTIC LAXATIVES

Osmotic agents such as magnesium citrate–based products, sodium phosphate–based products, and nonabsorbable carbohydrates are hypertonic products that, through osmosis, extract fluid into the intestinal lumen to soften stool and enhance colonic transit. In contrast, polyethylene glycol (PEG)–based solution is iso-osmotic and induces bowel movement by high-volume lavage. The osmotic laxatives were better than placebo in improving symptoms of chronic constipation in clinical trials. However, chronic use of magnesium hydroxide may result in severe hypermagnesemia in patients with renal impairment. Frequent sodium phosphate–based bowel cleansing should be avoided as this is associated with hyperphosphatasemia, hypocalcemia, and hypokalemia. In 19 trials, PEG consistently induced more bowel movements than placebo. A Cochrane review of 10 randomized trials showed that PEG was superior to lactulose for improving stool frequency and abdominal pain. Among the nonabsorbable carbohydrates, lactulose and sorbitol had similar laxative effects. However, bacterial metabolism of unabsorbed carbohydrates often leads to gas production and abdominal pain, which can limit long-term use.

ANTIFLATULENCE THERAPY

The management of excessive gas is seldom satisfactory, except when there is obvious aerophagia or disaccharidase deficiency. Patients should be advised to eat slowly and not chew gum or drink carbonated beverages. Bloating may decrease if an associated gut syndrome such as IBS or constipation is improved. If bloating is accompanied by diarrhea and worsens after ingesting dairy products, fresh fruits, vegetables, or juices, further investigation or a dietary exclusion trial may be worthwhile. Avoiding gas forming foods, exercising, losing excess weight, and taking activated charcoal are safe but unproven remedies. A low FODMAP (fermentable oligosaccharides, disaccharides, monosaccharides, and polyols) diet has been shown to be quite effective in reducing gas and bloating (see "Low FODMAP Diet") **(Table 338-2)**. Data regarding the use of surfactants such as simethicone are conflicting. Antibiotics may help in a subgroup of IBS patients with predominant symptoms of bloating. Beano, an over-the-counter oral β-glycosidase solution, may reduce rectal passage of gas without decreasing bloating and pain.

ANTIDEPRESSANT DRUGS

In addition to their mood-elevating effects, antidepressant medications have several physiologic effects that suggest they may be beneficial in IBS. In IBS-D patients, the tricyclic antidepressant imipramine slows jejunal migrating motor complex transit propagation and delays orocecal and whole-gut transit, indicative of a motor inhibitory effect. Some studies also suggest that tricyclic agents may alter visceral afferent neural function.

Tricyclic antidepressants is effective in IBS patients of all subtypes. The beneficial effects of the tricyclic compounds in the treatment of IBS appear to be independent of their effects on depression. The therapeutic benefits for the bowel symptoms occur faster and at a lower dosage. The efficacy of antidepressant agents from other chemical classes in the management of IBS is less well evaluated. Selective serotonin reuptake inhibitors (SSRIs) have also been studied in patients with IBS with conflicting results and significant heterogeneity among individual trials.

SEROTONIN RECEPTOR MODULATORS

Serotonin 5-HT_3 and 5-HT_4 receptors are found throughout the GI tract. Tegaserod, a 5-HT_4 receptor agonist, exhibits prokinetic activity by stimulating peristalsis. Clinical studies involving >4000 IBS-C patients reported reduction in abdominal discomfort and improvements in constipation and bloating compared to placebo. Diarrhea is the only major side effect. In 2007, the drug was voluntarily withdrawn from the market after a greater number of cardiovascular complications were observed in a database of 18,000 patients receiving tegaserod (0.11 vs 0.01% in placebo). In 2019, the FDA reviewed additional data and approved the use of tegaserod in women younger than 65 years old who do not have a history of ischemic cardiovascular disease and who have no more than one risk factor for cardiovascular disease.

TABLE 338-2 Some Common Food Sources of FODMAPs

FOOD TYPE	FREE FRUCTOSE	LACTOSE	FRUCTANS	GALACTO-OLIGOSACCHARIDES	POLYOLS
Fruits	Apple, cherry, mango, pear, watermelon		Peach, persimmon, watermelon		Apple, apricot, pear, avocado, blackberries, cherry, nectarine, plum, prune
Vegetables	Asparagus, artichokes, sugar snap peas		Artichokes, beetroot, Brussels sprout, chicory, fennel, garlic, leek, onion, peas		Cauliflower, mushroom, snow peas
Grains and cereals			Wheat, rye, barley		
Nuts and seeds			Pistachios		
Milk and milk products		Milk, yogurt, ice cream, custard, soft cheeses			
Legumes			Legumes, lentils, chickpeas	Legumes, chickpeas, lentils	
Other	Honey, high-fructose corn syrup		Chicory drinks		
Food additives			Inulin, FOS		Sorbitol, mannitol, maltitol, xylitol, isomalt

Abbreviations: FODMAPs, fermentable oligosaccharides, disaccharides, monosaccharides, and polyols; FOS, fructo-oligosaccharides.

SECRETAGOGUES

Lubiprostone, linaclotide, and plecanatide are secretagogues that stimulate net efflux of ions and water into the intestinal lumen and thus enhance transit and facilitate ease of defecation. By activating channels on the apical (luminal) enterocyte surface, these secretagogues increase intestinal chloride secretion. Other ion channels and transporters secrete sodium into the intestine to maintain electroneutrality, followed by the secretion of water. Lubiprostone is a bicyclic fatty acid derived from prostaglandin E_1 that activates type 3 chloride channels in the apical membrane of intestinal epithelial cells. Oral lubiprostone was effective in the treatment of patients with IBS-C in large phase 3, randomized, double-blind, placebo-controlled multicenter trials. The recommended daily dose is 24 mcg twice daily. In general, the drug is well tolerated. The major side effects are nausea and diarrhea. Linaclotide and plecanatide are minimally absorbed 14-amino-acid peptide guanylate cyclase-C (GC-C) agonists that bind to and activate GC-C on the luminal surface of intestinal epithelium. The subsequent increase in cyclic guanosine monophosphate activates the cyclic fibrosis transmembrane regulator and induces fluid secretion into the GI tract. These drugs are similar to endogenous peptides secreted by the small intestine (uroguanylin) or colon (guanylin). In two 12-week, double-blind, randomized, controlled trials, linaclotide (290 or 145 μg, once daily) reduced constipation and pain. A lower dose (72 μg once daily) was also more effective than placebo. Linaclotide has been approved by the FDA for treatment of IBS-C. Plecanatide (3- and 6-mg doses) also has been shown to be more effective than placebo in two phase 3 trials for IBS-C. The 3-mg once-daily dose has been approved by the FDA. The only significant side effect was diarrhea, which occurred in <5% of patients. Tenapanor, a small-molecule inhibitor of GI sodium-hydrogen exchange-3, is more effective than placebo when given at 50 mg twice daily in patients with IBS-C and has been approved by the FDA for treatment of IBS-C.

MODULATION OF GUT FLORA

Because altered colonic flora (gut dysbiosis) may contribute to the pathogenesis of IBS, this has led to great interest in using antibiotics, prebiotics, probiotics, and dietary measures to treat IBS.

Antibiotics Antibiotic treatment benefits a subset of IBS patients. In a double-blind, randomized, placebo-controlled study, neomycin dosed at 500 mg twice daily for 10 days was more effective than placebo at improving symptom scores among IBS patients. The nonabsorbed oral antibiotic rifaximin is the most thoroughly studied antibiotic for the treatment of IBS. In two identical double-blind, placebo-controlled studies with >1200 nonconstipated IBS patients, those receiving rifaximin at a dose of 550 mg three times daily for 2 weeks were significantly more likely to report adequate relief of IBS symptoms compared with those taking placebo. Currently, rifaximin is approved by the FDA for treatment of IBS-D. Moreover, a placebo-controlled randomized clinical trial has shown that patients with IBS-D who respond to rifaximin are more likely to respond to subsequent courses of rifaximin compared to placebo if they experience relapse of symptoms.

Prebiotics These are nondigestible food ingredients that stimulate growth and/or activity of bacteria in the GI tract. There have been four randomized trials to examine the effects of prebiotics. Three of the four studies reported that prebiotics worsened or did not improve IBS symptoms. This is not surprising given the adverse effects of a high-carbohydrate diet on IBS symptoms.

Probiotics These are defined as live microorganisms that when administered in adequate amounts confer a health benefit on the host. Multiple meta-analyses have suggested that probiotics might be an effective strategy in improving global IBS symptoms including abdominal pain and bloating; however, given the limitations of existing studies (small sample size, short duration, lack of rigorous endpoints, single-centered), it is unclear which probiotics to recommend for patients with IBS. Given the lack of high-quality data, the American Gastroenterological Association makes no recommendations for use of probiotics in patients with IBS. Large-scale studies of well-phenotyped IBS patients are needed to establish the efficacy of probiotics in IBS.

Low FODMAP Diet A diet rich in FODMAPs often triggers symptoms in IBS patients. FODMAPs are poorly absorbed by the small intestine and fermented by bacteria in the colon to produce gas and osmotically active carbohydrates **(Fig. 338-4)**. At the same time, on entering the colon, FODMAPs may serve as nutrients for the colonic bacteria and promote the growth of gram-negative commensal bacteria, which may induce barrier dysfunction and subclinical mucosal inflammation. Fructose and fructans induce IBS symptoms in a dose-dependent manner. In contrast, a low FODMAP diet reduces IBS symptoms in 50–80% of patients with IBS. A network meta-analysis of 13 randomized controlled trials of IBS patients found that a low FODMAP diet was superior to all other dietary interventions in reducing global IBS symptoms and primarily improves abdominal pain and bloating in patients with IBS. The current approach to low FODMAP diet implementation

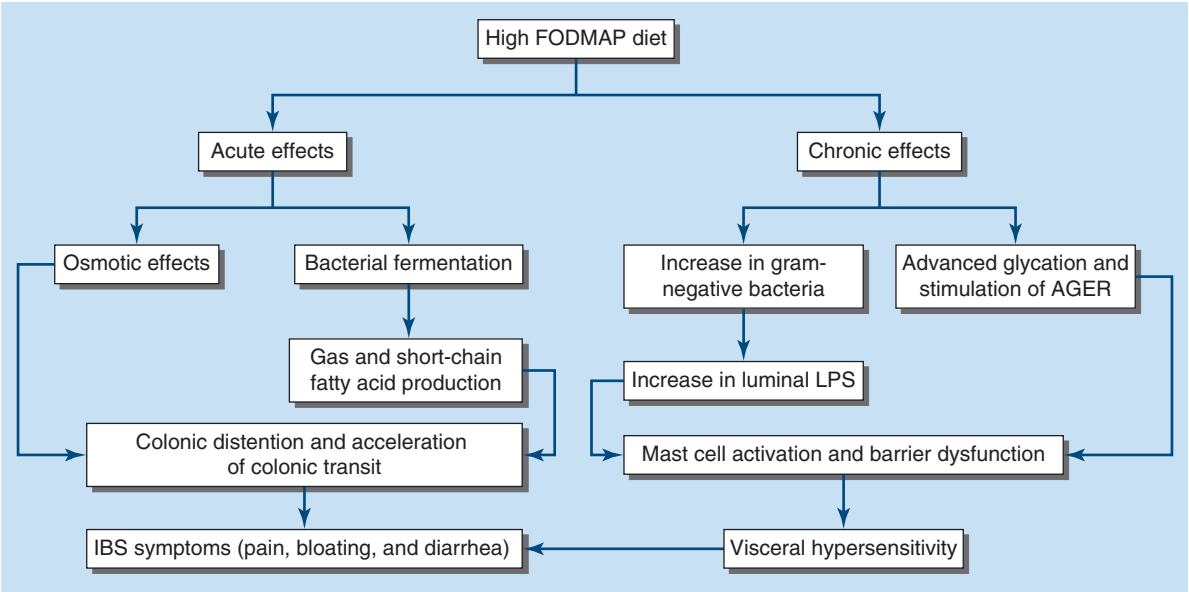

FIGURE 338-4 Pathogenesis of FODMAP-related symptoms. FODMAPs are poorly absorbed by the small intestine and fermented by gut bacteria to produce gas and osmotically active carbohydrates. These events act in concert to cause bloating, flatulence, and diarrhea. FODMAPs may also serve as nutrients for colonic bacteria, which may induce mucosal changes such as mast cell activation and barrier dysfunction. AGER, advanced glycosylation end product receptor; FODMAP, fermentable oligosaccharides, disaccharides, monosaccharides, and polyols; LPS, lipopolysaccharide. (*Adapted from P Singh et al: Am J Gastroenterol 117:947, 2022.*)

is a three-step "step-down" process with an initial 2- to 6-week restriction phase (which restricts all five FODMAP subgroups [fructose, lactose, fructo- and galacto-oligosaccharides, and polyols]), followed by a reintroduction phase in which food challenges with individual FODMAPs are done to identify an individual's dietary triggers, and finally, a long-term maintenance phase in which the diet is personalized based on the outcome of the reintroduction phase. Physicians should be careful in not implementing a low FODMAP diet among patients with a history of eating disorders and those showing signs or symptoms of avoidant restricting eating behavior. Given that between 20 and 50% of patients do not respond to a low FODMAP diet, the identification of patients who are more likely to respond to a low FODMAP diet at baseline would be highly beneficial.

SUMMARY

The treatment strategy of IBS depends on the severity of the disorder **(Table 338-3)**. Most IBS patients have mild symptoms. They are usually cared for in primary care practices, have little or no psychosocial difficulties, and do not seek health care often. Treatment usually involves education, reassurance, and dietary/lifestyle changes. A smaller portion have moderate symptoms that are usually intermittent and correlate with altered gut physiology, e.g., worsened with eating or stress and relieved by defecation. For IBS-D patients, treatments include gut-acting pharmacologic agents such as antispasmodics, antidiarrheals, and bile acid binders **(Table 338-4)**. In IBS-C

TABLE 338-3 Spectrum of Severity in IBS

	MILD	MODERATE	SEVERE
Clinical Features			
Prevalence	70%	25%	5%
Correlations with gut physiology	+++	++	+
Symptoms constant	0	+	+++
Psychosocial difficulties	0	+	+++
Health care issues	+	++	+++

TABLE 338-4 Possible Drugs for a Dominant Symptom in IBS

SYMPTOM	DRUG	DOSE
Diarrhea	Loperamide	2–4 mg when necessary/maximum 12 g/d
	Diphenoxylate hydrochloride and atropine sulfate (Lomotil)	1–2 tabs as needed or daily (can be taken up to 4 times daily)
	Cholestyramine resin	4 g with meals, can be started qd and increased to tid
	Eluxadoline	100 mg bid
	Alosetron[a]	0.5–1 mg bid (for severe IBS, women)
Constipation	Psyllium husk	3–4 g bid with meals, then adjust
	Methylcellulose	2 g bid with meals, then adjust
	Calcium polycarbophil	1 g qd to qid
	Lactulose syrup	10–20 g bid
	70% sorbitol	15 mL bid
	Polyethylene glycol 3350	17 g in 250 mL water qd, can be titrated to tid
	Lubiprostone	8 or 24 μg bid
	Magnesium hydroxide	15–60 mL qd
	Linaclotide	72, 145, and 290 μg qd
	Plecanatide	3 mg qd
	Tenapanor	50 mg bid
Abdominal pain	Smooth-muscle relaxant	qd to qid ac
	Tricyclic antidepressants	Start 25–50 mg hs, then adjust
	Low FODMAP diet	
Gas and bloating	Low FODMAP diet	
	Probiotics	qd
	Rifaximin	550 mg bid

[a]Available only in the United States.

Abbreviation: FODMAP, fermentable oligosaccharides, disaccharides, monosaccharides, and polyols; IBS, irritable bowel syndrome.

patients, increased fiber intake and the use of osmotic agents such as PEG may achieve satisfactory results. For patients with more severe constipation, a chloride channel opener (lubiprostone) or GC-C agonist (linaclotide or plecanatide) or NHE3 inhibitor (tenapanor) may be considered. For IBS patients with predominant gas and bloating, a low FODMAP diet may provide significant relief. Some patients may benefit from probiotics and rifaximin treatment. A small proportion of IBS patients have severe and refractory symptoms, are usually seen in referral centers, and frequently have constant pain and psychosocial difficulties. This group of patients is best managed with neuromodulators and other psychological treatments (Table 338-4). Clinical trials demonstrating success of a low FODMAP diet in improving IBS symptoms and quality of life provide strong evidence supporting the use of this dietary approach in the treatment of IBS. These observations, if confirmed, may lead to the use of the low FODMAP diet as the first line of treatment of IBS patients with moderate to severe symptoms.

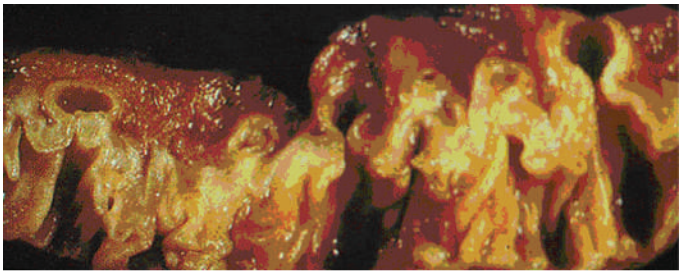
339 Diverticular Disease and Common Anorectal Disorders



Susan L. Gearhart

DIVERTICULAR DISEASE

Incidence and Epidemiology In the United States, diverticulosis affects one-half of the population aged >60 years, and the majority of affected individuals will have no associated symptoms. However, studies have shown that ~5% of individuals with diverticulosis will develop acute diverticular disease. In addition, 10–25% of individuals with diverticular disease will experience recurrent symptoms, and up to 10% will develop complications leading to surgery. Diverticular disease has become the fifth most costly gastrointestinal disorder in the United States and is the leading indication for elective colon resection. The incidence of diverticular disease is on the rise and most prevalent among middle-aged individuals. The majority of patients with diverticular disease report a lower health-related quality of life and more depression as compared to matched controls, thus adding to health care costs. Formerly, diverticular disease was confined to developed countries; however, with the adoption of westernized diets in developing countries, diverticulosis is on the rise across the globe. Immigrants to the United States develop diverticular disease at the same rate as U.S. natives. Although the prevalence among females and males is similar, males tend to present at a younger age. Known risk factors for the development of diverticular disease include the use of nonsteroidal anti-inflammatory drugs (NSAIDS), aspirin, steroids, opioids, smoking, and sedentary lifestyle.

Anatomy and Pathophysiology Two types of diverticula occur in the intestine: true and false (or pseudodiverticula). A true diverticulum is a saclike herniation of the entire bowel wall, whereas a pseudodiverticulum involves only a protrusion of the mucosa and submucosa through the muscularis propria of the colon **(Fig. 339-1)**. The type of diverticulum most commonly seen in the colon is the pseudodiverticulum. The diverticula occur at the point where the nutrient artery, or vasa recta, penetrates through the muscularis propria, resulting in a break in the integrity of the colonic wall. Diverticula are most commonly encountered in the sigmoid colon. This anatomic restriction may be a result of the relative high-pressure zone within the muscular sigmoid colon. Higher-amplitude contractions combined with constipated, high-fat-content stool within the sigmoid lumen in an area of weakness in the colonic wall result in the creation of these diverticula.

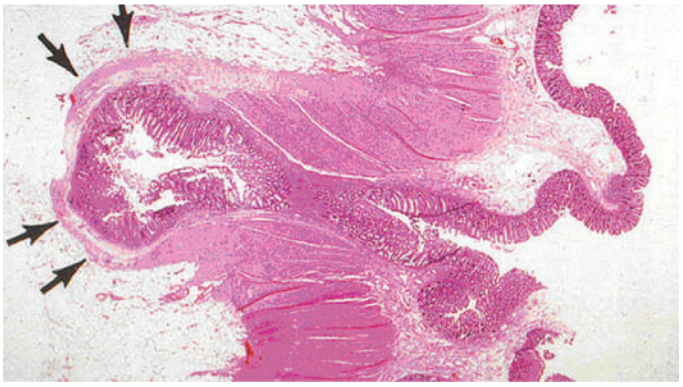


FIGURE 339-1 Gross and microscopic view of sigmoid diverticular disease. *Arrows* mark an inflamed diverticulum with the diverticular wall made up only of mucosa.

Consequently, the vasa recta is either compressed or eroded, leading to either perforation or bleeding.

As mentioned above, diverticula commonly affect the left and sigmoid colon; the rectum is always spared. However, in Asian populations, 70% of diverticula are seen in the right colon and cecum. *Diverticulitis* is inflammation of a diverticulum. Previous understanding of the pathogenesis of diverticulosis attributed the disease to poor dietary choices, and the onset of diverticulitis would occur acutely when these diverticula become obstructed. However, evidence now suggests that the pathogenesis is more complex and multifactorial. Better understanding of the gut microbiota suggests that dysbiosis is an important aspect of disease. Chronic low-grade inflammation is thought to play a key role in neuronal degeneration, leading to dysmotility and high intraluminal pressure. As a consequence, pockets or outpouchings develop in the colonic wall where it is weakest. Studies have also shown that it is more common for patients with diverticular disease to have abnormal collagen cross-linking. Researchers hypothesize that abnormal collagen cross-linking leads to loss of intestinal compliance and, therefore, higher intraluminal pressure, leading to pockets or outpouchings.

A newer approach to examine causality in diseases such as diverticulitis is to examine genome-wide associations (GWAs) using a variety of biobanks. Biobanks from Iceland, Denmark, and the United Kingdom have been examined for GWAs in diverticular disease and identified *LAMB4* and *TNFSF15* variants to be associate with early-onset, severe diverticular disease in otherwise healthy families. Although the exact function these genes play in the development of diverticular disease is unknown, the protein encoded by the gene *LAMB4* is part of the extracellular matrix lamin family, whereas the protein encoded by the gene *TNFSF15* is a member of the tumor necrosis family, which has implications in inflammation.

Presentation, Evaluation, and Management of Diverticular Bleeding Hemorrhage from a colonic diverticulum is the most common cause of hematochezia in patients >60 years, yet only 20% of patients with diverticulosis will have gastrointestinal bleeding. Patients at increased risk for bleeding tend to be hypertensive, have atherosclerosis, and regularly use anticoagulants and NSAIDs. Additional risk factors include obesity and a history of diabetes mellitus. Of note, due to increased use of anticoagulants in our aging population, there has been a rise in the incidence of diverticular bleeding. Most bleeds are self-limited and stop spontaneously with bowel rest. The lifetime risk of rebleeding is 25%.

Initial localization of diverticular bleeding may include colonoscopy, multiplanar computed tomography (CT) angiogram, or nuclear medicine tagged red cell scan. If the patient is stable, ongoing bleeding is best managed by angiography. If mesenteric angiography can localize the bleeding site, the vessel can be occluded successfully with a coil in 80% of cases. The patient can then be followed closely with repetitive colonoscopy, if necessary, looking for evidence of colonic ischemia. However, with highly selective coil embolization, the rate of colonic ischemia is <10%, and the risk of acute rebleeding is <25%. Long-term results (40 months) indicate that >50% of patients with acute diverticular bleeds treated with highly selective angiography have had definitive treatment. Alternatively, colonoscopic ligation with banding, placement of a detachable snare, and over-the-scope hemoclip have been shown to be effective methods to obtain hemostasis if the bleeding site can be localized. These approaches have been shown to prevent rebleeding or the requirement of emergent surgery. In the event that these measures fail to achieve hemostasis, a segmental resection of the colon may be undertaken. This may be advantageous in patients on chronic anticoagulation and immunosuppression as delayed bleeding and perforation have been reported in this subpopulation.

If the patient is refractory to angiographic or endoscopic treatments, unstable, or has required a large-volume transfusion, current recommendations are that surgery should be performed. If the bleeding has been localized, a segmental resection can be performed. If the site of bleeding has not been definitively identified, a subtotal colectomy may be required. In patients without severe comorbidities, surgical resection can be performed with a primary anastomosis. A higher anastomotic leak rate has been reported in patients who received >10 units of blood.

Stricture 5%
Fistula 2%

Presentation, Evaluation, and Staging of Diverticulitis Acute uncomplicated diverticulitis characteristically presents with fever, anorexia, left lower quadrant abdominal pain, and obstipation **(Table 339-1)**. The diagnosis of diverticulitis is best made on a contrast-enhanced abdominal and pelvic CT scan demonstrating the following findings: sigmoid diverticula, thickened colonic wall >4 mm, and inflammation within the pericolic fat without the collection of contrast material or fluid. Additional syndromes have been identified that relate to the presence of diverticulosis or diverticular disease. Symptomatic colitis-associated diverticulosis (SCAD) is uncommon (<1% of patients with diverticulosis) and occurs when inflammation is identified between the diverticula on endoscopic assessment. Symptoms of SCAD mimic irritable bowel disease. Symptomatic uncomplicated diverticular disease (SUDD) is a condition seen in patients with known diverticular disease and ongoing abdominal pain without evidence of overt inflammation on radiographic imaging.

Complicated diverticular disease is defined as diverticular disease associated with an abscess or perforation and less commonly with a fistula (Table 339-1). Symptoms of complicated diverticular disease may be similar to uncomplicated disease, or patients may exhibit signs of peritonitis indicating the presence of a diverticular perforation. If a pericolonic abscess has formed, the patient may have abdominal distention and signs of localized peritonitis. Laboratory investigations often demonstrate a leukocytosis. Rarely, a patient may present with an air-fluid level in the left lower quadrant on plain abdominal film. This should raise a concern for a giant diverticulum of the sigmoid colon and is managed with resection to avoid impending perforation.

Perforated diverticular disease is staged using the Hinchey classification system **(Fig. 339-2)**. This staging system was developed to predict outcomes following the surgical management of complicated diverticular disease. The Hinchey staging system has been modified to include the development of a phlegmon or early abscess (Hinchey stage Ia). In complicated diverticular disease with fistula formation, common locations include cutaneous, vaginal, or vesicle fistulas. These conditions present with either passage of stool through the skin or vagina or the presence of air in the urinary stream (pneumaturia). Colovaginal fistulas are more common in women who have undergone a hysterectomy.

TREATMENT

Medical Management of Diverticular Disease

Asymptomatic diverticular disease discovered on imaging studies or at the time of colonoscopy is best managed by lifestyle changes. Although the data regarding dietary risks and symptomatic diverticular disease are limited **(Table 339-2)**, patients may benefit from a fiber-enriched diet or supplements that include 30 g of fiber each day. The use of fiber decreases colonic transit time and, therefore, prevents increased intraluminal pressure, leading to the

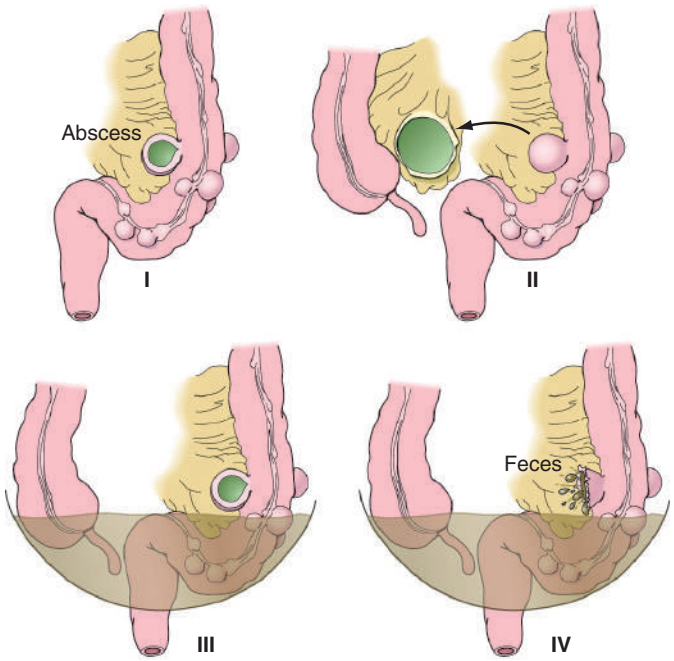

FIGURE 339-2 Hinchey classification of diverticulitis. Stage I: Perforated diverticulitis with a confined paracolic abscess. **Stage II:** Perforated diverticulitis that has closed spontaneously with distant abscess formation. **Stage III:** Noncommunicating perforated diverticulitis with fecal peritonitis (the diverticular neck is closed off, and therefore, contrast will not freely expel on radiographic images). **Stage IV:** Perforation and free communication with the peritoneum, resulting in fecal peritonitis.

development of diverticulosis. The incidence of complicated diverticular disease appears to also be increased in patients who smoke and are obese. Therefore, patients should be encouraged to refrain from smoking and to join a weight loss program. The historical recommendation to avoid eating nuts is based on no more than anecdotal data.

ANTIBIOTICS

The routine use of antibiotics in uncomplicated diverticular disease does not appear to reduce time to symptom resolution or reduce the risk of complications or recurrence. Two large, randomized trials (the AVOD trial and the Diabolo trial) and a large meta-analysis demonstrated that immunocompetent patients with uncomplicated diverticular disease had no difference in time to symptom resolution, recurrence rates, development of complicated diverticular disease, or surgery if treated with or without antibiotics. Currently, patients who are immunocompromised, have findings of extensive inflammation on radiographic studies, are at risk for disease progression, or have computed tomography (CT) findings of complicated diverticular disease should be treated with antibiotics. Known risk factors for disease progression included the American Society of Anesthesiologists (ASA) classification of III or IV, >5 days of symptoms, and elevation of C-reactive protein (CRP) or white blood cell (WBC) count.

If the use of antimicrobial therapy is desired, the current recommended antimicrobial coverage for uncomplicated acute diverticulitis is a third-generation cephalosporin (or ciprofloxacin if there is a known allergy to cephalosporins) and metronidazole targeting a mixed flora. Alternatively, single-agent therapy with a third-generation penicillin such as IV piperacillin or oral penicillin/clavulanic acid may be effective. The usual course of antibiotics is 5 days. A study compared the use of intravenous (IV) versus oral antibiotics in uncomplicated diverticular disease and noted no difference in recovery time or progression of the disease and recommended that safe home treatment on oral antibiotics after a 6-h observation in the emergency department is reasonable. Exclusion criteria for home treatment included complicated diverticular disease, immunocompromised patient, significant active comorbidities, poor social support, or a decline during observation.

DIET AND OTHER MEDICAL THERAPIES

Patients should remain on a limited diet until their pain resolves. The use of anti-inflammatory medications (mesalazine) in randomized clinical trials has shown them to be beneficial at reducing symptoms and disease recurrence in patients with SUDD. However, when objective signs of inflammation such as CRP and computerized imaging are taken into consideration, no benefit for the use of mesalazine has been shown.

Probiotics are increasingly used by gastroenterologists for multiple bowel disorders and may prevent recurrence of diverticulitis. Specifically, probiotics containing *Lactobacillus acidophilus* and *Bifidobacterium* strains may be beneficial; however, a systematic review was unable to show any benefit to the use of probiotics alone. The addition of fiber or mesalazine with probiotics has shown some promise in maintaining remission. Rifaximin (a poorly absorbed broad-spectrum antibiotic), when compared to fiber alone for the treatment of SUDD, is associated with 30% less frequent recurrent symptoms from uncomplicated diverticular disease.

COLONOSCOPY

Colonoscopy should be considered ~6 weeks after the first episode of uncomplicated diverticular disease and after the development of complicated diverticular disease as the overall prevalence of colon cancer is low in these patients (<2%) but higher incidence has been seen with complicated diverticulitis (6–8%). The parallel epidemiology of colorectal cancer and diverticular disease provides enough concern for an endoscopic evaluation before operative management.

SURGICAL MANAGEMENT OF DIVERTICULAR DISEASE

Preoperative risk factors influencing postoperative mortality rates include higher ASA physical status class **(Table 339-3)** and preexisting organ failure. In patients who are low risk (ASA P1 and P2), surgical therapy can be offered to those who do not rapidly improve on medical therapy. For uncomplicated diverticular disease, medical therapy can be continued beyond two attacks without an increased risk of perforation requiring a colostomy. However,

TABLE 339-2 The Use of Fiber in the Management of Diverticular Disease (DD)

JOURNAL, STUDY YEAR	PATIENTS (N)	INTERVENTION	STUDY LENGTH	FINDINGS
Lancet, 1977	18	Wheat or bran crisp bread	3 months	Significant reduction of symptoms score
BMJ, 1981	58	Bran, ispaghula, placebo	16 weeks	No difference
J Gastroenterol, 1977	30	Methylcellulose	3 months	Significant reduction in symptoms
BMJ, 2011	47,033	Vegetarian vs nonvegetarian	11.6 years	Vegetarians had a 31% lower risk of DD
Gastroenterology, 2012	2104	Fiber consumption	12 years	Fiber associated with great risk of DD
JAMA, 2008	47,288	Nut, corn, popcorn consumption	18 years	Higher nut, corn, and popcorn had lower risk of recurrence
Ann R Coll Surg Engl, 1985	56	Fiber consumption	66 months	Higher fiber associated with 19% reduction in symptom recurrence

patients on immunosuppressive therapy, in chronic renal failure, or with a collagen-vascular disease have a fivefold greater risk of perforation during recurrent attacks. A multicentered randomized clinical trial (DIRECT trial) comparing surgery with conservative management for recurrent SUDD demonstrated that elective surgical resection was associated with an improved quality of life and was more cost-effective at 5 years following resection as compared to conservative management. Surgical therapy is generally indicated in all low-surgical-risk patients with complicated diverticular disease. A randomized trial (LASER trial) examined the use of laparoscopic surgery for refractory or complicated diverticular disease and demonstrated improved quality of life and a reduction in recurrent symptoms by 50% when compared to conservative treatment.

The goals of surgical management of diverticular disease include controlling sepsis, eliminating complications such as fistula or obstruction, removing the diseased colonic segment, and restoring intestinal continuity. **Table 339-4** lists the operations most commonly indicated based on the Hinchey classification and the predicted postoperative outcomes. The current options for uncomplicated diverticular disease include an open or a minimally invasive resection of the diseased area with reanastomosis to the rectosigmoid. Preservation of portions of the sigmoid colon may lead to early recurrence of the disease. The benefits of minimally invasive resection over open surgical techniques include early discharge (by at least 1 day), less narcotic use, less postoperative complications, and an earlier return to work.

The options for the surgical management of complicated diverticular disease **(Fig. 339-3)** include the following open or minimally invasive procedures: (1) proximal diversion of the fecal stream with an ileostomy or colostomy and sutured omental patch with drainage, (2) resection with colostomy and mucous fistula or closure of distal bowel with formation of a Hartmann's pouch (Hartmann's procedure), (3) resection with anastomosis (coloproctostomy), or (4) resection with anastomosis and diversion (coloproctostomy with loop ileostomy or colostomy). (5) Laparoscopic technique of washout and drainage without diversion has been described for Hinchey III patients; however, a threefold increased risk of recurrent peritonitis requiring reoperation with washout alone has been reported. Robotic surgery resection for complicated diverticular disease is associated with a lower rate of conversion to an open procedure.

Patients with Hinchey stage Ia may be managed with antibiotic therapy only or followed by resection with anastomosis following further workup and symptom resolution. Patients with Hinchey stages Ib and II disease are managed with percutaneous drainage followed by resection with anastomosis following further evaluation and symptom resolution. Current guidelines put forth by the American Society of Colon and Rectal Surgeons suggest, in addition to antibiotic therapy, CT-guided percutaneous drainage of diverticular abscesses that are >3 cm and have a well-defined wall. Abscesses that are <5 cm may resolve with antibiotic therapy alone. Contraindications to percutaneous drainage are no percutaneous access route, pneumoperitoneum, and fecal peritonitis. Drainage of a diverticular abscess is associated with a 20–25% failure rate. Urgent operative intervention is undertaken if percutaneous drainage fails and patients develop generalized peritonitis, and most will need to be managed with a Hartmann's procedure (resection of the sigmoid colon with end colostomy and stapling of the rectosigmoid distal to the diseased segment). In selected cases, nonoperative therapy may be considered.

The management of Hinchey stage III disease is under debate. In this population of patients, no fecal peritonitis is present, and it is presumed that the perforation has sealed. Historically, Hinchey stage III has been managed with a Hartmann's procedure or with primary anastomosis and proximal diversion. Several studies have examined short- and long-term outcomes for laparoscopic peritoneal lavage to remove the peritoneal contamination and place drainage catheters should a communication to the bowel still exist. However, this procedure has been associated with an increased risk of requiring reoperation for ongoing peritonitis. Overall, ostomy rates are lower with the use of laparoscopic peritoneal lavage. No anastomosis of any type should be attempted in Hinchey stage IV disease or in the presence of fecal peritonitis. A limited approach to these patients is associated with a decreased mortality rate.

Recurrent Symptoms Recurrent abdominal symptoms following surgical resection for diverticular disease occur in 10% of patients. Recurrent diverticular disease develops in patients following inadequate surgical resection. A retained segment of diseased rectosigmoid colon is associated with twice the incidence of recurrence. The presence of irritable bowel syndrome may also cause recurrence of initial symptoms. Patients undergoing surgical resection for presumed diverticulitis and symptoms of chronic abdominal cramping and irregular loose bowel movements consistent with irritable bowel syndrome have poorer functional outcomes.

TABLE 339-4 Outcome Following Surgical Therapy for Complicated Diverticular Disease Based on Modified Hinchey Staging

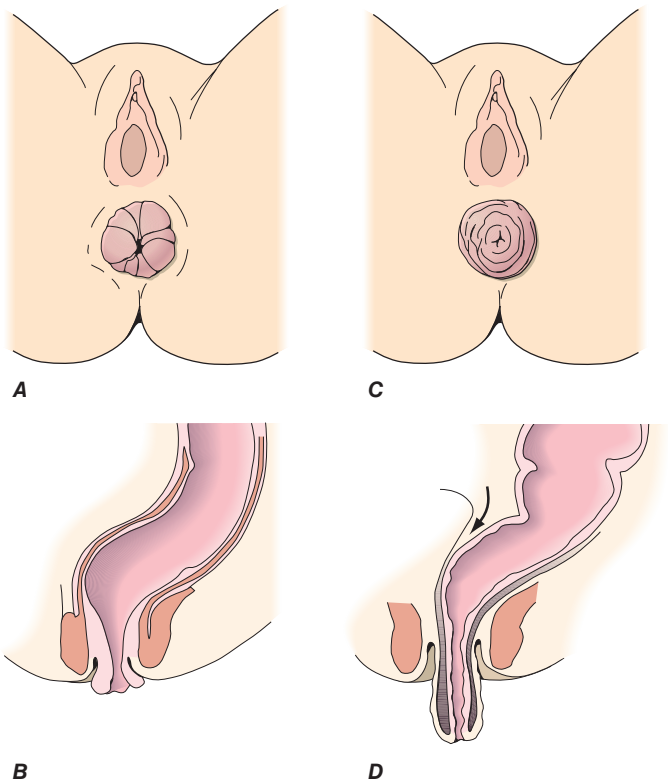

FIGURE 339-4 Degrees of rectal prolapse. Mucosal prolapse only (***A, B,*** sagittal view). Full-thickness prolapse associated with redundant rectosigmoid and deep pouch of Douglas (***C, D,*** sagittal view).

COMMON DISEASES OF THE ANORECTUM

RECTAL PROLAPSE (PROCIDENTIA)

Incidence and Epidemiology Rectal prolapse is six times more common in women than in men. The incidence of rectal prolapse peaks in women >60 years. Women with rectal prolapse have a higher incidence of associated pelvic floor disorders including urinary incontinence, rectocele, cystocele, and enterocele. About 20% of children with rectal prolapse will have cystic fibrosis. All children presenting with prolapse should undergo a sweat chloride test. Less common associations include Ehlers-Danlos syndrome, solitary rectal ulcer syndrome, congenital hypothyroidism, Hirschsprung's disease, dementia, cognitively impaired, and schizophrenia.

Anatomy and Pathophysiology Rectal prolapse (procidentia) is a circumferential, full-thickness protrusion of the rectal wall through the anal orifice. It is often associated with a redundant sigmoid colon, pelvic laxity, and a deep rectovaginal septum (pouch of Douglas). Initially, rectal prolapse was believed to be the result of early internal rectal intussusception, which occurs in the upper to mid rectum. This was considered to be the first step in an inevitable progression to full-thickness external prolapse. However, only 1 of 38 patients with internal prolapse followed for >5 years developed full-thickness prolapse. Others have suggested that full-thickness prolapse is the result of damage to the nerve supply to the pelvic floor muscles or pudendal nerves from repeated stretching with straining to defecate. Damage to the pudendal nerves would weaken the pelvic floor muscles, including the external anal sphincter muscles. Bilateral pudendal nerve injury is identified significantly more with full-thickness prolapse and fecal incontinence than unilateral injury.

Presentation and Evaluation In external prolapse, patient complaints include a palpable anal mass, bleeding per rectum, leakage of blood and mucus, and poor perianal hygiene. Prolapse of the rectum usually occurs following defecation and will spontaneously reduce or require the patient to manually reduce the prolapse. Constipation occurs in ~30–67% of patients with rectal prolapse. Differing degrees of fecal incontinence occur in 50–70% of patients. Patients with internal rectal prolapse will present with symptoms of both constipation and incontinence. Other associated findings include outlet obstruction (anismus) in 30%, colonic inertia in 10%, and solitary rectal ulcer syndrome in 12%.

Office evaluation is best performed after the patient has been given an enema, which enables the prolapse to protrude. An important distinction should be made between full-thickness rectal prolapse and isolated mucosal prolapse associated with hemorrhoidal disease (Fig. 339-4). Mucosal prolapse is known for radial grooves rather than circumferential folds around the anus and is due to increased laxity of the connective tissue between the submucosa and underlying muscle of the anal canal. The evaluation of prolapse should also include cystoproctography and colonoscopy. These examinations evaluate for associated pelvic floor disorders and rule out a malignancy or a polyp as the lead point for prolapse.

TREATMENT

Rectal Prolapse

The medical approach to the management of rectal prolapse is limited and includes stool-bulking agents or fiber supplementation to ease the process of evacuation. Surgical correction of rectal prolapse is the mainstay of therapy. Previously, the presence of internal rectal prolapse identified on imaging studies has been considered a nonsurgical disorder, and biofeedback was recommended. However, only one-third of patients will have successful resolution of symptoms from biofeedback. Two approaches are commonly considered: transabdominal and transperineal. Transabdominal approaches have been associated with lower recurrence rates, but some patients with significant comorbidities are better served by a transperineal approach.

Common transperineal approaches include a transanal proctectomy (Altmeier procedure), mucosal proctectomy (Delorme procedure), or placement of a Tirsch wire encircling the anus. The goal of the transperineal approach is to remove the redundant rectosigmoid

colon. Common transabdominal approaches include presacral suture or mesh rectopexy (Ripstein) with (Frykman-Goldberg) or without resection of the redundant sigmoid. Colon resection, in general, is reserved for patients with constipation and outlet obstruction. Ventral rectopexy is an effective method of abdominal repair of internal and full-thickness prolapse that does not require sigmoid resection. This repair has been shown to have improved pelvic floor functional results over other abdominal repairs. Transabdominal procedures can be performed effectively with laparoscopic and robotic techniques. Short- and long-term recurrence rates are low (<10%), and symptoms improved in more than three-fourths of patients.

FECAL INCONTINENCE

Incidence and Epidemiology Fecal incontinence is the involuntary passage of fecal material or the inability to control the initiation of defecation. The prevalence of fecal incontinence in adults in the United States approaches 15% and is expected to increase given our aging population. A higher incidence of incontinence is seen among older parous women. One-half of patients with fecal incontinence also suffer from urinary incontinence. The cause of fecal incontinence is often multifactorial; however, the majority of women with fecal incontinence are parous and may have experienced obstetrical injury to the pelvic floor, either while carrying a fetus or during the delivery. An anatomic sphincter defect may occur in up to 32% of women following childbirth regardless of visible damage to the perineum. Risk factors at the time of delivery include prolonged labor, the use of forceps, and the need for an episiotomy. Symptoms of incontinence can present two or more decades after obstetric injury. Medical conditions known to contribute to the development of fecal incontinence are listed in Table 339-5.

Anatomy and Pathophysiology The anal sphincter complex is made up of the internal and external anal sphincter. The internal sphincter is smooth muscle and a continuation of the circular fibers of the rectal wall. It is innervated by the intestinal myenteric plexus and is therefore not under voluntary control. The external anal sphincter is formed in continuation with the levator ani muscles and is under voluntary control. The pudendal nerve supplies motor innervation to the external anal sphincter. Obstetric injury may result in tearing of the muscle fibers anteriorly at the time of the delivery. This results in an obvious anterior defect on endoanal ultrasound. Injury may also be the result of stretching of the pudendal nerves during pregnancy or delivery of the fetus through the birth canal.

Presentation and Evaluation Patients may suffer with varying degrees of fecal incontinence. Fecal incontinence is classified into three categories based on the clinical presentation. These categories include passive incontinence (passage of stool without awareness), urge incontinence (leakage of stool despite attempts at holding), and fecal seepage (seepage of residue generally following defecation associated with normal continence). Beyond the immediate problems associated with fecal incontinence, these patients are often withdrawn and suffer from depression. For this reason, quality-of-life measures are an important component in the evaluation of patients with fecal incontinence.

The evaluation of fecal incontinence should include a thorough history and physical examination including digital rectal examination (DRE). Weak sphincter tone on DRE and loss of the "anal wink" reflex (S1-level control) may indicate a neurogenic dysfunction. Perianal scars may represent surgical injury. Other studies helpful in the diagnosis of fecal incontinence include anal manometry, pudendal nerve terminal motor latency (PNTML), and endoanal ultrasound. Centers that care for patients with fecal incontinence will have an anorectal physiology laboratory that uses standardized methods of evaluating anorectal physiology. Pudendal nerve studies evaluate the function of the nerves innervating the anal canal using a finger electrode placed in the anal canal. Stretch injuries to these nerves will result in a delayed response of the sphincter muscle to a stimulus, indicating a prolonged latency. Finally, endoanal ultrasound will evaluate the extent of the injury to the sphincter muscles before surgical repair. Unfortunately, all of these investigations are user-dependent, and very few studies demonstrate that these studies predict outcome following an intervention. Magnetic resonance imaging (MRI) has also been utilized in the evaluation of the sphincter muscle complex in treatment planning for fecal incontinence, but its role has not been well-established.

Rarely does a pelvic floor disorder exist alone. The majority of patients with fecal incontinence will have some degree of urinary incontinence. Similarly, fecal incontinence is a part of the spectrum of pelvic organ prolapse. For this reason, patients may present with symptoms of obstructed defecation as well as fecal incontinence. Careful evaluation including dynamic MRI or cinedefecography should be performed to search for other associated defects. Surgical repair of incontinence without attention to other associated defects may decrease the success of the repair.

• Scleroderma

TREATMENT

Fecal Incontinence

Medical management of fecal incontinence includes strategies to bulk up the stool, which help in increasing fecal sensation and complete evacuation. Stool bulking agents include fiber supplementation, loperamide, diphenoxylate, and bile acid binders. These agents help to bind the stool, resulting in more complete evacuation and decreasing the frequency of bowel movements. This can be particularly helpful in patients with mild symptoms of fecal incontinence. Patients may be offered a form of physical therapy called biofeedback. This therapy helps strengthen the external sphincter muscle while training the patient to relax with defecation to avoid unnecessary straining and further injury to the sphincter muscles. At a minimum, biofeedback is risk-free and most patients will have some improvement. For this reason, it should be incorporated into the initial recommendation to all patients with fecal incontinence. It is important to note that there is no medical or surgical therapy to reduce incontinence of flatus. Dietary alterations to reduce gas production and the use of probiotics are the only antidotal remedies.

Historically, the "gold standard" for the treatment of fecal incontinence with an isolated sphincter defect has been the overlapping sphincteroplasty. The external anal sphincter muscle and scar tissue, as well as any identifiable internal sphincter muscle, are dissected free from the surrounding adipose and connective tissue. An overlapping sphincter repair is performed in an attempt to rebuild the muscular ring and restore its function. However, long-term results following overlapping sphincteroplasty have been poor, with a 50% failure rate over 5 years.

Alternative therapies for the treatment of fecal incontinence included sacral nerve modulation, collagen-enhancing injectables,

and anal implantable self-expanding prostheses (THD Gatekeeper and Sphinkeeper). Sacral nerve stimulation (SNS) was the first implantable pacemaker and is a U.S. Food and Drug Administration (FDA)-approved adaptation of a procedure developed for the management of urinary incontinence. SNS is indicated in patients with two or more episodes of frank fecal incontinence per week. Long-term results for SNS have been promising, with nearly 80% of patients having a reduction in incontinence episodes by at least 50%. There are inherent challenges with the SNS device, and to avoid these challenges, percutaneous or transcutaneous tibial nerve stimulation (PTNS or TTNS) is being offered to patients with fecal incontinence. PTNS is offered in a clinical setting, while TTNS can be performed at home. Both require weekly sessions of stimulation of the tibial nerve, which serves to feedback to the third sacral nerve root. Collagen-enhancing injectables and anal self-expanding implants have been around for several years. Results from randomized trials have been variable but support the use of injectables/implantables in patients who are not candidates for sacral nerve modulation.

Finally, the use of stem cells to increase the bulk of the sphincter muscles is currently being tested. Stem cells can be harvested from the patient's own muscle, grown, and then implanted into their sphincter complex. Concern for cost and the need for an additional procedure have dampened enthusiasm.

MIXED CONSTIPATION AND FECAL INCONTINENCE

It is estimated that up to 20% of patients presenting for evaluation of fecal incontinence have mixed constipation and fecal incontinence. Fecal incontinence, in this instance, is related to the large number of laxatives required to produce stool evacuation. This condition is more difficult to manage and often requires close collaboration with different specialties. One promising intervention is the use of a transanal irrigation system (Peristeen by Coloplast). This system provides daily irrigations of the left side of the colon to assist with evacuations and has shown promising results. The daily assistance with evacuation leads to less need for oral laxatives and reduced episodes of incontinence. One drawback is long-term adherence to the irrigations.

HEMORRHOIDAL DISEASE

Incidence and Epidemiology Symptomatic hemorrhoids affect >1 million individuals in the Western world per year. Hemorrhoidal disease can occur at any age and affects females and males at similar rates. The prevalence of hemorrhoidal disease is less in developing countries. The typical low-fiber, high-fat diet prominent in developed countries is associated with constipation and straining and the development of symptomatic hemorrhoids. Other risk factors for hemorrhoids include pregnancy and high-impact activities (bike riding).

Anatomy and Pathophysiology Hemorrhoidal cushions are a normal part of the anal canal. The vascular structures contained within this tissue aid in continence by preventing damage to the sphincter muscle. Three main hemorrhoidal complexes traversing the anal canal include the left lateral, the right anterior, and the right posterior. Prolonged engorgement with straining leads to prolapse of this tissue into the anal canal. Over time, the anatomic support system of the hemorrhoidal complex weakens, exposing this tissue to the outside of the anal canal where it is susceptible to injury. Hemorrhoids are commonly classified as external or internal. External hemorrhoids originate below the dentate line and are covered with squamous epithelium and are not associated with an internal component. Internal hemorrhoids originate above the dentate line and are covered with mucosa and transitional zone epithelium and represent the majority of hemorrhoids.

Presentation and Evaluation Patients commonly present to a physician for two reasons: bleeding and protrusion. Pain is less common than with fissures and, if present, is described as a dull ache from engorgement of the hemorrhoidal tissue. Severe pain may indicate a thrombosed external hemorrhoid. Hemorrhoidal bleeding is described as painless bright red blood seen either in the toilet or upon wiping. Occasional patients can present with significant bleeding, which may be a cause of anemia; however, the presence of a colonic neoplasm must be ruled out in anemic patients, especially given the noted rise in young patients with colorectal cancer. Patients who present with protruding tissue complain about inability to maintain perianal hygiene and anal itching (pruritis) and are often concerned about the presence of a malignancy.

The diagnosis of hemorrhoidal disease is made on physical examination. Inspection of the perianal region for evidence of thrombosis or excoriation is performed, followed by a careful digital examination. Anoscopy is performed paying particular attention to the known position of hemorrhoidal disease. The patient is asked to strain. It is important to differentiate the circumferential appearance of a full-thickness rectal prolapse from the radial nature of prolapsing hemorrhoids (see "Rectal Prolapse," above). The stage and location of the hemorrhoidal complexes are defined.

TREATMENT

Hemorrhoidal Disease

The treatment for bleeding hemorrhoids is based on the stage of the disease **(Table 339-6)**. In all patients with bleeding, the possibility of other causes must be considered, and further studies should include endoscopic assessments.

With rare exceptions, the acutely thrombosed hemorrhoid can be excised within the first 48 h by performing an elliptical excision and clot extraction. This can often be performed at the bedside with local anesthesia; sitz baths, fiber, and stool softeners are prescribed. Additional nonoperative therapies for bleeding hemorrhoids include rubber band ligation, infrared coagulation, and sclerotherapy. Sensation begins at the dentate line; therefore, all procedures can be performed without discomfort either endoscopically or in the office. Bands are placed around the engorged tissue, causing ischemia and fibrosis. This aids in fixing the tissue proximally in the anal canal. Patients may complain of a dull ache for 24 h following band application. During sclerotherapy, 1–2 mL of a sclerosant (usually sodium tetradecyl sulfate) is injected using a 25-gauge needle into the submucosa of the hemorrhoidal complex. Care must be taken not to inject the anal canal circumferentially, or stenosis may occur.

For surgical management of hemorrhoidal disease, excisional hemorrhoidectomy with sharp dissection (Milligan-Morgan hemorrhoidectomy), bipolar electrocautery ligation (LigaSure), transhemorrhoidal dearterialization (THD), and stapled hemorrhoidectomy ("the procedure for prolapse or hemorrhoids" [PPH]) are the procedures of choice. All surgical methods of management

TABLE 339-6 The Staging and Treatment of Hemorrhoids

STAGE	DESCRIPTION OF CLASSIFICATION	TREATMENT
I	Enlargement with bleeding	Fiber supplementation Short course of cortisone suppository Sclerotherapy Infrared coagulation
II	Protrusion with spontaneous reduction	Fiber supplementation Short course of cortisone suppository Sclerotherapy Infrared coagulation
III	Protrusion requiring manual reduction	Fiber supplementation Short course of cortisone suppository Rubber band ligation Operative hemorrhoidectomy
IV	Irreducible protrusion	Fiber supplementation Cortisone suppository Operative hemorrhoidectomy

are equally effective in the treatment of symptomatic third- and fourth-degree hemorrhoids. Current postprocedure outcomes following hemorrhoidectomy target improvements in bleeding, pain, and recurrence rates. The sutured hemorrhoidectomy involves the removal of redundant tissue down to the anal verge, and unpleasant anal skin tags are removed as well. However, pain and postoperative bleeding are more common. The stapled hemorrhoidectomy is associated with less discomfort; however, this procedure does not remove anal skin tags, and an increased number of complications are associated with use of the stapling device. THD uses ultrasound guidance to ligate the blood supply to the anal tissue, hence reducing hemorrhoidal engorgement. Ligation with electrocautery uses a bipolar device (LigaSure) to remove the unwanted prolapsed tissue. Both THD and ligation with electrocautery have demonstrated similar short-term and long-term results; however, ligation with electrocautery requires less operative time. No procedures on hemorrhoids should be done in patients who are immunocompromised or who have active proctitis. Emergent hemorrhoidectomy for bleeding hemorrhoids is associated with a higher complication rate.

Acute complications associated with the treatment of hemorrhoids include pain, infection, recurrent bleeding, and urinary retention. Care should be taken to place bands properly and to avoid overhydration in patients undergoing operative hemorrhoidectomy. Late complications include fecal incontinence as a result of injury to the sphincter during the dissection. Anal stenosis may develop from overzealous excision, with loss of mucosal skin bridges for reepithelialization. Finally, an *ectropion* (prolapse of rectal mucosa from the anal canal) may develop. Patients with an ectropion complain of a "wet" anus as a result of inability to prevent soiling once the rectal mucosa is exposed below the dentate line.

ANORECTAL ABSCESS

Incidence and Epidemiology The development of a perianal abscess is more common in men than women by a ratio of 3:1. The peak incidence is in the third to fifth decade of life. Perianal pain associated with the presence of an abscess accounts for 15% of office visits to a colorectal surgeon. The disease is more prevalent in immunocompromised patients such as those with diabetes, hematologic disorders, or inflammatory bowel disease (IBD) and persons who are HIV positive. These disorders should be considered in patients with recurrent perianal infections.

Anatomy and Pathophysiology An anorectal abscess is an abnormal fluid-containing cavity in the anorectal region. Anorectal abscess results from an infection involving the glands surrounding the anal canal. Normally, these glands release mucus into the anal canal, which aids in defecation. When stool accidentally enters the anal glands, the glands become infected, and an abscess develops. Anorectal abscesses are perianal in 40–50% of patients, ischiorectal in 20–25%, intersphincteric in 2–5%, and supralevator in 2.5% **(Fig. 339-5)**.

Presentation and Evaluation Perianal pain and fever are the hallmarks of an abscess. Patients may have difficulty voiding and have blood in the stool. On physical examination, a large fluctuant area is usually readily visible. Routine laboratory evaluation shows an elevated WBC count. Diagnostic procedures are rarely necessary unless evaluating a recurrent abscess. A CT scan or MRI has an accuracy of 80% in determining incomplete drainage. If there is a concern about the presence of IBD, a rigid or flexible sigmoidoscopic examination may be done at the time of drainage to evaluate for inflammation within the rectosigmoid region. A more complete evaluation for Crohn's disease would include a full colonoscopy and small-bowel enterography.

TREATMENT

Anorectal Abscess

As with all abscesses, the "gold standard" is drainage. Office drainage of an uncomplicated anorectal abscess may suffice. A small incision close to the anal verge is made, and a Mallenkot drain is advanced into the abscess cavity. The Mallenkot catheter (a mushroom-shaped catheter with grooves) can be maintained by the patient for up to 1 week before being removed to avoid tissue ingrowth. For patients with a complicated abscess or who are diabetic or immunocompromised, drainage should be performed in an operating room under anesthesia. These patients are at greater risk for developing necrotizing fasciitis. The role of antibiotics in the management of anorectal abscesses is limited. Antibiotics are only warranted in patients who are immunocompromised or have obvious cellulitis on physical exam.

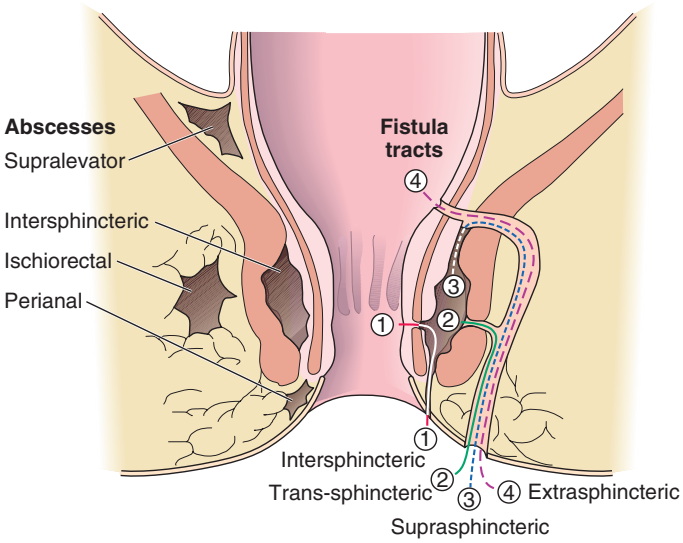

FIGURE 339-5 Common locations of anorectal abscess (*left*) and fistula in ano (*right*).

FISTULA IN ANO

Incidence and Epidemiology The incidence of fistulizing perianal disease parallels the incidence of anorectal abscess and is estimated to be 1 in 10,000 individuals. Some 30–40% of abscesses will give rise to an anal fistula. Although the majority of the fistulas are cryptoglandular in origin, 10% are associated with IBD, tuberculosis, malignancy, and radiation.

Anatomy and Pathophysiology An anal fistula is defined as a communication of an abscess cavity with an identifiable internal opening within the anal canal. This identifiable opening is commonly located at the dentate line where the anal glands enter the anal canal. Patients experiencing continuous drainage at 1 month following the treatment of a perianal abscess likely have an anal fistula. These fistulas are classified by their relationship to the anal sphincter muscles, with 70% being intersphincteric, 23% transsphincteric, 5% suprasphincteric, and 2% extrasphincteric (Fig. 339-5).

Presentation and Evaluation A patient with an anal fistula will complain of constant drainage from the perianal region associated with tenderness. Examination under anesthesia is the best way to evaluate a fistula. However, in cases with a complex fistula, a preoperative MRI will identify tracts with an accuracy of 80%. During surgery, hydrogen peroxide injected through the external opening will aid in identifying the internal opening. Goodsall's rule states that a posterior external fistula will enter the anal canal in the posterior midline, whereas an anterior fistula will enter at the nearest crypt. A fistula exiting >3 cm from the anal verge may have a complicated upward extension and may not obey Goodsall's rule.

TREATMENT

Fistula in Ano

A newly diagnosed draining fistula is best managed with an operative intervention including initial placement of a seton catheter (a vessel loop or silk tie placed through the fistula tract), which

maintains the tract patency and reduces the likelihood of recurrent infection and inflammation. Once the inflammation is reduced (4–6 weeks), the exact relationship of the fistula tract to the anal sphincters can be ascertained. Two general approaches are common: sphincter-cutting procedures and sphincter-sparing procedures. A simple fistulotomy or fistulectomy is a sphincter-cutting procedure and is usually performed for intersphincteric and low (less than one-third of the muscle) transsphincteric fistulas. In a systematic review, sphincter-cutting procedures were associated with a 94% success rate and a 13% rate of mild fecal incontinence. Sphincter-sparing surgery is usually performed for a higher transsphincteric fistula. These procedures include an anorectal advancement flap, ligation of the internal fistula tract (LIFT procedure), or insertion of fibrin or cyanoacrylate glue. Sphincter-preserving procedures are associated with up to 78% success rates with no incidence of fecal incontinence.

Fistulizing disease of the anus is common in Crohn's disease, and the use of mesenchymal stem cell therapy may improve healing rates of fistula associated with Crohn's disease. The ADMIRE study examined the use of allogeneic expanded adipose-derived mesenchymal stem cells in the treatment of complex perianal fistula in Crohn's disease. The study included 212 patients randomized to stem cell therapy or placebo. Fistula remission rates at 52 weeks were significantly higher with the use of stem cell therapy over placebo (59 vs 42%, respectively). Further studies are currently being performed to elucidate the benefits of stem cell therapy in perianal fistula. As with any stem cell therapy, the cost can be prohibitive to its standard use.

ANAL FISSURE

Incidence and Epidemiology Anal fissures occur at all ages but are more common in the third through the fifth decades. The prevalence is equal in males and females. It is associated with constipation, diarrhea, infectious etiologies, perianal trauma, and Crohn's disease.

Anatomy and Pathophysiology Trauma to the anal canal occurs following defecation. This injury occurs in the anterior or, more commonly, posterior anal canal. Irritation caused by the trauma to the anal canal results in an increased resting pressure of the internal sphincter. The blood supply to the sphincter and anal mucosa enters laterally. Therefore, increased anal sphincter tone results in a relative ischemia in the region of the fissure and leads to poor healing of the anal injury. A fissure that is not in the posterior or anterior position should raise suspicion for other causes, including tuberculosis, syphilis, Crohn's disease, and malignancy.

Presentation and Evaluation A fissure can be easily diagnosed on history alone. The classic complaint is pain, which is strongly associated with defecation and is relentless. The bright red bleeding that can be associated with a fissure is less extensive than that associated with hemorrhoids and is usually only noted on wiping. On examination, most fissures are located in either the posterior or anterior position. A lateral fissure is worrisome because it may have a less benign nature, and systemic disorders should be ruled out. A chronic fissure is indicated by the presence of a hypertrophied anal papilla at the proximal end of the fissure and a sentinel pile or skin tag at the distal end. Often the circular fibers of the hypertrophied internal sphincter are visible within the base of the fissure.

TREATMENT

Anal Fissure

The management of the acute fissure is conservative. Stool softeners for those with constipation, increased dietary fiber, topical anesthetics, glucocorticoids, and sitz baths are prescribed and will heal 60–90% of fissures. Chronic fissures are those present for >6 weeks. These can be treated with modalities aimed at decreasing the anal canal resting pressure including nifedipine ointment applied three times a day and botulinum toxin type A, up to 20 units, injected into the internal sphincter on each side of the fissure. Both treatments are associated with a fissure healing rate of >80%. Surgical management includes anal dilatation and lateral internal sphincterotomy. Usually, one-third of the internal sphincter muscle is divided; it is easily identified because it is hypertrophied. Recurrence rates from medical therapy are higher, but this is offset by a risk of incontinence following sphincterotomy. Lateral internal sphincterotomy may lead to incontinence more commonly in women.

340 Mesenteric Vascular Insufficiency

Daniel Willie-Permor, Mahmoud Malas

INTESTINAL ISCHEMIA

INCIDENCE AND EPIDEMIOLOGY

Intestinal ischemia occurs when splanchnic perfusion fails to meet the metabolic demands of the intestines, resulting in ischemic tissue injury. Mesenteric ischemia affects 2–3 people per 100,000 with an increasing incidence in the aging population. Mortality with acute presentation remains high (between 50 and 80%), and early diagnosis and prompt intervention are crucial in improving clinical outcomes. Intestinal ischemia is further classified into chronic mesenteric ischemia (CMI) and acute mesenteric ischemia (AMI). CMI is secondary to multiple major visceral arterio-occlusive disease with involvement of the superior mesenteric artery (SMA) most worrisome. AMI is most associated with

(1) arterio-occlusive mesenteric ischemia, (2) nonocclusive mesenteric ischemia, and (3) mesenteric venous thrombosis.

CMI is the failure to achieve normal postprandial hyperemic intestinal blood flow. This occurs due to an imbalance between supply and demand of oxygen metabolites to the intestinal tract similar to cardiac angina. CMI occurs due to significant atherosclerotic disease leading to the narrowing of the SMA and/or celiac artery origins.

AMI is the occurrence of an abrupt cessation of mesenteric blood flow, usually embolic or thrombotic in nature. Approximately 50% of AMI is due to embolus to the mid to distal SMA. The embolus etiology includes atrial fibrillation, recent myocardial infarction, soft atherosclerotic plaque, infective endocarditis, valvular heart disease, and recent cardiac or vascular catheterization. Approximately 25–30% of the cases are characterized by an acute-on-chronic thrombosis in patients with preexisting mesenteric atherosclerosis. Thrombotic occlusion most commonly occurs at areas of severe atherosclerotic narrowing at the SMA and the celiac artery.

Nonocclusive mesenteric ischemia represents 20% of the cases and is secondary to intestinal ischemia when subjected to acute hemodynamic instability. Patients above the age of 50, especially those with coexisting conditions like myocardial infarction, congestive heart failure, aortic insufficiency, and renal or liver disease, who are also undergoing cardiovascular surgery, face the highest risk. Hypovolemia, shock, and use of vasoconstrictive agents (e.g., digoxin, α-adrenergic agonists, cocaine) can precipitate ischemia in these patients. It is the most prevalent gastrointestinal disease complicating cardiovascular surgery. The incidence of ischemic colitis following elective aortic repair is 5–9%, and the incidence triples in patients following emergent repair.

Mesenteric venous thrombosis accounts for <10% of cases and is generally precipitated by a hypercoagulable state due to an underlying inherited disorder such as factor V Leiden, prothrombin mutation, protein S deficiency, protein C deficiency, antithrombin deficiency, and antiphospholipid syndrome. It may also occur as a result of acquired thrombophilia in malignancies, hematologic disorders, and use of oral contraceptives.

ANATOMY AND PATHOPHYSIOLOGY

The blood supply to the intestines is supplied by the celiac artery, SMA, and inferior mesenteric artery (IMA) **(Fig. 340-1)**. Extensive collateralization occurs between major mesenteric trunks and branches of the mesenteric arcades. Collateral vessels within the small bowel are numerous and meet within the duodenum and the bed of the pancreas. Collateral vessels within the colon meet at the splenic flexure and descending/sigmoid colon. These areas, which are inherently at risk for decreased blood flow, are known as Griffiths' point and Sudeck's point, respectively, and are the most common locations for colonic ischemia (Fig. 340-1, shaded areas). The splanchnic circulation can receive up to 30% of the cardiac output. Protective responses to prevent intestinal ischemia include abundant collateralization, autoregulation of blood flow, and the ability to increase oxygen extraction from the blood.

Occlusive ischemia is a result of disruption of blood flow by an embolus or progressive thrombosis in a major artery supplying the intestine. In >75% of cases, emboli originate from the heart and preferentially lodge in the SMA just distal to the origin of the middle colic artery. Progressive stenosis of typically two of the three major vessels supplying the intestine is required for the development of chronic intestinal angina. Involvement of the SMA is most worrisome. Nonocclusive ischemia is disproportionate mesenteric vasoconstriction (arteriolar vasospasm) in response to a severe physiologic stress such as shock. If left untreated, early mucosal stress ulceration will progress to full-thickness injury.

PRESENTATION, EVALUATION, AND MANAGEMENT

Patients with CMI typically present with insidious onset of symptoms and classically present with recurrent episodes of acute dull, crampy, postprandial epigastric pain, which has also been referred to as "intestinal angina." Patients also describe fear of eating resulting in weight loss.

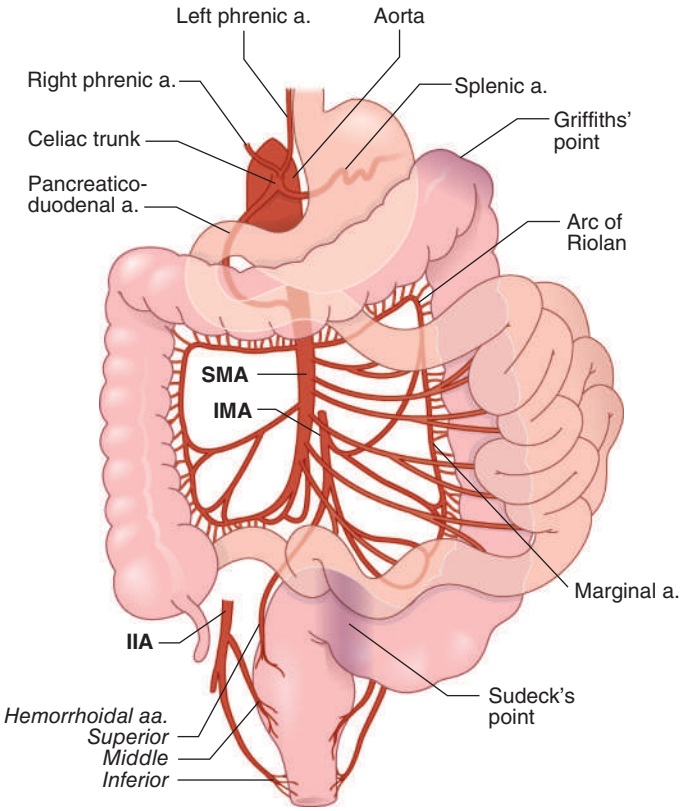

FIGURE 340-1 Blood supply to the intestines includes the celiac artery, superior mesenteric artery (SMA), inferior mesenteric artery (IMA), and branches of the internal iliac artery (IIA). Griffiths' and Sudeck's points, indicated by shaded areas, are watershed areas within the colonic blood supply and common locations for ischemia.

Chronic diarrhea may also be noted. Duration of symptoms is typically 6–12 months. Physical examination will often reveal a malnourished patient with other manifestations of atherosclerosis. Prompt diagnostic investigation is necessary to rule out gastrointestinal malignancies and other possible causes, and may include accelerated evaluation via esophagogastroduodenoscopy, colonoscopy, abdominal computed tomography (CT) scan, and abdominal ultrasound examination.

Duplex ultrasound has gained popularity as a screening tool for evaluation of the mesenteric vessels due to high sensitivity and specificity. Mesenteric duplex scan demonstrating a high peak velocity of flow in the SMA is associated with an ~80% positive predictive value of mesenteric ischemia. More significantly, a negative duplex scan virtually precludes the diagnosis of mesenteric ischemia. It is important to perform the test while the patient is fasting because the presence of increased bowel gas prevents adequate visualization of flow disturbances within the vessels or the lack of a vasodilation response to feeding during the test. Thin-sliced CT angiography is the gold standard diagnostic tool in assessing the degree of atherosclerotic disease of the aortic and visceral vessels as well as evaluating the bowels. Venous phase can also help diagnose mesenteric vein thrombosis.

The management of CMI includes aggressive medical therapy of atherosclerotic disease including cessation of smoking and antiplatelet and lipid-lowering medications. A full cardiac and vascular evaluation should be performed before intervention on CMI.

Treatment, involving either endovascular, open surgical, or hybrid revascularization, should be individualized based on the patient's comorbidities and anatomy. Endovascular revascularization involves targeted vessel treatment with visceral stents with the SMA anatomy being the key determinant. The revascularization of the celiac axis and IMA represents secondary focal points, offering potential therapeutic benefits. This approach becomes particularly relevant when the SMA is deemed unsuitable for intervention or when technical outcomes are deemed suboptimal. Open revascularization involves antegrade bypass from the supraceliac aorta or retrograde bypass typically from

the common or external iliac arteries with a synthetic or autogenous graft to the targeted vessels, usually the SMA and/or celiac artery. In patients with suitable lesions requiring revascularization, an endovascular approach is recommended as the first-line therapy. It is especially favorable for short segment stenosis with minimal to moderate calcification or thrombus. Angioplasty with endovascular stenting in the treatment of CMI is associated with an 80% long-term success rate. Open revascularization should be considered in patients with lesions not amenable to endovascular treatment, such as severe calcification, longer lesions, small vessel diameter, or failed endovascular interventions, or in a specific subset of younger, healthier patients, in whom the potential long-term advantages may outweigh the heightened perioperative risks. Retrograde open mesenteric stenting (ROMS) is a hybrid approach, combining aspects of both traditional open surgical bypass and percutaneous endovascular therapy. ROMS is primarily indicated for treating mesenteric ischemia, both acute and chronic, particularly in cases where conventional endovascular or open surgical approaches are not feasible or have been unsuccessful. This includes scenarios where there is significant stenosis or occlusion in the mesenteric arteries that cannot be adequately addressed through less invasive percutaneous methods from the aorta or in situations where immediate direct visualization and potential resection of the bowel are necessary due to the presence of necrosis or perforation. The technique involves a laparotomy that allows for direct bowel assessment and the exposure and stenting of the SMA using a retrograde approach through the midsegment of the SMA, thus allowing for immediate revascularization, assessment of bowel viability, and, if necessary, bowel resection. ROMS also offers the advantage of faster operative times compared to traditional bypass and avoids the placement of prosthetic material in potentially contaminated peritoneal cavities, which is a significant concern in the setting of bowel necrosis and peritonitis.

Acute intestinal ischemia remains one of the most challenging diagnoses. The mortality rate of AMI is >50%. The most significant indicator of survival is the timeliness of diagnosis and treatment. An overview of diagnosis and management of each form of intestinal ischemia is given in **Table 340-1**.

AMI resulting from arterial embolus or thrombosis presentation is nonspecific and requires a high index of suspicion for the diagnosis. The most common complaint, occurring in 95% of cases, is severe, acute, nonremitting abdominal pain that is strikingly out of proportion to the physical findings. The reason behind the pain being disproportionate to the clinical findings is that ischemia initiates from the mucosal layer and progresses toward the serosal layer. This may be associated with nausea (44%), vomiting (35%), diarrhea (35%), and blood per rectum (16%). Later findings will demonstrate peritonitis and cardiovascular collapse. Specific clinical features can help differentiate the underlying etiology, whether embolic or thrombotic. Patients with embolic ischemia are typically older adults with underlying conditions that predispose to embolism such as atrial fibrillation, prior embolic event, or recent infective endocarditis. Thrombotic ischemia typically presents as an acute occlusion in patients with underlying atherosclerotic disease who may have been previously diagnosed with CMI.

AMI is a surgical emergency requiring emergent admission to a monitored bed or intensive care unit for resuscitation with fluids and broad-spectrum antibiotics in addition to further evaluation. If the diagnosis of intestinal ischemia is being considered, consultation with a surgical service is necessary. Often the decision to operate is made on a high index of suspicion from the history and physical exam despite normal laboratory findings. In patients with suspected AMI, a CT angiography with 1-mm or thinner cuts should be used to detect mesenteric arterial occlusive disease most likely from embolic or thrombotic etiology and is the gold standard. Additional diagnostic modalities that may be useful in diagnosis, but should not delay surgical therapy, include electrocardiogram (ECG) and echocardiogram. Patients with AMI should be given a heparin bolus immediately and started on a therapeutic heparin drip. Correction of electrolyte abnormalities and empiric broad-spectrum antibiotic therapy should also be initiated instantly.

If CT angiography verifies acute embolic occlusion of the SMA, surgical exploration should not be delayed. The goal of operative exploration is to resect compromised bowel, restore blood supply, and preserve all viable bowel. The entire length of the small and large bowel beginning at the ligament of Treitz should be evaluated. The SMA artery should be localized, typically at the mesocolon of the transverse colon. A transverse arteriotomy of the SMA should be made with removal of embolus with an embolectomy Fogarty catheter passed in a retrograde and antegrade manner to restore blood flow. In the case of SMA occlusion where the embolus usually lies just proximal to the origin of the middle colic artery, the proximal jejunum is often spared while the remainder of the small bowel up to the transverse colon may become ischemic. Nonviable bowel should be resected. Questionable bowel

TABLE 340-1 Overview of the Management of Acute Intestinal Ischemia

CONDITION	KEY TO EARLY DIAGNOSIS	TREATMENT OF UNDERLYING CAUSE	TREATMENT OF SPECIFIC LESION	TREATMENT OF SYSTEMIC CONSEQUENCE
Arterio-occlusive mesenteric ischemia 1. Arterial embolus	Computed tomography angiography (CTA) Early laparotomy	Anticoagulation Cardioversion Thrombectomy Broad-spectrum antibiotics	Laparotomy Embolectomy Assess viability and resect nonviable bowel	Anticoagulation Resuscitation Broad-spectrum antibiotics Emergent surgical intervention Assessment of bowel
2. Arterial thrombosis	Duplex ultrasound CTA	Anticoagulation Broad-spectrum antibiotics Resuscitation	Endovascular approach: thrombolysis, angioplasty, and stenting Endarterectomy/thrombectomy or vascular bypass Assess viability and resect nonviable bowel	Anticoagulation Resuscitation Broad-spectrum antibiotics Emergent surgical intervention Assessment of bowel
Mesenteric venous thrombosis Venous thrombosis	CTA with venous phase	Anticoagulation Resuscitation	Anticoagulation Hypercoagulable workup	Anticoagulation Resuscitation Broad-spectrum antibiotics Support cardiac output Avoid vasoconstrictors
Nonocclusive mesenteric ischemia	Vasospasm: Hypoperfusion: CT	Resuscitation Support cardiac output Avoid vasoconstrictors Broad-spectrum antibiotics	Vasospasm Intraarterial vasodilators Hypoperfusion Assess viability and resect dead bowel	Resuscitation Broad-spectrum antibiotics Support cardiac output Avoid vasoconstrictors

Source: Modified from GB Bulkley, in JL Cameron (ed): *Current Surgical Therapy*, 2nd ed. Toronto, BC Decker, 1986.

should undergo a second-look laparotomy in a 24- to 48-h period. After revascularization, peristalsis and return of a pink color of the bowel wall should be observed. Palpation of major arterial mesenteric vessels can be performed, as well as applying a Doppler flowmeter to the antimesenteric border of the bowel wall, but neither is a definitive indicator of viability.

Acute-on-chronic mesenteric ischemia typically involves the orifice of the SMA. Therefore, the entire small bowel is compromised. Revascularization with an endovascular, open, and/or a hybrid approach should be individualized based the patient's critical status, comorbidities, and anatomy. Endovascular stenting, suction thrombectomy, and/or a thrombolysis catheter should be considered for intervention. The bowel should be evaluated for viability typically via a laparoscopic or exploratory laparotomy.

Nonocclusive or vasospastic mesenteric ischemia presents with generalized abdominal pain, anorexia, bloody stools, and abdominal distention. Often these patients are obtunded, and physical findings may not assist in the diagnosis or be obscured by the underlying etiology. The presence of leukocytosis, metabolic acidosis, and/or lactic acidosis is useful in support of the diagnosis of advanced intestinal ischemia; however, these markers may not be indicative of either reversible ischemia or frank necrosis.

Emergent admission to a monitored bed or intensive care unit is recommended for resuscitation and further evaluation, and the patient should be started on broad-spectrum antibiotics. Anticoagulation is not recommended as the goal is resuscitation to maintain hemodynamics. For select patients, intramesenteric infusion of vasodilators such as papaverine, prostaglandins, or nitroglycerin can be used for the reversal of spasm and mesenteric ischemia, but the priority should be resuscitation and treatment of the underlying pathology. If ischemic colitis is a concern, colonoscopy should be considered to assess the integrity of the colonic mucosa. Ischemia of the colonic mucosa is graded as mild with minimal mucosal erythema or as moderate with pale mucosal ulcerations and evidence of extension to the muscular layer of the bowel wall. Severe ischemic colitis presents with severe ulcerations resulting in black or green discoloration of the mucosa, consistent with full-thickness bowel-wall necrosis. Ischemic colitis is optimally treated with resection of the ischemic bowel and formation of a proximal stoma.

Onset of mesenteric venous thrombosis can be acute or subacute based on the location of thrombosis in the splanchnic circulation. Patients often present with vague abdominal pain associated with nausea and vomiting. Physical examination findings include abdominal distention with mild to moderate tenderness and signs of dehydration. Findings on CT delayed venous phase include diffuse bowel-wall thickening and thrombus within the splanchnic system. IV therapeutic anticoagulation, broad-spectrum antibiotics, and correction of electrolyte abnormalities should be performed. Surgical intervention is not performed unless there is evidence of peritonitis and/or bowel perforation. If there is evidence of bowel compromise, an exploratory laparotomy should be performed, with resection of the compromised bowel. Second-look laparotomy after 24–48 h should be attempted because anticoagulation can help prevent resection of viable bowel. Hypercoagulability testing should be performed, and if underlying inherited disorders are diagnosed, life-long anticoagulation is recommended.

341 Acute Intestinal Obstruction

Danny O. Jacobs

EPIDEMIOLOGY

Globally, although the incidence and prevalence of acute intestinal obstruction have increased over the past two decades, morbidity and mortality appear to be decreasing. Diagnosis remains challenging. The extent of mechanical obstruction is typically described as partial, high grade, or complete—generally correlating with the risk of complications and the urgency with which the underlying disease process must be addressed. Obstruction is also commonly described as being either "simple" or, alternatively, "strangulated" if vascular insufficiency and intestinal ischemia are evident.

Acute intestinal obstruction occurs either *mechanically* from blockage or from intestinal dysmotility when there is no blockage. In the latter instance, the abnormality is *functional*. Mechanical bowel obstruction may be caused by extrinsic processes, intrinsic abnormalities of the bowel wall, or intraluminal abnormalities **(Table 341-1)**. Within each of these broad categories are many diseases that can impede intestinal propulsion. Intrinsic diseases that can cause intestinal obstruction are usually congenital, inflammatory, neoplastic, or traumatic in origin, although intussusception and radiation injury can also be etiologic.

Acute intestinal obstruction accounts for ~1–3% of all hospitalizations and a quarter of all urgent or emergent general surgery admissions. Approximately 80% of cases involve the small bowel, and about one-third of these patients show evidence of significant ischemia. The mortality rate for patients with strangulation who are operated on within 24–30 h of the onset of symptoms is ~8% but triples shortly thereafter.

Extrinsic diseases most commonly cause mechanical obstruction of the small intestine. In the United States and Europe, almost all cases are caused by postoperative adhesions, carcinomatosis, or herniation of the anterior abdominal wall. Carcinomatosis most often originates from the ovary, but can originate from the pancreas, stomach, or colon. Rarely, metastasis from distant organs like the breast and skin can also occur.

Adhesions are responsible for the majority of cases of early postoperative obstruction that require intervention. Approximately 20% of patients who were treated conservatively and between 5 and 30% of patients who were managed operatively will require readmission within 10 years for recurrence.

Open operations of the lower abdomen, including appendectomy and colorectal and gynecologic procedures, are especially likely to create adhesions that can cause bowel obstruction **(Table 341-2)**. Although laparoscopic procedures may generate fewer postoperative adhesions compared with open surgery, the risk of obstructive adhesion formation is not eliminated. The risk of internal herniation is increased by abdominal procedures such as laparoscopic or open Roux-en-Y gastric bypass.

Volvulus, which occurs when bowel twists on its mesenteric axis, can cause partial or complete obstruction and vascular insufficiency

TABLE 341-1 Most Common Causes of Acute Intestinal Obstruction

Extrinsic Disease
Adhesions (especially due to previous abdominal surgery), internal or external hernias, neoplasms (including carcinomatosis and extraintestinal malignancies, mostly commonly ovarian), endometriosis or intraperitoneal abscesses, and idiopathic sclerosis
Intrinsic Disease
Congenital (e.g., malrotation, atresia, stenosis, intestinal duplication, cyst formation, and congenital bands—the latter rarely in adults)
Inflammation (e.g., inflammatory bowel disease, especially Crohn's disease, but also diverticulitis, radiation, tuberculosis, lymphogranuloma venereum, and schistosomiasis)
Neoplasia (note: primary small-bowel cancer is rare; obstructive colon cancer may mimic small-bowel obstruction if the ileocecal valve is incompetent)
Traumatic (e.g., hematoma formation, anastomotic strictures)
Other, including intussusception (where the lead point is typically a polyp or tumor in adults), volvulus, obstruction of duodenum by superior mesenteric artery, radiation or ischemic injury, and aganglionosis, which is Hirschsprung's disease
Intraluminal Abnormalities
Bezoars, feces, foreign bodies including inspissated barium, gallstones (entering the lumen via a cholecystoenteric fistula), enteroliths

TABLE 341-3 Most Common Causes of Ileus (Functional or Pseudo-Obstruction of the Intestine)

Intraabdominal procedures, lumbar spinal injuries, or surgical procedures on the lumbar spine and pelvis
Metabolic or electrolyte abnormalities, especially hypokalemia and hypomagnesemia, but also hyponatremia, uremia, and severe hyperglycemia
Drugs such as opiates, antihistamines, and some psychotropic (e.g., haloperidol, tricyclic antidepressants) and anticholinergic agents
Intestinal ischemia
Intraabdominal or retroperitoneal inflammation or hemorrhage
Lower lobe pneumonias
Intraoperative radiation (likely due to smooth muscle damage)
Systemic sepsis
Hyperparathyroidism
Pseudo-obstruction (Ogilvie's syndrome)
Ileus secondary to hereditary or acquired visceral myopathies and neuropathies that disrupt myocellular neural coordination
Some collagen vascular diseases such as lupus erythematosus or scleroderma

affecting the sigmoid colon most commonly comprising approximately two-thirds of all cases of volvulus and 4% of all cases of large-bowel obstruction. The cecum and terminal ileum can also volvulize, or the cecum alone may be involved as a cecal bascule. Risk factors include institutionalization, the presence of neuropsychiatric conditions requiring psychotropic medication, chronic constipation, and aging; patients typically present in their seventies or eighties. Colonic volvulus is more common in Eastern Europe, Russia, and Africa than it is the United States. It is rare for adhesions or hernias to obstruct the colon. Cancer of the descending colon and rectum is responsible for approximately two-thirds of all cases, followed by diverticulitis. Functional obstruction, also known as *ileus* and *pseudo-obstruction*, is present when dysmotility prevents intestinal contents from being propelled distally and no mechanical blockage exists. Ileus that occurs after intraabdominal surgery is the most commonly known form of functional bowel obstruction, but there are numerous other causes **(Table 341-3)**. Although postoperative ileus is most often transient, it is a common reason why hospital discharge is delayed. Pseudo-obstruction of the colon, also known as Ogilvie's syndrome, is a relatively rare disease. Some patients with Ogilvie's syndrome have colonic dysmotility due to abnormalities of their autonomic nervous system that may be inherited.

PATHOPHYSIOLOGY

The manifestations of acute intestinal obstruction depend on the nature of the underlying disease process, its location, and changes in blood flow **(Fig. 341-1)**. Increased intestinal contractility, which occurs proximally *and* distal to the obstruction, is a characteristic response. Subsequently, intestinal peristalsis slows as the intestine or stomach proximal to the point of obstruction dilates and fills with gastrointestinal secretions and swallowed air. Although swallowed air is a primary source of intestinal distension, intraluminal air may also accumulate from fermentation, local carbon dioxide production, and altered gaseous diffusion.

TABLE 341-2 Acute Small-Intestinal and Colonic Obstruction Incidences

CAUSE	INCIDENCE
Postoperative adhesions	>50% overall
Neoplasms	~20%
Hernias (especially ventral or internal types, where the risk of strangulation is increased)	~10%
Inflammatory bowel disease, other inflammation (obstruction may resolve if acute inflammation and edema subside)	~5%
Intussusception, volvulus, other miscellaneous diseases	<15%

Intraluminal dilation also increases intraluminal pressure. When luminal pressure exceeds venous pressure, venous and lymphatic drainage is impeded. Edema ensues, and the bowel wall proximal to the site of blockage may become hypoxemic. Epithelial necrosis can be identified within 12 h of obstruction. Ultimately, arterial blood supply may become so compromised that full-thickness ischemia, necrosis, and perforation result. Stasis increases bacteria counts within the jejunum and ileum. Bacteria, such as *Escherichia coli*, *Streptococcus faecalis*, and *Klebsiella*, and other pathogens may be recovered from intestinal cultures, mesenteric lymph nodes, the bloodstream, and other sites.

Other manifestations depend on the degree of hypovolemia, the patient's metabolic response, and the presence or absence of associated intestinal ischemia. Inflammatory edema eventually increases the production of reactive oxygen species and activates neutrophils and macrophages, which accumulate within the bowel wall. Their accumulation, along with changes in innate immunity, disrupts secretory and neuromotor processes. Dehydration is caused by loss of the normal intestinal absorptive capacity as well as fluid accumulation in the gastric or intestinal wall and intraperitoneally.

Anorexia and emesis tend to exacerbate intravascular volume depletion. In the worst-case scenario after high-grade distal obstruction, emesis leads to losses of gastric potassium, hydrogen, and chloride, while dehydration stimulates proximal renal tubule bicarbonate reabsorption. Intraperitoneal fluid accumulation, especially in patients with severe distal bowel obstruction, may increase intraabdominal pressure enough to elevate the diaphragm, inhibit respiration, impede systemic venous return, and promote vascular instability. Severe hemodynamic compromise may elicit a systemic inflammatory response and generalized microvascular leakage.

Closed-loop obstruction results when the proximal and distal openings of a given bowel segment are both occluded, for example, due to volvulus or a hernia. It is the most common precursor for strangulation, but not every closed loop strangulates. The risk of vascular insufficiency, systemic inflammation, hemodynamic compromise, and irreversible intestinal ischemia is much greater in patients with closed-loop obstruction. Pathologic changes may occur rapidly, such that emergent intervention is indicated. Irreversible bowel ischemia may progress to transmural necrosis even if obstruction is relieved. The provider should remember that patients with high-grade distal colonic obstruction who have competent ileocecal valves may present with closed-loop obstruction. In this instance, the cecum may progressively dilate such that ischemic necrosis results in perforation, especially when the cecal diameter exceeds 10–12 cm. Patients with distal colonic obstruction whose ileocecal valves are incompetent tend

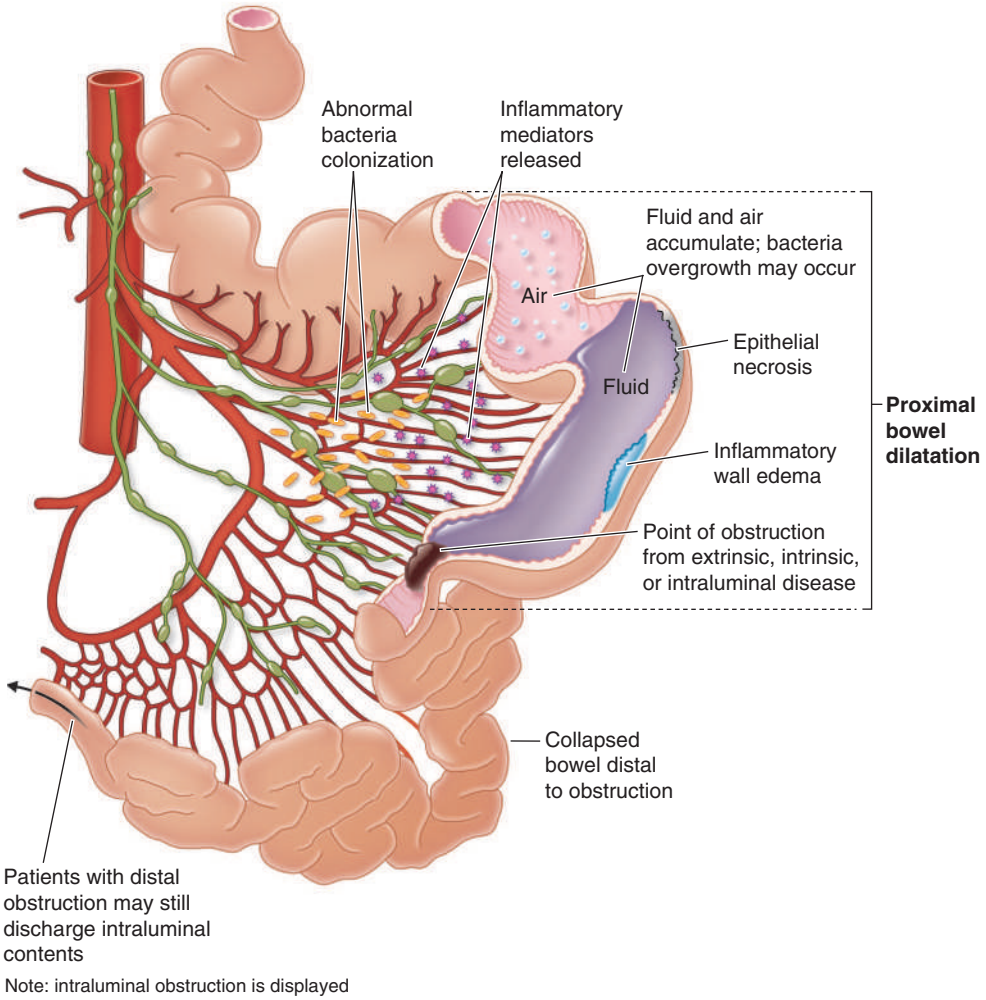

FIGURE 341-1 Pathophysiologic changes of small-bowel obstruction.

to present later in the course of disease and mimic patients with distal small-bowel obstruction.

HISTORY AND PHYSICAL FINDINGS

Even though the presenting signs and symptoms can be misleading, many patients with acute obstruction can be accurately diagnosed after a thorough history and physical examination is performed before imaging. Even though small-bowel obstruction with strangulation can be especially difficult to diagnosis promptly, early recognition allows earlier treatment, which decreases the risk of morbidity and mortality.

The cardinal signs are colicky abdominal pain, abdominal distention, emesis, and obstipation. More intraluminal fluid accumulates in patients with distal obstruction, which typically leads to greater distention, more discomfort, and delayed emesis. This emesis is feculent when there is bacterial overgrowth. Patients with more proximal obstruction commonly present with less abdominal distention but more pronounced vomiting. Elements of the history that might be helpful include any prior history of surgery, including herniorrhaphy, as well as any history of cancer or inflammatory bowel disease.

Most patients, even those with simple obstruction, appear to be critically ill. Many may be oliguric, hypotensive, and tachycardic because of severe intravascular volume depletion. Fever is worrisome for strangulation or systemic inflammation. Bowel sounds and bowel functional activity are notoriously difficult to interpret. Classically, many patients with early small-bowel obstruction will have high-pitched, "musical" tinkling bowel sounds and peristaltic "rushes" known as borborygmi. Later in the course of disease, the bowel sounds may be absent or hypoactive as peristaltic activity decreases. This contrasts with the common findings in patients with ileus or pseudo-obstruction where bowel sounds are typically absent or hypoactive from the beginning. Lastly, patients with partial blockage may continue to pass flatus and stool, and those with complete blockage may even evacuate bowel contents present downstream beyond their obstruction.

All surgical incisions should be examined, and the presence of a tender abdominal or groin mass strongly suggests that an incarcerated hernia may be the cause of obstruction. The presence of tenderness should increase the concern about the presence of complications such as ischemia, necrosis, or localized peritonitis. Severe pain with localization or signs of peritoneal irritation is suspicious for strangulated or closed-loop obstruction. It is important to remember that the discomfort may be out of proportion to physical findings mimicking the complaints of patients with acute mesenteric ischemia. Patients with colonic volvulus present with the classic manifestations of closed-loop obstruction: severe abdominal pain, vomiting, and obstipation. Asymmetrical abdominal distension and a tympanic mass may be evident.

Patients with ileus or pseudo-obstruction may have signs and symptoms like those with bowel obstruction. Although abdominal distention is present, colicky abdominal pain is typically absent, and patients may not have nausea or emesis. Ongoing, regular discharge of stool or flatus can sometimes help distinguish patients with ileus from those with complete mechanical bowel obstruction. The overall risk of ileus appears to be less in patients who undergo laparoscopic procedures.

LABORATORY AND IMAGING STUDIES

Laboratory testing should include a complete blood count and serum electrolyte and creatinine measurements. Serial assessments are often

useful. Mild hemoconcentration and slight elevation of the white blood cell count commonly occur after simple bowel obstruction. Emesis and dehydration may cause hypokalemia, hypochloremia, elevated blood urea nitrogen–to–creatinine ratios, and metabolic alkalosis. Patients may be hyponatremic on admission because many have attempted to rehydrate themselves with hypotonic fluids. The presence of guaiac-positive stools and iron-deficiency anemia are strongly suggestive of malignancy.

Higher white blood cell counts with the presence of immature forms and the presence of metabolic acidosis are worrisome for severe volume depletion or ischemic necrosis and sepsis. Presently, no laboratory tests are especially useful for identifying the presence of simple or strangulated obstruction, although increases in serum D-lactate, creatine kinase BB isoenzymes, or intestinal fatty acid binding protein levels may be suggestive of the latter.

Recommendations for diagnostic imaging continue to evolve. In all cases, the key is not to delay operative intervention unnecessarily when the patient's signs or symptoms strongly suggest that high-grade or complete obstruction or bowel compromise is present. Abdominal radiography, which must include upright or cross-table lateral views, can be completed quickly and may indicate the need for emergency surgical intervention in patients who are not in the immediate postoperative period. A "staircasing" pattern of dilated air and fluid-filled small-bowel loops >2.5 cm in diameter with little or no air seen in the colon are classical findings in patients with small-bowel obstruction. Little bowel gas appears in patients with proximal bowel obstruction or in patients whose intestinal lumens are filled with fluid.

Upright plain films of the abdomen of patients with large-bowel obstruction typically show colon dilatation. Small-bowel air-fluid levels may not be obvious if the ileocecal valve is incompetent. Although it can be difficult to distinguish from ileus, small-bowel obstruction is more likely when air-fluid levels are seen without significant colonic distension. Free air suggests that perforation has occurred in patients who have not recently undergone surgical procedures. A gas-filled, "coffee bean"–shaped dilated shadow may be seen in patients with volvulus.

More sophisticated imaging can be beneficial when the diagnosis is unclear. Computed tomography (CT) is the most frequently used imaging modality. Its sensitivity for detecting bowel obstruction is ~95% (78–100%) in patients with high-grade obstruction, with a specificity of 96% and an accuracy of ≥95%. Its accuracy in diagnosing closed-loop obstruction is much lower (60%). CT may also provide useful information regarding location or to identify circumstances where surgical intervention is urgently needed. Patients who have evidence of contrast appearing within the cecum within 4–24 h of oral administration of water-soluble contrast can be expected to improve with high sensitivity and specificity (~95% each).

Contrast studies may demonstrate a "bird's beak," a "c-loop," or "whorl" deformity on CT imaging at the site where twisting obstructs the lumen when a colonic volvulus is present. Abdominal radiography, unlike CT imaging, may not accurately distinguish obstruction from other causes of colonic dysmotility. Examples of some CT images are provided in Fig. 341-2.

Ultrasonographic evaluations are especially difficult to interpret but may be sensitive and appropriate studies to evaluate patients who are pregnant or for whom x-ray exposure is otherwise contraindicated or inappropriate.

CT imaging with enteral and IV contrast can also identify ischemia. Altered bowel wall enhancement is the most specific early finding, but its sensitivity is low. Mesenteric venous gas, pneumoperitoneum, and pneumatosis intestinalis are late findings indicating the presence of bowel necrosis. CT scanning after a water-soluble contrast enema may help distinguish ileus or pseudo-obstruction from distal large-bowel obstruction in patients who present with evidence of small-bowel and colonic distention. CT enteroclysis, though now rarely performed, can accurately identify neoplasia as a cause of bowel obstruction. Contrast enemas or colonoscopies are almost always needed to identify causes of acute colonic obstruction.

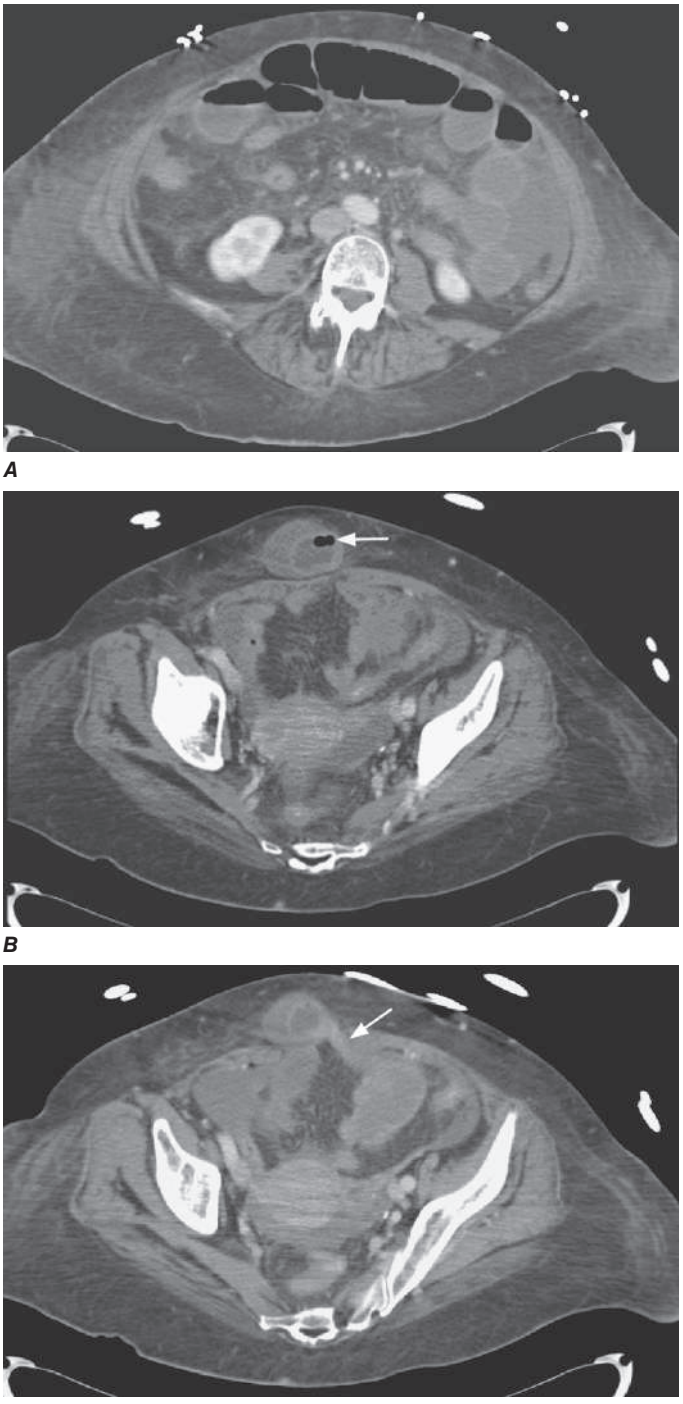

FIGURE 341-2 Computed tomography with oral and intravenous contrast demonstrating (***A***) evidence of small-bowel dilatation with air-fluid levels consistent with a small-bowel obstruction; (***B***) a partial small-bowel obstruction from an incarcerated ventral hernia (*arrow*); and (***C***) decompressed bowel seen distal to the hernia (*arrow*). (*Reproduced with permission from D Longo et al: Harrison's Principles of Internal Medicine, 18th ed. New York: McGraw-Hill; 2012.*)

Barium studies are generally contraindicated in patients with firm evidence of complete or high-grade bowel obstruction, especially when they present acutely. Barium should never be given orally to a patient with possible obstruction until that diagnosis has been excluded. In every other instance, such investigations should only be performed in exceptional circumstances and with great caution because patients with significant obstruction may develop barium concretions as an additional source of blockage and some who would have otherwise recovered will require operative intervention. Barium

opacification also renders cross-sectional imaging studies or angiography uninterpretable.

TREATMENT

Acute Intestinal Obstruction

An improved understanding of the pathophysiology of bowel obstruction and the importance of fluid resuscitation, electrolyte repletion, intestinal decompression, and the selected use of antibiotics has likely contributed to a reduction in mortality from acute bowel obstruction. Patients should be stabilized as quickly as possible. Nasogastric tube suction decompresses the stomach, minimizes further distention from swallowed air, improves patient comfort, and reduces the risk of aspiration. Urine output should be assessed using a Foley catheter. In some cases, for example, in patients with cardiac disease, central venous pressures should be monitored. The use of antibiotics is controversial, although prophylactic administration may be warranted if operation is anticipated.

Complete bowel obstruction is an indication for intervention. Stenting may be possible and warranted for some patients with high-grade obstruction due to unresectable stage IV malignancies. Stenting may also allow elective mechanical bowel preparation before operation. Because treatment options are so variable, it is helpful to make as precise a diagnosis as possible preoperatively.

ILEUS

Patients with ileus are treated supportively with IV fluids and nasogastric decompression while any underlying pathology is treated, taking care to optimize the use of narcotics. Pharmacologic treatments continue to be evaluated with some studies showing that treatment with peripherally active μ-opioid receptor antagonists (e.g., alvimopan and methylnaltrexone) or 5-HT_4 agonists that stimulate the release of acetylcholine from enteric neurons (e.g., mosapride and prucalopride) may accelerate gastrointestinal recovery in some patients who have undergone abdominal surgery.

COLONIC PSEUDO-OBSTRUCTION (OGILVIE'S DISEASE)

Neostigmine is an acetylcholinesterase inhibitor that increases cholinergic (parasympathetic) activity, which can stimulate colonic motility. Some studies have shown it to be moderately effective in alleviating acute colonic pseudo-obstruction. It is the most common therapeutic approach and can be used once it is certain that there is no mechanical obstruction. Cardiac monitoring is required, and atropine should be immediately available. Intravenous administration induces defecation and flatus within 10 min in the majority of patients who will respond. Sympathetic blockade by epidural anesthesia can successfully ameliorate pseudo-obstruction in some patients.

VOLVULUS

Patients with sigmoid volvulus can often be decompressed using a flexible tube inserted through a rigid proctoscope or using a flexible sigmoidoscope. Successful decompression results in sudden release of gas and fluid with evidence of decreased abdominal distension and allows definitive correction to be scheduled electively. Cecal volvulus most often requires laparotomy or laparoscopic correction.

INTRAOPERATIVE STRATEGIES

Approximately 60–80% of selected patients with mechanical bowel obstruction can be successfully treated conservatively. Most cases of radiation-induced obstruction should be managed nonoperatively if possible. Early consultation with a surgeon is prudent when there is concern about strangulation obstruction or other abnormality that needs to be addressed urgently. Deterioration signifies a need for intervention. At this time, the decision as to whether the patient can continue to be treated nonoperatively can only be based on clinical judgment, although, as described earlier, imaging studies can sometimes be helpful. The frequency of major complications after operation ranges from 12 to 47%, with greater risk being attributed to resection therapies and the patient's overall health. Risk is increased for patients with American Society of Anesthesiologists (ASA) physical status of class III or higher.

At operation, dilation proximal to the site of blockage with distal collapse is a defining feature of bowel obstruction. Intraoperative strategies depend on the underlying problem and range from lysis of adhesions to resection with or without diverting ostomy to primary resection with anastomosis. Resection is warranted when there is concern about the bowel's viability after the obstructive process is relieved. Laparoscopic approaches can be useful for patients with early obstruction when extensive adhesions are not expected to be present. Some patients with high-grade obstruction secondary to malignant disease that is not amendable to resection will benefit from bypass procedures.

ADULT INTUSSUSCEPTION AND GALLSTONE ILEUS

Primary resection is prudent. Careful manual reduction of any involved bowel may limit the amount of intestine that needs to be removed. A proximal ostomy may be required if unprepped colon is involved. The most common site of intestinal obstruction in patients with gallstone "ileus" is the ileum (60% of patients). The gallstone enters the intestinal tract most often via a cholecystoduodenal fistula. It can usually be removed by operative enterolithotomy. Addressing gallbladder disease during urgent or emergent surgery is not recommended.

POSTOPERATIVE BOWEL OBSTRUCTION

Early postoperative mechanical bowel obstruction is that which occurs within the first 6 weeks of operation. Although it tends to respond and behave differently from classic mechanical bowel obstruction and may be very difficult to distinguish from postoperative ileus, most are partial and can be expected to resolve spontaneously. A higher index of suspicion for a definitive site of obstruction is warranted for patients who undergo laparoscopic surgical procedures. Patients who first had ileus and then subsequently develop obstructive symptoms after an initial return of normal bowel function are more likely to have true postoperative small-bowel obstruction. The longer it takes for a patient's obstructive symptoms to resolve after hospitalization, the more likely the patient is to require surgical intervention.

342 Acute Appendicitis and Peritonitis

Danny O. Jacobs

ACUTE APPENDICITIS

INCIDENCE AND EPIDEMIOLOGY

Acute appendicitis is the most common acute general surgery emergency affecting the abdomen, with a rate of ~10–11 cases per 10,000 people annually over the past several decades affecting biological males and females equivalently. Appendicitis still occurs most commonly in 10- to 19-year-olds, although the worldwide incidence and average age at diagnosis appear to be increasing gradually, whereas disability from complications and mortality appear to be decreasing. Significant differences in geographic risk variation are noted in the United States and worldwide.

The risk of perforation is ~10–20% and is a significant cause of excess morbidity for all patients, but the risk appears to be significantly higher in patients <5 or >65 years of age. Patients with higher socioeconomic status appear to have lower risk of appendicitis with or without perforation. It is also important to note that the incidence of appendiceal tumors also appears to be increasing.

How best to manage patients who present with an appendiceal mass and small localized abscess without perforation is controversial, especially whether interval or immediate appendectomy should be performed when both can be appropriate depending on the clinical details.

PATHOGENESIS OF APPENDICITIS AND APPENDICEAL PERFORATION

Appendicitis was first described in 1886 by Reginald Fitz. Its etiology is still not completely understood. Fecaliths, incompletely digested food residue, lymphoid hyperplasia, intraluminal scarring, tumors, bacteria, viruses, and inflammatory bowel disease have all been associated with inflammation of the appendix with potentially different outcomes depending on pathogenesis.

Although not proven, obstruction of the appendiceal lumen is believed to be an important step in the development of appendicitis—at least in some cases. Here, obstruction leads to bacterial overgrowth and luminal distension, with an increase in intraluminal pressure that can inhibit the flow of lymph and blood. Then, vascular thrombosis and ischemic necrosis with perforation of the distal appendix may occur. For this reason, perforation that occurs near the base of the appendix should raise concerns about another disease process. Most patients who will perforate do so before they are evaluated by surgeons.

Appendiceal fecaliths (or appendicoliths) are found in ~50% of patients with gangrenous appendicitis who perforate but are rarely identified in those who have simpler disease. This suggests that the underlying pathophysiologic processes are different. Uncomplicated appendicitis (e.g., without gangrenous necrosis, appendicoliths, perforation, or tumors) does not always progress to perforation. It appears that at least some cases of simple acute appendicitis may temporarily resolve or be managed with antibiotic therapy, although at least one-third will require subsequent appendectomy. Nevertheless, appendicitis does not invariably progress to perforation, and the use of nonoperative therapies to treat uncomplicated appendicitis continues to be studied intensively.

These findings highlight the importance of clinical decision-making and risk assessment when deciding and discussing treatment options with patients who presumably have simple disease, for example, deciding who is an appropriate candidate for nonoperative management and who is not without bias. The latter is especially pertinent given the difficulty in assessing which patients might progress to perforation and which will not.

When perforation occurs, the resultant leak may be contained by the omentum or other surrounding tissues to form an abscess. Free perforation normally causes severe peritonitis. These patients may also develop infective suppurative thrombosis of the portal vein and its tributaries along with intrahepatic abscesses. The prognosis of the very unfortunate patients who develop this rare but dreaded complication is very poor.

TABLE 342-1 Some Conditions That Mimic Appendicitis

Crohn's disease	Meckel's diverticulitis
Cholecystitis or other gallbladder disease	Mittelschmerz
COVID-19 infection occasionally co-incident	Mesenteric adenitis
Diverticulitis	Omental torsion
Ectopic pregnancy	Pancreatitis
Endometriosis	Lower lobe pneumonia
Gastroenteritis or colitis	Pelvic inflammatory disease
Gastric or duodenal ulceration	Ruptured ovarian cyst or other cystic disease of the ovaries
Hepatitis	Small-bowel obstruction
Kidney disease, including nephrolithiasis	Urinary tract infection
Liver abscess	

CLINICAL MANIFESTATIONS

Improved diagnosis, supportive care, and surgical interventions are likely responsible for the remarkable decrease in the risk of mortality from simple appendicitis to currently <1%. Nevertheless, it is still important to identify patients who might have appendicitis as early as possible. Patients who have persistent symptoms that have not improved over 48 h may be more likely to perforate or develop other complications.

Appendicitis should be included in the differential diagnosis of abdominal pain for every patient in any age group unless it is certain that the organ has been previously removed **(Table 342-1)**.

The appendix's anatomic location, which varies, may directly influence how the patient presents. Where the appendix can be "found" ranges from local differences in how the appendiceal body and tip lie relative to its attachment to the cecum **(Figs. 342-1 and 342-2)**, to where the appendix is actually situated in the peritoneal cavity—for example, from its typical location in the right lower quadrant, to the pelvis, right flank, right upper quadrant (as may be observed during pregnancy), or even the left side of the abdomen for patients with malrotation or who have severely redundant colons.

Because the differential diagnosis of appendicitis is so extensive, deciding if a patient has appendicitis can be difficult **(Table 342-2)**. Many patients may not present with the classically described history or physical findings, and some may not have any abdominal discomfort early in the disease process. Soliciting an appropriate history requires detecting and evaluating symptoms that might suggest alternative diagnoses.

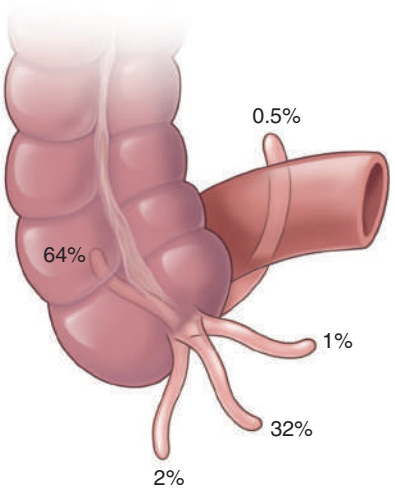

FIGURE 342-1 Regional anatomic variations of the appendix.

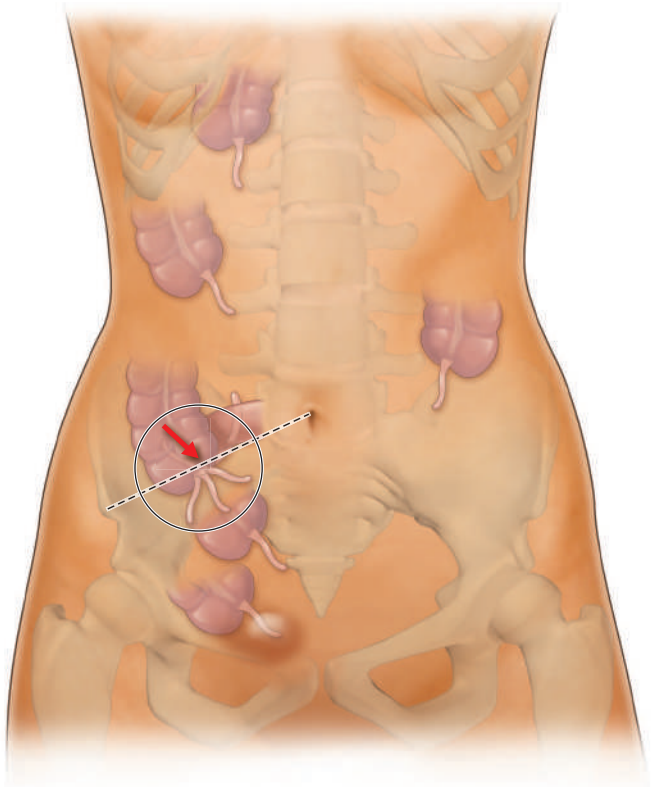

FIGURE 342-2 Locations of the appendix and cecum.

What is the classic history? Nonspecific complaints occur first. Patients may notice changes in bowel habits or malaise and vague, perhaps intermittent, crampy abdominal pain in the epigastric or periumbilical region. The pain subsequently migrates to the right lower quadrant over 12–24 h, where it is sharper and can be definitively localized as transmural inflammation when the appendix irritates the parietal peritoneum. Parietal peritoneal irritation may be associated with local muscle rigidity and stiffness. Patients with appendicitis will most often observe that their nausea, if present, followed the development of abdominal pain, which can help distinguish them from patients with gastroenteritis, for example, in whom nausea occurs first. Emesis, if present, also occurs after the onset of pain and is typically mild and scant. Thus, timing of the onset of symptoms and the characteristics of the patient's pain and any associated findings must be rigorously assessed. Anorexia is so common that the diagnosis of appendicitis should be questioned in its absence.

Arriving at the correct diagnosis is even more challenging when the appendix is not located in the right lower quadrant, in women of childbearing age, and in the very young or elderly. Because the differential diagnosis of appendicitis is so broad, often the key question to answer expeditiously is whether the patient has appendicitis or some other condition that requires immediate operative intervention. A major concern is that the likelihood of a delay in diagnosis is greater

TABLE 342-2 Relative Frequency of Common Presenting Symptoms

SYMPTOMS	FREQUENCY
Abdominal pain	>95%
Anorexia	>70%
Constipation	4–16%
Diarrhea	4–16%
Fever	10–20%
Migration of pain to right lower quadrant	50–60%
Nausea	>65%
Vomiting	50–75%

TABLE 342-3 Relative Frequency of Some Presenting Signs

SIGNS	FREQUENCY
Abdominal tenderness	>95%
Right lower quadrant tenderness	>90%
Rebound tenderness	30–70%
Rectal tenderness	30–40%
Cervical motion tenderness	30%
Rigidity	~10%
Psoas sign	3–5%
Obturator sign	5–10%
Rovsing's sign	5%
Palpable mass	<5%

if the appendix is unusually positioned. All patients should undergo a rectal examination. An inflamed appendix located behind the cecum or below the pelvic brim may prompt very little tenderness of the anterior abdominal wall.

Patients with pelvic appendicitis are more likely to present with dysuria, urinary frequency, diarrhea, or tenesmus. They may only experience pain in the suprapubic region on palpation or on rectal or pelvic examination. A pelvic examination in women is mandatory to rule out conditions affecting urogynecologic organs that can cause abdominal pain and mimic appendicitis such as pelvic inflammatory disease, ectopic pregnancy, and ovarian torsion. None of the currently available decision tools yet appear to be able to circumvent or obviate the need for expert clinical opinion. The relative frequencies of some presenting signs are displayed in Table 342-3.

Patients with simple appendicitis normally only appear mildly ill with a pulse and temperature that are usually only slightly above normal. The provider should be concerned about other disease processes beside appendicitis or the presence of complications such as perforation, phlegmon, or abscess formation if the temperature is >38.3°C (~101°F) and if there are rigors.

Patients with appendicitis will be found to lie quite still to avoid peritoneal irritation caused by movement, and some will report discomfort caused by a bumpy car ride on the way to the hospital or clinic, coughing, sneezing, or other actions that replicate a Valsalva maneuver. The entire abdomen should be examined systematically starting in an area where the patient does not report discomfort if possible. Classically, maximal tenderness is identified where the appendix is most often located—in the right lower quadrant at or near McBurney's point, which is approximately one-third of the way along a line originating at the anterior iliac spine and running to the umbilicus. Gentle pressure in the left lower quadrant may elicit pain in the right lower quadrant if the appendix is located there. This is Rovsing's sign (Table 342-4). Evidence of parietal peritoneal irritation is often best elicited by gentle abdominal percussion, jiggling the patient's gurney or bed, or mildly bumping the feet.

Atypical presentation and pain patterns are common, especially in the very old or the very young. Diagnosing appendicitis in children can be especially challenging because they tend to respond so dramatically to stimulation and obtaining an accurate history may be difficult. In addition, it is important to remember that the smaller omentum found in children may be less likely to wall off an appendiceal perforation. Observing the child in a quiet surrounding may be helpful.

TABLE 342-4 Classic Signs of Appendicitis in Patients with Abdominal Pain

MANEUVER	FINDINGS
Rovsing's sign	Palpating in the left lower quadrant causes pain in the right lower quadrant
Obturator sign	Internal rotation of the hip causes pain, suggesting the possibility of an inflamed appendix located in the pelvis
Iliopsoas sign	Extending the right hip causes pain along posterolateral back and hip, suggesting retrocecal appendicitis

Signs and symptoms of appendicitis can be subtle in the elderly who may not react as vigorously to appendicitis as younger people. Pain, if noticed, may be minimal and have originated in the right lower quadrant or, otherwise, where the appendix is located. It may never have been noticed to be intermittent, or there may only be significant discomfort with deep palpation. Nausea, anorexia, and emesis may be the predominant complaints. The rare patient may even present with signs and symptoms of distal bowel obstruction secondary to appendiceal inflammation and phlegmon or abscess formation.

LABORATORY TESTING

Laboratory testing does not identify patients with appendicitis. The white blood cell count is only mildly to moderately elevated in ~70% of patients with simple appendicitis (with a leukocytosis of 10,000–18,000 cells/μL). A "left shift" toward immature polymorphonuclear leukocytes is present in >95% of cases. A sickle cell preparation may be prudent to obtain in those of African, Spanish, Mediterranean, or Indian ancestry. Serum amylase and lipase levels should be measured.

Urinalysis is indicated to help exclude genitourinary conditions that may mimic acute appendicitis, but a few red or white blood cells may be present as a nonspecific finding. An inflamed appendix that abuts the ureter or bladder may cause sterile pyuria or hematuria. Every woman of childbearing age should have a pregnancy test. Cervical cultures are indicated if pelvic inflammatory disease is suspected. Anemia and guaiac-positive stools should raise concern about the presence of other diseases or complications such as cancer.

IMAGING

Plain films of the abdomen are rarely helpful and so are not routinely obtained unless the clinician is worried about other conditions such as intestinal obstruction, perforated viscus, or ureterolithiasis. Less than 5% of patients will present with an opaque fecalith in the right lower quadrant. The presence of a fecalith is not diagnostic of appendicitis, although its presence in an appropriate location where the patient complains of pain is suggestive and is associated with a greater likelihood of complications.

The effectiveness of ultrasonography as a tool to diagnosis appendicitis is highly operator dependent. Even in very skilled hands, the appendix may not be visualized. Its overall sensitivity is ~0.86, with a specificity of 0.81. Ultrasonography, especially intravaginal techniques, appears to be most useful for identifying pelvic pathology in women. Ultrasonographic findings suggesting the presence of appendicitis include wall thickening, an increased appendiceal diameter, and the presence of free fluid. Current practice in some institutions is to first perform ultrasonography and progress to other imaging studies only if the findings are equivocal or complications are suspected.

The sensitivity and specificity of computed tomography (CT) are at least 0.94 and 0.95, respectively. Thus, CT imaging, given its high negative predictive value, especially with the safe use of oral and intravenous contrast, may be helpful if the diagnosis is in doubt, although studies performed early in the course of disease may not have any typical radiographic findings. Overall, in patients in whom the diagnosis is uncertain, delaying operation at the time of presentation to obtain CT does not appear to increase the risk of perforation. CT scanning is a superior method for assessing the severity of acute appendicitis in the absence of peritoneal findings indicative of perforation, abscess, or suspicion of an associated malignancy.

Suggestive findings on CT examination include dilatation >6 mm with wall thickening, a lumen that does not fill with enteric contrast, and fatty tissue stranding or air surrounding the appendix, which suggests inflammation **(Figs. 342-3 and 342-4)**. The presence of luminal air or contrast is not consistent with a diagnosis of appendicitis. Furthermore, nonvisualization of the appendix is a nonspecific finding that should not be used to rule out the presence of appendiceal or periappendiceal inflammation.

SPECIAL PATIENT POPULATIONS

Appendicitis is the most common extrauterine general surgical emergency observed during pregnancy. Early symptoms of appendicitis such as nausea and anorexia may be overlooked. Diagnosing appendicitis in pregnant patients may be especially difficult because as the uterus enlarges the appendix may be pushed higher along the right flank even to the right upper quadrant or because the gravid uterus may obscure typical physical findings. Ultrasonography may facilitate early diagnosis. A high index of suspicion is required because of the effects of unrecognized and untreated appendicitis on the fetus. For example, the fetal mortality rate is four times greater (from 5 to 20%) in patients with perforation.

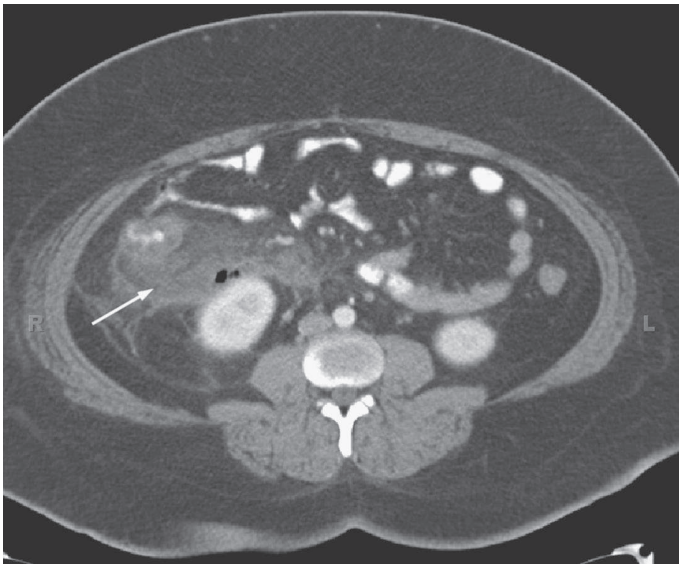

FIGURE 342-3 Computed tomography with oral and intravenous contrast of acute appendicitis. There is thickening of the wall of the appendix and periappendiceal stranding (*arrow*).

Immunocompromised patients may present with only mild tenderness and may have many other disease processes in their differential diagnosis, including atypical infections from mycobacteria, *Cytomegalovirus*, or other fungi. Enterocolitis is a concern and may be present in patients who present with abdominal pain, fever, and neutropenia due to chemotherapy. CT imaging may be very helpful, although it is important not to be overly cautious and delay operative intervention for those patients who are believed to have appendicitis.

TREATMENT

Acute Appendicitis

In the absence of contraindications, most patients who have strongly suggestive medical histories and physical examinations

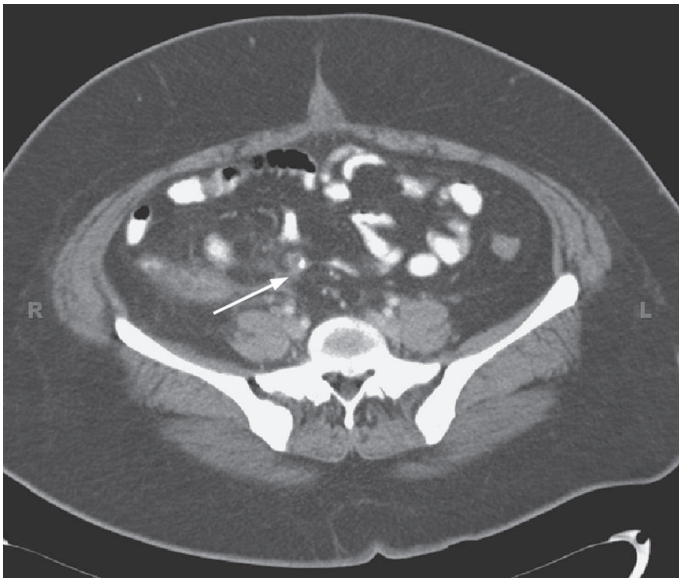

FIGURE 342-4 Appendiceal fecalith (*arrow*).

with supportive laboratory findings are candidates for appendectomy. Certainly, in some instances, imaging studies are not mandatory but are often obtained before surgical consultation is requested. Imaging and close observation are appropriate in patients whose evaluations are suggestive but not convincing.

Of course, CT may accurately indicate the other intraabdominal processes that warrant intervention. Whenever the diagnosis is uncertain, it is prudent to observe the patient and repeat the abdominal examination over 6–8 h. Any evidence of progression is an indication for operation. Narcotics can be given to patients with severe discomfort after an initial, thorough examination.

All patients should be fully prepared for surgery and have any fluid and electrolyte abnormalities corrected. Either laparoscopic or open appendectomy is a satisfactory choice for patients with uncomplicated appendicitis, although most procedures are now performed in a minimally invasive fashion to the patient's benefit in terms of recovery time and fewer overall potential complications. Endoscopic treatment for patients with uncomplicated appendicitis is being evaluated for efficacy.

Management of those who present with a mass representing a phlegmon or abscess can be more difficult. Such patients are most commonly treated with broad-spectrum antibiotics, percutaneous drainage especially if an abscess is noted >3 cm in diameter, parenteral fluids, and bowel rest. If they appear to respond to conservative management, the appendix can then be more safely removed 6–12 weeks later when inflammation has diminished.

A laparoscopic approach may also be useful when the exact diagnosis is uncertain. A laparoscopic approach may also facilitate exposure in those who are very obese. Absent complications, most patients can be discharged within 24–40 h of operation. The most common postoperative complications are fever and leukocytosis. Continuation of these findings beyond 5 days should raise concern for the presence of an intraabdominal abscess. The mortality rate for uncomplicated, nonperforated appendicitis is 0.1–0.5%, which approximates the overall risk of general anesthesia. The mortality rate for perforated appendicitis or other complicated disease is much higher, ranging from 3% overall to as high as 15% in the elderly.

ACUTE PERITONITIS

Acute peritonitis, or inflammation of the visceral and parietal peritoneum, is most often but not always infectious in origin, resulting from perforation of a hollow viscus. This is called *secondary peritonitis*, as opposed to *primary* or *spontaneous peritonitis*, when a specific intraabdominal source cannot be identified. In either instance, the inflammation can be localized or diffuse.

ETIOLOGY

Infective organisms may contaminate the peritoneal cavity after spillage from a hollow viscus, because of a penetrating wound of the abdominal wall, or because of the introduction of a foreign object like a peritoneal dialysis catheter or port that becomes infected. Secondary peritonitis most commonly results from perforation of the appendix, colonic diverticula, or the stomach and duodenum. It may also occur as a complication of bowel infarction or incarceration, cancer, inflammatory bowel disease, and intestinal obstruction or volvulus. Conditions that may cause secondary bacterial peritonitis and their mechanisms are listed in **Table 342-5**. Over 90% of the cases of primary or spontaneous bacterial peritonitis occur in patients with ascites or hypoproteinemia (<1 g/L).

Aseptic peritonitis is most commonly caused by the abnormal presence of physiologic fluids such as gastric juice, bile, pancreatic enzymes, blood, or urine. It can also be caused by the effects of normally sterile foreign bodies such as surgical sponges or instruments. More rarely, it occurs as a complication of systemic diseases such as lupus erythematosus, porphyria, and familial Mediterranean fever. The chemical irritation caused by stomach acid and activated pancreatic enzymes is extreme, and secondary bacterial infection may occur.

TABLE 342-5 Conditions Leading to Secondary Bacterial Peritonitis

Bowel perforation	Perforation or leakage of other organs
Appendicitis	Biliary leakage (e.g., after liver biopsy)
Anastomotic leakage	Cholecystitis
Adhesion	Intraperitoneal bleeding
Diverticulitis	Pancreatitis
Iatrogenic (including endoscopic perforation)	Salpingitis
Ingested foreign body	Urinary bladder
Inflammation	**Loss of peritoneal integrity**
Intussusception	Intraperitoneal chemotherapy
Neoplasms	Iatrogenic (e.g., postoperative foreign body)
Obstruction	Perinephric abscess
Peptic ulcer disease	Peritoneal dialysis or other indwelling devices
Strangulated hernia	Trauma
Vascular (including ischemia or embolus)	
Trauma (blunt or penetrating)
